At the moment torque sensors used on wind turbines are mostly realized with strain gauges but the latter are difficult to apply, require a telemetry system for signal transmission and a non-contact power supply, they are expensive and used mainly at the development stage rather than for continuous load monitoring. The aim of this paper is to present a batteryless non-contact SAW torque sensor suitable for easy aftermarket installation on high-speed shafts of wind turbine drivetrains.

Resonant wireless SAW torque sensors have been developed for automotive industry [2] but in this case the SAW die is attached by an adhesive directly to the surface of a relatively small part (shaft or flexplate) that can be cured in an oven. Dimensions of the wind turbine drivetrain high-speed shafts are too large (diameter is up to 200 mm) for curing them in ovens and subsequent calibration within a wide temperature range. At the same time, most gearbox manufacturers prefer not to install any bolt-on transducers on the shafts. This is the main motivation behind development of a novel clamp-on plate transducer with the SAW sensing elements that can be calibrated on a relatively short and light test shaft and then installed on the real large diameter wind turbine shaft. The design of this transducer is presented in Section II. Another issue is a design of the RF rotary coupler with a large gap between the rotor (sensor antenna) and the stator (reader antenna) that would tolerate strong vibrations of the shaft and provide wireless resonant frequency measurements insensitive to the angular position of the shaft and its radial and axial movement. Such a coupler is described in Section III. Results of calibration, testing of the torque sensor and its installation on a wind turbine are presented in Section IV.

II. THE SAW TORQUE TRANSDUCER DESIGN

A. SAW sensing elements

The torque applied to a shaft is measured by measuring strain on the surface of the plate clamped to the shaft. A clamp-on SAW torque transducer was theoretically studied in [3]. It had a beam connected between two clamp rings at an angle of 45° to the shaft axis that converted the torque into a uniaxial strain field on the beam surface. Our design of the transducer is different – it contains a relatively wide thin plate held by the two clamps and oriented along the shaft axis. It converts the applied torque into a biaxial shear strain field on the plate surface. This allows using the same SAW sensing elements as those developed for direct attachment to the shaft surface [4].

One of the sensing elements, HFSAW, contains three one-port SAW resonators connected in parallel, M1SAW, M2SAW and TSAW with the resonant frequencies $f_1 \approx 437$ MHz, $f_2 \approx 435$ MHz and $f_3 \approx 433$ MHz fabricated on Y+34° cut quartz substrate. All of them have unloaded $Q \approx 10000$ and the series resonant impedance close to 50 Ω. M1SAW and M2SAW are oriented at ±45° to the X axis of the substrate and the shaft axis so that $F_{m1} = f_1 - f_2$ linearly depends on the applied torque M. TSAW oriented at 30° to the X axis is used for temperature compensation since $F_t = f_2 - f_3$ depends differently on T than F_{m1}. The biaxial strain field on the plate surface gives a chance to perform differential frequency measurement of F_{m1} that reduced the influence of the variable impedance of the RF rotor couple, the bending moment normal to the plate surface and also doubles the torque sensitivity.

The HFSAW sensing element is bonded to the surface of the first plate transducer. There is also the second plate transducer with the sensing element LFSAW bonded to it.

The work has been supported by the European Commission FP7-SME-2011 INTELWIND project, Grant No. 283277.

LFSAW contains only two SAW resonators connected in parallel, M3SAW and M4SAW, similar to M1SAW and M2 SAW but with the resonant frequencies $f_4 \approx 431$ MHz and $f_5 \approx 429$ MHz. $F_{m2} = f_4 - f_5$ also linearly depend on M. Installing the two plate transducers on the shaft diametrically opposite to each other and calculating $F_m = (F_{m1} + F_{m2})/2$ reduces the influence of the bending moment parallel to the plate surface on the torque measurement result.

B. Mechanical design of the plate transducer

The plate transducers are designed for installation on the coupling shaft with the diameter of 120 mm and the thickness of 5 mm that connects the gearbox of the wind turbine to the generator. There are two main goals in the mechanical design of the transducers: (a) achieve a principal strain of at least 100-200 με on the plate surface at the maximum measurable torque of 5 kNm without yielding and (b) ensure a good repeatability of the measurement result and a low mechanical hysteresis.

Two of the designed transducers belonging to the first generation are shown in Fig. 1 before installation of the SAW sensing elements. They are made of stainless steel 316 cold finished and annealed. Both of them have a thin plate attached to the two relatively thick shoulders that are supposed to be clamped to the shaft by means of high-torque steel clamps. The transducer in Fig. 1a has four pins made of high carbon bright steel pressed into the back side of each of the shoulders. Their aim is to provide a repeatable strain transfer from the shaft surface to the plate. The second transducer does not have the pins but its shoulders have a cylindrical surface matching the curvature of the shaft. The shape and the dimensions of the plates are designed to ensure the principal strain of ≈130 με in the plate center at 5 kNm applied to the coupling shaft. Results of the finite element analysis (FEA) for the two plates installed on the coupling shaft are shown in Fig. 2 (a perfect mechanical contact is assumed).

The first generation of the transducers has been developed mainly for testing performance of different types of plate-shaft interfaces at a reduced amount of torque up to 800 Nm available from one of the Transense torque rigs. To withstand higher values of torque and stress associated with it, the second generation of the plate transducers has been manufactured using a higher specification stainless steel, PH17-4 SS. The two transducers with HFSAW and LFSAW bonded to

Figure 2. FEA results: (a) 130 με and (b) 127 με at the plate center at 5 kNm applied to the coupling shaft.

them are shown in Fig. 3. The back side of the shoulders also have a cylindrical surface matching the coupling shaft and the geometry of the plates ensures the principal strain of 216 με at 5 kNm applied to the coupling shaft. The maximum shear stress for the transducer is 80 MPa at 10 kNm that is considerably lower than the material shear yield strength.

III. LARGE DIAMETER RF COUPLER DESIGN

A number of the RF rotary couplers for passive SAW sensors have been studied theoretically and experimentally in [5]. However, most of them are aimed at relatively small diameters of the shafts and 1-5 mm gaps between the rotor and the stator. They are not suitable for the application under consideration that require the rotor-stator gap to be at least 20 mm because of large vibration amplitude of the coupling shaft. At the same time, radiation from the coupler has to be minimal for EMC so the coupler design based on radiating antennas like the one suggested in [6] is also not acceptable.

The proposed coupler design is based on the microstrips coupled back-to-back as in [5]. However, instead of FR4 PCB material, the substrate is made of the Rochacell® WF foam with the dielectric constant close to unity in order to scale up the coupler cross-section and reduce the electrical length of the microstrips. The coupler with the 20 mm gap is shown in Fig. 4 together with the torque transducer installed on the test shaft. The microstrip width is 23 mm and its height ensured the characteristic impedance close to 50 Ω. The annular stator microstrip is terminated by the matched load and the rotor

Figure 3. The second generation of the plate transducers with the SAW sensing elements installed.

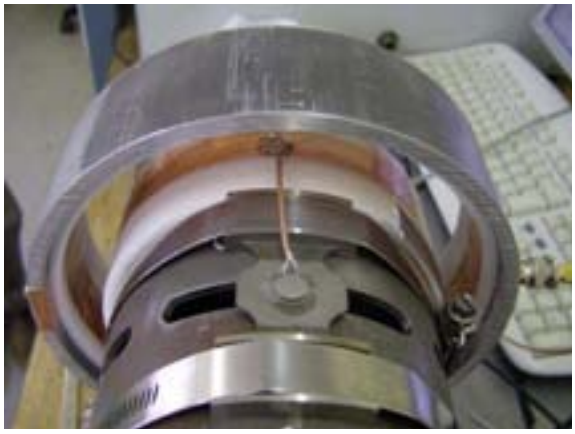

Figure 4. The RF rotary coupler with the SAW sensing element connected to it.

microstrip has two diametrically opposite gaps with one side grounded and another one connected to the sensing elements.

The angular variations of the measured frequency differences F_t, F_m and $F_{m1,2}$ as well as the standard deviation of the measured resonant frequencies are shown in Fig. 5. The pulsed SAW interrogator connected to the stator input (it is described in [7]) accumulates coherently 10 SAW responses and the PC logging software average 400 samples to reduce

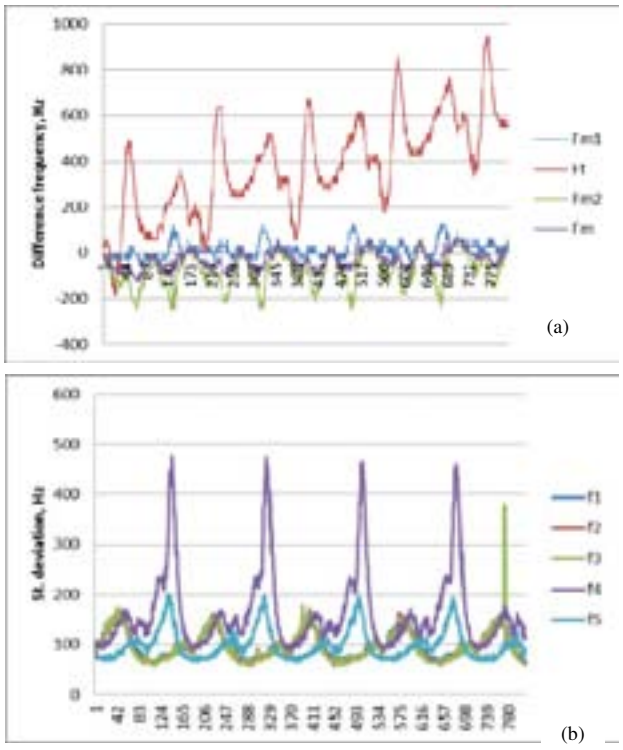

Figure 5. Angular variation of the measured (a) difference frequencies and (b) standard deviations of the resonant frequencies. Sample numbers are shown along the abscissa.

the noise in the frequency readings. The peak variation of F_m is below 100 Hz which is only 0.0083% of the estimated full range of the difference frequency variation due to ±5 kNm torque for the second generation plate transducer. The peak variation of F_t is 300 Hz (its drift is due to slowly changing temperature) that corresponds to the temperature reading variation of only ±0.1°C. The maximum standard deviation of F_m does not exceed 290 Hz that gives the estimated torque sensor resolution of 0.073% full range.

The coaxial cylindrical design of the RF rotary coupler with the wide microstrip is practically insensitive to the axial and radial displacement of the stator relative to the rotor by ±10 mm. Variation of F_m caused by the displacement does not exceed 1 kHz.

IV. Sensor Testing and Calibration

The first generation of the torque plate transducers has been tested on the 0.8 kNm torque rig after installation on the test shaft with the slots shown in Fig. 4. The slots in the shaft were made to increase the strain on the plate surface by the gain factor of $G_1 = 3$ compared to that for the real coupling shaft at the same value of torque. The room-temperature sensor characteristic achieved for the plate with the pins after 20 cycles of ±750 Nm exercising is shown in Fig. 6. The amount of hysteresis is quite large, 4.3 kHz which is 1.4% full range. Further exercising of the shaft slightly increased the hysteresis most likely because of the wearing-out of the pins.

A better result has been obtained for the plate transducer without the pins as shown in Fig. 7. The amount of hysteresis is 2 kHz or 0.9% full range and does not change with further exercising. The achieved torque sensitivity is 171 Hz/Nm while the theoretical value for the slotted test shaft is 213 Hz/Nm.

Since the linearity and the hysteresis obtained for the second plate are at the acceptable level, the next series of tests on a larger, 2 kNm torque rig have been performed for the second generation of the plate transducers also not having the pins (see Fig. 3). The two transducers were installed on a test shaft without slots but with thinner walls than those of the real

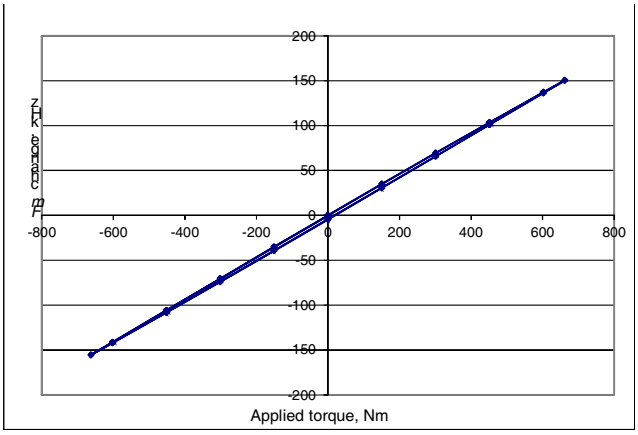

Figure 6. Variation of F_m with torque for the first generation of the plate transducer with pins on the slotted test shaft.

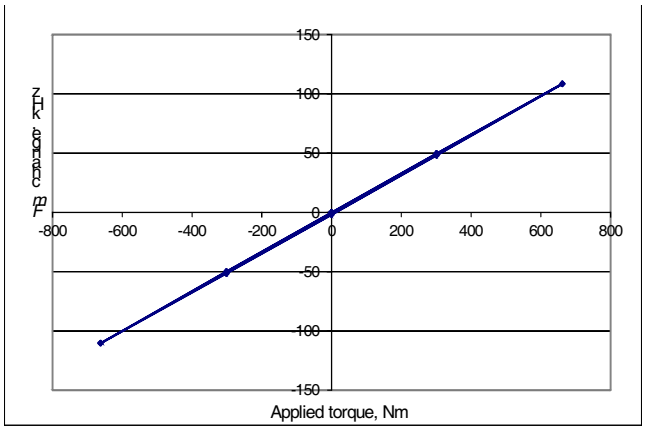

Figure 7. Variation of F_m with torque for the first generation of the plate transducer without pins on the slotted test shaft.

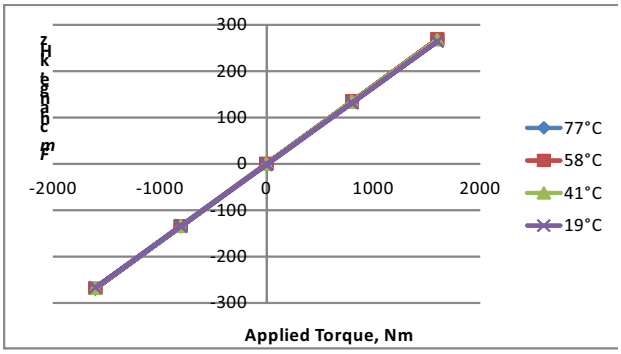
coupling shaft so that the gain factor for the strain was G_2 = 1.55. The set of calibration characteristics of the torque sensor measured at different temperatures is shown in Fig. 8. Special treatment of the plate-shaft interface helps achieve a low hysteresis of only 1.8 kHz at 77°C that is 0.34% full range. The torque sensitivity is 167 Hz/Nm for the test shaft and expected experimental value for the real coupling shaft is 108 Hz/Nm (the theoretical value is 121 Hz/Nm). After calibration, the torque measurement errors do not exceed ±11 Nm (±0.34% full range) on the test shaft within the entire temperature range. The torque sampling period is 1 ms.



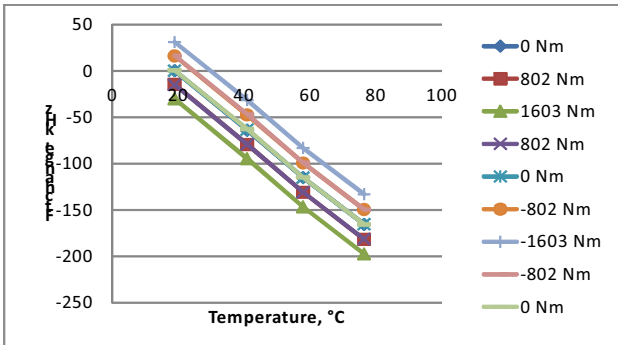


Figure 8. Calibration characteristics of the 2nd generation plate transducers installed on the test shaft without slots.

The calibrated torque sensor has been installed on the 750 kW NEG-MICON wind turbine at the Centre for Renewable Energy Sources & Saving (CRES) in Greece. After re-zeroing, the ambient temperature calibration was repeated on site. The torque readings of the SAW sensor turned out to be 22% lower than the applied torque indicated by a load cell. This could be due to the fact that the gain factor $G_{1,2}$ for the test shafts was found not experimentally but theoretically, by means of FEA. This introduced an uncertainty due to finite accuracy of FEA, unknown elastic constants of the coupling shaft material and imperfect mechanical contact at the shaft-plate interface. After introducing the correction factor, the SAW torque sensor has been integrated into a condition monitoring system of the wind turbine that is currently being tested.

V. Conclusions

A torque plate transducer based on passive wireless SAW strain sensing elements has been developed for installation on large diameter shafts by using heavy duty high torque clamps. The non-contact torque sensor employing the two plate transducers was calibrated on the test shaft and showed the torque measurement errors below 1% full range within the temperature range from 20°C to 80°C. A large diameter RF rotary coupler with the stator-rotor gap of 20 mm and small rotational error was also developed. Both the torque transducers and the RF coupler are suitable for aftermarket installation on large diameter shafts for wind turbines and other industrial and marine applications.

***Abstract*—We consider a broadband bulk acoustic resonator architecture – the so called High-overtone Bulk Acoustic Resonator (HBAR) – as a transducer acting as cooperative target to a RADAR interrogation unit. Specifically, we consider the compatibility of such an acoustic device as a passive buried sensor interrogated through a wireless link by an unmodified Ground-Penetrating RADAR (GPR). While the comb of modes is detected as a series of echoes well within the typical interrogation duration of GPRs, with a spacing between adjacent echoes representative of the acoustic velocity and hence the physical quantity under investigation, the poor coupling coefficient of each individual mode due to the spreading of the piezoelectric transducer coefficient over many modes reduces the interrogation range with respect to the acoustic delay line approach. A sensor identification scheme within the clutter of reflections from dielectric buried interfaces is proposed.**

I. Introduction

The High-overtone Bulk Acoustic Resonator (HBAR) design, based on a stack of materials [1], was originally considered as a solution for increasing the operating frequency of resonators while keeping a robust mechanical setup and high quality factor while removing the lithography constraint associated with patterning electrodes in a surface acoustic wave approach. Based on a stack of a thin piezoelectric active layer on top of a low-loss thick substrate, the transfer function of such a device is intrinsically broadband and characterized by a comb of modes. The mode spacing is given by the low-loss substrate thickness, while the envelope is given by the transfer function of the thin piezoelectric film and characterized by the overtones which are odd multiples of the fundamental frequency.

Using HBAR transducers as sensors has been considered early after the initial design considerations, whether for sensing physical properties [2], [3] or for gravimetric sensing [4].

II. HBAR as passive wireless sensors

The use of an HBAR as a wireless sensor is less common [5] than frequency source applications, and requires different design considerations: rather than focusing on a high quality factor which must only be high enough for the resonator discharge to last longer than the clutter, loading the resonator requires a significant electro-mechanical coupling. Defined as the ratio of the acoustic to electrical energy, a high enough coupling coefficient is needed to load the transducer during a wireless interrogation following a strategy similar to pulsed-RADAR probing [6].

Since an HBAR operates by transferring the acoustic energy from the piezoelectric layer to the thick substrate, the coupling coefficient of the piezoelectric substrate is transferred more or less efficiently to the HBAR modes and opens a design consideration for yielding HBAR transducers most suitable for wireless probing. The multiple modes of the HBAR under investigation here (Fig. 1, modes spaced by 4.6 MHz) distribute the thin film coupling coefficient to all the modes. Even though 163^o-lithium niobate exhibits a strong coupling of up to $K^2 = 50$ %, distributing this value to all the modes yields a low coupling for individual modes, explaining the poor interrogation range [7] with respect to a delay line [8] designed on a strongly coupled material. Interestingly, in the particular case of the device characterized in Fig. 1, the sum of all coupling coefficients defined as $K^2 \simeq \frac{\pi^2}{4} \times \frac{f_a - f_r}{f_r}$ with f_r and f_a the resonance and anti-resonance respectively [9] reaches 50%, or the material coupling coefficient of the active piezoelectric layer.

We thus consider two contributions to a figure of merit of the suitability of an HBAR as passive wireless sensor. On the one hand the coupling coefficient K defines the efficiency of the electromagnetic to mechanical conversion – or the ratio of the incoming electromagnetic energy to the stored mechanical energy – and should be maximized to improve the returned power level. The interrogation range is directly related to this quantity since in the RADAR equation, the equivalent cross section of the cooperative target is replaced with K^2 since the wave is converted from electromagnetic to mechanical and back to electromagnetic, multiplied by the internal acoustic losses of the transducer: a drop by a factor of 10 of the coupling coefficient yields an interrogation range drop of 3 since the cross section appears as the fourth-root power in the RADAR equation. On the other hand the quality factor Q defines the ability of the device to store energy through the ratio of the energy lost for each oscillation period to the stored energy. The quality factor of each individual mode should be high enough to clearly separate each mode contribution and thus prevent the comb of modes to blur in a continuous envelope in which individual echoes would no longer be detectable. Hence, the considered figure of merit is

$K^2 \times Q$ (no unit). [10]

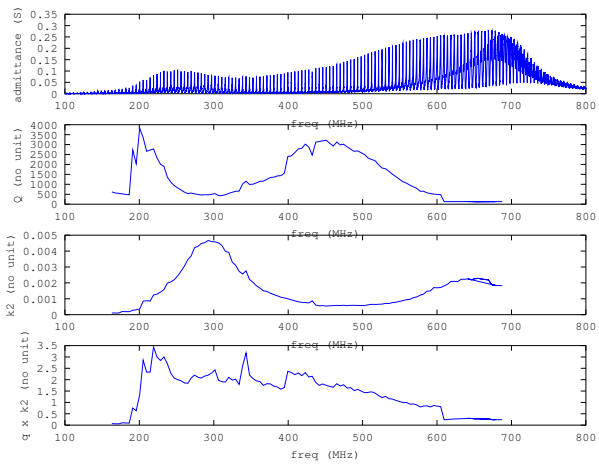

Fig. 1. Top to bottom: experimental admittance of the HBAR (lithium niobate on quartz) used in this report, quality factor and coupling coefficient. A figure of merit $K^2 \times Q$ is deduced, decreasing with frequency within the frequency range under investigation.

This observation yields some consideration as to the design of HBARs for use as passive wireless sensor. High quality factor, as required for frequency source applications, is no longer the most significant design factor: for wireless sensing, the incoming electromagnetic energy must be efficiently converted to a mechanical wave which itself is radiated back to the interrogation hardware. This electro-mechanical conversion coefficient K is unequally distributed over the modes as shown by modelling a lithium niobate (YXl/163^o-rotated cut) atop corindon (sapphire) stack (Fig. 2. Two cases are investigated: multitude of closely spaced modes when the low-loss substrate is thick (800 μm) or a few widely spaced (in the frequency domain) modes due to a thin substrate (100 μm). In the latter case, the distribution of the piezoelectric material K^2 over a few modes yields individual mode electro-mechanical coupling coefficients of a few percents, dropping by a factor of 10 in the case of a dense comb of modes. We hence conclude with a design tradeoff when manufacturing HBAR transducers dedicated to wireless sensing: the mode spacing must be low enough for the time domain echoes (separated by a delay equal to the inverse of the frequency spacing) to be well separated, while being large enough to minimize the number of modes in the piezoelectric layer envelope and hence maximize the coupling coefficient of each individual mode. We observe in both cases that the sum of the individual mode electro-mechanical coefficients yields a value of 47.5%$\pm$0.5%, in good agreement with the electro-mechanical coupling coefficient of the piezoelectric layer.

Furthermore, operating within the envelope of the fundamental mode of the thin piezoelectric layer is best suited since the piezoelectric thin film coupling coefficient K of the overtones drops as the overtone number N itself (*i.e.* K^2 drops as N^2, or a 9 to 14 dB drop when operating on $N = 3$ or $N = 5$ respectively with respect to the fundamental mode [11]). Hence, rather than operating at high frequency by using an overtone of the thin piezoelectric layer, the HBAR is best designed for operating as a wireless transducer by using a thinner piezoelectric layer so that the investigated modes remain in the fundamental mode of the active layer (Fig. 3).

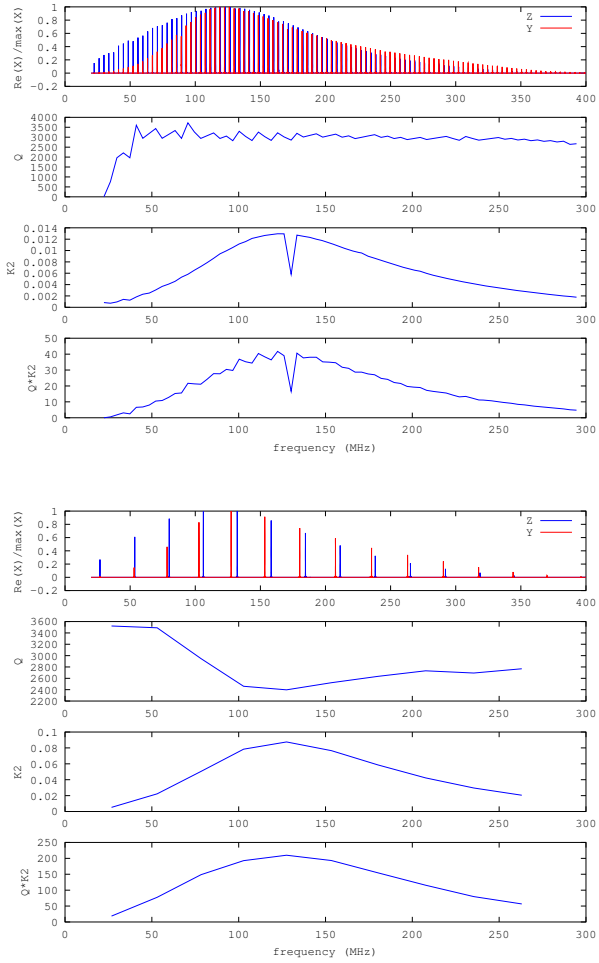

Fig. 2. Simulation of two configurations of HBARs in which a YXl/163^o lithium niobate layer is located atop a corindon substrate either 800 μm thick (top) or 100 μm thick (bottom). The thin piezoelectric film thickness defines the mode envelope while the substrate thickness defines the mode spacing. Top displays the normalized impedance (Z in blue) and admittance (Y in red), from which the quality factor (width at half height of the real part of the admittance) and the electro-mechanical coefficient K^2 – proportional to the distance of the admittance to impedance real parts maxima position. Finally, a figure of merit $Q \times K^2$ is computed.

Using the simulated data displayed on this figure, we have verified that the sum of the coupling coefficients of the modes within the envelope of the fundamental mode is 49.9% (close to the expected 50% of the lithium niobate layer), the sum of the coupling coefficients of the modes lying within the third overtone envelope is 3%, close to 49.9/9=5.5%, and the sum of the coupling coefficients of the modes lying under the fifth overtone is 0.8%, close to the expected 49.9/25=2%.

III. GPR FOR PROBING PASSIVE COOPERATIVE TARGETS

An alternative to the spectral approach of identifying a resonance frequency using a reflective frequency-sweep network analyzer to track the operating frequency of a single mode (FMCW based RADAR strategy) is to operate in the time domain. A HBAR is best suited for a time domain analysis since the Fourier transform of a comb of modes in the frequency domain is a comb of echoes in the time domain.

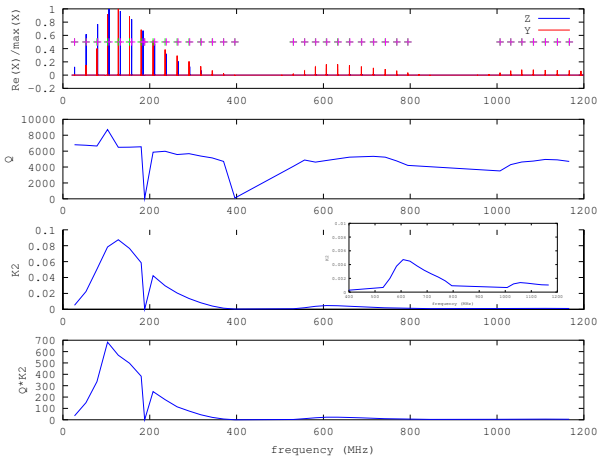

Fig. 3. Simulation of the S_{11} transfer function of an HBAR computed over a frequency range including the fundamental (0-500 MHz), third (500-900 MHz) and fifth overtone – on the top graph, the crosses indicate the position of the modes identified and automatically processed for computing the quality factor and the coupling coefficient. The fundamental mode of the piezoelectric layer extends from 0-500 MHz, the third overtone from 500 to 900, and the fifth overtone is above 900 MHz. The quality factor Q and electromechanical coupling coefficient K^2 are computed as well as the figure of merit $K^2 \times Q$, indicating that the only the fundamental mode of the piezoelectric layer should be considered. Inset of the third-from-top graph: zoom on the coupling coefficient of the third and fifth overtone of the piezoelectric layer.

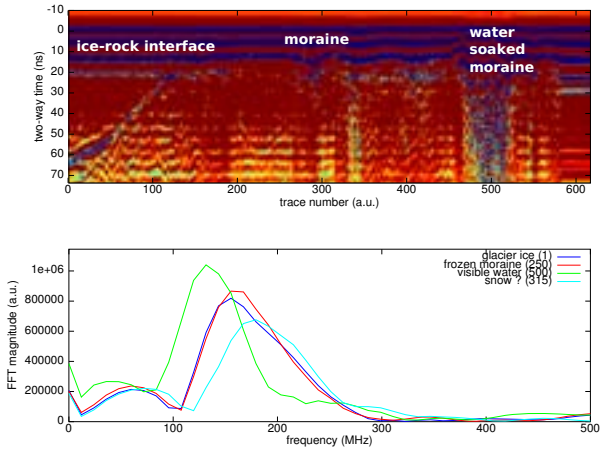

Fig. 4. Top: experimental B-scan GPR measurement over an area ranging from glacier ice (traces 0–100, with a clear interface from the bedrock visible for echoes delayed from 60 to 0 ns), to the moraine and surface-soaked water areas around trace 500, yielding the largest permittivity region and hence lowest operating frequency. Bottom: Fourier transform of the emitted pulse depending on the monitored region – the number next to the legend refers to the trace number as observed on the abscissa of the B-scan.

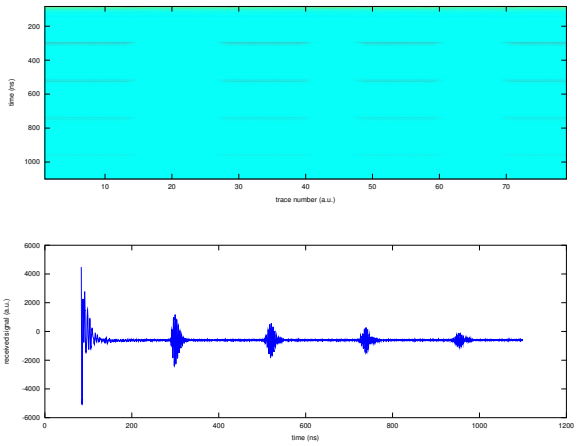

Fig. 5. Top: experimental B-scan of the HBAR sensor probed using a 200 MHz unshielded antenna, with-without-with... sequences of the HBAR located under the GPR. Bottom: experimental A-scan time domain reflections of the HBAR echoes recorded by the GPR.

A pulsed mode RADAR emitter as used in Ground Penetrating RADAR (GPR [12]) application is based on unloading a capacitor polarized by a high voltage (350 V in a Malå RAMAC unshielded-antenna emitter unit) in an avalanche transistor: the time constant of the resulting pulse is defined by the antenna reflection coefficient (S_{11}) minimum. This S_{11} minimum is given by the physical antenna dimensions and the surrounding medium permittivity. Practical use of a GPR in an environment ranging from ice to snow and water filled areas induces significant variation in the central frequency of the pulse spectrum (Fig. 4). In the classical patch-antenna equivalent permittivity approach, the GPR dipole antenna of length d operating frequency $f = \frac{c_0}{2d\sqrt{\varepsilon_r(eff)}}$ depends on the ground permittivity ε_r through $\varepsilon_r(eff) = 1/2 \times (\varepsilon_r + 1)$ with c_0 the electromagnetic velocity in vacuum [13, p.817]. Considering that $\varepsilon_r \in [3..15]$, the operating range might vary by up to a factor of 2.

This variable operating frequency is a strong incentive towards the HBAR thanks to the availability of modes in nearly one decade of frequency span. The dependence of these modes with the physical quantity under investigation is still an open question since the distribution of energy in the various materials of the stack is dependent on the overtone index. In order to illustrate this issue, the HBAR presented in Fig. 1 was probed using a GPR fitted with unshielded 200 MHz antenna (best suited for glacier investigation in this case) and then 500 MHz antenna (best suited for civil engineering investigations).

Due to the multitude of modes and hence of the echoes generated by the HBAR, identifying which echo is due to the sensor and which echo is due to passive buried interfaces is mandatory to apply a cross-correlation algorithm and identify the time delay in order to extract the monitored physical quantity. The classical Kirchhoff migration converts the hyperbolas observed in the (time, position) B-scans when a point-like reflector is detected by a scanning GPR: the hyperbola curvature is solely defined by the medium permittivity and the depth at which the target is located. As seen on Fig. 6, the HBAR delays by the time associated with the propagation duration in the acoustic transducer, hence shifting the hyperbola later in the B-scan. The deep hyperbolas are inconsistent with passive reflectors buried deep underground (in this example multiples of 200 ns or 26 m assuming a ground relative permittivity of 5) or would require inconsistent permittivities with respect to the surrounding environments. Hence, the shape of the hyperbola is a unique indicator of a HBAR response. Indeed, since the equation of the reflector depth t as the GPR scans along a line of abscissa x is $c^2t^2 = x^2 + d^2$ when probing a reflector located at depth d in a medium exhibiting an electromagnetic velocity c, the curvature of the hyperbolas at position $x = 0$

(hyperbola summit) is

$$\left.\frac{\partial^2 t}{\partial x^2}\right|_{x=0} = \frac{2}{cd} = \frac{2\sqrt{\varepsilon_r}}{c_0 d}$$

so that erroneously identifying a time-delayed echo of the HBAR would yield an unacceptable estimate of the permittivity, especially so if multiple echoes separated by constant time delays are observed.

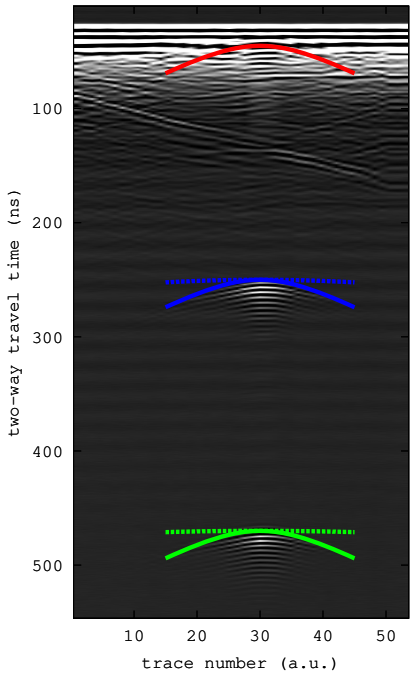

Fig. 6. Experimental B-scan recorded as the GPR is moved over the HBAR-sensor located 20 cm in ice. The top-most (red) hyperbola is due to the reflection on the antenna connected to the transducer. Two echoes, delayed by 200 ns (for a frequency comb spaced by 5 MHz steps), are identified as blue and green hyperbolas with the same shape as the initial reflection. Dashed line: the hyperbola shape if the passive dielectric interface were located at the indicated depth. Solid line: time translated electromagnetic reflection due to the acoustic delay: identifying the sensor reflection from passive interfaces is well defined.

One last unresolved issue is the dependence of the successive echo time delays with the physical quantity under investigation: since the acoustic velocity in the HBAR is a combination of the acoustic velocity in the piezoelectric transducer and the low loss substrate, the observed acoustic velocity depends on the energy distribution in these two layers. The relative energy distribution in each of these layers is dependent on the mode number, so that widely different overtone numbers might exhibit significant different dependence to a given physical effect. Hence, the preliminary calibration between the echo (time) separation and the physical quantity might be no longer valid if the probing frequency significantly differs from the frequency of the calibrated modes, a significant hindrance if the GPR operating frequency varies due to soil moisture content evolution over time and space.

IV. Conclusion

Having demonstrated the use of High-overtone Bulk Acoustic Resonators as passive cooperative targets suitable for applications in which the sensor is buried and hence no longer accessible for maintenance once installed, probed by a commercially available and unmodified Ground Penetrating RADAR, we describe design rules for optimizing the HBAR architecture to increase the interrogation range while keeping the sensing capability provided by the time delay between successive echoes. Maximizing the coupling coefficient requires operating on the thin piezoelectric film fundamental mode, while the low-acoustic loss substrate thickness is tuned to maximize individual mode coupling while keeping the returned echoes well separated. Identifying the echoes associated with the buried sensor as opposed to passive reflectors is achieved through time-domain separation and hyperbola curvature analysis.

Acknowledgments

This research was partly funded by the French National Research Agency (ANR) under the CryoSensors grant, the Université de Franche Comté BQR grant, and supported by the French RENATECH network and its FEMTO-ST technological facility. We acknowledge fruitful discussions with A. Reinhardt (CEA-LETI, Grenoble, France) and E. Lefeuvre (IEF, Orsay, France) concerning the figure of merit of HBAR used as passive sensors.

Passive Wireless Surface Acoustic Wave CO_2 Sensor for Geological Sequestration Sites Monitoring

Yizhong Wang, Minking K. Chyu, Qing-Ming Wang*
Department of Mechanical Engineering and Materials Sciences, University of Pittsburgh, Pittsburgh, PA, USA
*Email: qiw4@pitt.edu

***Abstract*—A passive wireless CO_2 sensing system based on surface acoustic wave technology and carbon nanotube nanocomposite was developed. The gas response of the nanocomposite was about 10% resistance increase under pure CO_2. The sensor frequency change was around 0.03% for pure CO_2. With paralyne packaging, the sensor frequency change from relative humidity of 0% to 100% at room temperature decreased from over 0.1% to less than 0.01%. The lowest detection limit of the sensor is 1% gas concentration, with 0.0036% frequency change. Wireless module was tested and showed over one foot transmission distance at preferred parallel orientation.**

Keywords—CO_2;SAW; Sensor; CNT ;Composite; Humidity

I. INTRODUCTION

One of the most feasible ways of carbon emission control is geological carbon dioxide sequestration [1, 2]. Monitoring of CO_2 leakage on the ground around the sites is vital for the safety of human beings and animals nearby. Due to limited power supply in the remote location of these sequestration sites, a type of wireless operated passive CO_2 sensor is needed.

Commercially available non dispersive infrared (NDIR) CO_2 sensor[3] operated based on laser detection is one of the most widely used CO_2 sensor in mining industry and building monitoring. However, the high power consumption makes it unsuitable for sequestration site monitoring.

The other major CO_2 sensors are mostly based on chemical reaction. The major functions in these sensor are recognition of the CO_2 gas molecule and transduction of that recognition into a useful signal, such as pH, resistance, conductivity, or capacitance. Among them, CO_2 sensor based on surface acoustic wave (SAW) shows great potential.

Equipped with a comb-shape transmitting inter digit transducer (IDT) and a receiving IDT on a piezoelectric substrate, the SAW sensor generates SAW after receiving agitation signal either through wireless antenna or from direct connected power source. The SAW signal then travels along the substrate surface and is intercepted by the receiving IDT and then transferred to the measuring instrument or sent over the wireless antenna. The physical change on the SAW travelling path, such as change in mass or conductivity, will cause the change in SAW velocity and amplitude, thus the change of sensor resonant frequency and attenuation.

There are a lot of SAW sensor on different gases, such as H_2[4, 5], H_2S[6] or VOC[7]. Most of the SAW gas sensor utilizes a sensitive film between the transmitting IDT and receiving IDT, and the sensor response changes accordingly when the sensitive film reacts with target gases. For CO_2 detection, many of the SAW sensor uses gas absorption thin films and measures the resonant frequency change due to the mass change of the film. For example, SAW sensor with ZnO film will have 0.03% frequency change with 10ppm CO_2 [8]. SAW sensor with PVA film[9], PAPP/PAPO film[10], SiO_x and Teflon film[11], Teflon film[12, 13], polyimide film[14], and many other types of films are reported. These SAW CO_2 sensors have different sensitivities, depending on the choice of resonant frequency and sensitive film. They are mostly compact and have low power consumption. However, the mass loading type of sensor suffers from long term drift and false alarm caused by absorption of unwanted gases.

Since SAW signal changes not only with the change of mass loading, but also with the change of the conductivity, permittivity, mobility of the charge carrier and other parameters of the sensitive film[15], there are also SAW gas sensors that respond to the change of conductivity change of the sensing film. For example, PbPc[16] film changes conductivity after reaction with CO_2 and causes considerable amount of frequency change of SAW sensor. Among the SAW CO_2 sensors that make use of conductivity changes of the sensing film, nanotube and insulator (such as polymer) composite attracts more attention due to the large surface to volume ratio of nanotubes, thus higher possible sensitivities. These nanotube composites include SnO_2 [17] and carbon nanotube (CNT)-SiO_2 [18] and many other compositions. By far CNT and polyethyleneimine (PEI) composite proves to be one of the most promising combinations due to its ease of fabrication and low cost. There are some researches on CNT-PEI CO_2 sensing from industry (Honeywell [19] and Nanomix [20]) and academic institutions [21]. Due to the nature of CNT-PEI composite, the CO_2 sensor performance will be greatly influenced by humidity. However, most of the past researches omitted to address the impact of humidity on sensor performance. Some built a reference sensor for humidity sensing so as to compensate the humidity effect. Since the response to humidity change is normally much greater than the response to CO_2 concentration change, such sensor will suffer from unstable sensing performance in real applications.

It's thus vital to find a suitable packaging method for SAW CO_2 sensor based on conductivity change. Parylene, a material long been used in electronic packaging industry, proved to be good candidate for humidity resistant [22]. Parylene film is water vapor repelling and gas permeable when the film is thin enough. So a thin parylene layer will allow CO_2 molecules to

Sponsored by US DOE Grant# DE-FE0002138

go through while stopping water vapor from getting contact with sensing film.

II. THEORETICAL ANALYSIS AND PERFORMANCE EVALUATION OF SAW CO_2 SENSOR

A. SAW Dependence on sensing film conductivity

A SAW propagating in X direction (in the case of ST cut Quartz) has a surface electrical potential which can be expressed as [16]:

$$\phi(x,t) = \phi_0 e^{j(\omega t - kx)} \tag{1}$$

where ω is the angular frequency of the SAW and k is the wave number (For ST cut quartz with a period of 60μm, the wave number is 52.35E+3).

And considering the relationship between the current density J_x in the conductive sensing film and the surface potential through the continuity equation [16]:

$$\frac{\partial J_x}{\partial x} = -\frac{\partial}{\partial t}\left(\frac{\rho_s}{d}\right) \tag{2}$$

where d is the thickness of the film.

When neglecting the diffusion current and considering only the anisotropic SAW substrate, the complex power flow into carrier can be calculated. The fractional velocity perturbation and the attenuation per wave number can be finally calculated as [16]:

$$\frac{\Delta v}{v_0} \cong -\frac{\beta}{k} = -\frac{K^2}{2}\frac{(\sigma d)^2}{(\sigma d)^2 + v_0^2(\varepsilon_0 + \varepsilon_1)^2} \tag{3}$$

$$\frac{\alpha}{k} \cong \frac{K^2}{2}\frac{v_0(\varepsilon_0 + \varepsilon_1)\sigma d}{(\sigma d)^2 + v_0^2(\varepsilon_0 + \varepsilon_1)^2} \tag{4}$$

Here β is the imaginary part of the propagation factor $\gamma = \alpha + j\beta$, k is the wave number, σ is the film conductivity, K^2 is the electromechanical coupling factor, $v_0 = \omega / k$ is the unperturbed SAW velocity (3158m/s for ST cut quartz and 4000m/s for $LiNbO_3$), ε_0 is the permittivity of the region above the substrate and ε_1 is that of the substrate, d is the thickness of the film.

Equation (3) and (4) describe the velocity and acousto-electric attenuation change due to the change of the film conductivity on SAW propagation path. When considering the total surface wave velocity, from perturbation theory [16]:

$$\frac{\Delta v}{v_0} = \frac{1}{v_0}\left(\frac{\partial v}{\partial m}\Delta m + \frac{\partial v}{\partial c}\Delta c + \frac{\partial v}{\partial \sigma}\Delta \sigma + \frac{\partial v}{\partial \varepsilon}\Delta \varepsilon + \frac{\partial v}{\partial T}\Delta T + \frac{\partial v}{\partial p}\Delta p\right) \tag{5}$$

Here m is the variables mass, c is the stiffness, T is the temperature and p is the pressure. Together with unperturbed wave velocity v_0, conductivity σ and dielectric coefficient ε, these are the major components that can cause SAW velocity change, thus frequency shift.

Equation (5) can be exploited to design high efficient SAW gas sensor based on parameters other than mass loading and conductivity change for future research.

Based on (3), the relationship between the sensing film conductivity and SAW sensor performance can be plotted as shown in Fig. 1. From the figure, it can be seen that the best combination of SAW substrate and sensing film is $LiNbO_3$ and composite with 1.6S/m sheet conductivity.

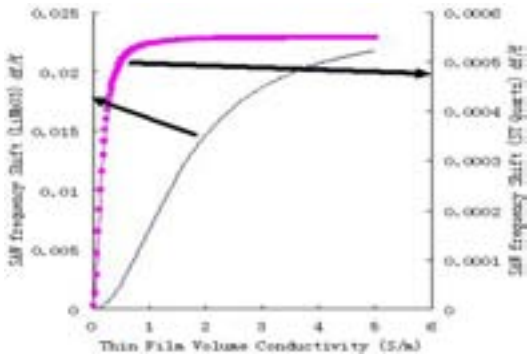

Fig. 1. SAW frequency shift corresponding to the thin film conductivity

B. SAW CO_2 Sensor Performance Evaluation

Based on preliminary test of the composite and the relationship from (3), the sensor performance can be estimated. A maximum of 0.1% frequency change is expected.

III. SURFACE ACOUSTIC WAVE SENSOR DESIGN, FABRICATION AND TEST SETUP

A. Piezoelectric Substrate Material Selection

The properties of common used piezoelectric materials are considered. $LiNbO_3$ is the best candidate for wireless communication. The conductivity dependence analysis above also shows that $LiNbO_3$ works best with sensing film of 1.6S/m sheet conductivity.

B. CNT-PEI Composite Fabrication

The CNTs are commercially available through Aldrich® (2g, St. Louis, Mo, USA) with 1-2nm outer diameter and 5-30um length. Dimethylformamide (DMF) is used to disperse CNT. CNT is mixed with DMF with 1:1000 weight ratio. The mixture is then agitated by ultrasonic convertor (Misonix® ultrasound liquid processors). The CNTs are well dispersed in the DMF solution after 90 minutes ultrasound at 70W. PEI is purchased from Aldrich with mean molecular weight of 25000. Starches are mixed with water using magnetic stir bar at elevated temperature around 100℃. The solution is then mixed with PEI.

The CNTs solution is drop coated on the sensing film region of the SAW sensor using pipette and let dry. The PEI-Starch solution is then applied onto the CNT film area and then washes away using deionized (DI) water so the CNTs will be surrounded by a thin layer of PEI and starch. The calculated volume conductivity of the resulted composite thin film based on resistance measurement proves to be within the optimum working zone of the SAW sensor, i.e. around 1.6S/m.

C. Design and fabrication of SAW Sensor

Two methods are adopted in sensor fabrication: photo lithography and shadow mask technology. 128°YX cut $LiNbO_3$ are selected for its excellent coupling coefficient (5.5% compared to 0.16% of ST cut quartz) and low transmission loss (0.26dB/cm compared to 0.95dB/cm of ST cut quartz). Surface acoustic wave velocity on $LiNbO_3$ is 4000m/s.

With IDT finger width and spacing of 15μm, the synchronous frequency of the SAW sensor from photolithography process is about 60 MHz, which limits the highest frequency of operation of SAW devices to a few GHz.

The IDT of the fabricated SAW sensor from shadow mask process has finger width of about 160um and spacing of about 150μm. The estimated resonant frequency of the sensor is 6.45MHz.

D. SAW Gas Testing System Setup

The gas testing system comprises of gas sources (Compressed Air gas tank and compressed CO_2 gas tank), flow controllers, one quartz gas testing flow chamber with oven, one sink connected with exhaust gas pipe, one current source measurement unit for thin film conductivity measurement (can be replaced by network analyzer in later characterization process), one computer connected to the current source unit for automatic data collection.

E. SAW Sensor Humidity Test Setup

The sensor is tested at several fixed humidity level. It's a common practice that in enclosed container with certain chemical solution, if the solution is over saturated at room temperature, the humidity level of the atmosphere above the solution will remain constant.

As shown in Tab. 1, the relative humidity of each saturated solution depends on the temperature of the solution. The testing environment can be assumed to have constant relative humidity.

TABLE I. RELATIVE HUMIDITY ABOVE SATURATED SOLUTIONS IN DIFFERENT TEMPERATURES (FROM OMEGA).

Relative Humidity (RH%)	***LiCl***	***$MgCl_2$***	***NaBr***	***$CaCl_2$***	***NaCl***	***KCl***	***K_2SO_4***
20℃	11.31	33.07	59.14	32.3	75.47	85.11	97.59
25℃	11.30	32.78	57.6	31	75.29	84.34	97.30
30℃	11.28	32.44	56.0		75.09	83.62	97.00

IV. EXPERIMENT RESULTS AND DISCUSSION

A. SAW Gas Sensor Performance

The fabricated SAW sensor with sensitive thin film is tested with network analyzer as measurement instrument. The SAW sensor performance is shown in Fig. 2.

After comparing test results from Fig. 2 with prediction, it can be seen that test results basically agree with prediction under 20% CO_2 concentration, while the predicted response based on resistance measurement is slightly higher than the real frequency measurement results, with over twice difference under pure CO_2. This might be caused by the slight difference in the fabrication process.

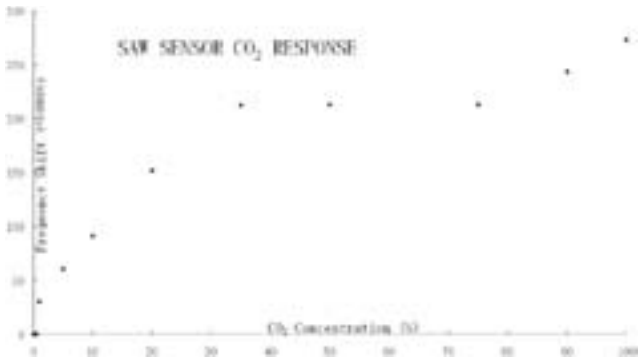

Fig. 2. SAW gas sensor performance.

Even the sensor response to CO_2 concentration higher than 20% is not as high as predicted, the fabricated sensor still shows reasonable response, with 0.003% frequency change under 1% CO_2. Since the CO_2 concentration in the air is around 400ppm, and occasional wild fire and other natural activities might further increase this concentration, 1% is safe for not to trigger false alarm and good enough for leakage monitoring.

B. SAW Sensor Humidity Response

The SAW sensor is then placed in the enclosed container above the saturated salt solution for testing. Test results from the top dotted points in Fig. 3 shows over 0.1% frequency change, which is over 3 times higher than the possible gas response.

C. Packaging Impact on SAW Sensor Humidity Response and Gas Sensing Performance

Parylene layer is coated by Specialty Coating Systems® PDS 2010. As seen in Fig. 3, coated SAW sensor shows an order of magnitude smaller frequency shift compared with uncoated SAW sensor, with less than 0.01% frequency change under saturated water vapor condition.

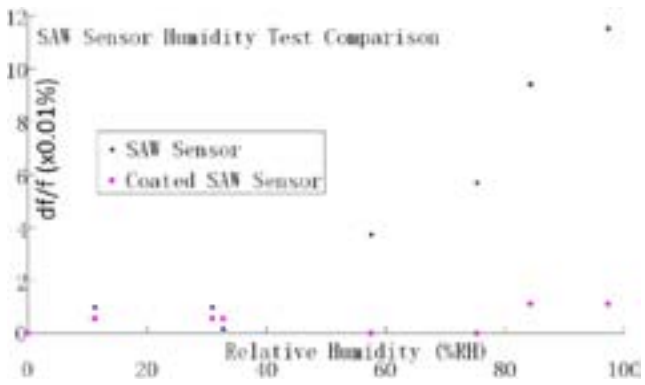

Fig. 3. SAW Sensor Humidity Response comparison after Parylene Coating.

The sensing performance between uncoated and coated sensors only have slight changes, which proves that the coating is gas permeable.

V. WIRELESS MODULE DESIGN, CONSTRUCTION AND TESTING

Due to fabrication limit, the maximum resonant frequency in current sensor design is below 100MHz, which means planar antenna is not the best choice so small scale macro size antenna is used. The inductor used in the project is 132-20SM_LB from Coilcraft®. For gas sensor with IDT from shadow mask, the design frequency is 6.45MHz. It can be calculated that for the design frequency, the desired capacitance is 1131.7μF.

Test results show that for a sensor with 23.633dB insertion loss, as observed for the fabricated SAW gas sensor, the maximum loss the antenna can have is about 68dB. In another word, the antenna range can be over one foot.

VI. CONCLUSION

A SAW CO_2 sensor was developed based on conductivity change upon gas concentration change. Gas test of sensor shows 0.03% frequency change under pure CO_2. Sensor test results basically agree with theoretical prediction of sensor performance. The impact of humidity, however, is more than two times larger than the gas response. After application of paralene coating, the humidity response is reduced to be less than 0.01% for saturated water vapor, while the gas sensing performance is not compromised. Wireless module is also built on coil and variable capacitor and the prelim results show the sensor capable of sensing over one foot distance. Overall, the sensor performance meets the requirement of wireless CO_2 leakage monitoring on geological sequestration sites.

***Abstract*— A two-way method to simultaneously transfer an ultra-stable optical frequency and an accurate timing over a fiber links is presented. The ultra-stable laser acts as frequency standard and as carrier for timestamps. Timestamps signals are encode by phase modulation with a spread spectrum pseudorandom modulation at 20 Mchip/s, provided by a pair of two-way satellite time transfer modems, one for each direction.**

Keywords— Time and frequency metrology, fiber links

I. Introduction

Ultra-stable optical fiber links have been successfully developed for 5 years enabling precise and accurate frequency transfer. The fractional frequency stability experimentally demonstrated is in the range of 10^{-18} after only 3 hours of measurement and frequency accuracy of a few 10^{-19}. Last year ground-breaking frequency transfer has been demonstrated on a record distance of 920 km on dedicated fiber [1]. Fiber links techniques were extended in our joined group to public fiber networks with simultaneous data traffic, providing a scalable technique at the continental level [2,3]. Fiber links with active noise compensation after a round trip demonstrated much more stable and accurate frequency comparisons than satellite-based frequency comparisons, achieved after a much shorter averaging time. This gives a tool for accurate remote clock comparisons, as modern atomic clocks having already demonstrated accuracy in the range of 10^{-16} or below [4-8]. This technique can also play a key-role in advanced time-frequency metrology and for advanced tests of fundamental physics [9]. Accurate frequency comparisons are essential for modern geodesy, high resolution radio-astronomy, and particle physics.

Not only frequency transfer but also accurate timing is important as it gives the ability to precisely synchronize distant experiments or distant detectors. A salient case is the neutrinos speed measurement from CERN to Gran Sasso. Fiber-optical two-way time transfer methods have been demonstrated on dedicated links with an accuracy of the order of one hundred of ps or better [10,11]. Long distance accurate time dissemination is usually based on GNSS signals, or geostationary telecommunication satellites, with timing accuracy of the order of 1 ns in the best case [12,13]. In this work we present a novel method based on two-way transfer method, to simultaneously disseminate an ultra-stable optical frequency and accurate timing over a public telecommunication network. The link is 540 km long, and carry simultaneously our signals on a dedicated "dark" channel and Internet data traffic on the other channels.

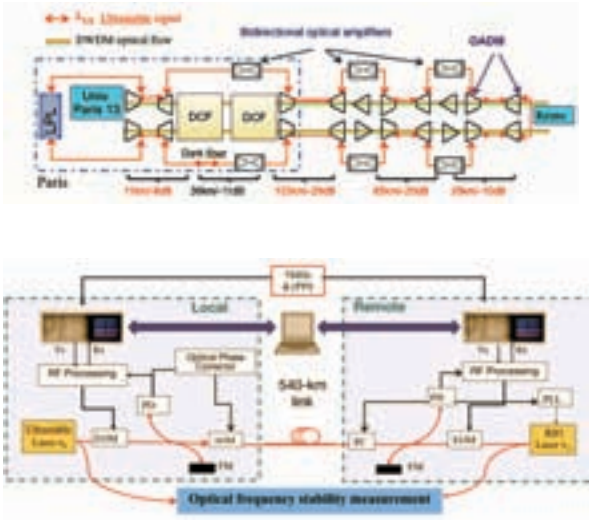

Fig. 1 : (a) 540-km link architecture. OADM (Optical Add-Drop Module), DWDM (Dense Wavelength Division Multiplexing), DCF (Data Center facility) (b) Sketch of the experimental set-up; FM : Faraday mirror, PD : photodiode, AOM : acousto-optic modulator, EOM : electro-optic modulator, OPC : Optical Phase Stabilization Correction, PLL : Phase-Locked Loop.

II. Experimental set up

A. Link architecture

At start our method exploits an ultra-stable laser at 1542 nm to carry both the frequency information as shown in

Ref [3] and the time stamps. The 540 km-long optical link (LPL-Reims-LPL) depicted in Fig. 1a is identical to the one reported in [3]. The timing signal is encoded through optical phase modulation. The scheme of the experiment is shown Figure 1b. Both ends of the links are located at the laboratory (Laboratoire de Physique des Lasers (LPL)). The French National Research and Education Network (NREN) RENATER give us access to the fibers of their network and allow us to set up our own equipment on the lines. The optical link is composed of five different fiber spans. Each span consists of two identical parallel fibers. The third, fourth and fifth spans are long-haul intercity links simultaneously carrying internet data traffic. Optical Add-Drop Multiplexers (OADMs) enable to add and drop the science signal in or from the telecommunication fibers. Total end-to-end attenuation for the 540 km link is 165 dB. 6 bi-directional amplifiers amplify the science signal by about 100 dB, so that the net optical losses exceed 65 dB. Figure 1b shows the hybrid time comparison and ultra-stable optical frequency distribution system. The detailed description of the ultra-stable optical frequency dissemination is given in [3].

B. Frequency transfer

As it was largely described elsewhere [2,3], we briefly remind the reader about the operation of the optical ultra-stable frequency transfer: The frequency signal consists of the frequency of an ultra-stable cavity-stabilised laser, which is partially coupled into the optical fiber. After a round trip propagation through the optical link, the fiber propagation noise is detected with an unbalanced Michelson interferometer where the returning back signal beats with the input signal. The phase noise is compensated by applying corrections with an Acousto-Optical Modulator (AOM) operated around 40 MHz. For the sake of simplicity we gather all error signal processing functions into a symbolic box called Optical Phase Correction (OPC). At the far end of the link the optical signal is regenerated by a narrow linewidth laser (3 kHz), phase-locked on the incoming light, and frequency-offset by 79 MHz. The optical frequency transfer stability is obtained by measuring the optical beat-note between the ultra-stable laser from the LOCAL subpart and the phase locked laser in the REMOTE subpart.

C. Accurate Timing transfer

Concerning time transfer, signals are provided by a pair of two-way satellite time transfer modems [15]. The transfer modems generate a pseudorandom noise modulation code at 20 Mchip/s carried on a radio frequency carrier around 70 MHz, that is related to the one-pulse-per-second (1 pps) and 5 MHz reference signals from a common clock. Orthogonal specific pseudo-random codes are allocated to each modem device. These equipments correlate the received signal with a local replica of the signal expected from the transmitting site and measures the time of arrival of the received signal with respect to the local clock. The time of arrival of both modems are collected by a computer. The data are then processed to compute the differential time delays.

We choose a low-index phase-modulation on the optical carrier to encode the time signal, so that enough energy is kept on the carrier and the signal-to-noise ratio is preserved for frequency transfer. Phase modulation is done at each link end with fiber pigtailed electro-optical modulator (EOM) exhibiting 4 dB insertion loss. The RF carrier frequencies are shifted shifted by 300 MHz, in order to avoid interference between optical signals and to enable efficient filtering of the time comparison signals. The low modulation depth (~1%) and the spread spectrum nature of the modulating time signals lead to a very pure optical spectrums, so that the optical frequency is transferred almost without degradation. The time signals are extracted by a second optical heterodyne beat-note of the local laser with the incoming signal at each link end, shifted in frequency. After successive frequency mixing and filtering the spread spectrum time signals are processed by the modems. Considering the frequency width of the pseudo-random codes (~20 MHz) and the large dynamic range of the signals in the detection system where parasitic signals are 40 dB larger than the useful signal, the RF processing of the signal is not trivial and require high performance filters and cautious operation.

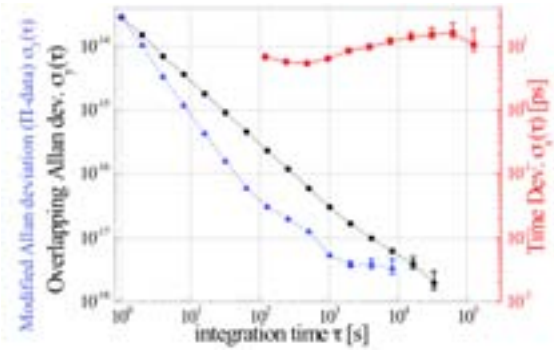

Fig. 2 : Left axis : Overlapping Allan deviation and modified Allan deviation of the frequency transfer as function of the integration time, while transferring an accurate timing. Right axis : Time deviation of the differential delay as a function of the integration time, while transferring an optical frequency.

III. RESULTS

The frequency transfer stability and the timing stability/ jitter were simultaneously measured and are plotted in Fig. 2. The frequency stability of the link reaches a resolution of $2x10^{-18}$ at 30 000 s averaging time, which is almost identical to the one reported in [3]. The accuracy of the frequency transfer is about $2x10^{-18}$. The time stability exhibits a noise smaller than 20 ps over the whole measurement time period.

We proceed standard calibration techniques to estimate the contribution of the varying delay of propagation to the uncertainty budget [15]. As the fiber optical length is unknown and fluctuates over time, a rigorous calibration test is indeed needed to guarantee the independence of the system from the optical fiber length. The propagation length was changed by short-cutting the links in the accessible places. We vary the link length from 10 m to 94 km, 400 km and the total length of 540 km. We measure that the differential time delay variation versus distance is at most 50 ps. We also performed several tests of disconnection/connection, power shutdown and restart without measuring appreciable time delay variation. Tests on fiber spools of 25 km, 50 km, 75 km and 100 km are consistent with the above reported results.

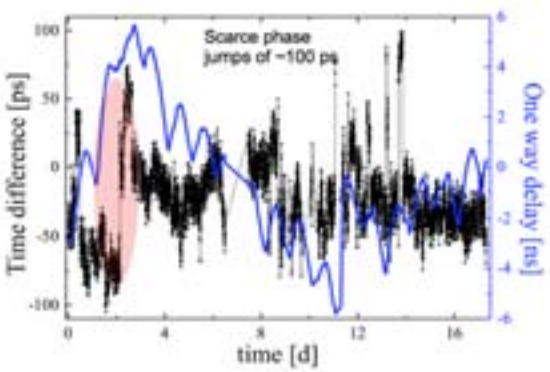

Fig. 3 : One-way time delay (blue plot, right axis) and differential delay (black plot, left axis) versus time for the 540-km fiber link (constant calibration time offset removed on both plots)

A variable optical attenuator was inserted into the common fiber path in order to keep the overall link attenuation approximately constant within ±2 dB. The delay variations in the modems depending on the variation of the received power were thus reduced. We checked experimentally the system sensitivity by changing the power of the signals from the optical detection up to the modem input. As long as the modems are operated in their optimal conditions (i.e. low input power level), the system shows a coefficient dependencies below 15ps/dB.

Fiber chromatic dispersion (FCD) play here a very little role as the frequency difference between the two counter-propagating time signals is very small. For instance FCD contribution for 300 MHz frequency difference between the 2 ways and for the 540-km link is below 25 ps. Polarisation Mode Dispersion (PMD) contributes also to the uncertainty budget. Derived from previous telecommunication fiber network characterization we estimates the timing fluctuations due to PMD well below 20 ps. This was confirmed by experiment by varying the input polarization state with Lefevre's three-loop rotating wave plate. We did not observe any significant variation within a measurement resolution of 50 ps. As both time measurements are collocated in this experiment, the set-up is not sensitive to the Sagnac effect and its contribution is therefore void.

The preliminary conservative accuracy budget we achieve with this experiment is 250 ps. The results is mainly dominated by scarce phase jumps of about 50-80 ps we observed on the datas. They can be related related to the propagation in the long-haul Internet fiber link, dysfunction of the SATRE modems, or uncontrolled effects within the RF processing chain. Additional tests performed by replacing the long-haul link with fiber spools did not reveal any phase jumps over several days of measurements. Despite efforts on the analysis and several trials to fix it, and due to their random and rare statistics, the cause of such behavior is not yet understood. The system is nonetheless quite robust : in addition to the results presented in Figure 3, we have several runs of about one week for which the peak-to-peak time fluctuations are below 200 ps while one-way fluctuations are in excess of 10 ns. The results in terms of timing stability and accuracy clearly outperform the satellite techniques [12].

Such technique can be extended to a wider range, in the case of slightly lower fiber losses and better distribution of the optical amplification. We believe that this method of accurate time transfer can be also extended to segmented optical links by the use of intermediate optical regeneration stations [2,3] which include RF signal processing techniques and station delay calibration procedures. Our method can be improved for example by developing new modems with wider pseudo-random codes. For a solely time transfer, the ultra-stable laser is not needed and the scheme proposed here can be drastically simplified. We point out finally that the use of heterodyne detection allows operation with very large optical losses, for which classical Intensity Modulation (IM) techniques are ineffective. This method has been proven to be applicable to non-dedicated fiber and installed long-haul fiber links carrying Internet data, opening the way to frequency and time dissemination on a continental scale via NRENs and european counter-part that could be used for that purpose.

***Abstract*—We report on the realization of the coherent optical link for time and frequency dissemination developed in Italy. The fiber backbone connects scientific laboratories that need accurate time and frequency measurements located in Torino, Milano, Bologna and Firenze. We briefly describe the technique, and report the status of installation and preliminary characterization.**

Keywords—Fiber link, Time and Frequency transfer

I. INTRODUCTION

Optical fiber links are a key enabling technology for science and metrology. They are suitable for the remote comparison of very accurate clocks, such as Cs fountains or optical clocks [1-3] and their resolution exceeds the state-of-the-art satellite techniques by several orders of magnitude. The coherent optical link allows to exploit the accuracy of an optical clock in few hundred seconds over hauls up to hundreds of km, a performance otherwise impossible. This is an outstanding issue, as optical frequency standards are recommended by the BIPM for the secondary representation of the second in the International System (SI) of units, and are the most promising candidates for its future redefinition [4]. It is possible to achieve frequency dissemination (and comparisons) at the 10^{-16} level of stability [2,3] and time dissemination at the 100 ps level [5] over hauls of 1000 km. This level of resolution needs for the compensation of the phase noise introduced by the fiber due to mechanical stresses and temperature variations, using a bidirectional Doppler cancellation technique [6].

The National Institute of Metrology (INRIM) realizes in Italy accurate T&F signals and disseminates them to a variety of scientific laboratories and industries. Presently, INRIM maintains two Cs fountain primary frequency standards, with an accuracy at the 10^{-16} level [7], and is developing an optical clock based on Yb atoms [8]. To improve the quality of T&F dissemination, INRIM started together with other major National Institutions, the LIFT project (the Italian Link for Frequency and Time, funded within Progetti Premiali 2012), to realize an optical link along a 642 km fiber that connects Torino to Milano, Bologna, and Firenze.

The aim of the project is the distribution of the INRIM reference T&F signals to a variety of scientific laboratories via optical fiber, with a target relative instability of 10^{-14} at 1 s and 10^{-18} at one day measurement time. Those laboratories represent national centers of excellence in their fields; this facility will further improve their scientific capabilities, allowing them to better exploit existing experiments and to establish new ones in the future.

Present partners of the project are the National Institute of Nuclear Physics in Firenze (INFN), in collaboration with the European Laboratory for Non-linear Spectroscopy (LENS) and Department of Physics and Astronomy of University of Firenze; the National Institute of Astrophysics (INAF) in Medicina, near Bologna, and the National Council of Research (CNR) through the National Institute of Optics (INO) in Firenze and the Institute of Photonics and Nanotechnologies (IFN) in Milano.

Both INFN and CNR are involved in high resolution spectroscopic measurements, and will benefit from T&F dissemination via optical fiber. In particular, at LENS a Sr optical clock is under evaluation [9], and its frequency comparison to the frequency standards of INRIM could allow a number of new fundamental physics experiments. The INAF radiotelescope can be both an high demanding user of the external T&F standards as well as a source for their close inter comparison with Pulsar-derived time scales or with the Celestial Reference Frame defined via Very Long Baseline Interferometry (VLBI). Closing the loop between sky observations and the new atomic frequency standards, even spread in different Italian locations, could lead to detect subtle systematic effects or in any case improve both sides of science.

T&F measurements with improved resolution are expected to be performed from 2014, in the second stage of the project, whilst in the first start-up stage the fiber backbone will be fully characterized and preliminary tests and checks will be completed.

II. Coherent Time and Frequency Dissemination through Optical Fiber

A key point of the project is to use the same infrastructure to disseminate both time and frequency. When performing frequency dissemination, an ultrastable laser (1542 nm) is sent to the user, and its frequency is simultaneously measured in the two laboratories, with the aid of optical frequency combs. The frequency of the delivered laser is perturbed by environmental noise in the fiber. However, it is possible to compensate this noise with an optoacoustic actuator; this technique requires that the end laboratory redirects the incoming signal to the start laboratory, where the delivered signal is compared with the received one, and the added noise is cancelled in real time. For the noise cancellation to be effective, there must be a fully-optical backbone with no optical/electrical conversions, and the light has to travel exactly the same path in both directions. This is quite different from typical fiber transmission techniques, and poses several requirements on the optical instrumentation.

To disseminate time signals, a pseudorandom noise will be encoded on the optical carrier, similarly to the two way satellite time and frequency transfer: instead of cancelling the phase noise of the carrier itself, the measured transmission delay will be calibrated and stabilized, with a resolution of 100 ps.

The optical fiber used in our project is a ~ 640 km dedicated fiber, with a total loss of ~180 dB, due to hauls and connectors losses. To adequately compensate for optical losses, we installed dedicated, fully bidirectional Erbium-Doped Fiber Amplifiers (EDFAs) along the path, that use the same active fiber in both directions (Figure 1).

Fig. 1. The map shows the optical path and amplification sites.

III. Link Implementation and Characterization

One of the demanding steps of the link implementation is to compensate for the optical losses in such a bidirectional transmission scheme: the gain of our dedicated EDFAs could be set only with the whole link operating, as the gain and optical signal-to-noise ratio (OSNR) of each stage is affected by the others. Setting the gain below ~22 dB, we prevent oscillation lasing effects and OSNR degradation due to backscattering and Amplified Spontaneous Emission (ASE) [10]. Currently, 9 amplifiers have been installed, and optical filters have been used to keep the OSNR at an adequate level. In Figure 1, the optical path is shown with the location of the amplification sites; Table 1 reports for each station the distance from Torino and the optical losses of the haul. Measurements of the phase noise added by the fiber was performed during EDFA installation on several amplification sites, by reflecting the signal back towards INRIM. These measurements allowed us to check the noise contribution from each haul and the phase-compensation capabilities of the control loop.

Figure 2 shows the phase noise power spectral density of the back-reflected signal without the Doppler cancellation (free running fiber link). It represents the phase noise of the fiber up to three different intermediate stations. It is worth noting that the phase noise accumulated in the Bologna-Firenze track (100 km) is comparable to the remaining part of the link (450 km) and exceeds the expected figure by several dB. The reason for this excess of noise are under investigation with the fiber provider.

Figure 3 shows the phase noise power spectral density of the correction signal applied to the actuator when the compensation loop was activated on the full 642 km optical fiber link.

Location	Length	Losses
To-Lancia	25 km	9 dB
Santhia	67 km	18 dB
Novara	77 km	18 dB
Lainate	50 km	15 dB
Milano	60 km	18 dB
Piacenza	67 km	16 dB
Reggio Emilia	94 km	23 dB
Bologna	74 km	19 dB
Rioveggio	38 km	10 dB
Firenze	72 km	18 dB
LENS laboratories	18 km	7 dB

Table 1.Lenghts and losses of the various link hauls.

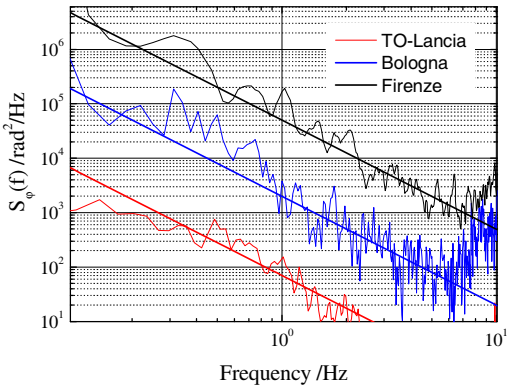

Fig. 2. Phase noise of several fiber link hauls: from INRIM to To-Lancia (25 km), to Bologna (+490 km) and to Firenze (+128 km). It is evident that anomaluos noise is present in the track between Firenze and Bologna.

Based on these measurements we can estimate the ultimate achievable stability of the transferred signal at Milano, Bologna and Firenze. The value obtained for the Torino Firenze link in terms of Allan deviation in 1 Hz bandwidth is

3×10^{-15}. This estimate is based on the assumption that the phase noise cancellation bandwidth is limited by the time (~ 6 ms) it takes the light to travel to the far fiber end and back [5].

Presently, we have completed and operated the link to Firenze but we have not yet extracted the signal for the intermediate users in Bologna and Milano. The laser transmitted from INRIM and delivered to LENS in Firenze is used as a reference to phase lock a 1542 nm diode laser. This laser is then frequency doubled and sent to a local Ti:Sa based optical frequency comb, to be compared with the local ultrastable laser at 698 nm used in the Sr clock experiment . In Figure 4 we report the frequency stability of the delivered laser measured against the local ultrastable laser in Firenze. There are also shown the stability of the free running fiber link (i.e. without noise compensation) and the stability of the 1542 nm laser at INRIM. The compensated link contribution is assessed to be $<1.5\times10^{-14}$ and does not degrade the stability performances of the delivered laser at 10 s. The Allan deviation of the delivered laser was measured in Torino using a twin stabilized laser as reference.

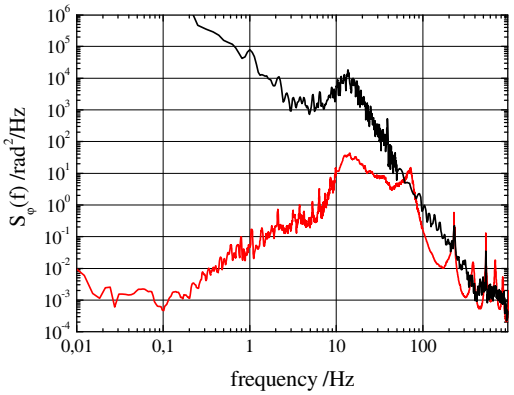

Fig. 3. Phase noise of the fiber link at Firenze (642 km), free running (black curve) and with Doppler compensation (red curve).

For an ultimate characterization, during next year, a second fiber link in an antiparallel configuration [2] is planned. This will allow us to determine the contribution of the non-compensated phase noise of the fiber itself, to detect possible sources of frequency inaccuracies, like cycle slips etc. and to state the ultimate stability performance of the optical link. Nevertheless, according to the preliminary characterization, the present optical link can already be used for frequency dissemination with high stability and accuracy.

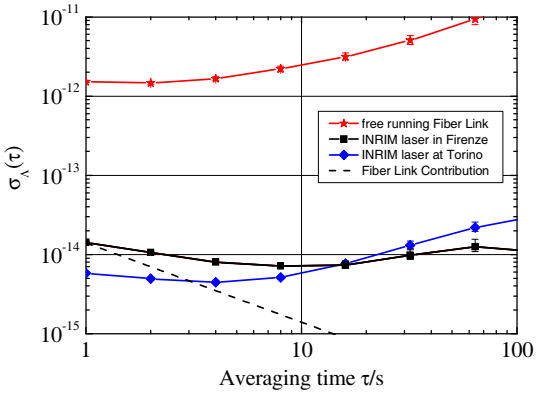

Fig. 4. Stability of the link: stablity of the free running link (red stars); stability of the INRIM 1542 nm laser measured at LENS vs the 698 nm Sr clock laser in closed loop (black squares); stability of 1542nm laser measured at INRIM (blu diamonds) and the deduced contribution of the compensated link (dashed line). Note that the measurement of the laser stability at INRIM is not taken contemporarely to the one in Firenze, hence the fluctuation of the noise around 100 s.

IV. Conclusions

We report on the implementation and preliminary characterization of the 642 km fiber link connecting Torino to Milano, Bologna and Firenze within the LIFT project. At present, the fiber backbone has been implemented and preliminary characterization is being carried on. The amount of phase noise added by the optical fiber that cannot be compensated is not a limitation, and we estimated that frequency dissemination at the 10^{-16} level of stability in few minutes of averaging time can be obtained. Experiments related to time distribution will also be performed in the next months.

Fiber frequency dissemination represents a dramatic improvement with respect to satellite techniques, and enables frequency comparisons and calibrations at unprecedented levels of uncertainty, paving the way for a number of scientific experiments in the fields of high resolution spectroscopy, radio-astronomy, fundamental physics.

The development of this National network is of major interest also for high–tech industries, making available high quality T&F signals in real time, without need of routine calibration. This infrastructure will be easily adapted to perform widespread dissemination towards a larger variety of users, with reduced costs. This secondary dissemination will use optical fibers as well, but instead of optical carrier it will distribute an amplitude modulated signal, much easier to be detected and used.

V. Acknowledgments

The authors thank G. Santarelli, H. Schnatz, G. Grosche and P. E. Pottie for their help and advice.

University of Florence thanks PTB for providing the 698 nm laser used in the characterization of the link.

University of Firenze, Politecnico of Torino and INRIM acknowledge the Italian Ministry of Education, University and Research (PRIN09-2009ZJJBLX) for funding the optical link.

INRIM acknowledges Compagnia di S. Paolo, the Italian Ministry of Education, University and Research (Progetti Premiali 2012), and the EMRP program (Project SIB02-NEAT-FT) for funding. The EMRP is jointly funded by the EMRP participating countries within EURAMET and the European Union.

University of Firenze acknowledges Ente Cassa di Risparmio di Firenze for funding.

The authors acknowledge GARR for the technical help with the fiber.

***Abstract*—The paper describes optical infrastructure for time and frequency transfer in the Czech republic. The infrastructure is heterogeneous and utilises resources of the Czech academic optical network. It allows to interconnect Cesium standards in distant sites with the national time and frequency laboratory and to distribute accurate time and stable frequency. We also present results and compare them with other methods of time transfer.**

I. Introduction

The request for accurate time and stable frequency transfer has significantly increased in recent years. As the standard methods using satellite navigation system like GPS are reaching their limits, the most challenging technology is based on optical fibers. There were developed techniques utilizing one-way transfer or two-way transfer in either single fiber or pair of fibers. We can observe increased number of both theoretical studies and practical field implementations. This paper describes design of dedicated optical infrastructure for time and frequency transfer (TF-infrastructure) in the Czech Republic. We also present our experience and first results.

The TF-infrastructure uses resources provided by existing Czech National Research and Educational Network (NREN) that is based on DWDM (Dense Wavelength-Division Multiplexing) technology. The network is operated by CESNET which is for several years involved in time and frequency metrology applications that use optical links and cooperates with the National Time and Frequency Standard in Institute of Photonics and Electronics (UFE). Both organizations are also participants of European research project NEAT-FT [5].

Present networks are designed for simultaneous transmission of data streams. Data are typically packetized and are processed in electronic devices, e.g. routers and switches. This involves necessity of repeated conversions from optical to electrical domain and vice versa - OEO. Statistical multiplexing of packets, digital signal processing and repeated OEO causes that precise timing of data in packet networks is not guaranteed at the link layer. Time and frequency transfer shall be implemented at physical layer that provides dedicated optical channels isolated each to other.

II. Project Goals

The design of TF-infrastructure is based on our preliminary experience with time transfer between Czech and Austrian national time and frequency laboratories UFE and BEV [4], whose regular operation started in August 2011. The topology is determined be existing DWDM network extended by dedicated dark fiber links.

TF-infrastructure is heterogeneous platform that covers many current and near future tasks of involved organizations. The goals include:

- Transfer time from several deployed Cesium primary standards and Hydrogen masers to LNTFS in UFE. Higher number of these interconnected clocks will improve accuracy and stability of UTC(TP) - the national approximation of UTC time scale.
- Compare national approximation of UTC with that one in neighboring countries.
- Check accuracy and stability of other connected atomic clocks.
- Distribute accurate time and stable frequency to demanding users.
- Obtain experience with the coherent frequency transfer as a preliminary activity aimed at intended building of optical clock.

Fig.1 shows the actual state of the TF-infrastructure: it joins four organization that operate atomic clocks and another two organizations that are provided by atomic time scale or frequency. The TF-infrastructure includes also links to neighboring countries Austria and Poland. The link to BEV in Vienna is in use and connectivity to Polish network is ready and we are able to set up time transfer channel to Polish laboratories GUM (Warsaw) or AOS (Borowiec).

III. Technology

The TF-infrastructure physical topology is a star with center in CESNET, while the transport layer topology is a star having center in Institute of Photonics and Electronics (UFE). The dark fiber between these two localities is currently used for time transport UFE – BEV but we are going to install there a DWDM system providing at least 16 bidirectional channels. Links between CESNET and involved organizations utilize available technology, in most cases it is a combination of commercial and open DWDM transmission systems:

- pair of channels (with the same wavelength in both directions) in a production DWDM optical network,

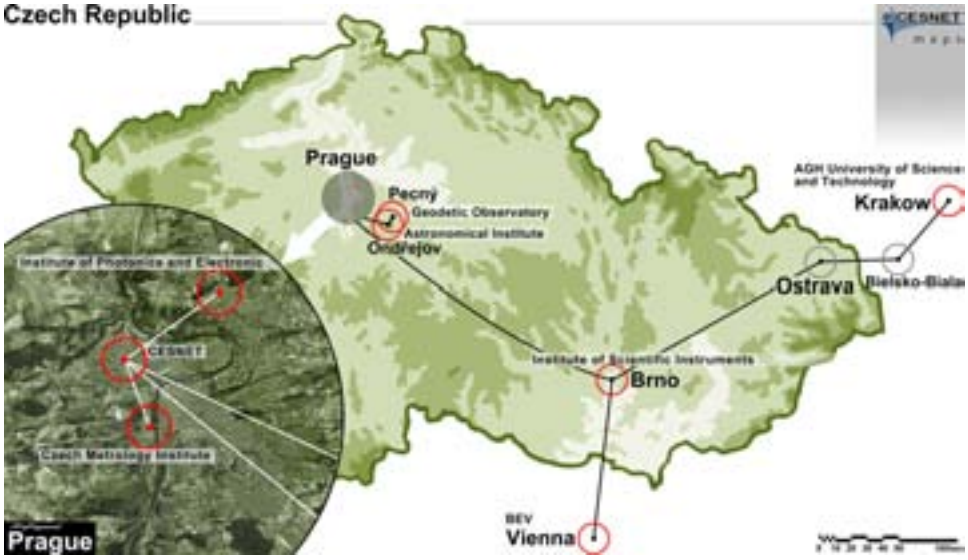

Figure 1. Map of TF-infrastructure

- pair of DWDM channels with different wavelengths in single fiber bidirectional transmission system,
- pair of DWDM channels (both uni- and bi-directional) in experimental links,
- dark fiber – usually the last mile in the urban area.

Despite this heterogeneous physical layer, the transport layer provides parameters required for accurate time transfer. Currently, channels for time transport are amplified by the same unidirectional amplifiers that are used for standard data channels but we already developed own bidirectional amplifiers in scope the project CzechLight [6]. Once deployed, these amplifiers will be dedicated for time (resp. frequency) transfer only. In future, we plan to install these new amplifiers even in the CESNET backbone links.

Typical example of TF-infrastructure is a fiber shared for both time transfer and standard data service (2x 10Gb/s) between CESNET and VUGTK (Geodetic Observatory in Pecny) as is depicted in Fig. 2. The geographical distance between both sites is 35.2 km. The main part of the line is represented by a 78 km long single fibre which has attenuation of about 21.2 dB. The link setup reserves four unamplified wavelengths in ITU grid for time transfer and supports up to 16 amplified DWDM wavelengths for standard 10Gbit/s Ethernet data channels. Time transfer wavelengths are available at connectors of ADD/DROP filters (see Fig.2). The direction CESNET to VUGTK uses channel #38 (1546.92 nm) of the ITU grid, the opposite direction uses channel #39 (1546.12 nm).

The link CESNET – VUGTK is considered a pilot implementation of the TF-infrastructure. Another part of it is the link to Vienna which is used for continuous time transfer between UFE and BEV for already two years [4]. Table I summarizes features of both links.

Table I. PAMETER OF TIME TRANSFER SETUP

	UFE – BEV	CESNET – VUGTK
Fiber	pair of unidirectional fiber	single bidirectional fiber
ITU channel (wavelength)	#32 (1551.72 nm) in both direction	#38 (1546.92 nm) and #39 (1546.12 nm)
Fiber length	550 km	78 km
Amplifiers	7x EDFA	no
Counters	SR-620 and CNT-91	interpolatin counter in FPGA

IV. RESULTS

Time transport between CESNET and VUGTK utilizes single bidirectional fiber, therefore symmetrical change of propagation delay, e.g. temperature dependence of chromatic dispersion, cancels in the first order. Similarly cancels influence of possible change of the fiber physical length, for example when the provider replaces a patch cord in the switch board. Possible exception of optical paths symmetry represents the fiber inside ITU grid filters (see the ADD/DROP elements in Fig.2) - length of that fiber 'pigtails' must be measured and the difference of propagation delay $T_{\Delta L}$ calculated.

As different wavelength is used in both directions, the corresponding propagation delay diference is done by formula:

$$T_{\Delta\lambda} = D_{fiber} \cdot \Delta\lambda \cdot L + D_{filter} \cdot \Delta\lambda \qquad (1)$$

Paper [3] discusses influence of other effects - Sagnac effect and birefringence of the fiber. However, these values are negligible for our link length compared with chromatic dispersion contribution.

The total difference of fiber propagation delay is:

$$\Delta T = T_{\Delta\lambda} + T_{\Delta L} \qquad (2)$$

Both terms in (2) can be calculated, therefore we can perform the calibration without using any other time transport system. In our case, $T_{\Delta L} = 0$ as fiber 'pigtails' length inside both filters match. Substituting wavelength difference 0.8 nm,

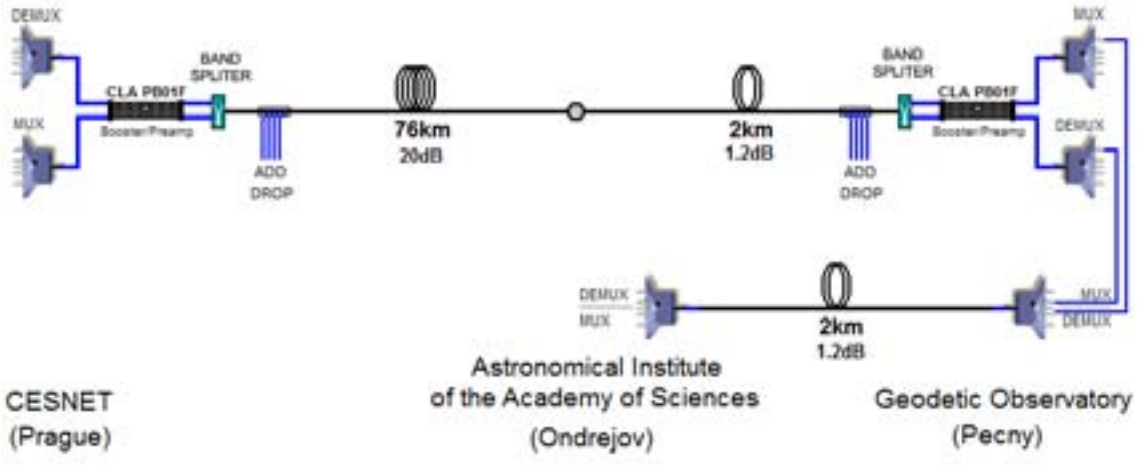

Figure 2. Link CESNET – VUGTK

filter chromatic dispersion 120 ps/nm, total fiber length 78 km, and 17 ps/nm/km as the chromatic dispersion coefficient for fiber type G.652 into (1), we evaluate propagation delay difference $\Delta T = 1.16$ ns.

The uncertainty of time transfer also depends on several physical effects, e.g. polarization mode dispersion, thermal dependency of refractive index of directionally disjoint paths (patchcords and filters), thermal dependency of fiber chromatic dispersion coefficient, and filters central wavelength thermal dependency. According to detailed analyzes in [3], uncertainty of any of these effects is up to few picoseconds and the sum does not exceed 10 ps for our setup. The common contribution to time transfer uncertainty is half of propagation delay uncertainty, i.e. no more than 5 ps. Similar contribution provides the uncertainty of 'pigtails' length measurement – error of 1 mm represents time difference of 5 ps. All these values are below main source of uncertainty, the error of utilized time interval counters. In former setup we used universal time interval counters SR-620 and Pendulum CNT-91, having random error 20 ps, resp. 50 ps. Recently, we developed own time interval counters based on interpolation delay line implemented in the FPGA chip having resolution about 20 ps. Detailed counter evaluation was not yet done but the estimated accuracy is 40 ps.

Fig. 3 and Fig. 4 provide comparison of optical time transfer with GPS based methods in term of TDEV for both UFE – BEV and CESNET – VUGTK. Graphs confirm that optical time transfer has smaller noise then both PPP method for both links. Noticable white phase noise is about 3 times lower in case of CESNET – VUGTK time transfer. The reason is probably the symmetry of the optical path due to single fiber without any optical amplifiers.

Evaluated difference (in 300 s intervals) between PPP and optical time transfer is shown in Fig. 5 and Fig. 6, respectively. Standard deviation of the difference between both measurements is 62 ps for link CESNET – VUGTK and 95 ps for UFE – BEV.

***Abstract*— In November 2012 the time transfer links between Physikalisch-Technische Bundesanstalt (PTB), Observatoire de Paris (OP/LNE-SYRTE), Swiss Federal Institute of Metrology (METAS), and TimeTech GmbH were calibrated using TimeTech's mobile TWSTFT calibration station for the first time.**

Keywords: TWSTFT; link calibration; mobile station

I. INTRODUCTION

Calibrated time transfer between two remote locations using the Two-Way Satellite Time and Frequency Transfer (TWSTFT) technique with telecommunication satellites requires the accurate knowledge of the internal delays of the equipment involved, the asymmetry between signal paths, and the delays of the connections of the equipment to local time scales. In case of a single satellite transponder used for both signal paths, these delays depend only on the ground equipment, because free space and atmospheric induced delays cancel out in the two-way combination. A single transponder also enables time transfer between two stations located at the same site. The traveling station is operated together with the fixed equipment at each site in a common-clock setup for some days. For each pair of ground sites the differences between the common-clock data reflect the delays of the fixed stations, while ideally the delays associated with the traveling equipment cancel out.

In November 2012 the time transfer links between Physikalisch-Technische Bundesanstalt (PTB), Observatoire de Paris (OP/LNE-SYRTE), Swiss Federal Institute of Metrology (METAS), and TimeTech GmbH (TIM) were calibrated using TimeTech's mobile TWSTFT calibration station assembled on a trailer.

The calibration trailer was firstly introduced at EFTF 2012 [1]. Its stability during the initial calibration campaign was verified by taking common-clock data at TimeTech before and after the trip to the metrology laboratories, and by triangle closures, which are based on the principle that the sum of calibrated links between three sites should be zero within the combined uncertainty.

We report on the current status of the calibration station and present the results of the calibration campaign, the uncertainty estimation, and comparisons to previous calibrations. Since the mobile station allows for a standardized and easily executable procedure at each laboratory, the systematic uncertainties are significantly below one nanosecond for the links contributing to TAI and UTC.

II. BRIEF DESCRIPTION OF CALIBRATION METHOD

TWSTFT between two remote laboratories 1 and 2 is based on the exchange of modulated radio signals via a communication satellite, which are coherent to the respective timescales UTC(1) and UTC(2). At both sites the signal of the remote site is compared to the local UTC(k). The difference between the measurements at laboratory 1 and 2 reflects the difference UTC(1) − UTC(2) plus the delays due to the ground station equipment, asymmetries of the signal path, and the Sagnac effect [2]

In mathematical term the two remote measurements are given by [3]

$$\begin{aligned} TW(k) = {} & UTC(k) - UTC(j) - 1PPSREF(k) + 1PPSREF(j) \\ & + TX(j) + SP(j) + RX(k) + SCD(k) - SCD(j), \end{aligned} \quad (1)$$

with k,j = 1 or 2, and k ≠ j. 1PPSREF(i) is the delay between the 1 PPS signal connected to the TWSTFT modem and the local representation of UTC, adjusted by the laboratory. TX(k) and RX(k) are the signal delays of the transmission and reception part of the respective ground station, SP(j) is the signal path delay from site j to site k, and SCD(k) and SCD(j) are the Sagnac delays for the two sides of the link. According to [3] the Sagnac effect is corrected with sufficient precision by applying fixed values calculated from the station positions

* Present address: Bureau International des Poids et Mesures (BIPM), Pavillon de Breteuil, F-92312 Sèvres Cedex, France

and the nominal position of the satllite.. The other delays are a priori unknown and have to be determined by calibrations.

In single transponder setup, where the same satellite antenna covers both stations 1 and 2, the signal path delays are equal: SP(1) = SP(2). Since the link is bi-directional, the delays through the Earth atmosphere cancel to first order. The timescale comparison is performed by exchanging the measurement data and reads

$$\begin{aligned} \mathrm{UTC}(1)-\mathrm{UTC}(2) &= \tfrac{1}{2}\left[\mathrm{TW}(1)-\mathrm{TW}(2)\right] \\ &+ \tfrac{1}{2}\left[\mathrm{DLD}(1)-\mathrm{DLD}(2)\right]+\left[\mathrm{SCD}(2)-\mathrm{SCD}(1)\right] \\ &+ \left[1\mathrm{PPSREF}(1)-1\mathrm{PPSREF}(2)\right] \end{aligned} \quad (2)$$

where DLD(k) denotes the station dependent delay difference defined by DLD(k) = TX(k) − RX(k).

The task of a link calibration is to determine the difference of station dependent delays [DLD(1) − DLD(2)] by operating a mobile station at site 1 in parallel with the fixed TWSTFT equipment in common-clock mode and then repeating the common-clock measurement at site 2. Common-clock mode means that the mobile station is operated close to the fixed stations and connected to the same reference signals. More details are in [1]. At both sites we define the common-clock difference (CCD) between mobile and fixed station as

$$\begin{aligned} \mathrm{CCD}(k) &= \tfrac{1}{2}\langle \mathrm{TW}_M - \mathrm{TW}(k)\rangle \\ &= \tfrac{1}{2}\left[\mathrm{DLD}(k)-\mathrm{DLD}_M\right]+\left[1\mathrm{PPSREF}(k)-1\mathrm{PPSREF}_M(k)\right], \end{aligned} \quad (3)$$

where <…> denotes the average over several measurements. DLD_M and $1\mathrm{PPSREF}_m(k)$ are the mobile station delay difference and the delay of the local UTC(k) with respect to the 1 PPS reference connector of the mobile station, respectively. There is no local UTC and SCD contribution in (3), because these contributions are the same for mobile and fixed station. The difference between the two CCD measurements yields

$$\begin{aligned} \mathrm{CCD}(2)-\mathrm{CCD}(1) &= \tfrac{1}{2}\left[\mathrm{DLD}(2)-\mathrm{DLD}(1)\right] \\ &+ \left[1\mathrm{PPSREF}(2)-1\mathrm{PPSREF}_M(2)\right] \\ &- \left[1\mathrm{PPSREF}(1)-1\mathrm{PPSREF}_M(1)\right]. \end{aligned} \quad (4)$$

The mobile station delay difference DLD_M cancels out, because it is the same at both laboratories (if the mobile station is not changed during the travel). The values for $1\mathrm{PPSREF}_m(k)$ have to be determined by local measurements at both sites. The calibration value for the link between site 1 and 2, CALR(1,2), is defined as

$$\mathrm{CALR}(1,2) = \left[\mathrm{CCD}(2)-\mathrm{CCD}(1)\right]+\left[\mathrm{SCD}(2)-\mathrm{SCD}(1)\right]. \quad (5)$$

The SCD contributions are calculated as recommended in [4]. After adding (5) to (2), the link performs calibrated time transfer between the UTC(1) and UTC(2). CALR(1,2) is stored in the ITU files of station 1 and with opposite sign in the respective files of station 2 [4].

III. MOBILE STATION

The mobile station consists of two parts: A small indoor rack with time and frequency distribution equipment and an outside trailer with on top antenna dish. Both parts are interconnected by a bi-directional optical fiber link in master-slave configuration. An overview scheme of the main components, the setup at a timing laboratory, and the connection to the laboratory's reference signals is shown in Fig. 1. The inside rack comprises a Pulse Distribution Amplifier (PDA) and the master reference generator for the optical link with integrated Time Interval Counter (TIC). The outdoor trailer hosts the slave reference generator, the TWSTFT modem, and all other equipment necessary for satellite communication, e.g. up- and downconverters. The antenna dish is motor-controlled and automatically points to the communication satellite using station and satellite position information. Computers and equipment for data storage and remote commanding is implemented in both indoor rack and outdoor trailer. The data communication is also realized via optical fiber.

The inside rack is connected to 5/10 MHz reference frequency and 1 PPS Ref signal coherent to the local UTC. The delay of the 1 PPS Ref signal with respect to local UTC however does not need to be known. Instead, it is split into two signals by a Pulse Distribution Amplifier (PDA). One of the pulses is used as input for the master reference generator, the second is connected to the stop channel of the inbuilt Time Interval Counter (TIC). The TIC start channel is connected to the local 1 PPS UTC(k) signal or a signal with known delay to UTC(k), provided by the laboratory. The TIC start channel is thus the calibration reference point, because the PDA, the internal cables in inside rack and outside trailer, and the optical link are the same during the complete calibration campaign and the delays cancel out in the calibration value (5).

A detailed description of the components of the mobile station is provided in [1].

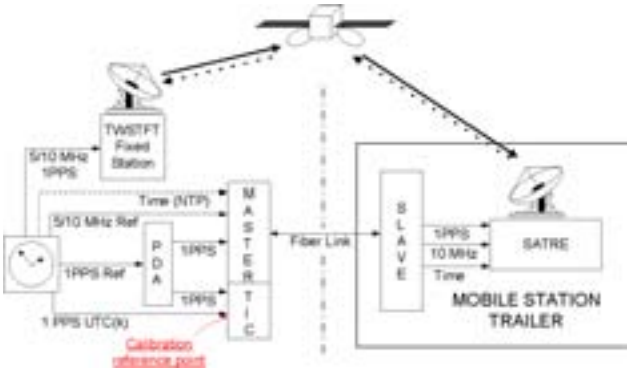

Figure 1. Scheme of main components of mobile station, setup at timing laboratory, and connection to laboratory reference signals.

IV. CALIBRATION WORKFLOW

Table I shows the designations of the local timescales at the participating laboratories and the identification of the fixed stations which are subject of the calibration. The timescale at TIM is denoted as TA(TIM), because it is not an official UTC realization. At OP the TWSTFT equipment is not directly connected to UTC(OP), but to a hydrogen maser (HM) which is measured externally with respect to UTC(OP).

TABLE I. LOCAL TIMESCALE AND STATION DESIGNATION.

Lab	Local timescale	Fixed station
TIM	TA(TIM)	TIM01
PTB	UTC(PTB)	PTB01
OP	UTC(OP)	OP01
METAS	UTC(CH)	CH01

The differential earth station delays between the fixed TWSTFT stations with respect to the mobile station TIM02 co-located at each site had to be determined. The first measurement at TIM at the beginning of the campaign was repeated at the end of the campaign to verify that the mobile station's internal delays have not significantly changed during the travel. The time schedule for the calibration campaign is shown in Table II.

TABLE II. CALIBRATION CAMPAIGN TIME SCHEDULE.

Day	Date	MJD	Activity
1	08.11.2012	56239	Start measurement at TIM
5	12.11.2012	56243	Travel to PTB
6	13.11.2012	56244	Start measurement at PTB
9	16.11.2012	56247	Travel to OP
12	19.11.2012	56250	Start measurement at OP
17	24.11.2012	56255	Travel to METAS
18	25.11.2012	56256	Start measurement at METAS
22	29.11.2012	56260	Travel to TIM
23	30.11.2012	56261	Start measurement at TIM
26	03.12.2012	56264	End of campaign

At each laboratory the trailer was placed outside at a location with good visibility to the communication satellite. The inside reference signals provided to the optical master reference generator (1 PPS, 10 MHz) are reproduced by the optical slave. Exemplarily, the placement of the trailer at OP is shown in Fig. 2.

Figure 2. Placement of the trailer at OP.

The communication satellite is Telstar 11N at longitude 37.5 ° W using a Ku band transponder. The nominal up- and downlink frequencies are 14.26 GHz and 10.96 GHz, respectively.

Since a standardized definition for a laboratory UTC reference point does not yet exist and access to signals in general depends on the local conditions, the connector for 1 PPS Ref and the calibration reference point at inbuilt TIC (see Fig. 1) were connected to dedicated long cables with BNC connectors in order to increase flexibility and avoid additional local cable length measurements. In the calibration values (5) the delay of the cable connected to the reference point cancels, because it is the same at all sites. In fact, the endpoint of the cable has turned into the reference point

The connection of the mobile station indoor equipment to the local 1 PPS signals is depicted in Fig. 3. At TIM and OP both cables were connected to fixed outputs of the distribution system. At PTB the signals were provided by laboratory cables and the interconnection was established by adapters. At METAS the 1 PPS Ref was taken from a fixed output, while the UTC signal was provided by a cable.

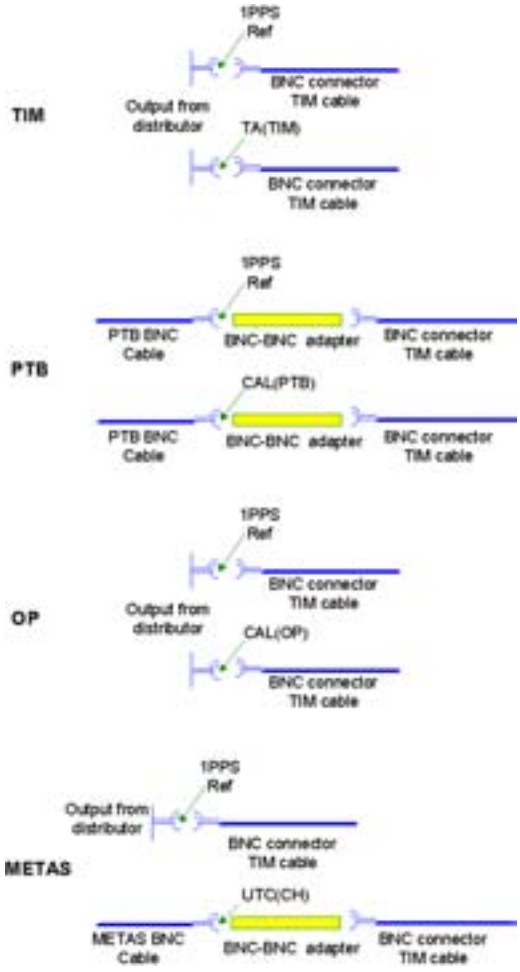

Figure 3. Connection of mobile station to local 1 PPS signals.

At TIM and METAS the distributor output and the endpoint of the cable were directly representing the local timescale, respectively. In contrast, at PTB and OP the signals had a delay with respect to the laboratories' UTC and HM reference points and are thus referred to as CAL(PTB) and CAL(OP) in Fig. 3, respectively. The delays with respect to local UTC were determined by additional local measurements.

The calibration values are calculated using averages of several samples generated from measurement sessions with 2 min duration, performed each 2 hours. The number of common-clock samples recorded at each laboratory are given in Table III. TIM-1 and TIM-2 denote the measurements at TIM at beginning and end of the campaign, respectively.

TABLE III. NUMBER OF CCD SAMPLES RECORDED AT EACH SITE.

TIM-1	PTB	OP	METAS	TIM-2
36	35	34	39	36

V. UNCERTAINTY ESTIMATION

The total calibration uncertainty is given by

$$U_{\mathrm{CALR}} = \sqrt{U_{a,k}{}^2 + U_{a,j}{}^2 + U_{b,1}{}^2 + U_{b,2}{}^2 + U_{b,3}{}^2}. \qquad (6)$$

$U_{a,k}$ and $U_{a,j}$ are the statistical uncertainties at lab k and lab j, respectively. Due to the relatively low number of samples (Table III), e.g. compared to GPS based calibrations [5], they are simply represented by the standard deviation (SD) of the common-clock (CCD) samples. They include the noise of the fixed and mobile TWSTFT equipment, the noise of the link itself, and the noise of the optical link between laboratory and outside trailer.

$U_{b,1}$, $U_{b,2}$, and $U_{b,3}$ are systematic uncertainty contributions: $U_{b,1}$ represents the delay stability of the mobile equipment [3]. An upper limit is estimated by the absolute value of the difference between the first CCD measurement at TIM and the verification measurement at the end of the campaign.

$U_{b,2}$ accounts for the uncertainty of the connection of the TWSTFT equipment to local UTC or reference signal. It consists of the uncertainty of the measurement of the 1 PPS signal from the internal PDA with respect to the reference signal using the internal TIC in the indoor rack ($1\mathrm{PPSREF_M(k)}$ measurement, see Fig. 1) and the uncertainty of the 1 PPS connected to the reference point, if this signal is not directly representing local UTC and the delay is determined by an external local measurement. Since the TIC inside the indoor rack is the same at both sites, only the measurement jitter contributes, while systematic errors are common and cancel out in (4). Although the jitter is the statistical uncertainty of the TIC measurement, it turns into systematic uncertainty of the CCD measurement, because the TIC mean value affects all TWSTFT data in the same way. If the 1 PPS signal connected to the fixed TWSTFT modem is monitored against the internal 1 PPS generated from the 5/10 MHz reference frequency, the jitter of these measurement also contributes to $U_{b,2}$. All contributions are added geometrically.

$U_{b,3}$ is related to all other suspected possible systematic effects. One of these effects is the stability of the local 1 PPS signal distribution. It can be accounted for by 0.1 ns, deduced from long-term laboratory experience [3], [5]. A second effect is accounted for by 0.2 ns related to changes in transmitter power and receiver signal-to-noise density ratio (C/N_0) changes, and the use of different pseudonoise (PN) codes for the CCD measurements compared to the operational links [3]. A third 0.25 ns uncertainty takes into account the group delay difference occurring due to different pulse rising times at different laboratories in the long cable connected to the reference point. The fourth contribution of 0.25 ns is due to the uncertainty of the 1 PPS generated by the optical slave generator. The last contribution of 0.01 ns uncertainty takes into account that adapters were used at PTB and METAS, but not at TIM and OP. The total contribution $U_{b,3}$ is set to 0.42 ns for all calibration values.

VI. RESULTS

The TWSTFT modem generated its internal 1 PPS signal (1 PPS TX) from the 5/10 MHz reference frequency. This pulse is initially triggered by the external 1 PPS when the modem is started. Additionally the 1 PPS TX can be measured continuously with respect to the external 1 PPS by an inbuilt TIC (IOTIC). This is very useful in the case that the 1 PPS and 5/10 MHz are not generated by the same clock. In the laboratories participating in this calibration campaign the external 1 PPS and the 5/10 MHz reference frequency are however coherently generated by the same source.

At TIM and METAS the IOTIC measurement is used for continuously monitoring the external 1 PPS against the internal 1 PPS TX. Thus, the 1PPSREF delay consists of a constant part due to the delay to local reference time signal and the IOTIC measurement, which is affected by jitter. At PTB, in contrast, the IOTIC measurement is not used and only the constant delay of external 1 PPS with respect to UTC(PTB) is taken into account. If the delay setting is not changed, it is completely absorbed by the calibration values (5) and no additional measurement noise increases the uncertainty. OP operates an old version of the TWSTFT modem without IOTIC. The 1 PPS TX is measured against external 1 PPS by an external SR620 TIC [6]. However, as in PTB a constant value for the delay of 1 PPS with respect to hydrogen maser reference point is set.

The 5/10 MHz and the 1 PPS signals connected to the mobile station's indoor rack were coherently generated from the same source in all four laboratories. Thus, the only relevant delay measurement for determining $1\mathrm{PPSREF_M}$ is that of the TIC in the optical link maser generator (cf. Fig. 1). During this campaign, the signal provided to the calibration reference point was continuously connected in all labs for the complete measurement period and thus continuously measured. As already mentioned, the delays of the mobile equipment parts were the same in all labs and are thus completely absorbed by the calibration values.

The 1PPSREF delay for each ground station and the related measurement uncertainty u_{F} are listed in Table IV, along with the $1\mathrm{PPSREF_M}$ measurement and its uncertainty u_{M} in the

respective lab (TIM-1 and TIM-2 denote the beginning and end measurement, respectively). The u_F uncertainty is the standard deviation (SD) of the fixed station IOTIC measurement. u_M consists of the SD of the measurement of the TIC in the optical link master generator and, at PTB and OP, an additional contribution given by the uncertainty of the local measurement, which was performed to determine the delay of the signal connected to the mobile station's calibration reference point with respect to the local reference point. For example, at PTB an SR620 counter was used for this task, and the systematic uncertainty of this device is specified as 0.5 ns by the manufacturer [6].

dREF is the delay difference 1PPSREF(k) – 1PPSREF$_m$(k) (last term in (3)). The uncertainty U_{Ref} is the geometrical sum of the two uncertainties u_F and u_M and an additional 0.02 ns contribution. The 0.02 ns account for the fact that the relation of 5/10 MHz zero-crossing and external 1 PPS is different at each lab. Thus, the initial triggering of the 1 PPS TX has an uncertainty, which was found to be at 0.02 ns level using the mobile TWSTFT modem's IOTIC.

TABLE IV. DETERMINATION OF REFERENCE AND DELAY DIFFERENCE BETWEEN FIXED AND MOBILE STATION .

Lab	1PPSREF [ns]	u_F [ns]	1PPSREF$_M$ [ns]	u_M [ns]	dREF [ns]	U_{Ref} [ns]
TIM-1	662.14	0.01	8.89	0.02	653.25	0.03
PTB	40.87	---	72.19	0.50	-31.32	0.50
OP	687.60	---	-46.56	0.14	734.12	0.14
METAS	753.03	0.02	-2.04	0.01	755.07	0.03
TIM-2	662.27	0.03	8.85	0.03	653.42	0.05

The TWSTFT measurements between fixed station and mobile station without reference delay difference applied are graphically depicted in Fig. 4, representing the ½ [DLD(k) - DLD$_m$] part in (3).

The CCD results, including all contributions of (3) are listed in Table V. For TIM station the average of beginning and end measurement is used. The uncertainty $u_{a,TIM}$ is the higher SD of the end measurement. The table also gives the Sagnac delay, which has to be used for calculating the calibration values (5).

TABLE V. COMMON-CLOCK DIFFERENCE AND SAGNAC DELAY FOR EACH PARTICIPATING GROUND STATION.

Lab	Start [MJD]	End [MJD]	CCD [ns]	$U_{a,Lab}$ [ns]	SCD [ns]
TIM	56239 56261	56243 56264	651.39	0.72	104.59
PTB	56244	56247	-31.48	0.30	99.11
OP	56250	56253	7791.39	0.23	92.00
METAS	56256	56260	675.67	0.59	105.32

The final calibration values and the related uncertainties are given in Table VI. The uncertainties $U_{b,2}$ are the geometrical sum of the U_{Ref} contributions of the respective Lab (Table IV). The combined uncertainty of all links contributing their data to BIPM for UTC generation are well below 1 ns.

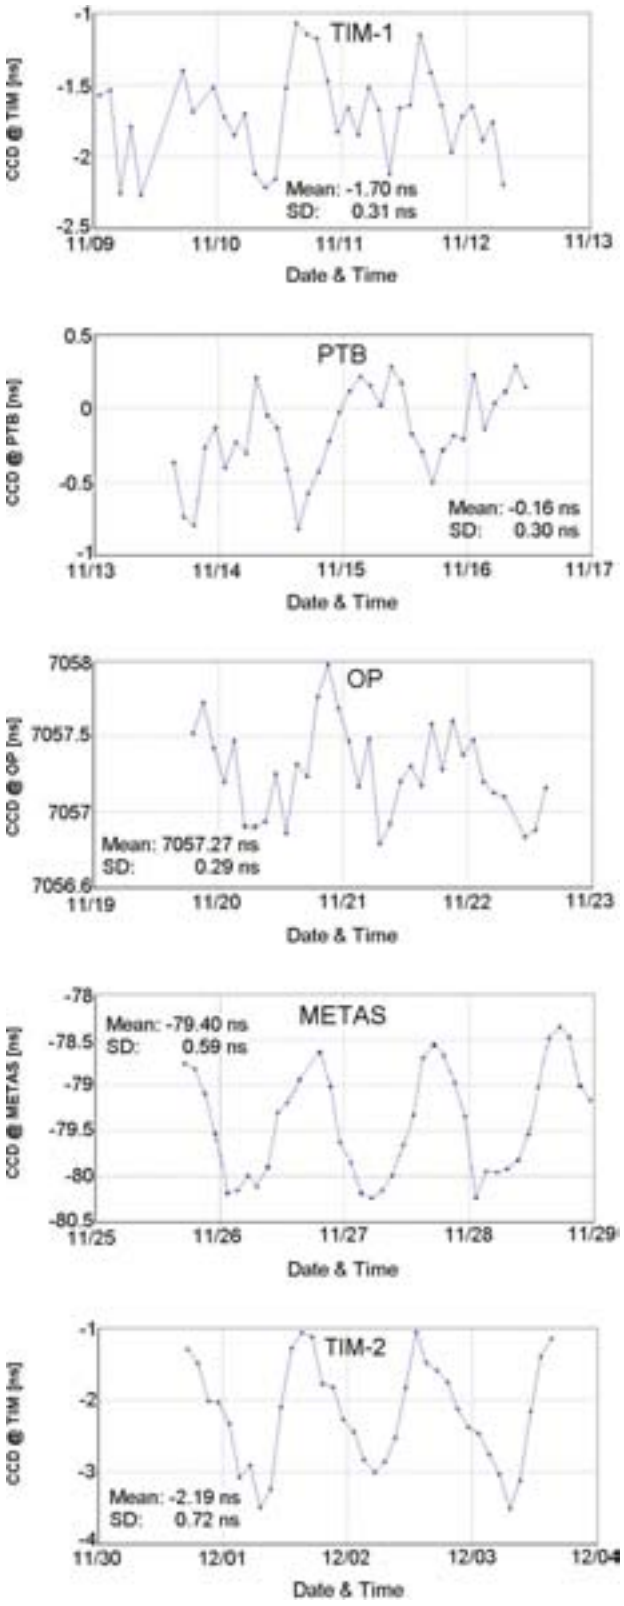

Figure 4. Common-clock differences without 1PPSREF-delay applied.

TABLE VI. CALIBRATION VALUES AND RELATED UNCERTAINTIES .

Link k-j	CALR(j,k) [ns]	$U_{a,k}$ [ns]	$U_{a,j}$ [ns]	$U_{b,1}$ [ns]	$U_{b,2}$ [ns]	$U_{b,3}$ [ns]	U [ns]
TIM-PTB	-688.35	0.72	0.30	0.32	0.50	0,42	1,07
TIM-OP	7127.41	0.72	0.23	0.32	0.14	0,42	0,93
TIM-CH	25.01	0.72	0.59	0.32	0.04	0,42	1,07
PTB-OP	7815,77	0.30	0.23	0.32	0.52	0,42	0,83
PTB-CH	713.36	0.30	0.59	0.32	0.50	0,42	0,98
OP-CH	-7102.40	0.23	0.59	0.32	0.14	0,42	0,84

VII. CLOSURE VERIFICATION

A verification of the calibration results can be done by the so-called triangle closure method. It is based on the principle that for 3 calibrated stations the sum

$$[\text{Lab}(1)-\text{Lab}(2)]+[\text{Lab}(2)-\text{Lab}(3)]+[\text{Lab}(3)-\text{Lab}(1)] \quad (7)$$

is zero, neglecting measurement noise and errors. (7) can be denoted as closure Lab(1)-Lab(2)-Lab(3).

In the calibration campaign 4 stations were participating. Thus, a total number of 4 triangle closures are enabled, as indicated in Fig. 5.

For the calculation of the closures, TWSTFT data of the complete period of the calibration campaign, from beginning to end (see Table II) are used. The newly calculated calibration values (Table VI) are applied to the respective links. The results are listed in Table VII. The data are distributed within a range of less than 2 ns around zero for all closures. The mean values are very close to zero within the 1-σ standard deviation (SD), showing that during the calibration campaign no unexpected systematic errors were occurring.

TABLE VII. RESULTS OF TRIANGLE CLOSURE VERIFICATION .

Closure	Min [ns]	Max [ns]	Mean [ns]	SD [ns]
TIM-PTB-OP	-0.82	0.81	0.01	0.29
PTB-CH-OP	-0.85	0.81	0.04	0.28
TIM-PTB-CH	-0.38	0.89	0.23	0.25
TIM-CH-OP	-0.89	0.50	-0.17	0.29

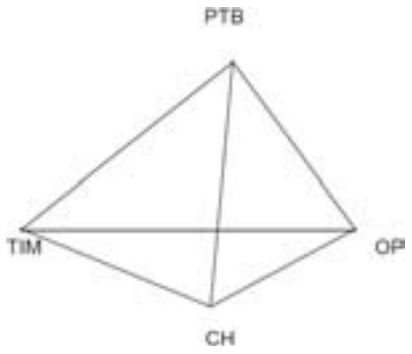

Figure 5. Scheme indicating the possible triangle closures.

VIII. COMPARISON TO PREVIOUS CALIBRATION

A second method to verify the calibration and to detect the long-term delay stability of the participating stations is the comparison to previous calibration campaigns. The difference is calculated by

$$\text{CALR\_dev} = \text{CALR}_{\text{Tt}} - \tfrac{1}{2}\left(\text{ESDVAR}_j - \text{ESDVAR}_k\right) - \text{CALR}_{\text{TM198}}. \quad (8)$$

CALR_{Tt} is the new calibration constant of the TimeTech calibration from Table VI, U_{tt} is the uncertainty from Table VI, ESDVAR_k and ESDVAR_j are the Earth station delay variations of station k and j, respectively, since the previous calibration, stored in the ITU files. ESIG_k and ESIG_j are the uncertainties of ESDVAR values. $\text{CALR}_{\text{TM198}}$ is the calibration value according to the BIPM calibration using GPS for bridging after a change of the satellite frequencies (Identification number TM198) [7] and U_{TM198} is the uncertainty. The combined uncertainty is calculated according to

$$U(\text{CALR\_dev}) = \sqrt{U_{\text{Tt}}^2 + \left(\frac{\text{ESIG}_j}{2}\right)^2 + \left(\frac{\text{ESIG}_k}{2}\right)^2 + U_{TM198}^2}. \quad (9)$$

The results of the calculations (8) and (9) and the used values are given in Table VIII. The deviation between old and current calibration value are very small (maximum –3.18 ns for PTB-CH link). This provides an indication for the success of the current calibration campaign.

TABLE VIII. CALIBRATION DEVIATION TABLE .

Link k-j	PTB-CH	PTB-OP	OP-CH
CALR_{tt} [ns]	713.36	7815.77	-7102.40
U_{tt} [ns]	0.92	0.76	0.77
ESDVAR_k	1035	1035	0.00
ESIG_k	2.80	2.80	0.00
ESDVAR_j	21.68	0.00	13.34
ESIG_j	2.00	0.00	2.00
$\text{CALR}_{\text{TM198}}$	209.88	7300.70	-7094.59
U_{TM198} [ns]	1.20	1.20	2.00
CALR_dev	-3,18	-2,43	-1,14
U(CALR_dev)	2.29	1.99	2.36

However, for both PTB-CH and PTB-OP link the deviations are slightly above the combined uncertainties, due to the long time period between current and previous calibration. This emphasizes that a frequent repetition of link calibrations shall be conducted, in order to ensure that the time transfer uncertainties of the operational links remain at low levels.

Previous link calibrations have been conducted with a portable station provided by Technical University Graz, Austria (see e.g. [8]). The setup of this station was very complicated labor extensive, because it required the manual installation and adjustment of the antenna dish and outside RF equipment at an adequate location. Due to the mobile station

based on a trailer the calibration process has now been simplified, because it requires only the installation of the small indoor rack. Thus, calibrations can be repeated periodically (or after major events like satellite changes) easily without time consuming preparations at the participating laboratories.

IX. CONCLUSION

In November 2012 the time transfer links between PTB, OP, METAS, and TimeTech GmbH were calibrated using TimeTech's mobile TWSTFT calibration station based on a trailer. The combined uncertainty of the calibration values for the links participating in the generation of UTC is at 1 ns level. The triangle closure sums are very close to zero, indicating that the calibration is not affected by unexpected systematic effects. The comparison to previous calibration results shows a maximum deviation of about –3 ns. Since the calibration procedure has been extremely simplified due to the mobile station on a trailer, frequent repetitions of the calibrations can now be aspired.

***Abstract*— Over the last twenty years, many technologies and services have come to rely on the GPS for precise timing. Concern is increasing about the wisdom of being reliant on a single timing solution provided by a single country and because of the susceptibility of the GPS signal to unintentional interference, jamming and spoofing. In this paper, we report on further development of our system for timing signal transfer from a precision reference clock using commercial satellite links. The system will have master stations tracking the satellite position and using TWSTFT measurements to synchronize their clocks, transmitting data with the reference timing signal to allow slave stations to adjust the PPS timing signal, compensating for the satellite motion and other uncertainties in the path delay. We will report on a simulation of the full system, including models for the master station clocks and TWTT measurements, using a Kalman filter to track the satellite position.**

Keywords—time transfer; satellite; TWSTFT; TWTT; timing; synchronization

I. INTRODUCTION

Over the last twenty years, many technologies and services have come to rely on the GPS for precise timing. However, concern is increasing about the wisdom of being reliant on a single timing solution [1] provided by a single country because of the susceptibility of the GPS signal to unintentional interference, jamming and spoofing [2]. There are several projects underway to develop similar systems or upgrade existing ones, e.g. Galileo, GLONASS. Only one of these systems (GLONASS) is currently fully available as an alternative, with the other systems projected to become operational progressively during the next decade. In the current situation, if the quality of the GPS signal deteriorates, some of the main information and communications channels would not be usable in many countries, causing a wide range of problems [1], [2]. Other approaches to timing transfer exist and are being developed: over optical media [3] or using high power LF signals [4] and over satellite links [5],[6],[7],[8]. Timing transfer over optical media shows promising performance but requires the installation of a dedicated network infrastructure. High power, low frequency radio signals are an established solution but cannot easily cover such a wide geographical area as a satellite solution.

In this paper, we report on further development of our system for timing signal transfer from a precision reference clock using commercial geostationary satellite links [7],[8]. The system will have a set of master stations tracking the satellite position and using TWSTFT measurements to synchronize their clocks. Data transmitted with the reference timing signal will allow slave stations to adjust the timing signal, compensating for the satellite motion and other uncertainties in the path delay. Using projected ephemeris data and comparing that data in real time with measurements, which themselves are affected by other sources of delay, is a challenging task when the goal is timing signal transfer with no more than 100 ns of jitter peak-to-peak at the receiving stations and motivates study of the system using simulations. The paper is structured as follows: in Section II, we briefly review the structure of the time transfer system and previous experimental and simulation findings. In Section III, a new simulation of the system is presented. Results from the simulations are presented in Section IV. Finally, in Section V we present our conclusions.

II. ONE-WAY SATELLITE TIME TRANSFER SYSTEM

The time transfer system under development by Mixed Processing Ltd and University of Limerick researchers will provide a complete off-the-shelf system for precision time transfer over geostationary satellite. The full system will consist of three master stations to fix the satellite position. The master stations communicate with each other and with the receive-only slave stations using bandwidth rented from a commercial satellite provider. One master station will have a high precision clock such as a Cesium atomic clock and two sub-master stations will have precision clocks with a high holdover capability e.g. Rubidium clocks. Each of the master stations, whether master or sub-master, will have a bi-directional link to the satellite. Finally, there are slave or receive-only stations which have a uni-directional (receive) link with the satellite. The slave stations will be sent a pulse-per-second (PPS) time signal and data that allows them to compensate for the timing uncertainty arising from the satellite motion and other sources. The master stations will exchange satellite ranging data to track the satellite position and align their clocks using TWSTFT. In order to determine accurately the propagation time of signals between the master station and the slave stations it will be necessary to consider and correct

for errors in the path delay determination arising from: satellite ephemeris errors, satellite motion, atmospheric effects, temperature induced delay variation in cables and outdoor equipment, the Sagnac effect and general measurement errors.

A. *Proof of Concept Experiment and Simulations*

A previous proof of concept experiment was successfully conducted with a single master station broadcasting a PPS timing signal to three slave stations with an accuracy of at worst 1 μs when compared to a GPS PPS reference, was reported on in detail in [7],[8]. In a three master station system, the stations measure their own range to the satellite and the three measurements may be used to calculate the satellite position by trilateration. However, the range measurements contain extraneous delays, not all of which can be known exactly, e.g. the delay through the satellite transponder or the exact value of the atmospheric delay. Furthermore, with three master stations, each with their own independent clock, two of the measurements contain an error with respect to the measurement taken by the primary master station, due to the clock difference between stations. One approach is to measure and estimate the extraneous delays as accurately as possible. Clearly equipment and cabling delays at each station can be measured while an estimate for the troposphere delay can be predicted using an atmospheric model [9]. At the Ku-band transmission frequencies, the effect of the ionosphere can be neglected [10]. Then, using the satellite ephemeris, the master stations can find a correction factor to account for the remaining unknown and variable extraneous delay. The primary master station calculates the satellite position using trilateration, using two-way time and frequency transfer to correct for the clock phase difference. However, a simulation of this approach demonstrated the sensitivity of the satellite position calculation to unknown variation in the extraneous delays [7].

III. An Approach Using a Kalman Filter

To test an alternative approach, a simulation for a three station system where the primary master station uses an extended Kalman filter to predict the satellite position, thus integrating its own measurements with those of the other two master stations, has been developed.

As is well known [11], a discrete-time Kalman filter uses a two stage procedure to first predict the next state x_k of a discrete-time system which may be described by a linear stochastic difference equation,

$$x_k = Ax_{k-1} + Bu_{k-1} + w_k \tag{1}$$

where A is the state transition matrix, u_{k-1} is an optional control input, B is an optional control matrix and w_k is an independent white noise process. A measurement z_k, which is related to the state of the system by a linear measurement matrix H as:

$$z_k = Hx_k + v_k \tag{2}$$

where v_k is an independent white noise process, must also be available. In a linear discrete-time Kalman filter, where there is no control input, the next state of the process is estimated using:

$$\begin{aligned} \hat{x}_k^- &= A\hat{x}_{k-1} \\ P_k^- &= AP_{k-1}A^T + Q \end{aligned} \tag{3}$$

where $\hat{x}_{k-1}$ is the a posteriori state estimate, $\hat{x}_k^-$ is the a priori state estimate, P_k is the estimate error covariance matrix, where the superscript minus denotes the a priori estimate, and Q is the process noise covariance matrix, which is used to include an estimate of our uncertain knowledge of the underlying process [12]. In the second stage of the Kalman filter, the Kalman gain matrix, K_k, is updated using the measurement matrix H, the a priori estimate error covariance P_k^- matrix and R the measurement noise covariance matrix. The noisy measurement is compared with the predicted measurement made using the a priori state estimate, and the error, adjusted by the Kalman gain is used to update the state prediction to produce the a posteriori state estimate and the updated error estimate covariance predictions.

$$\begin{aligned} K_k &= P_k^- H^T \left(HP_k^- H^T + R\right)^{-1} \\ \hat{x}_k &= \hat{x}_k^- + K_k\left(z_k - H\hat{x}_k^-\right) \\ P_k &= \left(I - K_k H\right)P_k^- \end{aligned} \tag{4}$$

A. *Kalman Filter System Model*

The Kalman filter approach used for the simulation was originally developed based on that described in [13], where a Kalman filter was used to track the position of a geostationary satellite using GPS satellites. In [13], the satellite path is described by the simple circular motion continuous-time dynamics model:

$$\dot{x} = Fx \tag{5}$$

where the first three rows of $x = \begin{bmatrix} X & Y & Z & \dot{X} & \dot{Y} & \dot{Z} \end{bmatrix}^T$ are the position vector of the satellite, the bottom three rows are its velocity vector, and the dynamics matrix $F = \begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ -\mu/r^3 & 0 & 0 & 0 & 0 & 0 \\ 0 & -\mu/r^3 & 0 & 0 & 0 & 0 \\ 0 & 0 & -\mu/r^3 & 0 & 0 & 0 \end{bmatrix}$ where $\mu = 398600.4418 \pm 0.0008\ \text{km}^3/\text{s}^2$ is the gravitational constant and $r = \sqrt{X^2 + Y^2 + Z^2}$. In the simulation reported upon here,

as the equations of motion are non-linear, a linearized system dynamics matrix is used to develop the Kalman filter equations

$$\Delta\dot{x} = dF\Delta x \tag{6}$$

where dF is the Jacobian of the continuous-time dynamics matrix. The linearized continuous-time dynamics matrix is then discretized to produce the discrete-time state transition matrix using a first-order approximation [12].

In [13], the simulation used ECI (Earth-Centred Inertial) co-ordinates and the results were converted to the ECEF (Earth-Centred Earth Fixed) system for analysis and display. The ECI frame has its origin fixed at the centre of the earth and may be considered a fixed frame of reference (neglecting the much longer period motions of the earth in space [14]) so that the equations of motion of the satellite are simpler to express in this frame. However, as the ground truth for the simulation will be satellite ephemeris data in ECEF co-ordinates, the system dynamics matrix was transformed into that co-ordinate system. Another reason for formulating the satellite motion model in the ECEF frame is that the earth rotates with respect to the ECI frame and using it requires finding the position of the vernal equinox at a particular time [15]. Such a requirement is to be avoided in an application whose purpose is to transfer a precise and accurate determination of time, as it will add additional uncertainty to the path tracking. Hence, the system dynamics matrix was converted into its equivalent in ECEF co-ordinates.

The measurements available to the Kalman filter are the range measurements between each master station and the satellite position given by:

$$\rho = \sqrt{(x_s - x_{mi})^2 + (y_s - y_{mi})^2 + (z_s - z_{mi})^2} \tag{7}$$

where (x_s, y_s, z_s) is the satellite position at the given time instant and (x_{mi}, y_{mi}, z_{mi}) is the position of the ith master station. Since these measurements are nonlinear, an Extended Kalman filter is used where the measurement matrix is replaced by the observational partial derivative matrix [13].

An important aspect of the system is that the clocks in the master stations, being independent and geographically separated, will not be synchronous. In the present simulation, the error due to the difference between the clocks and two-way time transfer (TWTT) is easily incorporated by using a discrete-time random process to model the bias, drift and drift rate in the clocks at each master station in a similar approach to that used in [13]. Using the clock bias output of the clock model (in seconds) and multiplying the difference between two clocks' bias by the speed of light c the resulting measurement error due to the phase difference may be modeled by in meters and added to the measurements.

$$\rho_k = \sqrt{(x_s - x_{mi})^2 + (y_s - y_{mi})^2 + (z_s - z_{mi})^2} + cb_{mi} - cb_{mj} + v_k \tag{8}$$

where b_{mi} is the bias on the ith master station clock and v_k is the measurement noise. The two-way time transfer measurement between the primary master clock and the ith clock at the ith master station can be modelled as [13]:

$$\Delta T_{ij} = cb_{mi} - cb_{mj} + \upsilon_{ij} \tag{9}$$

where υ_{ij} is the error in the TWTT measurement.

B. Kalman Filter Simulation Procedure

The simulation uses as ground truth archived satellite path data for E33A from November 2010 as was used in the original experiment [7] interpolated to provide the ground truth satellite path. Given the master station positions, the measurements to be used by the simulation can then be created offline using equation (8). In the simulation the procedure assumed is that communication between the master stations permits the primary master station to collate the range measurements from the two other stations as well as the phase difference between its own clock and those of the two other master stations. The Kalman filter for tracking the satellite position is then run at the primary master station. The primary master station will send the PPS timing signal to the slave stations with the estimated satellite position and its own range to the satellite. At the slave station, the slave uses the satellite position to calculate its own range to the satellite and it can then calculate the expected time of arrival of the PPS signal. To measure the performance of the simulation, the expected time of arrival is compared with the simulated real travel time of the signal to determine the residual time variation on the received PPS signal after adjustment in a procedure which simulates that in the original experiment [7], [8].

IV. Results

To verify the tracking capability of the Kalman filter, it was run without perturbations, apart from the satellite motion. The standard deviation of the tracking error, the difference between the ground truth satellite co-ordinates and the filter's estimate is 0.3m to 0.6m and the standard deviation of the adjusted PPS signal at the slave is 2ns. To make the simulation more realistic, perturbations are then added back to the simulation. Fixed extraneous delay quantities such as equipment delay, mean troposphere delay or the Sagnac effect are not included as within a simulation it is pointless to add them in and then subtract them again. Instead, the approach is to use normally distributed noise to simulate the variable and unknown part of the extraneous delays. Thus, a variable component to represent the unknown and varying atmospheric delays is added to the time of travel of the PPS sent from primary master to slave station. This quantity is also added to the range measurements. As shown in (8), the clock phase differences are added to the range measurements along with a measurement noise which represents all the other uncertainties such as those to do with the resolution and noise within the transmitter and receiver systems.

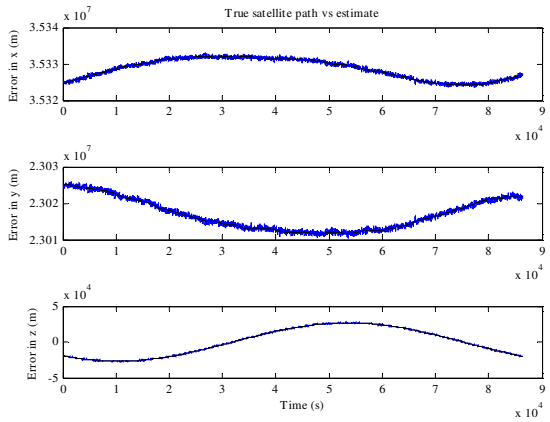

Fig. 1. Kalman filter tracking performance with perturbations.

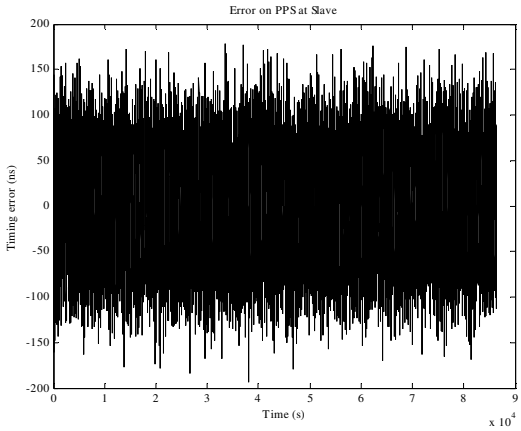

Fig. 2. Timing error after adjustment at slave.

Examples of typical simulated tracking and time transfer results obtained so far from the simulation are shown in Fig. 1 and Fig. 2. The standard deviation of the measurement noise was 15m, the variable component of the delay due to atmosphere was typically < 10m and the effect of noise on the TWTT measurements was modeled as < 1m. The measurement residual with these settings was typically 10-50m, resulting in a tracking error standard deviation of 200-400m. The simulated time transfer performance was within ± 150 ns as shown in Fig. 2.

V. CONCLUSION

In this paper we have described the proposal by Mixed Processing Ltd for an off-the-shelf system for timing signal transfer over geostationary satellite. The proposal for the full system with three master stations tracking the satellite position and broadcasting a timing signal to slave stations has now been simulated implementing a Kalman filter approach to the satellite tracking with some encouraging preliminary results. The simulation will now be used to explore the effect of variable extraneous delays on tracking and time transfer performance.

***Abstract*—The Space segment of BeiDou(Compass) global navigation satellite system consists of the 5 Geostationary Earth Orbit (GEO) satellites and 30 Non-GEO satellites (Medium Earth Orbit (MEO) satellites and Inclined Geo Stationary Earth Orbit (IGSO) satellites). At present the Beidou system（BDS） has begun to regional services based on the GEO satellites and the IGSO satellites. The range of services is covering China and neighboring countries and area. There are 5 GEO satellites on orbit. Users can receive the BeiDou system time which is steered to the UTC through the UTC(NTSC) by GNSS CV and TWSTFT. The time service performance of the BeiDou system is concerned by the time users. In this paper, the BeiDou system is introduced firstly, then the satellite time service and the data processing methods are analyzed, based on the analysis, the time service performance of the 5 GEO satellites is discussed, and the results show that eliminating the ionospheric delay and reducing the impact of the troposphere and relativistic effects, the time service performance of the 5 GEO satellites are all stable and their accuracy is quite close to 10ns which can meet the needs of the vast majority of high-precision time users.**

I. INTRODUCTION

The GNSS is a Global Navigation Satellite System that is used to pinpoint the geographic location and velocity of a user's receiver anywhere in the world, and transfer the system time to the user if necessary. With the development of GNSS, the four systems will provide Position, Navigation and Timing (PNT) to users, which are GPS, GLONASS, GALILEO and COMPASS (BEIDOU, BDS), among the four global navigation systems, the GPS and GLONASS have been operating for decades, and have been updated several times. The GALILEO and BDS are still under constructing, so time transfer technologies based on the two systems are being developed and tested.

The space segment of GPS and GLONASS consist of MEO satellites, however that of GALILEO includes MEO and GEO satellites, BDS includes MEO, GEO and IGSO satellites[1]. So far, 5 GEO satellites and 5 IGSO satellites and 4 MEO satellites have been launched, and they all are running normally. The 5+5+4 satellite system can provide stable regional service of PNT. The service range of BDS is now covering China and neighboring countries and area. With the construction of BDS, the application study is quickly developing. In this paper, the character of the five GEO satellites is analyzed; the method and data processing of time service based on the 5 GEO satellites are discussed in detail. Then the time service test is done by using the BDS receiver which is placed in the time keeping laboratory of National Time Service Center (NTSC).

This work is supported by a grant from the National Nature Science Foundation of China (No. 10873013)

II. THEORY OF BDS TIME SERVICE AND DATA PROCESSING

A. Theory of BDS Time Service

In this paper, the time service is that users can directly receive system time information through BDS receiver. In fact it is one-way time service based on BDS. Because the GEO satellite of BDS are more stable in orbit (satellite position) than that of IGSO and MEO satellite, and all of them are running well, in order to obtain precise BD time, it is necessary to study the time service through BD GEO satellite.

The method of how to obtain the BD time (BDT) is by calculating the deviation between local reference time and BD system time through receiver. In this paper, the reference time is UTC(NTSC) which is kept by NTSC. Figure 1 shows the process of one-way time service[2,3].

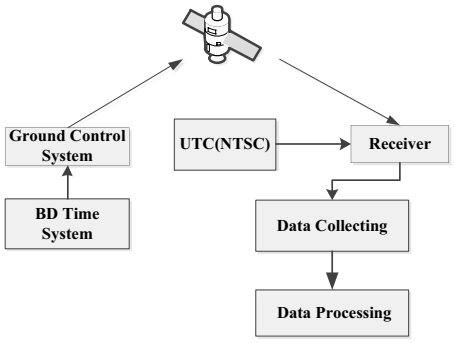

Figure 1 Process of One-Way Time Service

To introduce the one-way time service, a BD satellite (GEO or IGSO, No. i) is taken for an example. The satellite sends pseudo-code signal at the moment of t_0 (referring to satellite clock). Receiver receives this signal at the moment of

t_r (referring to local clock), and the launch time of satellite signal can be calculated by:

$$t_0 = t_r - \delta t_{iA} \quad (1)$$

The distance between satellite clock i and antenna receiver A can be expressed by

$$\rho_{i,A} = P_{i,A} + d_{trop} + d_{ion} + d_{Sagnac} + c\Delta t_{i,A} \quad (2)$$

Where, $\rho_{i,A}$ indicates pseudo-range on L_i frequency channel; $P_{i,A}$ is an indication of the geometry distance between satellite and receiver; d_{trop} is the correction of troposphere delay; d_{ion} is the correction of ionosphere delay; d_{Sagnac} indicates the correction of Sagnac effect, it means earth auto-rotation correction; c is light speed in vacuum 299792458m/s; $\Delta t_{i,A}$ the deviation between local clock A and satellite clock i is the only unknown parameter.

In formula (2), $\rho_{i,A}$ can be obtained from receiver directly, and the accurate coordinates of receiver antenna center are known data which are determined before antenna installation, the position of the satellite is transferred to the receiver through broadcast ephemeris. By using those data, the geometry distance $P_{i,A}$ between satellite and antenna can be calculated. Furthermore, d_{ion} , d_{trop} and d_{Sagnac} can also be calculated . So far, all the parameter but $\Delta t_{i,A}$ in formula (2) have been obtained, so the deviation between local clock A and satellite clock i $\Delta t_{i,A}$ can be worked out easily.

Based on the original observe data and the corrections of the satellite atomic clock obtained through ephemeris file, the deviation between satellite i and BDS time can be calculated, i.e. $\Delta t_{BD,i}$,

$$\Delta t_{BD,i} = a_0 + a_1\Delta t + a_2\Delta t^2 \quad (3)$$

Combining $\Delta t_{i,A}$ with $\Delta t_{BD,i}$, the deviation between local clock A and BDS time can be calculated , i.e. $\Delta t_{BD,A}$

$$\Delta t_{BD,A} = \Delta t_{i,A} + \Delta t_{BD,i} \quad (4)$$

As described above, after the deviation between local time and BDS time is got, the one-way time service through BDS has been accomplished.

B. Timing Data Processing

✧ Data Collecting and Data Processing Platform

The data collecting platform consists of a BDS receiver, a data collecting computer and a data processing computer, the input signal to BDS receiver includes a 1pps and a 10MHz frequency signal which are provided by UTC(NTSC). Data collecting computer receives and save the pseudo-rang and broadcast ephemeris information from the receiver in real time. Data processing computer calculates the deviation between the BDS time and the reference signal (UTC(NTSC)) $\Delta t_{BD,A}$. Figure 2 is the platform.

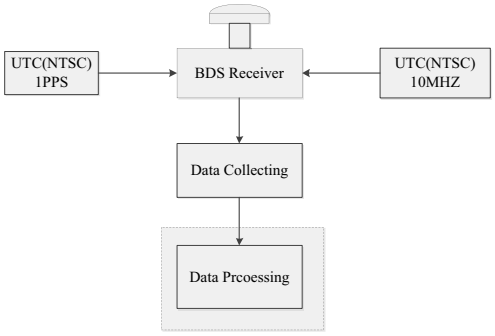

Figure 2 Data collecting and data processing platform

✧ Algorithm of Time Delay Corrections[]

The data processing of Beidou GEO satellite one-way time service is shown as figure 3. There mainly are three types of corrections in the algorithm, which are ionosphere delay, troposphere delay and Sagnac effect. The specific algorithms to correct the three types of error are described as follows.

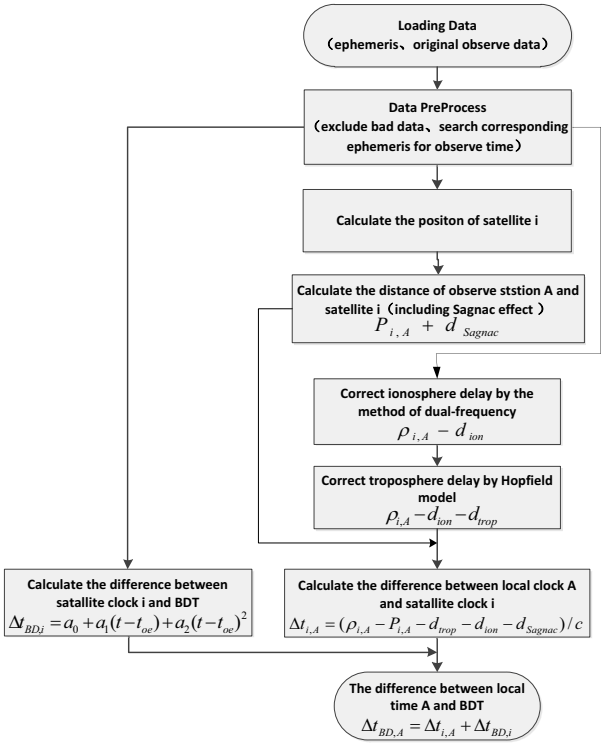

Figure 3 Data processing of Beidou GEO satellite one-way time service

Ionosphere Delay

Here, the correction method of ionosphere delay is dual-frequency correction algorithm, combined the observations of L_1 with that of L_2 , the formula (5) shows the pseudo-range eliminated ionosphere delay.

$$\rho = \frac{f_1^2 \rho_1 - f_2^2 \rho_2}{f_1^2 - f_2^2} \quad (5)$$

In formula (5), ρ is the pseudo-range without ionosphere delay; ρ_1 and ρ_2 are the pseudo-range with ionosphere delay on frequency range L_1 and L_2 respectively; f_1 and f_2 are the value of frequency on frequency range L_1 are L_2 respectively.

Troposphere Delay

Hopfield model is one of the widely used methods to correct the troposphere delay. It was developed an empirical tropospheric delay model by using data form different parts of the world, and it was based on the dry refractivity components as a function of station height. When the atmospheric temperature T, atmospheric pressure P and vapor pressure e_0 are of an observation station ground. The modified Hopfield model is expressed as:

$$\left.\begin{aligned} \Delta D_{trop} &= \Delta D_{dry}(E) + \Delta D_{wet}(E) \\ \Delta D_i(E) &= 10^{-12} N_i \sum_{k=1}^{9} \frac{\alpha_{k,i}}{k} r_i^k \end{aligned}\right\} \quad (6)$$

Where, $N_{dry} = \frac{77.6241P}{T}$, $N_{wet} = 371900\frac{e_0}{T^2} - 12.96\frac{e_0}{T}$, r_i can be calculated through equation (7):

$$\left.\begin{aligned} r_i &= \sqrt{(r_0 + h_i)^2 + (r_0 \cos E)^2} - r_0 \sin E \\ h_d &= 40136 + 148.72(T - 273.16) \\ h_w &= 1100 \\ r_0 &= 6378137m \end{aligned}\right\} \quad (7)$$

$\alpha_{j,i}$ can be expressed by formula (8).

$$\left.\begin{aligned} a_i &= -\frac{\sin E}{h_i}, b_i = \frac{\cos^2 E}{2h_i r_0} \\ \alpha_{k,i} &= [1, 4a_i, 6a_i^2 + 4b_i, 4a_i(a_i^2 + 3b_i), a_i^4 + 12a_i^2 b_i + 6b_i^2 \\ &\quad 4a_i b_i(a_i^2 + 3b_i), b_i^2(6a_i^2 + 4b_i), 4a_i b_i^3, b_i^4] \end{aligned}\right\} \quad (8)$$

In expressions above, $i = wet, dry$, E is the elevation of satellites.

Sagnac Effect

The error by Sagnac effect can be corrected in the calculating process of satellite position.

$$\begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} = \begin{bmatrix} \cos(\omega\tau) & \sin(\omega\tau) & 0 \\ -\sin(\omega\tau) & \cos(\omega\tau) & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x_{sat} \\ y_{sat} \\ z_{sat} \end{bmatrix} \quad (9)$$

$(x'\ y'\ z')$ stands for the corrected satellite position, ω is the earth auto-rotation speed, here ω =7.2921151467E-5 rad/s, τ is the transmission time of satellite semaphore. The calculation of τ need to use recursive calculation to correct satellite position with the initial value, which can be obtained using the pseudo-range divided by the light speed c, then the new τ can be gotten by the new pseudo-range to compute the new sent time of satellite semaphore. As described above, the satellite position is corrected. GEO satellites compared to other types of satellite, its position changes little, so in this paper, the emphasis is time service based on the GEO satellite of BDS. The time delay caused by the Sagnac effect can be expressed as:

$$T_{Sagnac} = 218.1976 \sin(Long_{Sat} - Long_{pos}) \cos(Lat_{pos}) \cos(Lat_{Sat}) \quad (10)$$

For a GEO satellite, the $\cos(Lat_{Sat})$ is 1, then the formula (10) can be written as formula (11):

$$T_{Sagnac} = 218.1976 \sin(Long_{Sat} - Long_{pos}) \cos(Lat_{pos}) \quad (11)$$

III. TEST AND RESULTS ANALYSIS

The test of BD GEO satellite time transfer began at January 1 2013, and end at January 31 2013. The data is from a BeiDou dual-frequency multichannel receiver of time keeping laboratory of NTSC. The input reference signal of BeiDou receiver includes a 1pps and a 10MHz from UTC(NTSC). The receiver has been adjusted by using two GPS CV receivers which are put in the time center of BDS and NTSC separately.

Figure 4 shows the result of UTC(NTSC)-GEO k (k=1 TO 5) from MJD 56239 to 56323.

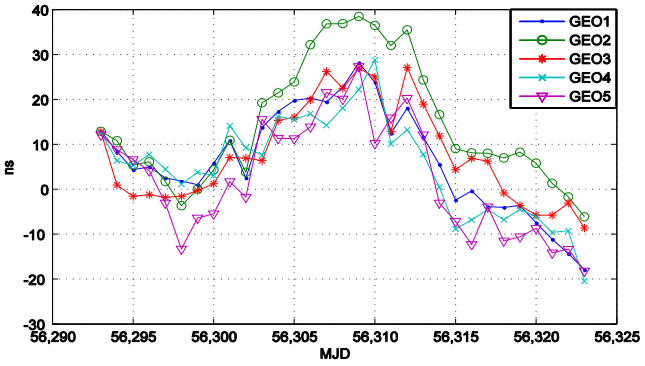

Figure 4 UTC(NTSC)-BDT by GEO k (k=1 to 5)

From Figure4, it is obvious that the fluctuation of time service by GEO 2 is much bigger than that of the other satellites. The reason we think is that GEO 2 was lunched at the end of last year, its state is not stable, the satellite clock is still in the term of test. The other line GEO1, GEO 3, GEO4 and GEO5 show good consistency.

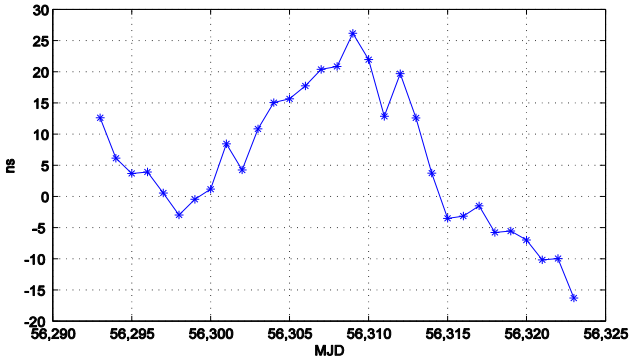

Figure 5 Average of UTC(NTSC)-BDT of GEO 1,3,4,5

In order to research the performance of time service by the five GEO satellites, the four stable data of GEO satellite are averaged with equal weight. Figure 5 is the average of the four groups of data. The table 1 shows the statistic result of different GEO satellite.

Table1. Performance time service by GEO 1~5

Item	G1	G 2	G 3	G 4	G 5	AVE*
MEA	6.56	14.39	7.79	5.24	2.59	5.55
STD	11.65	13.69	10.86	11.03	12.67	10.99
RMS	2.63	3.92	2.63	2.40	2.53	2.62

*AVE is the average of UTC(NTSC)-BDT by GEO 1, GEO3, GEO4 and GEO5. MEA is mean value, STD is standard deviation.

From the table 1, the same conclusion can be gotten that the fluctuation of GEO2 is bigger than that of the other satellites. Compared with UTC(NTSC), the highest precision time service is 10.86ns, the worst is 13.96ns.Figure 6 shows the time residual compare with AVE, which can be calculated by formula 12.

$$\mathrm{UTC(NTSC)} - \mathrm{AVE}\text{-}[\mathrm{UTC(NTSC)}\text{-}\mathrm{BDT(\ GEO\ k)}] = \mathrm{BDT(\ GEO\ k)}\text{-}\mathrm{AVE} \quad (12)$$

Where, k=1, 2, 3, 4,5.

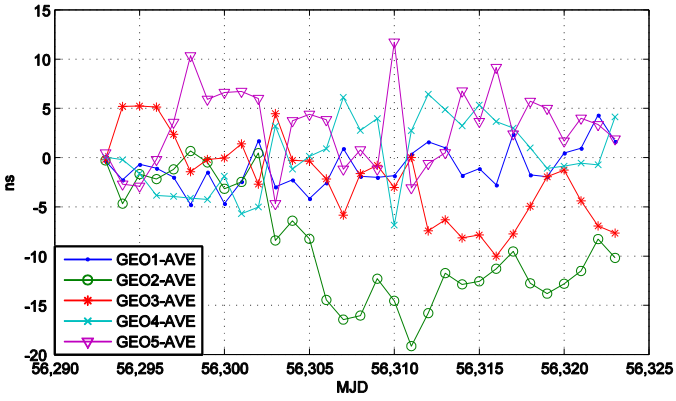

Figure 6 Residuals compared with average of GEO k

Table 2 Performance BDT(GEO k)-AVE

Item	G 1	G 2	G 3	G 4	G 5
AVE	-1.02	-8.85	-2.25	0.31	2.95
STD	2.12	5.83	4.29	3.66	4.03
RMS	0.46	2.10	0.95	0.72	0.98

Table 2 shows that the maximum AVE is 8.25 (GEO2), the minimum is 0.31 (GEO4); the maximum STD is 5.83 (GEO2), the minimum is 2.12 (GEO1); the maximum RMS is 2.10 (GEO2). To analyze the frequency stability of time service of every GEO satellite, the Allan deviation of the UTC(NTSC)-BDT(GEO k) is calculated by stable32. Figure 7 shows the Allan deviation of them. Form figure1, we could find except GEO2 the time service by the other GEO satellites expresses evident consistency.

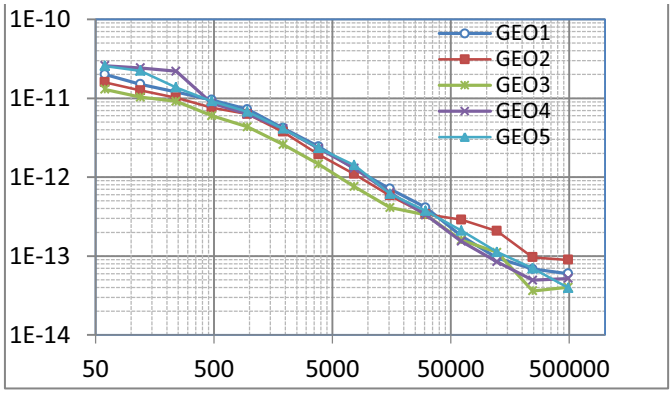

Figure 7 Stability of the UTC(NTSC)-BDT by GEO k

Analyzing the Figure 7, we find that the short term stability and long term stability of UTC(NTSC)-BDT by GEO 3 are all better than that of the others. The reason is that the observation condition is better than that of the others. the elevation at NTSC is about 50° , and the position of GEO 3 is at longitude 115°on the equatorial orbit. The longitude of the observation site is 107°, so GEO 3 is easy to be observed under the same condition. Figure 8 shows the Allan deviation of of UTC(NTSC)-BDT by GEO 3.

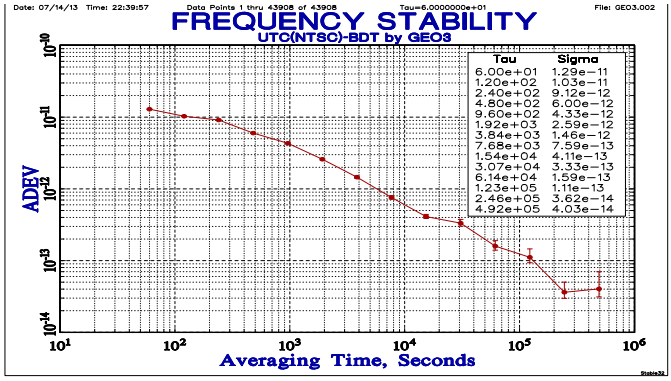

Figure 8 Stability of the UTC(NTSC)-BDT by GEO 3

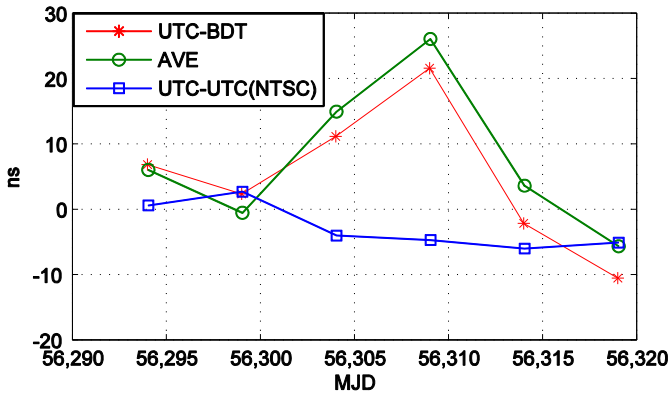

Figure 9 Deviation of BDT compared with UTC

Figure 9 shows the the deviation of BDT compared with UTC through UTC(NTSC)[5]. AVE in Figure 9 is an indication of the average of UTC(NTSC)-BDT by GEO k, k=1,3,4,5. Analyze the three lines, we could find that the fluctuations of lines are caused by BDS time and GEO satellite. The standard deviation of UTC-BDT is 11.1 in the period of test.

IV. SUMMARY

From the test and analysis, it is apparent that the deviation between BDT and UTC(NTSC) keeps in tens of nanoseconds in the period of experiment. Based on the different GEO satellites, though the deviation compared with UTC(NTSC) and UTC shows good consistency , there is still some diversity. The worst result is from GEO 2, and the best from GEO3. For GEO 2, it still in testing, the operation is unstable, however for GEO 3, its operation is stable and its observation condition is the best one of the five GEO satellites. Because the one-way time service by GEO satellites is the best in the three types of satellites [6], the result of the test shows that BD time service is about tens of nanoseconds at present. However, along with Beidou navigation system's gradually maturing and the orbit determination technology's improvement, the precision of Beidou one-way time service will be improved continuously.

***Abstract*—Bi-directional methods are widely used in scientific and productive measurements. By the symmetric principle, systematic errors are largely cancelled. The technique of Two-Way *Satellite* Time and Frequency Transfer (TWSTFT) is a typical example. Using the reciprocated radio signals emitted at two Earth laboratories and exchanged through a geostationary telecommunication satellite, the atmosphere delay effects are greatly reduced in the combination of the up and down signals. Applications to time transfer of the optical fibre technique, here under the acronym TWOTFT (Two-Way *Optical fiber* Time and Frequency Transfer) developed rapidly. The reciprocity of the signal in both the directions allows balancing the propagation path delays in the fibre since they average out almost entirely by employing the two-way method. Based on historical documents and the latest developments and in view of metrology, we briefly review and preview the two-way techniques for application in accurate time transfer for UTC.**

Keywords- UTC, TWSTFT, TWOTFT

I. TWO-WAY SATELLITE TIME AND FREQUENCY TRANSFER (TWSTFT)

A. Initiation 1960-1986 [1]

As a promising tool for accurate time and frequency transfer, the technique of Two-Way Satellite Time and Frequency Transfer (TWSTFT, in the earlier documents, the term TWSTT, Two-Way Satellite Time Transfer, was used) started its experimental steps earlier than GNSS. Long before the GPS time transfer became popular in the 1980s', attempts to use the geostationary telecommunication satellites to compare clocks can be dated back to August 1960. Then Echo 1 the large silvered Mylar balloon was used for one-way time transfer attempts. The result was not ideal due to the unknown propagation delays in the atmosphere. In 1962, the USNO and the NPL used the first active-mode communication satellite, Telstar, to perform the very first transatlantic two-way clock comparisons. In 1965, the first transpacific clock comparisons through the communication satellite Relay II were carried out between the USNO and the Radio Research Laboratory in Japan (Figure 1).

In most of these early experiments, a one-pps signal was modulated onto the carrier wave of a video signal for transmission. Oscilloscopes, Polaroid cameras and other primitive methods of measurement were employed. The type A (u_A) and type B (u_B) uncertainties reached during the Telstar and Relay experiments were about 10~100 ns and 100~1000 ns levels respectively. Ten years later, by using the ATS-1 satellite, the u_A and u_B were reduced to 1 ns and 10 ns respectively. In the end of 1970s, experiments proved that u_A could be further improved to around 0.2 ns. An experiment in Europe in 1983 attained a similar result using the Intelsat-V satellite and MITREX modem.

B. Development 1987-1997 [2]

Hardware technology has been quickly developed. The costs and the dimensions of the devices became smaller. Timing laboratories could invest in the required equipment with a more automated and operational timing transfer system.

In 1987, routine experiments began to use commercial Ku-band satellites. The NIST, the USNO and the NRC, joined later by the European laboratories TUG, NPL, NMi, VSL DTAG, PTB and OCA, started routine continuous observations (three measurements per week).

In the 1980s, the GPS had been used for accurate time transfer, and the GPS common-view was at that epoch the most advanced technique giving an accuracy of a few nanoseconds between European laboratories and 10 nanoseconds between continents. Unfortunately it was declared by the US military that in the near future the GPS system would be degraded for civilian users (Selective Availability). In addition the increasing of the altitudes of GPS satellites orbits was considered.

Meanwhile, significant improvement of atomic clock performances was expected in the years to come. So the timing community did not have simply to replace the GPS, but to find a new and more accurate technique. This was the 2-way time transfer. The importance of the clock comparisons has been emphasized in Resolutions and Recommendations by the General Conference on Weights and Measures (CGPM, Resolution 4 of the 18th CGPM, 1987) and the International Radio Consultative Committee – (CCIR, presently

Radiocommunication Sector of the International Telecommunication Union, ITU-R), calling for an international effort to establish the geo-satellite links on a permanent basis.

The 11th CCDS (Consultative Committee for the Definition of the Second, now the Consultative Committee for Time and Frequency, CCTF) in its declaration S1 (1989) encouraged the use of two-way time transfer and suggested the creation at the BIPM of an ad-hoc working group on the TWSTFT. The task of the Working Group was to specify the operational system, e.g.: satellites and frequency bands; specifications of Earth stations; station calibration; measuring procedures and schedules; data exchange and processing, etc. The first ad-hoc Group meeting was held at the VSL, in Delft, the Netherlands, on 15 June 1989.

The second meeting was held at Graz, Austria on 27-28 Oct. 1992 and was devoted to the exchange of information on the state-of-the-art of the method, available satellites and equipment, administrative issues, and reflections on possible operational links or experiments.

Ten laboratories actively intended to joint in the experimental plan. They were TUG, IEN(IT), PTB, FTZ(DTAG), NIST, USNO, NPL, VSL, LPTF(OP) and OCA. The modems available were of MITREX, SATRE, ATLANTIS and NIST. There were about 20 modems operational in different laboratories.

In 1992, several commercial satellite systems were available, and modems adapted for the technique were commercialized. Some ten UTC laboratories were equipped with different types of modems and other facilities for the clock comparisons with TWSTFT.

In March 1993, the BIPM ad-hoc Working Group was transformed to the permanent CCDS/CCTF Working Group on TWSTFT. Its first meeting was held in October 1993 at NPL, UK. The result of the European line-up campaign was reported. Stability in TDEV of hundred ps was reachable, cf. Figure 2.

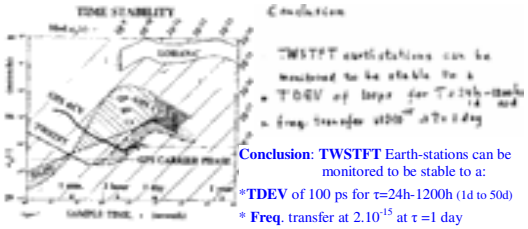

Figure 2. Report to the 5th TW WG in 1997 (hand writing transparent slides probably from PTB) [2]

C. *Application in UTC 1999-present [2]*

The International Telecommunication Union (ITU) approved in 1995 a recommendation fixing the standard data format for the TWSTFT operations.

The first TWSTT link officially introduced in the UTC computation was TUG-PTB in *Circular T* 139 published on 17 August 1999. GPS therefore lost its solo role as the tool for clock comparison in UTC for more than a decade. In 2000, there were four TW time links fully operational: TUG-PTB, VSL-PTB, NPL-PTB and USNO-NPL, as shown in the Figure 3 although at least 10 laboratories were operating TW stations.

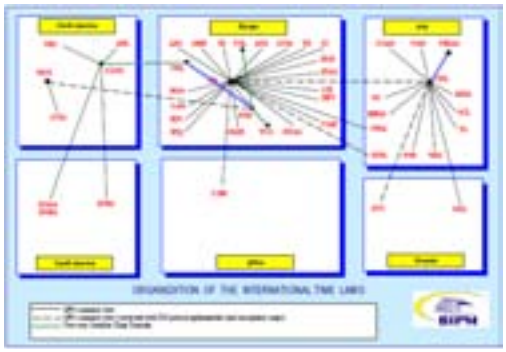

Figure 3. Configuration of the international UTC time link network in 2000

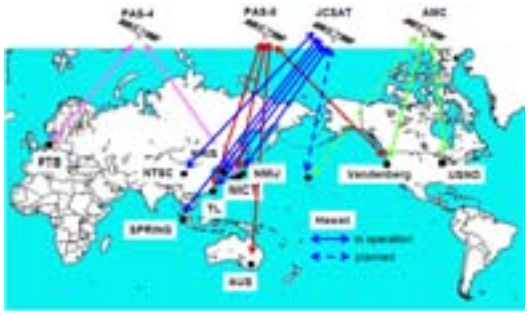

Figure 4. TWSTFT links in/between Asia, Europe and America in 2005 [2]

Figure 5. Setups of the Asia-Europe TWSTFT link between PTB-NICT [2]

The Asian-Pacific laboratories actively participated in the TWSTFT. In 2005, the high accurate Europe-Asia transcontinental link between NICT and PTB was established, Figures 4 and 5.

To contribute to UTC, the TWSTFT links must be calibrated, either indirectly through GPS links or through a mobile TW calibrator (Figure 6). Several calibration campaigns were organized in and between Europe (Table I), America and

Asia.

Figure 6. The TWSTFT mobile calibrators of TimeTech, USNO and VNIIFTRI [2]

TABLE I. CALIBRATION CAMPAIGNS IN EUROPE [2]

Calibration Period	Laboratories/campaigns
May-June 2003	IT-PTB-IT
July 2004	PTB-OP-NPL-VSL-PTB
Oct.-Nov. 2005	PTB-SP-VSL-NPL-OP-IT-PTB
May-June 2006	TUG-PTB-CH-TUG
Sept.-Oct. 2008	PTB-NPL-OP-IT-VSL-CH-TUG
2012-2013	PTB, CH, OP, VSL, ESTEC, AOS …

Meanwhile, in the passed years, the u_A in the GPS links dramatically decreased thanks to GPSPPP. From 2011 the combination of TWSTFT and GPSPPP is used to compute the UTC time links so as to take the advantages of the both techniques (Figure 7).

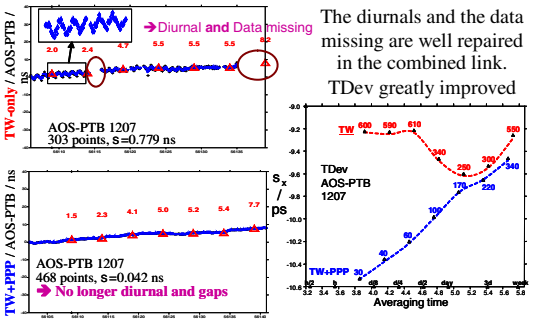

Figure 7. Combination of TWSTFT and GPSPPP

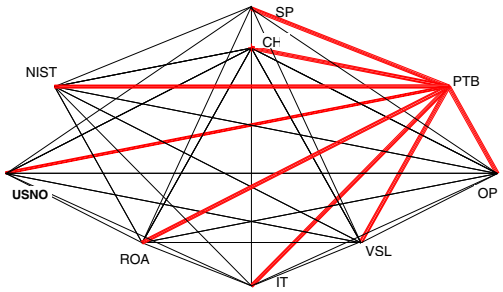

Figure 8. European-America TWSTFT network. Red lines are the UTC links

More than two third of the clocks in UTC and almost all the primary frequency standards are compared using TWSTFT. However, the TWSTFT is measured as a network but used as a single-link. The TW data are highly redundant. In general, for a N-point network, there are N(N-1)/2 independently measured links. Among them, only N-1 are used (red links in Figure 8). We have then (N²-3N+2)/2 redundant links. Full use of the high redundancy could be an effective way to improve UTC.

The concept of the TWSTFT network time transfer provokes several approaches in (quasi) real-time clock comparison and UTC dissemination with the TW network [2].

Figure 9 is the transcontinental TWSTFT network maintained at TL, NICT and USNO etc.

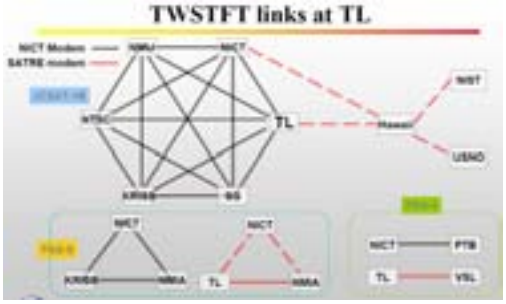

Figure 9. Asia-America TWSTFT network [2]

In addition to its direct contribution to UTC, TWSTFT has also served to test and validate the *new* GNSS techniques and methods incorporated to time transfer for UTC in the past 15 years, such as the GPS all in view, the GPSP3, the GPSPPP and GLONASS.

II. ONCOMING DEVELOPMENT

A. *Use of Carrier phase and DPN [2]*

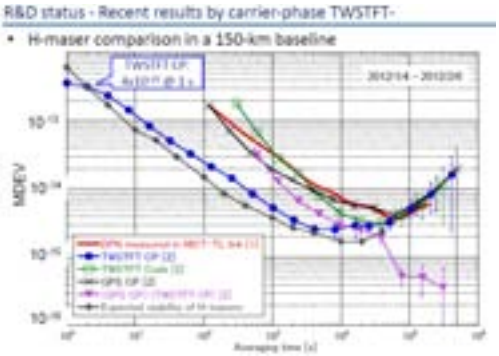

Figure 10. The MDev of the different techniques: DPN, TW CP, TW code, GPS CP vs. HM [2]

The current TWSTFT observable is only the code, which, affected of measurement noise and diurnals, is at its limits in accuracy. Further improvements should come from the uses of other observables, such as the DPN (dual pseudo-random noise) and carrier phase information. The DPN allows doubly reducing the measurement uncertainty, in particular that originated by the diurnals. Because the resolution of the carrier phase is 100 to 1000 times more precise than that of the code, TWSTFT carrier phase transfers may attain theoretically a stability of 0.1 ps in time and 10^{-12}@1s or 10^{-16}@1-day in frequency.

Figure 10 shows the MDev of the different techniques: DPN, TW CP, TW code, GPS CP with respect to the expected stability of a hydrogen maser.

B. *Two-way Optical Fibre Time and Frequency Transfer (TWOTFT) [3,4]*

The recent developments in the application of the optical fibre allow time transfer with a combined uncertainty (u_A and u_B) at the level of hundred ps. As same as TWSTFT, TWOTFT is based on telecommunication facilities, but this time, the optical fibre networks.

Optical clocks reach a fractional frequency uncertainty of order 10^{-17} and outperform the best cesium-based atomic standards in both accuracy and stability [4]. This outstanding performance makes them the most promising tool for the redefinition of the SI unit of time, the second, and an ideal tool for various tests of fundamental physics. Scientific programs or European space missions like the development of the GNSS Galileo, the Cosmic Vision program of ESA, or the ACES mission rely on the availability of highly accurate and ultra-stable frequencies or timing signals. However, today's conventional satellite based techniques lack the required performance for clock comparisons with relative frequency instability below 10^{-17} at one day measurement time.

Although the goal of fibre link is orientated to the next generation of optical clocks, some of its present outputs can be used immediately for improving the UTC generation, such as supporting time link calibrations and validations of high accurate GNSS time transfer methods.

The principle of the two-way transfer is the symmetry of the go and back signals whatever they go through the atmosphere or optical fibre or other media. Both TWSTFT and TWOTFT work with the same principle.

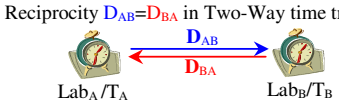

Figure 11. The symmetry in the two-way transfer signals go through atmosphere or optical fiber[5]

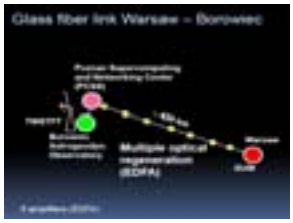
There are some 14 UTC laboratories that actively work on the optical fiber time and frequency transfers [5].



420 km – the distance along optical fiber
Combined uncertainty is estimated to be 112.3 ps

Figure 12. The characterization of the optical fiber link between UTC(AOS)-UTC(PL) [2]

AGH, GUM and AOS developed glass fibre time and frequency transfer facilities between two UTC laboratories and maintain a permanent, real-time time and frequency transfer link between UTC(AOS) and UTC(PL) (Figure 12) available at www.optime.org.pl/node/47. Meanwhile, AOS-PL started from May 2013 (1305) sending the fibre link data to the BIPM. Figure 13 illustrates the Tdev obtained from the TL 25 km fibre experiment.

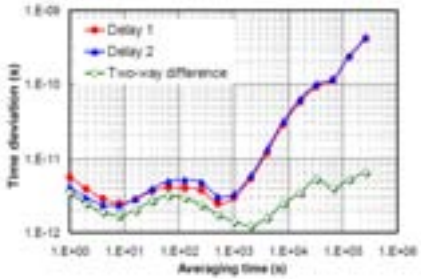


Figure 13. TL 25 km fiber time link experiment [5]

TWOTFT could fundamentally change the UTC generation. One application could be in the calibration of time links. TWOTT can reach hundred ps stability in a few minutes and therefore is an effective new tool for UTC link calibration vs. satellite methods with several days' measurements.

We suggest adapting the ITU TWSTFT data format for TWOTFT. Hence all the data exchanges, calibrations and processing as well as the related methodology could be kept with only slight modifications. This will speed up its applications. TWOTFT, with a potential uncertainty of hundred ps, could introduce fundamental changes in the UTC construction, such as the time link strategy and even the configuration of the international UTC time transfer network.

Since more than three decades, the UTC generation has been using the space-techniques. A new era of the ground based techniques (e.g. moving clock in the past) is back …

ACKNOWLEDGEMENTS

We thank the pioneers of the TWSTFT: B Guinot, G de Jong, F Cordara, P Hetzel, D Kirchner, D Knight, A Soering, W Klepczynski, W Hanson and T J Quinn. We thank also all the TWSTFT laboratories for their contributions to UTC and to the reference [2] based on which this paper is written.

Dual-Frequency Time Transfer Unit for Comparisons of the Remote Clocks Using GLONASS and GPS Signals

P. Bogdanov, A. Bandura, M. German, K. Kol'chenko, O. Nechaeva
"Russian Institute of Radionavigation and Time" JSC
St.Petersburg, Russia

Abstract— **Dual-frequency Time Transfer Unit (TTU) using GLONASS and GPS signals developed at "Russian Institute of Radionavigation and Time" JSC (RIRT) is intended for determining the offset between local clocks and GLONASS-time and GPS-time with the purpose of subsequent determining the mutual time and frequency offset between remote clocks, as well as for generating time scale signals synchronized to Russian National Universal Time Coordinated UTC(SU). The results of tests showed that the accuracy characteristics of the new Time Transfer Unit are higher than the same characteristics of the previous TTU model developed at RIRT as well as of TTS-3 and TTS-4 receivers, mostly when operating by GLONASS signals.**

Keywords- Time Transfer Unit, remote clock, GLONASS-time, GPS-time, accuracy estimate

I. INTRODUCTION

The method of using GLONASS and GPS signals is still being used for accurate comparisons of the remote clocks [1].

Time Transfer Unit (TTU) using GLONASS and GPS signals was developed at Russian Institute of Radionavigation and Time (RIRT) in 2002 and became the first Russian device to realize this method [2]. However, its abilities were considerably limited as it was made on the base of 16-channel single-frequency GLONASS/GPS receiver.

In this connection, the new Time Transfer Unit (TTU-1) based on 36-channel dual-frequency GLONASS/GPS receiver was developed in 2011. TTU-1 is intended for determining the offset between local clocks and GLONASS-time and GPS-time with the purpose of subsequent determining the mutual time and frequency offset between remote clocks, as well as for generating time scale signals synchronized to Russian National Universal Time Coordinated UTC(SU).

II. FUNCTIONALITY, MAIN CHARACTERISTICS AND COMPOSITION OF TTU-1

TTU-1 has the following main technical characteristics:

- determining the offset between a local clock and GLONASS-time and GPS-time with the error no more than 35 ns (rms) using GLONASS signals and no more than 20 ns (rms) using GPS signals over 13-min measurement interval;

- determining the mutual offset between two remote clocks using GLONASS or GPS signals with the error no more than 5 ns (rms) for the distances between clocks up to 100 km and no more than 10 ns (rms) for the distances up to 8000 km over 13-min measurement interval;

- determining the mutual frequency offset between two remote clocks at the distances up to 100 km using GLONASS or GPS signals with the error no more than $5 \cdot 10^{-14}$ over 1-day observation interval and no more than $1 \cdot 10^{-14}$ over 10-days observation interval;

- synchronizing the output signals 1 Hz, 1/60 Hz and 1/300 Hz to UTC(SU) or GLONASS-time with the error no more than 50 ns (rms).

The new Time Transfer Unit is presented in Fig. 1.

TTU-1 consists of the following components:

- an antenna box with built-in amplifier;

- a comparison unit including a receiver, a synchronizing device, an indication device and a power supply unit;

- a personal computer with special software which realizes the algorithms for TTU-1 functioning;

- a mounting kit.

The antenna box and the receiver are calibrated during their manufacturing process. The calculated signal delays for GLONASS and GPS signals are accounted for during the measurements processing. The special testing equipment with GPS/GLONASS signal simulator is used to calibrate the devices. Now the total error of the determined absolute signal delays is about 5 ns. Besides, the delay corrections are measured for each GLONASS frequency with the error no more than 1 ns.

TTU-1 provides the following output data:

- time measurement results in the standard international format "cggtts_format_v2" [3] including:

L1C - L1 code measurements;

L2C - L2 code measurements;

Figure 1. The new Time Transfer Unit

L3C - ionosphere-free combination of dual-frequency code measurements;

CL3 - ionosphere-free combination of dual-frequency code measurements;

- radionavigation parameters and digital information included into navigation message from SV in the standard international format RINEX.

III. TTU-1 TEST RESULTS

The accuracy of time scale comparisons (rms) was estimated for three sets of TTU-1 (6RRT, 10RRT, 2RRT) installed at RIRT and one set supplied to "Rostest-Moskva" company (ROST).

The value of the root mean squared of linear fit residuals for all measurements over 1 day was used as an accuracy estimate.

The results of the accuracy estimates for time comparisons between local clock and GLONASS/GPS-time, the instrumental accuracy estimates for the mutual time offset and frequency offset of local clocks (τ = 1 day) and the accuracy estimates for mutual time comparisons between local clocks at RIRT and "Rostest-Moskva" are presented in Tables I - IV.

The results show that TTU-1 accuracy characteristics satisfy technical requirements. At the same time, the results show that for the distances up to 100 km the required accuracy of comparisons between remote clocks can be provided only by single-frequency measurements.

TABLE I. ACCURACY ESTIMATES FOR TIME COMPARISONS BETWEEN LOCAL CLOCK AND GLONASS/GPS-TIME

Set	Comparison error (rms), ns

The results of the accuracy estimates for time comparisons between local clock and GLONASS/GPS-time and between remote clocks with using TTU and TTS-3 and TTS-4 receivers are presented in the Tables V - VIII.

TTUs are installed at RIRT (3RRT, 7RRT) and Main and Reserved Central Synchronizers of GLONASS (CSm and CSr).

TTS-3 and TTS-4 receivers produced by PIK Time Systems are installed at Russian Time and Frequency Service sites Mendeleevo (SU), Irkutsk (Im), Khabarovsk (Km) and Novosibirsk (Nm).

TABLE VIII. THE ACCURACY ESTIMATES FOR THE MUTUAL TIME OFFSET BETWEEN LOCAL CLOCKS USING TTS-3/TTS-4

Sites	Comparison error (rms), ns			
	GLONASS		*GPS*	
	L1C	*L3C*	*L1C*	*L3C*
SU(TTS-3)–Im(TTS-3)	13.0-15.8	-	5.3-7.8	-
SU(TTS-3)–Km(TTS-4)	17.4-20.6	-	6.4-9.8	-
SU(TTS-3)–Nm(TTS-4)	9.3-12.5	-	5.9-8.5	-
Im(TTS-3)-Km(TTS-4)	6.8-11.8	-	4.6-6.9	-
Im(TTS-3)-Nm(TTS-3)	6.0-8.9	-	5.9-8.3	-
Km(TTS-4)-Nm(TTS-4)	10.0-14.4	9.3-10.7	5.2-8.5	2.3-2.6

The results presented in Tables I – IV and V - VIII show that the accuracy characteristics of the new TTU-1 are higher than the same characteristics of TTU equipment as well as of TTS-3 and TTS-4 receivers, mostly when operating by GLONASS signals.

IV. NOTATION OF MEASUREMENT TYPE FOR TIME SCALE COMPARISONS BY GNSS SIGNALS

According to CGGTTS GPS/GLONASS Data Format Version 02 the following frequency and code types are used for pseudo-range measurements:

L1C – L1 C code;

L1P – L1 P code;

L2C – L2 C code;

L2P – L2 P code.

The type L3C and L3P for ionosphere-free combination can also be used according to "Proposals to use geodetic-type receivers for time transfer using the CGGTTS format" [4].

But now the new "Glonass-K" SV also transmits signals with code division at L3 frequency band and, as a result, L3C type is supposed to be used.

So, there is a contradiction because according to the existing notation L3C should be used for both ionosphere-free combination and observations at L3 frequency band.

To sum up, we find reasonable to develop a new version of the data format for GPS/GLONASS and future GPS/GLONASS/Galileo time receivers and all existing and planned signals and methods of their processing.

V. CONCLUSION

The results of tests and experimental operation showed that the accuracy characteristics of the new Time Transfer Unit meet specified requirements and are higher than the same characteristics of the previous TTU model as well as of TTS-3 and TTS-4 receivers, mostly when operating by GLONASS signals.

The improvement of time comparison accuracy is possible in the mode of post-processing with using a *posteriori* ephemeris and other data presented by GNSS information processing centers, for example, by Information and Analysis Center (IAC) of “TSNIIMASH” Federal State Unitary Enterprise.

ACKNOWLEDGMENT

Authors thank the colleagues from RIRT and “Rostest-Moskva” for their assistance in testing the equipment and processing and analyzing the results obtained.

***Abstract*—This paper proposes a method to combine GPS and GLONASS measurements for time transfer in All-in-View, using calibration data for both GPS and GLONASS. GLONASS has to date a complete constellation, but its use for time transfer is made difficult by the existence of biases for each satellite-receiver pair. These biases contain both a receiver contribution, due to the different frequencies emitted by the different GLONASS satellites, and a satellite contribution, varying with time, and coming from the satellite clock products. Up to recently, these biases were determined with respect to the calibrated GPS solution. We propose here to determine these biases for the two stations of a time link, in a constrained least square analysis, where the constraint is given by the GLONASS calibration data obtained from a link calibration with these two stations. With these biases, it is then possible to obtain an All-in View solution combining GPS and GLONASS measurements and calibrated for the GPS as well as GLONASS signals. The method was tested on the link Brussels-Paris for which a calibration was performed for GPS and GLONASS. Using one month of data, the impact of using or not the GLONASS calibration results is in that case smaller than 2.5 ns peak to peak.**

Keywords—GPS, GLONASS, Time Transfer

I. INTRODUCTION

GPS signals are used since the eighties [1] to perform precise and accurate Time and Frequency Transfer (TFT). In its classical version, the GPS time transfer is performed using clock offsets collected in a fixed format, called CGGTTS (Common GPS GLONASS Time Transfer Standard), as described in [2,3]. These clock offsets represent the differences between the ground clock (UTC(k) in most cases) and the reference timescale of the GNSS. They are obtained from the pseudorange measurements, corrected for the signal travel time (satellite-station), for the troposphere and ionosphere delays, and for the relativistic effects. A smoothing is then performed over 13 minute observation tracks. Originally developed for C/A code receivers, the method was then upgraded to take advantage of the dual-frequency receivers: combining codes carried by the L1 and L2 frequencies allows removing the ionosphere delays at the first order (i.e. 99.9 percent of the effect), thanks to the ionosphere-free dual-frequency combination. This led to a factor 2 improvement in the stability of the intercontinental time links up to averaging times of 10 days (e.g. [4]). Initially, the time transfer solution was based on the Common View (CV hereafter) [1], i.e. the clock comparison is computed as a weighted average of the differences between the CGGTTS results obtained in both stations for each satellite separately. In that case the weighting coefficient can be a function of the elevation since low elevation observation is more affected by noise and multipath. In order to improve the long distance clock comparisons, it was proposed to replace the CV approach by the All in View (AV hereafter) approach [5]. This consists in computing separately for each station the weighted average of the CGGTTS results and thereafter to compute the difference between the solutions obtained in the two stations.

In parallel, the time-transfer technique based on Precise Point Positioning (PPP) has proven to be a very effective technique allowing the comparison of atomic clocks with a statistical uncertainty of 0.1 ns, and a frequency stability reaching 10^{-15} at an averaging time of one day [6-8]. PPP [9,10] is based on a consistent modeling and analysis of GPS (and possibly GLONASS) dual-frequency code and carrier-phase measurements. The present paper however will concentrate only on CGGTTS results, i.e. code-only analysis; nevertheless the approach can be applied as well to PPP.

The next section reviews the state of the art of time transfer using GLONASS data, then Section III presents the calibration of the link Brussels-Paris set up in order to validate the method developed in Section IV to produce a fully calibrated combined GPS+GLONASS time transfer solution. The conclusions and perspectives of the paper are proposed in Section V.

II. GLONASS TIME TRANSFER: STATE OF THE ART

The main difference between GPS and GLONASS is that all GPS satellites share the same two carrier frequencies L1 and L2, while each GLONASS satellite transmits on a different frequency using a 15-channel frequency division multiple access (FDMA) technique spanning either side from 1602.0 MHz, known as the L1 band and either side of 1246.0 known as the L2 band. Due to the frequency-dependent nature of the hardware delays in the receiver and in the antenna, these are different for each satellite group emitting a given pair of frequencies L1, L2, inducing inter-frequency biases (ISB) up to 25 ns in the code measurements and hence in the CGGTTS data. These ISB in the CGGTTS data must be removed before these data can be used in either CV or AV.

Using GLONASS and GPS for time and frequency transfer in a combined analysis (for the AV and PPP approaches) requires a single common reference for all the satellite clock products used in the analysis. This is not the case with the broadcast satellite clocks, and also not the case with the IGS rapid or final satellite clock products. GLONASS satellite clocks are indeed provided in the navigation message with respect to the GLONASS system time, while GPS satellite clocks are referred to GPS time. GLONASS clocks are not yet

provided in the IGS products. However since 2008, the IGS analysis centre ESOC provides combined GPS and GLONASS products in which the satellite clocks from both constellations are given with respect to the same reference time scale [11]. These products can therefore be used for the combination of GPS and GLONASS data for time transfer. ESOC operates daily computations, and for each day they determine a bias for each receiver-satellite pair. As only differences between receiver and satellite clock parameters appear, it is only possible to solve for the GLONASS clock parameters in a relative sense. ESOC therefore fixes one bias for one given station-satellite pair, but this bias can change from day to day so that all biases change accordingly. As a consequence, using GLONASS measurements with ESOC or equivalent products for time transfer requires the estimation of inter-satellite biases (ISB) in addition to the clock solution for each satellite and on a daily basis. Indeed we have for GPS satellites:

$$(t_{rec} - ref) = meas\_GPS - (t_{sat} - ref) - CAL(rec)$$

and for GLONASS satellites: (1)

$$(t_{rec} - ref) = meas\_GLO - (t_{sat} - ref) - ISB\,(rec, sat, day)$$

where (t_{rec}-*ref*) is the synchronization error between the local clock and the reference of the satellite clock products, *meas_* is the code measurement corrected for the geometric distance and atmospheric delays, *CAL(rec)* is the station hardware delay for GPS. $ISB\,(rec, sat, day)$ is a daily bias for the satellite-receiver pair and has a magnitude around 400 ns, because the ESOC GLONASS clock products are also biased in order to be roughly aligned with the broadcast satellite clocks.

The necessary tools for using of ionosphere-free codes of GLONASS in CGGTTS are presented in [12], and are complemented with the approach recommended for the combination of CGGTTS results from GPS and GLONASS in All in View. This approach is based on a first computation of GPS-only AV solution, followed by the determination of the ISBs with respect to the GPS AV solution, and finally by the computation of the new AV solution combining GPS data and GLONASS data corrected for the ISBs. The results presented in [12] for 25 time links showed that correcting the GLONASS solution for ISBs reduces strongly the noise of the GLONASS solution, with a reduction from 35 % to 90% for the time links investigated (see an example in Figure 1, top). The combination of GPS and GLONASS ionosphere-free combinations in AV solutions were also compared to the GPS-only AV solutions for a set of 25 time links (see one example Figure 1, bottom). For some links where one of the receivers has a quite large GPS code noise level, the noise of the combined solution is better than the noise of the GPS-only solution. For the other time links, the noise level of both solutions is equivalent. For all the links investigated in [12], the statistical uncertainty of the combined GPS+GLONASS (corrected for ISBs) AV solution was smaller than 0.95 ns.

As explained before, we are presently obliged to determine the ISBs daily and for each satellite, while physically these ISBs should be constant with time and the receiver biases should be equal for two satellites emitting the same frequencies. Furthermore, as the biases are determined with respect to the calibrated GPS AV solution, it does not account for any GLONASS receiver calibration data. This is the reason why we propose a new approach in the next sections.

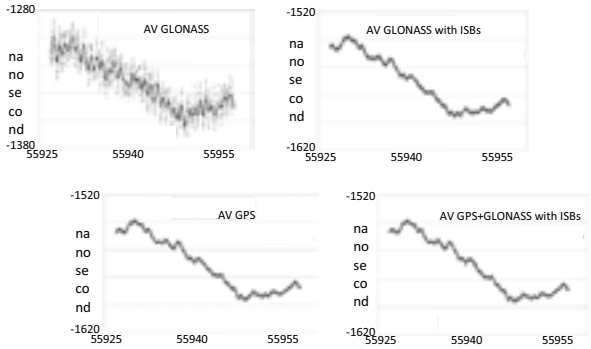

Fig. 1 (from [12]) : time transfer solution between AOS (Poland) and AUS (Australia); up: improvement of the GLONAS AV solution when correcting for the ISBs, bottom: comparison between the GPS AV solution and the GS+GLONASS AV solution when ISBs have been corrected for. Grey dots are the raw AV results, black dots are Vondraked smoothed (1D+5) results.

III. BRUX-OPM8 LINK CALIBRATION

An experimental GLONASS+GPS calibration has been realized in June 2013, using a traveling GNSS station, containing a Septentrio PolaRx4TR-PRO receiver, a 30 m antenna cable RG-8 (Belden 8214), and a Trimble Antenna Choke Ring 59800.00. The scheme of the calibration follows the procedure proposed in [13].The traveling station was first installed in common-clock at the Royal Observatory of Belgium (ORB), in colocation with the station BRUX, the reference station for participation of the ORB to the IGS and to the TAI. The traveling station was then installed in common-clock at the LNE-SYRTE, in colocation with the station OPM8. In both the OPM8 and BRUX stations the receiver is a Septentrio PolaRx4TR-PRO. After coming back, the traveling station was re-installed at ORB in order to have an additional set of measurements and to cross-check the calibration results.

Using 5 days of data of colocation with the traveling receiver for BRUX and for OPM8, we computed separately for C1, P1, C2 and P2 the pseudorange differences between the traveling receiver and the station receiver. We deduced the differential hardware delays (receiver+antenna) between the stations BRUX and OPM8 for GPS P1 and P2, as well as for each of the GLONASS frequencies. In a first time, the computation was done for each GLONASS satellite rather than for each GLONASS frequency in order to assure the hypothesis that satellite emitting the same frequencies have indeed the same receiver and antenna hardware delays. The differential hardware delays in the GLONASS P3 band for the link OMP8-BRUX are shown in Figure 2. Note that even if the calibration was done for P1 and P2 separately, in the following we only speak about P3 as it is the observable classically used for the computation of TAI. Furthermore, notice that no

uncertainty on these biases was estimated up to now. This paper is only devoted to the demonstration of the feasibility of the approach proposed in Section IV. The error budget is beyond the scope of the paper and will be one of the goals of future studies.

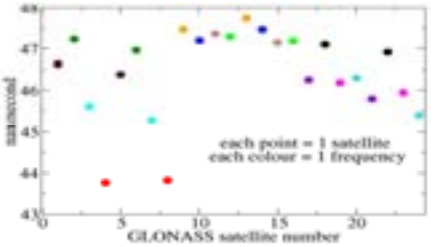

Fig 2. Differential GLONASS hardware delays of the P3 link OPM8-BRUX, computed for each satellite separately.

We can observe in Figure 2 that the satellite pairs corresponding to a given frequency channel have differential hardware delays with a difference smaller than half a nanosecond, except for satellites 20 and 24, which are on the frequency channel +2. This should be investigated in the future. We also observe that the dispersion of the differential delays between the frequencies remains within 4 nanosecond. This is quite small with respect to some other results found in the literature [e.g. 12] but can be explained by the fact that the two stations BRUX and OPM8 are equipped with the same receiver type.

IV. AV GPS+GLONASS FULLY CALIBRATED

Recall that AV can only be computed when the CGGTTS results are based on satellite clock products having the same reference for GPS and GLONASS, as for example the ESOC products. The results of a combined GPS+GLONASS AV proposed in [12] and summarized in Section II are calibrated only for the GPS part. The ISBs are then determined with respect to the calibrated GPS results. In this section we propose a new approach which allows providing a combined GPS+GLONASS AV calibrated for GPS as well as for GLONASS. The basic idea is that the ISBs appearing in equation (1) can be separated into two components: $D(rec, sat)$ the physical station (receiver+antenna) hardware delay for the frequencies of the GLONASS satellite, which is constant over time, and $B(day, sat)$ a satellite bias which varies from day to day, associated with the GLONASS satellite clocks, and which is the same for all the GNSS stations. This reads:

$$ISB(rec, sat, day) = B(day, sat) + D(rec, f_{sat}) \quad (2)$$

where f_{sat} is the satellite frequency. Therefore, the difference between the ISBs of two stations is equal to

$$\begin{aligned} ISB(rec1, sat, day) - ISB(rec2, sat, day) \\ = D(rec1, f_{sat}) - D(rec2, f_{sat}) \\ = \Delta_{12}(f_{sat}) \end{aligned} \quad (3)$$

and should be constant over time. The difference $\Delta_{12}(f_{sat})$ can furthermore be determined by relative calibration, as was done for the link BRUX-OPM8 and presented in the previous section.

Using these differential delays in CV is very simple: each of the differences between clock results made in the two stations on the satellite k should be corrected using $\Delta_{12}(f_k)$:

$$\begin{aligned} CV(sat, t) = REFGLO(rec1, sat, t) \\ - REFGLO(rec2, sat, t) - \Delta_{12}(f_{sat}) \end{aligned} \quad (4)$$

where *REFGLO(rec,sat,t)* is the clock solution from the CGGTTS computed with (or equivalently transformed from broadcast satellite orbits and clocks to) the ESOC products.

The differential delays can also be used for AV (and similarly in the future for PPP), but in that case the determination of the AV (or PPP) solution must be done at the same time for both stations. The reason is that for each station the biases $ISB(rec, sat, day)$ must be determined with respect to the GPS AV solution of the station, while verifying the relation

$$ISB(rec1, sat, day) - ISB(rec2, sat, day) = \Delta_{12}(f_{sat}) \quad (5)$$

We propose therefore, to first determine a GPS-only AV solution, and then to use a constrained least square approach to determine the ISBs of both stations. The constraints given by equation (4) are introduced as additional observations. The matrix system to be solved reads:

$$PAx = Py \quad (6)$$

where the vector x contains the unknown ISBs of the two stations, and the vector y contains all the differences between the GLONASS clock solutions and the GPS_AV solution, as well as the constraints, i.e. the calibration values $\Delta_{12}(f_k)$. The matrix A contains for each observation and constraint the derivative with respect to the ISBs, and the matrix P contains the weights attributed to the observations and constraints. The observations are weighted with the $sin^2(elevation)$. The constraints should receive a high weight, larger than the sum of the weights of all the observations. Finally, the biases of the two stations are determined as

$$x = (A^T P A)^{-1} A^T P y$$

These biases $ISB(rec, sat, day)$ can then be applied to the $REFGLO(rec, sat, t)$ in each of the stations, and the combined AV can then be computed using both the GPS and GLONASS (corrected for ISBs) clock solutions from the CGGTTS files.

This approach to compute a fully calibrated GPS+GLONASS AV time transfer was applied on BRUX and OPM8 data covering one month (June 6 to July 7, 2013). In a first step the CGGTTS results were computed for both stations using the ESOC products and the RINEX to CGGTTS software R2CGGTTS.V51 [12] slightly modified in order to use directly the ESOC products rather than the broadcast satellite orbits and clocks. In the second step the least square approach was used to determine the BRUX and OPM8 ISBs for each satellite and each day, constrained by the differential delays determined by calibration and presented in Figure 2. The differences between the ISBs so-obtained and the ISBs obtained without GLONASS calibration constraint are depicted in Figure 3 for BRUX and OPM8. These differences range between -2 and +2 nanosecond, and are not constant over the one month period analyzed. The large peaks for OPM8 at mjd 56456 are due to

an incomplete daily RINEX file, reducing the number of observations used to determine the ISBs.

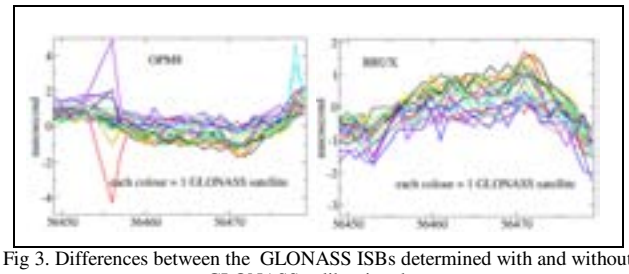

Fig 3. Differences between the GLONASS ISBs determined with and without GLONASS calibration data

Figure 4 presents the difference between the combined GPS+GLONASS solutions using or not the GLONASS calibration constraint to determine the ISBs of BRUX and OPM8. The global impact of using or not the GLONASS calibration constraint on the combined AV solution is, for this one month period and this particular baseline, between -1.2 and +1.2 nanosecond. Finally, Figure 5 shows the time transfer solution over one month for BRUX-OPM8, based on the AV solution using GPS-only, and using GPS+GLONASS with and without taking the GLONASS calibration into account.

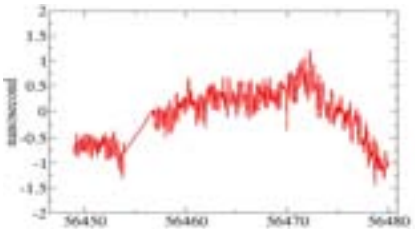

Fig 4. Differences between the time transfer solution OPM8-BRUX computed with AV in both stations determined with and without the calibration constraint.

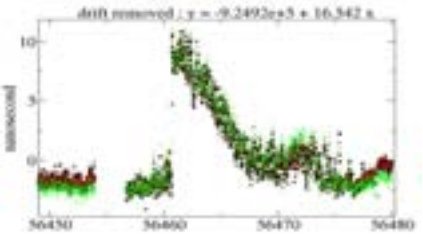

Fig 5. Comparisons between the time transfer solution for OPM8-BRUX computed with AV in both stations using GPS-only (black), GPS+GLONASS with (green) and without (red) the GLONASS calibration data.

V. CONCLUSONS

This paper proposed a method to combine GPS and GLONASS measurements for time transfer in All-in-View, using calibration data for both GPS and GLONASS. It is based on a three step approach:

1. Determining for each GLONASS frequency the differential hardware delay between the two stations of the time transfer link. This can be done by relative calibration using a traveling GNSS station;
2. Computing for each station the GPS-only AV solution;
3. Estimating for each receiver-satellite pair the biases between the GLONASS results from the CGGTTS and the GPS-only AV solutions. These biases should be estimated for both stations at the same time using a least square approach in which the differential hardware delays determined at item (1) are introduced as constraints on the biases estimated here;
4. Computing for each station the combined GPS+GLONASS solution in which the GLONASS results have been corrected for the ISBs determined in Item 3; and make the difference of the AV solutions of the two stations.

This procedure was tested successfully on a link between Brussels and Paris. The difference during one month between the time transfer solutions based on a combined GPS+GLONASS AV, obtained with and without GLONASS calibration results is in this case smaller than 2.5 ns peak to peak. This study will be extended to more baselines, and the uncertainty budget will be further evaluated. It will then be applied to Precise Point Positioning.

ACKNOWLEDGMENT

The authors thank Tim Springer and the ESOC for helpful discussions and availability of orbits and clock products.

***Abstract*—GAGAN (GPS – Aided Geo Augmented Navigation) is an Indian SBAS (Satellite Based Augmentation Systems). In contrast to the European EGNOS, this system already supports the navigation function and it transmits signals both in L1 and L5 frequency channels. We used the GAGAN signals for an experimental common-view time transfer between IPE Prague and PTB Braunschweig which is a distance of 370 km and we also tested the time transfer properties using a single clock common-view. The L1 and ionosphere-free code measurements have markedly lower accuracy compared to a GPS common-view because of rather narrow bandwidth of the SBAS signal in L1 frequency channel. L5 code measurement provides much better precision. It results from the single clock common-view that the observed fluctuations can be described as white noise with standard deviations of 6 ns, 1.3 ns and 14 ns for L1, L5 and ionosphere-free combination. The results obtained from the carrier phase measurements are promising. The single clock common-view precision was approximately 30 ps RMS even for the ionosphere-free combination. Interesting results followed from the comparison at the long distance where relatively fast fluctuations induced by ionosphere are obvious in the single frequency measurements. We believe that using GAGAN and other SBASs for permanent carrier phase frequency transfer could be an ideal solution for continuous comparisons of precise frequency sources.**

I. Introduction

GAGAN (GPS-Aided Geo Augmented Navigation) is an Indian satellite navigation system which augments GPS and makes it suitable for safety critical applications. It is one of the SBAS (Satellite Based Augmentation Systems). GAGAN uses geostationary satellites transmitting signals almost identical to the GPS signals thus it can be used for time and frequency transfer in similar way. In contrast to the European EGNOS, this system already supports the navigation function and it transmits signals both in L1 and L5 frequency channels. The signals are also available in good quality in Europe.

The GAGAN project involves establishment of 15 Reference Stations, 3 Navigation Land Uplink Stations, 3 Mission Control Centers and installation of all associated software and communication links. GAGAN is planned to get into full operation by the year 2014 and after its final operational phase completion will be compatible with other SBAS [1]–[3].

This work has been sponsored by the Czech Office for Standards, Metrology and Testing within the Project III/13/13 of the Program of Metrology Development in 2013.

The first GAGAN transmitter was integrated into the GSAT-4 geostationary satellite, and had a goal of being operational in 2008. Following a series of delays, GSAT-4 was launched on 15 April 2010, however it failed to reach its orbit. GSAT-8 (PRN 127) was successfully launched on 21 May 2011 and is positioned in geosynchronous orbit at 55° E. GSAT-10 (PRN 128) was successfully launched on 29 September 2012 and is positioned at 83° E. GSAT-15 is planned to be launched during 2014–15.

II. Using SBAS For Time Transfer

The SBAS satellites broadcast pseudo-random ranging signals of the same type as GPS together with data messages including ephemerides of the geostationary satellites (Message Type 9). When users are equipped with receivers capable to measure the delay between the received signal and an external time reference, it is possible to use this signal for comparison of time scales by the common-view technique.

SBAS makes use of geostationary satellites contrary to GPS. Therefore the variations in the relative position between the satellite and a receiver are small and very slow. The elevation and azimuth of the satellite can be considered nearly unchanging which has significant influence on the character of the multipath effect and the behavior of the ionospheric and tropospheric delay.

Multipath propagation is caused by signal reflection off objects in the vicinity of the receiver antenna. Multipath is then characterized locally. If the distance between the receivers is small, the overall error of comparison is given by the error from the multipath. Azimuth and elevation of a GPS satellite change dramatically during flyover. Therefore the variations in delay of reflected signals are fast and the measured delay fluctuates because of interference of the direct and reflected signals. Concerning a geostationary satellite, changes in azimuth and elevation are extremely slow and the error caused by multipath propagation fluctuates very slowly as well.

While going through the ionosphere and troposphere, the signal from a satellite is delayed up to some tens of nanoseconds. These delays are usually strongly reduced in the common view comparison, but even the residual error is proportional to the ionospheric and tropospheric delays at both sites and their variations still affect the comparison. Both atmospheric delays depend strongly on satellite elevation. This

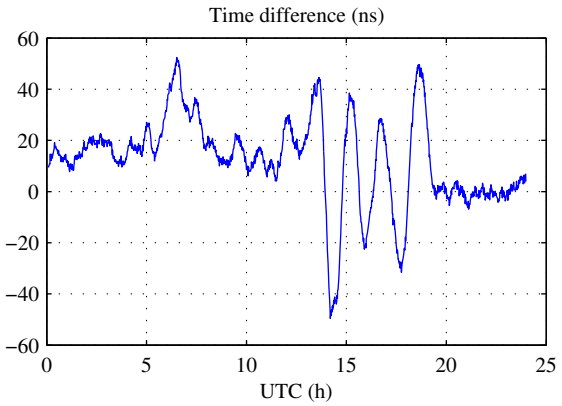

Figure 1. UTC(TP) − GAGAN, code measurements, ionosphere-free combination, $\sigma = 17$ ns.

dependence is extremely high in case of the tropospheric delay. It varies in the range of 6:1 for satellite elevation between 10° and 90°. The ionospheric delay varies in the range of 3:1 for the same range of elevation. Periodic daily changes in ionospheric delay are typically observed with minimum in early morning hours and maximum after the noon. Because the azimuth and elevation are nearly constant concerning geostationary satellite, the variations in the ionospheric delay are then small and slow compared to GPS. Possible variations in the tropospheric delay then respect only actual weather conditions.

It results from the above that the use of the SBAS signals for time transfer should provide much better time stability, but on the other side there cannot be expected a good chance to suppress the multipath effect on the basis of its averaging in time.

III. Experimental Measurements

In the experiments we used the GAGAN PRN 127 satellite signals in L1 and L5 frequency channels. A pair of GTR51 receivers capable to receive the SBAS signals in both frequency channels was used for the reception and measurement data processing. One of the receivers used the Novatel GPS-703-GGG antenna, the second receiver used the Novatel GPS-704X antenna with an external amplifier.

In the first experiment we directly compared the UTC(TP) time scale with the GAGAN system time. The comparison was based on all measurement data from MJD 56231. The resulting plots of the time difference UTC(TP) − GAGAN determined from L1, L5 and ionosphere-free code measurements are in Fig. 1. No ionospheric delay correction is applied on the plots. The ionosphere-free combination is noisiest, but it is best reflective of the properties of the GAGAN system time scale and the broadcast ephemerides. The standard deviation of this plot is 17 ns which corresponds to change of the radial distance between the satellite and the receiver antenna around 5 m RMS. This result indicates a good GAGAN system time and ephemerides quality.

In the second experiment we used the GAGAN signals for common-view between IPE Prague and PTB Braunschweig. The distance between these two sites is around 370 km. The goal of this experiment was to evaluate the time transfer using a SBAS geostationary satellite at a distance when the ionospheric and tropospheric delays play an important role together with the multipath and receiver noise.

As we compared two independent time scales, their difference naturally changed in time. For averaging intervals up to several hours the UTC(PTB) time scale provides significantly better stability than the UTC(TP). Therefore we can consider that the time difference stability is fully determined by UTC(TP) which has typical modified Allan deviation

$$\mathrm{MDEV}(\tau) = 6.4 \cdot 10^{-12}\sqrt{\tau}, \quad \tau > 10\,\mathrm{s}. \tag{1}$$

For characterization of the time transfer stability we will use the time deviation TDEV which is then

$$\mathrm{TDEV}(\tau) = 0.22\sqrt{\tau} \quad [\mathrm{ns},\ \mathrm{hour}]. \tag{2}$$

The time transfer instability substantially larger than the TDEV above has surely its origin in the time transfer. On the other side, instability of the time transfer smaller than the TDEV above will stay masked by the measured time difference instability and cannot be observed in the results of the experiment.

We processed all code and carrier phase measurements in L1 and L5 frequency channels from MJD 56231. The satellite elevation was 18° in Braunschweig and 21° in Prague. Changes in both azimuth and elevation were below 0.1°. The carrier-to-noise ratio was around 40 dBHz. The resulting time difference evaluated from the from L1, L5 and ionosphere-free code measurements is in Fig. 2. The results of the carrier phase measurements are in Fig. 3. The corresponding TDEV plots are in Fig. 4 and Fig. 5.

The L1 code measurement has markedly lower accuracy compared to a typical GPS common-view. This is caused by the rather narrow bandwidth of the SBAS signals in this frequency channel [4]. The observed fluctuations can be described as white noise with standard deviation of 7 ns. The L5 code measurement provides much better precision.

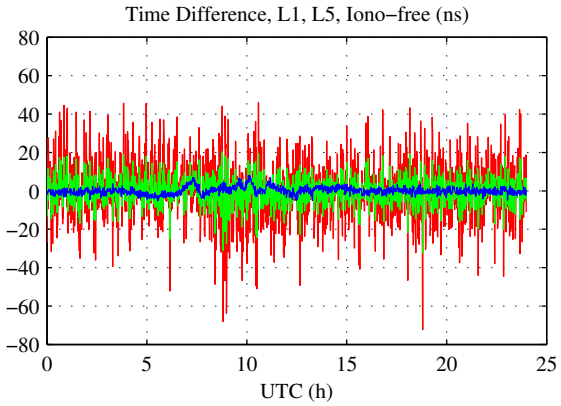

Figure 2. UTC(PTB)−UTC(TP) via GAGAN PRN 127, code measurements, L1 (green), L5 (blue) and ionosphere-free combination (red).

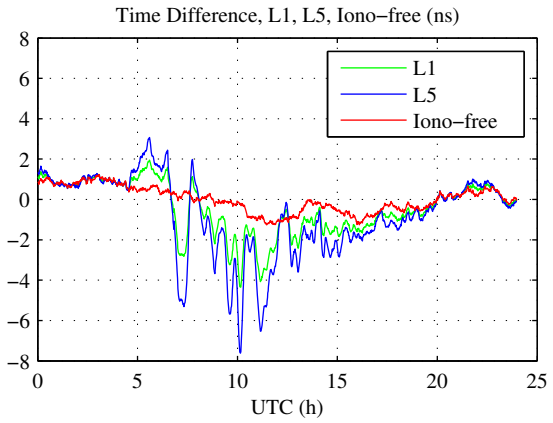

Figure 3. UTC(PTB) − UTC(TP) via GAGAN PRN 127, carrier phase measurements, L1, L5 and ionosphere-free combination. Fluctuations in L1 and L5 measurements are caused by ionosphere.

In this case we assessed the stability TDEV < 1.3 ns for averaging intervals from 1 min to several hours which is a behavior similar to a GPS common-view with no additional processing. Since the geostationary satellite moves just slightly towards the receivers, the observed variations caused by the multipath effect are very slow compared to GPS. The low L1 measurement precision was also projected into the L1/L5 ionosphere-free combination.

On the other side the results obtained from the carrier phase measurements are promising. The stability of the ionosphere free combination is TDEV($\tau = 1$min) < 40 ps. For longer averaging intervals it is masked by the expected instability of the measured time difference.

Interesting results followed from our comparison of the single frequency measurements and the ionosphere free combination where relatively fast fluctuations induced by ionosphere are obvious in the single frequency measurements. These fluctuations start at sunrise. During the daytime, the amplitude of these fluctuations reaches 5 ns in the L1 frequency channel and fully disappears before local midnight. This behavior is

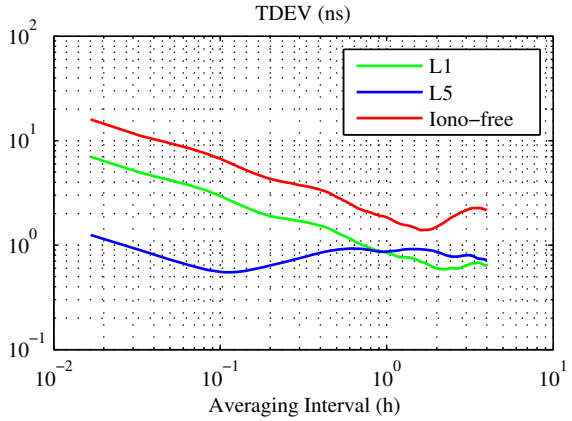

Figure 4. TDEV of UTC(PTB) − UTC(TP) via GAGAN PRN 127, code measurements, L1, L5 and ionosphere-free combination.

Table I
RESULTS OF SINGLE CLOCK COMMON-VIEW ON A SMALL BASELINE.

	Code (ns RMS)	Carrier phase (ps RMS)
L1	6.2	25
L5	1.3	29
Iono-free	14.1	33

quite far from simple ionospheric delay models. The slight imbalance of these fluctuations towards negative values is in a good agreement with the fact that the satellite elevation in Braunschweig is lower and thus the signal is more delayed in the ionosphere. These effects are fully suppressed in the ionosphere-free combination.

The third experiment took place in IPE Prague on MJD 56444. We used the GAGAN signals for a single clock common-view on a small baseline. In this situation the atmospheric delays are fully eliminated and we can evaluate the impact of the multipath and noise of the receivers. The receivers were denoted TPX and TPY. Both antennas were installed on the roof of the institute. The distance between the antennas was approximately 5 m. Both receivers were provided with the UTC(TP) time reference.

Code and carrier phase measurements in L1 and L5 frequency channels from the whole day were processed. All the data were sampled with the 10-s period. Fig. 6 and Fig. 7 show the comparison results. The displayed time differences are in fact equal to comparison error because both receivers were fed with the same reference. RMS of the comparison error in L1, L5 and ionosphere-free combination for code and carrier phase measurements are summarized in Tab. I. The corresponding TDEV plots are in Fig. 8 and Fig. 9.

The resulting code measurement precision in L5 is comparable with a GPS common-view. The L1 and ionosphere-free code measurements are significantly noisy because of the narrow bandwidth of the L1 signal. No substantial multipath effect was observed in the measurements. The carrier

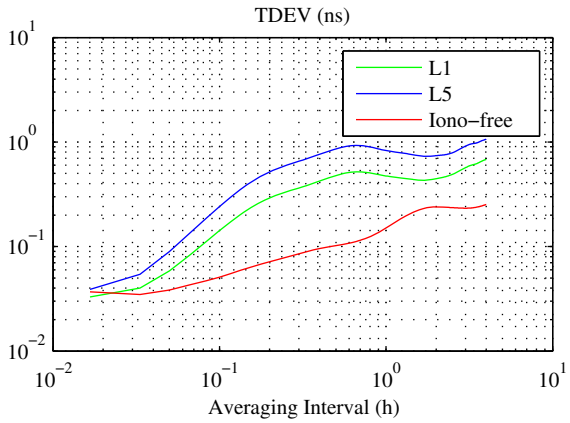

Figure 5. TDEV of UTC(PTB) − UTC(TP) via GAGAN PRN 127, carrier phase measurements, L1, L5 and ionosphere-free combination. TDEV of iono-free combination is covered by instability of UTC(PTB) − UTC(TP) difference.

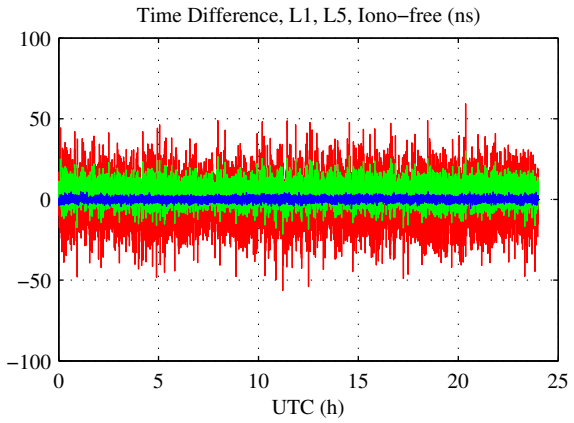

Figure 6. UTC(TPX) − UTC(TPY) via GAGAN PRN 127, code measurements, L1 (green), L5 (blue) and ionosphere-free combination (red).

phase measurements in both frequency channels as well as the ionosphere-free combination provide very good precision around 30 ps and better. This includes also very slow fluctuations which are probably related to temperature instabilities of the antenna cables and the reference time distribution.

IV. Conclusion

In contrast to the European SBAS EGNOS, the Indian GAGAN already provides both L1 and L5 signals thus it can be used for ionosphere-free time comparisons. Experimental measurements focused on the use of the GAGAN SBAS for the time transfer were done. The accuracy of ephemerides was estimated below 5 m and the system time seems to be stable and close to UTC. These results indicate that this system can be used for comparisons on relatively long baselines.

Unfortunately, the narrow L1 signal bandwidth degrades the L1 and ionosphere-free code measurements to 6 ns and 14 ns respectively. The precision of L5 code comparisons is near 1 ns which is similar to GPS. Some improvement of the code measurement could be probably achieved using a directional antenna.

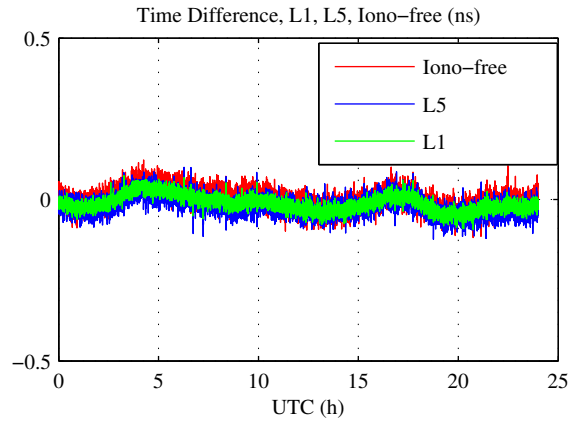

Figure 7. UTC(TPX) − UTC(TPY) via GAGAN PRN 127, carrier phase measurements, L1, L5 and ionosphere-free combination. Fluctuations in L1 and L5 measurements are caused by ionosphere.

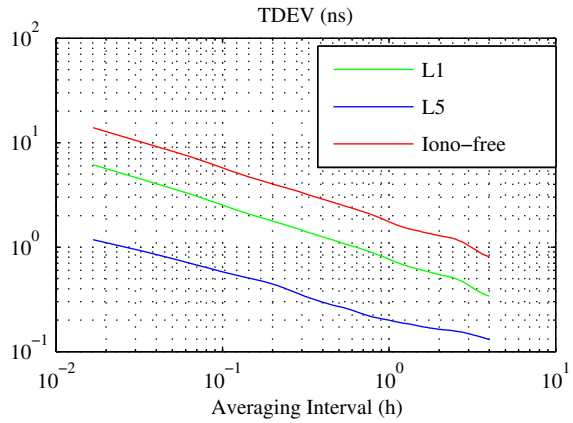

Figure 8. TDEV of UTC(TPX) − UTC(TPY) via GAGAN PRN 127, code measurements, L1, L5 and ionosphere-free combination.

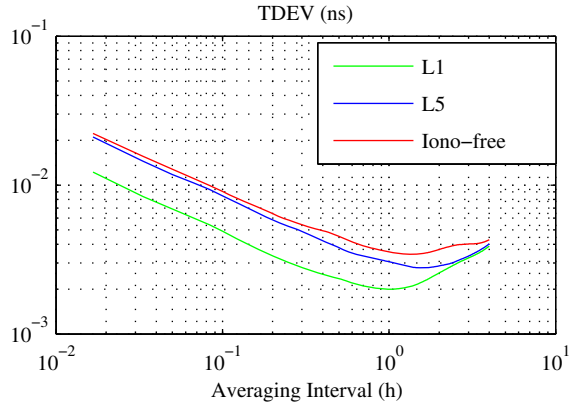

Figure 9. TDEV of UTC(TPX) − UTC(TPY) via GAGAN PRN 127, carrier phase measurements, L1, L5 and ionosphere-free combination. TDEV of iono-free combination is covered by instability of UTC(PTB) - UTC(TP) difference.

The carrier phase measurements are promising on the other hand. The standard deviation of fluctuations within one day was around 30 ps even for the ionosphere-free combination. Such phase measurement is available continuously which makes L1/L5 SBAS an ideal solution for comparisons of highly precise frequency sources at relatively long distances.

***Abstract*—Time and frequency transfer method using code and carrier phase by BDS has been developed by NIM. The CCD and long baseline results are comparable with GPS. The standard deviation of the BDS P3 code and carrier phase results in the CCD experiment could be better than 1 ns and 100 ps with one day measurement. The combination of BDS and GPS code measurement for time and frequency transfer led to the improved precision and robustness.**

Keywords- time and frequency transfer; GNSS; BDS

I. INTRODUCTION

Since 2003, the Beidou Navigation Satellite Demonstration System was officially brought into service. By the end of 2012, there are six GEO(Geostationary Earth Orbit), five MEO(Medium Earth Orbit) and five IGSO(Inclined Geosynchronous Satellite Orbit) satellites in orbit. Since 27th Dec 2012, BDS(BeiDou Navigation Satellite System) Signal in Space Interface Control Document-Open Service Signal B1I(Version 1.0)[1] has been released. The developing BDS system with the coverage of part of Asia-Pacific area at present has provided the official service and can be used for time and frequency transfer in this area.

II. TIME AND FREQUENCY TRANSFER BY BDS AND COMBINATION WITH GPS

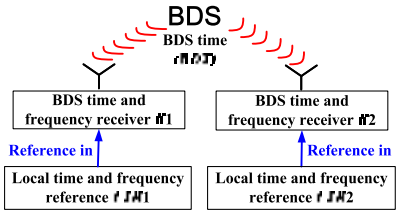

Figure 1. Time and frequency transfer by BDS

Time and frequency transfer methods by GPS(Global Positioning System) and GLONASS(GLObal Navigation Satellite System) are divided into three types that are C/A code, P3 code and carrier phase time and frequency transfer according to the measurement signals. The basic principles of time and frequency transfer by BDS are similar to those of them[2] as shown in Fig. 1.

Based on BDS OEM model with the first operation mode(mode 1)[2] with time and frequency directly synchronized to the local time and frequency reference by a internal phase lock loop, the original BDS observation can be acquired and the BDS code and carrier phase time and frequency transfer could be implemented preliminarily.

From the overall, BDS has more likeness with GPS. BDS has the similar communication mechanism to GPS, including the CDMA(Code Division Multiple Access) mode for all satellites. However, the GEO satellites that not are involved in the GPS space orbit generate one of the main differences in the error correction for BDS time and frequency transfer from GPS time and frequency transfer because of the difference of the calculation for satellite position between GEO and non-GEO satellites as shown in (1)-(5). In addition, the time difference from UTC is different from that of GPS.

$$\Omega_k = \Omega_0 + \dot{\Omega} t_k - \dot{\Omega}_e t_{oe} \tag{1}$$

$$\begin{cases} X_{GK} = x_k \cos\Omega_k - y_k \cos i_k \sin\Omega_k \\ Y_{GK} = x_k \sin\Omega_k + y_k \cos i_k \cos\Omega_k \\ Z_{GK=} y_k \sin i_k \end{cases} \tag{2}$$

$$\begin{bmatrix} X_k \\ Y_k \\ Z_k \end{bmatrix} = R_Z(\dot{\Omega}_e t_k) R_X(-5^\circ) \begin{bmatrix} X_{GK} \\ Y_{GK} \\ Z_{GK} \end{bmatrix} \tag{3}$$

$$R_X(\varphi) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\varphi & \sin\varphi \\ 0 & -\sin\varphi & \cos\varphi \end{bmatrix} \tag{4}$$

$$R_Z(\varphi) = \begin{bmatrix} \cos\varphi & \sin\varphi & 0 \\ -\sin\varphi & \cos\varphi & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{5}$$

For the users of GNSS(including BDS) time and frequency transfer, the user position that should be known precisely in advance is not cared about in the solution in generally. The most important job is processing for error correction and the solution of the receiver clock bias. In terms of different measurement signals, measurement methods and models of the error correction, the different measurement precision and accuracy could be obtained. For code measurement, ionospheric error, tropospheric error, Sagnac effect, relativistic effect and satellite clock error[3] would be taken into consideration and enough information can be acquired from navigation ephemeris of GNSS in real-time. If one doesn't have to or is not eager for the real-time processing, IGS(International GNSS Service)-like products that refer to precise ephemeris will provide him the better precision with the much more complicated post-processing. For carrier phase time and frequency transfer solution, we'd better use these kind of precise products to get the corresponding precision of error correction or we use the differential method to have the most errors cancelled, and the solution of the integer ambiguity and the detection of the cycle jump are the most difficult parts for the whole processing of carrier phase time and frequency transfer. There is some near real time precise product for real-time carrier phase processing, however, the more and deeper try and tests to apply product in carrier phase time and frequency transfer need to be implemented.

For code based BDS time and frequency transfer, we use the combination of C1 code(civil code modulated in L1 carrier 1561.098 MHz(f_1)) and P2 code(some undocumented civil code modulated in L2 carrier 1207.140 MHz(f_2) that can be measured by BDS receiver we used) as shown in (6), and we can simply name the combination as P3 code.

$$P3 = \frac{f_1^2}{f_1^2 - f_2^2} C1 - \frac{f_2^2}{f_1^2 - f_2^2} P2 \tag{6}$$

III. Experiment Setup and Numric Results

To verify the performance and feasibility of BDS for time and frequency transfer, on the basis of Fig. 1, the CCD(Common Clock Difference) experiments, the zero baseline experiments with the different references and the long baseline(straight-line distance between two receivers) experiments with the different references have been implemented, using the two BDS OEM modules(BD01 and BD02, both involving GPS measurements) and the other GPS time and frequency transfer receivers including IMEU, and IMEN sites(NIMTFGNSS-1 receivers[2]), IMPR and BJNM sites(Septentrio PolaRx2eTR and PolaRx3eTR receivers respectively) of NIM located at NIM.

CCD experiment reflects the noise level of the time and frequency transfer link. Fig. 2 and 3 show CCD results of BDS code and carrier phase time and frequency transfer and the standard deviation of the data averaging one day are 639 ps and 17 ps separately. GPSTFP software[4] for GPS carrier phase time and frequency transfer was modified to be adapted for BDS. BDS has the comparable performance with GPS for time and frequency transfer in code and carrier phase.

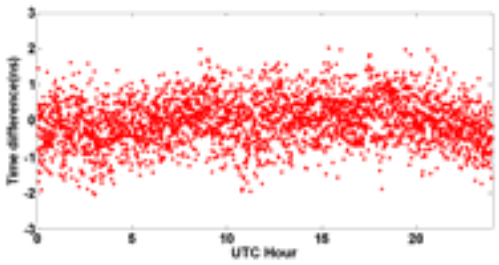

Figure 2. CCD by P3 code of BDS

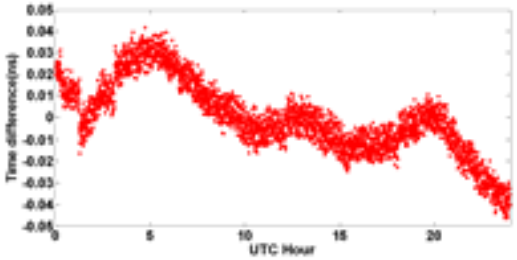

Figure 3. CCD by carrier phase of BDS

The development of multiple techniques for time and frequency transfer has generated the redundancy, so the combination of multiple techniques by data fusion principle that is one of the focuses by BIPM should be one good choice to convert the redundancy to the precision. We take the simple mean value *GBC* of GPS P3 code and BDS P3 code result by (7) as their combination. From the results of CCD experiments using BDS, GPS and the combined method at the same time, the standard deviations of them are 0.9 ns, 0.7 ns and 0.6 ns respectively. When we combine BDS with GPS to transfer time and frequency, the advantage of robustness over either of GPS and BDS thanks to the complementation of GPS and BDS and improvement in noise level have been acquired as shown in Fig. 4. Corresponding to these, we could get the better short term stability from the combined results. As well, we could get the weighted mean as (8) by figuring out the weights W_B for BDS and W_G for GPS using the noise level of each technique according to the basic principle of date fusion. The noise level would be thought as the standard deviation of the results for each type of link in the CCD experiments. However, from our CCD results, BDS has the quite comparable noise level with GPS, and we might get the quite negligent difference between using (7) and using (8).

$$GBC = \frac{1}{2}\left(P3_{GPS} + P3_{BDS}\right) \tag{7}$$

$$GBC = W_G \cdot P3_{GPS} + W_B \cdot P3_{BDS} \tag{8}$$

We compared the differences between NIMDO(UTC(NIM) disciplined oscillator) and UTC(NIM)hepingli(one Cesium clock with one micro-stepper steered by UTC at Hepingli campus of NIM) in the zero baseline experiments using the corresponding BDS, GPS and the combined links. From Fig. 5, the results are quite similar to those of GPS time and frequency transfer. GPS1 link consists of BD01 and BD02;

GPS2 link consists of IMPR and IMEN. As expected, these show that the combined GPS and BDS link is more stable than either of the single GNSS links. It is less noisy and robust maybe because the impacts of the atmosphere errors and the other effects have been reduced to some extent.

The results of BDS carrier phase show the good agreements with those of both BDS P3 code and GPS carrier phase got from NRCan_PPP software in Fig. 6.

The long baseline experiment characterizes the remote transfer performance of the transfer. Fig. 7 shows the comparison of five links between UTC(NIM)hepingli and UTC(NIM)(at Changing campus), including one BDS link, two GPS links and two combined links of GPS and BDS in about 40 km baseline. GPS1 link is between BD01 and BD02; GPS2 link is between IMPR and BJNM. The BDS link has the similar trend with the GPS links and the combination had the effect on the improvement on noise level of the transfer. All results are normalized for better view; link calibration was not implemented, so the results are meaningful for frequency transfer indeed.

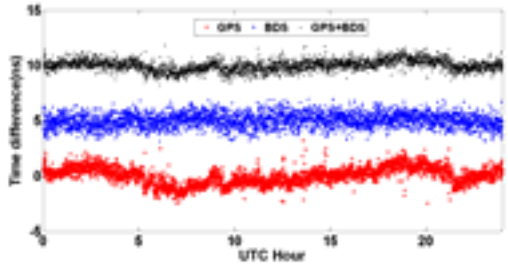

Figure 4. Comparison 1 among BDS, GPS and the combination

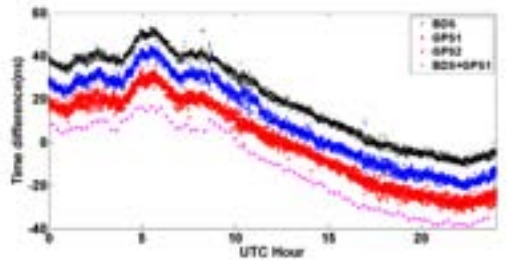

Figure 5. Comparison 2 among BDS, GPS and the combination

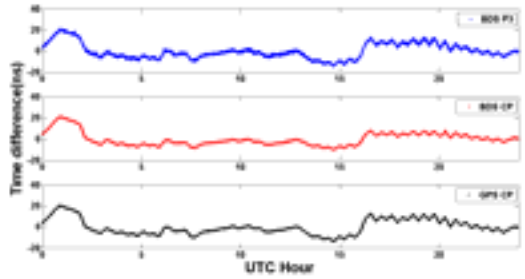

Figure 6. Comparison among BDS and GPS methods

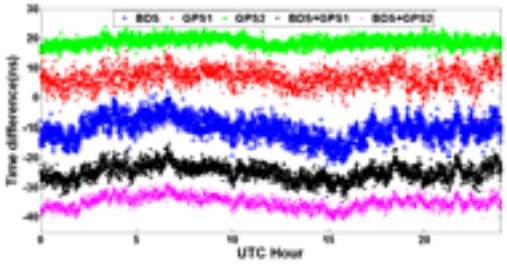

Figure 7. Comparison 3 among BDS, GPS and the combination

IV. Uncertainty Analysis

The uncertainty for time and frequency transfer usually includes the uncertainty evaluation of type A and type B. For type A, the only one item is the measurement jitter of the results for the time transfer link in the CCD experiment. For type B, uncertainty for calibration of GNSS time transfer link is the main part, which is usually better than 5.5 ns; the standard uncertainty components due to ionospheric and tropospheric errors are 0.3 ns and 0.7 ns respectively valid for baselines up to 5000 km[5]; due to the cables and the converters calibrated by VNA(Vector Network Analyzer), the standard uncertainty component is less than 0.1 ns. Thus we can get the combined uncertainty u_c by (9) as 5.7 ns, 5.7 ns and 5.6 ns respectively for GPS, BDS and the combination in our experiments.

$$u_c = \sqrt{u_A^2 + u_B^2} \tag{9}$$

V. Conclusion and Prospect

From the results of our experiments, the performance of BDS by code and carrier phase can match those of GPS for time and frequency transfer. Anyway, more experiments especially in the longer baseline are needed for verification. With the development of the near real-time or real-time precise ephemeris products, near real-time BDS carrier phase time and frequency transfer will be studied and tested at NIM. The combination of two systems(GPS and GLONASS[6] or BDS and GPS) would improve the robustness and noise level of time and frequency transfer, the combination of GPS, GLONASS and BDS would be more interesting in the future with the completeness of the BDS global constellation.

***Abstract*—An overview of the key methods used to reduce the uncertainty of the systematic shifts of the strontium ion optical frequency standard is presented. An uncertainty of 10 mHz at a clock frequency of 445 THz is obtained, limited by the uncertainty of the blackbody radiation shift. The uncertainty estimates of other shifts such as micromotion and electric quadrupole shifts are on the order of 1 mHz or less. The effectiveness of the methods used to reduce or cancel the shifts is illustrated with experiments comparing two ion traps. One has strong micromotion levels while the other, the reference trap, provides good control over the shifts. Despite nominal shifts of 70 Hz in the trap with large micromotion levels, the agreement with the reference trap is at the sub-Hz level.**

I. Introduction

A number of optical frequency standards have delivered record-breaking performance largely surpassing that of the best cesium fountain clocks which realize the SI second [1]. The lowest uncertainty evaluations are obtained with trapped and laser cooled single-ion systems [2]–[9], while the highest stabilities are obtained with optical lattice clocks [10]–[15].

This paper gives an overview of the recent improvements made to reduce the uncertainty of the systematic shifts of the $^{88}Sr^{+}$ ion optical frequency standard developed at the National Research Council of Canada (NRC). The reference frequency is realized with the 0.4-Hz-wide $5s\,^2S_{1/2} - 4d\,^2D_{5/2}$ transition at 445 THz. The most important systematic shifts for this transition are the micromotion and the electric quadrupole shifts. Typically, the electric quadrupole shift is on the order of a few Hz while the micromotion-related shifts can be several 10's of Hz in magnitude when no measures are taken to minimize them.

In the following sections, these shifts will be discussed with emphasis on the performance obtained in controlling their uncertainties. Since the cancellation and reduction methods implemented are very effective, the blackbody radiation shift has become the most important source of uncertainty in the realization of the unperturbed $^{88}Sr^{+}$ ion clock frequency. This shift will also be discussed briefly to show how its uncertainty was decreased by more than one order of magnitude compared to previously published work [16] and what are the limiting factors in its evaluation. The effectiveness of the cancellation methods is illustrated with a frequency comparison of two ion traps; one is a Paul trap with large micromotion levels which cannot be completely minimized in the current design [17], while the other, used as a reference trap, is a recently-built endcap trap with micromotion measurement and control along three orthogonal axes.

The methods developed for the control and evaluation of the shifts reduce the total uncertainty to a level of 10 mHz at 445 THz, a fractional frequency uncertainty of 2.3×10^{-17}. For comparison, the fractional uncertainty obtained previously with our Paul trap ranged from 1×10^{-13} [16] to 3×10^{-14} [17]. For a detailed description of the NRC endcap trap system and the methods discussed in this paper, the reader is referred to [8] and [9].

II. Electric Quadrupole Shift

The electric quadrupole shift (EQS) is caused by the interaction between an electric field gradient at the ion and the quadrupole moment of the upper state of the clock transition. The field gradient results from a trap potential modified by electric charge buildup and patch potentials on the trap structure. It varies slightly each time strontium metal is deposited on the electrodes during loading. Just a few years ago, the EQS was considered to be the largest source of uncertainty in single-ion systems based on an electric quadrupole transition [16], [18]–[21].

Unlike micromotion shifts which can be minimized as discussed in Sec. III, there is no simple method of controlling the field gradient at the ion and minimize the EQS. Instead, the shift is canceled by using the fundamental properties of the quadrupole interaction. To first order in perturbation theory, the electric quadrupole shift in Hz units, Δf_Q, of a magnetic sublevel $m_{J'}$ of the upper state of the clock transition is given by [17], [18], [22]

$$\Delta f_Q = \frac{1}{4}\,\nu_Q\,\left(3\cos^2\theta - 1\right)\left[m_{J'}^2 - \frac{J'(J'+1)}{3}\right], \quad (1)$$

where ν_Q is a characteristic frequency proportional to the electric field gradient and the electric quadrupole moment [23]. θ is the angle between the field gradient principal axis and the quantization axis defined by the ambient magnetic field. For the clock transition of $^{88}Sr^{+}$, $J' = 5/2$.

We have proposed a method which uses a property of (1) associated with the magnetic quantum numbers [9], [17], [24]. It can be implemented in two ways. In the first one, we note that the term in square brackets in (1) is zero when summed over $m_{J'}$:

$$\sum_{m_{J'}=-J'}^{J'} \left[m_{J'}^2 - \frac{J'(J'+1)}{3} \right] = 0. \tag{2}$$

This property is a consequence of the traceless nature of the electric quadrupole interaction energy. Experimentally, the averaging over the $^2D_{5/2}$ magnetic sublevel energies is realized by measuring three pairs of Zeeman components that connect to all of the possible $m_{J'}$ sublevels. One can view this method as an extension of method used to cancel the linear Zeeman shift which is realized by averaging the frequencies of a symmetric pair of components [25].

Alternatively, we use the intercept method which simply states that $\Delta f_Q = 0$ in (1) when $m_{J'}^2 = J'(J'+1)/3$. It is implemented by measuring the frequencies of two symmetric pairs of Zeeman components with different $m_{J'}^2$ sublevels, from which the quadrupole-shift-free clock frequency at the virtual value of $m_{J'}^2 = J'(J'+1)/3$ is calculated. For the $^{88}Sr^+$ ion, the intercept occurs at $m_{J'}^2 = 35/12$. An advantage of the intercept method is that only two pairs of components need to be measured to cancel the EQS. Both methods were used in the results reported in this paper.

These methods yield extremely high EQS cancellation levels. Experimentally, the cancellation is continuous as the lock program cycles through the selected Zeeman components when determining the S–D transition linecenter. We recently estimated that the fractional uncertainty on the canceled EQS shift is $< 3 \times 10^{-19}$, a cancellation level of more than four orders of magnitude [9].

The EQS cancellation methods described above simplify the uncertainty analysis of all the shifts that have a magnetic sublevel dependence. A welcome consequence is the cancellation of the tensor Stark shift [9] which can be rather large when the micromotion is not minimized, as in our Paul trap.

III. Micromotion Shifts

The interaction of the trap rf fields with the ion causes Stark and second-order Doppler shifts. For the most part, these so-called micromotion shifts result from ion displacement caused by stray electric fields. Micromotion shifts can also be caused by a phase difference between the voltages applied to the endcap electrodes and by thermal motion [26]. For the present discussion, we will ignore these smaller contributions [9].

Remembering that the tensor part of the Stark shift is canceled along with the EQS as mentioned in Sec. II, only the scalar part, $\Delta\nu_{\text{scalar}}$, needs to be considered. It is given by

$$\Delta\nu_{\text{scalar}} = -\frac{\Delta\alpha_0}{2h} \left\langle E^2 \right\rangle, \tag{3}$$

where h is Planck's constant, E the electric field at the ion, and $\Delta\alpha_0 = \alpha_0(D_{5/2}) - \alpha_0(S_{1/2})$ is the static differential scalar polarizability of the clock transition. $\Delta\alpha_0 = -4.83(17) \times 10^{-40}$ J m^2/V^2 for the $^{88}Sr^+$ ion [27].

The recently-built endcap trap was designed with three mutually orthogonal laser beam access ports for measurement of the micromotion levels and with three mutually orthogonal trim electrodes for control of the ion position. The mean-squared velocity of the ion at the trap frequency Ω is minimized and precisely measured using the carrier-normalized micromotion sideband intensities [9]. After minimization, the sum of the intensity ratios along the three orthogonal directions is $0.021(7)$, which translates into a scalar Stark shift of $\Delta\nu_{\text{scalar}}/\nu_0 = 2.2(7) \times 10^{-17}$.

The second-order Doppler shift is given by

$$\Delta\nu_{\text{D2}} = -\frac{\nu_0}{2} \frac{\left\langle v^2 \right\rangle}{c^2}, \tag{4}$$

where ν_0 is the clock transition frequency, c the speed of light, and $\left\langle v^2 \right\rangle$ the mean-squared velocity of the ion. The micromotion sideband intensity measurements provide the component of $\left\langle v^2 \right\rangle$ resulting from ion movement at the trap frequency [9]. The mean-squared velocities at other frequencies must be considered separately. For a trap frequency of $\Omega/2\pi = 14.4$ MHz and the sideband intensity measurements reported above, $\Delta\nu_{\text{D2}}/\nu_0 = -2.2(7) \times 10^{-17}$.

It is no coincidence that the Stark and second-order Doppler shifts caused by micromotion are equal in magnitude but opposite in sign as we have purposely set the trap frequency to obtain that result. The following discussion gives the relations that describe the optimum trap frequency to cancel the micromotion shifts in the pseudo-potential approximation.

The classical equations of motion for a charged particle in an rf electric field provide the relation between $\left\langle v^2 \right\rangle$ and $\left\langle E^2 \right\rangle$. After replacement of the result in (4), one obtains

$$\Delta\nu_{\text{D2}} = -\frac{\nu_0}{2} \left(\frac{e}{m\,\Omega\,c} \right)^2 \left\langle E^2 \right\rangle, \tag{5}$$

where m is the ion mass and e the elementary charge. The net micromotion shift, $\Delta\nu_\mu$, is simply the sum of (3) and (5):

$$\Delta\nu_\mu = -\frac{1}{2} \left[\frac{\Delta\alpha_0}{h} + \nu_0 \left(\frac{e}{m\,\Omega\,c} \right)^2 \right] \left\langle E^2 \right\rangle. \tag{6}$$

The term in square brackets can be nulled by adjusting the trap frequency provided $\Delta\alpha_0$ is negative. The trap frequency for $\Delta\nu_\mu = 0$ is given by

$$\Omega_0 = \frac{e}{m\,c} \sqrt{-\frac{h\,\nu_0}{\Delta\alpha_0}}. \tag{7}$$

For $^{88}Sr^+$, $\Omega_0/2\pi = (14.4 \pm 0.3)$ MHz. The uncertainty of 3.5% on $\Delta\alpha_0$ yields a micromotion suppression factor of 28. Therefore, the micromotion shifts of $\pm 2.2 \times 10^{-17}$ are reduced to 1×10^{-18} when combined. This is the uncertainty estimate of the net micromotion shift.

IV. Blackbody radiation shift

The blackbody radiation (BBR) field causes a scalar Stark shift of the clock transition given by (3), where $\Delta\alpha_0$ is replaced by $\Delta\alpha_0'$ to take into account a small dynamic correction that arises from the frequency distribution. The main source of uncertainty for the $^{88}Sr^+$ BBR shift is the uncertainty of $\Delta\alpha_0'$. Fortunately, an order of magnitude improvement over previous estimates [16] was recently reported in [27].

TABLE I. $^{88}Sr^{+}$ UNCERTAINTY BUDGET

Source	Shift	Uncertainty
Blackbody radiation shift	5.62×10^{-16}	2.2×10^{-17}
1092-nm ac Stark shift	-4×10^{-18}	2×10^{-18}
Collisional shift	0×10^{-18}	2×10^{-18}
Net micromotion shift	0×10^{-18}	1×10^{-18}
Second-order Doppler (thermal)	-3×10^{-18}	1×10^{-18}
Electric quadrupole shift	0×10^{-19}	3×10^{-19}
674-nm ac Stark shift	4×10^{-20}	2×10^{-20}
422-nm ac Stark shift	7×10^{-21}	7×10^{-21}
Quadratic Zeeman shift	8.3×10^{-20}	2×10^{-21}
Tensor Stark shift	0×10^{-22}	4×10^{-22}
Total shift	5.54×10^{-16}	2.3×10^{-17}

A model of the BBR field was developed to estimate $\langle E^2 \rangle$ and its uncertainty [9]. The model takes into account the trap components temperatures, the emissivities of the materials, the trap geometry, and multiple reflections. The temperatures were measured on a test trap, similar to the frequency standard endcap trap, using a small glass thermistor. The temperatures increased by about (33 ± 10)°C for an applied rf voltage amplitude of 212 V. The effect of electrode heating on the BBR field is mitigated by the low emissivity of the endcap electrodes; the shift increases by only 0.013 Hz from 0.237 Hz with rf heating. With modest accuracy in the BBR model, the contribution of $\langle E^2 \rangle$ to the uncertainty is only 0.005 Hz.

The total uncertainty on the BBR shift is 2.2×10^{-17}, still limited by the uncertainty on $\Delta\alpha_0'$. The current radiation model will begin to contribute significantly to the uncertainty budget of the BBR shift when the uncertainty on $\Delta\alpha_0'$ is reduced by a factor of two or more.

V. UNCERTAINTY BUDGET

The fractional uncertainty estimates for the clock transition frequency of the $^{88}Sr^{+}$ ion are summarized in Table I. In addition to the shifts discussed in the previous sections, several others are included for completeness [9]. The total fractional uncertainty obtained by adding in quadrature is 2.3×10^{-17}.

Table I shows that the BBR shift completely dominates the $^{88}Sr^{+}$ ion uncertainty budget, and that important gains can be made by improving on both the value of $\Delta\alpha_0'$ and the evaluation of the BBR field at the ion. An order of magnitude decrease in the uncertainty of these parameters is experimentally feasible. Moreover, the 1092-nm ac Stark shift can be drastically reduced by using a mechanical chopper instead of relying on an acousto-optic modulator for light shuttering [9]. With these potential improvements, the total uncertainty on the shifts could reach a level of 3×10^{-18} according to our current understanding of the shifts.

VI. COMPARISON OF TWO TRAPS

Two $^{88}Sr^{+}$ ion traps were compared to show the effectiveness of the methods discussed in Sections II and III to cancel or reduce the uncertainty of the systematic shifts. The first is the endcap trap with systematic shifts evaluated at 2.3×10^{-17}. It is used as a reference. All the currently known methods to reduce and cancel the shifts are implemented in that system: EQS cancellation, optimum trap frequency to suppress the micromotion shifts, and micromotion minimization. The second is the Paul trap which implements the same methods except for incompletely minimized micromotion. As a consequence, there is a large rms electric field at the ion estimated at 136 V/cm. It was determined by detuning the Paul trap frequency from the optimum value of 14.4 MHz and by observing the changes in the net micromotion shift.

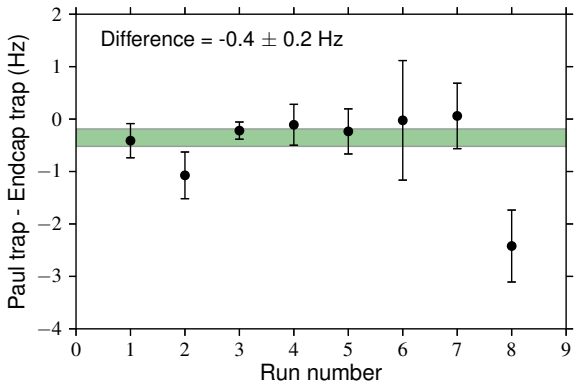

Fig. 1. Difference in the $^{88}Sr^{+}$ ion S–D frequency as realized by the Paul and endcap traps. For each measurement run, the uncertainty was determined from the Allan deviation of the frequency difference. The horizontal band is centered on the mean and it extends by $\pm 1\sigma$. Although it could easily be tagged as an outlier, the last point was included in the present analysis. If it is removed, the frequency difference becomes -0.3 ± 0.1 Hz.

The comparison data are reported in Fig. 1. The mean difference observed is $f_{\text{Paul}} - f_{\text{Endcap}} = -0.4 \pm 0.2$ Hz. The sub-Hz frequency difference is small compared to the actual shifts in the Paul trap. The scalar Stark and the second-order Doppler shifts are, respectively, $+70$ Hz and -70 Hz, the magnitude of the tensor Stark shift on the inner Zeeman components is ≈ 90 Hz, and the EQS is a few Hz. As reported in Sec. II, the EQS and tensor Stark shift are negligible after the application of the EQS cancellation method.

The uncertainty evaluation of the Paul trap indicates that most shifts are controlled with good accuracy except for the micromotion shifts and the BBR shift. The latter has not been evaluated in the Paul trap, but its contribution to the difference is expected to be below ≈ 0.1 Hz. We thus expect that the difference observed is mostly from micromotion. The preliminary data shown in Fig. 1 indicate that the micromotion shifts are reduced by a factor of 28 in the worst case, and by more than two orders of magnitude for the mean. This result validates the current value attributed to $\Delta\alpha_0$ and illustrates clearly the benefits of tuning the trap frequency to suppress the net micromotion shift.

VII. CONCLUSION

Significant progress was made during the last few years on the evaluation of the NRC $^{88}Sr^{+}$ ion systematic shifts. The total uncertainty evaluation has decreased by more than three orders of magnitude since 2005.

The main improvement came from the construction of an endcap trap designed with optical access ports for minimization of micromotion along three orthogonal axes. Further reduction in the micromotion uncertainty is obtained by selecting a trap frequency that purposely makes the scalar Stark and

second-order Doppler shifts cancel each other. The level of suppression is limited by the uncertainty on the differential scalar polarizability of the clock transition, $\Delta\alpha_0$. Also, the EQS cancellation method provides extremely efficient reduction of the electric-quadrupole and tensor Stark shifts, to levels much smaller than the total uncertainty on the clock transition frequency. With these improvements, the BBR shift has become the dominant source of uncertainty. Nevertheless, its contribution has been reduced by an order of magnitude with a recent evaluation of the differential scalar polarizability and a model of the BBR field that takes into account heating of the trap electrodes. The final fractional frequency uncertainty on the clock transition is 2.3×10^{-17}, mostly from the BBR shift.

The effectiveness of the methods used to cancel the shifts was demonstrated by comparing two ion traps; one of them had 70 Hz micromotion shifts while the other had its shifts controlled at the 10 mHz level. The sub-Hz agreement obtained validates the methods used, especially the value of $\Delta\alpha_0$ which determines the level of suppression of the net micromotion shift.

ACKNOWLEDGMENT

The authors would like to thank Bill Hoger and Wojciech Pakulski for the construction and maintenance of a number of custom-made electronic devices used to operate the ion trap systems.

***Abstract*— Direct comparison between a single $^{40}Ca^+$ clock and an ^{87}Sr lattice clock has resulted in a frequency ratio of 0.957 631 202 358 049 9(2 3). The rapid nature of optical comparison allowed the statistical uncertainty of the frequency ratio Ca^+/Sr to be 1×10^{-15} in 1000 s and the value is consistent with that calculated from separate frequency measurements of $^{40}Ca^+$ using the International Atomic Time (TAI) link. The total uncertainty of the measured ratio is smaller than that obtained at the absolute frequency measurement. The absolute frequency of $^{40}Ca^+$ we measured deviates from other published values by more than three times our measurement uncertainty.**

***Keywords*— Single Ca^+ ion trap, Sr lattice clock**

I. INTRODUCTION

Comparison between independent frequency standards is the most reliable means to fully evaluate their reproducibility and stability. Comparison also enables the evaluation of the systematic shift by measuring dependence of the frequency on various experimental parameters. Optical frequency standards have a strong advantage in the speed of this comparison process, requiring less than 1,000 seconds evaluating a fractional frequency difference at the 10^{-16} level uncertainty. In contrast, state-of-the-art Cs fountain clocks operating in the microwave regime require more than six hours of integration time. Optical frequency combs can be employed as a bridge enabling the measurement of the relative instabilities of standards based on different atomic transitions. Such frequency ratio measurement can yield information on possible temporal variations of fundamental constants [1].

In this paper, we report a frequency comparison of a $^{40}Ca^+$ $^2S_{1/2}$-$^2D_{5/2}$ single-ion clock transition against the ^{87}Sr $^1S_0$-$^3P_0$ lattice clock transition [2]. The $^{40}Ca^+$ clock in this work has exceptional fractional frequency instability of parts in 10^{-16}. Neutral strontium and calcium ions are popular as quantum absorbers in the realization of optical clocks; worldwide five neutral strontium lattice clocks are already in operation [3–7], and calcium ions are ideal for portable optical clocks because of the availability of laser-diodes at all required wavelengths. $^{40}Ca^+$ clocks are being developed at NICT [8], Univ. of Innsbruck [9], and WIPM [10]. With such interest and development in these two optical standards around world it is imperative that we establish a benchmark frequency ratio with high precision.

II. SINGLE CA^+ OPTICAL CLOCK

The experimental setup for the Ca^+ clock was reported in [8]. An increase in production efficiency of $^{40}Ca^+$ ions was achieved by a photoionization process. A magnetic shield was installed on the vacuum chamber that reduced by more than 20 times stray ac magnetic fields. Mechanical shutters and acousto-optic modulator (AOM) shutters were installed to avoid coupling of cooling laser during the interrogation period. Further optimization of the clock laser [11] reduced its spectral width to less than 5 Hz, and a noise cancellation technique [12] implemented on the 40 m of optical fiber between it and the ion trap. These improvements resulted in an observed line width of the clock transition of about 25 Hz.

TABLE I. SYSTEMATIC SHIFTS OF THE $^{40}CA^+$ CLOCK

	***Shift* (Hz)**	***Uncertainty* (Hz)**
Gravitational	3.42	< 0.1
Blackbody radiation	0.39	0.05
Ac Stark due to 397 nm	0.27	0.54
Ac Stark due to 397 nm	0	0.20
Ac Stark due to 397 nm	0	0.30
Erectric quadrupole ($^2D_{5/2}$ M_J=3/2)	0.1	0.34
Quadratic Doppler	0	< 0.1
Second-order Zeeman	0	< 0.1
Stark due to secular motion	0	< 0.01
Stark due to micromotion	0	<0.1
Servo error	0	0.5
Total	4.2	0.89

The systematic shifts and the respective uncertainties to determine the Ca^+ clock transition frequency are shown in Table 1. In this table, the black body radiation frequency shift [13] was evaluated from measurements of temperature by constructing an identical ion-trap equipped with platinum resistance thermometers. A GPS based elevation measurement yields an estimation of the gravitational shift. From the magnetic field bias of 3 μT we estimate the quadratic Zeeman shift. In order to evaluate the electric quadrupole shift the dependence of the resonant frequencies on the upper magnetic sublevels was investigated [14]. Ac Stark shift due to cooling lasers was estimated from linear fitting of the clock frequency to the intensity of 397-nm light. Ac Stark shift due to the 854-nm light used for quenching the ion from the $^2D_{5/2}$ levels was estimated from the comparison between frequencies measured

This research was supported in part by the Japan Society for the Promotion of Science through its FIRST program.

with and without use of 854-nm light. We also measured frequency shifts by changing the power of the clock laser. The servo error was estimated from the analysis of the residual error.

III. Sr Lattice Clock

The optical lattice clock utilized as a stable frequency reference in this work is based on the $^1S_0$-$^3P_0$ transition (λ = 698 nm) of optically trapped spin-polarized fermionic ^{87}Sr atoms [3]. The clock is in a different room, 10 m from the Ca^+ clock. The absolute frequency of the ^{87}Sr lattice clock at NICT agrees with other clocks in various institutes within the so-called Cs-limit [7]. The systematic uncertainty has been evaluated to be 5×10^{-16}. Using a 60 km fiber link [15] we confirmed the agreement of the clock frequencies at the 10^{-16} level with another ^{87}Sr lattice clock in The University of Tokyo. This experiment also demonstrated that the instability of the clock at NICT reached 5×10^{-16} in 1000 s [16]. Since then the instability of the clock laser was improved by implementing optical compensation against vibration-induced phase noise. By this technique the short term stability is $< 2 \times 10^{-15}$ at 1 s. Systematic shifts and their uncertainties have been recently evaluated after some minor renovations which has resulted in a systematic correction of −1.25(22) Hz. In this paper we report on the use of our lattice clock as an independent optical frequency reference for the evaluation of the Ca^+ clock.

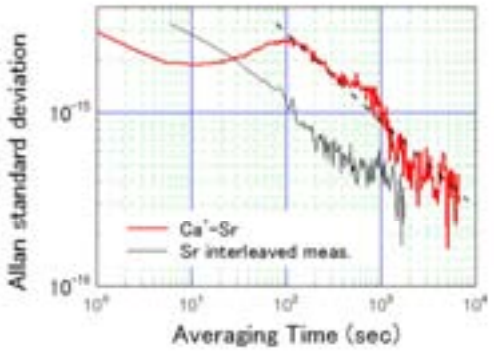

Figure 1. Instability of the frequency ratio (red) determined by the instability of Ca+ clock. An interleaved measurement of the Sr lattice clock has resulted in lower instability as shown in black.

IV. Frequency Comparison

A Ti:Sapphire-based optical frequency comb [17] bridges the two clocks and the frequency ratio ν_{Ca}/ν_{Sr} is measured as follows. The beat signal between the clock laser for the Sr lattice clock and the nearest comb component is first phase locked to a stable RF frequency f_{PLL} which is generated by a direct digital synthesizer with reference to a hydrogen maser. In this case, the repetition frequency f_{rep} is expressed as follows,

$$f_{rep} = (\nu_{Sr} - f_{ceo} - f_{PLL}) / N_1. \quad (1)$$

where N_1 and f_{ceo} are the mode number of the comb component and the carrier-envelope offset frequency of the comb. Measurement of the beat frequency f_b between the Ca^+ clock frequency and the nearest comb component (mode number N_2) yields the transition frequency ν_{Ca} according to

$$\nu_{Ca} = f_{ceo} + N_2 f_{rep} + f_b. \quad (2)$$

The frequency ratio ν_{Ca}/ν_{Sr} can be calculated as

$$\nu_{Ca}/\nu_{Sr} = n + \{(1-n) f_{ceo} - n f_{PLL} + f_b\} / \nu_{Sr}, \; n = N_2/N_1. \quad (3)$$

The instability of ν_{Ca}/ν_{Sr} is shown in Fig. 1. It slowly decreases with increasing integration time over 1-10 s, showing our clock laser is slightly above the thermal noise limit. The long term instability is $2.4 \times 10^{-14}/\tau^{1/2}$, where τ is the integration time, which is limited by the Ca^+ clock. The instability of the Sr lattice clock is $1 \times 10^{-14}/\tau^{1/2}$ according to an interleaved stabilizing operation. This is shown as the thin black trace in Fig. 1.

The Ca^+ frequency is estimated by forty quantum projection measurements in a cycle time of 17 seconds with a Fourier-limited linewidth of about 25 Hz. Random initial preparation of Zeeman substates ($m_J = \pm 1/2$) halves the number of effective measurements. The quantum projection limit estimated using these parameters is $2 \times 10^{-14}/\tau^{1/2}$, and is consistent with the observed long term stability shown as a broken line in Fig. 1.

The frequency ratio ν_{Ca}/ν_{Sr} measured for a half year is summarized in Fig. 2. The results indicate that both optical clocks have a day-to-day reproducibility better than 1×10^{-15}. Taking into account a statistical uncertainty of 1.8×10^{-16} and systematic uncertainties of Ca^+ clock and Sr clock ($2.2 \times 10^{-15}$and 5×10^{-16} respectively), we conclude the frequency ratio ν_{Ca}/ν_{Sr} is 0.957 631 202 358 049 9 with a fractional uncertainty of 2.3×10^{-15}.

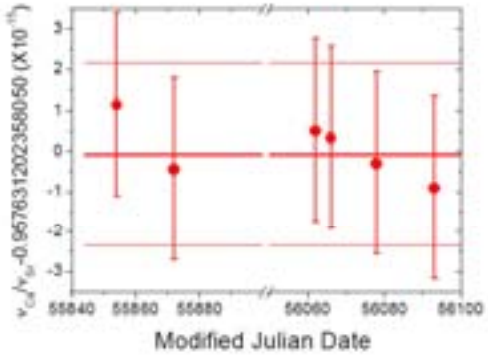

Figure 2. Frequency ratio obtained for half a year. The reproducibility of less than 10^{-15} is consistent with the systematic uncertainties of two clocks. The thick and thin lines indicate the weighted average and the uncertainty, respectively.

V. Absolute Frequency of $^{40}Ca^+$

The frequency of the Ca^+ clock transition was also evaluated by a microwave link to International Atomic Time (TAI). We measured a beat frequency between the clock laser and the nearest comb component of a frequency comb stabilized to a hydrogen maser. The maser was calibrated to

UTC(NICT). The link uncertainties consist of those in the UTC(NICT)-TAI link and TAI-TT link. We estimate that UTC(NICT) during the Ca^+ frequency measurement could be different from the five-day average calculated using the BIPM Circular T by the amount of the instability of UTC(NICT) over those five days. Forty-five days of our signal integration resulted in an instability of TAI-UTC(NICT) of 1.9×10^{-15}. Thus, the uncertainty due to the TAI link is evaluated to be 1.9×10^{-15} including minor contributions from the calibration of TAI to the SI second (3×10^{-16}). With considerations of the systematic uncertainty of the Ca^+ clock shown in Table 1 and the statistical uncertainty, the total fractional uncertainty of the absolute frequency measurement is 3.0×10^{-15}. We therefore determine that the absolute frequency for our measurement is 411 042 129 776 398.4(1.2) Hz. Combining the measured frequency ratio ν_{Ca}/ν_{Sr} with the absolute frequency of our Ca^+ clock we evaluate the absolute frequency of the Sr lattice clock to be 429 228 004 229 871.9 (1.2) Hz. This frequency is consistent with our previous measurement [7].

While our Ca^+ clock has a day-to-day reproducibility at the 10^{-16} level, the frequency is disparate by more than three times the measurement uncertainty when compared to two other published results [9, 10]. To address this discrepancy we are planning further experiments; firstly satellite-based inter-continental comparisons directly to other clocks, and secondly we will repeat the frequency measurement using an In^+-Ca^+ clock currently under development in our laboratory [18].

VI. Summary and Future Plan

We have measured the frequency ratio between the $^{40}Ca^+$ $^2S_{1/2}$-$^2D_{5/2}$ transition and the ^{87}Sr $^1S_0$-$^3P_0$ transitions with an uncertainty of 2.3×10^{-15}. The frequency ratio measurement demonstrated for the first time that the Ca^+ clock is able to reach the 10^{-16} level of instability. All optical comparison has also enabled quick and rigorous evaluation of the systematic shifts of the Ca^+ ion clock. The frequency ratio ν_{Ca}/ν_{Sr} was consistent with the absolute frequency measurement of the Ca^+ clock.

The Ca^+ and Sr optical clocks investigated here are two of the most popular in ion-based and lattice-based systems. The systematic uncertainty of the Ca^+ clock in this work is at the 10^{-15} level. The systematic uncertainties of both clocks are currently projected to be smaller than current state-of-the-art cesium fountain clocks and therefore further improved measurement of the ratio ν_{Ca}/ν_{Sr} may become an infrastructure of frequency metrology, enabling frequency comparison of two physically separated optical clocks more precisely than that of comparisons via SI second.

Furthermore, an In^+-Ca^+ clock is also under development in our laboratory [18-20]. Natural linewidth of the $^1S_0$-$^3P_0$ clock transition (λ = 237 nm) of In^+ ion is 0.8 Hz. Its BBR shift and electric quadrupole shift are estimated extremely small. We can therefore expect to reach the 10^{-18} level of uncertainty using this transition. It is presently difficult to generate 159-nm radiation for direct laser cooling of In^+ ions. Sympathetic cooling of In^+ with Ca^+ followed by the sideband cooling using the $^1S_0$-$^3P_1$ transition (λ = 230 nm) is therefore useful to reduce temperature of In^+ ions efficiently [21]. Ionic chains consisting of a single In^+ ion and a few Ca^+ ions have been observed in a linear trap. We are now constructing a setup for observing the $^1S_0$-$^3P_0$ clock transition.

Abstract— **This paper reviews our work on CMOS-integrated active MEMS resonators. Design, analysis and results are presented on CMOS-MEMS resonators fabricated at the Front-End-of-Line (FEOL) of a standard CMOS technology, realized without the need for any post-processing or packaging. Unreleased Resonant Body Transistors (RBTs) are driven capacitively to form longitudinal resonance confined by Acoustic Bragg Reflectors (ABRs), and sensed piezoresistively using an n-channel Field Effect Transistor (nFET). This first generation hybrid CMOS-MEMS RBTs consume footprints of 5µm×3µm, and operate above 11 GHz with quality factors (*Q*) of 24-30 and temperature stability <3 ppm/K, matching well with theory. In addition, acoustic mode localization using features of standard CMOS technology is discussed. The active transduction mechanisms developed for CMOS-MEMS resonators can be extended to piezoelectric III-V semiconductors available in mm-wave ICs (MMICs). Our recent work on switchable MEMS–HEMT resonators in AlGaN/GaN is presented using a standard GaN MMIC platform, providing a means of realizing configurable high-*Q* MEMS resonators in MMICs for high frequency, high power applications.**

Keywords-RF MEMS; resonator; CMOS-MEMS; GaN; HEMT; Resonant Body Transistor

I. INTRODUCTION

RF micro-electromechanical (MEM) resonators, with frequency-quality factor products ($f \cdot Q$) often exceeding 10^{13}, can provide a high performance, low-power, compact IC-compatible alternative to traditional LC tanks, off-chip Quartz crystals and SAW devices in clocking, communication, and sensing applications. Key challenges to wide-spread implementation of these devices include frequency scaling, incompatible fabrication with ICs and complex packaging. The work presented here focuses on new transduction mechanisms and new resonant structures that enable intimate integration with ICs at multi-GHz frequencies.

A. Frequency Scaling to Multi-GHz

The past decade has seen a continuous push towards multi-GHz frequencies for applications including personal navigation (94 GHz) and short distance local area networks (LAN) (60 GHz), imaging, and high-definition video links. A majority of MEMS resonators rely on passive transduction mechanisms such as electrostatic and piezoelectric transduction to sense acoustic resonance. However, in such passive systems, parasitic feed-through increasingly becomes dominant over the resonance signal at higher frequencies, reducing the dynamic range or out-of-band rejection of the signal. In-line amplifiers are ineffective at amplifying the signal over the parasitic feedthrough, necessitating the exploration of different sensing mechanisms.

The concept of Field Effect Transistor (FET) sensing in MEMS devices has been around since Nathanson's Resonant Gate Transistor in 1967 [1]. In Si-based resonators, FET sensing has been demonstrated up to 113 MHz [2] and in piezoelectric GaN-based resonators, up to 2 MHz [3]. Active sensing with piezoresistive elements has also been demonstrated up to 61 MHz [4]. The authors have previously demonstrated Resonant Body Transistors (RBTs) [5, 6] with internal dielectric drive and FET sensing up to 37 GHz. FET sensing has thus been shown to reach order of magnitude higher frequencies than possible with passive resonators due to the active amplification of the resonance signal before the presence of parasitics. The authors have demonstrated the first CMOS integration of RF RBTs with no post-processing or special packaging, taking advantage of high gain, high yield transistors in an all-access technology.

B. CMOS integration of MEMS resonators

The intimate integration of CMOS and MEMS is advantageous primarily because of reduced parasitics from on-chip and off-chip routing for high frequency operation, smaller size and weight, and decreased power consumption due to constraints on impedance matching networks. Typical methods for CMOS-MEMS co-fabrication include modular MEMS-first or MEMS-last processes, in which the circuit is independently fabricated before or after the mechanical structure is formed. This leads to increased mask count, reduced yield, process constraints, and performance compromise due to thermal budget [7]. Non-modular CMOS-MEMS co-fabrication has been demonstrated using the Back-End-of-Line (BEOL) CMOS stack, reducing mask count but limiting the structure to large feature sizes and materials to metals and low-quality dielectrics [8, 9]. Furthermore, as with most MEMS devices, these BEOL MEMS require a release step to freely suspend the moving structures. This necessitates costly, complex encapsulation methods and costly hermetic seal packaging [10, 11], and may impact the yield of the technology.

To address these challenges, the authors present the development of *unreleased* Si-based MEMS resonators in CMOS (Fig. 1). This solid-state solution allows seamless integration into Front End of Line (FEOL) processing with no post-processing or packaging. The unreleased nature of these resonators eliminates the release etch step and packaging, with the added benefit of increased robustness in harsh environments. Implemented with FET-sensing, these devices take advantage of high performance transistors, pushing operation frequencies to the multi-GHz domain. As a proof of

This work is sponsored in part by the FCRP IFC, FCRP MSD, NSF CAREER Award and DARPA Young Faculty Award.

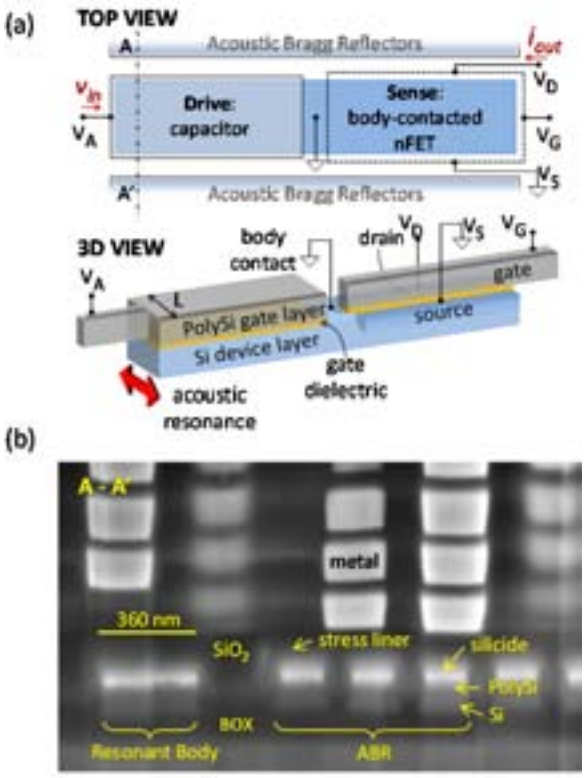

Figure 1. (a) Top and 3D views of Si-based CMOS-MEMS resonator excluding Acoustic Bragg Reflectors (ABRs). The resonator is driven capacitively on the left, and sensed through piezoresistive modulation of the nFET drain current on the right. Details of FET layout and doping layers are not shown. (b) SEM of CMOS stack obtained using FIB. The resonant cavity comprised of the single crystalline silicon (SCS) device layer and ABRs is seen fully buried under the metal layers.

concept, IBM's 32nm SOI process was chosen for its high f_T transistors, the small feature sizes down to <60 nm and the presence of a buried oxide (BOX) layer for acoustic localization of vibrations in the Si device layer.

On the mechanical side, the challenge for building unreleased MEMS resonator lies in maintaining its high quality factor (Q) inside a solid medium. The energy loss of elastic wave radiation into the surrounding medium can be mitigated by adding "acoustic mirrors" such as acoustic Bragg reflectors (ABRs) or phononic crystals (PnC). Both of these are periodic structures composed of two or more materials that can reflect waves coherently over a band of frequencies, acting as near-perfect acoustic mirrors at the resonance frequency. Out of the reflection frequency band, these reflectors act as leakage paths, damping undesired modes and giving unreleased resonators unique trait of spurious mode suppression.

ABRs have been employed to thickness mode piezoelectric resonators for wireless applications in high frequency integrated circuits [12, 13], which are composed of multiple depositions of alternating materials, resulting in acoustic isolation in one dimension for a single frequency per wafer. In-plane isolation can be achieved using lithographically defined ABRs, as demonstrated in a suspended plate [14]. This configuration enables resonators of multiple frequencies to be fabricated side by side on the same chip. In contrast to the 1D

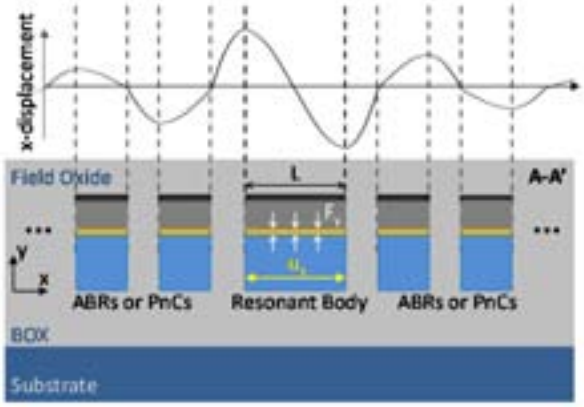

Figure 2. Cross-section of unreleased resonator with surrounding ABRs or PnC. The ABRs or PnC have solid inclusions (e.g. SiO_2 in the STI). The entire structure is sandwiched between capping materials (e.g. field oxide and buried oxide). The mode shape of an RBT in IBM 32nm SOI, corresponding to the A-A' line cut in Fig. 1, is shown.. Capacitive force is applied along the y-axis across the gate dielectric on the drive side of the resonator. Acoustic vibrations are excited in the resonant cavity along the x-direction through the Poisson effect and decay exponentially as a function of length along the ABRs.

mode confinement of ABRs, PnCs provide 2D or 3D lithographically-defined acoustic isolation. They have been explored by several groups for microscale applications, including acoustic mirrors for resonators in suspended plates [15], acoustic waveguides, and filters [16]. Most of these previous demonstrations of ABRs and PnCs are based on suspended released structures, with PnCs most commonly seen as air-filled perforations in a single material. However, the same principle can be implemented for an unreleased structure, where the in-plane resonance is confined by ABRs or PnCs and sandwiched between uniform materials on top and bottom, with PnCs designed as solid inclusions (Fig. 2). In addition, other reflection mechanisms such as high contrast grating can also in principle be borrowed for lithographically defined in-plane mode isolation [17].

In our demonstration, ABRs are built lithographically in FEOL processing in CMOS, defined in the same set of masks as the unreleased RBT. PnCs can be built in the BEOL metal stack, acting as 3D acoustic isolation for improved Q.

C. From Silicon to III-V semiconductors

One limitation of building CMOS-MEMS resonators in standard Si technology is that the driving mechanism is limited primarily to electrostatic transduction. Thermal actuation is also possible using CMOS materials, but it has much larger power consumption [4]. Electrostatic transduction exhibits low electromechanical coupling coefficient ${k_T}^2$ (.00001-.01%), resulting in high motional impedance R_m (up to MΩs). This can be dealt with by utilizing matching networks for these on-chip CMOS-MEMS devices [18]. However, for applications requiring low insertion loss and high bandwidth, high ${k_T}^2$ transduction mechanisms such as piezoelectric transduction are preferred. Piezoelectrically transduced resonators have dominated the market with successful products including the SAW and FBAR [19, 20].

Resonators composed of III-V materials, particularly wide band gap materials such as GaN, offer high transduction efficiency and device configurability through piezoelectric properties, large power handling, high frequency operation, and direct integration with III-V electron devices and circuits. GaN technology provides high electron velocities, charge densities (1×10^{13} cm^{-2} in AlGaN/GaN), and critical electric fields (>3 MV/cm), ideal for high power (>10W/mm), high frequency (>100 GHz) ICs. Moreover, GaN exhibits high piezoelectric coefficients ($k_T{}^2$ up to 2%) and low mechanical damping ($f \cdot Q > 10^{12}$). This technology platform therefore enables the integration of low loss, high-Q MEMS resonators with millimeter-wave ICs (MMICs) and high power electronics.

The same concept of FET sensing of acoustic resonance discussed for CMOS can be implemented in GaN using High Electron Mobility Transistors (HEMTs). Similarly, acoustic localization of unreleased resonators can be achieved by patterning the GaN and surrounding materials to form acoustic reflectors. In thsis review, we present our first results on switchable multi-GHz MEMS-HEMT resonators in GaN and their implications for channel-select radio design.

II. Active Sensing for GHz-Frequency Resonators

A. The Need for Active Sensing in CMOS

Passive schemes such as electrostatic or piezoelectric transduction have traditionally been used in the majority of MEMS resonators. The equivalent circuit model of such passive transduction, either electrostatic or piezoelectric, can be represented by a simple Butterworth-Van-Dyke (BVD) model (Fig. 3 (a)). The drive and sense capacitors are represented by C_0, and the mechanical resonance is represented by an RLC branch, with electrical feedthrough represented as C_f. For such passive schemes, as resonators scale to higher frequencies, the out-of-band rejection of the signal can be severely compromised by feedthrough, and cannot simply be mitigated by subsequent amplifier stages. To illustrate this effect, we take electrostatic sensing as an example, and consider a dielectrically driven and sensed resonator with a resonant length L whose geometry can be realized using FEOL fabrication in an SOI CMOS process (Fig. 3(a)). The electrostatic squeezing force from the top can translate to resonant mode in plane through the Poisson effect [21].

For simplicity, we assume that all dimensions, materials, Q, and the feedthrough capacitance C_f of such a device remain constant while only the length of the resonant cavity L changes as 1/f where f is the resonance frequency. Thus the shunt capacitor C_0 also reduces as 1/f since the non-resonant dimension is held constant. The motional impedance R_m scales as $W/C_0^2 f^2$ where W is the non-resonant dimension and hence remains constant with frequency in this configuration. Meanwhile the impedances of C_m and L_m cancel at resonance. Under these assumptions, the expected out-of-band rejection of the voltage gain from input to output reduces from >10dB at 100 MHz and to less than 0.1dB at 10 GHz. For such resonators, an in-line amplifier stage would indiscriminately amplify the resonance signal along with the feedthrough, thus providing no improvement in the out-of-band rejection.

Active sensing provides one solution to overcome the limits of out-of-band rejection by amplifying the mechanical signal

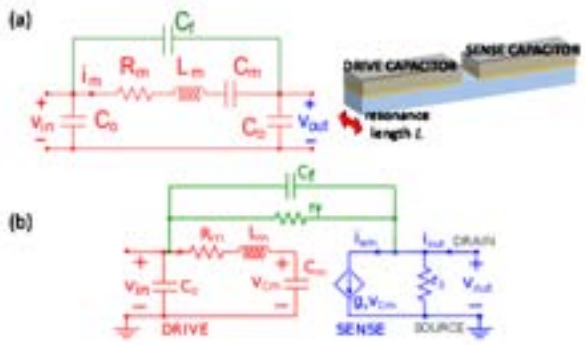

Figure 3. (a) Small signal model and schematic of passive electrostatic MEMS resonator. (b) Small signal model of the RBT consisting of an RLC branch modeling the mechanical resonant system (red) and a modified transistor small signal model (blue). Lumped feedthrough parasitics (green) are modeled by C_f and r_f.

before the presence of parasitics. The small signal equivalent circuit of a capacitively driven, piezoresistively sensed resonator is provided in Fig. 3 (b), consisting of a 1-port passive BVD model and a modified transistor π-model. The drive capacitor is represented by C_0 while the RLC components model the mechanical mass-spring-damper system of the resonator. The piezoresistive sensing is represented by a transconductance g_α. The integration of such an electromechanical amplification element into the resonant cavity enables improvement in the out-of-band rejection of the signal before the contribution of feedthrough parasitics modeled by the C_f and r_f.

B. Active Sensing: Resistive vs. FET Sensing

With the integration of the MEMS resonator into the FEOL IBM CMOS technology, FETs inherent to the process can be used to sense of acoustic vibrations. FET sensing relies on piezoresistivity as the dominant effect to modulate the mobility of carriers along the channel and result in a small signal output current. Secondary contributions to the current modulation include modulation in channel length, threshold voltage, gate capacitance and electrostriction. For simplicity these secondary effects are omitted from the small signal model presented in Fig. 3 (b).

Consider a resonator with the same geometry as that of the capacitively sensed resonator of the previous section, with the only variation being that of sense transducer. A schematic of this device is shown in Fig. 1 (a). In this device, strain induced at resonance is related to the input voltage in the same manner. Assuming the FET is biased in saturation, the change of the output current in terms of the drain bias current I, the mobility μ and the channel resistivity ρ is given by:

$$\frac{\Delta I}{I} = \frac{\Delta\mu}{\mu} = -\frac{\Delta\rho}{\rho} = -g_R v_{in} \quad (1)$$

where g_R is a coefficient with units V^{-1} that models the piezoresistive modulation in terms of the v_{in}. The small signal output voltage from the sensing FET is given in terms of its output resistance r_0 by $v_{out} = -Ir_0 g_R v_{in}$ with voltage gain of $A_v = -Ir_o g_R$. Given the large output resistance of the FET, the gain A_v can attain high values relative to simpler resistive sensing, in which a current is driven through a resistor R embedded in the resonant body. For the same mechanical structure and the same bias current, FET sensing thus has a

voltage gain that is r_o/R higher than its resistive counterpart. For a typical FET, this gain can be orders of magnitude higher than the resistive one. For the devices considered in this work, this ratio is as high as 200.

To assess the noise performance of FET sensing, the drain noise current PSD is first evaluated. For a FET in saturation this is given in terms of the thermal noise coefficient γ and the transconductance g_{mFET}:

$$i_{dn}^2 = 4k_B T \gamma g_{mFET} \quad (2)$$

For short channel devices γ is close to unity. Comparing the input referred noise PSD of both FET and resistive sensing, we have:

$$\frac{\overline{v_{in}^2}\big|_{FET}}{\overline{v_{in}^2}\big|_{Res}} = \gamma g_{mFET} R \quad (3)$$

For typical designs, g_{mFET} is a fraction of mS, such that the input referred noise of FET sensing is much lower than that of resistive sensing. For the devices considered in this work, g_{mFET} is of the order of 500μS, resulting in an input referred noise for the FET of only 5% that of its resistive counterpart. Moreover, FET output resistance remains sufficiently large regardless of the small dimensions necessary for frequency scaling, allowing both for voltage and current sensing.

The downside of FET sensing comes from its higher power dissipation. When biased in saturation, the sensor FET consumes more DC power than the resistive sensor. For the RBTs described in this work, designed for I_D of 60μA and V_D of 500mV, the FET sensing power dissipation is more than 80 times larger than the resistive sensing.

III. Energy Localization for CMOS-MEMS

One of the challenges for building unreleased resonator fully embedded in the CMOS stack lies in the generation of acoustic reflectors in the solid medium surrounding medium surrounding the resonant cavity and localizing the resonance. This can be achieved with frequency bandgap structures including ABRs and PnCs. Both of these are periodic structures composed of multiple materials, which can be conveniently found in the CMOS stack. For example, dummy transistors can be implemented in the FEOL as ABRs, consisting of Si and low-k dielectric; while dummy CMP fill in the metal layers and vias in the BEOL can be engineered to form ABRs or PnCs at the targeted frequency range. These concepts are elaborated as the following sections.

A. Acoustic Bragg Reflectors in FEOL

ABRs are the acoustic analogue of the optical distributed Bragg reflectors used in optical fibers. Typical ABRs consist of alternating materials of quarter wavelength with mismatched acoustic impedance, Z_{ac}, which is defined in terms of the elastic compliance c_{11}, the acoustic velocity c_l, the effective Young's modulus of the cavity *E*, the Poisson ratio ν and mass density ρ as

$$Z_{ac} = \frac{c_{11}}{c_l} = \sqrt{\frac{(1-\nu)\rho E}{(1+\nu)(1-2\nu)}} \quad (4)$$

The reflection coefficient at an interface between two materials is commonly known as

$$R = \frac{(Z_1 - Z_2)}{(Z_1 + Z_2)} \quad (5)$$

The reflectivity off multiple layers can be calculated through an iterative method [22]. The net reflectivity increases and converges to 1 with the number of reflecting surfaces. The converging rate differs for different material pairs, as illustrated by a comparison of material pairs in CMOS (Fig. 4). Similarly to other bandgap structures, this convergence rate can be equivalently represented as the frequency bandgap. Larger acoustic impedance contrast results in larger bandgap, translating to a faster converging rate.

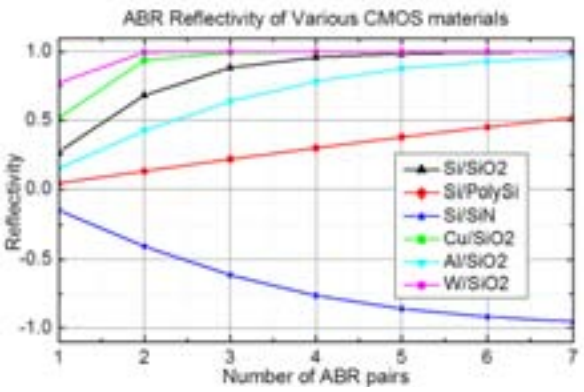

Figure 4. Comparison of the acoustic reflectivity of various ABR material pairs. For finite number of ABR pairs, the reflectivity increases with the number of pairs and converges to 1 or -1 rapidly for materials commonly found in CMOS.

In our FEOL ABR design, Si/SiO_2 was chosen as the material combination for ABRs as these materials occur in transistors and low-k dielectrics in Shallow Trench Isolations (STI). The acoustic impedance mismatch between Si and SiO_2 is $Z_{rel} = Z_{Si}/Z_{SiO_2}$~1.65 and the resultant reflectivity achieved using only 7 pairs of ABRs is *R*~ 99.4% based on 1D analysis [22]. A 2D correction result in a lower reflectivity depending

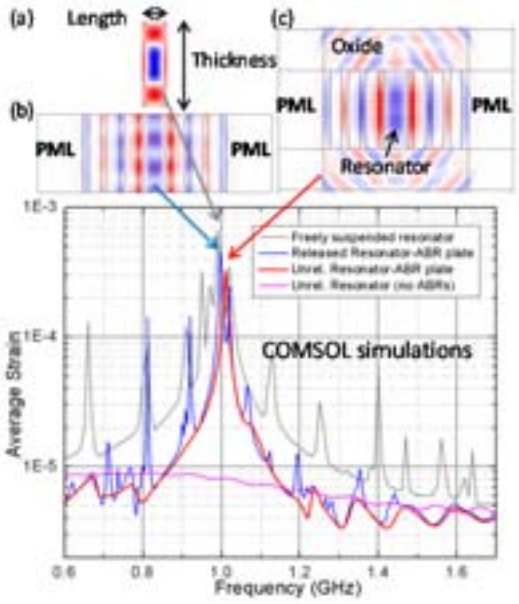

Figure 5. Frequency sweep in COMSOL for sideviews of free bar (a), released resonator-ABR plate (b), unreleased resonator-ABR structure embedded in oxide (c), and simple unreleased resonator embedded in oxide. Frequency response is for resonators of thickness-length ratio of 6.5 and ABR number of 7. Characteristic x-strain contour plots are given at an aspect ratio of 3.5 and ABR number of 3.

on the aspect ratio and resultant solid angle subtended by the reflector. This drop in reflectivity leads to the drop of Q from ~7500 in the 1D model to ~100 in the 2D model for 7 ABRs.

As illustrated in Fig. 2 & 4. The ABR serves as a near-perfect boundary, with reflectivity of 1 or -1 (1 for the Si/SiO_2 combination), in which the wave penetrates, but in an evanescent form. The portion of the wave in the ABR carries little energy propagation at resonance, and is part of the standing wave. Because the typical ABR has reflectivity of ±1 at resonance, it can be equivalently analyzed as a free or fixed boundary condition at the resonance frequency.

Fig. 5 shows frequency domain simulation in COMSOL comparing the performance of unreleased resonator with its released counterparts. The unreleased resonator has the Perfectly Matched Layer (PML) as boundary, and the released ones have simply free boundaries. The simulation shows that released bars have high Q peaks, but many spurious modes. On the other hand, the unreleased resonator with ABRs exhibits amplitude of vibration only 20% less than the released structure, with complete spurious mode suppression. More design variations and analysis on ABRs can be found in [22, 23].

B. Acoustic Bragg Reflectors as Deep Trenches

In real design environment in FEOL CMOS, the aspect ratio of the unreleased resonator is limited to <1 due to constraints of lithographic design rules and thickness of the device layer. To achieve higher aspect ratio for better Q in the ABR framework, other structures in CMOS are investigated. Some CMOS processes (e.g. IBM 45nm and below) have a high aspect ratio structure called Deep Trench (DT) used in high density DRAM capacitors or electrical isolation [24]. With aspect ratio exceeding 5:1, these DTs can be repurposed as structural elements for acoustic energy localization.

To demonstrate the feasibility of this concept, we have fabricated resonators defined using Deep Trench Capacitors in the Microsystems Technology Laboratories (MTL) at MIT (Fig. 6) [23]. Analogous to CMOS DTs, these devices use DT structures that are etched into single crystalline silicon (SCS) and filled with conformal dielectric and poly-Si. Identical DTs are spaced into a single array forming an ABR structure. A resonance cavity is sandwiched between two such arrays, with two transducer DT capacitors inserted into the cavity acting as internal dielectric transducers. [25]. Both the mechanical DTs and transducer DTs are defined in the same mask and are therefore self-aligned. These DT resonators exhibit Q >2000 operating at 3.3 GHz with no spurious modes in a multi-GHz range, with motional impedance R_X of only 1.23kΩ.

While this marks the best result to date in unreleased resonator performance, there are certain limitations to the DT resonator. (1) The DT structure is available in limited CMOS technologies, and can therefore not be applied to a generic solution for CMOS-MEMS integration. (2) Because the DTs are filled with doped poly-Si, the resistivity is at the range of 10^{-3} Ω·cm, and the RC delay becomes prohibitive for multi-GHz operation. (3) The CMOS foundry parameters are not optimized for mechanical applications for such DTs, so these DTs commonly contain voids, which can cut the wave paths and destroy its design purpose as ABRs.

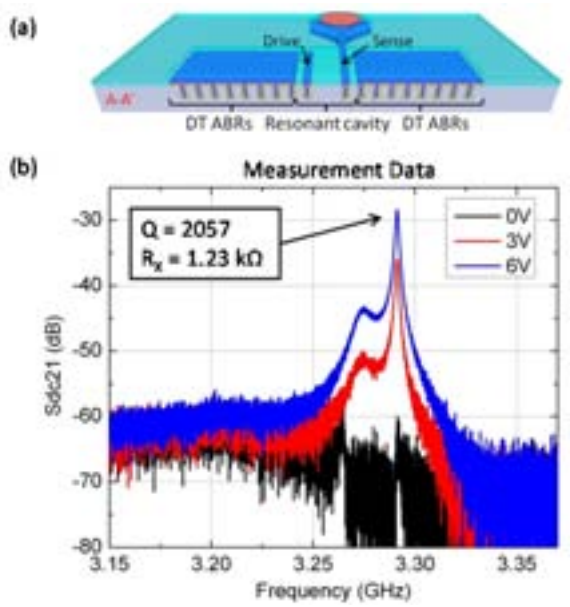

Figure 6. (a) Schematic of unreleased Deep Trench (DT) MEMS resonator. Acoustic Bragg reflectors (ABRs) formed from periodically spaced DTs define a high-Q resonant cavity in the center of the device. DT capacitors inside the resonant cavity form electrostatic drive and sense transducers. (b) Measured frequency response of DT resonators with 7.2 µm long resonant cavity, DT length of 950nm, and 1.7µm DT pitch in the ABRs. Devices with 50 ABRs are shown, with Q of 2057 and Rx of 1.23kΩ. Wide frequency sweeps show no spurious modes in a multi-GHz range.

C. Phononic Crystals in BEOL

While high aspect ratio for high Q unreleased resonators in CMOS is not always possible using the 1D ABR framework, there are a variety of structures in the CMOS stack that allow for 2D and 3D confinement of acoustic energy. In addition to patterning of surrounding Si and STI in FEOL, metal layers and vias in the BEOL can be patterned into a phononic crystal (PnC). Additionally, contacts connecting the first metal layer and the transistors and larger contacts to the substrate can be patterned into periodic arrays to enhance energy localization.

The PnC is the acoustic analogue of the photonic crystal, which is used extensively in optical waveguides and resonators [26, 27]. In contrast to the ABR that creates bandgap only in one dimension, the PnC relies on periodicity in 2D or 3D to create a frequency bandgap in all directions.

One example of a bulk CMOS resonator confined by a 2D PnC is shown in Fig. 7. Here we see a COMSOL simulation of the resonant mode of such a design, based on parameters and material properties of TSMC's 0.18um CMOS process. The resonant cavity consists of 5 transistors side by side on the same Si island (targeting a 5th harmonic bulk mode), sandwiched by contacts on either side, and capped by a PnC structure defined in the first 6 metal layers. Through a geometric parameter sweep, the PnC can be optimized for a center bandgap frequency around 2 GHz. In this complex geometry, both BEOL PnC and in-plane contact spacing should be adjusted together for optimized mode shape. A Q of 500 at 2.07 GHz is obtained in simulation, with a shear wave mode localized inside the resonant cavity.

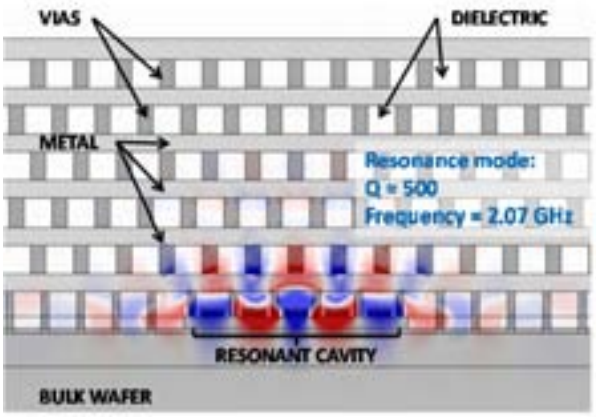

Figure 7. FEA simulation of resonant mode obtained using metal PnCs in the BEOL and vias between 1st metal layers and the transistor (CA bars). A 5th harmonic shear wave mode can be obtained from geometric optimization, with the blue and red indicating strain-x intensity.

IV. RBTs IN IBM'S 32SOI TECHNOLOGY

A. Design and Simulation

Based on the previous discussions, two constituent building blocks are essential for the development of multi-GHz CMOS-MEMS resonators: 1) FET sensing of acoustic vibrations due to its amplification of the mechanical signal before parasitics at high frequencies, and 2) ABRs or PnCs formed with structures inherent to the CMOS stack for energy localization. These concepts are demonstrated using the IBM's 32nm SOI technology to form unreleased resonators above 10 GHz [28]. Due to material restrictions in CMOS, electrostatic transduction is implemented to drive the resonator.

1) Design of Unreleased Resonator

As illustrated in Fig. 1, the unreleased RBT is created by modifying a standard CMOS body-contacted nFET, integrating a MOS capacitor on the same Si island as the nFET. On either side of this active device, an array of seven Si dummy features, composed of Si device layer/gate dielectric/poly-Si stack and separated by Shallow Trench Isolation (STI), form acoustic Bragg reflectors for mode confinement. This solid-state vibrating structure is sandwiched by the buried oxide (BOX) below and intermetal dielectric above.

In operation, superimposed DC and RF voltage $V_A + v_{in}$ is applied across the driving capacitor, generating an electrostatic force that excites acoustic wave in the plane of the wafer through the Poisson effect. On the sensing side, the FET is biased into saturation with DC gate and drain voltages, V_G and V_D, respectively. At resonance, strain modulates the carrier mobility inside the channel piezoresistively, and generates the drain current as $i_D = I_D + i_{out}e^{j\omega_0 t}$.

The mode shape and amplitude of vibrations U_0 of this unreleased resonator can be calculated using the model for damped vibrations in dielectrically driven released bar resonators [29]. This analogy is based on two assumptions: 1) each of the ABR layers is at an odd multiple of a quarter wavelength, ensuring no phase change at the ABR boundary so that it can be treated as a free or fixed boundary. 2) The aspect ratio of the structure is large, so that it can be approximated using a one-dimensional model, i.e. the wave leakage through the top and bottom is negligible.

In the course of design of the resonators, several structural aspects of the foundry-provided nFETs were modified. Standard FET doping layers which define the source/drain and body doping were changed to allow ABRs to be designed as close to the devices as possible. The shapes of the active device region of the SOI process and Poly gate regions were modified to create longitudinal bar like structures for definition of the resonant cavity. The number of metal contacts was reduced to reduce distortion of the resonant mode of vibrations. A summary of the resonator design parameters is provided in Table I.

TABLE I. DESIGN PARAMETERS OF CMOS-MEMS RBTS FABRICATED IN THE IBM 32NM SOI CMOS PROCESS.

Parameter	Value
Length (resonance dimension)	360 nm
Width	2.5 µm
# ABR pairs	7
Device footprint	5 µm × 3 µm
Capacitor doping	p or n-type
FET type	Body contacted nFET
FET W/L	10.3

2) Finite Element Analysis

As a result of limitations of simple 1D analysis, 3D finite element analysis (FEA) of the acoustic mode shape is necessary for Q analysis and design optimization. Here, the 3D model is constructed of half the resonant cavity, cut across the axis of symmetry. To correctly reflect the actual structures in the IBM 32nm SOI process, the 3D model is constructed consisting of the handle wafer, buried oxide layer (BOX), the resonant structure capped by the stress liner and the pre-metal dielectric. It also includes the sensing FET with source/drain contacts and contacts to the resonator body and drive capacitor. This geometry is shown in Fig. 8(a).

The top of the structure (above the FET and ABRs) was selected to be a free boundary condition. This is due to the fact that the subsequent layers are made of the low-κ dielectric (SiCOH) [30], which has very low acoustic impedance as compared to the materials in the acoustic cavity: Si ($Z_{Si}/Z_{SiCOH} \cong 10.5$) and SiO2 ($Z_{SiO2}/Z_{SiCOH} \cong 6$). The boundary terminating the handle wafer at the bottom was selected to be a low reflection boundary condition, to account for wave radiation loss into the substrate. This low reflection boundary condition is similar in function to Perfectly Matched Layers (PMLs), more commonly used for impedance matched boundary conditions in 2D simulations.

A frequency sweep of the structure is carried out by applying a squeezing force on the dielectric between the capacitor plates. Fig. 8(b) shows the resulting mode shape and stress plot in the longitudinal direction. The predicted resonance frequency is around 11.5 GHz for a longitudinal mode contained in the resonator and ABRs.

B. Small Signal Model

A small signal model for the CMOS-integrated RBT has been introduced in §II.A (Fig. 3(b)). The amplitude of vibrations U_0 is obtained from the electromechanical force convolved with the acoustic mode shape of the composite

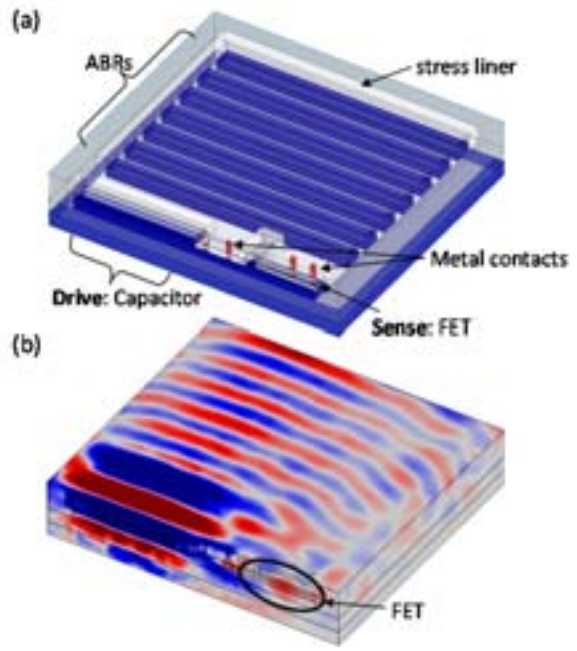

Figure 8. 3D Finite element analysis of unreleased RBT showing (a) Symmetric half-plane of the 3D geometry of resonant cavity and ABRs, including the full FEOL stack materials starting with the handle wafer up to the first metal layer. (b) stress plot along the resonance direction. The mode has a *Q*~110 at frequency of 11.6 GHz.

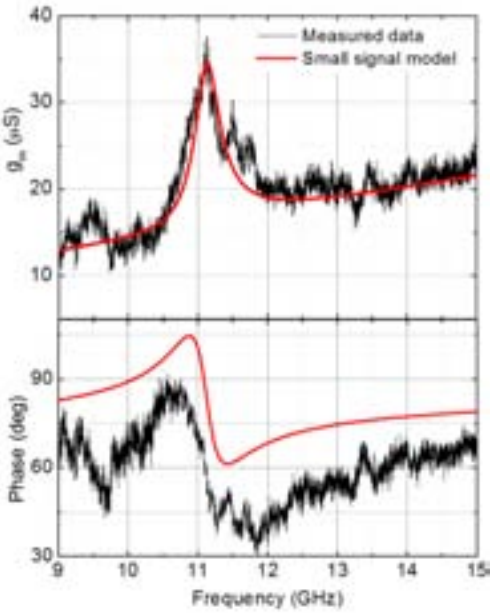

Figure 9. Measured response of nFET-ncap resonator at V_G= 0.4 V, V_A = 0.5 V (black) in close agreement with the equivalent small signal model (red) (Fig. 4). Extracted model parameters are included in Table II. The model shows a good response for the primary mode, but additional spurious modes are not captured by the single LC branch. The systematic offset in the phase is the result of imperfect open/short de-embedding.

structure with a resonance frequency of ω_0 and resonance length L. The motional current i_m, which is the electrical equivalent of the acoustic velocity, arises from the changing dimensions of the drive capacitance C_0, and its value at resonance is given by:

$$i_m = V_A \frac{dC_0}{dt} = \frac{2j\omega_0 V_A C_0 U_0}{L} \tag{6}$$

Thus the input current is proportional to and in phase with the velocity of acoustic vibrations. The motional RLC values may be calculated from the following equations.

$$R_m = \frac{v_{in}}{i_m} \tag{7}$$

$$L_m = Q\frac{R_m}{\omega_0} \tag{8}$$

$$C_m = \frac{1}{Q\,R_m\,\omega_0} \tag{9}$$

On the sensing side, the electromechanical trans-conductance g_α represents the piezoresistive modulation of the drain current I_D at resonance. The electromechanical output current i_{em} is proportional to the piezoresistive coefficient Π_{Si} and the Young's modulus of Si, E_{Si}:

$$i_{em} = \frac{\Delta\mu}{\mu} I_D = \frac{\pi(-\Pi_{Si})E_{Si}U_0 I_D}{L} \tag{10}$$

At resonance, this is used to calculate g_α in terms of i_{em} as:

$$g_\alpha = \frac{i_{em}}{V_{Cm}} = \frac{i_{em}}{v_{in}} j\omega_0 R_m C_m \tag{11}$$

In a well-designed structure, the feedthrough capacitance C_{fg} and body-contact feedthrough capacitance C_{fb} are both much smaller than the total gate capacitance C_{gg}, and the resonance frequency of the RBT ω_0 is much smaller than the cut-off frequency of the sensing FET ($\omega_0 \ll \omega_T$). Under these conditions, the overall transconductance g_m is:

$$g_m = \frac{i_{out}}{v_{in}} = \frac{g_\alpha}{s^2 L_m C_m + sR_m C_m + 1} + \frac{1}{r_f} + sC_f \tag{12}$$

This simplified small signal model can be used in circuit simulators to model the RBT behavior for the purpose of CMOS-MEMS co-design.

C. Experimental Results

Resonators were tested in a two-port configuration in a Cascade PMC200 RF probe system. Open and short structures on the die were used to de-embed routing parasitics down to the first metal level. RF measurements were carried out at 300K with -21.9 dBm input power and 30Hz IF BW using an Agilent PNA-X N5245A. The overall input-to-output transconductance as per the definition for a MOSFET were extracted as $g_m = \frac{i_{out}}{v_{in}} = Y_{21} - Y_{12}$.

1) RF measurements

Under the biasing conditions described in §IV.A, the nFET-ncap RBT exhibits frequency response of the input-to-output transconductance g_m shown in Fig. 9. A measured resonance peak of *Q*~30 at 11.1 GHz can be seen, matching closely with the predicted resonance frequency from the 3D simulation in Fig. 8.

This RF response can be fitted with the small signal model in Fig. 3(b). The driving capacitor C_0 was obtained from layout. The parameter values for R_m, L_m and C_m were extracted following (7-9) using measured value of Q and f_0. With these values, g_α was calculated based on (10) and (11), and r_0 was determined from the early voltage extracted from the FET DC. The value of C_f and r_f were extracted from the

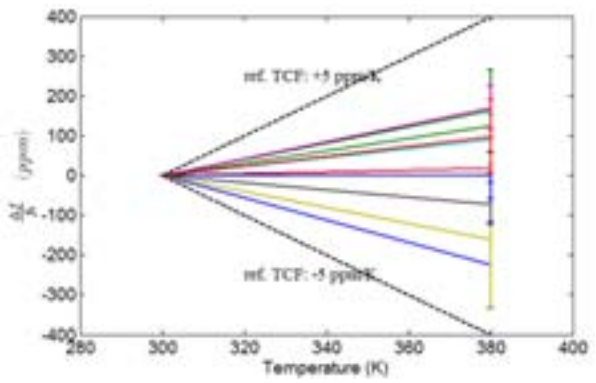

Figure 10. Extracted TCFs for multiple spurious modes on a single device. All the TCFs lie within ±3 ppm/K range. This result is consistant for all the devices.

broadband floor of the RF measurement. Fig. 9 plots the fitted data alongside the measurement data. It is important to note both from the fitted curve and experiment that the output current is 90° out of phase from the input voltage. Detailed values of the small signal model are listed in Table II.

TABLE II. EXTRACTED PARAMETERS OF 11.1 GHZ RESONATOR.

Parameter	Value
C_0	14 fF
R_m	1.1 MΩ
L_m	0.49 mH
C_m	4.2e-19 F
g_α	-0.62 µS
C_f	0.22 fF
r_f	290 kΩ
r_0	20 kΩ

2) Temperature Stability

Thermal stability is an important characteristic of any resonator required for reliable operation in oscillators, filters, sensors, and other communication and navigation systems. Si resonators typically exhibit temperature coefficient of frequency (TCF) of -20 to -30 ppm/K, but use of materials with positive temperature coefficient of Young's modulus (TCE) such as SiO_2 has been demonstrated for thermal compensation [31]. The CMOS-integrated resonators presented here are inherently surrounded by SiO_2 in the BOX and STI fill used to define ABRs, and are expected to show TCF compensation from the complimentary Si/SiO_2 pairing.

The temperature stability of the CMOS-MEMS resonators are characterized at room temperature (298K), 340K and 380K. Two different families of TCF are observed. Those showing positive TCF indicate oxide-dominated modes, and those with negative TCF show Si-dominated modes. All TCF data are observed to lie between ±3 ppm/K which agrees well with analysis and simulation (Fig. 10). Some modes are observed with sub-ppm TCF which demonstrates almost complete thermal compensation.

V. ALGAN/GAN MEMS RESONATORS

The concept of active transistor sensing in multi-GHz resonators can be extended from Si to other materials including III-V materials, used extensively for mm-wave ICs (MMICs). Specifically, wide band-gap compound semiconductors such as GaN are used increasingly for high power (>10W/mm), high frequency (>100 GHz) applications due to high electron velocity, charge density (1×10^{13} cm^{-2} in AlGaN/GaN), and critical electric field >3 MV/cm. In its Wurtzite crystal structure, GaN also exhibits high piezoelectric coefficients (k_T^2 up to 2%) necessary for low insertion loss, large bandwidth MEMS filters [32, 33].

A. Active HEMT sensing in GaN resonators

To achieve high frequency operation, AlGaN/GaN MEMS resonators in this work are driven piezoelectrically and sensed with a High Electron Mobility Transistor (HEMT). This type of device implements 2D electron gas (2DEG) electrodes, inherent to the AlGaN/GaN heterostructure (Fig. 11(a)). Large spontaneous and piezoelectric polarizations form a sharp potential well confining electrons in a 2D plane just below the interface between AlGaN and GaN [34]. Typical electron densities of the 2DEG are as high as $n_s \sim 1\times10^{13} cm^{-2}$ and the mobility can reach $1500\ cm^2/Vs$. This makes the 2DEG conductive enough to serve as an electrode for piezoelectric transduction, or as the channel for the HEMT (Fig. 11(a),(b)).

These AlGaN/GaN MEMS resonators are driven through the piezoelectric effect by applying an AC voltage between the Schottky metal contact and the 2DEG electrode. When driven into mechanical resonance, the resonance strain affects the charge polarization in AlGaN and GaN, which turns into a change of charge density inside the HEMT channel, translating to an AC modulation of the HEMT drain current. The AlGaN/GaN heterostructure has a unique feature of switchable piezoelectric transduction [35]. A negative DC bias can be used to deplete away the 2DEG. This negative voltage bias can be used to shut off both the driving and sensing transducers, ideal for applications requiring configurable frequency response such as cognitive radio.

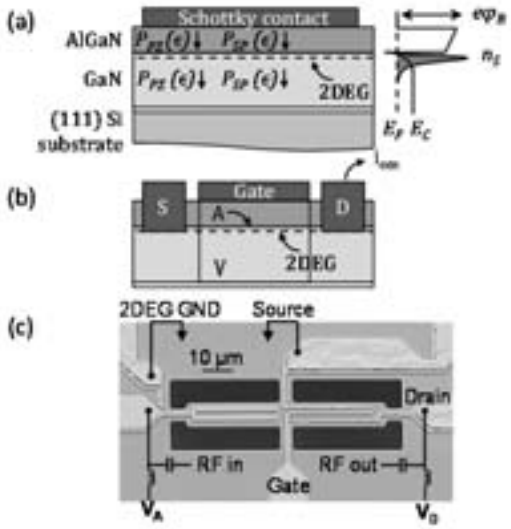

Figure 11. (a) 2DEG confined in conduction band potential well at the interface between AlGaN and GaN. (b) HEMT structure, with Ohmic metal S/D contacts to the 2DEG channel and Schottky metal gate. (c) SEM of piezoelectric-drive, HEMT-sensed 8.7×70 µm resonator. The HEMT has gate length of 1 µm.

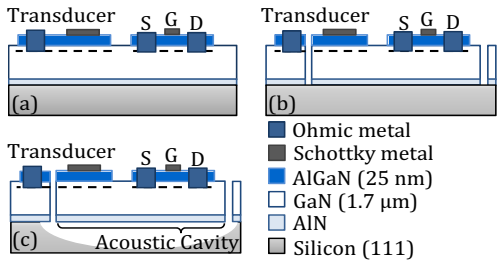

Figure 12. Fabrication involves two additional steps to (a) existing GaN MMIC technology, including (b) adeep GaN etch, and (c) a release step.

Combined with the high power, high frequency capabilities of GaN technology, this AlGaN/GaN MEMS resonator design could enable the integration of high-Q MEMS resonators with millimeter-wave ICs (MMICs) and high power electronics.

B. Small Signal Model

The piezoelectric-drive, HEMT-sensed GaN resonator has the small signal model identical to Fig. 3(b). However, a new expression for mechanical transconductance g_α must be considered due to the different physics contributing to drain current modulation. When driven into acoustic resonance, strain fields defined by the mode shape induce a polarization field through the direct piezoelectric effect in both GaN and AlGaN. The divergence of such polarization generates volume charge ρ throughout the heterostructure. In addition, an interface charge σ is generated by a discontinuity in the polarization at the AlGaN/GaN interface. These charges can be integrated in the region under the gate:

$$Q_{mech} = \iiint \rho dV + \iint \sigma dA \tag{13}$$

This translates into an AC modulation of the drain current:

$$i_{em} = \frac{Q_{mech}}{Q_{channel}} I_D \tag{14}$$

in which I_D and $Q_{channel}$ are the DC drain current and channel charge, respectively. With this expression, the g_α can be calculated through the same expression as (11).

C. Experimental Results

Fabrication of these devices requires only 2 modifications to a standard GaN technology This begins with an AlGaN(25nm)/GaN(1.7μm) stack gown by Molecular Beam Eptaxy on a (111) silicon substrate, using a thin AlN nucleation layer. The growth for the stack was performed at Raytheon and subsequent fabrication was completed at MIT. After steps creating the HEMT and the Schottky contact which are standard in GaN MMIC fabrication [36], two additional steps including a deep GaN etch to define the resonator and a XeF_2 release etch are performed to complete the devices (Fig. 12).

An SEM of the piezoelectric-drive, HEMT-sensed resonator is shown in Fig. 11(c). Fig. 13(a) shows the measured DC behavior of the HEMT embedded in the resonant structure after the XeF_2 release step, with $V_T = -5.75V$.

Using HEMT sensing, resonators up to 3.5 GHz were realized and detected with standard 2-port measurements as shown in Fig. 13(b). The active device is measured in air with 50Ω termination. A resonance at 2.67 GHz is obtained with a Q of 650 in air, with $f{\cdot}Q$ of $1.7{\times}10^{12}$. A COMSOL simulation of the stress distribution of this resonance is shown as an inset in Fig. 13(b), with maximum stress under the gate of the transistor. This translates into an efficient modulation of the

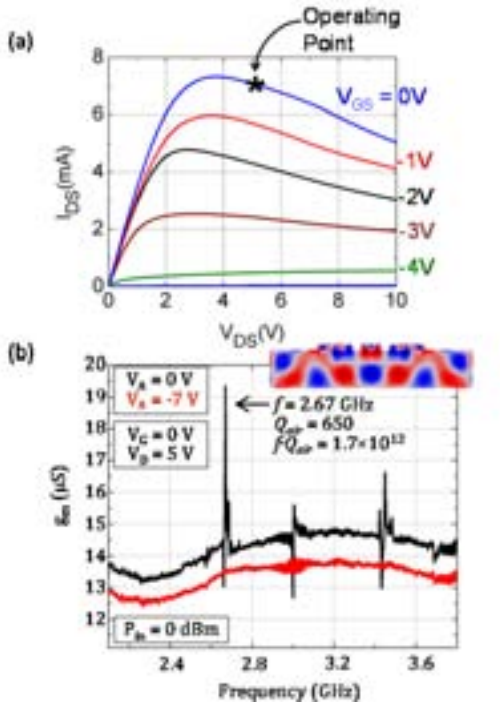

Figure 13. (a) Measured IV curves of the HEMT embedded in resonator after release step. (b) Measured frequency response of PE drive-HEMT sense AlGaN/GaN resonator, in air. The transconductance, $g_m = Y_{21} - Y_{12}$, is suppressed when the 2 DEG under the drive electrode is depleted.

charge density in the channel of the HEMT. The resonance can be suppressed by applying a negative voltage to the drive electrode, depleting the 2DEG and suppressing C_0 by 13×.

VI. Conclusion

The first CMOS-based unreleased RBTs are demonstrated in IBM's 32SOI process with resonance frequencies above 11 GHz, Qs of 24-30 and footprint of less than 5μm×3μm. These devices are fabricated at the transistor level of the CMOS stack and are realized without the need for any post-processing or packaging. CMOS-integrated RBTs are the first step towards realizing on-chip acoustic frequency sources with reduced size, power consumption, and parasitics in wireless communication, navigation and sensing systems.

Comparative analysis and experimental results from multiple resonator designs show the merits of active transduction mechanisms for scaling of resonators to multi-GHz frequencies. Device performance can be further enhanced by characterizing material properties of the CMOS stack and performing 3D geometric optimization. Furthermore, CMOS resonators demonstrate thermal stability under ±3ppm/K due to the complimentary nature of TCE of Si and SiO2. This poses the possibility for TCF manipulation for design of temperature sensors with high TCF or oscillators with sub-ppm/K sensitivity.

Seamless integration into a standard CMOS process obviates the need for complex and costly custom processes for MEMS fabrication. The demonstration of resonators fabricated side-by-side with CMOS circuitry greatly reduces parasitics of off-chip access, constraints of limited IO, and power

consumption associated with impedance matching networks. Such benefits can provide increased system speed and dynamic range, particularly at RF and mm-wave frequencies of operation.

Finally, to meet requirements of high power handling and high transduction efficiency, III-V semiconductors can be selected as an alternative to silicon, still taking advantage of active sensing mechanisms for high frequency. GaN-based MEMS resonators are demonstrated up to 3.5 GHz with a Q of 650 in air, and $f \cdot Q$ of 1.7×10^{12}, potentially enabling the integration of high-Q MEMS resonators with MMICs and high power electronics.

ACKNOWLEDGMENT

CMOS fabrication was made possible by TAPO, DARPA LEAP, and IBM. The authors thank William Hoke and Thomas Kazior at Raytheon for GaN growth. Fabrication of GaN took place at MIT's Microsystems Technology Laboratories and Harvard's Center for Nanoscale Systems.

***Abstract*—A novel CMOS-MEMS composite ring resonator capable of a dual-mode operation has been proposed to enable self-temperature sensing in a single device. To maximize the temperature sensitivity between the dual modes, two resonant modes of a single resonator vibrating in orthogonal axes (i.e., in-plane and out-of-plane) are chosen due to the large difference of their temperature coefficients of frequency (TC_f's). By adjusting the constituent ratio and the position of metals and dielectrics through CAD layouts, different TC_f's have been successfully demonstrated in a single CMOS-MEMS resonator. By measuring the TC_f's of the in-plane (INP) and out-of-plane (OOP) mode concurrently, a beat frequency with a temperature coefficient of 72 ppm/°C was characterized. By employing a divider-based scaling concept, an estimated maximum beat frequency sensitivity of 3,244 ppm/°C can be obtained under proper scaling numbers.**

Keywords—CMOS-MEMS, dual-mode, beat frequency, resonators, back-end of line (BEOL)

I. Introduction

Temperature sensors are critical building blocks in modern electronic circuits for SOC power management [1] or environmental temperature monitoring [2] applications. Conventional CMOS-based temperature sensors are based on many different sensing schemes, including BJT-based PTAT [2], thermal diffusivity [3], and temperature dependent inverter-delay [4]. However, these complex circuits suffer the process variations in advanced technology nodes, leading to a large sensing inaccuracy. Individual calibration and trimming process can improve their sensing accuracy but would introduce extra cost. On the other hand, MEMS resonator has a strong potential to deliver better sensing accuracy due to its large temperature coefficient of frequency (TC_f), hence offering an alternative way for temperature sensing. In addition, advanced CMOS technology nodes provide more precise line width control in lithography and etching processes, hence reducing the process variation for CMOS-MEMS resonant type temperature sensors [5].

To address the aforementioned issue, many integrated MEMS resonator systems with large TC_f's were developed in standard CMOS technologies [6][7]. The metal-alloy (AlCu) and oxide (SiO_2) layers in the CMOS back-end-of-line (BEOL) process have negative and positive temperature coefficient of elastic modulus (TC_E), respectively, that provides an advantageous feature for designing the proper TC_f. By engineering the constituent ratio of these materials, various resonators with different temperature coefficients of frequency can be implemented on a single chip.

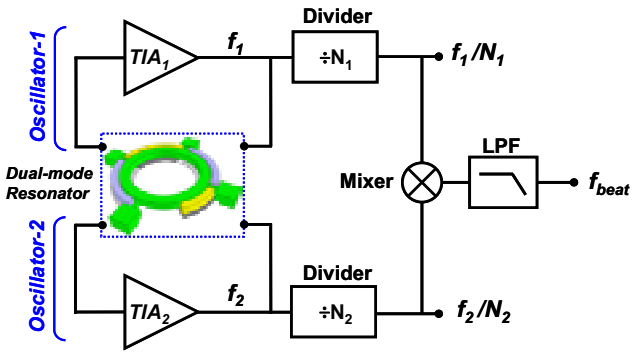

Fig. 1: Conceptual figure of a CMOS-MEMS temperature sensor when dual-mode MEMS resonator is employed.

In this work, we proposed a ring-shaped dual-mode CMOS-MEMS resonator which offers different TC_f's in a single device suited for temperature sensing. To generate the beat frequency that is sensitive to the environmental temperature change [8], a potential system configuration was proposed in Fig. 1 where two transimpedance amplifiers are connected to the corresponding electrodes to enable dual-mode oscillation. Two frequency dividers follow each oscillator loop to allow frequency scaling that provides a great flexibility for beat frequency generation. The temperature information can be deduced from the beat frequency, which is defined by

$$f_{beat} = \frac{f_1}{N_1} - \frac{f_2}{N_2} \quad (1)$$

where f_1 and f_2 are the oscillation frequencies, and N_1 and N_2 are the divider ratios, respectively. Notably, the proof-concept device was designed in a TSMC 0.35μm CMOS platform, but the design concepts and fabrication methods are compatible to advanced technology nodes, such as 90nm or 65nm process.

This work was supported by the National Science Council (NSC) of Taiwan.

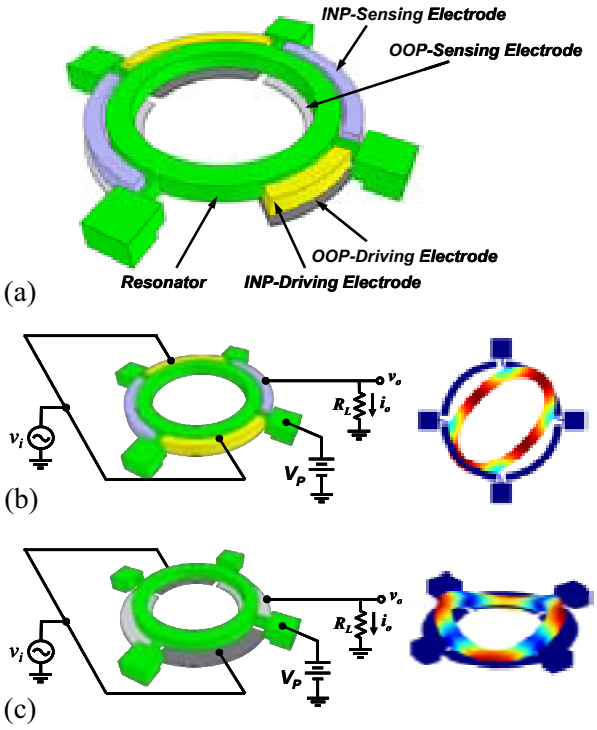

Fig. 2: Perspective-view schematics and mode shapes of a dual-mode CMOS-MEMS ring resonator. (a) Electrode configurations of the resonator that can be used to excite the (b) in-plane mode and (c) out-of-plane mode simultaneously.

II. Dual-mode Resonator Design

The perspective-view of the proposed resonator is shown in Fig. 2(a). The resonator is supported by four supporting tethers at shared in-plane and out-of-plane vibrating nodal points to enable high *Q* and eliminate the effects of thermal stress. To feature dual-mode operation, the resonator is surrounded by its in-plane and out-of-plane electrodes. Fig. 2(b) and (c) provide the electrical configurations for exciting the in-plane mode (INP) and out-of-plane mode (OOP), respectively. The vibrating mode shapes of the INP and OOP mode are also shown in Fig. 2(b) and (c).

To design the corresponding TC_f of each mode (INP and OOP), the vibration frequency of the composite MEMS resonator with laminated structural materials can be expresses as

$$f_{INP}(T) = \frac{2.683}{2\pi R^2}\sqrt{\frac{\sum E_i I_i(T)}{\sum \rho_i A_i(T)}} \tag{2}$$

$$f_{OOP}(T) = \frac{6}{2\pi R^2}\sqrt{\frac{\sum E_i I_i(T)}{\sum \rho_i A_i(T)\left(4+\frac{\sum E_i I_i(T)}{G_{eq}C(T)}\right)}} \tag{3}$$

where *R* is the radius of the ring; *C* is the torsion constant; G_{eq} is the equivalent shear modulus; and E_iI_i and ρ_iA_i are the bending stiffness and unit mass per area of the *i*-th material of the resonator, respectively [9]. The AlCu metal layers have a negative TC_E of -620 ppm/°C [10] while the oxide layers have a positive TC_E of +180 ppm/°C [11]. The interconnects between metals (i.e., VIAs) are made by tungsten (W), providing a negative TC_E of only -6 ppm/°C [12]. By adjusting the constituent ratio and the position of metals and dielectrics through the CAD layouts, different TC_f's have been successfully demonstrated in a single CMOS-MEMS resonator. The linear TC_f of each mode can be obtained by taking a derivative of equation (2) and (3) at a specific temperature point, given by

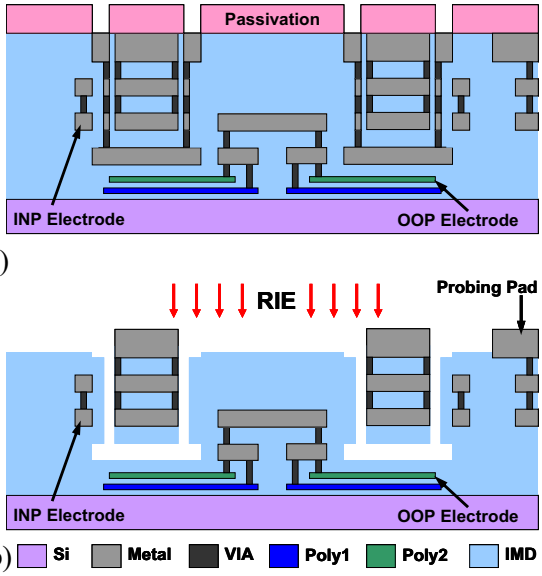

Fig. 3: Post-CMOS process. (a) Unreleased CMOS chip prepared by the foundry. (b) Metal etching and RIE pad opening.

$$TC_f = \frac{1}{f(T_o)}\left(\frac{\partial f(T)}{\partial T}\right)_{T_o} \tag{4}$$

where *f(T)* is a general frequency equation. From (2)-(4), the estimated TC_f's of the INP and OOP mode of the dual-mode resonator is -51ppm/°C and -92ppm/°C, respectively.

III. Post-CMOS Fabrication Process

To fabricate the proposed MEMS resonator, a previous-developed metal wet-etching process was adopted to release the resonator [7] due to its excellent selectivity between metal and oxide. Fig. 3(a) shows the cross-sectional view of a CMOS chip prepared by the foundry. Part of the passivation layers are removed from the top to define the resonator shape where the sacrificial metals are exposed to the environment. The metal etchant composed of sulfuric acid (H_2SO_4) and hydrogen peroxide (H_2O_2) was utilized to remove the sacrificial metals (AlCu and W-VIA), where the sulfuric acid is the etchant and hydrogen peroxide is the catalyst. An additional reactive ion etching (RIE) process was applied for opening the bond-pad areas, as shown in Fig. 3(b).

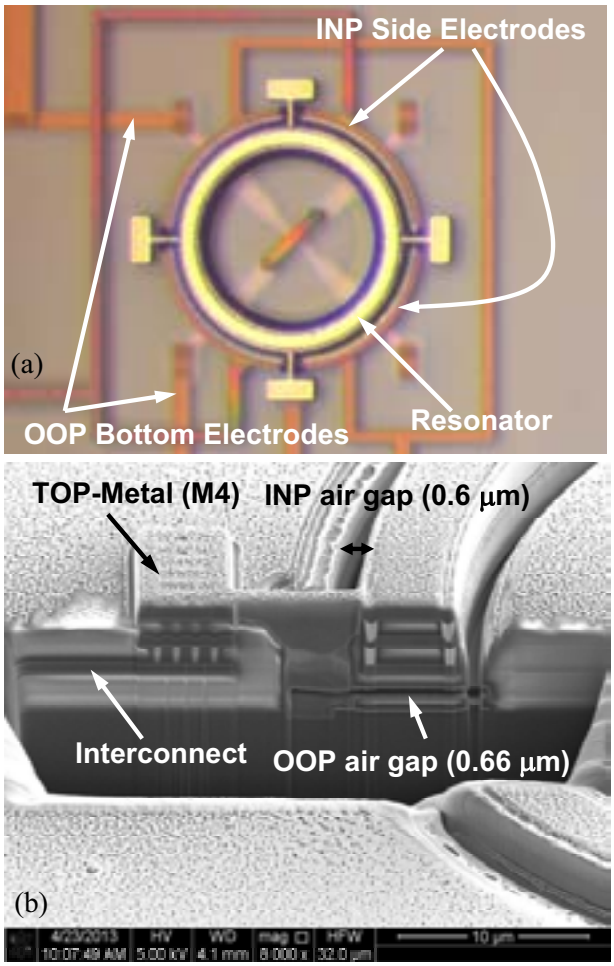

Fig. 4: (a) Optical image of the ring resonator. Electrical routings are identified. (b) SEM image of a focused-ion-beam (FIB) cut view of the resonator.

Fig. 4(a) is the optical view of the fabricated CMOS-MEMS resonator where the detailed electrical routings are identified. Fig. 4(b) is the FIB-cut cross-sectional view of the fabricated resonator, showing the laminated structural layers. The tungsten-VIAs were laid out at the edge of the ring to increase the in-plane driving and sensing transducer areas. The in-plane and out-of-plane gap spacing are around 0.6μm and 0.66μm, respectively.

IV. Characterization Results

The CMOS-MEMS resonator was placed in a cryogenic vacuum probe station and the resonance response was characterized by a vector network analyzer. The resonator is electrostatically actuated and capacitively sensed in a typical two-port configuration. By arranging the probes, the resonance spectra of both INP and OOP modes can be characterized. The output sensing electrode was connected to a transimpedance amplifier (TIA) ASIC to convert the output current into voltage for improving the signal-to-noise ratio. Fig. 5 presents the

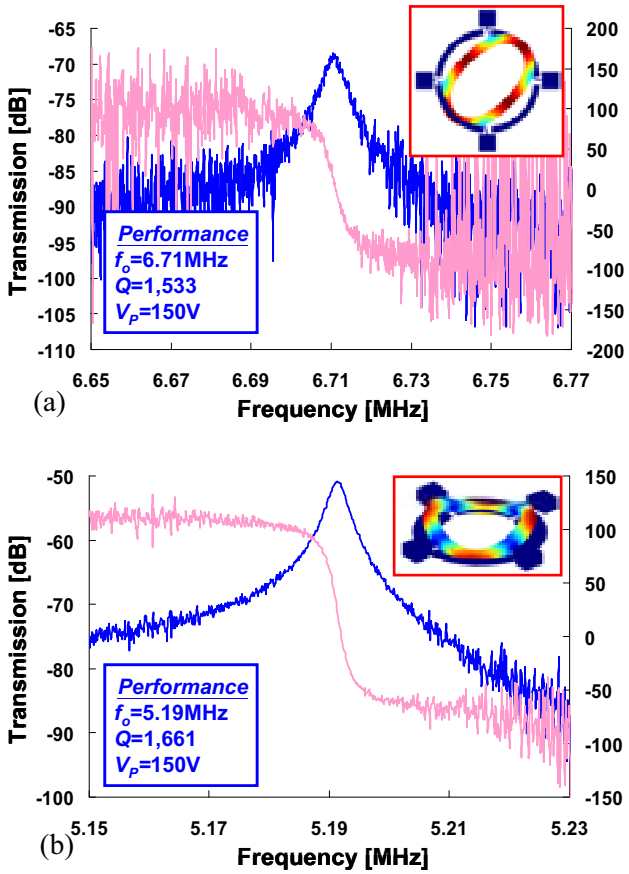

Fig. 5: Measured frequency spectra of the (a) in-plane vibration mode and (b) out-of-plane vibration mode for the dual-mode CMOS-MEMS resonator.

measured frequency responses for the dual-mode resonator. The INP mode of the resonator has a resonance frequency of 6.71MHz with a quality factor Q of 1,533 (cf. Fig. 5(a)) while the OOP mode of the resonator has a resonance frequency of 5.19MHz with a quality factor Q of 1,661 (cf. Fig. 5(b)]. The frequency responses were characterized at room temperature.

To understand the temperature sensitivity and cross-axis interference of the dual-mode operation, one pair of the side electrodes and bottom electrodes are connected together to drive the resonator into their INP and OOP modes simultaneously. Under such a experimental setup, the measured thermal responses are shown in Fig. 6(a). The TC_f of the INP mode is -57ppm/°C and that of the OOP mode is -95ppm/°C, respectively. The measured TC_f's are in good agreement with the calculated values. By adapting (1) with N_1=N_2=1 (i.e., no divider is used), an estimated beat frequency (f_{beat}) of 1.524MHz with a TC_{fb} of +72ppm/°C was obtained. However, by properly choosing N_1=N_{OOP}=50 and N_2=N_{INP}=64, an estimated maximum beat frequency sensitivity of +3,244ppm/°C can be obtained by a liner curve fit (f_{beat} = 1.192kHz @-23°C), as shown in Fig. 6(b). In a sense, the temperature sensitivity of the beat frequency could be flexibly tuned by the divider ratio.

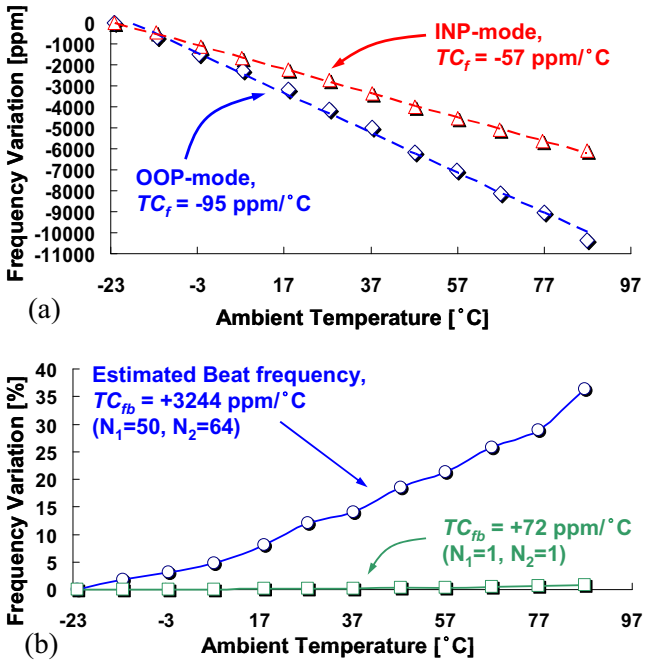

Fig. 6: (a) Measured TC_f's of the dual-mode resonator. (b) Estimated raw TC_{fb} (N_1=N_2=1) and best-case TC_{fb} (N_1=N_{OOP}=50, N_2=N_{INP}=64) with proper scaling numbers

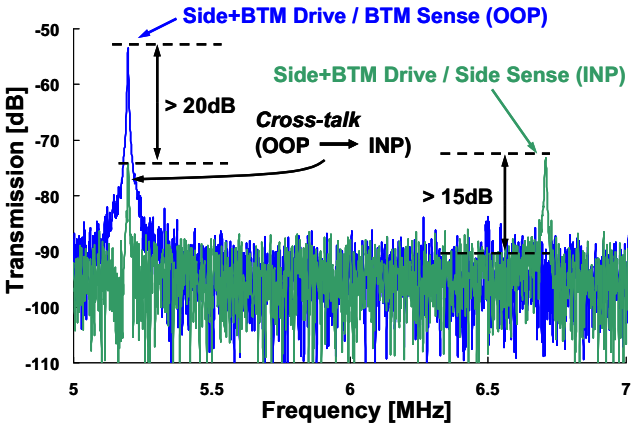

Fig. 7: Measured cross-axis sensitivity of the dual-mode CMOS-MEMS resonator.

Finally, the cross-axis sensitivity was characterized. For a dual-mode resonator via its vibration modes in orthogonal axes, the signal isolation from one axis to the other should be maximized. To characterize this sensitivity, the driving signal was applied on the side (in-plane) and bottom (out-of-plane) excitation electrodes simultaneously and the sensing signal was picked up from the side or the bottom electrodes separately. The measurement result is shown in Fig. 7, where the blue curve (5.2MHz, -53dB) was picked up from the bottom electrode and the green curve (6.7MHz, -73dB) was observed from the side electrode. In conclusion, the measured cross-axis sensitivity at least -15dB (i.e., the cross-talk signal is attenuated by 15dB) was characterized in this prototype device.

V. Conclusion

In this work, a prototype CMOS-MEMS dual-mode ring resonator was designed, fabricated, and fully characterized using a 0.35μm CMOS process. The design concept and fabrication process is compatible with advanced CMOS technology nodes. A TC_f difference of 38 ppm/°C between modes was achieved in this prototype, which is the largest difference compared to other MEMS dual-mode resonators to date. To enhance the temperature sensitivity, a potential system configuration was also proposed in this work based on a divider-based circuit. Although the dual-mode CMOS-MEMS resonator was characterized under a open-loop condition, the practical system implementation will be carried out in future.

***Abstract*—In this work we present room-temperature measurements of graphene nanoelectromechanical resonators (GNERs) demonstrating quality factors (Qs) greater than 200 at resonance. A nominal resonant frequency (f_o) of 200 MHz is attained by applying strain to the suspended graphene using an SU-8 polymer clamp. Additionally, the device f_o can be tuned by more than 5% by application of a DC gate bias on the order of 5V. Chemical vapor deposited (CVD) graphene is used to demonstrate the scalability of the process.**

I. Introduction

Graphene has received much attention owing to its exceptional electrical and mechanical properties [1], [2]. For electronic applications, graphene has been considered as a potential channel material for RF field-effect transistors (FETs) due to its high carrier mobility, saturation velocity, and current carrying capacity [3], [4]. In nano-mechanics research, graphene has been used to construct RF mechanical resonators [5], [6], [7], which take advantage of its high tensile strength,high stiffness, and low mass.

It was recently demonstrated that a graphene nanoelectromechanical resonators (GNER) can be operated as a mechanically resonant FETs to improve transduction [6], [7]. In this configuration, shown in Fig. 1, a sheet of graphene is suspended over a local metal gate electrode, and a drain-source bias (V_{ds}) is applied across the graphene. By applying both a DC voltage and an RF signal to the gate, mechanical vibrations are actuated in the graphene. Motion of the graphene relative to the gate induces a capacitive displacement current in the device (similar to that seen passive MEMS devices), as well as a current due to the field-effect modulation of channel charge. By means of this second current component, the mechanical resonance signal is sensed and amplified by the transconductance (g_m) of the graphene FET structure.

This active sensing technique creates the possibility of using graphene NEMS resonators in RF circuits such as filters and oscillators [8]. Active sensing may be especially beneficial in filtering applications since it may be used to reduce insertion loss (IL), a parameter that is especially important for maintaining an acceptable receiver noise figure.

Nonetheless, there are still obstacles to implementing GNERs in these applications, including process scalability concerns, low quality factors (Q) at room temperature, and low resonance frequencies (f_o). In this work we present measurements on GNERs that address these problems by employing a stress-enhanced design to boost f_o, and chemical vapor deposited (CVD) graphene to demonstrate the potential for wafer-level fabrication.

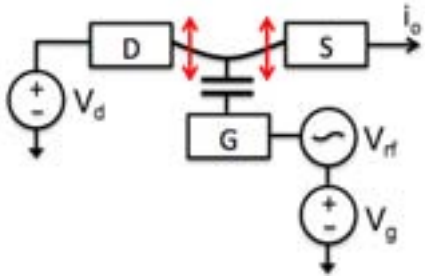

Fig. 1. Diagram showing operation of GNER.

II. Experiment

The process used to fabricate GNERs is described in detail elsewhere [9], but will be briefly outlined here. To begin, metal gates are patterned on fused silica substrates using deep-UV lithography. A layer of silicon dioxide (SiO_2) is deposited on top of the gates using plasma-enhanced chemical vapor deposition (PECVD). To improve adhesion and reduce potential wrinkling of the graphene, the oxide is chemical-mechanical polished (CMP) to reduce its roughness below 0.5 nm. CVD grown graphene is then transferred to the substrate using the technique outlined in [9].

Device channels are patterned in the graphene using electron beam lithography (EBL) and an oxygen plasma etch. Source and drain electrodes (1/15/50 nm of Ti/Pd/Au) are then patterned using EBL, and an SU-8 polymer clamp is patterned on top of the graphene in order to clamp the graphene in the shape of a drum. The sample is then hardbaked at 170C, causing the SU-8 clamp to contract and apply strain to the graphene. The devices in this work employ clamps with a circular geometry rather than a doubly-clamped structure. We find that this improves the uniformity of the strain applied to the graphene, and also serves to suppress higher-order modes that often arise in doubly clamped structures, which may adversely affect Q.

In the final fabrication step, the device is immersed in buffered oxide etchant and dried in a critical point dryer to remove the sacrificial oxide under the graphene channel and suspend the device. A scanning electron microscope (SEM) image of a finished device is shown in Fig. 2.

All measurements are conducted at room temperature in a

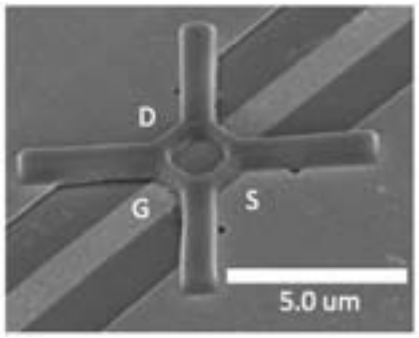

Fig. 2. SEM image of GNER.

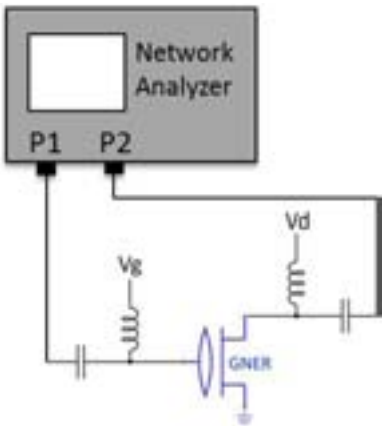

Fig. 3. RF measurement setup: gate and drain DC biases are applied through bias-T's. The input and output ports art P1 and P2, respectively.

Desert Cryogenics probe station at pressures lower than 10^{-6} torr. DC measurements are performed using an Agilent 4155c Semiconductor Parameter Analyzer. RF measurements were performed with the setup shown in Fig. 3, using an Agilent N5230A Network Analyzer.

III. Results and Discussion

Fig. 4 shows a measurement of drain current (I_{ds}) as a function of the DC gate-to-source bias (V_{gs}) for a GNER measured with a constant V_{ds}. The clamp geometry for this device is a 1.5-μm-diameter circular drum, and the graphene channel width and length underneath the clamp are 3-μm and 1.5-μm, respectively. The gate-to-channel spacing for this device is approximately 70 nm. A field-effect mobility (μ_{fe}) of 300 cm^2/V-s is calculated from these current-voltage measurements, which while lower than other data on CVD graphene samples which show mobilities as high as 40,000 cm^2/V-s [10], is sufficient to achieve g_m in excess of 15 μS. The lower mobility achieved here is most likely due to contamination of the graphene channel material during the more involved fabrication process to achieve these structures.

Fig. 5(a) shows a plot of the S_{21} magnitude for the same GNER as a function V_{gs} and frequency. Increasing V_{gs} increases the electrostatic force on the graphene, which induces additional strain in the membrane, causing f_o of the device to shift from approximately 201 MHz at 0 V to 198 MHz at 4 V. The reduction in f_o at higher V_{gs} is due to a spring softening effect that has been observed in many nanomechanical devices

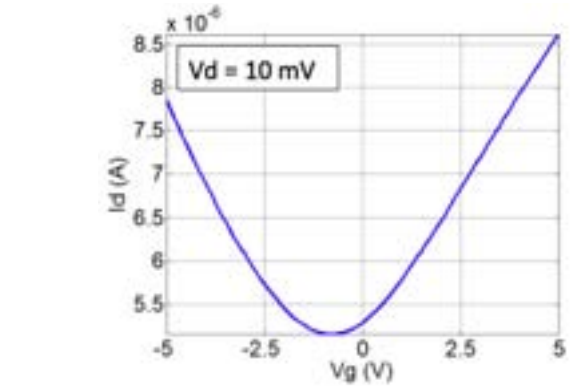

Fig. 4. Low-field transport measurement.

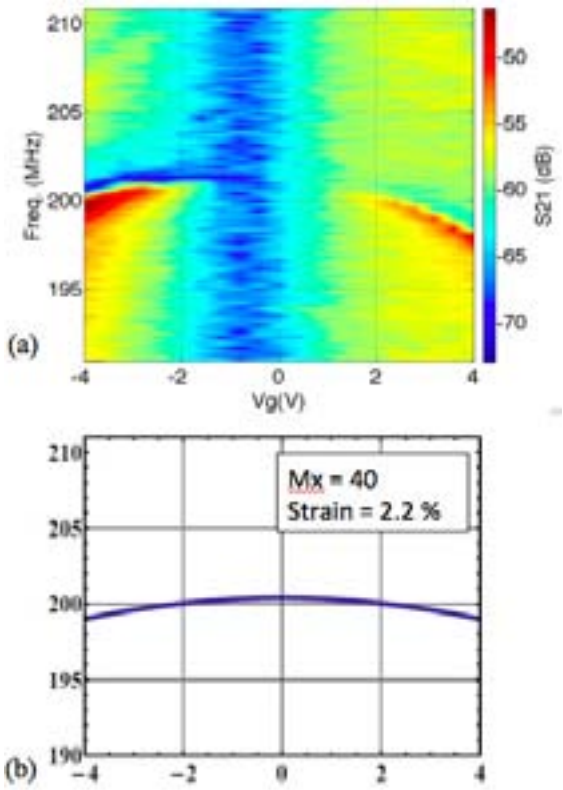

Fig. 5. (a) S_{21} magnitude as a function of frequency and V_{gs}. (b) Fitting of the resonant frequency tuning characteristic, used to extract resonator mass and strain.

[11]. Using the mechanical model for a circular membrane resonator given in [12], the tuning characteristic of fo can be modelled, as shown in Fig. 5(b), and the mass and built-in strain of the graphene can be determined. These models yield a mass of approximately 40 times that of intrinsic graphene, and a strain of 2.2%. This mass enhancement is attributed to the same contamination to which we ascribe the mobility reduction.

The small signal electrical model for the device is shown

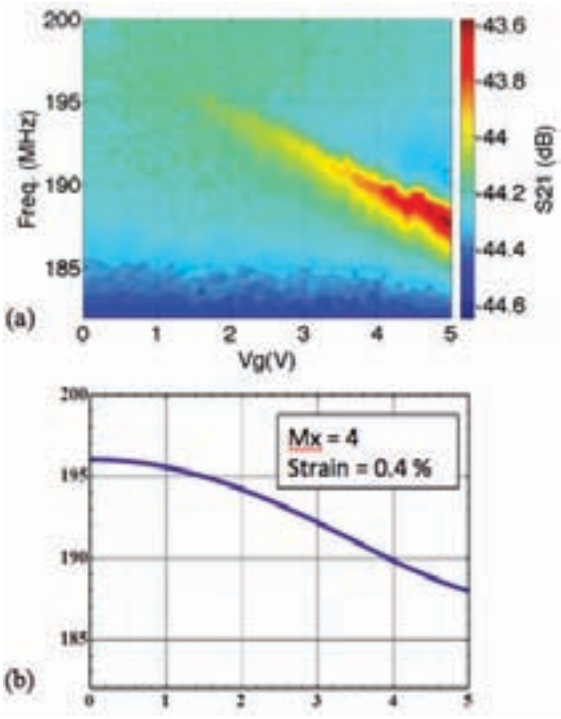

Fig. 6. S_{21} magnitude as a function of frequency and V_{gs}, which demonstrates a greater tuning range due to lower built-in stress from the SU-8 clamp.

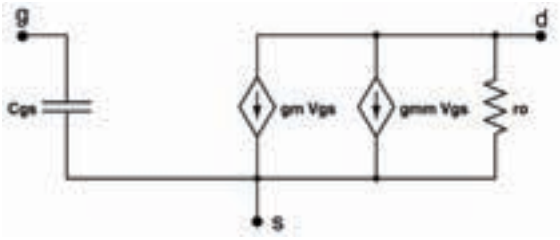

Fig. 7. Small signal electrical model for a GNER.

in Fig. 7. The small signal output current is given by

$$I_d = j\omega C_{tot}\tilde{V}_{gs} - j\omega\frac{\tilde{z}}{z_0}C_g V_{gs} + V_{ds}\frac{dG}{dV_{gs}}\tilde{V}_{gs} - V_{ds}\frac{dG}{dV_{gs}}\frac{\tilde{z}}{z_0}V_{gs} \quad (1)$$

$$\tilde{z} = -\frac{1}{m}\frac{C_g}{z_0}V_g\frac{1}{\omega_0^2 - \omega^2 + \frac{j\omega_0\omega}{Q}}\tilde{V_{gs}} \quad (2)$$

$$g_m = V_{ds}\frac{dG}{dV_{gs}} \quad (3)$$

where C_{tot} is the total capacitance of the device, $\tilde{V}_{gs}$ is the RF voltage amplitude, $\tilde{z}$ is the resonator displacement amplitude, $\tilde{z_0}$ is the average gate to channel distance, C_g is the gate capacitance, m is the resonator mass, and G is the graphene conductance.

The first two terms in this equation are the feedthrough current and the mechanical displacement current seen in traditional passive MEMS devices [7]. The third term is identical

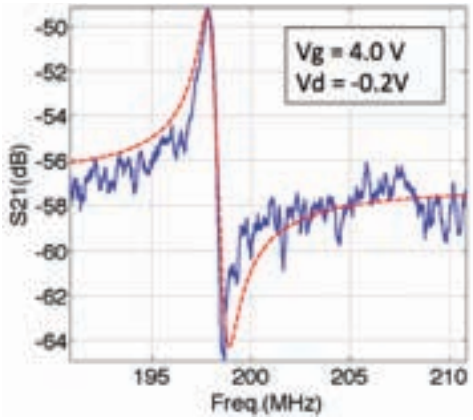

Fig. 8. S_{21} with model fit for a single bias point.

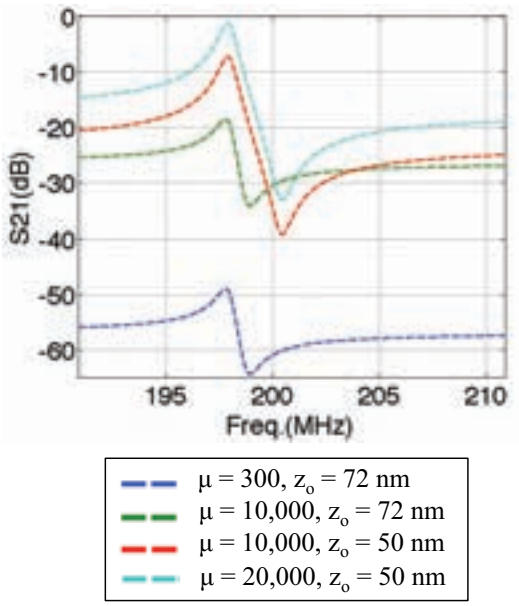

Fig. 9. Projected improvement of GNERs. The bottom trace is identical to the fit in Fig. 8. The other traces are for devices with identical lateral dimensions, but with improved mobility and lower z_0.

to the output current of a typical FET. The fourth term is due to the mechanical motion of the membrane being amplified by the device g_m. Using the extracted mass of the device from Fig 5, and the output current terms given in (4), the S_{21} of the device can be modelled as shown in Fig. 8. This device has a Q of 250 at an f_o of 197.8 MHz. The discrepancy in the model is probably due to capacitive parasitics not accounted for in the model, and spatial nonuniformity in the strain being applied to the graphene.

Fig. 9 shows projections for improved GNER transduction with decreasing z_0, and higher material quality which is reflected in increased μ_{fe}. The bottom trace in the figure is the same fit from Fig. 8. The additional traces are model simulations showing that as mobility is increased to 20,000 cm^2/V-s and z_0 is decreased to 50 nm, the same device may exhibit an IL approaching 0 dB. This IL would make GNERs competitive with existing resonator technologies such as film bulk acoustic resonators (FBARs).

IV. Conclusion

In this work we have shown that the room-temperature Q and f_o of GNERs can be improved by applying additional strain to the graphene membrane using an SU-8 clamp. A small-signal model is presented based on both the electrical and mechanical parameters of the device which shows good agreement with measured data. Although the electrical transport of the graphene used in this study is reduced due to contamination in the fabrication process, projections of resonator performance with improved material quality for a device with similar geometry indicate that GNERs may have IL values that are very comparable with other resonator technologies such as FBARs.

Micromechanical Disk Array for Enhanced Frequency Stability Against Bias Voltage Fluctuations

Lingqi Wu, Mehmet Akgul, Wei-Chang Li, Yang Lin, Zeying Ren, Tristan Rocheleau, and Clark T.-C. Nguyen
Department of EECS, University of California, Berkeley, CA, USA, Email: wulingqi@berkeley.edu

***Abstract*—A 215-MHz polysilicon capacitive-gap transduced micromechanical resonator array employing 50 mechanically coupled radial-contour mode disks—the largest such array yet fabricated and measured—has achieved 3.5× better frequency stability than single stand-alone disks against fluctuations in the dc bias voltage (V_P) normally applied across electrode-to-resonator gaps during device operation. The key to enhanced frequency stability is the electrode-to-resonator capacitance (C_o) generated by the parallel combination of input/output electrodes overlapping each resonator in the array that in turn reduces the efficacy of the bias voltage-controlled electrical stiffness. Here, a new equivalent circuit based on negative capacitance provides improved visualization that helps to identify methods to suppress electrical stiffness induced frequency variation. The circuit model indicates that the more resonators in an array, the smaller the frequency shift imposed by a given bias voltage change. Both modeling and measurement suggest that the most stable MEMS-based oscillators (e.g., against supply noise and acceleration) are ones that utilize mechanically-coupled arrays of resonators.**

***Keywords*—array, negative capacitance, electrical stiffness, micromechanical resonator, frequency stability, capacitive-gap transducer.**

I. Introduction

High-Q capacitive-gap transduced micromechanical resonators constructed via MEMS technology have recently taken center-stage among potential next generation timing and frequency reference devices that might satisfy present and future applications. Notably, oscillators referenced to very high Q capacitively transduced MEMS resonators have already made inroads into the low-end timing market, and research devices have been reported to satisfy GSM phase noise requirements [1] [2]. Meanwhile, such devices have also posted some impressively low acceleration sensitivities, with measured sensitivity vectors less than 0.5ppb/g [3].

Interestingly, theory predicts that the acceleration sensitivity of these devices should be even better than this, if not for frequency instability due to electrical stiffness [3]. Indeed, electrical stiffness is predicted to set lower limits on not only short-term stability, but long-term as well, especially when one considers frequency variations due to charging or temperature-induced geometric shifts [4].

Pursuant to circumventing electrical stiffness-based instability, this work introduces a more circuit design-friendly model that uses negative capacitance to capture the influence of electrical stiffness on device and circuit behavior. This new circuit model reveals that capacitive-gap transduced micromechanical resonators can offer better stability against electrical-stiffness-based frequency instability when used in large mechanically-coupled arrays. Measurements confirm that a 215-MHz 50-resonator disk array achieves a 3.5× enhancement in frequency stability against dc-bias voltage variation over a stand-alone single disk counterpart. The new equivalent circuit predicts the measurement data and its trends quite well, creating good confidence for using this circuit to guide new oscillator and filter designs that, depending on the application, can enhance or suppress electrical stiffness.

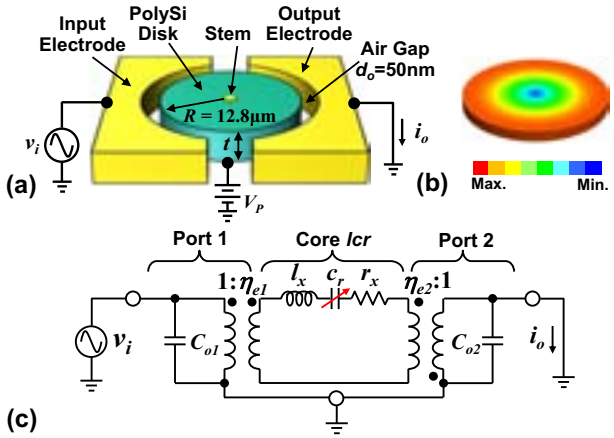

Fig. 1. (a) Schematic of a 215-MHz radial-contour mode polysilicon disk resonator in a two-port excitation and sensing configuration. (b) Radial-contour mode shape. (c) Classic equivalent electrical circuit for a capacitive gap micromechanical disk resonator with electrical stiffness lumped into the variable capacitance c_r.

II. Contour Mode Disk Resonator

Fig. 1(a) depicts a capacitive gap polysilicon contour mode disk resonator in a typical bias, excitation, and detection scheme. This device comprises a 2μm-thick (t=2μm) polysilicon disk supported by an anchored stem attached at the center of the disk and surrounded by two electrodes separated by a tiny 50nm air gap (d_o=50nm). The device is excited into resonance via a combination of a dc-bias voltage V_P applied to the conductive polysilicon resonant structure and an ac signal applied to the input electrode, which together induce a force at the frequency of v_i that drives the disk into a contour mode resonance with equal radial expansion and contraction around its perimeter, as shown in Fig. 1(b), when the frequency of v_i matches the resonance frequency. Once vibrating, the V_P-biased time varying capacitance between the disk and its output electrode generates an output current.

To conveniently model and simulate the behavior of this micromechanical disk resonator, [5] provided expressions for the element values of the electrical equivalent circuit shown in Fig. 1(c), which take the form

$$l_x = m_m,\ r_x = c_m,\ c_r = \frac{1}{k_m - k_e},\ \eta_{en} = \frac{V_P C_{on}}{d_o} \qquad (1)$$

where m_m, k_m, c_m, η_{en}, and C_{on} are the equivalent dynamic mass, mechanical stiffness, damping, electromechanical coupling factor, and electrode-to-resonator capacitance at corresponding ports, respectively. The electrical stiffness k_e models the frequency pulling effect of the force generated by time-varying changes in electric field strength as vibration changes the parallel-plate capacitive electrode-to-resonator gap and can be expressed as [6]

$$k_e = \frac{V_P^2 (C_{o1} + C_{o2})}{d_o^2} = \frac{V_P^2 \epsilon A}{d_o^3} \qquad (2)$$

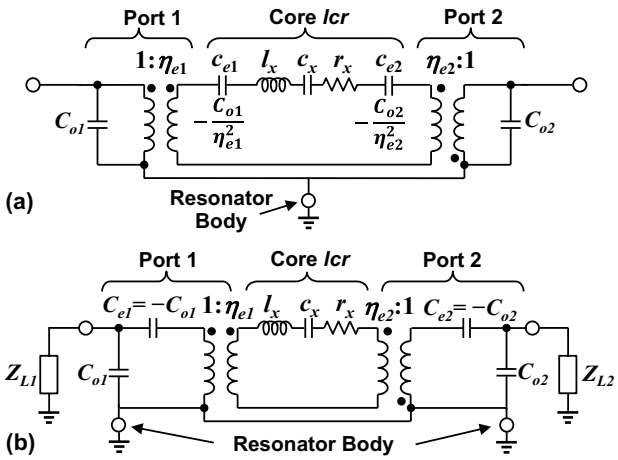

Fig. 2. Negative capacitance small-signal equivalent circuits for a two-port capacitive-gap micromechanical contour mode disk resonator: (a) Negative capacitance equivalent circuit with electrical stiffness separated from mechanical stiffness. (b) Negative capacitance equivalent circuit with electrical stiffness reflected through transformers to outside the core *lcr* loop.

where ϵ is the permittivity of the gap material (i.e., vacuum in this case) and A is the total overlap area between the resonator and its electrodes. Since the force generated by k_e is in phase with displacement and acts to accentuate motion, it acts against the mechanical spring restoring force, so subtracts from the mechanical stiffness, yielding a total resonator stiffness of $(k_m - k_e)$. Changes of any variables in k_e, such as dc-bias voltage noise, capacitance variation due to mechanical vibration, or charging induced bias voltage drift, can cause frequency stability issues for capacitive-gap MEMS resonators [7] [8].

The classic equivalent circuit in Fig. 1(c) models the influence of electrical stiffness on resonance frequency via the arrow through capacitor c_r (that indicates this capacitor is tunable) and by setting the value of c_r equal to $1/(k_m - k_e)$. Although this method for capturing electrical stiffness adequately predicts the resonance frequency, it does not convey clearly to a circuit designer the impact of electrical stiffness on the overall circuit performance. Modeling the electrical stiffness in this way in fact hides some very important capacitive-gap resonator behaviors when emplaced into certain circuits. This model also encourages designers to dismiss the impact of electrical stiffness, since many designers just neglect the k_e part in the value of c_r when drawing up equivalent circuits.

III. Negative Capacitance Equivalent Circuit

To remedy the above deficiencies, the circuit of Fig. 2(a) explicitly models the electrical stiffness contributed by each electrode-to-resonator gap as separate negative capacitors c_{en}, where *n* denotes the port. Using (1) and (2), c_{en} becomes

$$c_{en} = -\frac{1}{k_{en}} = -\frac{d_o^2}{V_P^2 C_{on}} = -\frac{C_{on}}{\eta_{en}^2} \tag{3}$$

Here, c_{en} entirely captures the electrical stiffness, allowing c_x in Fig. 2(a) to represent the pure mechanical stiffness. Further reflecting the negative capacitors c_{en} through the transformers on both sides to outside the core *lcr* loop yields C_{en} in the circuit of Fig. 2(b) as follows:

$$C_{en} = \eta_{en}^2 c_{en} = -C_{on} \tag{4}$$

where the physical shunt electrode-to-resonator capacitors C_{on} are now matched by negative capacitors with identical values. This new circuit reveals the potential for cancellation of the C_{on}'s in certain circuit configurations, which where possible, would remove entirely frequency changes induced by electrical stiffness, thereby stabilizing the frequency against all variables in (2)—something highly desirable for oscillator applications that require very high frequency stability.

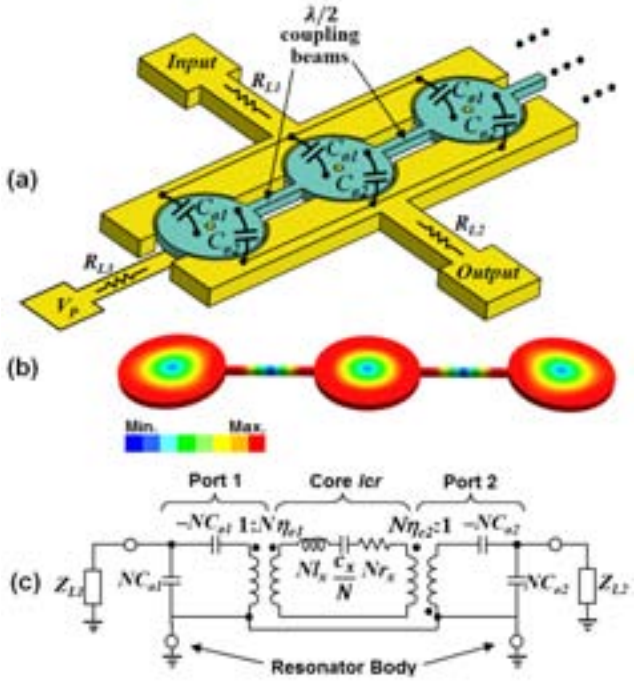

Fig. 3. (a) Schematic of a disk array-composite resonator with disks linked by λ/2 coupling beams to enforce in phase vibration of each individual resonator. (b) Simulated modal depiction of a 3-resonator disk array with all disks vibrating in phase in radial-contour shapes. (c) Negative capacitance equivalent circuit of a disk array-composite with *N* resonators based on element values of the single resonator equivalent circuit in Fig. 2(b)

Pursuant to determining which circuit configurations best promote k_e cancellation, Fig. 2(b) adds load impedances Z_{Ln}. In order for C_{on} to negate the electrical stiffness represented by $-C_{on}$, approximately same amount of current should flow through C_{on} and $-C_{on}$, which indicates that C_{on} should pass most of the current flowing into the parallel combination of C_{on} and Z_{Ln}. In other words, the impedance of Z_{Ln} should be much larger than that of C_{on}, or

$$|Z_{Ln}| \gg \frac{1}{\omega_o C_{on}} \tag{5}$$

From (5), to reduce electrical stiffness, both Z_{Ln} and C_{on} should be large. If Z_{Ln} has no reactive component, operation at high frequency also suppresses electrical stiffness. To address cases where a resonator might be used with reconfigurable drive and sense circuits that present non-constant loads, and to reap the motional resistance and power handling advantages of arrays, this work focuses on coupled-array-based methods to increase C_{on} towards better frequency stability against changes in electrical stiffness.

IV. Micromechanical Disk Array

Fig. 3(a) presents a micromechanical disk array-composite constructed by mechanically linking individual disk resonators via half-wavelength coupling beams. Here, coupling of resonators yields a coupled multi-mode system, where at each mode, all resonators vibrate at precisely the same frequency [9], allowing their outputs to be combined to boost input and output currents, thereby decreasing the motional resistance and increasing power handling. As first demonstrated in [1], the use of half-wavelength couplers both insures that all resonators vibrate in phase, as shown in Fig. 3(b); and spreads the mode

TABLE I. COMPARISON OF EQUIVALENT CIRCUIT ELEMENT VALUES FOR A 50-RESONATOR DISK ARRAY AND A SINGLE DISK RESONATOR

Parameters	Single Disk Resonator	Disk Array with N=50
C_{on} (fF)	9	451
η_{en}	1.58×10^{-6}	7.91×10^{-5}
l_x (H)	1.81×10^{-12}	9.03×10^{-11}
r_x (Ω)	1.17×10^{-7}	5.85×10^{-6}
c_x (F)	3.29×10^{-7}	6.59×10^{-9}

frequencies apart, making it easier to select a specific mode (when only one is wanted, e.g., in an oscillator application) by proper electrode phasing. Of course, this coupled array strategy not only produces a larger total output current and smaller motional resistance [10], but also attains much larger electrode-to-resonator overlap capacitors C_{on}, and thus reduces the electrical stiffness and its associated instability, according to (5).

For a disk array with N mechanically coupled disk resonators, the stiffness k_m, mass m_m, damping c_m, electromechanical coupling factor η_{en}, and electrode-to-resonator overlap capacitance C_{on} are all N times larger than for a single disk resonator. Thus, simple multiplication or division by N is all that is needed to derive coupled array equivalent circuit element values from those of a single disk resonator, as shown in Fig. 3(c). Note that although the electrical stiffness goes up by N according to (2), so does the mechanical stiffness, so their ratio k_e/k_m remains the same and the fundamental efficacy by which k_e pulls the frequency, as governed by

$$f_o = f_{nom}\sqrt{1-\frac{k_e}{k_m}} \qquad (6)$$

does not increase (where f_o is the resonance frequency and f_{nom} is the nominal resonance frequency with no electrical stiffness). Instead, with C_{on} presenting a much smaller impedance, more current flows through C_{on} than Z_{Ln}, allowing it to cancel more of C_{en}, thereby negating the electrical stiffness induced frequency instability via circuit interaction.

TABLE I summarizes the equivalent circuit element values for a 215-MHz 50-nm-gap disk array using 50 resonators (with Q=20,000 and V_P=10V) and compares them with that of a stand-alone single disk resonator. With a 451fF electrode-to-resonator overlap capacitance much larger than the 9fF of a single disk, the 50-resonator array should greatly suppress electrical stiffness induced frequency instability.

V. FABRICATION PROCESS

The fabrication process for the all-polysilicon contour mode disk resonator arrays of this work deviates from previous ones, such as that of [11], in that it does not use self-aligned peg-stem anchors and it employs chemical mechanical polishing (CMP) to remove electrode overhangs. The process begins with film depositions and etches identical to those of [11] to achieve the substrate isolation layer, polysilicon interconnects, and the bottom sacrificial layer. At this point, unlike previous self-aligned processes, a mask is used to define, pattern, and etch stem anchor holes into the bottom sacrificial oxide, followed by a 2-μm LPCVD in-situ doped polysilicon film that fills the holes to form the stems and serves as the resonator structural material. Here, an AMSL300 DUV Stepper is used to realize very precise alignment, with less than 100nm error—good enough to achieve Q's comparable to those of devices with self-aligned stems.

After depositing an oxide hard mask over the structural polysilicon, disk devices and coupling links are patterned and

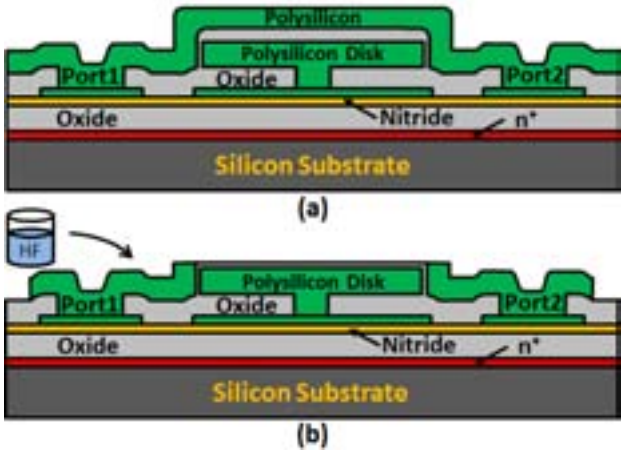

Fig. 4. Cross-sections showing the last few steps in the fabrication process for a 215-MHz all-polysilicon disk resonators with CMPed electrodes.

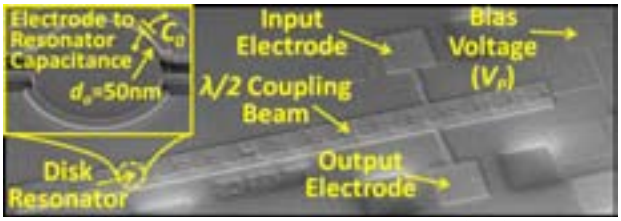

Fig. 5. SEM of a 215-MHZ 50nm capacitive-gap transduced contour mode disk array employing 16 mechanically coupled resonators.

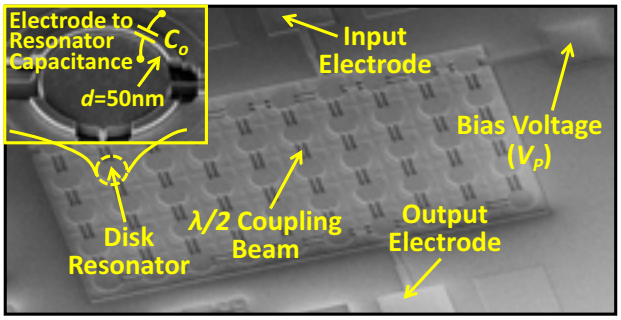

Fig. 6. SEM of a 215-MHZ 50nm capacitive-gap transduced contour mode disk array employing 50 mechanically coupled resonators.

etched as before, the gap-defining sacrificial sidewall oxide spacer is deposited, electrode to interconnect contact vias are etched, and the polysilicon electrode material LPCVD'ed 3-μm thick, all to yield the cross-section of Fig. 4(a). At this point, the process again deviates from that of [11] in that before patterning and etching the electrodes, the top polysilicon is first CMP'ed down to the hard mask. This step removes the electrode overhangs of Fig. 4(a), achieving the cross section of Fig. 4(b), and in the process greatly increasing the pull-in voltage of these devices, where contact between the disk and the electrode overhang is often the first to occur when dc-bias voltages increase. As before, devices are released in 49 wt. % hydrofluoric acid for ~40min.

Fig. 5 and Fig. 6 present SEMs of fabricated 215-MHz 50-nm capacitive-gap transduced half-wavelength-coupled disk arrays employing 16 and 50 resonators, respectively, in straight line and rectangular placement configurations.

VI. EXPERIMENTAL RESULTS

To gauge the degree to which arraying enhances frequency stability against dc-bias voltage changes, measured plots of frequency versus dc-bias voltage are in order, for both mechanically coupled disk array-composite resonators using various numbers of resonators, as well as for a single stand-alone disk for comparison. To this end, measurements were made under a

2μtorr vacuum environment in a Lakeshore FWPX vacuum probe station and using an Agilent E5071C network analyzer in the direct two-port excitation and sensing scheme depicted in Fig. 1(a). Fig. 7 presents measured curves that clearly show a shrinking frequency dependence on dc-bias voltage as the number of resonators used in an array increases. In particular, the 50-resonator 215-MHz disk array experiences a 20ppm frequency change when V_P varies over a 7V span, from 2V to 9V, 3.5× smaller than the 70ppm of a stand-alone device.

To confirm the validity of the negative capacitance equivalent circuit of Fig. 3(c), simulated plots using this circuit are also included in Fig. 7, showing very good agreement between theory and measurement. These simulations assume the load impedance Z_{Ln} derives from a combination of series trace resistance R_{L1} and R_{L2} from input/output electrode leads, as well as similar lead resistance R_{L3} from the V_P port, all shown in Fig. 3(a). Since probe coax and bond pad capacitance are nulled by calibration, the Z_{Ln} in these measurements is mainly resistive. It should be noted that the total equivalent load resistance $R_{Ln,tot}$ of a disk array in this work is generally larger than that of a single resonator and actually increases with the number of disks in the array. This comes about because, at least in the current layout, the distance between the V_P pad and the furthest resonator increases as the number of resonators increases, as seen from Fig. 5, resulting in a corresponding increase in series resistance R_{L3}. TABLE II summarizes overlap capacitance and equivalent load resistance values for disk arrays with N=1, 8, 16, and 50, clearly showing larger values as the number of resonators increases, at least for straight line arrays with N=8 and N=16, like that of Fig. 5. The series resistance of the 50-resonator array depicted in TABLE II is actually smaller than those of the 8- and 16-resonator ones, since its layout uses a rectangular or matrix topology, rather than a straight line, so the average distance of its resonators from its V_P pad ends up being smaller.

According to (5), increases in load resistance like those in TABLE II should also contribute to an overall nulling of the electrical stiffness, and thereby enhance frequency stability against dc-bias voltage fluctuations. Indeed, as the number of array resonators increases, electrical stiffness erodes due to increases in both electrode-to-resonator overlap capacitance and load resistance—a double whammy effect perfectly predicted by the negative capacitance equivalent circuit.

VII. Conclusions

The 50-resonator capacitive-gap transduced micromechanical disk array demonstrated here is the largest such array yet fabricated and measured and enables a mere 20ppm frequency change over a 7V dc-bias voltage variation−−a 3.5× reduction over a single stand-alone disk resonator counterpart. That the new negative capacitance equivalent circuit model introduced perfectly predicts this phenomenon, while also aiding circuit visualization, bodes well for its continued use in future resonator circuits for which tailored electrical stiffness strengths are desired. Indeed, the demonstrated stability enhancing attributes of mechanically-coupled arrays that make them less vulnerable to dc-bias voltage noise, dielectric charging, and external vibrations, together with already demonstrated array-derived reductions in the standard deviation of array resonance frequency [12], present strong cases for a more prevalent use of arrays in next generation MEMS-based frequency reference devices.

***Abstract*—Vibrating nanoelectromechanical systems (NEMS) made of atomically-thin two-dimensional (2D) crystalline nanostructures have demonstrated attractive potential for making new actuators and sensors. Nanoscale devices in new types of 2D materials are generally first obtained by mechanical exfoliation, which can often lead to irregular and asymmetric geometries. Here we investigate irregular molybdenum disulfide (MoS_2) nanoflakes and ultrathin 2D nanomechanical resonators at high & very high frequencies (HF/VHF). We explore the effects of irregularities and imperfections, such as incomplete drumhead structures partially covering microtrenches, upon the device characteristics. We observe that such irregular and seemingly nonideal boundary conditions with free edges do not compromise device performance. Instead, they provide an additional geometrical degree of freedom which allows novel engineering of the device vibrations, such as controlling the mode shape and mode index, and tuning the frequency ratios between different resonant modes. This capability may be interesting for designing multimode resonators in nanomechanical circuits.**

Keywords—molybdenum disulfide (MoS_2); two-dimensional (2D) crystal; nanoelectromechanical systems (NEMS); resonator; boundary condition; mode shape; multimode resonance

I. Introduction

Two-dimensional (2D) layered materials have attracted significant research interests for their unique properties and technological potential for novel nanodevice applications [1–4]. Started with graphene, new 2D materials continue to be isolated and explored. Early explorations into these 2D materials and devices have been mostly based on samples obtained by mechanical exfoliation [5–7]. This technique allows researchers to quickly access nanostructures isolated from the new layered materials and study their properties. Practical exfoliation processes of today (*e.g.*, the 'Scotch tape' method), however, can often lead to random sizes and shapes for the structures of interest. Such structural irregularities may be particularly relevant in 2D nanoelectromechanical systems (NEMS) made of suspended ultrathin crystals. Specifically, in drumhead-structured NEMS resonators made by exfoliated 2D crystals covering microtrenches [8], what would be the effects of incomplete coverage and hence a new configuration of the boundary condition? This irregularity has not yet been studied systematically. Often devices with such structures are deemed nonideal, defective, and may be simply discarded and never studied. In this work, we carefully assess the impact of the incomplete coverage boundary condition on exfoliated MoS_2 drumhead HF/VHF nanomechanical resonators. We show that the incomplete clamping does not compromise device performance; rather, it leads to interesting mode crossing and controllable spacing between multimode resonances.

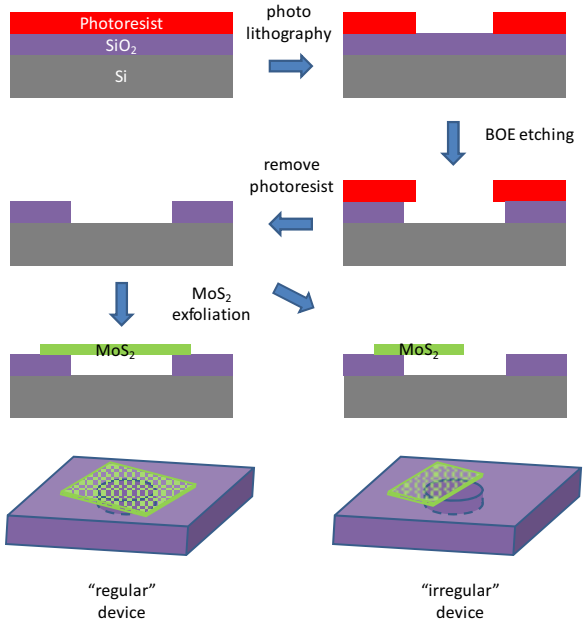

Fig. 1. Illustration of fabrication process for making MoS_2 nanomechanical resonators: spinning coating of photoresist on the SiO_2/Si wafer; defining pattern with photo lithography; BOE etching of SiO_2; removing photo resist; mechanical exfoliation of MoS_2. The schematics of both "regular" (MoS_2 flake fully covering the microtrench) and "irregular" (MoS_2 flake partially covering the microtrench) devices are shown at the bottom.

II. Experimental Techniques

A. Device Fabrication

The devices are prepared by mechanically exfoliating MoS_2 so that MoS_2 flakes are suspend on microtrenches in a 290nm-thick SiO_2 thermally grown on Si substrate. The microtrenches are predefined by photo lithography, followed by a buffered

oxide etch (BOE) to remove the exposed SiO_2. The etch time is controlled such that the entire depth (290nm) of SiO_2 is removed, exposing the flat Si surface underneath [8]. The resulting wafer has arrays of flat-bottom microtrenches. MoS_2 flakes covering the microtrenches make drumhead-structured nanomechanical resonators. Mechanical exfoliation of MoS_2 is more challenging than that of graphene, generally resulting in lower yields and smaller flakes, especially for suspended devices. Small flakes sometimes do not completely cover the microtrenches, enabling partially clamped drumhead structures. Figure 1 shows schematics of the device fabrication process and the resulting fully and partially clamped structures.

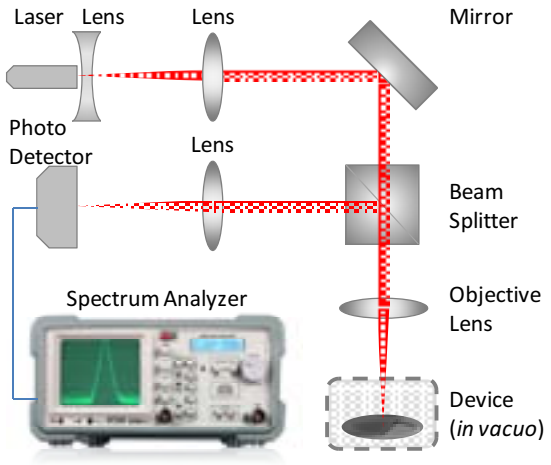

Fig. 2. Simplified schematic of the laser interferometry system for detection of MoS_2 nanomechanical resonance. The laser spot is focused onto the device surface, and reflected light is directed towards the photo detector by the beam splitter. The signal from the photo detector is fed to a spectrum analyzer.

B. Measurement Apparatus and Techniques

Nanomechanical resonances of the MoS_2 drumhead devices are measured using an optical readout technique. A simplified schematic of the measurement system is illustrated in Fig. 2. In our custom-built interferometry setup, the laser beam from a 633nm He-Ne laser first goes through a beam expander followed by a 50× microscope objective lens with optical window correction (NA=0.5). The laser is focused on the MoS_2 nanosheet and the spot size is ~1μm. The interference between light waves reflected from the MoS_2 nanosheet and the underneath reflecting Si surface determines the intensity of the optical signal from the device. Out-of-plane motion of the MoS_2 nanosheet modulates the interferometric output signal and can be analyzed in frequency domain. The interferometric signal is detected by a low-noise photodetector (PD), and fed into a spectrum analyzer. The ultrahigh motion sensitivity of the measurement system allows us to detect the minimal motions of the MoS_2 nanosheets arising from intrinsic thermomechanical fluctuations and thus find their thermo-mechanical resonances without external driving. We adjust on-device laser power to be ≤500μW, so that heating effect is negligible (no heating-induced frequency change within the range of applied power), while maintaining a good signal-to-noise ratio. All our measurements are conducted in moderate vacuum (p~6mTorr) at room temperature (T~300K).

III. Results and Discussions

Figure 3 demonstrates measured resonance response from a typical device with geometrical irregularity of partial coverage and incomplete clamping boundary condition. As shown by the wide-range frequency response and individual resonance curves, such devices often exhibit multiple resonances in the HF/VHF bands. The dashed red lines in these plots show the fit to the model of damped harmonic resonator with finite quality (Q) factors, demonstrating excellent agreement.

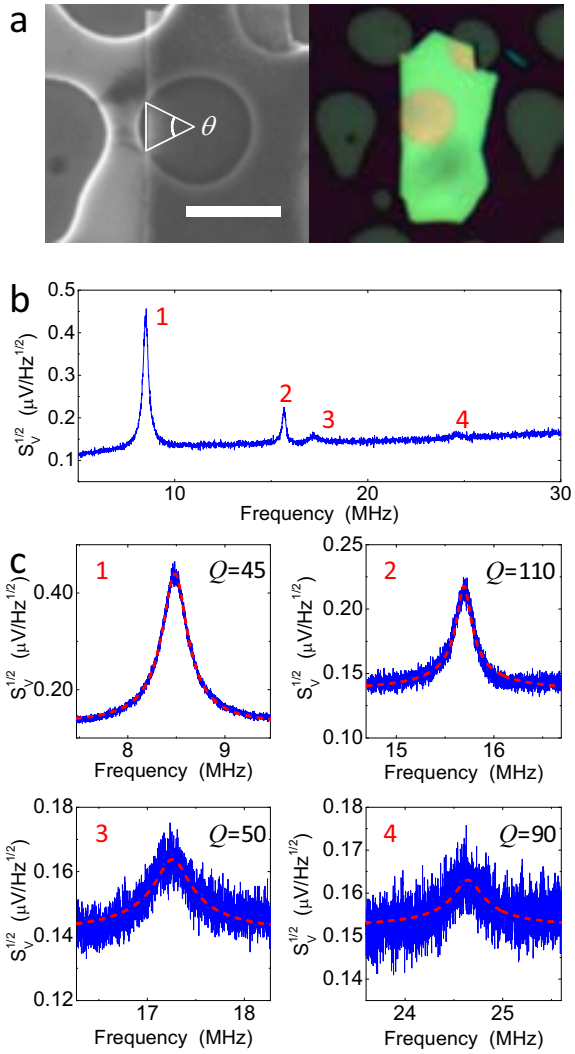

Fig. 3. Measured resonance response from a typical device based on a MoS_2 nanoflake partially covering the microtrench. **a**. SEM and optical image of the device. Scale bar (SEM only): 5μm. The definition of 'open angle' θ is shown in the SEM image. **b**. Measured thermomechanical noise spectrum, showing multiple resonances. **c**. High-resolution frequency scans centered around each of the individual thermomechanical resonances.

We have measured multiple devices with and without this type of geometric irregularity (*i.e.*, both partially covered and fully covered), and observe robust resonance behavior in both categories, with resonance frequencies and Q factors in similar ranges. Table 1 lists the measured devices. The devices with MoS_2 flakes completely covering the microtrench (and thus do

not have this type of geometric irregularity) are shown in bold font (*i.e.*, devices #5 and #6).

TABLE I. PARAMETERS OF MEASURED VHF MoS_2 RESONATORS

Device ID #	Device SEM Image	Micro-Trench Diameter d (μm)	MoS_2 Thickness t (nm)	1st Mode Resonance Frequency f_1 (MHz)	Quality Factor Q
1		2.69	62.2±0.7	48.1	200
2		2.41	57.5±2.1	43.77	160
3		2.53	43.0±1.4	53.72	370
4		5.99	30.3±0.3	48.10	70
5		**1.90**	**6.1±0.7**	**49.70**	**80**
6		**1.51**	**27.2±0.5**	**57.89**	**80**

To quantify the degree of geometric irregularity in the incompletely clamped devices, we define the 'open angle' θ, as shown in Fig. 3a. It corresponds to the center angle of the open arc where the portion of the flake is not clamped and has a free edge. To fully understand how mode shape and resonance frequency of each mode varies with this geometric irregularity, we perform finite element modeling (FEM, using COMSOL) for the first three resonance modes of MoS_2 resonators (see Fig. 4, *dashed lines*: d=1μm and t=100nm; *symbols*: d=10μm and t=10nm) with varying θ values between 0º and 180º.

We make a few observations from the simulation results, as shown in Fig. 4. First, the effect of partial coverage on the resonance frequency (f_i, i being the mode number/index) is not monotonic. Take the lowest mode f_1 for example: as θ increases, f_1 first decreases and then increases. The other two modes (f_2 & f_3) also show similar dependence on θ. Second, the detailed shapes of the $f_i(\theta)$ curves, such as the position of the minimum, depend on the individual mode. Mode crossing between the second and the third lowest mode is observed at θ≈137º. Third, the $f_i(\theta)$ tendency does not depend on the dimensions of the device. Varying the thickness and the lateral size of the resonator structure does not affect the shapes of the $f_i(\theta)$ curves. For a larger thin device (d=10μm, t=10nm) and a smaller thick device (d=1μm, t=100 nm), the simulation results completely overlap each other after rescaling in frequency, despite the 100 fold difference in aspect ratio (d/t).

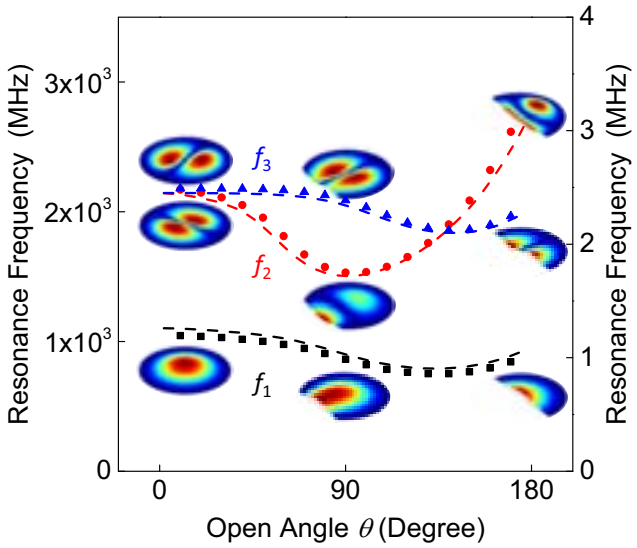

Fig. 4. Computed resonance frequencies and mode shapes for the three lowest modes for MoS_2 resonators with open angle $0<\theta<180$º. The three different colors denote the three modes. Calculations are shown for a small/thick device (*dashed lines*: d=1μm, t=100nm, left y axis) and a large/thin device (*symbols*: d=10μm, t=10nm, right y axis). The θ=0 case corresponds to the fully covered geometry.

These observations on the $f_i(\theta)$ curves clearly suggest a possibility of mode shape engineering and frequency control by designing and tuning the device's θ value. For fully covered devices (θ=0 only), one is limited with the frequency ratios between the modes, and with some degenerate mode pairs (usually appear as pairs with random, uncontrollable frequency splitting). With $\theta\neq$0, one can adjust the θ value and choose many possible frequency ratios between different modes within the allowed range, and the sequence of mode shapes can also be changed by choosing the proper θ values.

The observed behavior can be qualitatively understood by examining the interplay between two effects that depend on θ: (i) the change in the clamping boundary condition with varying θ, and (ii) the decrease in resonator size and mass as θ increases. Resonators with more clamped ends or boundaries can have higher resonance frequencies than their counterparts with free ends/edges, as more clamped edge provides more restoring force and thus a larger effective spring constant. In the range of small θ values, the effect of decreasing drumhead coverage is mostly reducing the clamping edge. This effect can be visualized in the mode shape. At θ=90º, the larger-displacement region in the center of the disk clearly 'diffuses' towards the free edge where the clamping condition is eased due to the missing coverage and lack of clamping. The resulting softening of the overall spring constant leads to lower resonance frequency. As θ continues to increase, the effect of decrease in resonator size (and hence the device mass) becomes dominant, and the frequency increases again.

Similarly, the behavior of the higher modes in Fig. 4 can be understood. For convenience, here we call each continuous area enclosed by nodal lines a 'motional region'. For the second mode f_2 whose nodal line in the mode shape is parallel to the free edge (the second lowest mode at low θ values), it has two motional regions. As the free edge starts to move inward, the outer motional region (the one closer to the free edge) quickly loses its clamped length at boundary as θ increases, while losing its device area at a slower pace. This effect takes place on f_2 faster than on the first mode f_1, because for each value of θ a larger fraction of the outer motional region in the f_2 mode is being removed compared with the motional region in the f_1 mode. This results in the initial faster decrease in f_2. As θ continue to increase, in this f_2 mode the nodal line start to move away from the free edge, which effectively decrease the size of the inner motional region (the one away from the free edge) and thus increases f_2. This effect is more pronounced as θ approaches 180º, when the outer motional region is most gone and effect is almost entirely on downsizing the inner motional region, which results in the fast increase in f_2 and mode crossing of f_2 becoming larger than f_3.

In the third mode f_3, where the nodal line is perpendicular to the free edge, the drumhead is divided into two motional regions that are equally affected by the advancing of the open arc and free edge. For both of the two motional regions, the ratio between clamping and surface area changes at roughly the same rate as that for the single motional region in the lowest resonance mode f_1. Therefore, the change in its resonance frequency f_3 follows a similar tendency as the lowest mode f_1, and at higher θ values, f_3 is surpassed by the second mode f_2.

We can also use a simple analytical model to qualitatively describe this behavior. We start with θ=0 (a fully covered, fully clamped device), as illustrated in Fig. 5a. For the lowest mode with full azimuthal symmetry, the potential energy of such a device with out-of-plane flexural deflection $w(r,\theta)$ is

$$U = \frac{D}{2}\int_0^{2\pi} d\varphi \int_0^R \left(\frac{\partial^2 w}{\partial r^2} + \frac{1}{r}\frac{dw}{dr}\right)^2 r dr, \qquad (1)$$

where $D=E_Y t^3/[12(1-\nu^2)]$ is the bending rigidity (E_Y is Young's modulus, t is thickness, and ν is Poisson's ratio). Its effective spring constant can be estimated accordingly, by

$$k_{eff} = \frac{d^2}{dw_{eff}^{\ 2}} U = \int_0^{2\pi} d\varphi \times \frac{D}{2}\frac{d^2}{dw_{eff}^{\ 2}} \int_0^R \left(\frac{\partial^2 w}{\partial r^2} + \frac{1}{r}\frac{dw}{dr}\right)^2 r dr \cdot \qquad (2)$$

For situations with $\theta \neq 0$ (Fig. 5b), assuming all the restoring force comes from the clamped edge, the effective spring constant can be written as

$$k_{eff} = \frac{d^2}{dw_{eff}^{\ 2}} U = \int_0^{2\pi-\theta} d\varphi \times \frac{D}{2}\frac{d^2}{dw_{eff}^{\ 2}} \int_0^R \left(\frac{\partial^2 w}{\partial r^2} + \frac{1}{r}\frac{dw}{dr}\right)^2 r dr, \qquad (3)$$

by extending the assumption of azimuthal symmetry for first order approximation. Therefore

$$k_{eff} \propto (2\pi - \theta). \qquad (4)$$

With similar assumptions and approximations the effective mass of the resonator is found to be proportional to the surface area of the resonator,

$$m_{eff} \propto \left[(2\pi - \theta) + \sin(\theta/2)\cos(\theta/2)\right]. \qquad (5)$$

In Fig. 5c we plot the normalized resonance frequency $f_1(\theta)/f_1(\theta=0)$, using Eqs. (4) and (5). It clearly captures the main features of the f_1 mode shown in Fig. 4, *i.e.*, f_1 first decreases then increases, between θ=0º and θ=180º.

Schematics of the clamping conditions for completely and incompletely covered devices. **c**. Calculated ratios (normalized quantities) using Eqs. (4) & (5).

IV. Conclusions

In summary, we have demonstrated using irregular MoS_2 nanoflakes for making HF/VHF nanomechanical resonators with robust performance and interesting multimode characteristics that are comparable to or even better than in their counterpart ideal structures. In combination with FEM and intuitive modeling, we show the possibility of mode shape engineering and frequency control by exploiting this additional geometric degree of freedom, *i.e.*, the open angle θ, degree of coverage in incompletely clamped drumhead structures.

Abstract— **Miniaturized, multi-band and high frequency oscillators that are compatible with CMOS processes are highly desirable for the synthesis of compact, stable, and low power frequency sources for reconfigurable radio frequency communication systems and cognitive radios. Aluminum nitride (AlN) contour mode MEMS resonators (CMR) are emerging devices capable of high *Q*, low impedance, and multi-frequency operation on a single chip. The frequency stability of these AlN MEMS devices is of primary importance in delivering oscillators that exhibit low phase noise, and low sensitivity to temperature and acceleration. In this article we describe how the resonator dynamics impacts oscillator performance and present some preliminary demonstrations of ultra-high-frequency (UHF) oscillators. An example of an oscillator prototype we synthesized with a 586 MHz AlN CMR exhibited phase noise < - 91 dBc/Hz and – 160 dBc/Hz at 1 kHz and 10 MHz offsets, temperature stability of 2 ppm from - 20 to + 85 ºC, and acceleration sensitivity < 30 ppb/G.**

I. INTRODUCTION

Low phase noise (PN) frequency sources from 100 MHz to 1.5 GHz rely on mechanical resonators such as quartz crystals and surface acoustic wave devices to form stable references. Despite the impressive performance, these components cannot be directly integrated with CMOS electronics, are relatively bulky and are far from attaining the ultimate size, weight and power consumption that would be desirable for high-end commercial, industrial, and especially military applications. Furthermore, the synthesis of next generation highly reconfigurable radio frequency (RF) systems and cognitive radios hinges upon the deployment of new components that are smaller in size, are CMOS integrable, and can be dynamically reconfigured.

Thin film micro and nanoscale resonators have emerged as a promising class of devices to address these needs and synthesize stable frequency sources [1-6]. Thin film piezoelectrics have shown to be the only viable transduction mechanism to demonstrate Ultra High Frequency (UHF) references. Aluminum nitride (AlN) contour-mode resonators (CMR) [5, 6] can provide high *Q* and low motional impedance and are especially suited for the implementation of CMOS-integrable multi-frequency sources on a single chip.

Nonetheless, the ultimate performance of these devices is hindered by their miniaturized dimensions, their complex dynamics and the unknown noise mechanisms associated with it. In this summary paper we explain how the non-linear dynamics of the AlN resonators are due to self-heating. Furthermore, we experimentally show how the dynamics of the resonator can be exploited to evade amplifier noise and reduce the close-in PN of the oscillator. We also present measurement results of the intrinsic noise of these resonators in an open-loop configuration, a particularly challenging task at high frequencies, but of paramount importance in order to fully understand the limiting mechanisms of phase noise.

With the aim of delivering temperature stable oscillators, we introduce geometrical variations in the resonator layout to enable low power ovenization. Preliminary demonstration of UHF sources have yielded oscillators with PN < -91 dBc/Hz and – 160 dBc/Hz at 1 kHz and 10 MHz offsets for a 586 MHz carrier, temperature stability of 2 ppm from - 20 to + 85 ºC, and acceleration sensitivity < 30 ppb/G.

II. DYNAMICS OF MICROSCALE ALN MEMS RESONATORS

A. Principle of Operation of AlN MEMS Resonators

AlN CMRs (Fig. 1) are devices formed by a c-axis oriented thin film of AlN sandwiched between metal electrodes. The top electrode is generally patterned into interdigitated electrodes in a manner similar to what is done with surface acoustic wave (SAW) devices. The bottom electrode is used to confine the electric field and excite what is known as a symmetric lamb wave mode. The electrode configuration ensures that the CMR has a high electromechanical coupling (generally 1 % < k_t^2 < 2.5 %). The sound velocity of CMRs is about twice the one of a SAW device built with the same

The project was funded by the DARPA MTO through the MESO/DEFYS program. Award n. FA86501217264

material set. Hence the period of the interdigitated electrodes, which is used to define the center frequency of the CMR, is about twice the size of a SAW resonator. The CMR, being formed by a suspended membrane, can attain a higher Q than a thin film SAW device. Qs ranging from 2,000 to 4,000 in air have been recorded from 20 MHz to 1 GHz. Recent studies have shown that damping in the CMR is mostly affected by anchor loss [7] below 500 MHz, whereas interfacial dissipation dominates above 500 MHz. The device geometry has been optimized to mitigate anchor losses [8], improve k_t^2 [9], and minimize spurious modes [10]. The resonator k_t^2 and Q have a direct impact on the performance of an oscillator. A high k_t^2 helps reducing the power required to sustain oscillations, and ultimately improves the oscillator phase noise (PN) floor as the resonator has a lower motional resistance. In general, a high Q reduces the power required to attain a certain PN value.

B. Fabrication of AlN MEMS Resonators

The AlN CMRs are fabricated by using standard processes that are common to the seminconductor industry for the making of integrated circuits [6]. The repeatable synthesis of these devices has been enabled by the development of low temperature sputtering processes for the deposition of highly oriented AlN thin films [11]. Being the device formed by a dielectric and two metal electrodes, the methods for deposition of the main materials and their patterning are compatible with complementary metal oxide semiconductor (CMOS) devices. Demonstration of direct integration of AlN CMRs with CMOS processes has been reported in the literature [12]. Additionally, efforts for large scale 3D heterogeneous integration of these devices with CMOS are ongoing.

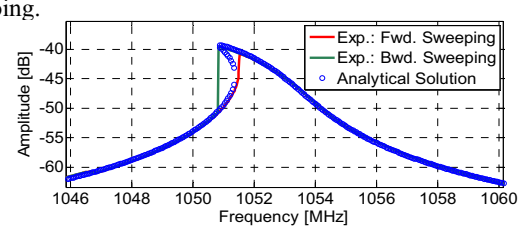

Figure 2. Characteristic non-linear admittance response (amplitude only) of a 1 GHz AlN CMR at high power. Experiments were fit by a duffing-like system of non-linear equations.

C. Non-Linear Dynamics of AlN MEMS Resonators

When driven by high power levels, the AlN CMRs exhibit Duffing-like non-linearity. Our studies on amplitude-frequency (A-f) response and intermodulation distortion have revealed that the source of this non-linearity is the self-heating of the resonator [13, 14]. We have labeled this non-linearity as thermal, as it is highly dependent upon the temperature coefficient of frequency of the CMR and its thermal time constant (Fig. 2). The resonator non-linearity has a direct impact on the performance of an electronic oscillator. The A-f effect converts the resonator amplitude noise into phase noise modulation, hence worsening the oscillator performance. On the contrary, non-linearity could be advantageously exploited to improve PN. A proper design of the oscillator operating point could ensure noise cancellation [15, 16]. As SAW devices resort to temperature compensated substrates, in most cases they do not exhibit this kind of non-linearity.

III. ALN MEMS BASED OSCILLATORS

A. Oscillator Design

Being the motional impedance of the CMR similar in value to the one of a SAW device, the same design techniques used for the synthesis of SAW oscillators can be adopted for CMRs. In most cases, a single transistor (or a coupled pair in the case of a differential solution) is used to sustain oscillations. Pierce and Colpitts oscillators are the most common configurations (Fig. 3). Either discrete or on-chip amplifiers have been used to sustain oscillations. In either case, the resonator is connected to the amplifier through wirebonds to traces designed on a printed circuit board (PCB). Si, SiGe and GaAs transistors have all been tested for the synthesis of AlN CMR oscillators.

Given the motional impedance of the resonator, the Barkhausen criterion is readily met by various values of the coupling capacitors (C_g and C_d in Fig. 4). Their value is generally set so as to minimize power consumption in the oscillator and eliminate any parasitic oscillation at high frequency. For a given motional impedance, power consumption in an oscillator tends to increase with the square of the frequency. This aspect needs to be taken into account when evaluating the performance of an oscillator. The figure of merit (FoM) of an oscillator takes this into account by scaling the PN performance by the amount of power consumption required to achieve such value.

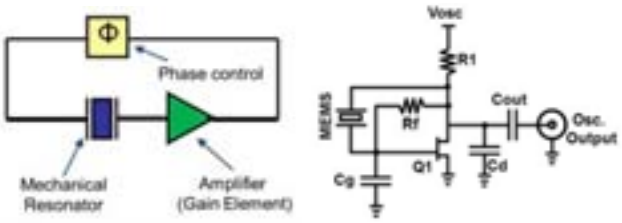

Figure 3. (left) Schematic representation of a closed loop oscillator. The resonator is the frequency setting element, whereas the amplifer is used to adjust the gain vs. frequency. Phase is separately adjusted to control the resonator operating point in a closed-loop system. (right) Schematic circuit of a simple Pierce oscillator used to demonstrate UHF oscillators. Transistor Q1 is used to sustain oscillations. A proper operating point, set by change the phase in the feedback loop, can ensure phase noisce canceling.

More details on the specific design of the oscillator circuit can be found in [17, 18].

B. Noise Sources and Methods to Attain Minimum Phase Noise

The main noise sources in an oscillator are either white phase fluctuations (generally encountered in any device due to Brownian motion) or flicker phase and frequency fluctuations, respectively in the sustaining amplifier or the resonator. The latter are known as parametric noise sources and do not scale

with the output power. Additional phase noise can also be generated by amplitude-frequency conversion due to non-linearity in the resonator.

The oscillator floor is generally set by the amplifier noise figure and the amount of power handling in the resonator. A lower noise figure and higher power handling will linearly improve the PN floor of the oscillator. These improvements occur for offset frequencies above the resonator mechanical time constant, known as the Lesson's frequency ($f_o/2Q_{loaded}$, where f_o is the resonator center frequency and Q_{loaded} is the loaded Q of the resonator in the circuit).

The phase diffusion of the amplifier (either white or flicker) is processed by the resonator dynamics. The resonator acts as an integrator and divides the power spectral density of the noise by f^2 for offset frequencies below the Lesson's frequency. This means that, in the case of additive white noise, a higher Q will reduce the amplifier and resonator noise, for a given oscillator output power. In the case of amplifier parametric noise, the output power will not scale the overall PN, but the Q would set the corner frequency at which the noise spectrum will change from $1/f$ to $1/f^3$ (or $1/f^2$ to $1/f^3$ depending on the location of the flicker corner frequency). Resonator non-linearity can worsen the oscillator PN by converting amplitude noise to frequency noise. Nonetheless, this non-linear phenomenon can also be exploited for evading amplifier phase fluctuations [15, 16]. In fact, a non-linear resonator exhibits specific phase/frequency relationship for which the oscillator dynamics can be substantially modified. Intuitively, as described in [19], the resonator time constant can be made infinite at special operating points generated by the resonator non-linearity. When the resonator is locked in that particular state in a closed-loop oscillator, then the amplifier phase fluctuations can be eliminated. An example of this demonstration is shown in Fig. 4.

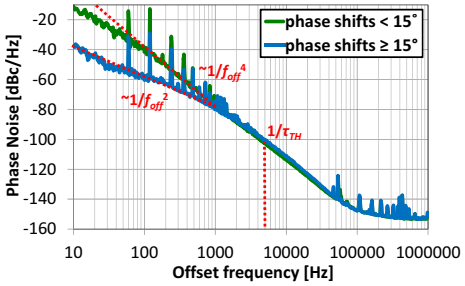

Figure 4. PN plot for a non-linearly driven AlN 220 MHz CMR in a close loop oscillator. For specific phases of the closed loop configuration, the oscillator exhibits clear PN cancellation. τ_{th} is the resonator thermal time constant.

It is important to note that this cancellation works only for noise sources external to the resonator. Hence, the ultimate noise will be set by the resonator intrinsic phase and frequency fluctuations. Therefore, it is of paramount importance to measure the intrinsic phase noise of the AlN CMR. We have performed this task in [20], where we have shown evidence that the oscillator phase noise is limited by the resonator flicker frequency fluctuations. These fluctuations cause a $1/f^3$ slope in the power spectral density of PN, which is a characteristic of many AlN CMR-based oscillators. The physical origin of these frequency fluctuations is still unknown (metal electrodes, AlN thin films defects or dielectric relaxation, substrate effects, piezoelectric coefficient modulation, *etc.*) and is under investigation.

C. Oscillator Ovenization

The oscillator temperature stability is of paramount importance in ensuring device operation over commercial or industrial temperature standards. Frequency stability in the order of few part per million (ppm) over a temperature range of about 125 °C is generally required. Since the AlN CMR intrinsic temperature coefficient of frequency (TCF) is about - 27 ppm/K, an uncompensated device cannot meet these stringent specifications. For this reasons methods to reduce the resonator TCF by introducing an external compensating material such as SiO_2 have been implemented [21]. This technique is successful in reducing the TCF to a fraction of few ppm/K, but it is frequency dependent and requires the introduction of an additional material in the resonator stack. This step also comes with drawbacks in terms of fabrication complexity and reduction in k_t^2. To obviate to these issues, we have decided to take advantage of the miniaturized dimension of the resonator and use heaters integrated in the body of the resonator to readily ovenize the device with just few mW of power (Fig. 5). In this implementation a serpentine heater embedded in the AlN CMR body is used simultaneously as the heater and temperature sensor. When inserted in a simple analog feedback circuit [22], the resonator temperature is maintained constant at the desired value set by the initial calibration of a Wheatstone bridge. It is important to note that any temperature fluctuations external to the resonator is not compensated by this approach.

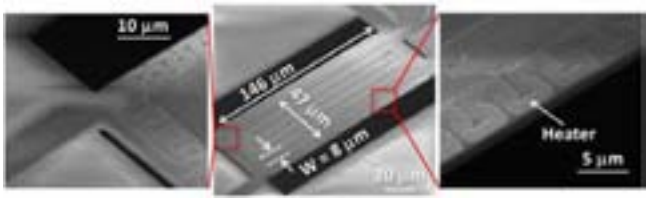

Figure 5. Scanning electron micrograph of an ovenized AlN CMR resonator.In this implementation, the heater is placed on the perimeter of the resonator body.

D. Oscillator Acceleration Sensitivity

The acceleration sensitivity of an oscillator can ultimately impact its use in the field. The presence of an external, low frequency vibration that couples into the resonator is up-converted to the carrier frequency and manifests itself as an increase of the oscillator PN at a specific offset [23]. The acceleration sensitivity is affected by many aspects of the oscillator including primarily the resonator mechanical supports, the way the resonator is bonded to the PCB, and the length of the wirebonds. Assuming a proper device assembly, though, the ultimate limit will be set by the resonator geometry. In the case of AlN CMRs, the structure is particularly subject to vibration in the vertical direction. In fact, the resonator is formed by a thin membrane; hence it has the lowest stiffness in the vertical direction. Finite element analysis of the resonator acceleration sensitivity has yielded $\Gamma < 0.05$ ppb/G. This value is about 10X better than the best commercially available quartz crystals.

E. Prototype Oscillator

A prototype oscillator was assembled by connecting a 586 MHz ovenized AlN CMR to a GaAs sustaining amplifier. Temperature stability was ensured by inserting the resonator in a Wheatstone bridge and controlling its temperature set point through an external analog feedback circuit. The oscillator was simultaneously tested for PN, temperature stability and acceleration sensitivity. The results of these tests are reported in Fig. 6. The oscillator exhibited phase noise < - 91 dBc/Hz and – 160 dBc/Hz at 1 kHz and 10 MHz offsets, temperature stability of 2 ppm (when manually tuned) from - 20 to + 85 ºC, and acceleration sensitivity < 30 ppb/G (limited by resonator to PCB mounting). Overall, the oscillator performance is on par or better than commercially available SAW oscillators.

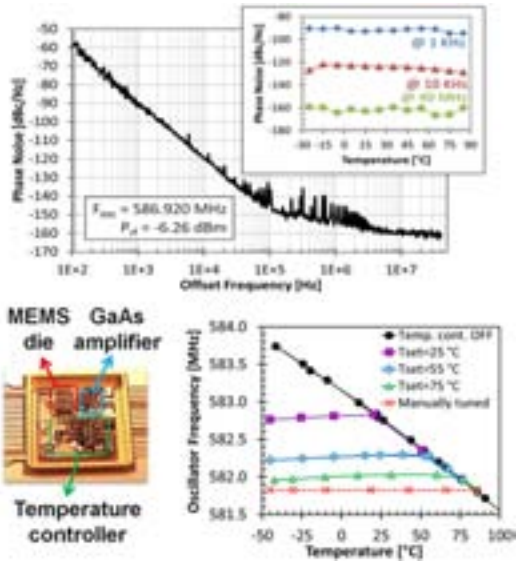

Figure 6. Photograph of a packaged 586 MHz oscillator based on an AlN CMR, its phase noise, and temperature stability.

IV. Conclusion

This paper provided an overview of the latest developments on the use of AlN CMRs for the synthesis of high frequency oscillators. Device operation and oscillator design were reviewed. Fundamental noise mechanisms and methods of evading phase noise were presented. Temperature and acceleration sensitivity were also discussed. Preliminary UHF prototypes have shown performance that are on par with existing commercial devices, but take on a fraction of their volume and, most importantly, can be directly integrated with electronics. Further developments and concerted effort from many research groups will help elucidate the fundamental limits of this technology and continue fueling the timing market revolution made possible by MEMS.

***Abstract*—This paper reports on the first demonstration of a high frequency (245 MHz) single transistor oscillator based on Graphene-Aluminum Nitride (G-AlN) nano-plate resonator (NPR). For the first time, a 2-dimensional (2D) electrically conductive graphene layer was integrated on top of an ultra-thin (500 nm) AlN nano-plate and excited into a high frequency contour-extensional mode of vibration by piezoelectric transduction. The resulting ultra-thin, low mass and high frequency G-AlN nanomechanical resonator showed high values of electromechanical coupling coefficient (k_t^2≈1.8%) and quality factor (Q_m≈1000) which enabled the implementation of a low phase noise (-87 dBc/Hz @ 1kHz offset and -125 dBc/Hz floor) single transistor oscillator. The experimental results also demonstrate the great potential of the proposed technology for the implementation of a new class of ultra-sensitive and low noise G-AlN resonant sensors.**

Keywords—Graphene; Aluminum Nitride (AlN); MEMS; NEMS; Oscillators; Nano Plate Resonator

I. INTRODUCTION

Micro and Nano Electro Mechanical Systems (MEMS/NEMS) resonators have shown great potential for multiple sensing applications thanks to the unique combination of extremely high sensitivity to external perturbations (due to their very reduced dimensions) and ultra-low noise performance (due to the intrinsically high quality factor, *Q*, of such resonant systems). Among different MEMS/NEMS resonant sensors, the AlN nano plate resonant sensor (NPR-S) technology [1], which involves exciting high frequency (100 MHz to 10 GHz) bulk acoustic waves in piezoelectric nano plates (thickness < 1 μm) made out of AlN, has emerged as one of the most promising solutions for the realization of extremely sensitive, miniaturized and low power sensors due to their high *Q* factor values and power handling capabilities [2].

The performance of AlN NPR-S in terms of sensitivity, limit of detection and detection speed can be further improved by scaling thickness and decreasing the equivalent density of the AlN NPR maintaining, at the same time, high values of *Q* factor and transduction efficiency [3]. The physical and electrical properties of the metal electrodes fundamentally limit volume and frequency scaling of conventional MEMS/NEMS piezoelectric resonators [4]. Furthermore, it has been recently shown that metal electrode damping and interface strain are responsible for the *Q* limits in conventional AlN Lamb wave resonators [5].

In this work, a stepping stone towards the development of ultra-high resolution and fast resonant sensors is set by integrating a 2D graphene electrode on top of an AlN resonant nano plate [6] and using such G-AlN resonator to implement a low phase noise single transistor oscillator. Graphene is a one-atom thick layer of the mineral graphite with excellent electrical conductivity and extremely light weight. The ultra-low mass 2D graphene layer is employed, in lieu of a relatively thicker and heavier metal film, as top electrically floating electrode in the lateral field scheme [3] used to excite vibration in the piezoelectric nano plate. Such 2D graphene top layer not only represents the thinnest and lightest conductive electrode ever used to excite vibration in a piezoelectric NEMS resonator but it also has the potential to be used as an effective chemical interactive material with the largest possible surface to volume ratio [7].

II. GRAPHENE-ALUMINUM NITRIDE NANO PLATE RESONATOR

The three-dimensional schematic representation of the G-AlN NPR is shown in Fig. 1. The high frequency bulk acoustic mode of vibration is excited into the AlN nano plate by means of an interdigital bottom electrode and an electrically floating top electrode which acts to confine the excitation field across the thickness of the piezoelectric layer [8].

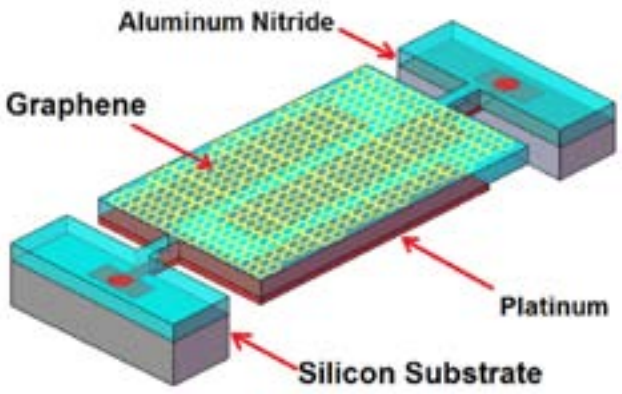

Fig. 1: Schematic representation of the G-AlN NPR

This work was partially supported by DARPA Young Faculty Award contract number: N66001-12-1-4221

Given the equivalent mass density, ρ_{eq} , and Young's modulus, E_{eq}, of the material stack (AlN and electrodes) that forms the resonator, the center frequency, f_0, of this laterally vibrating mechanical structure, is univocally set by the pitch, W_0, of the interdigital bottom electrode. The resonance frequency of the device can be expressed as (1) [9]

$$f_0 = \frac{1}{2W_0}\sqrt{\frac{E_{eq}}{\rho_{eq}}} \quad (1)$$

A fundamental parameter for gravimetric sensing applications is the resonator sensitivity, S, to mass per unit area, which, for a NPR-S loaded on its top surface, can be expressed as in (2) [10]

$$S = -\frac{f_0}{2\rho_{eq}T} \quad (2)$$

Table 1 compares the expected sensitivity, S, of the G-AlN NPR with one of the conventional AlN NPRs, based on the same core design but employing a 150 nm thick gold top electrode instead of the 2D graphene top electrode (gold is typically used as top metal electrode in NEMS resonant sensors since it can be easily functionalized with thiolated ligands). 3 fold improvement in sensitivity is expected with this first prototype of G-AlN NPR-S.

TABLE 1: COMPARISON OF SENSITIVITIES

	ρ_{eq}(kg·m^{-3})	E_{eq}(GPa)	T(μm)	S (kHz·μm^2/fg)
AlN	7022	348	0.70	18.1
G-AlN	4192	396	0.55	53.1

T is the equivalent thickness of the material stack

A combination of top-down microfabrication techniques (6 masks) and bottom-up growth for graphene was employed to fabricate the G-AlN NPR of this work (Fig. 2). A macroscopic sheet of graphene (1.5x1.5 cm limited by furnace dimensions) was grown directly on a copper (Cu) foil using a chemical vapor deposition (CVD) method and then transferred onto the pre-fabricated NEMS die. High quality graphene was maintained throughout the fabrication process (Fig. 3). [6]

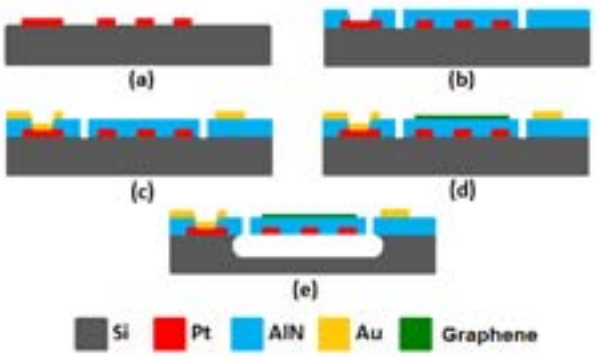

Fig. 2: Microfabrication process: (a) sputter deposition and lift-off of Pt bottom electrode; (b)Sputter deposition of AlN, wet etch to open vias and dry etch to define device lateral dimensions; (c) sputter deposition and lift-off of top Au probing pads; (d) graphene transfer and patterning; (e) graphene protection and XeF_2 dry release of the G-AlN NPR. Steps (a) to (c) were processed at wafer level, while (d) and (e) at the die level.

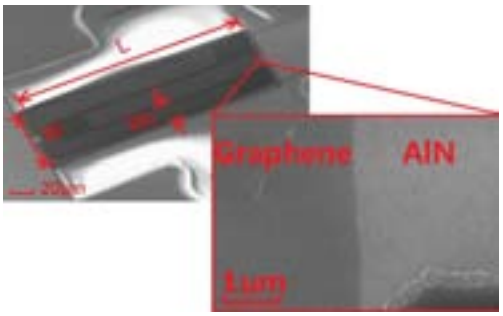

Fig. 3: SEM image of the fabricated G-AlN NPR and high magnification view of the anchor part which shows the boundary of the graphene plate. (W=60μm, L=200μm, W_0=20μm)

III. EXPERIMENTAL RESULTS

The fabricated G-AlN NPR was tested at room temperature and atmospheric pressure in a RF probe station and its electrical response was measured by an Agilent E5071C network analyzer after performing a short–open–load calibration on a reference substrate. The electromechanical performance of the device was extracted by Butterworth-Van Dyke (BVD) model fitting and compared to one of the conventional AlN NPRs, fabricated on the same substrate and based on the same core design but employing a 150 nm thick gold top electrode instead of the 2D graphene top electrode (Fig. 4 and Table 2).

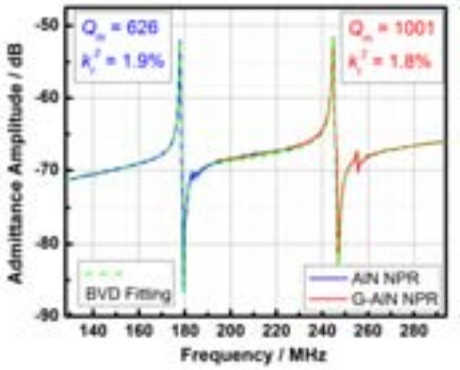

Fig. 4: Measured admittances and BVD fitting of the fabricated G-AlN NPR and the conventional AlN NPR.

Table 2 shows the comparison between the BVD model fitting parameters of the fabricated G-AlN NPR and the conventional AlN NPR. Higher operating frequency and comparable $k_t^2 \cdot Q_{load}$ was achieved with the G-AlN NPR. Despite the relatively high sheet resistance (~1.5kΩ/□) of the in-house synthesized graphene layer, the 2D graphene electrode introduced only a relatively small and tolerable value of electrical resistance, R_s, compared to the 250 times thicker and 3750 times heavier gold electrode. It is worth noting that much lower sheet resistance (~60 Ω/□) can be achieved in commercially available graphene [11] which would further reduce the electrical loading of the graphene electrode to < *2%* of the total loss of the system.

TABLE 2: COMPARISON OF BVD FITTING

	f_0	Q_{load}	k_t^2	C_0	R_m	R_s
AlN	178MHz	432	1.90%	324fF	285Ω	128Ω
G-AlN	245MHz	408	1.81%	282fF	157Ω	228Ω

Both the G-AlN NPR prototype and the conventional AlN NPR were directly wire-bonded to Pierce oscillator circuits implemented with an ATF-551M4 E-pHEMT GaAs transistor. (Fig. 5)

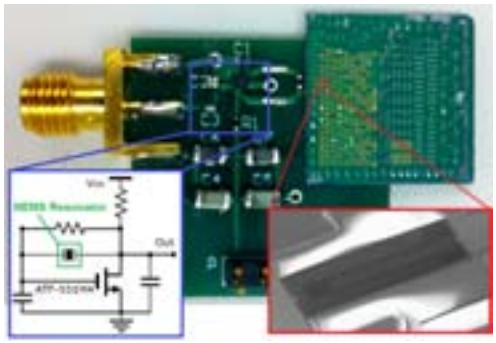

Fig. 5 Oscillator circuit

The phase noise was measured for best bias conditions using an Agilent N9010A EXA signal analyzer. Despite the 250 fold smaller volume of the top electrode and the 38% higher operating frequency, improved phase noise performance was recorded for the G-AlN device due to its higher mechanical Q ($Q_m \approx 1000$). (Fig. 6)

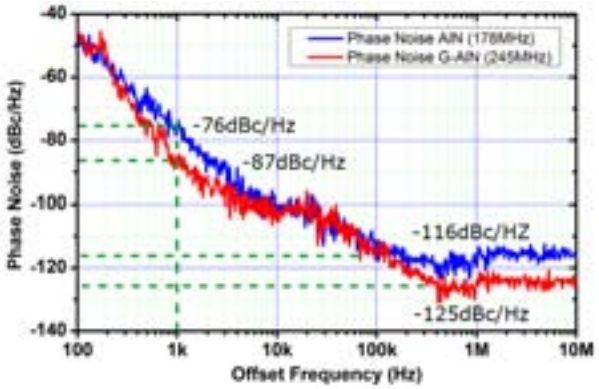

Fig. 6 Measured phase noise of the two oscillators

This experimental result demonstrates that the introduction of the graphene electrode not only enables the fabrication of AlN NPRs with lower volume and mass and improved sensitivity to mass loading but also, despite the volume scaling, allows the achievement of high values of Q_m, which guarantees ultra-low noise performance of the oscillator. The reduced mass and volume, and the increased frequency of operation of such G-AlN NPRs combined with their high Q factor values demonstrate the great potential of the proposed technology for the implementation of a new class of resonant sensors capable of achieving unprecedented values of limit of detection and detection speed.

IV. CONCLUSIONS

In this paper, a high frequency (*245 MHz*) Graphene-Aluminum Nitride (G-AlN) nano plate resonator (NPR) was designed, fabricated and tested. For the first time, a 2-dimensional electrically conductive graphene layer was integrated on top of an ultra-thin (*500 nm*) AlN nano plate and excited into a high frequency contour-extensional mode of vibration by piezoelectric transduction. Despite a bottom metal interdigital electrode is still employed in this first prototype, the fabricated G-AlN resonator is characterized by reduced mass (~53%) and volume (~20%), increased sound velocity, hence resonant frequency (~38%), and unchanged device figure of merit ($k_t^2 \cdot Q_{load}$) compared to one of the conventional AlN NPRs, fabricated on the same substrate and based on the same core design but employing a 150 nm thick gold top electrode instead of the 2D graphene top electrode. The achieved high electromechanical performance of the ultra-thin, low mass and high frequency G-AlN nanomechanical resonator enabled the implementation of a low phase noise (-87 dBc/Hz @ 1kHz offset and -125 dBc/Hz floor) single transistor oscillator.

These experimental results demonstrate that reliable electrical transduction of high frequency mechanical vibration in an ultra-thin and low-mass G-AlN nano plate is possible and can be employed for the making of a new class of resonant sensors with improved sensitivity (Table 1) and noise performance (Fig. 6), hence with unprecedented detection capabilities.

ACKNOWLEDGMENT

The authors wish to thank the staff of the George J. Kostas Nanoscale Technology and Manufacturing Research Center at Northeastern University where the devices were fabricated. This work was partially supported by DARPA Young Faculty Award contract number: N66001-12-1-4221 and NSF Award: ECCS-1202376.

***Abstract*— A 61-MHz Pierce oscillator referenced to a single polysilicon surface-micromachined wine-glass disk resonator has achieved phase noise marks of -119dBc/Hz at a 1-kHz offset and -139dBc/Hz at far-from-carrier offsets. When divided down to GSM's 13MHz, this corresponds to -132dBc/Hz at 1-kHz and -152dBc/Hz at far-from-carrier offsets, both of which satisfy GSM reference oscillator phase noise requirements. This Pierce oscillator achieves such performance using a single disk, not an array, while only consuming 78 microwatts of power, a reduction by a factor of ~4.5 compared with previous work. When power consumption is considered, this performance marks the best figure of merit at 1-kHz carrier offset among published on-chip oscillators to date. Such low phase noise and power consumption posted by a tiny MEMS device may soon become key enablers for low power "set-and-forget" autonomous sensor networks with substantial communication capability.**

Keywords*— *MEMS, oscillator, micromechanical, wine-glass disk, low phase noise, low power, resonator, RF MEMS.

I. Introduction

Reference oscillators based on high-Q MEMS resonators have recently become viable alternatives to traditional quartz versions. With resonator Q's exceeding 100,000, such oscillators have posted impressive phase noise performance, even achieving marks that meet the challenging GSM specification using a mechanically-coupled resonator array-composites occupying only 0.1mm^2 of area and consuming only 350μW of power [1]. While such devices offer compelling savings in power and space compared to quartz for cell phone applications, further reductions in these attributes are still desired for future autonomous wireless sensor networks [2], where nodes would be expected to operate and communicate for long periods without the luxury of replacing their power sources.

Pursuant to further reducing power and area consumption, this work introduces a 61-MHz Pierce oscillator referenced to a single polysilicon wine-glass disk resonator, cf. Fig. 1, reducing die area from 0.1mm^2 to 0.01mm^2, a factor of 10, compared with previous arrayed devices. Furthermore, even with this size reduction, the low noise figure of the improved amplifier design used here yields an oscillator with no degradation in phase noise performance even while total power consumption is lowered drastically. This Pierce oscillator design achieves measured marks of -119dBc/Hz at 1-kHz offset and -139dBc/Hz at far-from-carrier offsets, both of which satisfy GSM specifications (i.e., divided down to GSM's 13MHz, these correspond to -132 dBc/Hz at 1-kHz and -152dBc/Hz at far-from-carrier offsets) while consuming only 78μW power.

Much of the described work was supported by DARPA.

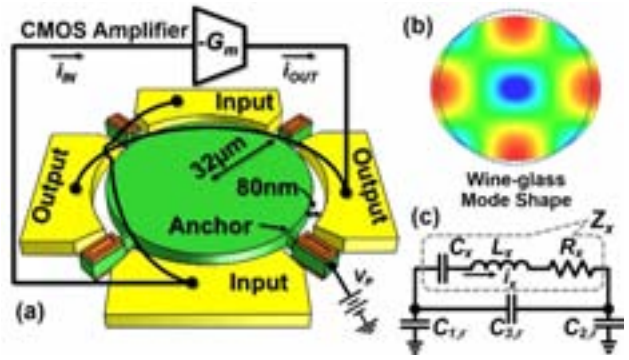

Fig. 1. Perspective-view schematic of (a) a micromechanical wine-glass disk resonator combined with a sustaining transconductance amplifier to form a Pierce oscillator, (b) resonator mode shape, and (c) equivalent electrical circuit.

II. Resonator Operation and Modelling

The wine-glass disk resonator used in this work, depicted in Fig. 1(a), comprises a 3μm-thick, 32μm-radius polysilicon disk supported at quasi nodal points by four beams and surrounded by electrodes spaced only 80nm from its edges. To excite the resonator into motion, a bias voltage V_P is applied to the disk and an ac drive voltage to the input electrode. These voltages combine to produce a force across the input electrode-to-resonator gap that at resonance can excite the wine-glass (i.e., compound (2, 1)) mode shape, shown in Fig. 1(b), which comprises expansion and contraction of the disk along orthogonal axes. The frequency of resonance is defined [3]

$$f_{nom} = \frac{K}{R}\sqrt{\frac{E}{\rho(2+2\sigma)}} \qquad (1)$$

where R is the disk radius, $K = 0.373$ for polysilicon structural material, and E, σ, and ρ are the Young's modulus, Poisson ratio, and density of the structural material, respectively.

In the electrical domain, the resonator behaves as the equivalent LCR tank shown in Fig. 1(c), where $C_{1,r}$, $C_{2,r}$, and $C_{3,r}$ are intrinsic and parasitic capacitors seen at the input and output nodes of the resonator. The dc-biased (V_P) vibrating electrode-

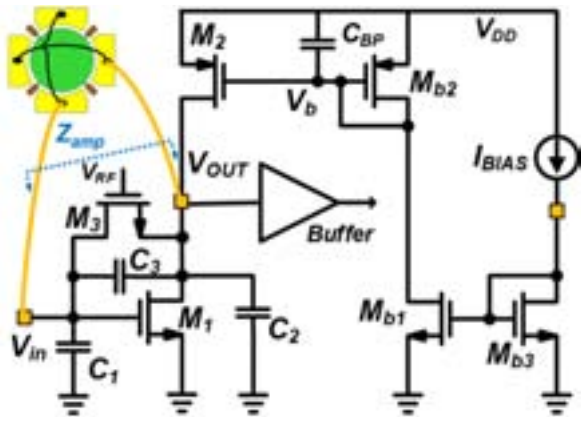

Fig. 2. Schematic of the CMOS amplifier used in the Pierce oscillator, including bias network and parasitic capacitance at input and output nodes.

to-resonator capacitors generate motional currents at each electrode proportional to the disk velocity. If the electrodes are placed as shown in Fig. 1, with the current directions indicated, the input and output currents are in-phase, and current flow can be modeled by a single motional current i_x through the *LCR* tank. The elements R_x, L_x, and C_x link to the mechanical properties of the resonator as follows [4]:

$$R_x = \frac{c_r}{Q\eta^2}, \quad L_x = \frac{m_r}{\eta^2}, \quad C_x = \frac{\eta^2}{k_r}, \quad \eta = V_P \frac{\partial C}{\partial r} \qquad (2)$$

where c_r, m_r, and k_r are the damping, mass, and stiffness of the resonator, respectively, determined via equations given in [5], $\partial C/\partial r$ is the change in resonator-to-electrode capacitance per unit radial displacement.

III. Oscillator Design

As shown in Fig. 2, the Pierce oscillator topology used in this work combines a frequency selective resonator with a single trans-conducting gain device: in this case, the MOS transistor M_1. M_2 serves as a load transistor, while M_3 provides feedback to properly dc-bias transistor M_1. For oscillation to occur, two conditions must hold: 1) the gain around the loop must be larger than unity; and 2) the phase shift around the loop must be zero. Focusing first on the latter, transistor M_1 introduces 180° of phase shift between the input and output voltages. However, at resonance the phase shift across the wine-glass mode disk resonator is 0°, so an additional 180° is needed to satisfy criterion 2. To supply this, the resonator must operate in the inductive region and resonate with C_1, C_2, and C_3, which comprise the total parasitic capacitors from the resonator, the amplifier, and surrounding structures, e.g., bond pads, at the input and output nodes, as shown in Fig. 2.

A. Linear Analysis

At start-up the amplitude of oscillation is small, the whole circuit stays linear, and the impedance looking into the gate and drain of M_1 can be modeled using small signal equivalent circuits, c.f. Fig. 3. Here, impedances Z_1, Z_2, and Z_3 include all resistive and reactive components of devices M_1 (except its transconductance g_{m1}), M_2, and M_3, plus the resonator's parasitic capacitors.

The critical condition for oscillation occurs when Z_{amp} and Z_x sum to zero. For oscillation to start, $|\mathrm{Re}(Z_{amp})|$ must be larger

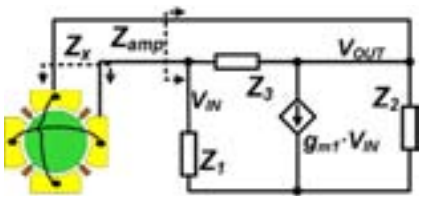

Fig. 3. The small signal equivalent circuits of the oscillator with impedances Z_1, Z_2, and Z_3, which include all the components of the transistors M_1 (except its transconduance g_{m1}), M_2, M_3, and the resonator's parasitic capacitance.

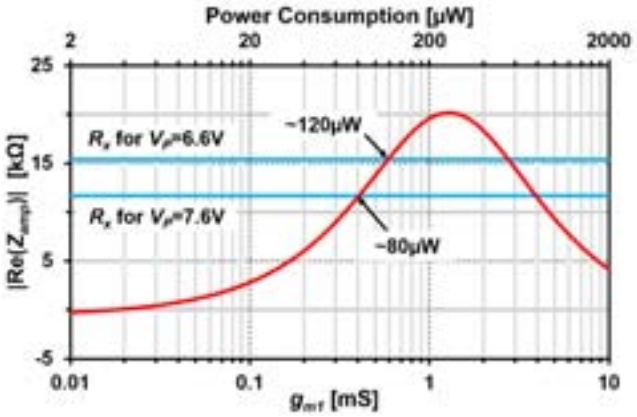

Fig. 4. Theoretical plot of $|\mathrm{Re}(Z_{amp})|$ vs. transconductance, g_{m1}, of the M_1 transistor and the required power consumption to achieve this g_{m1} with V_{DD}=2V. The blue lines correspond to calculated motional resistances of the resonator for different V_P's and indicate theoretical minimum powers required for oscillation.

than R_x. However, Z_1-Z_3 constrain the achievable $|\mathrm{Re}(Z_{amp})|$ to a maximum value as depicted by the red curve in Fig. 4, which is the theoretical plot of $|\mathrm{Re}(Z_{amp})|$ versus g_{m1} (bottom *x*-axis) and the required power consumption for V_{DD} of 2V (top *x*-axis). If the real part (resistances) of Z_1-Z_3 are large, then only the capacitors C_1, C_2, and C_3 remain, in which case the maximum value of $|\mathrm{Re}(Z_{amp})|$ becomes [6]:

$$\left|\mathrm{Re}\left(Z_{amp}\right)\right|_{\max} = \frac{1}{2\omega C_3\left(1 + C_3\left(\frac{1}{C_1} + \frac{1}{C_2}\right)\right)} \qquad (3)$$

If this value is smaller than R_x, no oscillation ensues, even if g_{m1} increases. From (3), there are two ways to increase $|\mathrm{Re}(Z_{amp})|_{\max}$: 1) raise the values of C_1 and C_2 at the cost of burning more power; and 2) reduce the input-to-output feedthrough capacitance C_3. The last of these reveals why self-sustained oscillation of a micromechanical resonator is possible using a Pierce circuit, despite its large motional resistance R_x. Indeed, the C_3 of a 61-MHz wine-glass disk resonator is on the order of 40-50fF, many times smaller than the 6pF in a typical 60-MHz quartz crystal, allowing $|\mathrm{Re}(Z_{amp})|_{\max}$ to exceed the disks R_x of 15kΩ. Interestingly, the C_3 of a wine-glass disk resonator is so small, and it allows a $|\mathrm{Re}(Z_{amp})|_{\max}$ greater than 20kΩ without the need to increase C_1 and C_2. In comparison, with C_3 =6pF, a typical quartz crystal cannot muster a $|\mathrm{Re}(Z_{amp})|_{\max}$ more than 118Ω, even with C_1 and C_2 as large as 14pF. Of course, the much smaller R_x =70Ω of a typical 60-MHz quartz crystal does not require that $|\mathrm{Re}(Z_{amp})|_{\max}$ be so large, but the needed C_1 and C_2 values are still on the order of 10pF. Since larger C_1 and C_2 demand higher transistor drive power, a MEMS-based Pierce oscillator circuit with a relatively small C_3 that in turn allows small

C_1 and C_2 should permit much lower power consumption. If the resonator R_x can be further lowered, e.g., by increasing its dc-bias voltage V_P, as illustrated in Fig. 4, the power consumption of a MEMS-based Pierce oscillator should shrink even more. Fig. 4 in fact shows that an increase in V_P by 1V decreases the oscillation power requirement by 33% (from 120μW to 80μW).

Once oscillation starts, the amplitude builds up exponentially from initial thermal noise with a time constant [7]

$$\tau = -\frac{2L_x}{\mathrm{Re}\{Z_{amp}\} + R_x} \qquad (4)$$

The total time required to reach steady-state oscillation depends on the time constant (4), the amount of noise in the system, and the initial energy impulse, the last of which can be tailored by an appropriate switch-on procedure at start-up.

B. Pierce vs. Transimpedance Amplifier (TIA)

The TIA used to instigate and sustain oscillation in previous work [1][5] comprised a fully differential CMOS amplifier biased by a common-mode feedback circuit that effectively canceled common-mode noise, especially low-frequency noise caused by vibration [8]. The Pierce oscillator presented here, however, with its single-ended Pierce topology, sacrifices this common-mode feedback to achieve lower noise-figure, hence lower phase noise, than previous TIA-based oscillators. This is made possible by 1) using only two active transistors compared to a minimum of four in the TIA; 2) using a very large shunt-shunt feedback MOS resistor, M_3, for biasing compared to the much smaller gain-setting resistor required by the TIA, where the larger the resistance, the smaller the current noise; and 3) using C_{BP}, at the cost of some area increase, between the gate of M_2 and V_{DD}, as shown in Fig. 2, to filter noise from bias transistors M_{b1}-M_{b3} and from V_{DD}. Per the last item, recall that the TIA of [5] relied on common-mode feedback to reject bias-derived noise, but note that the efficacy of this approach is only as good as the matching of its transistors.

Finally, the smaller transistor stack of the Pierce oscillator circuit allows it to operate at lower V_{DD}, hence lower power, without driving the two transistors into their triode regions.

IV. Experimental Verification

The wine-glass disk resonators used for testing were fabricated via a previously described three-polysilicon self-aligned stem small lateral-gap process [9]. Fig. 5 presents the scanning electron micrograph (SEM) of a fabricated 61-MHz wine-glass disk resonator along with a typical measured frequency response, where Q's of 130,000 in vacuum and motional impedances of 14kΩ with V_P=7V were common among devices.

The amplifier IC was fabricated in a 0.35μm CMOS technology. Although the entire die, shown in Fig. 6(a), occupies an area of 900μm×500μm, the actual sustaining amplifier with its biasing circuits only consumes about 60μm×45μm while the 44pF C_{BP} occupies about 200μm×100μm. The attenuation of noise at node V_b in Fig. 2—52dB in this case—depends on the pole, $g_{m,b2}/C_{BP}$, where $g_{m,b2}$ is the transconductance of diode-connected transistor M_{b2} in Fig. 2 and $1/g_{m,b2}$ is the resistance looking into M_{b2}. Therefore, for the same attenuation, the area of C_{BP} can be reduced easily by 2 to 4 times by simply decreasing $g_{m,b2}$. The rest of the IC area is consumed by 1) an on-chip buffer used to drive 50-Ω measurement systems; 2) by-pass capacitors that further reduce noise on DC supply lines that would normally be distributed among other on-chip integrated circuits; and 3) multiple bond pads.

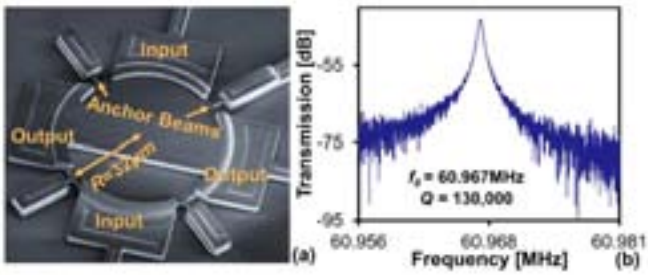

Fig. 5. (a) SEM of a fabricated wine-glass disk resonator and (b) the measured frequency response of the resonator used in this work.

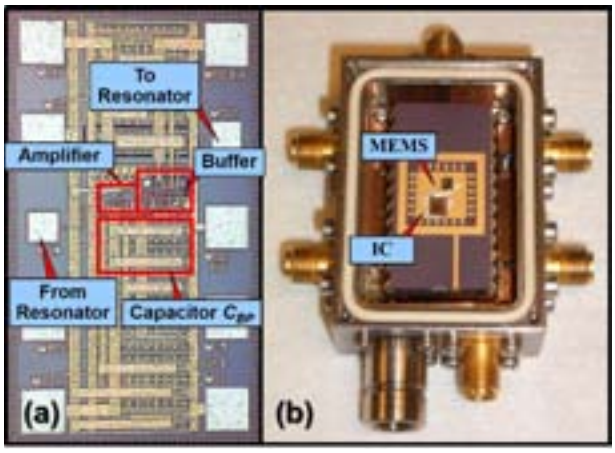

Fig. 6. (a) Die photo of custom-made IC. (b) Photo of the packaged oscillator in a custom-designed vacuum box.

The amplifier die was bond-wired to the resonator and package, as shown in Fig. 6(b), to yield the oscillator under test. To maintain high (i.e., over 50,000) resonator Q, and thereby minimize phase noise [10], the MEMS-based oscillator must operate in a stable vacuum environment, provided via the custom-made miniature vacuum chamber, depicted in Fig. 6(b), that encloses a printed circuit board (PCB) board housing the MEMS/CMOS device package and provides electrical feedthroughs to allow connection to outside instrumentation. Power and bias voltages for the oscillator were provided by a custom low-noise analog supply board. The output of the oscillator was measured using an Agilent E5500 phase noise test setup configured to use a low-noise PLL.

When biased with sufficient V_P to provide positive loop gain, the inset of Fig. 7 shows the output waveform of the packaged MEMS oscillator operating in vacuum. Fig. 7 additionally presents measured phase noise data for the Pierce oscillator alongside data for a TIA oscillator employing the same MEMS resonator design. Here, the Pierce oscillator achieves -119dBc/Hz at 1-kHz offset and -139dBc/Hz at far-from-carrier offsets from its 61-MHz oscillation frequency. When divided down to GSM's 13MHz, this corresponds to -132dBc/Hz at 1-kHz and -152 dBc/Hz far-from-carrier, both of which satisfy GSM reference

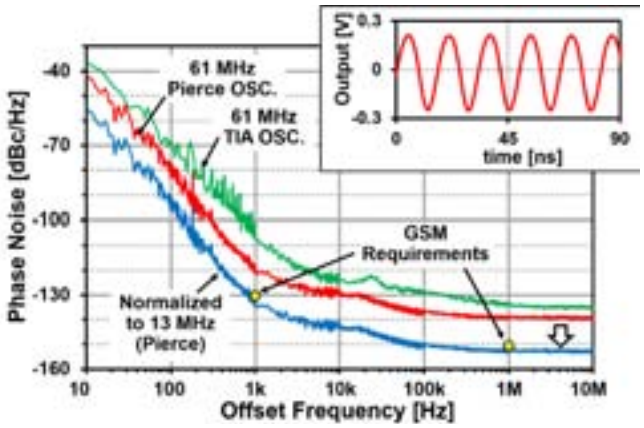

Fig. 7. Measured phase noise of 61-MHz oscillators comparing the new Pierce topology and an older TIA topology similar to [5], as well as the Pierce oscillator phase noise divided down to 13MHz for comparison to the GSM spec. Inset: the measured output waveform of the Pierce oscillator.

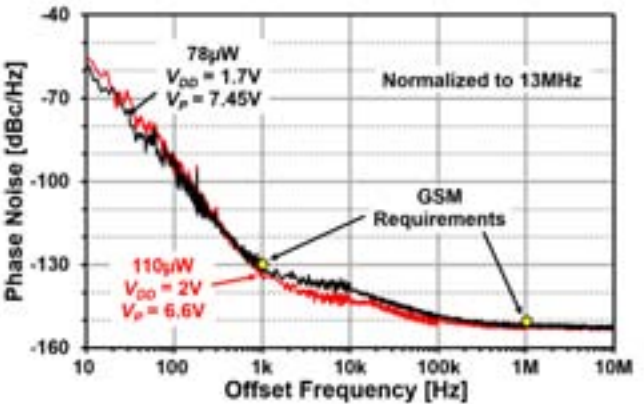

Fig. 8. Measured phase noise of the oscillator operating at two V_{DD} values. A reduction in V_{DD} and I_{BIAS} can be seen to decrease power consumption by 29% with only a modest decrease in phase noise performance.

oscillator phase noise requirements. This Pierce oscillator not only provides phase noise improvements of 9dB at 1-kHz offset and 7dB far-from carrier versus the TIA version of [5] using a similar single disk; it also reduces power consumption down to 78μW, which is ~4.5 times smaller.

Fig. 8 presents phase noise measurements for the Pierce oscillator that investigate the degree to which increases in resonator dc-bias V_P allow lower supply voltages, hence, lower power consumption. Here, a 0.85V increase in V_P allows V_{DD} and I_{BIAS} reductions that decrease overall power consumption from 110μW to 78μW, with very little degradation of phase noise.

For fair comparison of this work to other oscillators, a figure of merit (*FOM*) that accounts for the total power consumption required to achieve a given phase noise can be used:

$$FOM = 10\log\left(\mathcal{L}(\Delta f).\frac{P_{diss}}{1mW}.\left(\frac{\Delta f}{f_0}\right)^2\right) \qquad (5)$$

where $\mathcal{L}(\Delta f)$ is the oscillator phase-noise at Δf offset frequency and P_{diss} is its total power consumption. Use of (5) yields Table I, where the present Pierce oscillator achieves the best *FOM* at 1kHz amongst any published on-chip oscillator to date.

TABLE I. PERFORMANCE COMPARISON

Device Type	**This work**	Wine-Glass array [1]	AlN [11]	FBAR [12]	Quartz [13]
f_{osc} [MHz]	**61**	61	4.9	2000	10
Power [μW]	**78**	350	120	22	~1500
Normalized (13MHz) Phase Noise @ 1 kHz [dBc/Hz]	**-132**	-136	-130	-122	-135
FOM@1kHz [dB]	**-225**	-223	-221	-220	-211

V. CONCLUSIONS

The demonstration by this work of a 61-MHz capacitive-gap transduced wine-glass disk Pierce oscillator capable of meeting GSM specifications while using only 78μW of power marks a milestone for MEMS-based frequency control technology. Compared with previous TIA-based renditions, this oscillator reduces power and area consumption by 4.5 times and 10 times, respectively, and, to best of the author's knowledge, now posts the highest *FOM* of any published on-chip oscillator to date. That the small port-to-port feedthrough capacitance of the MEMS resonator is largely responsible for the *FOM* improvement is quite intriguing and suggestive of design approaches that might lead to further *FOM* increases. Whether or not such increases are achieved, the power reduction already achieved by the demonstrated oscillator while maintaining GSM-compliant phase noise performance already makes a very compelling case for application to future autonomous wireless sensor networks.

***Abstract*—A quartz resonator operating at 995 MHz in the fundamental mode has been characterized in a closed loop oscillating system under different drive levels to determine its nonlinear behavior and optimum phase noise performance. The best phase noise achieved was -106dBc/Hz at a 1 kHz offset frequency. The same quartz technology was used to build VCXOs in both the Colpitts and Pierce configurations at several frequencies above 650 MHz. The lowest phase noise level achieved in the Colpitts configuration operating at 705 MHz is –111dBc/Hz at a 1 kHz offset frequency while a Pierce Oscillator operating at 662 MHz achieved a phase noise of –112.8dBc/Hz at the same offset. Power consumption in these VCOs is typically on the order of 30-90mW.**

***Index Terms* -- Quartz, MEMS, oscillators, resonator, nonlinear dynamics, drive level dependency, DLD, phase noise, Duffing**

I. Introduction

Quartz resonators are often used for high performance navigation, radar systems, and communications systems, both commercial and military. In addition to exhibiting low phase noise, these resonators offer high stability over temperature and vibration. Typically these resonators operate at frequencies < 100MHz and need to be multiplied up to UHF frequencies or are used as the reference for phase locked loops. In this work, we propose fundamental mode quartz oscillators operating at UHF frequencies (> 500MHz) as a method of reducing the size, weight, and power (SWAP) of these systems and for improving the performance of phase locked loops operating at microwave frequencies. Due to their small size, UHF quartz resonators are naturally less susceptible to vibration than lower frequency quartz.

Competing technologies in the UHF region, such as surface acoustic wave (SAW) resonators and bulk acoustic wave resonators (BAW) can have low phase noise but temperature stabilities approximately an order of magnitude higher than quartz while dielectric resonators are large and have too high loss rendering them impractical at these frequencies. In order to achieve stable operation over temperature at these frequencies, designers typically use either a stable quartz reference oscillator multiplied up to the desired frequency or a higher overtone device. Multiplication processes add noise in addition to the 6dB associated with the multiplication process. Additionally, the circuitry required for the multiplication increases the size and power consumption of the system according to the number of multiplication stages. In phased lock loop applications, the lower the reference frequency the larger the required multiplication which leads to higher added noise levels. Quartz oscillators are commonly designed for higher overtones (typically 3rd and 5th) but assuming a fundamental frequency of 100MHz, this does not allow for operation close to 1 GHz. Higher overtones generally have higher motional resistance R_1, making sustained oscillation difficult and they are also plagued with problematic spurious modes [1].

Traditionally, engineers attempted to avoid nonlinear operation because it was usually associated with unstable oscillations and poor phase noise performance. Quartz resonators operating at UHF are smaller in size than lower frequency crystals which makes them more susceptible to nonlinear behavior under lower drive levels (~ 0dBm) Thus, understanding how UHF resonators behave under different drive levels is an important part of designing oscillators at these frequencies. Pioneering research on this topic was done in the 1990s by Greywall and Yurke in which they proposed taking advantage of the nonlinearity in a mechanical resonator to improve phase noise in a magnetically driven oscillator system [2, 3].

Recently, Lee et al demonstrated stable oscillation at ~ 1MHz of an electrostatic silicon MEMS resonator driven beyond the critical bifurcation point and they were able to characterize the resonator nonlinearity by measuring the admittance under various drive levels [4]. Efforts at HRL have focused on extending this characterization up to UHF (>500MHz) and the methodology and results have been documented [5, 6]. HRL's work uses the same process to characterize the fundamental mode operation of a 995MHz resonator.

Because many navigation and radar applications require temperature stability beyond the natural stability of the resonator, we have developed a number of Colpitts and Pierce VCXOs operating at frequencies >600MHz to allow for external temperature stabilization.

II. Quartz Technology

The basic equation used to describe the nonlinearity in the quartz as well as other flexural beam type resonator is the well known Duffing equation [7]:

$$m\frac{d^2x}{dt^2} + \gamma\frac{dx}{dt} + k_1 x + k_3 x^3 = A\sin(\omega t + \varphi) \quad (1)$$

This equation describes a mass and spring system with a cubic nonlinearity, k_3x^3, resulting in nonlinearities in the spring constant with a periodic driving force. This is a good representation for characterizing the resonator in an open loop configuration. Fig. 1 shows a Van Dyke model representation of a resonator. C_0 corresponds to the static parasitic capacitance of the resonator. Motional inductance, L_1, and motional resistance, R_1, correspond to the effective modal mass, m, and damping, γ, respectively in the Duffing equation. For the typical linear case,

motional capacitance, C_1, is analogous to model stiffness k_1 but is represented by the combination of k_1 and k_3 when nonlinearities are present.

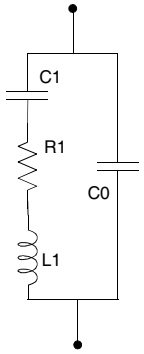

Figure 1. The Van Dyke circuit model of a quartz resonator.

The 995 MHz fundamental AT-cut quartz (35º15') thickness shear mode resonator, fabricated at HRL, consists of a blank of AT-cut quartz with a cut angle of 35º15'. The resonator has top and bottom side circular shaped aluminum electrodes that are 100 µm in diameter and 0.08 µm thick. The active region of the quartz plate is 290µm x 320 µm and 1.6 µm thick. The quartz resonator is vacuum sealed with a silicon cap for protection before dicing. The fabrication process is described in [8]. The physical layout of the resonator and a picture of the fabricated device are shown in Fig. 2.

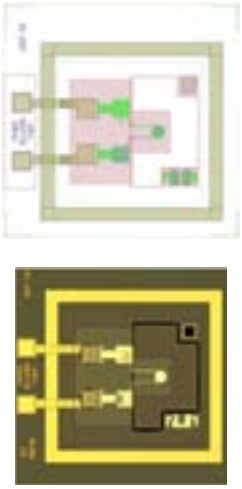

Figure 2. Physical layout of the resonator and photograph of fabricated device.

The device was first measured in an open loop configuration and the Van Dyke model fitted parameters are shown in Table I.

R_1	66.618 Ω
C_1	0.177 fF
L_1	145 µH
C_0	0.482 pF
Series f_o	995 MHz
Q	13600
f x Q product	1.35×10^{13}

Table I. Van Dyke model fitted parameters for the HRL AT-cut quartz resonator.

The 995MHz resonator was characterized with the Agilent E4991A RF Impedance Analyzer by directly probing resonator's contacts. Fig. 3 shows the magnitude of the measured admittance values for the resonator versus drive level in the open loop configuration. The results indicate that at a 100mVrms drive level, the resonator is well within the linear operating region. By a 300mV drive level, the admittance curve is bent over, indicating strong nonlinear effect (Duffing). The slight frequency shift of the peak is believed to be due to heating effects of the quartz.

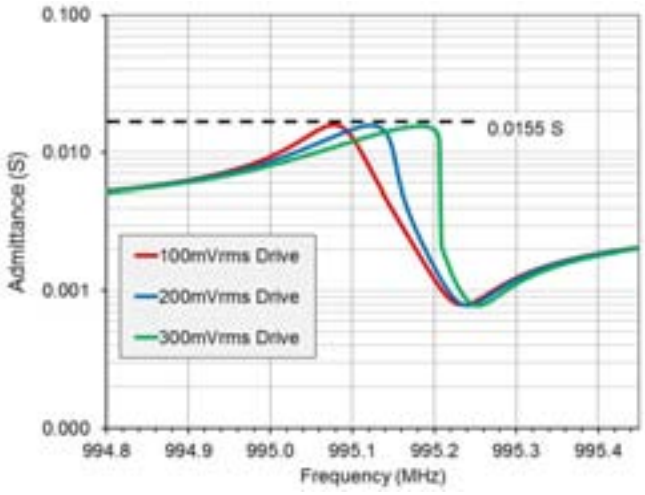

Figure 3. Magnitude of measured admittance for the resonator in an open loop configuration.

III. Nonlinear Characterization

A block diagram for the nonlinear characterization of the resonator is presented Fig. 4. The main components for the sustaining circuit in our test loop oscillator are a low noise amplifier, voltage controlled phase shifter, voltage controlled attenuator, and power splitter.

The low noise amplifier must exhibit high gain to ensure that the system will oscillate under a variety of amplitude and phase conditions on the resonator. The ZX60 is a GaAs FET amplifier

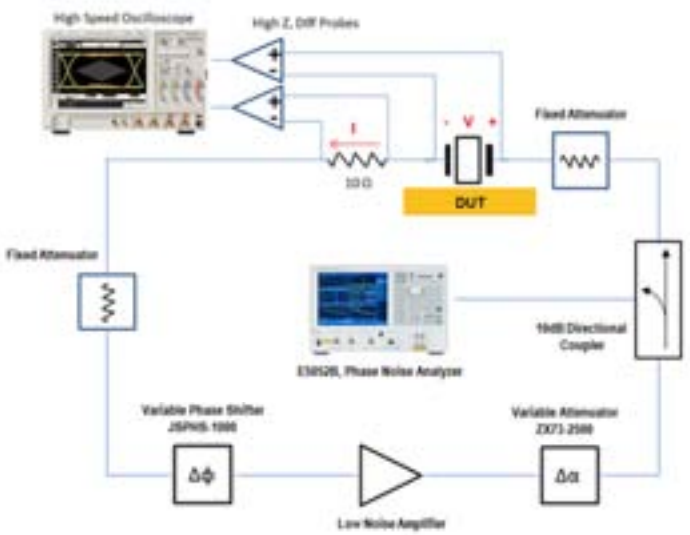

Figure 4. Block diagram of the measurement setup for the nonlinear characterization of the resonator.

which has 25dB gain and a noise figure of 0.5dB. Under lower drive levels the amplifier is well matched, but under higher drive levels reflections from the amplifier can distort the voltage and current measurements of the resonator and thus, alter the admittance curve. The JSPHS-1000 phase shifter provides 180º of phase shift from 700 to 1000 MHz, and the ZX73-2500 has approximately 40dB of attenuation range. A number of fixed coaxial attenuators are surrounding the amplifier to mollify the effects of reflections from the amplifier.

The resonator circuit is mounted on FR4 circuit board as shown in Fig. 5. A 10Ω resistor mounted in series acts to sense current. This value was chosen as a compromise between loading the resonator and reading a detectable voltage. Too high of a series resistance may lower the Q to the point that nonlinear behavior is affected while too low of resistance will yield undetectable voltages. A 10Ω resistor is ~15% of the resonator R_1 and does not load the Q down to a point where linear oscillator performance is seriously degraded.

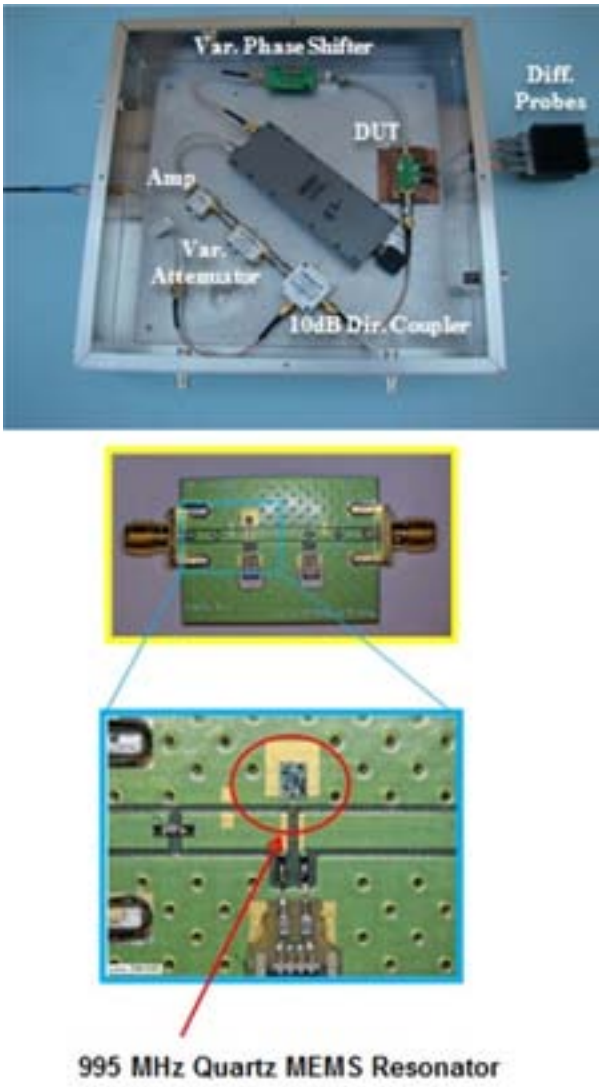

Figure 5. Picture of the experimental setup and mounted resonator.

Zero Insertion Force (ZIF) probe connections are used to interface to differential active probes (Agilent Infiniimax 5 GHz Probe System, model 1132A). Voltage across the resonator is measured directly by one probe and the current is derived from the probed voltage across the 10Ω resistor. An Agilent 5052B phase noise analyzer measures the oscillator output.

Upon establishing an oscillation condition, a LABVIEW computer program reads the voltage from the oscilloscope and adjusts the variable attenuator to achieve the desired voltage across the resonator. Our measurements focused on resonator drive levels that were determined to yield a strong nonlinear behavior as indicated by the open loop characterization. The voltage and corresponding current, frequency of operation, and phase noise are measured. The phase shifter is adjusted in 5° increments and the process is repeated until the phase shifter reaches a state where the oscillation condition is not satisfied. For each data point, the admittance is calculated via the ratio of the peak values for the current and voltage (I/V).

Fig. 6 depicts the results of the magnitude of the admittance vs. the frequency of oscillation which is observed to be linear at 125mV drive and nonlinear for drive voltages greater than 175mV. The low noise amplifier was not capable of driving the resonator greater than 200mV at these high frequencies. The main focus of our work is to compare the phase noise levels at 1 kHz offset at different points on the admittance curve shown in Fig. 7. The phase noise at the 1 kHz offset is usually specified for benchmarking UHF oscillators.

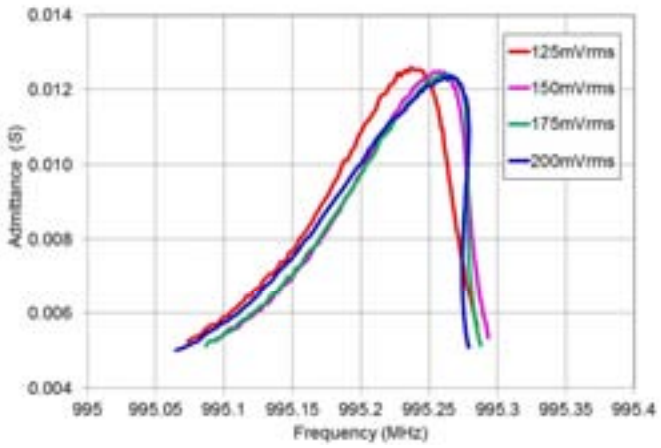

Figure 6. Admittance plot for the resonator in a closed loop configuration.

From Fig. 6, one can see that the admittance curves follow a pattern similar to that measured in the open loop case of Fig. 3. Consistent with earlier work, the peak of the admittance curve is slightly shifted in the closed loop case. In addition, the closed loop case exhibits higher bi-stability than the open loop case providing the potential for two different oscillation conditions at the same frequency. For our setup the attenuation of the voltage variable attenuator and the phase of the voltage variable phase shifter are altered interchangeably to 1) maintain the proper voltage across the resonator and 2) maintain the oscillation condition. The addition of these two variables in the loop allows for oscillations to be achieved at two different frequencies because the admittance of the resonator is different for each state.

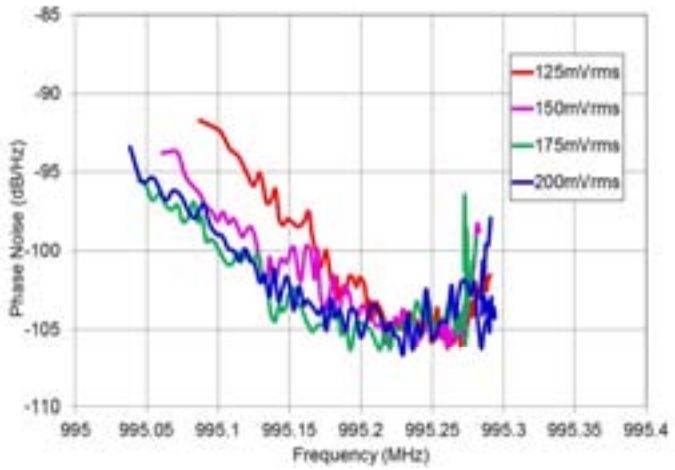

Figure 7. Plot of the phase noise of the 995 MHz oscillator at a 1 kHz offset.

As shown in Fig. 7, the best achieved phase noise at a 1 kHz offset is approximately -106dBc/Hz. From the plot it is apparent that driving the resonator into a nonlinear regime improves the bandwidth of the low phase noise region. At the low frequency end of the operating range, a larger phase noise improvement is exhibited. As the frequency increases, we approach bi-stability.

IV. VCXO Performance

Having demonstrated that the quartz technology allows for 1 GHz operation, the next step is to build discrete oscillators to further characterize the UHF resonators. VCXO circuits were chosen to test the frequency pull characteristics of the resonator and to allow for the integration of future temperature compensation circuitry. Although most of the initial designs used a Pierce topology, a Colpitts topology was also used to provide a phase noise and frequency tuning comparison.

The schematics for both topologies are shown in Fig. 8. Both circuits use one tuning element. The active transistor in the Pierce oscillator is the NEC68033 bipolar transistor in an SOT-23 package and the tuning element is an Aeroflex-Metelics varactor, model MTV4030-09. The MTV4030 series has an abrupt junction and the -09 has a capacitive tuning range between 6.3 (0V) and 1.73pF over a 15V bias range. The Colpitts oscillator uses the same NEC68033 device with the corresponding tuning element being an Aeroflex-Metelics model MTV4030-11 varactor in the same package. The -11 varactor has a capacitance varying between 9.61 (0V) and 2.36pF over the same voltage range.

Fig. 9 shows the phase noise performance of the VCXO using the Pierce topology. At zero varactor bias, the free running frequency of oscillation is 662 MHz and the collector voltage is 3.5V with a collector current of 9.5mA. The phase noise at a 1 kHz offset is -112.8dBc/Hz and the phase noise profile follows the expected $1/f^3$ slope until ~10 kHz when it changes over to 1/f. A noise floor of ~ -155dBc/Hz is finally achieved close to 1 MHz.

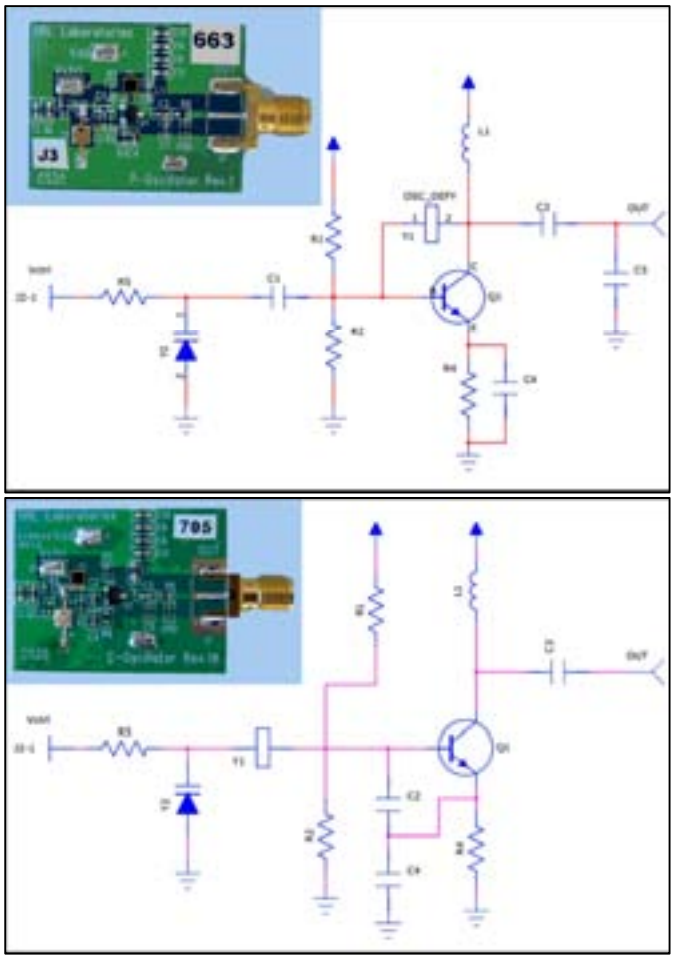

Figure 8. Schematic and photograph of a voltage controlled Pierce oscillator (top) and Clapp oscillator (bottom).

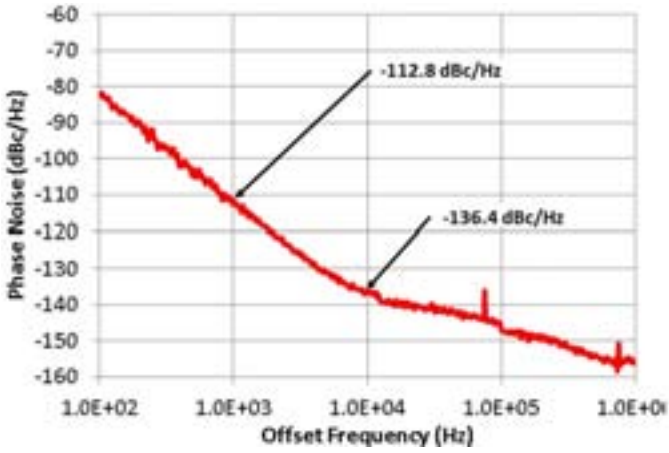

Figure 9. Phase noise measurement of the 663 MHz Pierce oscillator at a 1 kHz offset.

The output of the Colpitts oscillator is shown in Fig. 10. With a collector bias voltage of 6V and a collector current of 14mA, the free running frequency at zero varactor bias is 705 MHz. The measured phase noise at a 1 kHz offset is ~ -111.2dBc/Hz. From the plot, one can observe a slope of $1/f^3$ until a 10 kHz offset which transitions into the expected 1/f slope.

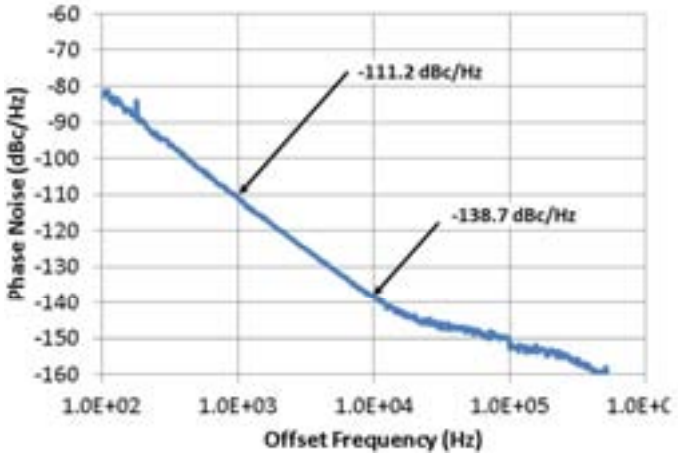

Figure 10. Phase noise measurement of the 705 MHz Colpitts oscillator at a 1 kHz offset.

The VCXO tuning range is lower than what is theoretically possible for both cases. For the Pierce oscillator, the stiffness factor, C_0/C_1 (see Table I above), predicts a pulling range of 140 kHz which translates to 140ppm for our operating frequency. The resulting tuning range is closer to 25ppm which is substantially lower. Similarly, the theoretical tuning range for the Colpitts oscillator is 140ppm and the actual tuning range is 30ppm. Reasons for these discrepancies include extra loading capacitances which limit the tuning range in all VCXOs and the choice of varactor which has less than a 5:1 tuning range. A varactor with a higher capacitance ratio should increase the tuning range.

V. Summary

A 995 MHz quartz resonator has been made to oscillate in the fundamental mode. Characterization of the phase noise under different drive levels and loop phase was completed to determine the optimum operating point for phase noise performance. In order to further characterize the resonator technology, VCXOs were constructed in the 650-750 MHz range. Phase noise results on the order of -112dBc/Hz are an improvement over our previous results. Upcoming efforts in nonlinear characterization will involve comparing the phase noise using different amplifiers to determine their effect on oscillator performance. Future work with VCXOs will involve using higher frequency resonators and integrating microprocessor controlled temperature compensation circuitry to develop an UHF TCXO.

jalovset@rockwellcollins.com

***Abstract*— Some micro/nanoscale resonator oscillators' phase noise and temperature stability performance is inferior to traditional quartz crystal oscillators. But, does that matter? In other areas, micro/nanoscale resonator oscillators have demonstrated one or two orders of magnitude better performance. Measured devices have demonstrated frequency stability under vibration and a resiliency to shock not possible in traditional-sized quartz. Certain applications may have component specifications which can be derived differently by keeping in mind how a micro/nanoscale component will respond differently under these environmental conditions.**

A comparison of most important requirements for oscillator components in communication, navigation, and radar radio applications is presented. Areas of specification relief are identified related to measured performance of micro/nanoscale oscillators. Rockwell Collins has measured developmental and Commercial-off-the-shelf (COTS) Microelectromechanical systems (MEMS) / Nanoelectromechanical systems (NEMS) resonator oscillators as part of the DARPA Mesodynamics Architectures (Meso) program. This includes piezoelectric, piezoresistive, and electrostatic devices. Rockwell Collins has used these devices to demonstrate improved performance to existing radio hardware.

I. Current Oscillator Applications

A. *Traditional SATCOM*

Traditional satellite communication (SATCOM) terminals are typically land or ship-based and operate over relatively benign temperature ranges and vibration environments. Historically a Low Noise Block downconverter (LNB) is placed near the antenna to convert the SATCOM carrier frequency down to a lower Intermediate Frequency (IF) to reduce cable losses. At the other end of the cable is a modem that processes and demodulates the IF signal to data. The LNB and modem often have independent reference oscillator circuits (Fig. 1).

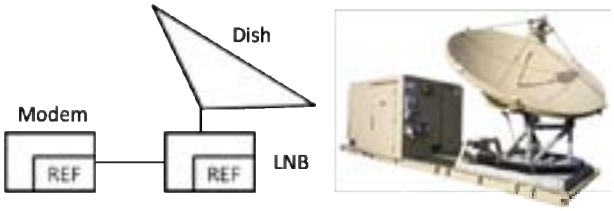

Fig. 1 Traditional SATCOM Terminal Architecture

B. *Airborne SATCOM Terminals*

To meet the need for continuous data connectivity, SATCOM terminals are increasingly being deployed on commercial and military aircraft. The antenna and LNB that are deployed near the skin of the aircraft face extreme temperature and vibration environmental requirements. The SATCOM antennas are typically mounted at the top, centerline, mid-fuselage or at the top of the tail. These mounting locations provide the optimal view of satellites. Equipment in the platform's avionics bay enjoy a temperature-controlled environment. Avionics bay equipment vibration requirements are tougher than terrestrial and maritime terminals but not as harsh as the environment near the skin of the aircraft.

The Radio Technical Commission for Aeronautics (RTCA) is a volunteer group comprised of avionics and aviation experts that develop technical guidance for government regulatory agencies and industry. DO-160F published by the RTCA defines a series of minimum standard environmental test conditions and procedures for airborne equipment. Airframe manufacturers and airlines may elect to specify more stringent standards. Chapter 8 of DO-160F specifies the minimum vibration conditions for avionics. These are further broken down by platform type (fixed wing, helicopter, etc.) and mounting location (fuselage, equipment rack, etc.). The most difficult vibration profile for the SATCOM antenna is the tail mount location defined by Curve E – Empennage & Fin Tip [1] (Fig. 2). In contrast, the vibration profile for equipment mounted in the avionics bay is much less, Curve B2 – Instrument Panel, Console, & Equipment Rack [1].

This work was sponsored by the Defense Advanced Research Projects Agency (DARPA) Mesodynamics Architectures Dynamics Enabled Frequency Sources (DEFYS) program and administrated through the Air Force Research Laboratories (AFRL) under contract number FA8650-10-C-7035.

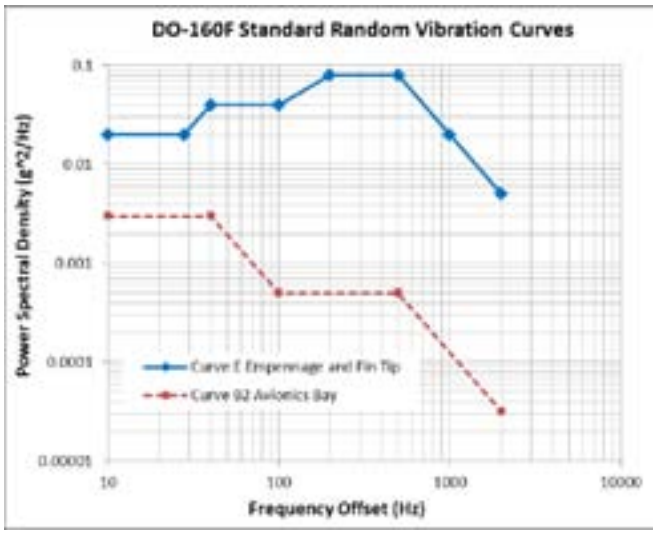

Fig. 2 DO-160F Standard Random Vibration Curves

As a reference oscillator for this application, consider the Wenzel 100MHz Rugged Oven Controlled Crystal Oscillator (Part Number 501-24760-01). This oscillator is a Commercial-Off-The-Shelf (COTS), macroscale quartz crystal oscillator with good phase noise performance and minimal sensitivity to vibration (0.5 ppb/g) [2]. But the vibration environment for mounting near the skin of the aircraft (Curve E Empennage and Fin Tip) is so difficult that the phase noise degradation is significant (Fig 3).

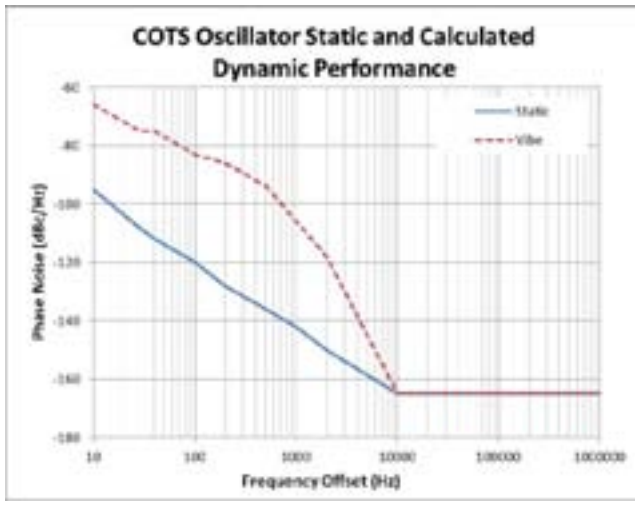

Fig. 3 COT Oscillator Static and Dynamic Phase Noise Performance

Aircraft use an adapted architecture to overcome this performance degradation. The LNB imports the reference signal from the modem where the vibration is less harsh (Curve B2 Avionics Bay). The phase-locked loop (PLL) for the LNB local oscillator has a loop bandwidth larger (typically greater than 10kHz) than the vibration frequencies (typically less than 2kHz) to suppress vibration induced phase noise in the voltage-controlled oscillator (VCO) and the phase noise degradation due to the less severe vibration in the avionics bay is minimal. Similar schemes are often employed in radar systems as well (Fig. 4).

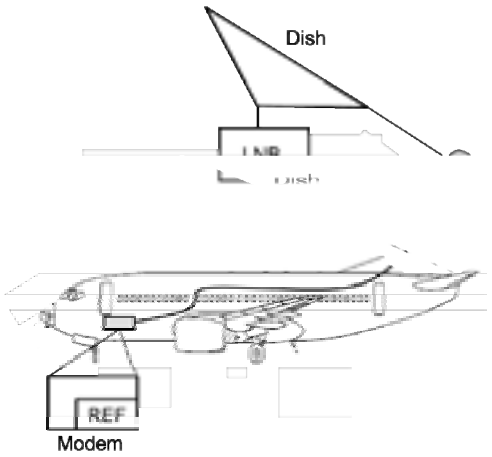

Fig. 4 Airborne SATCOM Architecture

II. TEST RESULTS

Rockwell Collins tested a 698 MHz fixed frequency oscillator, developed by HRL Laboratories under the DARPA Meso program. The Pierce oscillator (Fig. 5) was built using a wafer-scale packaged microscale quartz resonator and a transistor with positive feedback [3].

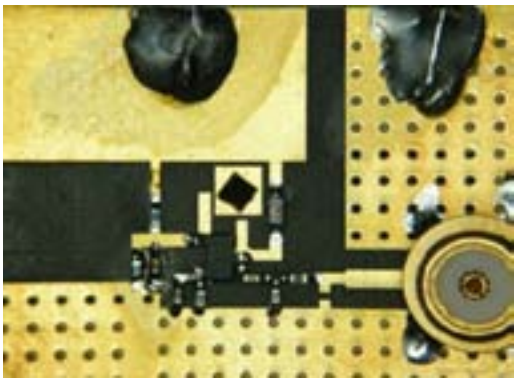

Fig. 5 HRL Microscale Quartz Oscillator at 698MHz

Rockwell Collins performed sinusoidal vibration testing of HRL oscillators. The evaluation board was tested in the X, Y, and Z axes. In the test set up (Fig. 6), sinusoidal vibration frequency is controlled from the waveform generator and amplitude is controlled by the amplifier. An accelerometer was placed near the resonator to confirm stimulus. Cables were clamped in various ways to prove that cable resonance was not distorting the measurement (Fig.7). Sideband modulation power was measured on an E4440A spectrum analyzer and compared to an E5052 phase noise analyzer. The device under test (DUT) sensitivity was calculated using the following equation:

$$\mathcal{L}\left(f_{vibe}\right) = 20\log\left(\frac{\overline{\Gamma} \bullet \overline{A} f_0}{2 f_{vibe}}\right) \qquad (1)$$

where f_{vibe} represents the frequency of the sinusoidal vibration in Hz, $\bar{A}$ represents the vibration intensity in g-rms, f_0 represents the fundamental oscillator frequency in Hz, and $\mathcal{L}$ represents the power of the vibration-induced sideband in dBc relative to the carrier power.

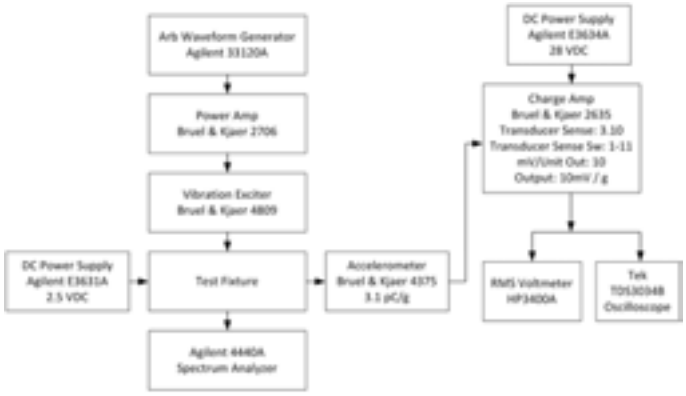

Fig. 6 Test Setup for Vibration Measurements

Fig.7 Vibration Table with Cables Clamped (left) Z-axis Setup with Accelerometer Placed Near Resonator (right)

Fig.8 shows the results of the HRL oscillator. Multiple points represent calculated Γ for varied vibration intensity. The HRL oscillator has several measurements better than 0.1 ppb/g.

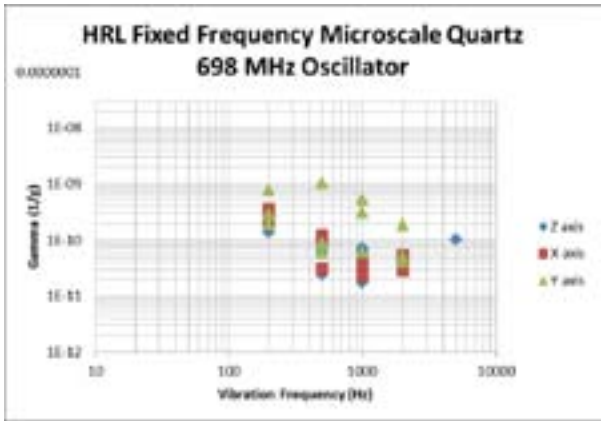

Fig.8 Vibration Sensitivity of HRL 698MHz Oscillator

III. FUTURE APPLICATIONS

Future systems for airborne systems desire less restrictive architectures. For example, modular or removable terminals that encompass the entire system (antenna, LNB, modem, etc.) could be mounted on the aircraft skin with only power and ethernet connections in addition to structural mounting. This would allow mission tailoring for military aircraft (select L, Ku, or Ka-band SATCOM) or optimization of commercial aircraft (installed for oceanic flights but removed for short flights to reduce weight and fuel expenditures). Unmanned Air Systems (UAS) are also becoming increasingly reliant on SATCOM systems. These platforms face extreme temperature ranges since constant temperature does not need to be maintained without people on board. UAS platform vibration profiles are even harsher since many of the platforms are quite small with a relatively small mass that is easily disturbed compared to manned aircraft. In these new applications, the reference oscillator must endure the harshest vibration profiles.

Microscale and nanoscale oscillators are a promising new technology that may be able to address these applications. Their relatively small mass compared to traditional oscillators makes them less sensitive to vibration. The vibration sensitivity of the HRL oscillator was measured and the average of the z-axis measurements is shown below (Table 1).

Table 1 - HRL Oscillator Z-Axis Vibration Sensitivity

Vibration Frequency (Hz)	G-sense (g^2/Hz)
200	0.16
500	0.06
1000	0.05
2000	0.05

The phase noise of a COTS oscillator and the 698MHz microscale oscillator developed by HRL are compared in Fig. 9. The native frequency of the Wenzel oscillator is 100MHz and the HRL oscillator is 698MHz. Both oscillators have been scaled to 1GHz for comparison.

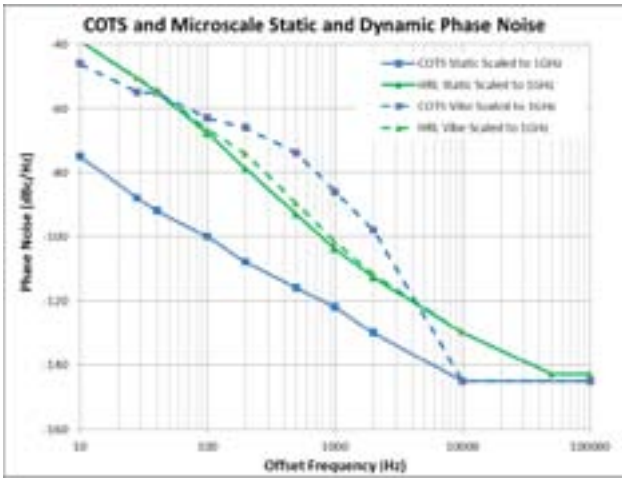

Fig. 9 COTS and Microscale Oscillator Static and Dynamic Phase Noise

Under static conditions, the COTS oscillator has superior phase noise performance compared to the HRL oscillator. At vibration frequencies less than 2 kHz under the harsh vibration conditions of DO-160F Profile E, the phase noise of the COTS oscillator degrades significantly. As a qualitative comparison, the single sideband phase noise was integrated from 10-2000Hz. The COTS oscillator degrades almost 30dB while the HRL oscillator increases less than 1dB (Table 2). Degraded phase noise performance can lead to reduced communication range [4].

Table 2 Single Sideband Jitter Integrated over 10-2000Hz

	COTS (dB)	HRL (dB)
Static	-67.5	-31.2
Dynamic	-34.6	-31.0

While the static phase noise performance of the HRL oscillator is not as good as the COTS oscillator, its dynamic performance under the same vibration profile is superior from 40-2000Hz offset frequency. This is an advantage for small mobile platforms facing harsh vibration environments such as UAVs, and larger platforms with installations near the skin of the aircraft.

IV. COTS AND HRL OSCILLATOR COMPARISON

A comparison of relevant parameters for the COTS and microscale oscillators is listed in Table 3. Some of the most promising aspects of microscale oscillators are their relatively small size and low power. The HRL oscillator is about one hundredth of the volume and about one thousandth of the power consumption of the COTS oscillator. Frequency stability of current microscale oscillators is not adequate for most applications. Most COTS oscillators have a frequency stability better than 100ppm. Research efforts are underway investigating ovenization techniques to improve frequency stability in microscale oscillators. Under static conditions, the COTS oscillator has superior phase noise performance at a 1kHz offset compared to the HRL oscillator. Applying the DO-160F Curve E vibration conditions, the microscale oscillator phase noise suffers minimal degradation while the COTS oscillator phase noise has increased significantly and surpasses the microscale oscillator phase noise.

Table 3 - Comparison of COTS and HRL Oscillator

Parameter	COTS	HRL

V. CONCLUSION

Microscale quartz crystal oscillators offer superior vibration performance to COTS quartz crystal oscillators in 100x smaller size. While their static phase noise is inferior to macroscale COTS quartz oscillators, they can achieve the same or better phase noise performance as COTS oscillators in high vibration scenarios. The microscale oscillator will require better frequency stability versus temperatures for most communication and navigation applications. Many radar systems measure frequency returns relative to themselves. Therefore, their frequency drift requirements may be more tolerant.

***Abstract*—We present a new characterisation technique for atomic vapor cells, combining time-domain measurements with absorption imaging to obtain spatially resolved information on decay times, atomic diffusion and coherent dynamics. The technique is used to characterise a microfabricated Rb vapor cell, with N_2 buffer gas, placed inside a microwave cavity. High-resolution images of the population (T_1) and coherence (T_2) lifetimes in the cell are presented. Atom-wall collisions and atomic diffusion result in a 'skin' of reduced T_1 and T_2 times around the edge of the cell. The technique also allows polarisation-resolved imaging of the microwave magnetic field inside the cell. Our technique is useful for vapor cell characterisation in atomic clocks, atomic sensors, and quantum information experiments.**

I. Introduction

The use of alkali vapor cells in atomic physics has a history extending back several decades [1], and has led to important applications in precision measurement [2] and quantum information [3]. Recent years have seen great interest in newly developed miniaturised and microfabricated vapor cells, with sizes on the order of a few millimeters or smaller. Applications include miniaturised atomic clocks [4], and magnetometers measuring both DC [5] and radio-frequency [6] fields. As new applications, one of our groups has recently demonstrated imaging of microwave magnetic fields using a vapor cell [7], and detection of microwave electric fields has been reported in Ref. [8]. Thanks to microfabrication, vapor cells have been miniaturised to a point where spatially resolved information on their properties, and on the external fields applied to them, is essential to their characterisation and performance.

In this paper, we describe a new characterisation technique, applying time-domain Ramsey, and Rabi measurements and absorption imaging [9] to a microcell. Time-domain measurements in vapor cells are currently experiencing a renaissance in interest [10]. Absorption imaging is well established in use with ultracold atoms, however its use with room-temperature atoms is a relatively unexplored area. We use these tools to characterise a microfabricated vapor cell [4] and a microwave cavity designed for compact vapor cell atomic clocks [11], obtaining spatially resolved images of decay times in the cell and images of the microwave field applied to the cell.

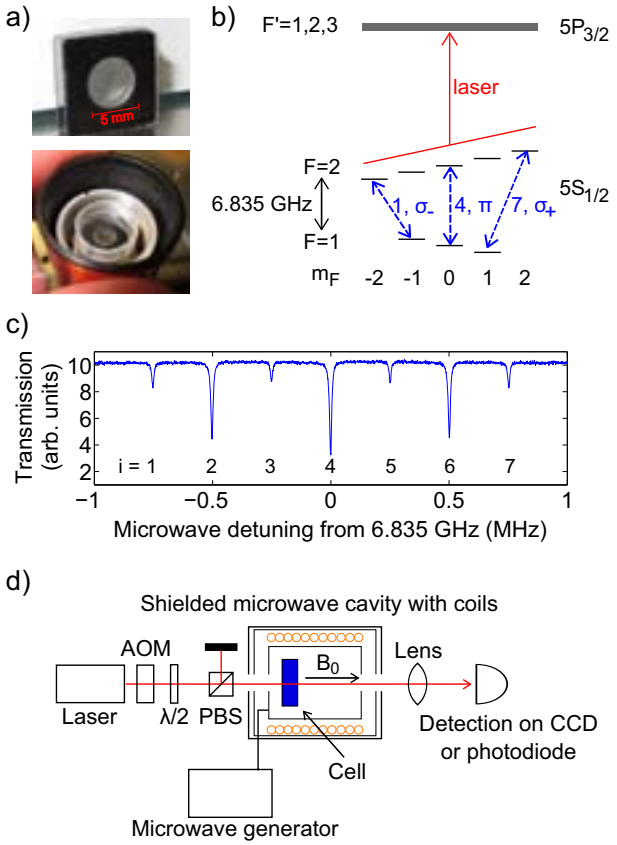

Fig. 1. a) Top: the microfabricated vapor cell used in this paper; Bottom: the cell inside the microwave cavity and coils; b) The ^{87}Rb D2 line. Due to Doppler and collisional broadening on the optical transitions, the excited state hyperfine levels F' are not resolved. Transitions between the Zeeman-split m_F levels of the ground state hyperfine structure can be individually addressed by the microwave field. The three hyperfine transitions used in this work ($i = 1, 4, 7$) are shown in dotted blue; c) A double resonance spectrum, showing laser transmission through the cell as the microwave frequency is scanned. Transmission is reduced whenever the microwave comes on resonance with a hyperfine transition; d) The experimental setup.

Readers are directed to Ref. [12] for a more in-depth coverage of this work.

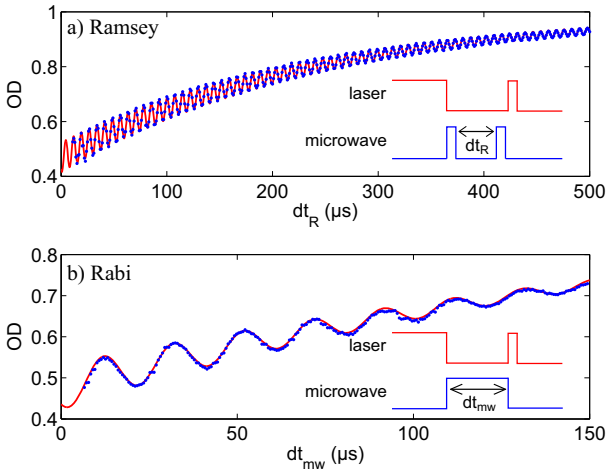

Fig. 2. Cell OD response to a) Ramsey, and b) Rabi sequences, recorded using a photodiode. Data is shown as blue dots, while the fitting curves (described in the text) are in red. Note the different scales. The insets show the laser and microwave sequences used. The OD increases with laser dark time, as the hyperfine population difference relaxes.

II. Equipment and Setup

We use the microfabricated cell shown in Figure 1a. The cell has a $5\,\mathrm{mm} \times 2\,\mathrm{mm}$ internal diameter and thickness, and contains natural abundance Rb and $63 \pm 2\,\mathrm{mbar}$ of N_2 buffer gas [4]. The cell is inserted into a microwave cavity [11], which is surrounded by a solenoid coil providing a static magnetic field (see Figure 1d). The resulting Zeeman splitting allows all seven ^{87}Rb hyperfine transitions to be individually addressed, as shown in the double-resonance spectrum of Figure 1c. We label the transitions $i = 1 \ldots 7$, in order of increasing frequency [12]. The cell temperature was set to 90°C for all data presented in this paper.

We use a laser frequency stabilised on the ^{87}Rb D2 line, pulsed using an acousto-optical modulator (AOM) to perform optical pumping [13] and absorption measurements using the single laser beam. Microwave signals near 6.835 GHz are produced by a frequency generator, and coupled into the cavity.

III. Experiment Sequences

We use pulsed Ramsey and Rabi sequences to characterize the vapor cell. Ramsey sequences provide both T_1 and T_2 times, where the T_1 times refer to population relaxation between all $F = 1$ and $F = 2$ sublevels, whilst the T_2 times are specific for the particular hyperfine m_F transition probed. Rabi sequences provide the microwave magnetic fields strengths applied to the cell.

In a typical sequence, we first apply an optical pumping pulse to the vapor that depopulates the $F = 2$ state. It is followed by microwave pulses that coherently manipulate the atomic hyperfine state. Finally, we measure the optical density (OD) in the $F = 2$ state with a probe pulse. Detection is performed using either a photodiode, or absorption imaging on a CCD camera.

We performed a first characterisation of the cell using a photodiode as the detector, described in the next two sections, III-A and III-B. An approximate laser intensity of $5\,\mathrm{mW/cm^2}$ was used.

A. Ramsey Measurements

In Ramsey sequences, we introduce two microwave pulses between the pump and probe laser pulses, separated by an evolution time dt_R (see Figure 2a). These result in coherent oscillations between the two coupled hyperfine m_F states, which we can record by scanning dt_R over multiple runs of the experiment. The oscillation frequency is given by the microwave detuning. Ramsey sequences are robust to laser and microwave field induced decoherence, as the majority of the atomic evolution occurs in the dark, with the microwave and optical fields off. As such, they provide a good measure of the T_2 time of the cell.

Figure 2a shows an example Ramsey sequence. A large-diameter laser beam was used, illuminating the entire cell, and the microwave was slightly detuned by δ from the $i = 4$ transition. The data is fit with the equation

$$\begin{aligned} \mathrm{OD} &= A - B\exp(-dt_R/T_1) \\ &\quad + C\exp(-dt_R/T_2)\sin(\delta\, dt_R + \phi) \end{aligned} \tag{1}$$

Where A, B, C, ϕ, T_1, T_2, and δ are fitting parameters. The fit gives the two relaxation times as $T_1 = (245 \pm 0.5)\,\mu$s and $T_2 = (322 \pm 4)\,\mu$s. The exact detuning of the microwave from resonance is given by the Ramsey oscillation frequency, $\delta = 2\pi \times (135.764 \pm 0.006)$ kHz.

B. Rabi Measurements

A Rabi sequence consists of a single microwave pulse applied during the dark time between the laser pumping and probe pulses. The microwave pulse drives Rabi oscillations between the two coupled hyperfine states, at a frequency proportional to the microwave magnetic field strength. By tuning the microwave frequency to transitions $i = 1$, 4, and 7, we are sensitive to the σ_-, π, and σ_+ components of the microwave magnetic field, respectively. This allows us to measure each vector component of the microwave magnetic field [7], [12].

An example Rabi sequence is shown in Figure 2b. A 1 mm diameter laser was used, and the microwave frequency was tuned exactly to the $i = 4$ transition, having been calibrated using a Ramsey sequence. Defining τ_1, the population difference lifetime, and τ_2, the Rabi oscillation lifetime, the data is fit with the equation

$$\begin{aligned} \mathrm{OD} &= A - B\exp(-dt_{mw}/\tau_1) \\ &\quad + C\exp(-dt_{mw}/\tau_2)\sin(\Omega\, dt_{mw} + \phi), \end{aligned} \tag{2}$$

where A, B, C, ϕ, τ_1, τ_2, and Ω are fitting parameters. We obtain $\tau_1 = (231 \pm 9)\,\mu$s and $\tau_2 = (94 \pm 3)\,\mu$s. On the $i = 4$ transition, we are sensitive to the π component of the microwave magnetic field, and so $\Omega_4 = 2\pi \times 50.39 \pm 0.05$ kHz corresponds to $B_\pi = 3.600 \pm 0.003$ μT at the point interrogated by the laser [12].

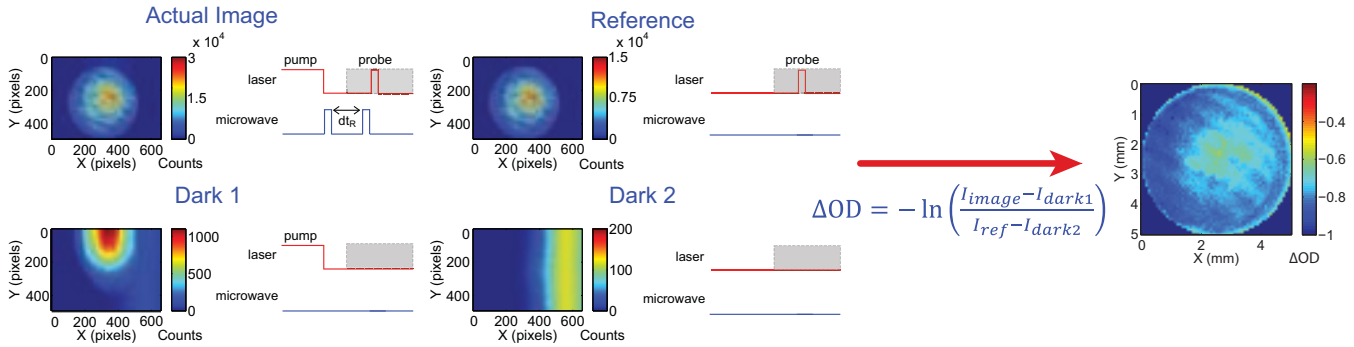

Fig. 3. Absorption imaging. Left: four images are used to create an image of the relative OD (ΔOD). These are the actual image (I_{image}), with the full experimental sequence of pumping, microwave pulses (in this example a Ramsey sequence), and probe pulse; a reference image (I_{ref}), consisting of a probe pulse, without optical pumping or microwave pulses; a dark image for the actual image (I_{dark1}), taken with pump pulse but no microwave or probe pulses; and a dark image for the reference image (I_{dark2}), taken with both the laser and microwave off. Grey boxes indicate when the camera electronic shutter is open. Right: These four images are then used to calculate ΔOD.

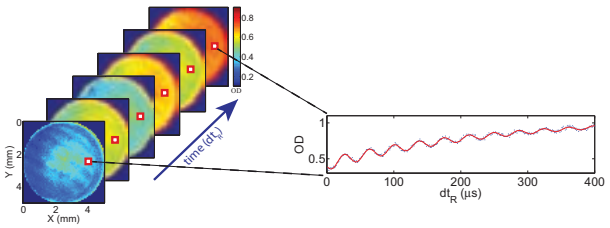

Fig. 4. Left: Images of the cell OD during a Ramsey sequence, at $dt_R = 5, 25, \ldots 105\,\mu$s. An experiment run results in an image of the optical depth for each dt timestep. Right: Examining a single pixel, we see oscillations in the OD in time, which we can fit using Eq. (1) to obtain T_1 and T_2 at that location.

IV. Spatially Resolved Imaging of Relaxation Times and Microwave Field Strength

We now turn our attention to measurements using the CCD camera. We use the technique of absorption imaging, which was developed in experiments with ultracold atoms to obtain accurate images of atomic density distributions in a given hyperfine state [9]. We record four images to create an image of the observed variation in optical density ΔOD, as described in Figure 3 and Ref. [12]. As a consequence of adapting the technique to hot atoms, we cannot directly obtain the OD from the four images [12], however this can in turn be obtained by normalising ΔOD to the OD measured with no optical pumping. The use of reference and dark images significantly reduces our sensitivity to short and long term drifts in the imaging system and to spatial variations in the laser intensity profile.

An image of the cell OD is produced for each dt timestep of an experimental sequence, as shown in the left-hand side of Figure 4. Each pixel has a time-varying signal (Figure 4, right-hand side), which is fit with either Eq. (1), for Ramsey sequences, or Eq. (2), for Rabi sequences.

In order to obtain a strong signal, the laser intensity averaged over the 5 mm cell diameter was set to $30\,\mathrm{mW/cm^2}$ for the data presented in the following sections, IV-A and IV-B.

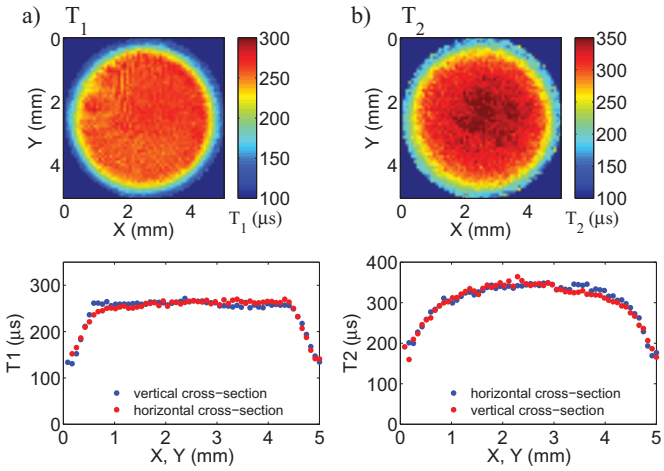

Fig. 5. Measured T_1 and T_2 times across the cell. The top panels show a) T_1 times obtained from fitting a Ramsey sequence; and b) T_2 times obtained from the same Ramsey sequence. The bottom panels show cross-sections of each image, averaged along 3 pixel wide lines passing horizontally and vertically through the image centres. Close to the walls, there is a significant decrease in T_1 and T_2 due to Rb-wall collisions.

A. Imaging Relaxation

Figure 5 shows images of the T_1 and T_2 times across the cell, produced using a Ramsey sequence with the microwave frequency set slightly detuned from the $i = 4$ (clock) transition, and the microwave input power to the cavity set to 21.8 dBm,. Each pixel of the Ramsey data was fit using Eq. (1), yielding T_1 and T_2 times with $\pm 1\%$ and $\pm 4\%$ fitting uncertainties, respectively.

The bottom panels of Figure 5 show cross-sections of the T_1 and T_2 images. The relaxation rate is uniform across the centre of the cell, with T_1 times around 265 μs, and dropping away to 150 μs at the cell edge, due to the depolarisation of Rb atoms after collisions with the cell walls [12]. This 'skin' of reduced atomic lifetimes near the cell edge is reproduced in a model of the T_1 time presented in Ref. [12]. The T_1

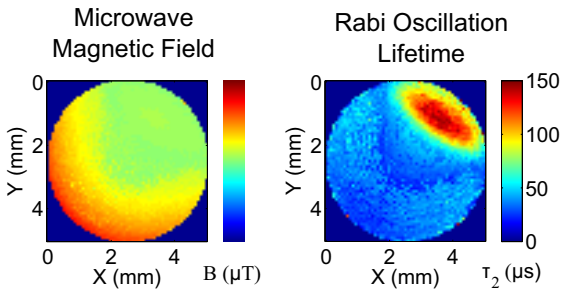

Fig. 6. Left: Image of the π component of the microwave magnetic field, obtained using a Rabi sequence on the clock transition. Right: Images of the corresponding Rabi oscillation lifetime, τ_2.

times obtained in the centre of the cell are larger than the values obtained using the photodiode in section III-A, as the photodiode measurements averaged the relaxation time over the entire cell, including the regions near the cell walls.

The T_2 time across the cell, shown in the right-hand panels of Figure 5, has a much smoother profile than the flat-top profile of the T_1 images, with the influence of the cell walls extending to the cell centre. T_2 values in the centre of the cell peak at around $350\,\mu$s.

B. Imaging the Microwave Magnetic Field

Figure 6 shows the π component of the microwave magnetic field, obtained using a Rabi measurement on the clock transition, $i = 4$. The right panel shows the corresponding decay time of the Rabi oscillations (τ_2). The microwave frequency was calibrated using a Ramsey sequence, and tuned exactly to resonance, and the microwave power at the input to the cavity was 26.8 dBm. Each pixel was fit using Eq. (2), and the microwave magnetic field strength was then calculated as described in Ref. [12]. The σ_- and σ_+ components were also imaged [12], with measured field strengths below $1.5\,\mu$T. The π component, whose dominance follows from the cavity design [11], is more than 3 times stronger, with field strengths up to $5\,\mu$T.

The lifetime, τ_2, of the Rabi oscillations is significantly shorter than the T_2 time, principally due to inhomogeneities in the microwave magnetic field [1]. This can be seen in Figure 6, where the τ_2 time is inversely correlated with the magnitude of the microwave magnetic field inhomogeneity, which in turn is linked to the field strength. The strong spatial variation in τ_2 highlights the importance of our technique for cell and cavity characterisation, in particular for high precision devices such as vapor cell atomic clocks.

V. Conclusions

We have used time-domain spatially resolved optical and microwave measurements to image atomic relaxation and the polarisation-resolved microwave magnetic field strength in a microfabricated Rb vapor cell placed inside a microwave cavity. The population and coherence relaxation times were measured to be uniform across the cell centre, with values at 90°C of $T_1 = 265\,\mu$s and $T_2 = 350\,\mu$s, respectively. Depolarising collisions between Rb atoms and the cell walls resulted in T_1 and T_2 times around $150\,\mu$s near the cell edge, and diffusion of these atoms lowered relaxation times within $0.7\,$mm of the cell wall. Images of the cavity microwave magnetic field show significant spatial inhomogeneity, due to perturbations to the cavity introduced by the dielectric cell material. For a given hyperfine transition, we can identify the cell region maximising the number of Rabi oscillations, and hence the region of optimal coherent manipulation.

Our measurement technique is fast, simple, and produces high resolution images for vapor cell and microwave-device characterisation. It is of particular interest for characterising cells in miniaturised atomic clocks and sensing applications. It is also of interest for characterising the cell and cavity properties in larger and high-performance vapor cell atomic clocks.

***Abstract* — The detailed design of the Swiss Miniature Atomic Clock (Swiss–MAC) was presented by CSEM in 2012. This paper describes the progress made in the meantime towards the realization of the integrated Swiss–MAC, by presenting a first prototype showing preliminary but very promising performances.**

I. INTRODUCTION

Miniature atomic clocks (MACs), typically based on the coherent population trapping scheme (CPT) [1], show the promise of having miniature (< 1 cm^3) and low-power (< 100 mW) portable microwave frequency standards [2]. The Swiss–MAC was designed to target such state of the art specifications. The current prototype integrates most of the desired functionalities, except the vacuum encapsulation of the physics package and the integrated temperature regulation of the atomic vapor cell. The prototype (Fig. 1) is powered by a separate PCB equipped with a battery pack and different monitoring and debugging inputs/outputs. The main PCB has a dimension of 50 x 100 mm^2 with 1/3rd of its surface populated by jumpers and connectors.

Fig. 1. Picture of the full Swiss–MAC prototype (caps removed).

II. SWISS–MAC DESIGN

The core physics package, as designed and presented in 2012 (Fig. 2) [3], is realized by a stacking of standard functionalized PCB layers (Fig. 3). It has dimensions down to 11 x 11 x 8.5 mm^3 (1 cm^3), including the functionalized atomic vapor cell with dimensions downsized to 4 x 4 x 1.6 mm^3 (26 mm^3). The cell is surrounded by a flex circuit for electrical connection (heater, Tsensor and C-coils) and by an internal magnetic shielding.

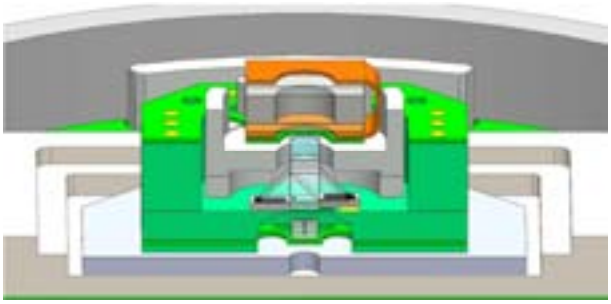

Fig. 2. Design of the physics package (sectional view).

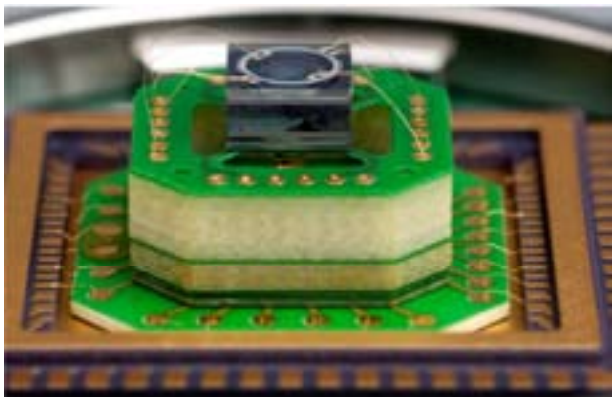

Fig. 3. Picture of the current physics package with stacked PCB layers. Internal magnetic shielding is not shown.

The core physics package is mounted in a commercial ceramic package for vacuum encapsulation. The resulting assembly (Fig. 4) is surrounded by an external Ø 42 mm magnetic shielding, the overall volume of the physics package reaching 22 cm^3. The SMAC prototype is controlled by means of a LabVIEW® interface communicating with an MSP430 microcontroller. The latter drives the 3rd generation of a dedicated proprietary ASIC, with built-in RF lock loop and laser lock loop, and with integrated laser bias current source, three temperature sensors, and four additional current sources.

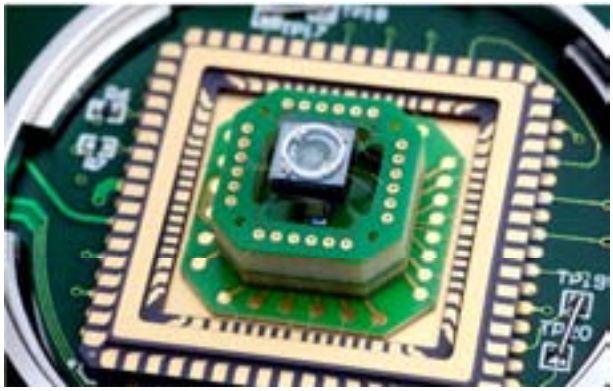

Fig. 4. Picture of the physics package with ceramic package and external magnetic shielding ring (caps not shown).

III. LOW-POWER INTEGRATED ELECTRONICS

Lowering the overall power consumption of the miniature atomic clock is partially done by integrating most of the electronics in an application-specific integrated circuit (ASIC). Version 3.0 of the RF chip integrates the RF frequency and the laser frequency lock loops (v2.0) [4], as well as four additional current sources for heating the laser and the atomic cell and for driving the Helmholtz coils (v3.0). Fig. 5 shows a graphical representation of the functionalities integrated in the different versions of the ASIC.

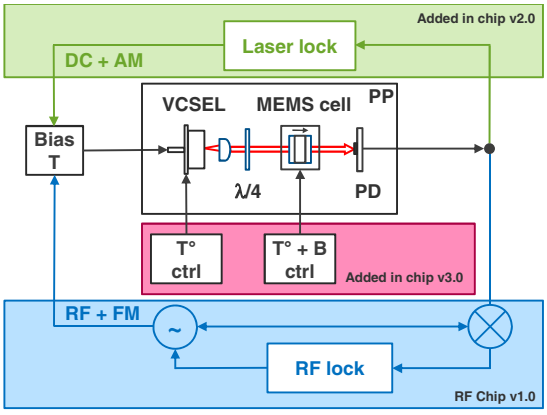

Fig. 5. Graphical representation of the 3 different chip versions.

Fig. 6 shows the layout and a picture of the chip version 3.0 that has been integrated into the Swiss–MAC prototype. The battery operated chip could successfully drive a laboratory CPT atomic clock (laser and RF frequencies lock loops) with 26 mW of power consumption [4].

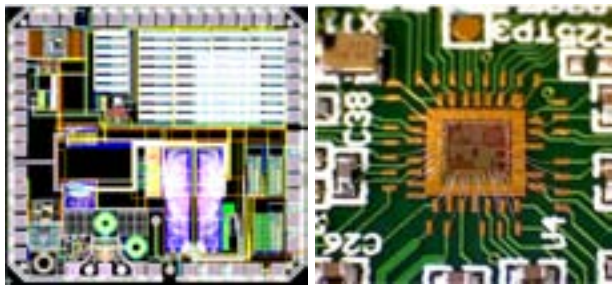

Fig. 6. Chip layout (left) and chip bonded on the Swiss–MAC PCB (right).

Ongoing work allowed to successfully temperature stabilize the laser and to lock its optical frequency on one Rubidium-87 absorption line with 42 mW of total power consumption, the physics package being exposed to room temperature air without vacuum encapsulation.

IV. MINIATURE ATOMIC VAPOR CELLS

Fabricating small leak free atomic cavities with reproducible filling is still challenging. An important effort has been done to develop wafer level fabrication of millimeter size atomic MEMS cells made of silicon and glass by using an alkali azide solution to fill the cell cavities.

After full evaporation of the solvent, the cavities are sealed by anodic bonding under controlled atmosphere. Metallic rubidium and nitrogen are obtained by UV decomposition of the crystallized rubidium azide.

The first cells (10 x 10 mm^2) fabricated in this way showed promising performances for a CPT miniature atomic clock and optimization of the buffer gas mixture is still ongoing.

The cells were miniaturized down to 1 x 1 mm^2 but much of the work has nevertheless been pursued on 4 x 4 mm^2 cells in order to add functionalities to the glass windows (Fig. 7). Both faces have integrated heaters, temperature sensors and Helmholtz coils.

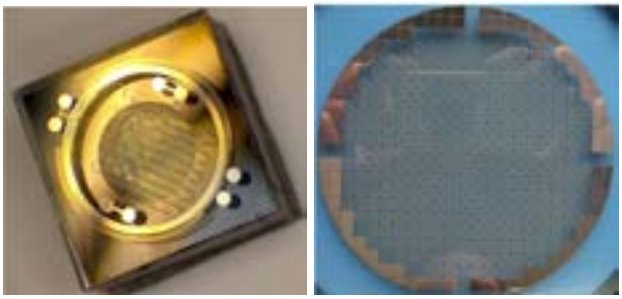

Fig. 7. Functionalized 4 x 4 x 1.6 mm^3 atomic MEMS cell (left) and 4 inch functionalized glass wafer (right).

The functionalized cells are currently characterized. Heating the cells up to 100°C has been achieved without problems and ^{87}Rb 0-0 CPT signals have been measured in a laboratory setup. Integrating the functionalized cells in the prototype is still ongoing.

V. RESULTS

The SMAC prototype is currently in its integration and test phase. The main lock loops could already be closed and preliminary frequency stability measurements could successfully be realized by using an external ^{87}Rb miniature glass atomic vapor cell (100 mm^3). The preliminary performances (Fig. 8) demonstrate a frequency stability of $\sigma_y = 3 \cdot 10^{-11}$ at one day integration time (no drift removal), while being at $\sigma_y = 6 \cdot 10^{-11}$ at 1 s, showing that our integrated electronics supports sub 10^{-10} short term frequency stability. The ^{87}Rb MEMS atomic vapor cells are being integrated in the Swiss–MAC prototype and further improvements and tests are ongoing. The complete prototype will be functional and fully characterized by the end of 2013.

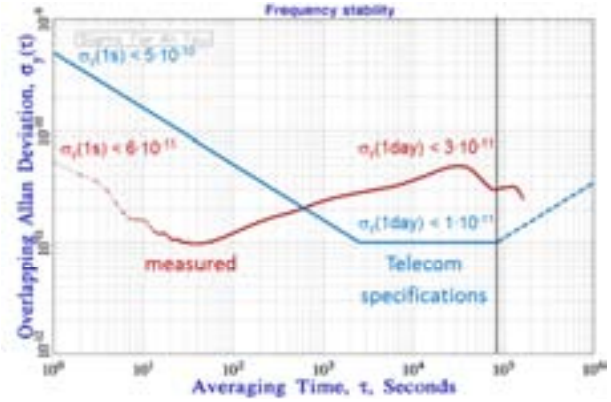

Fig. 8. Preliminary performances obtained with the Swiss–MAC prototype using an external ^{87}Rb miniature glass cell.

ACKNOWLEDGMENT

This research activity is performed in the frame of a multidivisional research program and CSEM would like to thank the Swiss Confederation, the Canton of Neuchâtel, the Canton of Basel and the Cantons of Central Switzerland for their financial support. Fruitful discussions and contributions from J.-F. Léchenne, M. Toimil, P. Pilloud, R. Rusconi, T. Le, S. Bitterli and J. Kaufmann are acknowledged.

***Abstract*—We evaluate the potential of a new generation microwave cavity by double resonance spectroscopic studies. Both, the cell and the microwave cavity are microfabricated. This allows a substantial size reduction for the physics package, without compromising the RF field geometry and the optical quality of the cell windows. We demonstrate short term stability of $5 \times 10^{-12}\tau^{-1/2}$ (1-100 s), and below 1×10^{-12} up to 10^3 s. Finally, we report on the AC stark shift effect, one of the main limiting factors for long term clock stabilities.**

I. Introduction

Numbers of compact commercial double resonance (DR) clocks are using Loop-Gap Resonators (LGR) having the size of half the wavelength. Different names have been given to these resonators, magnetron-type resonator [1] or slotted-tube cavity [2], but still, loops and gaps define the field geometry. Reducing the size of this type of resonator is a challenging task which requires a complete redesign, and some successful alternatives have been presented in the past. One can cite, among others, Deng who proposed a "modified coaxial cavity" [3] and Braun et al. with two parallel non radiating RF feed loops [4]. This paper reports on a novel type of microwave resonator, the μ-LGR [5], [6], and its spectroscopic evaluation. Such a study aims towards a miniature atomic clock having similar stability performances to a compact commercial atomic DR clock but with a significant size and power consumption reduction.

II. Double Resonance (DR) and Experimental Setup

We use the DR interrogation technique [7]. Its principle consists in creating an inversion of the populations within the hyperfine ground states of a rubidium vapour by optical pumping, while the applied microwave, when at resonance, tends to equilibrate these populations. The DR spectrum is obtained by sweeping the frequency of the microwave frequency while the transmission of the cell is recorded (see Figure 2). In the clock operation, the clock signal, or $|F_g = 1, m_F = 0\rangle \leftrightarrow |F_g = 2, m_F = 0\rangle$ transition, is used as a reference to steer and stabilize the quartz oscillator at the basis of the microwave generation chain. In our setup, the pumping light is produced by an in-house made laser head [8] using a DFB laser of which light is resonant with the D2 line of the rubidium (780 nm). The laser head inbuilt sub-Doppler spectroscopic setup allows four different optical frequency references that can be used to lock the laser frequency. At the output of the laser head, the laser beam is split into two. One part is sent to a wavelength meter (HighFinesse WSU/30), the other part, before interacting with the Rubidium atoms, passes through different optics elements in order to control its polarization and power, and spatially homogenize its intensity. The enriched ^{87}Rb vapour is confined in a thick micro-fabricated cell [9], designed in parallel with the μ-LGR. The cell's internal volume has a cylindrical shape with dimensions of 4.05 mm height and 4 mm diameter. It is also filled with a buffer gas (BG) mixture of Argon and Nitrogen in order to reduce the collisions of the rubidium atoms with the cell's wall, as well as to diminish the sensitivity to temperature fluctuations [10]. The 6.834 GHz microwave radiation is produced from the 2.278 GHz output of a commercial synthesizer, via a frequency tripler. A similar DR setup is described in [11].

A. μ-LGR details

The μ-LGR was already presented at previous conferences [5], [12]; it consists of a multiple stack of printed planar loop-gap structures (see Figure 1) inductively coupled to a coaxial fed printed loop. The total cavity volume is < 0.9 cm^3. The development was done through software simulations in order to optimize the field orientation factor (FOF) [13], and study the influence of relevant geometrical features [5]. The advantages of such a cavity are:

- an excellent field geometry favouring the π-transitions, therefore the clock transition (see Figure 2). The FOF is measured to be 0.7; in other words, within the cell volume, 70% of the RF magnetic field power is parallel to the symmetry axis of the cell.
- a low RF power need, less than -20 dBm are required.
- an easy and low cost fabrication with an excellent reproducibility, thanks to the micro-fabrication process.

III. Experimental results

The clock transition resonance signal was recorded in many different experimental configurations; laser intensity and frequency as well as RF power and cell temperature were varied. Optimization of the clock signal, extraction of its intrinsic properties, as well as characterization of its environmental sensitivity were carried out.

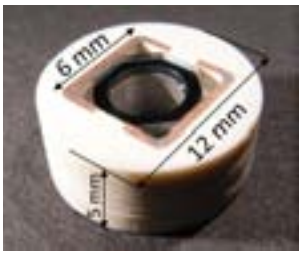

Fig. 1. μ-LGR containing the microfabricated cell.

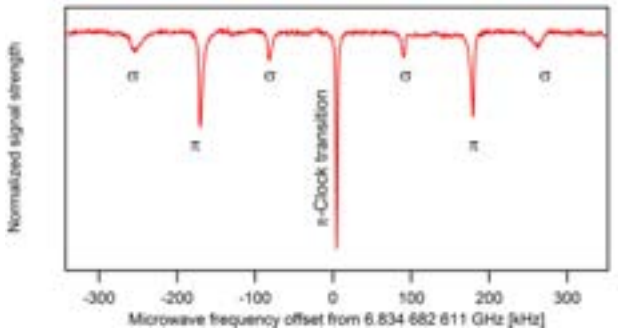

Fig. 2. Zeeman's spectrum at low RF power showing the π-transitions strongly favoured, sign of an excellent field geometry.

A. Clock signal lineshape

Figure 3 shows an optimized clock signal and its lorentzian fit. It has a contrast $> 7\%$ with a discriminator slope of 12 pA/Hz. Such a signal has a potential shot-noise limit of $2.5 \times 10^{-12}\tau^{-1/2}$. Contrasts up to 30% with similar shot-noise limit have also been measured, but the optimization was performed with the constrain to keep the light intensity as low as possible (less than 1 $\mu\mathrm{W/mm^2}$) in order to minimize the light shift effects (see discussion below). The total shift of 5 kHz matches well with the theoretical BG induced pressure shift.

Linear extrapolation of the linewidth to zero light intensity at low RF power gives an intrinsic value of less than 590 Hz; which is in excellent agreement with the 585 Hz theoretically predicted by the diffusion model in a cylindrical cell [14].

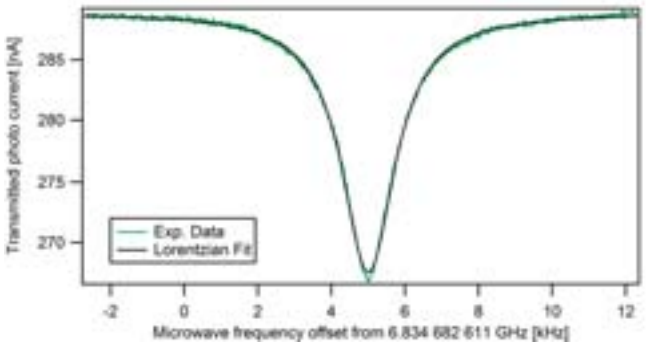

Fig. 3. Optimized DR signal and its lorentzian fit. the Linewidth is < 1.8 kHz for a contrast of $> 7\%$.

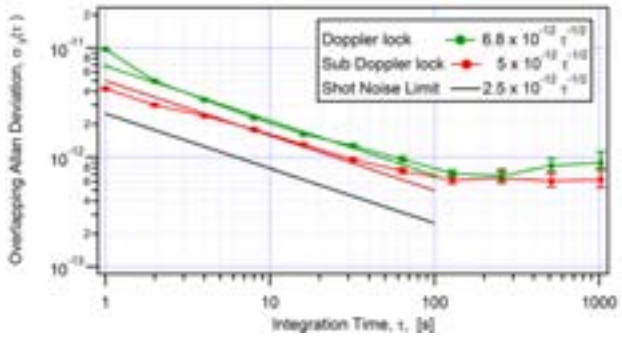

Fig. 4. Clock stability obtained with two different laser configurations: (red) laser frequency locked to CO23-21 dip of an external cell sub-Doppler spectrum; (green) laser frequency locked to the BG broadened peak of the clock cell ($|F_g = 2\rangle \rightarrow |F_e\rangle$). The shot-noise limit is draw in black.

B. Clock short-term stability

The short to medium term stabilities (see Figure 4) were measured using the optimized signal shown on Figure 3. Two different laser locking schemes were used. For the laser frequency locked to the sub-Doppler dip of the spectrum of the reference cell of the laser head (crossover between $|F_g = 2\rangle \rightarrow |F_e = 3\rangle$ and $|F_g = 2\rangle \rightarrow |F_e = 1\rangle$ transitions, or CO23-21), we obtained a short-term stability below $5 \times 10^{-12}\tau^{-1/2}$. A similar stability, $6.8 \times 10^{-12}\tau^{-1/2}$, is obtained when the frequency of the laser is referenced to the buffer gas broadened peak ($|F_g = 2\rangle \rightarrow |F_e\rangle$) of the clock cell itself. These obtained stabilities show a strong potential for a miniature atomic clock with the short to mid-term performances of a compact one.

C. Light-shift studies

Light shift effect, or AC Stark shift, is a well known process, and is also one of the main sources of instability in the different types of atomic frequency standards [15]. It is a direct consequence of the coupling between two states through an optical field, and can be calculated by the perturbation theory [16]. Since in the case of a real atom, many levels are coupled to the ground state levels, the contribution of each has to be taken into account [17]. The total light induced shift can be expressed as follows:

$$\Delta\nu_{LS} = \left(\frac{\Omega_L}{4\pi}\right)^2 \sum_{F_e=0}^{4} \left(\frac{\eta'_{F_e}\delta\nu'_{L_{F_e}}}{(\frac{\Gamma^*}{4\pi})^2 + (\delta\nu'_{L_{F_e}})^2} - \frac{\eta_{F_e}\delta\nu_{L_{F_e}}}{(\frac{\Gamma^*}{4\pi})^2 + (\delta\nu_{L_{F_e}})^2} \right). \quad (1)$$

where Ω_L is the optical Rabi frequency, $\delta\nu_{L_{F_e}}$ and η_{F_e} the frequency detuning and transition strength for the transition $|F_g = 1\rangle \rightarrow |F_e\rangle$ (the ' denotes for the transitions from the state $|F_g = 2\rangle$). Γ^* relates to the lifetime of the excited states. The frequency detunings are given by:

$$\delta\nu_{L_{F_e}} = \nu_L - \nu_{F_e} \quad (2)$$

for which ν_L is the laser frequency, and ν_{F_e} is the optical frequency for the atomic transition $|F_g = 1\rangle \rightarrow |F_e\rangle$, taking into account the induced BG collisional shift. The total pressure as well as the gas ratio are considered and the optical pressure shift coefficients taken from Rotondaro et al. [18].

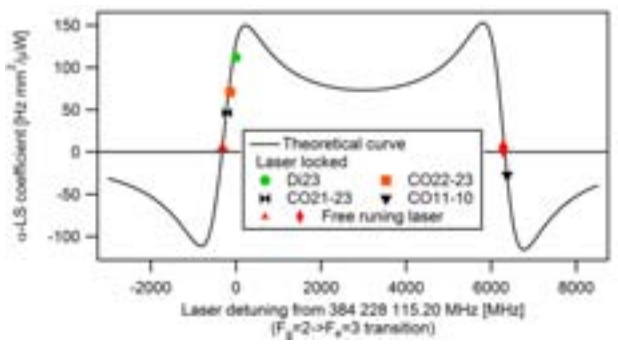

Fig. 5. Experimental (markers) and theoretical (line) light shift coefficients as a function of the laser frequency.

Figure 5 shows the theoretical and experimental intensity light shift coefficients (α-LS$= \frac{\partial \Delta\nu}{\partial I}$) as a function of the laser frequency. The experimental α-LS coefficients are measured by extracting the slope of the total shift of the clock signal as a function of the laser intensity at a given optical frequency. The abscissa zero detuning point corresponds to the direct transition $|F_g = 2\rangle \rightarrow |F_e = 3\rangle$, called Di23, of the unperturbed ^{87}Rb atom. A laser locked to this transition was used as a calibration reference for the wavelength meter. After the calibration, the optical frequencies were measured when the laser was locked to the other patterns of the sub-Doppler spectrum (crossover dips) of the reference cell. These experimental frequencies match within 1 MHz the theoretical values, validating the calibration over the full spectrum range. For the laser in free running mode, its frequency fluctuations during the measurement time imposes abscissa error bars of the order of ± 5 MHz. Both modes were tested at the four lockable frequencies in order to validate the α-LS coefficients obtained with the laser in free running mode. Similar coefficients are obtained with only 4% difference.

Equation (1) predicts two laser frequencies at which the α-LS coefficient is zero. These are offset from the Di23 transition of -327 MHz and 6321 MHz. The experimental α-LS coefficients measured at the -327 MHz offset is < 1.5 Hz mm$^2/\mu$W or $2.2 \times 10^{-12}/\%$ at 1 μW/mm^2. With a relative laser intensity fluctuation $< 10^{-3}$ at 10^4 s (in terms of Allan deviation), the α-LS coefficient contribution to the clock instability is $< 2.2 \times 10^{-13}$. The α-LS coefficient being laser frequency dependant, another coefficient has to be considered. Locally, the clock sensitivity to the laser frequency, $\frac{\partial \nu_{clock}}{\partial \nu_{laser}}$, is called β light shift [19], or β-LS coefficient. Since this coefficient scales linearly with the laser intensity (see (1)), a smaller intensity will therefore minimize its influence on the clock frequency. For a laser intensity of 1 μW/mm^2, at the -327 MHz offset, the relative β-LS coefficient is calculated to be 5.1×10^{-17} /Hz. Locked to a sub-Doppler atomic transition, our DFB-laser has a relative frequency stability $< 2 \times 10^{-11}$ at 10^4 s [8]. These frequency fluctuations results in a potential clock instability contribution of $\sim 4 \times 10^{-13}$. Table I summarizes the potential clock instabilities induced by the laser fluctuations in the two different lock schemes mentioned in section III-B. These results show a potential instability limit for the light shift clearly below 1×10^{-12} at 10^4 seconds.

TABLE I. α- AND β-LIGHT SHIFT COEFFICIENTS AND THEIR CORRESPONDING INDUCED CLOCK INSTABILITIES FOR A LASER INTENSITY OF 1 μW/mm^2.

	Coefficients	Parameter variations 10^4 s	Clock instability contribution
α-LS	$< 2.2 \times 10^{-12}/\%$	$< 10^{-3}$ rel.	$< 2.2 \times 10^{-13}$
	Doppler Lock strength		
β-LS	5.1×10^{-17}/Hz	$< 2 \times 10^5$ Hz [20]	$\sim 1 \times 10^{-11}$
	Sub-Doppler Lock strength		
β-LS	5.1×10^{-17}/Hz	$\sim 8 \times 10^3$ Hz	$\sim 4 \times 10^{-13}$

IV. Conclusion & Next steps

We have presented our spectroscopic studies using a new generation of physics package. The setup was also used as a clock demonstrator; two laser frequency locking scheme were used. Both allow excellent short term stabilities below $7 \times 10^{-12}\tau^{-1/2}$, and staying below 1×10^{-12} up to 10^3 seconds. Experimental and theoretical AC Stark shift were also presented, and an excellent agreement between them is observed. Though AC Stark shift remains one of the most limiting factor in terms of medium to long term stabilities, its limitation can be potentially reduced down to 4.6×10^{-13} at 10^4 s. Further spectroscopic studies still remain to be done, especially in term of temperature shift, power shift and the use of other light sources such as a microfabricated lamp [21], or other laser sources. Nevertheless, this study demonstrates a strong potential of the μ-LGR as part of a miniature atomic clock with highly competitive performances.

***Abstract*— Recent progress are reported on a compact cesium cell atomic frequency standard based on pulsed coherent population trapping. The Dick effect has been modelized and measured. The short term frequency stability has been improved to $3.2\times10^{-13}\ \tau^{-1/2}$. Important steps have been taken toward the understanding of the impact of laser power fluctuations on the mid-term stability, currently limited at 3.10^{-14} at 200s.**

Keywords—atomic clock, coherent population trapping, vapor cell clock, Dick effect, line pulling

I. INTRODUCTION

Compact and stable frequency standards are needed in many applications such as GPS or Galileo, the European GNSS. Double resonance (microwave and optical) alkali-metal vapor-cell atomic clocks are currently used for this purpose. However the next generation of space clocks could be based on the coherent population trapping (CPT) phenomenon [1]. In such clocks the microwave interrogation, and the microwave cavity, are suppressed. The atomic vapor in the cell is pumped and probed, in the same time, by two laser beams whose frequencies are separated by the microwave clock frequency. Because of their scheme simplicity and potential high performances, CPT clocks are promising candidates for on-board applications.

In this paper we report investigations on some frequency stability limitations of a CPT clock prototype. In order to maximize the short-term stability our prototype tries to combine a high signal amplitude and a narrow resonance width by using a so-called double Λ scheme and a Ramsey interrogation technique [2, 3]. The experimental set-up is described in Section II. The short-term stability was previously limited to $7\times10^{-13}\ \tau^{-1/2}$ [4]. After a careful investigation we shown that the stability was not limited by the signal-to-noise ratio but by the Dick effect [5]. Dick effect leads to a limitation of the stability of a frequency standard due to the sampling process of the atomic interrogation. The high frequency noise of the local oscillator (LO) is down converted by an aliasing effect [5, 6, 7]. This is addressed in Section III. The choice of a more suited LO allowed an improvement of the frequency stability to $3.2\times10^{-13}\ \tau^{-1/2}$, still limited by the LO noise. Section IV addresses the mid-long term limitation of the frequency stability. A new effect is explored, line pulling by neighboring transitions induced by the double Λ scheme.

II. EXPERIMENTAL SETUP

The lasers are tuned to the Cs- D_1 line at 895 nm, the inset in Fig.1 shows a scheme of the involved energy levels. In order to build a double Λ scheme (simultaneous σ^+ and σ^- optical transitions, see inset), the laser beams are orthogonally linearly polarized. As shown in Fig. 1, the superimposed beams of two phase-locked extended cavity diode lasers (ECDL), 9 GHz apart, are switched on and off by an acousto-optic modulator (AOM) before crossing the Cs-buffer gas cell. Compared to conventional CPT clocks, the pulsed interaction provides a Raman-Ramsey signal which allows a good frequency discriminator, whose slope is limited by the atomic relaxation in the cell (a few milliseconds), avoiding the power broadening of the resonance.

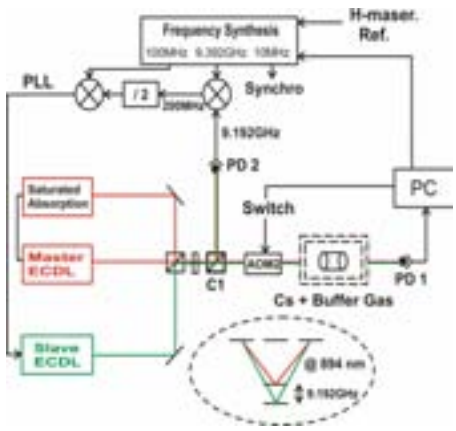

Fig. 1. Experimental setup. Red: Master extended cavity diode laser (ECDL). Green: Slave ECDL, locked at 9GHz from the master frequency using a phase locked loop (PLL). Clock evaluation is made by comparison with an H-maser. Inset: D1 Cs energy levels, red: master laser, green: slave laser. Cell : Ar/N2 mixture, P=21torr, P_{Ar}/P_{N2}=0.6, T=29°C.

The cell is enclosed in magnetic shields and temperature regulated. The transmitted laser intensity is measured by the photodiode PD1, linked to the computer (PC), which drives the time sequence of the AOM and lock the frequency synthesizer on resonance (the frequency splitting between the lasers). The clock frequency is measured versus an H maser of the laboratory.

III. Impact of Local Oscillator Noise on Short-Term Frequency Stability

In a sequentially operated clock, the effect of the LO frequency noise can been characterized by the sensitivity function $g(t)$ [5, 6, 7]. $g(t)$ is the sensitivity of the response of the atomic system, the signal S, to a phase step $\Delta\varphi$ of the interrogation oscillator at time t.

$$g(t) = \lim_{\Delta\varphi \to 0} \delta S(t, \Delta\varphi) / \Delta\varphi \qquad (1)$$

Its shape depends on the atomic system and on the kind of interrogation used. For our CPT pulsed clock, $g(t)$ has been measured and numerically calculated from the evolution equation of the density matrix ρ [8, 9], see Fig 2.

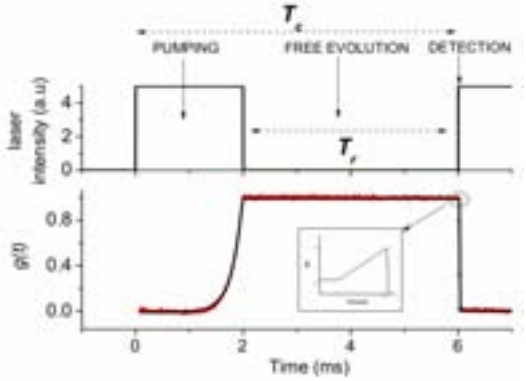

Fig. 2. Up : Sequence used, Pumping time: 2ms, Ramsey time: 4ms, detection 10µs after turn on of lasers, detection duration : 25µs. Laser intensity: 200µW/cm²/laser. Down : sensitivity function for CPT system Black : Numerical calculation, Red: measurements.

As $g(t)$ is zero during almost all the pumping period, the frequency noise of the local oscillator (LO) will only be detected during the Ramsey time Tr, leading to the generation of an imperfect correction signal. To fix the ideas, one can say that the larger the pumping time, the worse the frequency lock loop of the OL frequency on the atom will work. T_c is the length of an interrogation cycle, the duty cycle defined as Tr/Tc is 0.7 which is a favorable case compared to 0.3 in a cold atom setup [10]. The limitation to the fractional Allan deviation is [5, 6, 7]:

$$\sigma_y^2(\tau) = \frac{1}{\tau g_0^2} \sum_{m=1}^{\infty} |g_m|^2 S_y(m/T_c), \qquad (2)$$

Where $S_y(m/Tc)$ is the one-sided power spectral density (PSD) of the relative frequency fluctuations of the free running interrogation oscillator at Fourier frequency m/T_c, i.e. the harmonic frequencies of the operation frequency. The Fourier coefficient of $g(t)$ are given by :

$$g_m = \frac{1}{T_c} \int_0^{T_a} g(t) e^{-2\pi i m t / T_a} dt. \qquad (3)$$

As in the fractional Allan deviation expression (2) S_y is weighted by the Fourier coefficients of $g(t)$, its shape is of prime importance. Fig 3 compares three sensitivity functions corresponding to a squared (red), a 2 level system kind (blue) and a CPT system kind (black). The value of pumping and Ramsey time for the 2 level system kind are taken has typical one [11]. The starting point of the slope -40 dB/dec limits the bandwidth where the noise is still seen by the clock. After this point S_y will be weighted as $1/f^4$ in the Allan deviation calculation, meaning that the clock will no longer be sensitive to the LO frequency noise. For our clock, this point happens for harmonics three times higher than for a two level system. Such a behavior is due to the sharp decrease of $g(t)$ at the detection.

$$\alpha + \beta = \gamma \qquad (1) \qquad (1)$$

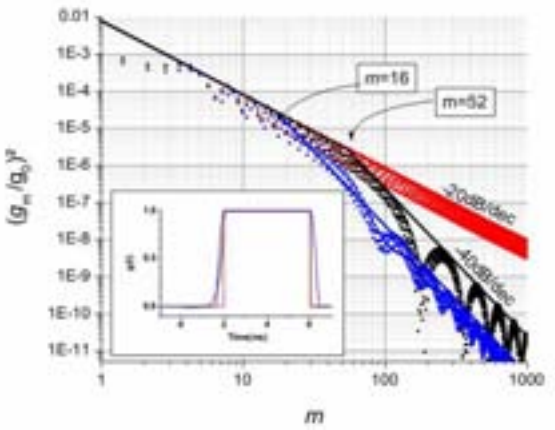

Fig. 3. Fourier coefficient of $g(t)$ for different $g(t)$ shapes : Squared type (red), CPT type (black) , 2 level type (blue). Inset: $g(t)$ shapes.

Our model has been successfully tested by injecting noise in the frequency multiplication chain, measuring it and comparing the corresponding measured and calculated frequency stability, see Fig 4.

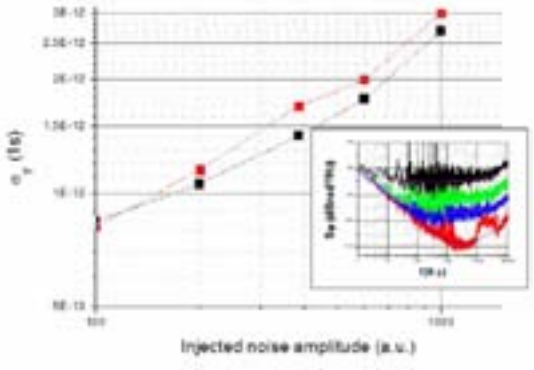

Fig. 4. Fractional Allan deviation at 1s, black: calculated value using the noised phase noise PSD. Red: measured. Inset : PSD of phase noise of the multiplication chain, for different injected noise amplitudes.

The understanding of the conversion phenomenon of LO frequency noise in our pulsed CPT clock led us to install a new 100 MHz quartz oscillator (Rakon, LNO100) to feed the multiplication chain. As shown in Fig. 5 it allowed reducing the S_y components at the first harmonics of the frequency interrogation, i. e. in the most critical domain where the weighting function g_n/g_0 is maximum. The noise contribution

of the 100MHz oscillator (green in Fig. 5) to the total microwave noise is now below the noise contribution of the multiplication chain, in almost all the sensitivity bandwidth.

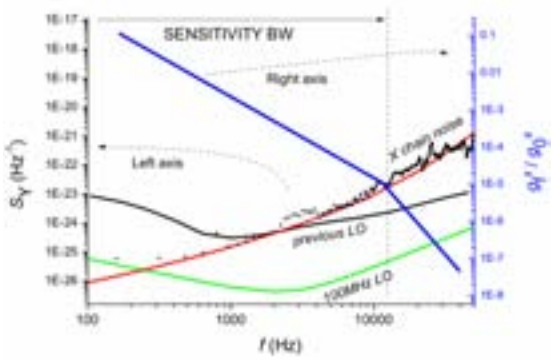

Fig. 5. Left axis: one-sided power spectral density (PSD) of the relative frequency fluctuations of the free running interrogation oscillator at Fourier frequency m/T_c : Black: Contribution of the prvious LO, Green: Contribution of LN0 100 oscillator. Red: Noise contribution of the multiplication chain Black dots: Setup with LN0 100 oscillator Right axis: Fourier coefficient of $g(t)$.

Following the LO change, the frequency stability have been measured, improving our short term stability from 7×10^{-13} to 3.2×10^{-13} at 1 second, see Fig 6.

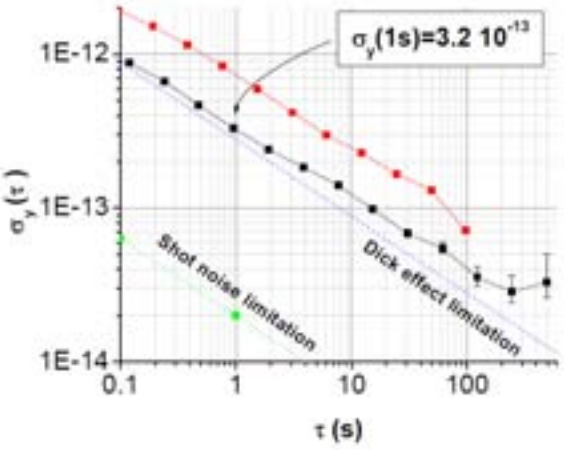

Fig. 6. Short term frequency stability. Black: previous stability. Red: Measurement after LO change. Green: calculation in case of the actual signal and shot noise limitation.

IV. Toward the Understanding of Long-Term Stability Limiting Effects

Vapor cell frequency standards are known for their relative high short-term frequency stability, and a frequency drift limiting the mid-long term stability. Until now our setup have always shown a stability degradation before 2000 s of integration time. Our last noise budget evaluation pointed out that the sensitivity of the clock to laser power fluctuations would limit the clock stability between 5×10^{-14} and 0.8×10^{-14} according as the noises are uncorrelated or fully correlated [12], respectively. Usual AC Stark shift models do not explain the measured shifts. Different hypotheses have then been made [13], and among them, the dissymmetry variation with the laser power seems to explain well the frequency shifts. The dissymmetry of the fringe system was measured for different powers, and the corresponding calculated frequency shifts have been plotted next to the measured ones, see Fig 7.

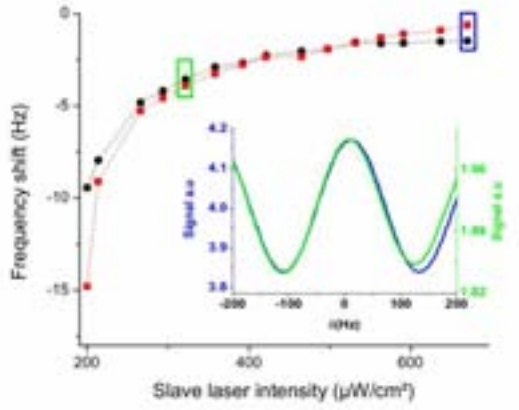

Fig. 7. Frequency shift as a function of slave laser power, master laser power unchanged Black: Calculated frequency shift due to dissymetry Red: measured frequency shift. Inset: Fringe system for slave laser intensity 150μW/cm² (green) and 500μW/cm² (blue), master laser intensity: 400μW/cm².

A main dissymmetry source arises from the double Λ scheme which allows $\Delta m_F = 2$ transitions, see dashed grey lines in Fig. 7, left. They are close (245Hz) to the clock resonance, and of pretty high amplitude (20% of 0-0 amplitude) for typical operating parameters, so that the detected signal is the sum of the three resonances.

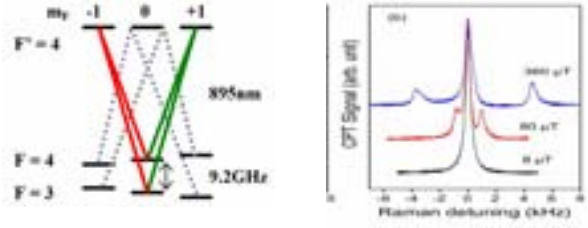

Fig. 8. Left: Optical transitions induced in the double Λ scheme. Only the clock levels ($m_F = 0$), and the nearest Zeeman sublevels are shown. $F = 3$ and $F = 4$ are the hyperfine levels of the ground state, F' is one excited level of the D_1 line. The clock transition is induced by the transitions shown in solid lines. The transitions in dashed lines induce hyperfine transitions with $\Delta m_F = 2$. Right: microwave spectrum around the clock transition at different values of the magnetic field.

The neighboring resonances split of the clock resonance with frequencies is given by the Breit-Rabi formula [14]:

$$\upsilon_{z,\pm} = \pm 11.1649B + 0.002672B^2 \quad (4)$$

where $\nu_{z,\pm}$ (Hz) refers to the transitions ($F = 3$, $m_F = +1$) - ($F = 4$, $m_F = -1$) and ($F = 3$, $m_F = -1$) - ($F = 4$, $m_F = +1$), respectively; B is in μT. It is worth to note that the frequencies $\nu_{z,\pm}$ are the frequency differences between these transitions and the clock transition, and that they are not symmetrically

spaced from the clock transition. Their effect can be seen directly in Fig. 9, which shows the measured clock frequency as a function of the magnetic field. The pulling by the neighboring transitions induces an oscillation around the classical quadratic Zeeman shift. This effect increases for larger imbalance of the neighboring peak amplitudes. For laser beams polarized perfectly linearly and orthogonally the amplitudes are equals. However a weak ellipticity of one beam polarization is enough to impact the equilibrium, increasing the shift. Fig. 9a shows the CW CPT signal for different elliptical polarization of the laser beams achieved by setting a retardation plate. The measured and calculated resulting shifts are shown in Fig. 9b as a function of the magnetic field in the case of the largest unbalance of Fig. 9a.

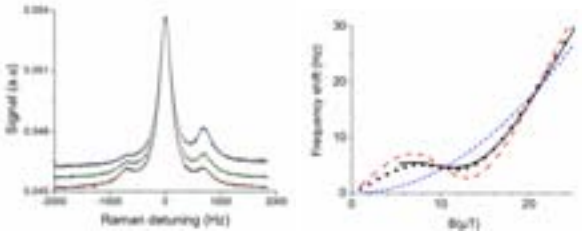

Fig. 9. CPT signal with a CW interrogation for three different polarisation states. B = 60 µT. b). Shift of the observed clock frequency as a function of the applied magnetic field. Dashed blue line: theoretical shift of the 0-0 transition, solid black line: experimental data, dashed red line: shift calculated with amplitudes of the blue curve on the left, dotted black line: shift calculated with a fit of the peak amplitudes.

Using laser beams with parallel polarizations it is possible to observe the two $\Delta m_F = 2$ transitions only without the clock transition. We have measured a frequency sensitivity to laser power 4 to 10 times higher than for the double Λ scheme. This shows that those $\Delta m_F = 2$ transitions are very sensitive to a laser power variation. Finally the power sensitivity of the clock frequency in the usual double Λ scheme has been measured as a function of the magnetic field, see Fig 10. A zero sensitivity point is shown. This point is of a great interest. By operating the clock with this specific magnetic field value the sensitivity of the frequency to any power fluctuation would be drastically reduced. A full explanation of this effect is under investigation.

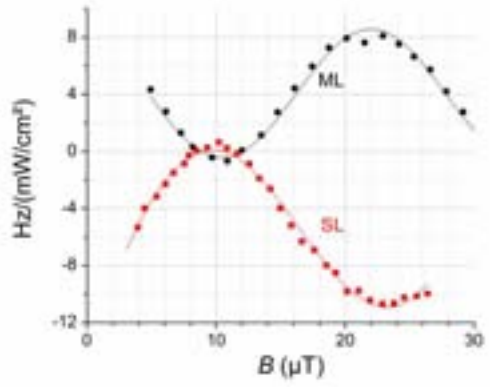

Fig. 10. Measured power shift rate of the clock frequency versus the magnetic field value. Dark dots : the master laser (4-3' transition) intensity is modulated. Red dots: the slave laser (3-3' transition) intensity is modulated.

V. Discussion

In summary we have described how a pulsed CPT clock is sensitive to frequency noise of the LO by Dick effect. This study allowed lowering the clock frequency instability down to 3.2×10^{-13} at 1s. The long term stability is still limited after 200s integration around $2\text{-}3\times10^{-14}$. We have shown that laser power fluctuations could lead to a signal distortion through line pulling effect of neighboring transitions. This line pulling effect varies with the static magnetic field value. For a specific value, a cancellation of power sensitivity of the clock frequency has been shown. Using this value as operating point could lead to a drastic reduction of power sensitivity of the clock. Further studies are needed to explain and experimentally confirm the interest of such a working point.

***Abstract* - We demonstrated a digitized atomic clock which is based on the transient oscillation of detuned coherent population trapping (DCPT). In the Λ structure atomic states system, the DCPT oscillation frequency exactly equals the absolute value of the frequency difference between the two pump laser fields minus the two ground states hyperfine splitting frequency. This DCPT atomic clock obtains the standard frequency by adding/subtracting the DCPT frequency from the laser modulation RF frequency. And it does not require a phase locking loop circuit to lock the standard frequency to the atomic transition. In addition, its data processing section can be easily digitized with high accuracy. The frequency instability of $1X10^{-11}/\tau^{1/2}$ (τ=1000s) has been achieved.**

Atomic clocks have been developed for over half a century [1]. From microwave clocks to optical clocks; from atomic fountain clocks [2] to chip scale atomic clocks [3,4], they have varying sizes and properties. However, to achieve a stable standard frequency, they all require an analog phase locking loop circuit to lock the output frequency to the atomic transition frequency. The stability of these clocks depend directly on the behavior of the phase locking loop; and the analog phase locking loop performance is limited by the hardware, which makes it difficult to actively control and adjust for better frequency identification accuracy.

We proposed and demonstrated an atomic clock based on the detuned coherent population trapping (DCPT) transient oscillation phenomenon [5, 6]. This DCPT atomic clock does not require a phase locking loop to stabilize the standard microwave frequency. We have theoretically proven [7] that when two laser fields transmit through a typical Λ system alkali atomic cell, and the two laser frequency difference is detuned from the CPT resonance by a few KHz, laser intensity will have a damping oscillation as it passes through the atomic cell. Also, the oscillation frequency exactly equals the absolute value of the frequency difference between the two pump optical fields minus the two ground states' hyperfine splitting frequency. Usually the two pumping optical fields are generated through a VCSEL which is modulated by a microwave oscillator, and the frequency difference of the two laser bands is equal to the microwave frequency. Therefore, we can directly measure the frequency detuning, which equals the DCPT oscillation frequency, and then add (or subtract) the value to the output frequency of the microwave oscillator to achieve the standard frequency. By this method, we can further simplify the structure of the CPT atomic clock, and make it easier to be digitized and miniaturized. Since the DCPT oscillation frequency is usually only a few KHz and very easy for AD conversion with enough accuracy, we can actively process the data to obtain higher frequency accuracy.

In 2009, we proposed the DCPT scheme to implement the atomic clock and have theoretically proven the detuning coherent population trapping transient oscillation phenomenon [6,7]. According to the semi-classic theory, the evolution of the density matrix operator $\hat{\rho}$ can be described by the quantum Liouville equation. Here, we mainly consider the matrix element ρ_{33}, the population of the excited state, which directly related to the transmitted laser intensity. Considering certain approximations and assumptions, we derived the analytical solution to ρ_{33}, which can be described as Eq. (1) [6, 7].

$$\rho_{33} = \mathrm{Re}\left\{ A\exp\left[-\left(\gamma_2 + \frac{\Omega^2}{\Gamma} \right) + i\Delta \right] t \right\} + \frac{2\kappa_3 \lambda}{\Gamma} \qquad (1)$$

In the equation (1), the first term damps to zero at the rate of $\gamma_2+\Omega^2/\Gamma$, which is equal to the line width of the CPT resonance. Therefore it creates a small damping in the oscillation signal, characterized as a damping oscillation with frequency exactly equals to the detuning frequency Δ. So we refer to it as "Transient Oscillation".

Based on the theoretical result, we have implemented and experimentally verified the digitized atomic clock based on

transient oscillation of detuned coherent population trapping (DCPT). In this design, the output standard frequency was achieved by directly adding/subtracting the transient oscillation frequency of DCPT to/from the RF frequency, which is used for the VCSEL modulation. We modulated the RF frequency with a 100 Hz square wave, and the RF frequency was set to alternate between the ground state hyperfine splitting frequency and the detuned frequency (a few kHz higher/lower). After the laser beam passes through the rubidium atom cell, a series of laser intensity oscillations (Fig.1.) was detected when the RF frequency was detuned. This is the DCPT transient oscillation signal, and the frequency is equal to the detuning frequency.

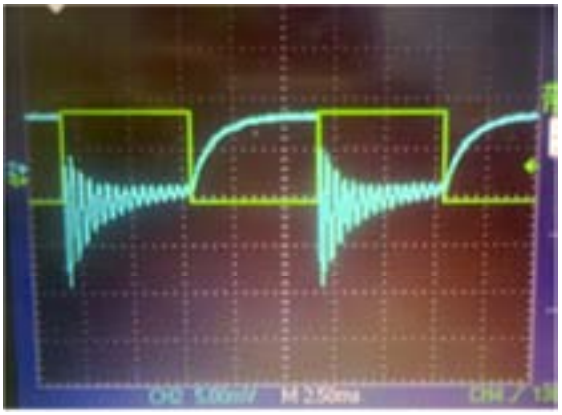

Fig.1. The DCPT oscillation signal. The RF frequency modulated by a 80Hz square wave and RF frequency is set to alternate between the ground state hyperfine splitting frequency and the detuned frequency which is 2KHz.higher than the hyperfine splitting.

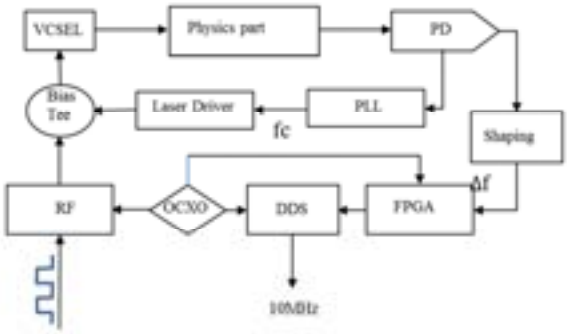

Fig.2. experimental setup

Our experiment setup is shown in Fig.2. The injection current of VCSEL is modulated by a RF signal to generate a series of sidebands; the baseband and one of the nearest sidebands will be used [8] to excite the DCPT transient oscillation. The RF frequency is modulated by a 80Hz square wave signal between the CPT resonance central frequency and few kHz detuned from it. The two laser bands' frequency difference will be switched between the two, and the two prepared laser fields will go through the ^{85}Rb cell. Then, periodically damping oscillations of the transmitted laser power at the detuning frequency are detected by the photon detector. The oscillations will be amplified to create a corresponding electronic signal, which would then be shaped into a square wave signal. From this, the frequency of detuning can be directly calculated by digital methods. At the same time, the OCXO 10 MHz reference signal of the RF oscillator will also be sent to the direct digital synthesizer (DDS) as its reference signal. Therefore, the DDS output frequency will shift with the reference signal shift and be proportional to the RF frequency shift. The DCPT oscillation frequency will be calculated by the FPGA, and will generate a delta-frequency word for the DDS to precisely compensate the detuning and shift. Subsequently, the 10 MHz standard frequency signal will be generated by the DDS, and will be proportional to the hyperfine splitting of the two ground states, working as an atomic frequency standard

In our DCPT atomic clock, the oscillation signal is detected, amplified, and reshaped, in order to facilitate digital processing. A typical digital method (Equal precision frequency measurement) is used to measure the DCPT oscillation frequency. As illustrated by Fig.3. We use a 3MHz signal to compare with the reshaped square wave whose frequency is equal to the DCPT oscillation and obtain the DCPT oscillation frequency. Since the detuning frequency is 10^3 Hz, using this typical digital processing with instability higher than 10^{-6}, we can extract the oscillation frequency with 10^{-3} Hz accuracy, which allows us to expect that the DCPT atomic clock will achieve very good frequency stability.

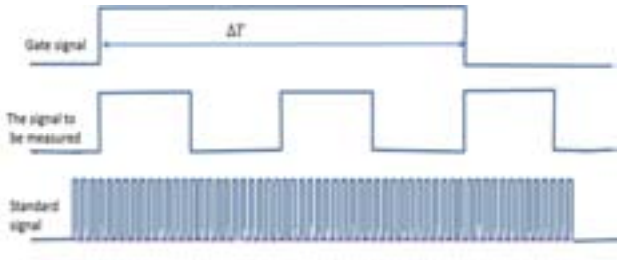

Fig.3. DCPT oscillation frequency measuring method. Using the DCPT reshaped square wave signals' (typically 3KHz) rising edge to open and close the gate, and compare the ΔT with the standard signal (3MHz)

When the detuning frequency is obtained, it will be calculated to generate a delta-frequency word for the DDS to correct the 10MHz output frequency. Since the DDS and the

RF oscillator have the same reference crystal oscillator, the RF and the DDS 10MHz will always maintain a fixed ratio. When the RF shifts, the DDS output also shifts with this constant ratio. From the changes of the detected DCPT oscillation frequency, we will be able to know how much the RF shifted, as well as the DDS output frequency shift. Then we can compensate for the shift by modifying the delta-frequency word, which has $1/2^{48}$ accuracy, and is accurate enough for the standard frequency generation.

We also used another method to get the DCPT oscillation frequency. In this data processing part, the DCPT oscillation frequency is extracted by a filter which is a simulation filter generated by MATLAB tools. As there exists a picket fence effect in the Fourier transform from the time domain to the frequency domain, we use the narrow-band simulation filter to scan the period of the square wave simultaneously. When 1/2 of the period is equal to integer multiple of the DCPT oscillation period, the spectral line intensity of oscillation frequency will be at a maximum. Using this method, the spectrum leakage can be decreased and the oscillation frequency can be extracted accurately. In both processing methods, the frequency reading accuracy is only related to the detuning frequency and the reference signal stability, but not related to the atomic transition frequency. Therefore we may extend this method to optical frequency and produce optical clocks and optical frequency combs.

When we use the RF oscillator signal as the reference frequency, and use the detected oscillation frequency to compensate for the RF frequency detuning as well as its shift with time, we will be able to obtain the DCPT atomic clocks standard frequency, which equals the two ground states hyperfine splitting frequency. In our preliminary experiments, the frequency instability of $1\times10^{-11}/\tau^{1/2}$ (τ=1000s) has been achieved (Fig.4.).

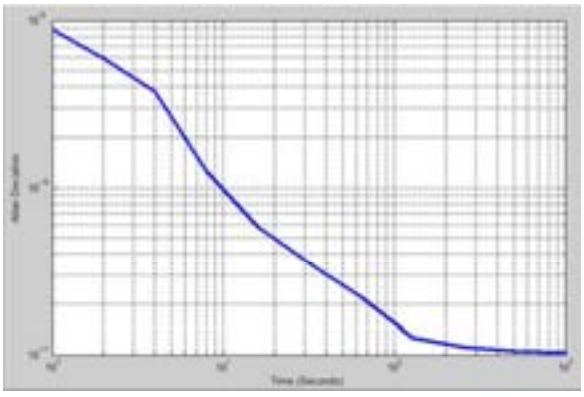

Fig.4. Measured Allan deviation for the ^{85}Rb DCPT atomic clock

Comparing with traditional atomic clocks, this DCPT atomic clock does not require a phase locking loop circuit to lock the microwave frequency. This eliminates the instability and loose locking probability brought on by the phase locking loop, which makes the DCPT atomic clock more stable and more reliable, especially when used in harsh environments. In addition, the DCPT oscillation signals have amplitude 3 to 4 times that of the CPT signals, which further benefits signal reshaping, AD conversion, and analysis. Its digital data processing is convenient for active analysis to increase the frequency reading accuracy, which gives the potential for achieving better frequency stability. In addition, the electrical component also can be easily integrated. As a result, this scheme has great potential in the design and manufacture of miniature atomic clocks. Finally, since the DCPT oscillation frequency reading accuracy is only related to the detuning frequency and the reference signal stability, but not related to the atomic transition frequency, we may extend this method to optical frequency for optical clock and optical frequency comb.

***Abstract*—We report on the current performance of our atom interferometry gravity gradiometer. After careful elimination of the main sources of fluctuations and biases in the atom interferometer, we achieve a sensitivity of 3×10^{-9} g per second to differential gravity; by modulating the position of a set of source masses, we achieve a relative statistical uncertainty of 1.1×10^{-4} to the gravitational constant G.**

I. Introduction

In recent years, atom interferometry provided new techniques for the measurement of inertial forces, with important implications both in fundamental physics and applied research. The remarkable stability and accuracy that atom interferometers have reached for acceleration measurements can play a crucial role for science and technology. Quantum sensors based on atom interferometry [1] had a rapid development during the last two decades, and different schemes were demonstrated and implemented.

Atom interferometry has been demonstrated for precise measurements of gravity acceleration [2], [3], [4], [5], Earth's gravity gradient [6], [7], [8], and rotations [9], [10], [11], [12]. Currently, experiments based on atom interferometry are in progress to test Einstein's Equivalence Principle [13], [14] and to measure the Newtonian gravitational constant G [8], [15], [16], while experiments to test general relativity [14], [17] and the $1/r^2$ Newton 's law [18], [19], [20], [21], searching for quantum gravity effects [22] and gravitational waves detection [23], [24] have been proposed. Accelerometers based on atom interferometry have been developed for many practical applications including metrology, geodesy, geophysics, engineering prospecting and inertial navigation [7], [25], [26], [27], [28]. Further advances in atom optics are expected to improve the current performances of such sensors by orders of magnitude.

Operating an atom interferometer at its full performance requires a precise control over a number of experimental parameters. In this paper we describe an atom interferometer for precision measurement of gravity gradients. In particular, we focus on a specific experimental configuration for the measurement of the gravitational field produced by local source masses, presently being used for the measurement of the gravitational constant G. We show that our current sensitivity and long term stability are compatible with the measurement of G with a precision of 10^{-4} by controlling a limited number of parameters. A challenge in order to attain such extreme performances is to carefully control the external degrees of freedom of the atomic probe. We then analyze the influence of the position and velocity of the atoms in a fountain on the precision of gravity gradient measurement by atom interferometry.

II. Apparatus

Our apparatus consists of a double atom interferometer performing a simultaneous measurement of the differential acceleration experienced by two clouds of cold rubidium atoms with vertical separation [36], [16], [32]. The instrument is used to measure the gravitational field generated a well characterized set of source masses [29].

The atom interferometer is based on the scheme of the Kasevich-Chu light-pulse gravimeter [2]. Three Raman pulses separated by the time interval T in a $\pi/2-\pi-\pi/2$ sequence realizes an atom interferometer with a Mach-Zender-type geometry. At the output of the interferometer, the probability of detecting the atoms in one of the two hyperfine levels of the Rb ground state is given by $P=(1-\cos\phi)/2$, where ϕ represents the phase difference accumulated by the wave packets along the two interferometer arms. In the presence of a gravity field, atoms experience a phase shift

$$\phi = k_{eff} g T^2 \tag{1}$$

depending on the local gravitational acceleration g and on the time interval T between the Raman pulses [2]. The gravity gradiometer consists of two absolute accelerometers operated in differential mode. Two spatially separated atomic clouds in free fall along the same vertical axis are simultaneously interrogated by the same Raman beams to provide a measurement of the differential acceleration induced by gravity on the two samples. A Lissajous figure results from the composition of the trace of the upper accelerometer versus the lower one. The differential phase shift $\Phi=\phi_u-\phi_l$, which is proportional to

the gravity gradient, is obtained from the eccentricity and the rotation angle of the ellipse best fitting the experimental data [31].

The scheme of our interferometer is shown in Fig. 1 for two different configurations of the source masses (C_1 and C_2), together with a picture of the apparatus. A magneto-optical trap (MOT) with beams oriented in a 1-1-1 configuration collects ^{87}Rb atoms and launches them vertically at a temperature of about $2.5\,\mu$K. After juggling the atoms loaded in the MOT [30], two atomic clouds are launched with a constant vertical separation of $\sim 30\,$cm. Shortly after launch, the two atomic samples are velocity selected and prepared in the $(F = 1, m_F = 0)$ state using a combination of Raman π pulses and resonant blow-away laser pulses. The interferometers take place around the center of the vertical tube shown in Fig. 1. In this region, surrounded by two μ-metal shields (76 dB attenuation factor of the magnetic field in the axial direction), a uniform magnetic field of $25\,\mu$T along the vertical direction defines the quantization axis. The field gradient along this axis is lower than $5\,$nT/mm. After the Raman interferometry sequence, the normalized population of the ground state is measured in a chamber placed just above the MOT by selectively exciting the atoms on the $F = 1, 2$ hyperfine levels and detecting the resulting fluorescence.

The gravity gradient can be measured in two different configurations of source masses, in order to isolate the effect of source masses from other biases of acceleration difference between the two clouds (Earth's gravity gradient, Coriolis forces, etc.). The position of source masses is modulated between the two configurations shown in figure 1 with a period $T_{mod} \simeq 55\,$min. Such scheme is suited for the determination of the gravitational constant G.

III. Methods

The theoretical, shot-noise limited acceleration sensitivity of the atom interferometer can be deduced from equation 1 assuming a phase error per shot $\sim \sqrt{N}$, where N is the number of detected atoms. With $N \sim 10^6$ and $T \sim 0.15\,$s, the shot-noise limit is in the range of $10^{-9}\,$g per shot. In order to reach this sensitivity level we investigated main sources of instability in ellipse contrast, bias and phase angle. The most critical sources of noise instabilities are fluctuations in the main experimental parameters (laser frequencies and intensities, magnetic coils atc.) and in the atomic trajectories. The two issues are discussed in the following sections.

A. Influence of experimental parameters

As shown in [32] it is possible to obtain a reliable value for Φ with an ellipse containing a few tens of points. We typically use 720 points per ellipse, corresponding to a measurement time $t_{ell} \sim 1400\,$s. Thus the slow changes in bias and contrast, occurring on a time scale longer than t_{ell}, are efficiently rejected. The short term sensitivity will be mainly determined by detection noise, and possibly by fast fluctuations of ellipse contrast and position, such as those caused by changes in the detection efficiency or in the Raman laser power.

Noise sources which equally affect the upper and lower atom interferometer (i.e. vibrations, tidal effects, relative phase noise of Raman lasers, etc.) are rejected as common mode in the gravity gradient measurement. We have then investigated those experimental parameters which affect the two atom interferometers differently; such parameters can in principle limit the sensitivity and long term stability of gravity gradient measurements. The double differential scheme used for the G measurement further cancels additional noise sources. Indeed, in this configuration the G measurement can only be perturbed by effects which either depend on the position of source masses, or change on a time scale shorter than the cycling

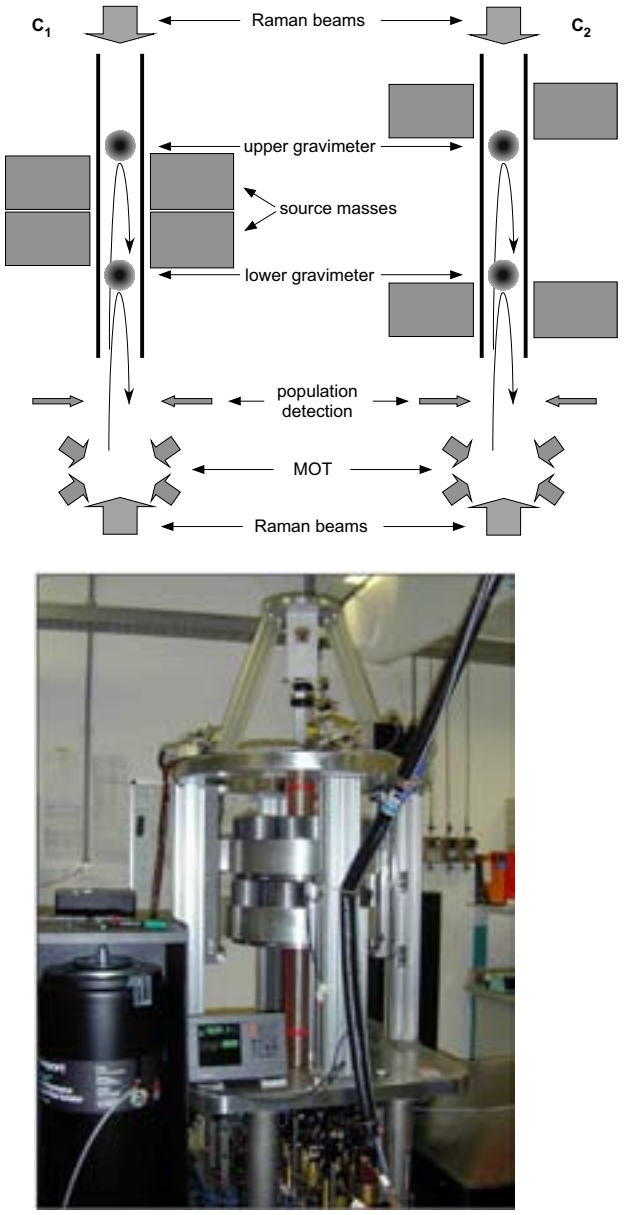

Fig. 1. Above: scheme of the gravity gradiometer (from [32]). ^{87}Rb atoms, trapped and cooled in a magneto-optical trap (MOT), are launched upwards in a vertical vacuum tube with a moving optical molasses scheme, producing an atomic fountain. Near the apogees of the atomic trajectories, a measurement of their vertical acceleration is performed by a Raman interferometry scheme. External source masses are positioned in two different configurations (C_1 and C_2) and the induced phase shift is measured as a function of masses positions. Below, a picture of the apparatus for the atomic fountain, including the source masses for G measurement.

time T_{mod} of masses positions.

We separately investigated the effect of various parameters. We recorded the ellipse phase angle in the two configurations of source masses, Φ_{C1} and Φ_{C2}, for different values of each parameter α; for each value of the parameter, we calculated the average ellipse angle $\bar{\Phi} = (\Phi_{C1} + \Phi_{C1})/2$ and the difference $\Delta\Phi = \Phi_{C1} - \Phi_{C2}$ of ellipse angle between the two different masses positions. From $\bar{\Phi}(\alpha)$ we can deduce requirements on the long term stability of the parameter α for gradient measurements, as well as on the stability of α on time scales shorter than T_{mod} for G measurements; from $\Delta\Phi$ we can deduce requirements on the long term stability of α for G measurements.

B. Influence of atomic motion

Both the accuracy and sensitivity of atom interferometry inertial measurements are affected by atomic motion [33]. The differential interferometric phase depends on the position and velocity of the two atomic clouds mainly through gravitational and magnetic gradients, rotations, and wavefront curvature of Raman beams.

Our atomic samples are vertically separated by ad distance Δh. Therefore in presence of a gravity gradient γ we have

$$\phi = k_{eff}\left(g_{up} - g_{dw}\right)T^2 = k_{eff}\gamma\Delta h T^2 \qquad (2)$$

For $T = 160$ms and $\Delta h = 30$ cm the induced phase shift is 0.336 rad corresponding to a differential acceleration of $\sim 10^{-7}$g. Fluctuations in the initial position or velocity of the atomic samples will convert into noise of the atom interferometry measurement through the gravity gradient. Something similar occurs due to magnetic gradients in the atom interferometer, due to second-order Zeeman effect.

In order to mitigate the effect of gravity gradients, we choose two configurations of the source masses which compensate the Earth gravity gradient at the location of the atomic samples during the atom interferometry sequence (see figure 2). Cancellation of the Earth gravity gradient in our apparatus is possible due to the high density of tungsten used for our source masses.

As long as the atoms are launched with some residual horizontal velocity along the East-West direction, the Coriolis force yields a phase shift on the atom interferometer output. The ellipse phase shift ϕ_{Coriol} due to Coriolis effect is proportional to the velocity difference Δv_{E-W} between the two clouds along the East-West direction:

$$\phi_{Coriol} = -2\Omega k_{eff} T^2 \cos\theta_l \Delta v_{E-W} \qquad (3)$$

where Ω is the angular velocity of Earth's rotation and θ_l is the latitude angle. With our numbers (i.e. $T = 160$ ms and $\theta_l \simeq 43°$) this reads ϕ_{Coriol}[mrad]$\simeq -43\,\Delta v_{E-W}$[mm/s].

In our experiment the two clouds are launched to about 60 and 90 cm above the MOT position, and the launching velocities are $v_l \simeq 3.5$ m/s and $v_u \simeq 4.3$ m/s for the lower and upper cloud respectively. If both clouds are launched with the same tilt angle θ_{tilt} along the E-W direction, their horizontal E-W velocities will differ by about 25% from each other, and the resulting Coriolis shift will be

$$\phi_{Coriol} = -2\Omega k_{eff} T^2 \cos\theta_l (v_u - v_l)\sin\theta_{tilt} \qquad (4)$$

On the other hand, the horizontal velocity spread corresponding to the $\sim 3\,\mu$K transverse atomic temperature is expected to contribute to the noise on the ellipse phase angle via the Coriolis effect. In order to compensate for this, we apply a uniform rotation rate to the retro-reflecting Raman mirror during the atom interferometry sequence by means of PZT actuators, as suggested in [34], [35].

Wave-front distortions of Raman beams depend essentially on the details of the front-wave distorsions introduced by the retro-reflecting optics, which are not in common between the upwards and downwards Raman beam. During the interferometer sequence distorsions are translated into an additional phase shift that affects atoms with a nonzero radial velocity. In principle, such offset can be numerically evaluated by studing the surface conformation of the interested optics. *In situ* analysis are not feasible, and extrapolation at zero atomic temperature is not obvious [33].

Nearly all of such effects cancel out in the doubly differential measurement for G, provided that the atomic trajectories are the same in the two configurations of source masses. This might not be the case if either

- fluctuations in atomic trajectories occur on a time scale faster than the period of modulation of source masses positions
- the movement of source masses induces changes in the atomic trajectories, either due to any deformation of the mechanical structure holding the vacuum system and attached optics/coils, or due to changes in magnetic fields

The former would limit the reproducibility of G measurement, while the latter would cause a systematic shift on the G measured value.

For instance, if the mass movement induces a change of E-W tilt $\Delta\theta$, the corresponding systematic shift of ellipse phase is $\Delta\phi_{Coriol} \simeq -34\,\Delta\theta_{tilt}$. Thus in order to keep the systematic effect on G measurement within ~ 50 ppm, i.e. $\Delta\phi_{Coriol} < 30\,\mu$rad, then it is necessary to measure $\Delta\theta$ within one μrad, i.e. to control the shift in the center of atomic distribution, induced by the masses movement, with micrometer precision.

Similar considerations apply to the effect of wavefront curvature of Raman laser beams as well as to magnetic and gravity gradients.

Besides the effects of trajectory fluctuations, other possible sources of systematic shift in the G measurement are those which are not canceled at all in the doubly differential measurement. This is the case of the gravity gradient induced by the source masses themselves. In fact, in our setup the geometry of source masses is chosen in such a way that the gravitational potential is stationary in the region of the atom interferometry measurement, i.e. at the apogees of atomic trajectories [36]. The curvature of gravitational potential is

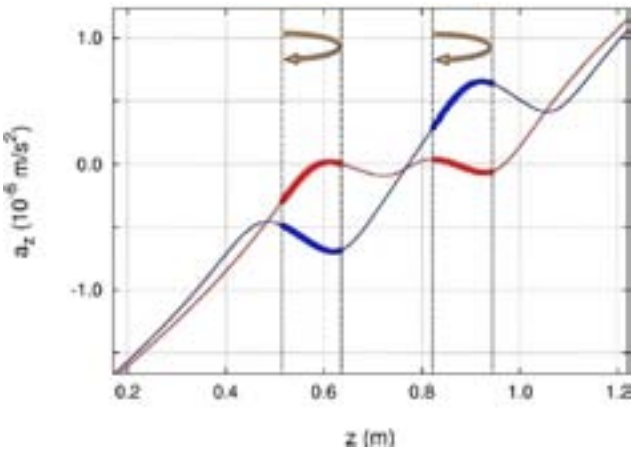

Fig. 2. Calculated relative acceleration along the axis of source masses for the two configurations (red: close masses; blue: far masses). The highlighted areas correspond to the atom trajectories during the atom interferometry sequence.

larger in the horizontal plane than in the vertical direction. In the case of point-like atomic clouds with a common traverse displacement from the symmetry axis of source masses, the differential interferometric phase varies by $42\,\mu$rad/mm^2 around the axis. Thus, in order to keep the systematic shift on G well below 10^{-4}, the atoms must stay within 1 mm from the symmetry axis. In the more physical situation of atomic clouds with finite size, the gravity gradient produces a systematic shift in the G measurement which is proportional to the square of the cloud size. In order to keep the systematic shift on G well below 10^{-4}, the width of atomic cloud should be smaller than 1 mm. For clouds with larger size, it is necessary to compute the phase shift to correct the measured data. This requires a precise knowledge of the density distribution in the atom clouds; i.e. the centers and widths must be measured with sub-mm precision in the region of the atom interferometry interrogation.

Similar considerations apply for vertical size and vertical displacement from the stationary point of the gravitational potential. We thus characterized the atomic density distribution in our fountain. In the following we will separately describe the measurement of vertical and horizontal degrees of freedom.

For the knowledge of vertical positions and velocities we employed time of flight (TOF) measurements. We determined the istant t_a at which the velocity selected atoms reach the trajectory apogee, i.e. when $v_z = 0$. Such condition can be easily identified using a Raman π transition: if atoms are at rest roughly half of them, performing the transition, will acquire a momentum recoil of $+\hbar k_{eff}$ while the remaining fraction $-\hbar k_{eff}$. As a consequence the detected signal shows two distinguishable and symmetrical peaks. Afterwards we measured the istant t_d at which the sample cross the detection region. Knowing the vertical position z_0 of the detection light sheet we can derive the apogee vertical coordinate z. This can be done independentely on both the clouds. An accuracy of ± 0.1 mm in vertical position has been reached, which leads to a systematic error on G of 2 ppm if atoms are properly placed on the stationary point of the gravitational potential.

We measured the position of MOT and tilt angles of the two clouds in the atomic fountain. To correctly evaluate systematic effects on G, all these measurements shall be performed with respect to the symmetry axis defined by the source masses and the gravity. To this purpose, we carefully aligned the Ramam beams along such axis and we used them to probe the atomic samples. We aim to reach a level of verticality better than 100 μrad.

We measured the horizontal distribution of atomic clouds at different heights in the ballistic flight of the fountain. We employed the Raman laser beams to define a reference frame for the atomic positions. A portion of radius $r \simeq 4$ mm of the downward-propagating Raman beam was selected with a diaphragm mounted on a 2D translation stage. We addressed the atoms with three Raman pulses in rapid sequence, and finally detected the number of atoms in $F = 1$. The horizontal distribution of atomic density was then probed in both clouds simultaneously by scanning the position of the diaphragm.

The number of detected atoms is proportional to the atomic density in the column selected by the diaphragm and to the transition probability of Raman beams. We deduced the distribution of transition probability from the intensity profile of Raman beams and from the direct measurement of transition probability versus Raman power. Performing this kind of measurement along two orthogonal directions provides a complete 2D picture of both the samples.

IV. Results

A. Sensitivity and long term stability

The dependence of the instrument sensitivity to differential gravity measurements as a function of the relevant experimental parameters allows to identify the main limits to the stability of Φ, once the typical fluctuations of the parameters are known. We constantly monitor the value of most relevant experimental parameters (i.e. the power of MOT, probe, repumper and Raman laser beams, the current in MOT compensation coils, in pulse coil and in bias solenoid, the tilt of Raman mirror) as well as the temperature in different points of the apparatus. We deduce that the main contributions arise from the instability of MOT laser beams intensity ratio, current in the bias solenoid and MOT compensation coils, and tilt of the Raman mirror. However, noise in the coils current is fairly white, and would not entail the long term stability, while fluctuations in laser powers and mirror tilt exhibit a low frequency flickering.

In order to improve the long-term stability, we actively stabilize the main experimental parameters, i.e. the optical intensity of cooling, Raman and probe laser beams, acting on the RF power driving acousto-optical modulators, and the Raman mirror tilt, acting on the piezo tip/tilt system.

The servo on cooling and Raman lasers intensity is done by means of a slow digital loop, sampling the four powers (up and down cooling beams, master and slave Raman beams) every 72 experimental cycles (i.e. ~ 2 min) and driving the RF power corresponding AOMs through a numerical loop filter. Residual fluctuations are below $0.3\,\%$.

The active control of cooling, Raman and probe laser intensities, together with Coriolis compensation, improves the long term stability of differential gravity measurements considerably. We reach a resolution of ~ 0.2 mrad on the

ellipse phase angle, corresponding to $\sim 5 \times 10^{-11}$ g after an integration time of about two hours.

We tested the long term stability of the measurement of the gravitational field of local masses by modulating the position of the source masses as shown in fig. 1. Typical elliptical plots in the two configurations of source masses are shown in fig. 3. We move the masses from the close (C_1) to the far (C_2) configuration and viceversa every ~ 27 minutes, corresponding to 720 measurement cycles of 1.9 s each plus a dead time of ~ 5 minutes to translate the masses. We reverse the direction of the Raman effective $k-$vector after each launch, in order to cancel possible k_{eff}-independent systematic errors, such as those arising from II order Zeeman shift and I order light shift [33]. We thus obtain two ellipses of 360 points each, corresponding to direct and reverse $k-$vector. We fit each set of 360 points to an ellipse, and from each pair of ellipses we determine the angle $\Phi_n(i) = \Phi_n^{dir}(i) - \Phi_n^{rev}(i)$ as the difference between direct and reverse angles, and the standard error $\delta\Phi_n(i) = \sqrt{\delta\Phi_n^{dir}(i)^2 + \delta\Phi_n^{rev}(i)^2}$. Here $n = 1, 2$ corresponding to the two configurations of source masses. From each couple $\{\Phi_1(i), \Phi_2(i)\}$ a value for the rotation angle $\Delta\Phi(i) = \Phi_1(i) - \Phi_2(i)$ due to the position of the source masses can be obtained.

Fig. 4 shows the Allan deviation of the experimental data up to an integration time of 50 hours, for a fixed configuration of source masses and for the difference of measurements in the two configurations. In the first case (gravity gradient measurement) the short-term stability is 3×10^{-9} g/$\sqrt{\text{Hz}}$, and we achieve a statistical uncertainty of 5×10^{-11} g after about two hours. In the second case (G measurement) we achieve a statistical uncertainty of 10^{-4} after an integration time of ~ 100 hours.

B. Atomic trajectories

The Coriolis compensation helps to improve the noise in the atom interferometry measurement. When plotting the rms error of ellipse phase angle versus the mirror rotation rate, we find that the optimal rotation rate, corresponding to the maximum contrast, is equivalent to the opposite of the local projection of the Earth rotation rate. In such conditions, the rms noise on ellipse fitting is minimum. The compensated error on ellipse angle is ~ 50 % lower than without compensation, while the contrast increases by ~ 4 % only.

We measured the density distribution map of the two atomic clouds at different heights with the method described in section III-B. We compared similar measurements in both source masses configurations in order to investigate possible effects related to the mass movement. The method provides a good spatial resolution ($\sim 100\mu$m), however it is not sensitive enough to measure accurately small changes (< 0.2 mm/s) in the transversal velocity. The launching direction of the atomic clouds turns out to be extremely stable.

From numerical computation we deduce that a cloud of radius $\sigma = 5$ mm and offset 5.0 ± 0.1 mm yields an angular correction of 1.450 ± 0.030 mrad on Φ, corresponding to an error on G of ~ 60 ppm.

We probe the atomic density distribution in-situ at the MOT location by tuning the frequency of one Raman laser

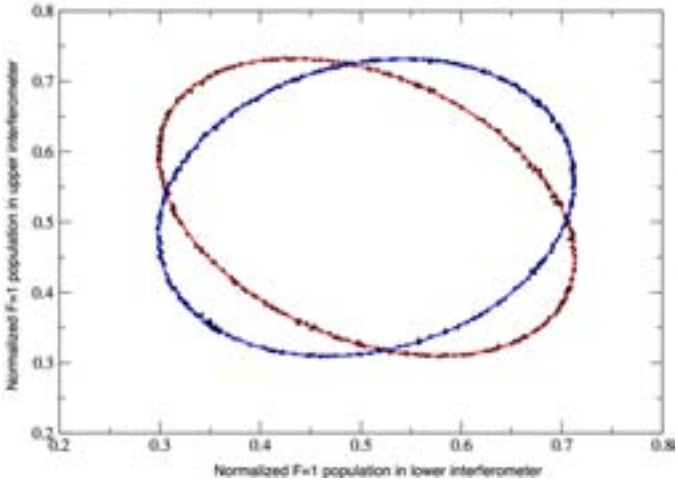

Fig. 3. Two experimental ellipses obtained with 360 experimental points each, for two different configuration of the source masses.

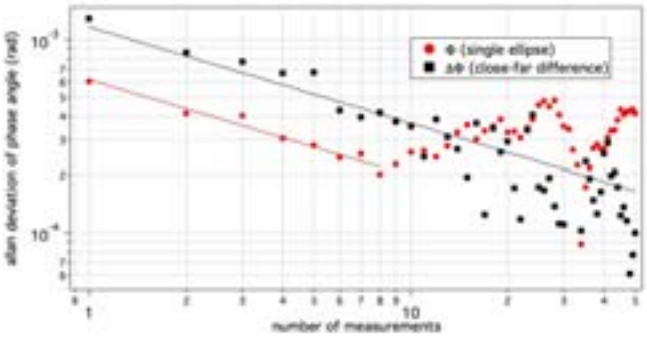

Fig. 4. Allan deviation of the atom interferometry phase; red circles represent the measurement of gravity gradient for a given position of the source masses: each measurement contains 360 points, corresponding to a measurement time of ~ 12 minutes; black squares represent the differential phase measurement for two configurations of source masses: each measurement contains 1440 points, corresponding to a measurement time of ~ 56 minutes (including the dead time for source masses translation). One-parameter fit with $A \times \sqrt{N}$ is shown with solid lines.

to the $F = 2 \rightarrow F' = 3$ transition. Using a diaphragm we select a thin portion (radius 0.5 mm) of the resonant upwards-propagating beam, to push the atoms away from the trap region. We measured the MOT position versus some relevant parameters such as total cooling power, up-down beams power ratio, compensation and MOT coils current. We conservatively conclude that the MOT center is stable within $\pm 100\mu$m on a time scale of few days.

V. Conclusion

We studied the sensitivity and long term stability of a gravity gradiometer based on Raman atom interferometry. We discussed the influence of the most relevant experimental parameters, in particular for a measurement of the Newtonian gravitational constant.

A serious issue in precision gravity measurements by atom interferometry is the control of atomic trajectories. We determined the center and width of the atomic clouds with sub-millimeter precision, both in the interferometric region and at the MOT location.

Our experiment can run continuously for several days, showing a reproducibility of the gravity gradient measurement compatible with the stated sensitivity on the time scale of a few weeks. Our measurement of the differential gravity signal of source masses reaches a statistical uncertainty of 1.1×10^{-4} after ~ 100 hours of integration time. A measurement of G by atom interferometry at the level of 100 ppm is within reach.

***Abstract*-. In this paper we report the results we obtained with a prototype of pulsed optically pumped (POP) Rb clock. In terms of frequency stability, an Allan deviation $\sigma_y(\tau)=1.7\times10^{-13}\tau^{-1/2}$ has been measured, where τ is the integration time. In addition, the long term frequency drift results below 10^{-14}/day. In the paper we also describe a technique to stabilize the amplitude of the microwave signal using the atoms themselves as discriminator. Moreover, an anomalously large temperature sensitivity of the clock frequency and a technique to keep it under control are also reported. Finally, we describe some non linear effects that modify the shape of the clock signal represented by the Ramsey central fringe.**

I. Introduction

In the pulsed optical pumping (POP) scheme the three phases of optical pumping, microwave excitation and detection of the transition signal are separated in time [1]. Besides suppressing the laser induced light shift, the pulsed operation allows a full optimization of the laser parameters both in the pumping and in the detection stages, where different power level are required. A Rb clock adopting this scheme has been implemented at INRIM and a short term frequency instability of $1.7\times10^{-13}\tau^{-1/2}$ was measured [2], together with a long term frequency drift below 10^{-14}/day [3]. The drift is thought to be due to a residual sensitivity to environmental parameters like temperature, atmospheric pressure and humidity.

These results represent a record achievement for a vapor-cell frequency standard and make the POP clock potentially very attractive for a variety of applications, including telecommunication and space radio-navigation .

Besides reporting these outstanding results, in this work we discuss some key techniques we exploited in order to obtain them and to make them repeatable.

First, we describe the technique to stabilize the amplitude of the microwave signal used to interrogate the Rb atoms; specifically, the microwave amplitude is locked using the atomic sample itself as discriminator.

Moreover, we report on the observation of an enhanced temperature sensitivity (ETS) of the clock frequency [4]. Specifically, despite we used in our cell a temperature compensated mixture of buffer gases, the observed temperature sensitivity is $\approx 1\times10^{-10}$/°C, more than one order of magnitude larger than the expected value. Yet, this phenomenon cannot be ascribed to cavity pulling and/or to spin exchange that are in fact negligible in our setup. We explain this effect in terms of a simple model based on the on the ideal gas law and we also describe a technique to keep it under control.

Finally, we describe a few phenomena that may affect the Ramsey fringes observed in our system. Specifically, cycle memory and atomic density effects can deviate the shape of the Ramsey central fringe from the common sinusoidal behavior. A simple three-level model well reproduces the experimental observations [5].

The paper is organized as follows.

In Section II we describe the set-up of the POP clock, its main operation phases, the Ramsey fringes and the stability performances.

In Section III we report on the microwave amplitude locking technique while the ETS is described in Section IV. Section V is devoted to the characterization of the Ramsey central fringe lineshape.

Conclusions are in Section VI.

II. The POP Rb clock

The prototype is based on a pulsed approach in which the clock transition is detected by observing Ramsey fringes on a laser absorption signal.

The experimental set-up is represented in Fig. 1.

It is composed of three main parts:

1) physics package;

2) optics;

3) electronics.

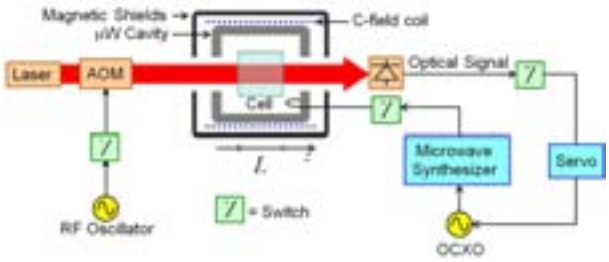

Fig. 1. Experimental setup of the POP clock.

The physics package is layer structure and several components can be identified (Fig. 2).

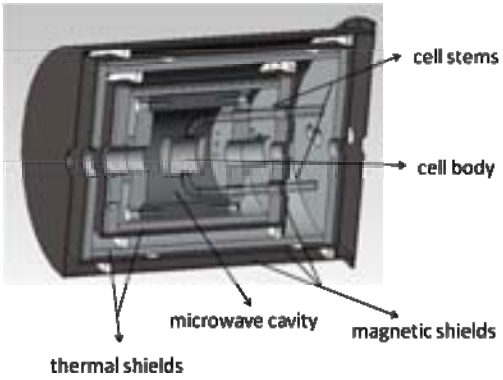

Fig. 2. Physics package of the POP clock.

The quartz cell contains the ^{87}Rb atoms and a buffer gas mixture N_2+Ar, at the total pressure P_s = 25 Torr. As shown in Fig. 2, the cell exhibits two large stems required to have a cold point in the cell; in this way, the condensation of Rb atoms inside the main body of the cell is in principle avoided.

The cell is placed in a Mo cavity resonating at 6.834 GHz. A quantization magnetic field along the cavity axis is applied (B_0 = 1.5 μT). Moreover, three mu-metal magnetic shields complete the physics package for an overall shielding factor of 1000.

Two thermal ovens working at different temperatures were implemented. The internal one works at 65.5 °C and is devoted the cell body-cavity system and the external one at 63.5 °C for the stems. The thermal stability for both the oven is of the order 1 mK for integration times up to 10000 s.

All the physics package is placed in vacuum structure in order to isolate the system from environmental fluctuations.

The optics is composed of a DFB laser at 780 nm (D_2 line) and delivers a full power of 15 mW. An AOM is used to switch on and off the laser during the pulsed operation.

The electronics is composed of a low phase noise synthesis chain delivering a signal at 6.834 GHz starting from a 10 MHz OCXO.

The synthesis chain (SC) is based on non-linear transmission lines (NLTL) [6]; a direct multiplication stage converts the signal from the 10 MHz of the OCXO to about 7GHz. The phase noise of the OCXO plus the SC is shown in Fig. 3; it has been obtained by the beat note of two nominally identical devices. The Dick effect turns out 7×10^{-14} at 1s.

A digital electronics was also implemented on FPGA to drive all the clock operation phases.

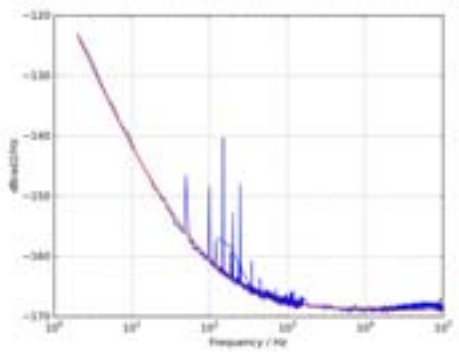

Fig. 3. Phase noise of the SC.

The clock operation is based on a pulsed optical pumping, followed by a microwave interrogation according to a Ramsey scheme, and a laser pulse for optical detection, as represented in Fig. 4. A typical timing sequence is also shown in the figure.

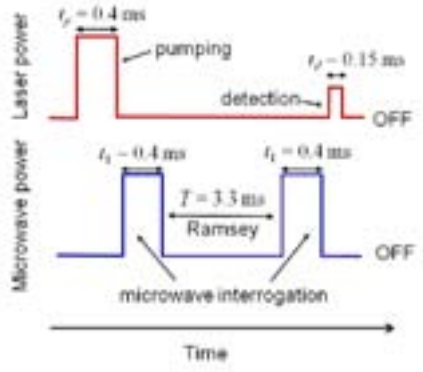

Fig. 4. Timing of the different operation phases of the POP clock

Fig. 5 shows the observed Ramsey fringes using a DFB laser locked to the D_2 line.

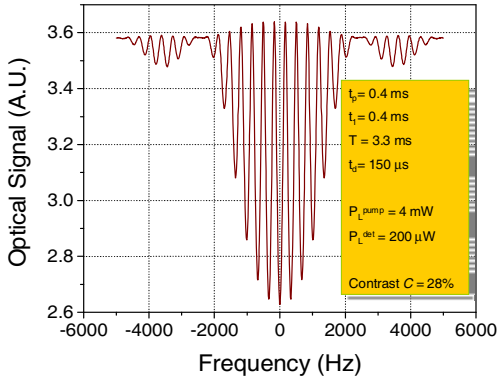

Fig. 5. Ramsey fringes observed with D2 line for a cell temperature 65.5 °C. The timing and the adopted laser powers are indicated in the figure.

A contrast of the 28 % for the central fringe is achieved. The corresponding frequency stability is reported in the following Fig. 6 and in terms of Allan deviation we have 1.7×10^{-13} at 1s; the white frequency region reaches the level of 5×10^{-15} at 10000s.

The drift has not been removed from the data and turns out -3×10^{-15}/day.

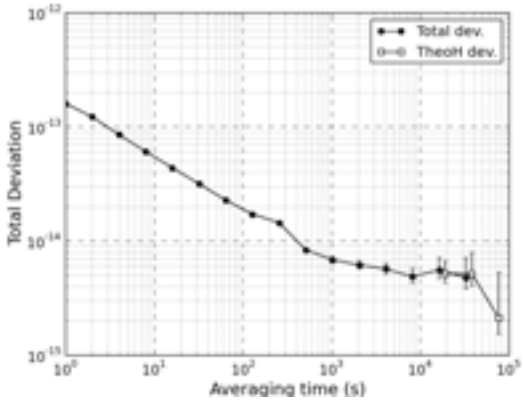

Fig. 6. Allan deviation of the POP clock with optical detection using D2 line as optical pumping.

III. Microwave Locking Technique

In order to obtain good frequency stability performances in the medium-long term period, it is often necessary to implement an active control of some parameters such as microwave and/or laser power.

Specifically, in the case of the POP clock, the microwave power is a particularly critical quantity since it may induce frequency fluctuations and or frequency drift through the cavity pulling effect. Moreover, since the cavity Q may degrade, the entity of the drift may change. It is then necessary a technique to lock the microwave amplitude to a signal coming from the atoms themselves.

To do that, we recall that the atomic signal P is essentially related to the population inversion Δ at the end of the second microwave pulse. It is easy to see that P can be written as [1]:

$$P \propto \frac{1 - e^{-\gamma_2 T} \sin^2 \theta \cos \Omega_\mu T}{2} \qquad (1)$$

where $\theta = b\, t_1$ is the microwave pulse area defined by the microwave Rabi frequency b and the duration t_1; Ω_μ is the microwave detuning between the interrogating frequency ω and the atomic frequency ω_{hfs}; γ_2 is the atomic coherence relaxation rate. Equation (1) then provides not only a frequency discriminator signal (proportional to cos $\Omega_\mu T$) but also an amplitude discriminator signal (proportional to $\sin^2\theta$).

In terms of the two locking variables Ω_μ and θ, the signal may be represented as a paraboloid around the two locking points, $\Omega_\mu = 0$ and $\theta = \pi/2$ (see Fig. 7).

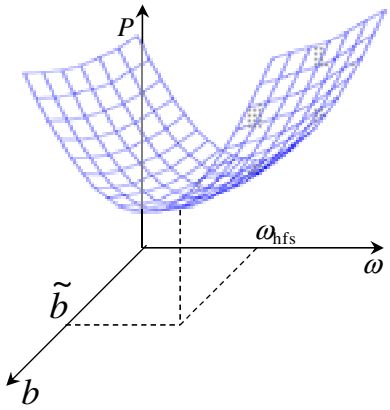

Fig. 7. Paraboloid which represents the signal (1). We call $\tilde{b}$ the microwave amplitude value which realizes the $\pi/2$ pulses.

We recall that the technique to lock the microwave signal frequency to the atomic frequency is similar to that adopted in an atomic fountain: two successive interrogations at frequencies $\omega \pm \Delta\omega$ are done and the corresponding signals are compared; specifically the difference between those signals has the meaning of error signal. The process is indefinitely repeated so that the LO frequency is continuously corrected and referenced to the ^{87}Rb atomic frequency.

To implement also the locking of the microwave amplitude we extended the algorithm previously described, so that the locking technique exploits four points, two for the microwave frequency and two for the microwave amplitude.

From a block scheme point of view, the locking of the microwave amplitude can be represented as in Fig. 8.

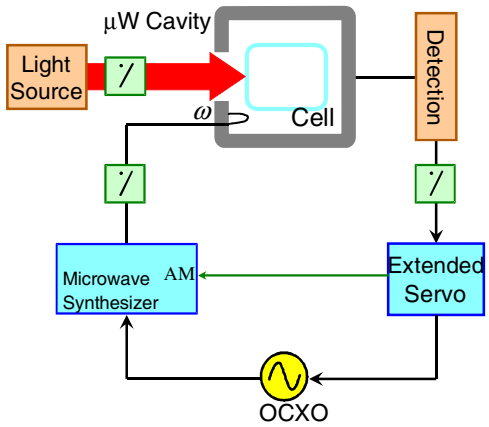

Fig. 8. Block scheme showing the technique adopted to actively stabilize the amplitude of the microwave signal to the atoms.

To show the importance of the microwave amplitude locking, we refer to Fig. 9 in which the clock frequency stability is reported. Figure 9 reports the clock stability with and without the servo of the microwave amplitude. It is possible to see a drift of the frequency of the order of -3×10^{-14}/day when the servo is not implemented. After the implementation of the servo system the frequency drift is reduced to -7×10^{-15}/day, also a benefit is observable on the short term behavior.

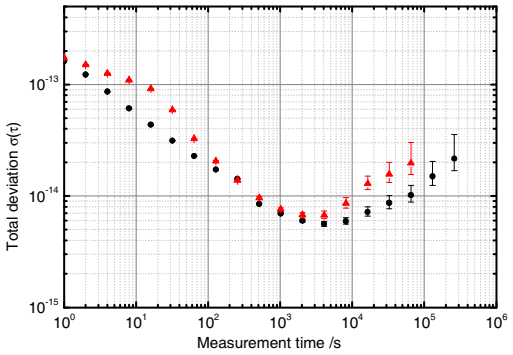

Fig. 9 Stability of the POP with (black circles) and without (red triangles) the microwave stabilization loop.

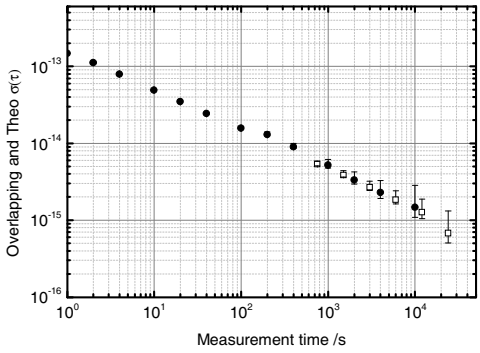

Fig. 10 Stability of a subset of data taken from the main set of fig. 9.

In Fig. 10 a subset of the data with the amplitude servo is analyzed, taken in a quieter environmental period of time. No significant drift appears, indicating the possible ultimate stability of the POP approach on the medium term, once the thermal criticalities should be resolved.

IV. Enhanced Temperature Sensitivity of the Clock Frequency

It is well established that the unperturbed ground state hyperfine frequency ν_0 of alkali-metal atoms is shifted by the interaction with buffer gas atoms/molecules [7]. This shift versus the cell temperature is a parabola: working around the maximum of the parabola it is in principle possible to reduce the temperature sensitivity of the clock frequency vs temperature (Fig. 11). Referring the coefficients of the curve to the inversion temperature T_i and fitting the experimental points with a parabola, the clock frequency can be written as:

$$\nu(T) = \nu_0 + P_S\left[\beta_i' + \gamma_i'(T - T_i)^2\right] \quad (2)$$

where β'_i=174 Hz/Torr and γ'_i = -0.00071Hz/K^2 Torr.

Supposing to work at a temperature T so that $|T\text{-}T_i|$<0.2 K, the temperature stability of the clock frequency is expected to be 4×10^{-12}/K.

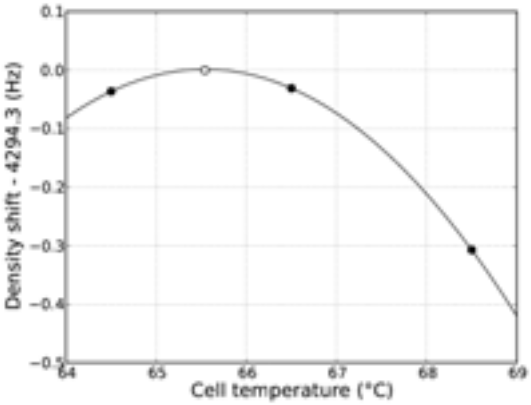

Fig. 11. Clock frequency shift versus temperature.

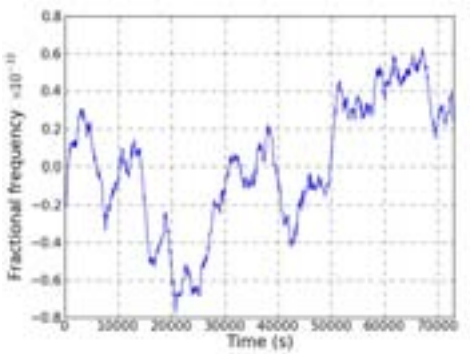
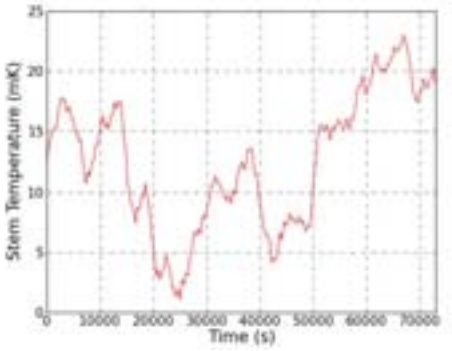
However, despite the use in the cell of a compensated mixture of buffer gases and the cell working temperature is set on the maximum of the parabola, a high sensitivity of the clock frequency vs temperature is observed.

In particular, the measured coefficient is of the order of 1×10^{-10}/K. To understand the origin of this phenomenon, we consider that a high unexpected correlation between the clock frequency and the stem temperature is observed (Fig. 12).

The effect is explained according to a model based on the ideal gas law.



(a)



(b)

Fig. 12. Correlation between the clock frequency (a) and the stem temperature (b).

A. The model

We consider the model represented in Fig. 13. The cell is divided in two parts: part A (volume V_a) is the clock cell placed inside the microwave cavity and thermally coupled to

the internal oven at the temperature T_a; part B is defined by the two stems (volume V_b) that are outside the microwave cavity; they are thermally coupled to the external oven at the temperature T_b.

It is easy to see that thanks to the ideal gas law, the atomic density n_a of buffer gas particles taking part to the interaction is given by:

$$n_a \approx n_s\left(1-\frac{T_a-T_b}{T_b}\mathrm{v}_b\right) \tag{3}$$

where n_s is the buffer gas density in the entire cell and $\mathrm{v}_b = V_b/(V_a+V_b)$.

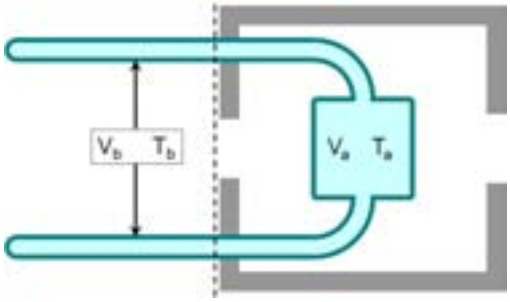


Fig. 13. Model used to explain the observed large temperature sensitivity.

From Eq. (3) it is easy to see the density of buffer gas atoms really involved in the interaction with Rb atoms depends on T_a and T_b, and for consequence may fluctuate due to variations of T_a and T_b. Conversely, n_s is fixed at the cell sealing time and is related to P_s by the ideal gas law (in our case $n_s \approx 8\times10^{17}$ cm^{-3}.

In a form totally equivalent to (2), the buffer gas shift can be written in terms of n_a:

$$\nu(T_a,T_b)=\nu_0+n_a\left[a'_{0i}+a'_{2i}(T_a-T_i)^2\right]\approx \nu_0+n_s\left(1-\frac{T_a-T_b}{T_b}\mathbf{v}_b\right)\left[a'_{0i}+a'_{2i}(T_a-T_i)^2\right] \tag{4}$$

with $a'_{0i} \approx 5.5\times10^{-15}$ Hz cm^{-3}, $a'_{2i} \approx -2.2\times10^{-20}$ Hz K^{2}cm^{-3} for our buffer gas composition. Deriving Eq. (4) with respect to and T_b (T_a) keeping constant T_a (T_b) we have:

$$\left.\frac{\partial\nu}{\partial T_b}\right|_{T_a=const} \approx n_s\, a'_{0i}\frac{\mathrm{v}_b}{T_b} \Rightarrow \frac{\partial\nu/\nu_0}{\partial T_b}\approx\frac{P_s\beta'_i\mathrm{v}_b}{\nu_0 T_b}=1.4\times10^{-10}/\mathrm{K} \tag{5}$$

that is of the same order of magnitude of the observed effect.

Similarly, we have:

$$\left.\frac{\partial\nu}{\partial T_a}\right|_{T_b=const} \approx n_s\, a'_{0i}\left[-\frac{\mathrm{v}_b}{T_b}+2\frac{a'_{2i}}{a'_{0i}}(T_a-T_i)\right] \tag{6}$$

From (5) it turns out that a new point where the clock frequency is insensitive to temperature fluctuations of the cell is found. In fact, Eq. (6) is null when:

$$T_a = T_i+\frac{a'_{0i}}{2a'_{2i}}\frac{\mathrm{v}_b}{T_b} \tag{7}$$

On the other hand, from (5) and (6) it is observed that $\left.\frac{\partial\nu}{\partial T_b}\right|_{T_a=const} = -\left.\frac{\partial\nu}{\partial T_a}\right|_{T_b=const}$ when the cell temperature is set to the inversion temperature T_i. This means that designing the physics package so that T_a and T_b are correlated the two temperature coefficients compensate each other.

According to previous equations, several solutions can be applied to reduce this anomalously large temperature sensitivity of the clock frequency:

- to make the cell with v_b negligible;
- good control of the temperature not only of the cell but also of the stems;
- adopt a mixture of three buffer gas to reduce not only the linear term but also the pressure coefficient β_i'.

In our system we used essentially the second technique, implementing an active temperature control devoted to the stems only. Moreover, to limit thermal bridges from the environment to the physics package, the vacuum structure was wrapped with highly insulating material.

In this way, the clock frequency stability in the medium long term remains at the level of 1×10^{-14} or better for integration times of the order of 1 day.

V. Lineshape of the Central Ramey Fringe

According to Eq. (1), it is expected that the shape of the Ramsey central fringe (RCF) is a pure cosine (in the following we assume $\theta = \pi/2$). Actually, in this section we discuss a couple of non-linear effects that contribute to the shape of the RCF. In a more detail, high-order harmonics appear in the Ramsey pattern and RCF is no more a pure cosine function of Ω_μ. This non-linear behavior may be attributed to two different physical causes. The first one is related to the incomplete extinction of the atomic coherence in the ground state between one operation cycle and the following one. This "phase memory" is responsible of the residual light-shift in a pulsed optically pumped (POP) clock and has been extensively discussed elsewhere [8, 9]. Here we show that a not complete separation among the different operation phases of the POP clock leads to a not elementary shape of the RCF.

The second effect is related to the optical thickness of the atomic sample. We observed in fact that the amplitude of high-order harmonics depends on the temperature (and then on the atomic density).

B. A. Cycle Memory Effect

Figure 14 shows the RCF as observed in a low temperature regime (45.5 °C) for a pumping time of 0.4 ms.

It is evident that the minimum appears flattened and the RCF is not well described by Eq. (1); that is, the shape is not a pure cosine function.

It can be demonstrated [5] that this phenomenon is related to a not complete extinction of the memory between one cycle and the successive one and as a consequence high-order harmonics appear on the signal. Specifically, the signal can be written as [5]:

$$\Gamma_p'(L) = \Gamma_p'(0)\left\{1 - \zeta\left[1 + \overline{\Delta}_{Ramsey}(\Omega_\mu)\right]\right\} \quad (8)$$

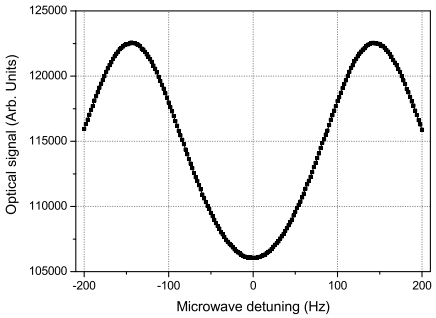

Fig. 14. RCF detected for the following values of the parameters: t_p = 0.4 ms, t_d =150 µs, T = 3 ms, t_1=0.4 ms.

where $\Gamma_p'(L)$ and $\Gamma_p'(0)$ are the laser pumping rates during the detection phase and the exit and at the entrance of the cell (of length L) respectively; ζ is the optical thickness of the medium and $\overline{\Delta}_{Ramsey}(\Omega_\mu)$ is the average over r cycles of the population inversion at the end of the Ramsey interaction phases:

$$\overline{\Delta}_{Ramsey}(\Omega_\mu) = \frac{1}{r}\sum_{k=1}^{r}\Delta^{(k)}_{Ramsey}(\Omega_\mu) \quad (9)$$

where each $\Delta^{(k)}_{Ramsey}(\Omega_\mu)$ is proportional to $\cos^k(\Omega_\mu T)$.

In particular, for the curve of Fig. 14 the ratio between the second order harmonic amplitude and the first order one turns out as large as 8.5 %.

In Fig. 15 we report the $\Gamma_p'(L)$ for three values of the pumping rate time as calculated according the model developed in [5].

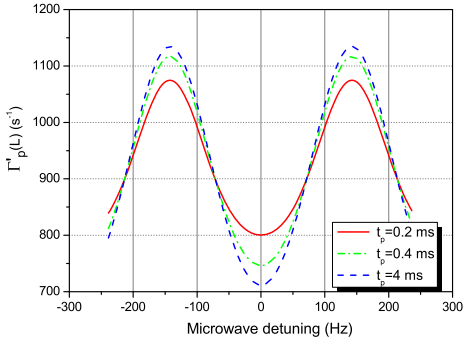

Fig. 15. RCF calculated for T= 3 ms, t_1 = 0.4 ms, $\Gamma_p(0)$= 20000 s^{-1}; $\Gamma'_p(0)$= 2000 s^{-1}; dash line t_p= 4 ms; dash dot line: t_p = 0.4 ms; continuous line: t_p= 0.2 ms.

As the pumping time increases, the laser pulse area $\Gamma_p t_p$ is able to suppress the memory between consecutive cycles and no high order harmonics are observed. To avoid this memory effect it is then required that the laser pulse area during the pumping phase satisfies the relation:

$$\Gamma_p t_p >> 1 \quad (10)$$

C. *High density case*

In this subsection we will investigate the effects related to the thickness of the atomic sample. Fig. 16 in particular refers to a RCF as detected at a temperature of 65.5 °C. To assure that the operation cycles are well separated and to exclude that any modification of the line shape may be attributed to the memory effect, a pumping time of 4 ms and a laser pumping rate of 20000 s^{-1} have been used, so that condition (10) is satisfied.

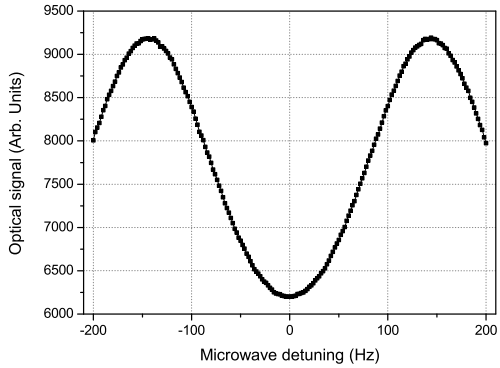

Fig. 16. RCF as observed in the high density regime (65.5 °C); T= 3 ms, t_1 = 0.4 ms, t_p= 4 ms; t_d = 0.15 ms.

It is observed that the curve is not a pure cosine function but the minimum appears flattened with respect the two side maxima, highlighting the presence of a second harmonic component in the Ramsey signal.

Since this effect cannot be due to the cycle memory, another mechanism should be responsible of it. To gain in physical insight, we observed the RCF for different atomic densities and through a non linear fit of the experimental curves we inferred the amplitude of the second harmonic component present on the signal. At the same time, we compared the experimental observations with the theoretical behavior obtained through the simple model used to interpret the results of subsection V*A*. The results are shown in Fig. 17.

From a theoretical point of view, it is found that the laser pumping rate at the detection stage is given by:

$$\Gamma_p'(L) = \Gamma_p'(0)e^{-\zeta}\left\{I_0(\chi) + 2\sum_{k=1}^{\infty} I_k(-\chi)\cos(k\,\Omega_\mu T)\right\} \quad (11)$$

where $I_k(x)$ are the modified Bessel functions of the first type with k integer ≥ 0 [10]. The argument χ is defined as χ=

$\zeta\ \Delta_{pump}\ e^{-\gamma_2 T}$; in this relation Δ_{pump} is the population inversion generated by the pumping light.

Since the $I_k(x)$ are monotone functions of the argument, the amplitude of the high-order harmonics increases with the product $\zeta\ \Delta_{pump}$; then, this effect is proportional to the optical length of the cell and to the population inversion generated by the pumping light. We note, however, that also γ_2 increases with the atomic density due to spin-exchange contribution [ref], leading to a suppression of the effect above a certain density value and explaining the two different regimes observed in Fig. 17. In other words, up to about 65 °C the second harmonic component amplitude increases due to the enhancement of the optical thickness of the medium ζ with temperature. Above that value, spin-exchange prevails and overcomes the pure density effect through the increasing of γ_2.

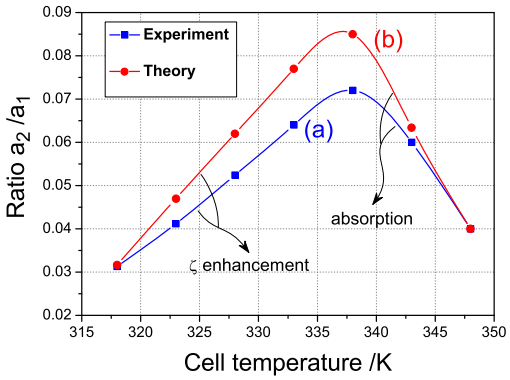

Fig. 17. Ratio between the coefficients a_2 and a_1 representing the amplitudes of the second and first-harmonic respectively versus the cell temperature; (a) experiment; (b) theory.

VI. Conclusions

In conclusion, we have implemented and characterized a Pulsed Optically Pumped frequency standard with optical detection. The frequency stability performances we achieved are among the best in the field of vapor cell clocks, both in the short and in the medium long term period.

We discussed also a technique to stabilize the microwave signal amplitude to the atomic signal. This technique is needed to control the drift of the clock frequency.

We also showed that due to the presence in our cell of large stems and because of a temperature gradient between the stems and the cell body, the clock frequency suffers of an unexpected large temperature sensitivity. To reduce it a tight control of the temperature stems has been implemented.

Finally, we discussed two phenomena that modify the shape of the Ramsey central fringe which results no more given by a simple cosine function of the microwave detuning but high-order harmonics may be present on the signal.

Study of an Observation Method Based on Crossed Polarizers for High-contrast Coherent Population Trapping

Yuichiro Yano, Shigeyoshi Goka

Email: yano-yuichiro@ed.tmu.ac.jp

***Abstract*—In this paper, we propose an observation method based on crossed polarizers to obtain high-contrast coherent population trapping (CPT) resonance with parallel linearly polarized light (lin‖lin field). Experimental results show that a high resonance contrast of 88.4 % can be observed using a ^{133}Cs gas cell and D_1-line vertical-cavity surface-emitting laser (VCSEL).**

I. Introduction

Atomic clocks based on coherent population trapping (CPT) resonance with a vertical-cavity surface-emitting laser (VCSEL) have attracted much attention for very small atomic references[1]. CPT atomic clocks are in great demand for many applications, such as, telecommunications, navigation systems, and synchronization of networks[2]. Atomic clocks are generally demanded for high frequency stability. In particular, short-term frequency stability is an important parameter for base stations of telecommunication systems. The short-term frequency stability, described as the Allan standard deviation $\sigma_y(\tau)$, is estimated as

$$\sigma_y(\tau) \propto \frac{\Delta f}{f_0}\frac{1}{SNR}\tau^{-1/2} \quad (1)$$

where Δf is the resonance linewidth, f_0 is the resonance frequency, and *SNR* is the signal-to-noise ratio. Contrast, which is generally used as a measure of *SNR*, is defined as the amplitude of CPT resonance over the background signal level[3]. Since short-term stability is determined from contrast and linewidth, both narrower linewidth and higher contrast are required to enhance short-term stability. A high-contrast CPT resonance can easily be observed in a high intensity laser field; however, the resonance linewidth broadened due to the power broadening effect[4]. It is difficult to enhance contrast together with linewidth. To solve this technical issue, a number of methods have been developed in the last decade (e.g., D_1 enhancement[5], pulsed CPT[6] , push-pull pumping[7],and polarization selective detection[8]).

In this paper, we focus on the Faraday effect in CPT and propose a method based on crossed polarizers for observing high-contrast CPT. The contrast and linewidth were measured using our proposed method and were compared with the results of the conventional observation method under the same experimental conditions using a ^{133}Cs gas cell and the D_1-line VCSEL. Since the Faraday effect is a magneto-optical phenomenon, we measured the dependence of resonance characteristics on transmission angle and magnetic field. The results show that transmission angle and magnetic field exist to maximize short-term stability. From these results, we conclude that our method has the potential to enhance the short-term stability of CPT atomic clocks.

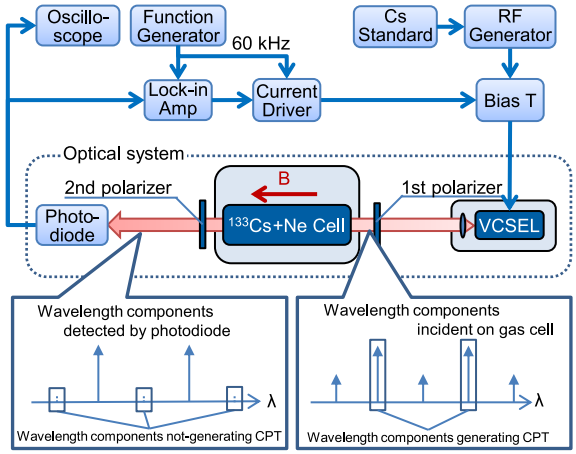

Fig. 1. Schematic of experimental setup

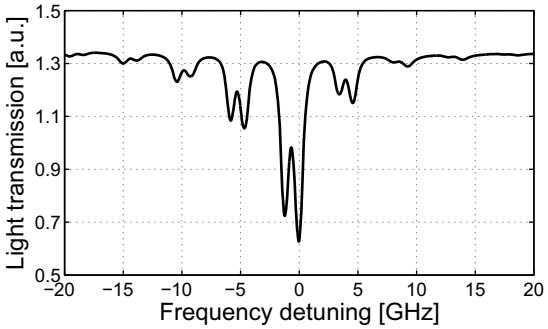

Fig. 2. Absorption profile of ^{133}Cs-D_1 line using VCSEL

II. Experimental Setup

Figure 1 shows the experimental setup of the proposed observation method. The two polarizers used near-infrared sheet polarizer. These polarizers were placed on both sides of the gas cell, and the transmission axes were set nearly

orthogonal to each other. Due to effect of the first polarizer, a parallel linear beam (lin$\|$lin field) was incident on the gas cell. The second polarizer selected the optical polarization of wavelength components incident on the photodiode. The light intensity signal transmitted through the second polarizer was detected by a photodiode, and the detected photodiode signal was connected to the oscilloscope.

The polarization of wavelength components that excited CPT was rotated by the Faraday effect while passing through the cell[10]. On the other hand, the polarization of wavelength components that did not excite CPT was not rotated. Therefore, the incidence of the non-exciting CPT wavelength components on the photodiode was suppressed by the second polarizer. As a result, the photodiode DC current could be reduced because the unwanted wavelength components incident on the photodiode decreased; thus, high-contrast CPT resonance could be obtained.

To excite CPT, we used a single-mode VCSEL fabricated by Ricoh Company, Ltd. The wavelength of the VCSEL is 895 nm to excite ^{133}Cs at the D_1-line. The VCSEL was driven by a DC injection current using a bias T and was modulated at 4.6 GHz using an analog signal generator to generate the first-order sidebands around the laser carrier. The absorption profile of the ^{133}Cs-D_1 line using VCSEL is shown in Fig.2. There were two absorption peaks in the transmitted light around a minimum, corresponding to two excited levels: $|F' = 3\rangle$ and $|F' = 4\rangle$. The frequency diffrence of the two excited states ($|F' = 3\rangle$ and $|F' = 4\rangle$) is sufficiently separated, that we can select excite state $|F' = 3\rangle$ or $|F' = 4\rangle$ as the absorption line. In this experiment, we selected $|F' = 3\rangle$ as an excited state to stabilize the wavelength of the VCSEL, since clock transition amplitude locking $|F' = 3\rangle$ is better than that of locking $|F' = 4\rangle$ under lin$\|$lin excitation [9].

A Pyrex gas cell containing a mixture of ^{133}Cs atoms and Ne buffer gas at a pressure of 2.0 kPa was used. The gas cell was cylindrical, it had a diameter of 20 mm and optical length of 22.5 mm. The gas cell temperature was maintained at 42.0 °C. The gas cell and Helmholz coil were covered with a magnetic shield to prevent an external magnetic field from affecting the magnetic field inside the cell. The internal magnetic field of the gas cell was created by Helmholz coil. The internal magnetic field was calibrated using the frequency diffrence between magnetic field insensitive transition and magnetic field sensitive transition by using σ-σ excitation. The axis of the magnetic field was set to be parallel to the direction of the laser light (C-axis direction). The frequency reference of the analog signal generator was connected to the Cs standard (Symmetricom 5071A High-performance tube).

III. Experimental results and Discussion

A. Line shape of CPT resonance with proposed method

Figure 3 shows the observed CPT resonance with the proposed method. When the transmission axis of the second polarizer was optimized, good reduction of background signal level (DC level) was achieved. Since the signal was greater than the DC level, the conventional contrast which was simply defined as sinal over DC level exceeded 100 %. In this paper, contrast is defined so as not to exceed 100% as follows.

$$\text{Contrast} := \frac{\text{Signal}}{\text{Signal} + \text{DC level}} \tag{2}$$

Although the DC level was suppressed by proposed method, weak light leakage occuerred and this light was received by the photo detector. The light leakage was caused by the lowness of the extinction ratio of the polarizers. Thus, if polarizers with higher extinction rate were used, the DC level could be suppressed. Owing to DC level reduction, the contrast reached 88.4 % with the proposed method. Since the contrast with the conventional lin$\|$lin observation method was 3.3 %, the contrast with our method was about 25 times better than that with the conventional method. And, a linewidth of 1.15 kHz is obtained with the proposed method. The linewidth was about twice as narrower as the conventional one of 2.15 kHz. This result means that the resonance with the proposed method has not only higher contrast but also narrower linewidth.

B. Contrast dependence on transmission angle of second polarizer

Figure 4 and 5 show the DC level and signal as a function of the transmission axis of the second polarizer. The magnetic field was set to 93 μT. The DC level was obtained as a quadratic function of the transmission angle of the second polarizer. The extinction rate of the polarizers was estimated to be about 10^4 from this result. The extinction rate was higher than that of a standard quarter-wave plate by several orders of magnitude. Since higher contrast was obtained with a higher extinction rate, the proposed method has an advantage over the polarization-selective method [8] using a quarter-wave plate.

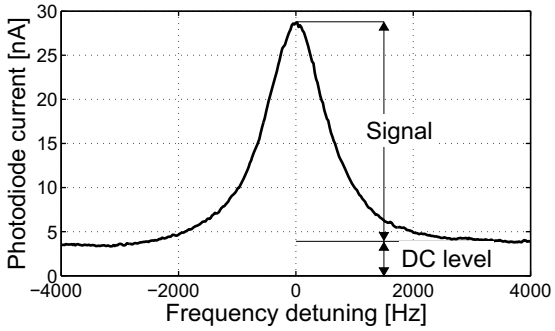

Fig. 3. Line shape of CPT resonance with crossed polarizers method

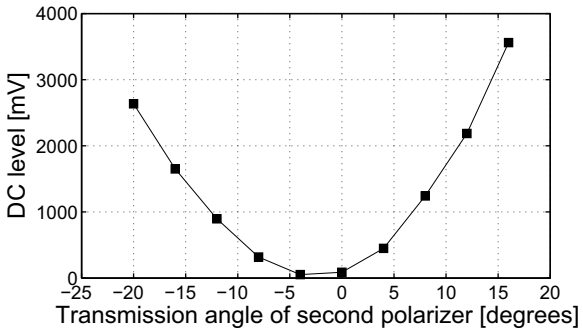

Fig. 4. DC level as a function of trasmission angle of second polarizer

By comparing the signal and DC level,it can be seen that the behavior of signal was different from that of the DC level. Therefore, this indicates that the polarization of wavelength components contributing to CPT was rotated. Figure 6 shows the contrast estimated from the signal and DC level. Since the signal has a high value despite DC level reduction, the contrast dramatically increased near 0°. In this experiment, a resonance contrast over 10 % was obtained in the range from -15 to 5°. Since the signal increased with increasing absolute value of transmission angle, even if the polarization rotation was small, it is expected that high contrast resonance can be obtained by appropriate adjustment of the transmission axis.

C. Characteristics dependence of magnetic field

Figure 7 shows the signal and DC level as a function of magnetic field in the range from 15 to 93 μT. The transmission angle of the second polarizer was optimized so as to maximize contrast. In weak magnetic fields ($<$ 15 μT), the signal was so small that we could not observe CPT resonance, and the maximum value of magnetic field of 93 μT was limited by the current source output supplying the Helmholz coil. The signal linearly increased with increasing magnetic field. On the other hand, the DC level was costant regardless of changes in the magnetic field. It is clearly shown that the Faraday rotation affected only the wavelength components contributing CPT. Figure 8 shows the contrast estimated from measured results. The contrast increased with increasing magnetic field. We assume that nearly 100 % contrast can be obtaiend in the strong magnetic field.

Next, we show the linewidth dependence of the magnetic field in Fig.9. The linewidth broadened with increasing magnetic field and approximately proportional to the magnetic field. However, the linewidth obtained with the proposed method is less than 2.15kHz of linewidth with the conventional excitation method in this range of magnetic field. The narrowest linewidth obtained was 760 Hz, which is about three

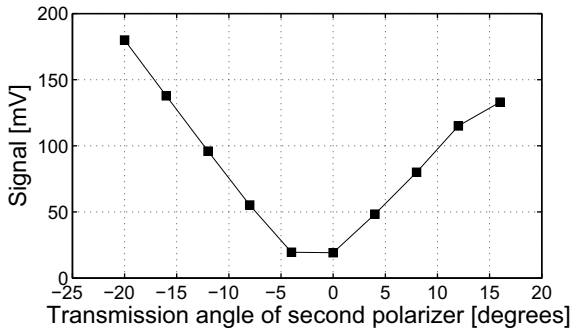

Fig. 5. Signal as a function of trasmission angle of second polarizer

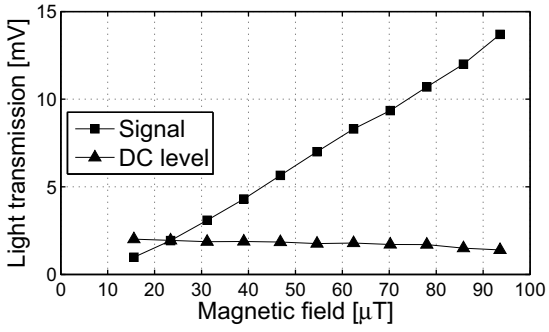

Fig. 7. Signal and DC level as a function of magnetic field

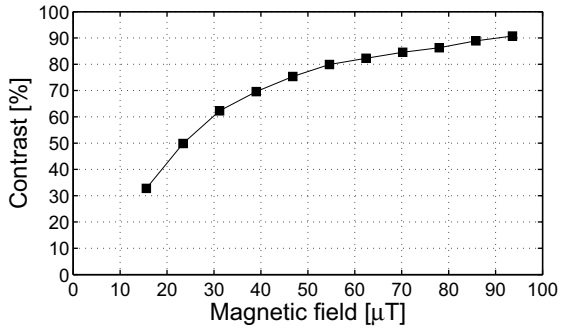

Fig. 8. Contrast as a function of magnetic field

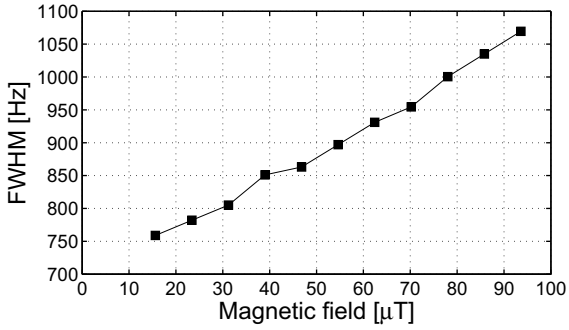

Fig. 9. Linewidth as a function of magnetic field

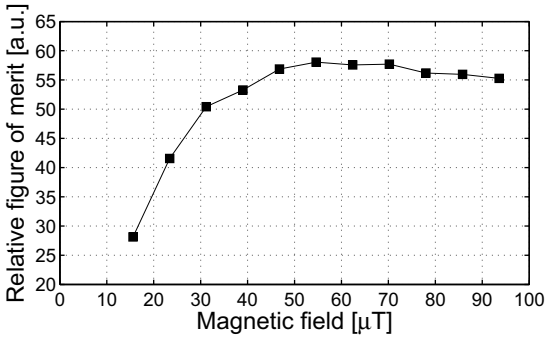

Fig. 10. Figure of merit as a function of magnetic field

times narrower than conventional one at a magnetic field of 5 μT.

Figure 10 shows the relative figure of merit (FoM) gainst changes in magnetic field. Since from Eq.(1) short-term stability is determined by contrast and linewidth, FoM is defined as follows.

$$\text{FoM} := \frac{f_0}{\Delta f} \cdot \text{Contrast} \tag{3}$$

In small magnetic fields ($< 40\mu$T), the FoM increased because the increase in contrast was dominant. However, in large magnetic fields ($> 60\mu$T), the FoM decreased with broadenning linewidth. Therefore, it is identified that magnetic strength exists so as to maximize the FoM of CPT resonance. In this experiment, the maximum value of FoM was obtained at 54.6 μT, and this value is 58 times better than the conventional one.

IV. Conclusion

We propose a new observation method based on crossed polarizers for observing high-contrast CPT resonance. When the transmission axis of second polarizer and magnetic field were optimized, the observed resonance had a contrast of 88.4% and linewidth of 1.15 kHz. Taking into account the 3.3% conventional contrast with lin$\|$lin excitation, the contrast with our method was about 25 times better than that with the conventional method. In addition to increasing the contrast, the linewidth with the proposed method was also two times narrower than the conventional one. We indicate that the resonance contrast and linewidth is dependent on the transmission angle of second polarizerand magnetic field. By optimizing the transmission angle of the second polarizer and magnetic field, the figure of merit was 58 times better than the conventional one. Therefore, this method has the potential to enhance the frequency stability of CPT atomic clocks.

***Abstract*—The AC Stark shift (the light shift) is very important in the performance of laser-pumped vapor cell atomic frequency standards. The frequency stability of a compact rubidium vapor cell atomic frequency standard with an AC Stark shift suppression laser pumping method was evaluated. The applications of such a device include serving as primary reference clocks in communication systems such as Stratum 1 reference clocks.**

Keywords—AC Stark shift; light shift; vapor cell atomic frequency standard; frequency stability; optical pumping

I. INTRODUCTION

It is known that the AC Stark shift (the light shift), which is caused by the interaction between the atom and the applied optical field, plays an important role in the performance of laser-pumped vapor cell atomic frequency standards [1]. Methods have been developed to suppress/eliminate the negative impact of the AC Stark shift on vapor cell atomic frequency standards, both in the coherent-population-trapping (CPT) configuration [2–5] and in the population-altering-pumping (PAP) configuration [6–8]. For example, using a pulsed light source to pump a rubidium vapor cell eliminates the AC Stark shift because the rubidium atoms do not interact with the optical field when they are interrogated by the microwave field [6].

For a compact vapor cell atomic frequency standard, it is not trivial to implement a pulsed light source for optical pumping because of the need of an optical switch with a high extinction ratio such as an acousto-optic modulator and a separate vapor cell for laser frequency stabilization. Thus, a continuous wave optical pumping scheme in the PAP configuration was developed [7]. This method takes advantage of excited state hyperfine splitting in atoms to suppress the total AC Stark shift by adjusting the Rabi frequencies of the transitions between the clock transition energy levels and various hyperfine energy levels in the excited states of the atoms. Furthermore, the buffer gas pressure in the vapor cell is optimized to reduce the slope of the AC Stark shift with respect to the laser frequency detuning in the vicinity where the laser frequency is stabilized. The proof of concept results were reported using a large glass rubidium cell [7] and a micro-machined rubidium cell [8].

II. EXPERIMENT SETUP

Figure 1 depicts the experiment setup. A glass rubidium cell with an inner diameter of 8.5 mm and an inner length of 13.5 mm was embedded inside a microwave cavity/oven assembly. The rubidium D_1-line (λ = 795 nm) was used for optical pumping. The frequency of a diode laser was stabilized to the average frequency of the transitions of $|F = 2\rangle \rightarrow |F' = 1\rangle$ and $|F = 2\rangle \rightarrow |F' = 2\rangle$ by adjusting the injection current. The slow change of the laser power was corrected using the laser temperature. A neutral density (ND) filter attenuated the laser beam intensity while a half waveplate and polarizer set the laser beam polarization with respect to the direction of the bias magnetic field. The strength of the bias magnetic field was adjusted according to the measured frequency of the magnetic field sensitive transition $|F = 1, m_F = 1\rangle \rightarrow |F = 2, m_F = 1\rangle$.

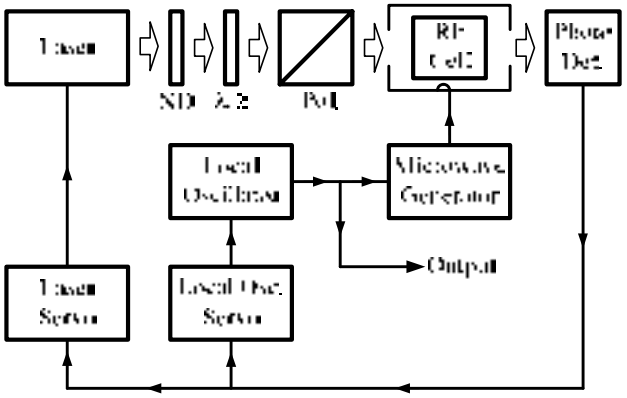

Fig. 1. Experiment setup. ND: neutral density filter. λ/2: half waveplate. Pol.: linear polarizer. The bias magnetic field and its adjustment are not shown in the figure (see text).

Figure 2 shows one of the initial measurements. Here the relative frequencies of the clock transition were measured with various total laser powers at three different linear polarization orientations. The measurement shows that indeed the AC Stark shift has been suppressed if the laser beam polarization is chosen correctly.

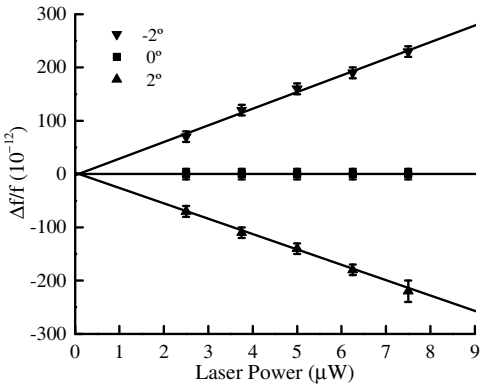

Fig. 2. Relative frequencies of the clock transition measured at various total laser powers and different linear polarization orientations. The reference direction (0°) was chosen to be the linear polarization direction that suppressed the total AC Stark shift.

III. Experiment Results

Several test runs were performed with the setup initially. After the various operating parameters were adjusted, the output frequency of the setup was measured continuously for more than 426 days. Figure 3 shows the measured short term frequency stability [9]. The expected performance of the reference system is also plotted in Fig. 3. It is seen that the measured Allan deviation is probably limited by the reference system in the averaging time between ~20 s and 10^5 s. Figure 4 shows that the relative frequency (averaging time = 1000 s) was bounded within $\pm 2.5\times10^{-12}$ during the entire measurement period.

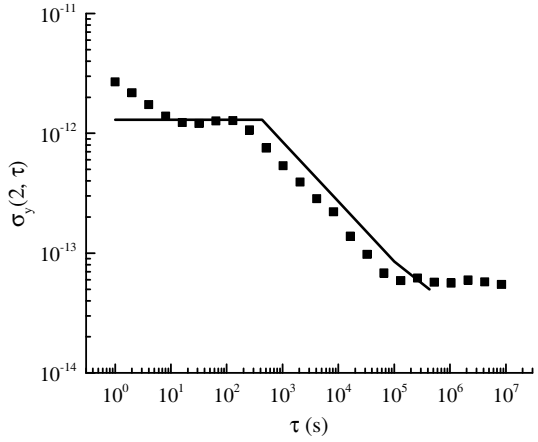

Fig. 3. Short term frequency stability. The squares represent experimental data. The solid line represents the expected performance of the reference system.

IV. Summary

A continuous wave population-altering-pumping method was implemented in a compact rubidium vapor cell atomic frequency standard to suppress the AC Stark shift. A short term frequency stability of $\sigma_y(\tau) < 3\times10^{-12}\ \tau^{-1/2}$ (τ in s) was obtained while the flicker frequency noise limited the longer term frequency stability to $\sigma_y(\tau) \approx 6\times10^{-14}$ for $10^5\ \text{s} < \tau < 10^7$ s. The absolute value of the relative frequency (averaging time = 1000 s) was measured as $<2.5\times10^{-12}$ during a measurement period of 426 days. The possible applications include serving as primary reference clocks in communication systems.

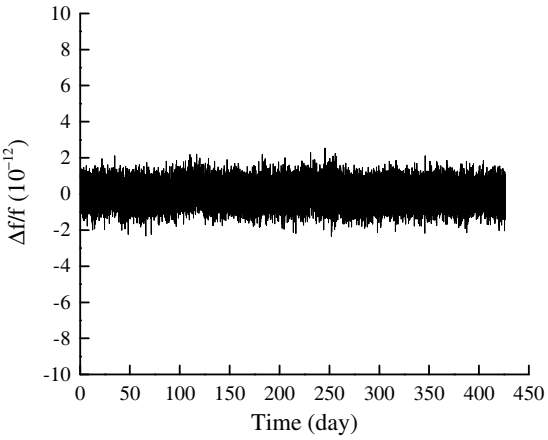

Fig. 4. Relative frequency (averaging time = 1000 s) vs. time.

***Abstract*— We have completed a series of experiments examining the effect of laser polarization noise on the short-term stability of a CPT atomic clock, when the CPT signal is generated in the "standard" fashion. Specifically, we have examined CPT signal amplitudes, CPT-signal noise, and CPT linewidths for various levels of randomly fluctuating circular polarization. We find that CPT signal amplitudes increase in the presence of polarization noise due to a decreasing efficiency of trapping states. However, we also find that CPT linewidths increase, since polarization fluctuations add to atomic dephasing, and that CPT-signal noise increases. This latter effect is due to bulk population movement between trapping states when the laser polarization changes. Consequently, more sophisticated CPT signal generation schemes that eliminate the trapping of atomic population might be more resilient to laser polarization noise.**

Keywords—atomic clocks, CPT, coherent population trapping, chip-scale clock, stochastic fields, polarization noise

I. Introduction

In the coherent-population-trapping (CPT) atomic clock, the microwave atomic signal is generated in an all optical fashion [1]. Briefly, sidebands are placed on the optical carrier at one-half the frequency of the ground state hyperfine splitting, ν_{hfs}, (i.e., 6.8 GHz for ^{87}Rb), and when the separation between the two sidebands, $2\Delta_s$, matches the ground state hyperfine splitting both levels are simultaneously coupled to the same excited state. Given that atomic excitation pathways interfere, when the two hyperfine states are coupled to the same excited state the pathways interfere destructively (i.e., the atom cannot make a real transition to the excited state). If the atoms cannot be excited, then there is no absorption of the laser light, and consequently the intensity of light transmitted by the vapor *increases*. The transmitted light thereby acts as a monitor of the atoms' interaction with a microwave signal (i.e., the laser sideband separation), and this can be used to lock the frequency of a quartz crystal oscillator to ν_{hfs}.

One obvious advantage to this design is that the microwave cavity of the traditional vapor-cell clock is eliminated. In addition to allowing for "chip-scale" atomic clocks [2], elimination of the microwave cavity removes many of the microwave power shifts that can give rise to frequency instability [3]. In particular, effects like alkali surface migration on the resonance cell's glass walls [4], which affect the microwave cavity Q, are eliminated. Nevertheless, though the CPT clock has real advantages over the conventional laser-pumped atomic clock [5], its novel nature suggests that it may be subject to new adverse processes that play little, if any, role in the conventional laser-pumped clock. One of these processes concerns the effect of laser polarization fluctuations on the CPT clock signal [6], which the present work investigates.

This work was funded by U.S. Air Force Space and Missile Systems Center under Contract No. FA8802-04-C-0001.

II. The Problem

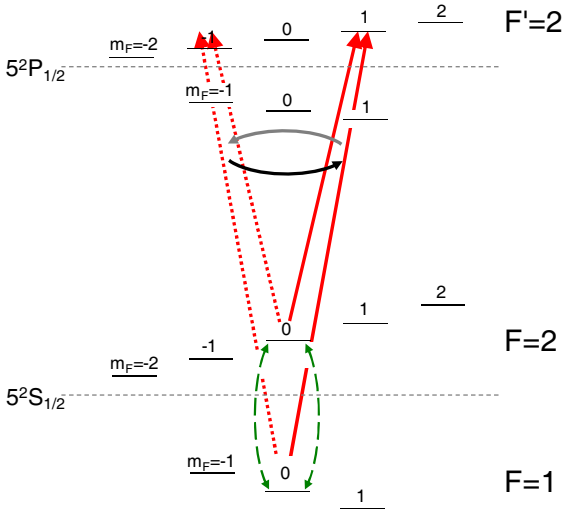

Fig. 1. In the typical CPT clock, two modes of a laser couple an atom's two $m_F = 0$ ground-state sublevels to the same excited state; here, the common excited sate is F' = 2, $m_F = +1$. The simultaneous coupling creates a coherence in the ground-state, indicated by the dashed green lines, and it this coherence that is at the heart of the CPT phenomenon. If the laser polarization fluctuates, then the common excited state will momentarily change to F' = 2, $m_F = -1$, and this will affect the ground-state coherence.

In the "standard" realization of the rubidium (Rb) CPT clock, the laser light is circularly polarized and connects the (F = 2, $m_F = 0$) and (F = 1, $m_F = 0$) ground state Zeeman sublevels to the (F' = 2, $m_F = +1$) Zeeman sublevel of the $5^2P_{1/2}$ excited state; this is illustrated in Fig. 1. As is well-known, this "lambda-system" coupling creates a coherence between the two $m_F = 0$ ground state sublevels, and it is this coherence that is at the heart of the CPT signal. If the circular polarization switches from right-circularly polarized light to left-circularly polarized and back again, then a transient will be introduced into the CPT signal since the common excited state changes:

(F' = 2, $m_F = +1$) → (F' = 2, $m_F = -1$) → (F' = 2, $m_F = +1$). If the polarization variations are stochastic [7], then the time series of these CPT transients will appear as noise on the CPT signal.

III. The Experiment

Figure 2 shows a block diagram of our experimental arrangement. We start with a cleaved-facet Fabry-Perot diode laser, which does not suffer intrinsic polarization fluctuations [8]. Though not shown in the figure, the laser light passes through an electro-optic modulator (EOM) that places sidebands on the laser at 3.4 GHz, and a neutral density filter. The modulated and linearly polarized field then passes through a ferroelectric liquid crystal (FLC) polarization rotator that has a bandwidth of 10 kHz. This polarization rotator changes the field's polarization by ninety degrees depending on an applied voltage supplied by a function generator. The field then passes through a quarter-wave plate, creating right or left circularly polarized light depending on the sense of linear polarization transmitted by the FLC polarization rotator.

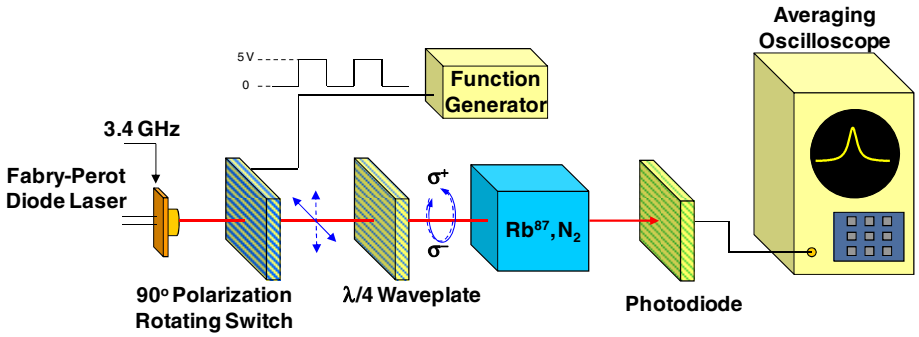

Fig. 2. Block diagram of our experimental arrangement. The Rb cell is maintained at 48 °C, corresponding to an alkali density of ~ 10^{11} cm^{-3}, and the Rb atoms are contained with a 50 torr N_2 buffer gas. The laser light passes through an electro-optic modulator (not shown) that places sidebands on the laser at ~ 3.4 GHz. In our experiments the sideband-to-carrier power ratio is 0.18, and we sweep the sidband spacing through the CPT resonance to generate the CPT lineshape. The sweep rate is relatively slow (i.e., 2.9 kHz/sec).

Our Pyrex resonance cell is 3.9 cm long with a 2.2 cm diameter, and for these experiments was maintained at 48 °C with braided heating wire wrapped around the cell body. The absorbance of the vapor, κ_o, was measured as 0.57: $I(L) = I_o e^{-\kappa_o}$ with I_o defined as $I_s 10^{-ND}$ (i.e., the sideband intensity after passing through the neutral density filter). The resonance cell was located in a set of three mutually perpendicular Helmholtz coils with a diameter of 66 cm: two pairs cancelled out the Earth's magnetic field, while the third provided a quantization axis for the atoms along the laser beam's propagation direction (i.e., B_z = 0.5 gauss). Our vapor of isotopically enriched ^{87}Rb vapor was contained with 50 torr of N_2, so that the dominant relaxation mechanism in our experiments was electron-spin randomization (also known as S-damping) [9].

In previous experiments, we investigated the response of the ^{87}Rb lambda system to a step-change in laser polarization [10]. We found that the *simplest* model capable of capturing the dynamics was an 8-parameter model, which indicates the complicated nature of CPT in the presence of polarization variations. Briefly, four parameters are needed to describe the re-establishment of electron-spin polarization following the laser's polarization change (i.e., movement of population from one "trapping state" to another), and four parameters are needed to describe the transient nutation that occurs in the CPT signal as the 0-0 coherence reestablishes equilibrium: a nutational amplitude, A_2, the dephasing rate, γ_2, a nutational frequency, $2\delta = 2\Delta\nu_s - \nu_{hfs}$, and a nutational phase, ϕ.

In separate experiments we also exposed the ^{87}Rb lambda system to squarewave laser-polarization modulation, and discovered that when the modulation frequency is greater than γ_2 the CPT resonance will split into a doublet [11]. This has implications for the short-term stability of CPT atomic clocks, since at a minimum it suggests that broadband polarization noise will degrade the CPT atomic-Q. Recently, we verified this prediction, and developed an Independent-Modulator Approximation theory to describe CPT signal amplitudes and linewidths in the presence of laser-polarization noise [12].

Here, we continue with this theme by considering not only the amplitude and linewidth of CPT signals in the presence of laser-polarization fluctuations, but also CPT-signal noise. To generate random laser polarization fluctuations, we first divide our sweep time across the CPT resonance, T = 1 sec, into subintervals δt, with $\delta t = 10^{-3}$ sec; and for each of these subintervals we define a Bernoulli distributed random variable, x(t), that can be either zero or one. Every time a one appears in the Bernoulli process, the function generator controlling the FLC changes: 0 → 5 V or 5 → 0 V. Thus, a zero in the Bernoulli process means that the laser-field's polarization remains constant, while a one implies that the polarization changes. Consequently, the number of polarization changes that occur over the entire time period of the sideband frequency sweep across the CPT resonance is equal to the number of ones that appear in the Bernoulli process over this period. If we define p as the probability for a one to appear in the Bernoulli process, then the mean number of polarization changes during a sweep, $\langle n \rangle$, will be given by $pT/\delta t$, and therefore the average polarization changing rate, R_p, is just $2\pi\langle n \rangle/T = 2\pi p/\delta t$. The fastest polarization-changing rate we can access in our experiment is $2\pi/\delta t = 6283$ s^{-1}, which is much faster than γ_2. In what follows, we characterize the stochastic polarization fluctuations by their correlation time, $1/\gamma_p \equiv -\delta t/\mathrm{Ln}[1-2p]$, which is derived in the Appendix.

Figure 3a shows an example of our CPT lineshape in the *absence* of stochastic polarization fluctuations for a relative

light intensity, I_o/I_s, of 6.3×10^{-2}, which is the light intensity that maximized the CPT contrast. The solid line through the data is a Lorentzian fit, which has a half-width half-maximum, $\Delta\nu_{1/2}$, of 580 s^{-1} (i.e., 92 Hz). Figure 3b shows an example of a CPT lineshape in the *presence* of stochastic polarization fluctuations; for this particular case p = 0.3. Comparison with Fig. 3a shows that the stochastic polarization fluctuations have led to a decrease in the CPT amplitude (i.e., $\Delta I_{CPT}/I_T = 0.22\%$), and a significant broadening of the CPT lineshape (i.e., $\Delta\nu_{1/2}$ = 1480 s^{-1}). Nevertheless, the CPT lineshape is still Lorentzian.

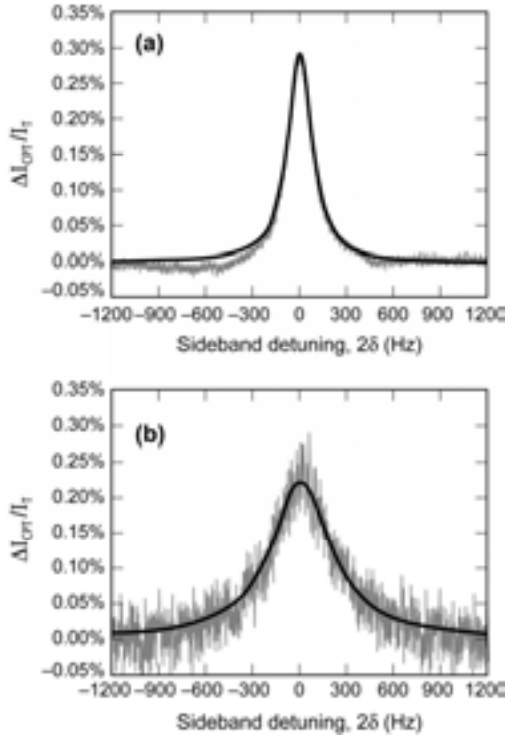

Fig. 3. (a) An example of our CPT lineshapes in the absence of stochastic polarization variations (i.e., p = 0); the data was taken with a relative light intensity, I_o/I_s, of 0.06, and the solid line through the data is a Lorentzian least-squares fit: Amplitude = 0.28% and $\Delta\nu_{1/2}$ = 580 s^{-1}. (b) An example of our CPT lineshape in the presence of stochastic polarization variations (i.e., p = 0.3); the data was taken with a relative light intensity, I_o/I_s, of 0.06, and the solid line through the data is a Lorentzian least-squares fit: Amplitude = 0.22% and $\Delta\nu_{1/2}$ = 1480 s^{-1}.

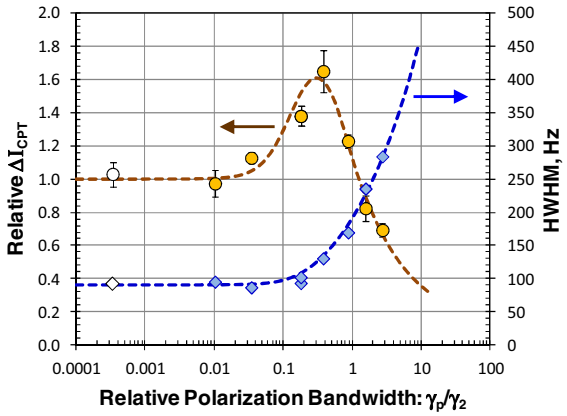

Fig. 4. Relative CPT signal amplitude and linewidth as a function of the polarization bandwidth. The points in white, furthest to the left, actually correspond to p = 0, and the dashed curves are simply aids to guide the eye.

Figures 4 and 5 show our principal results. In Fig. 4 we present the relative CPT amplitude and linewidth as a function of γ_p/γ_2. Note that as the polarization bandwidth, γ_p, increases there is an initial increase in the CPT amplitude as the trapping of atomic population is reduced. For large polarization noise bandwidths, however, this beneficial effect of polarization noise is lost [12]. Figure 5 shows the relative intensity noise (RIN), in a one hertz bandwidth and at a Fourier frequency of 327 Hz, as a function of γ_p/γ_2. The large increase in RIN with γ_p is due to the fact that large transmitted-light transients are induced in the signal following a polarization change as atomic population moves from one trapping state to another (i.e., $\langle S_z\rangle \Rightarrow -\langle S_z\rangle$) [12]. (The increase in RIN with γ_p for the laser tuned off resonance is due to the fact that the transmission of the FLC is not exactly balanced for its two polarization states.)

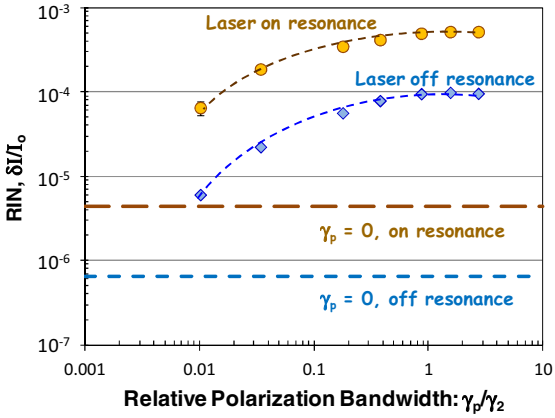

Fig. 5. Relative intensity noise (RIN) of the CPT signal as a function of the polarization bandwidth. The dashed lines through the data are simply meant as aids to guide the eye. Laser on/off resonance refers to the laser tuned on or off the Doppler-broadened absorption profile.

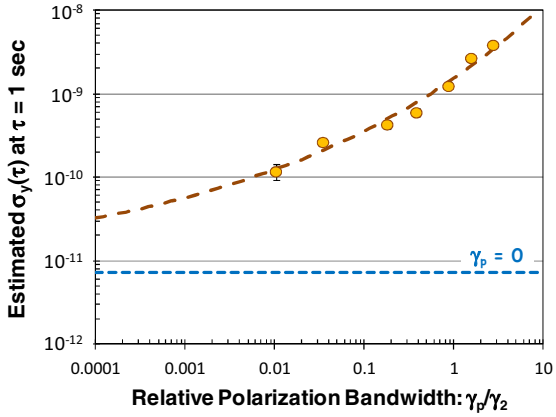

Fig. 6. Estimated performance of a CPT atomic clock as a function of polarization noise bandwidth. The dashed curve is a fit to the data.

Taking the short-term Allan deviation, $\sigma_y(\tau)$, as [13]

$$\sigma_y(\tau) = \frac{0.4\Delta\nu_{1/2}\times RIN}{\nu_{hfa}\left(\Delta I_{CPT}/I_o\right)}, \qquad (1)$$

Fig. 6 puts all of our data together to show the estimated short-term stability of a CPT clock as a function of the relative

polarization-noise bandwidth. Fitting the data to an empirical form, we get

$$\sigma_y(\tau) = \sigma_{y,o}(\tau)\,\mathrm{Exp}\left[A\left(\gamma_p/\gamma_2\right)^{\beta}\right], \qquad (2)$$

with $\sigma_{y,o}(\tau) = 8\times10^{-12}/\tau^{1/2}$, A = 5.36, and β = 0.138. Clearly, even for very low levels of laser polarization noise, there can be a dramatic loss of short-term frequency stability.

IV. Summary

We have completed experiments examining the effect of laser polarization noise on the short-term stability of a CPT atomic clock. For "moderate" polarization noise levels, we find that the CPT amplitudes increase due to a loss in the efficiency of trapping states when the laser polarization varies rapidly; this beneficial effect of polarization noise, however, cannot overcome the detrimental effects of polarization noise. In particular, at all levels of polarization noise there is an increase in the CPT signal's dephasing rate, and due to bulk population movement between trapping states there is a very large increase in the transmitted light's RIN.

Given the importance of population movement between trapping states under laser-polarization noise conditions, one must ask if more sophisticated CPT-signal generation techniques that reduce population trapping might not prove more resilient to laser polarization noise. In future work we plan to repeat our experiments using one or more of these sophisticated techniques (e.g., push-pull optical pumping [14]) in order to test this hypothesis.

Appendix

Let $\zeta(t)$ be a random process describing the polarization state of the laser: $\zeta = +1 \Rightarrow$ right-circularly-polarized light and $\zeta = -1 \Rightarrow$ left-circularly-polarized light, and constrain the polarization changes so that $\zeta(0) = +1$ (i.e., the random process always begins with the laser right-circularly-polarized). Then the polarization state of the field at some time t is just

$$\zeta(t) = (-1)^{k(t)} = \cos[k(t)\pi]\,. \qquad (A.1)$$

Here, k(t) is a binomial random process given by

$$k(t) = \sum_{i=1}^{n} x(t_i)\,, \qquad (A.2)$$

where $n \equiv t/\delta t$ = the number of "draws" of the Bernoulli random variable, x(t). The average value of $\zeta(t)$, $\langle\zeta(t)\rangle$, is then

$$\langle\zeta(t)\rangle = \sum_{k=1}^{n}\cos(k\pi)\binom{n}{k}p^k(1-p)^{n-k} = (1-2p)^{t/\delta t}, \qquad (A.3)$$

where $\binom{n}{k}$ is a binomial coefficient.

To compute the power spectrum, we first compute the correlation function of $\zeta(t)$:

$$\zeta(t)\zeta(t\pm\tau) = (-1)^{2k\pm m} = \cos(m\pi), \qquad (A.4)$$

where m is the number of polarization changes in the time interval τ. This, however, is just given by Eq. (A.3) with n replaced by $m = |\tau|/\delta t$. To obtain the power spectrum, we take advantage of the Wiener-Khintchine relations:

$$L(\omega) = \int_{-\infty}^{\infty} e^{-i\omega\tau}\langle\zeta(t)\zeta(t\pm\tau)\rangle d\tau = \int_{-\infty}^{\infty} e^{-i\omega\tau}(1-2p)^{|\tau|/\delta t}\,d\tau\,. \qquad (A.5)$$

Equation (A.5) yields a Lorentzian spectrum with a correlation time, γ_p^{-1}, equal to $-\delta t/\mathrm{Ln}[1-2p]$:

$$\frac{L(\omega)}{N} = -\frac{1}{\pi}\frac{\delta t\,\mathrm{Ln}[1-2p]}{(\mathrm{Ln}[1-2p])^2 + (\omega\,\delta t)^2}, \qquad (A.6)$$

where N is a normalization constant.

***Abstract*—Downhole sonic measurements provide compressional and shear wave propagation speeds of formations for hydrocarbon exploration purposes. We developed a new logging-while-drilling (LWD) tool that provides shear speed measurements in oil wells that are drilled in slow formations, where shear head waves are not excited using the conventional monopole source. To provide quality multimode measurements, azimuthally distributed transmitter and receiver elements of good output or sensitivity matching are required. We designed such devices, characterized them in-house, and tested them in the oil wells. This paper introduces our downhole sonic tool development method, focusing on receiver characterization and results.**

Keywords—downhole multimodes measurements, logging-while-drilling sonic tool, receiver sensitivity matching

I. INTRODUCTION

Tools for downhole sonic measurement were developed about half a century ago as a part of a suite of geophysical survey tools used to explore for hydrocarbons. By the 1990s, with the development of digital electronics, downhole sonic tools provided the measurements using array receivers and multiple transmitters, with computer-controlled data acquisition and a digital signal processing system [1]. Compressional- and shear- (or P- and S-) wave propagation velocities are inverted from full waveforms using semblance methods [2]. Combined with body wave velocity and density from nuclear measurements, sonic measurements are used to characterize a formation in terms of its mechanical properties.

The conventional measurements are limited for fully characterizing formation rock, especially in a "slow formation," a formation that has a slower shear wave propagation speed than that of well fluid. Shear refracted waves cease to be present under such a condition. An alternative measurement—shear slowness inversion from borehole modes—has been invented for such a case. The first multimode sonic measurements were developed for the wireline tool using a dipole source [3]. Shear velocities are inverted from borehole flexural signals utilizing model-based inversion techniques. Dispersion curves are sensitive to radial and azimuthal velocity variation in the formation near the wellbore surface location. Borehole stresses, induced by drilling and/or tectonic stresses, are one of the causes of such velocity variations, and advanced sonic measurements are useful not only to provide shear slowness in slow formation, but also for better understanding of the borehole stress state [4]. Such information is valuable when provided during the early stage of well drilling for safe and effective well placement. For this reason, the demand for logging-while-drilling (LWD) measurements is increasing.

We developed a new multimode sonic tool using a borehole quadrupole mode for LWD application. This paper introduces the sonic tool development process and the characterization methods, using the latest tool as an example.

II. SONIC TOOL DEVELOPMENT PROCESS

Development of a downhole sonic tool includes designing an acoustic measurement system. Fig. 1 shows the acoustic tool development process. Items in blue boxes are the key building blocks of both the base technologies and the human resources, whose areas of expertise are acoustics/physics, sensors, experiments, mechanics, electronics, embedded and acquisition software, signal processing, data evaluation and interpretation, and field operation. For sonic tool development, we start from numerical modeling to understand borehole acoustics under the presence of the tool structure. Hardware prototypes are built using technologies that enable measurement under harsh drilling conditions of high temperature (150 ^{o}C) and pressure (170 MPa), and mechanical shocks while deploying the tool kilometers below the surface. After building prototype parts, we integrate them into the tool and characterize the tool using in-house test facilities. The characterized tool is sent to the field to acquire data, and we then validate new measurements by comparing them with existing available measurements.

We apply and iterate the development process to design our acoustic measurements through the entire development cycle.

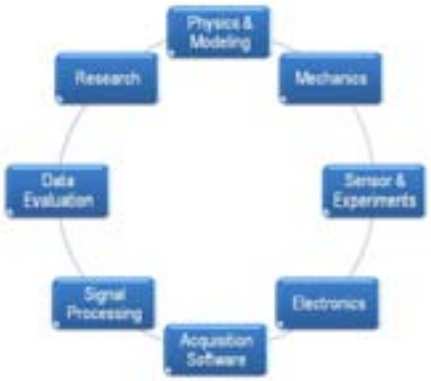

Fig. 1. Acoustic tool development process.

III. SONIC TOOL STRUCTURE OVERVIEW

LWD tools are mechanically designed as a part of rigid drill pipes. Fig. 2 shows a schematic view of the latest LWD multimode sonic tool. The nominal diameter and length of the tool are 0.12 and 9 m, respectively. The transmitter and receivers are mounted on the outer surface of the collar. The attenuator is a set of grooves that are machined on the inner surface of the collar to attenuate and delay direct tool arrivals. In monopole mode, the grooved section effectively attenuates and delays the pipe extensional mode signal. Details of the groove design methodology are introduced separately from this paper [5]. For slow shear inversion, we utilize borehole quadrupole mode. Unlike the wireline dipole sonic tool, a rigid LWD collar is not suitable for dipole measurements. The collar dipole mode is strongly coupled with the borehole flexural mode, and makes shear inversion challenging. On the other hand, the collar quadrupole mode is less coupled to the borehole mode in the range of borehole modes of interest.

The transmitter consists of four identical units positioned on the collar every 90°. Fig. 3 presents the schematic view of four units on the left as red and blue circles, particle displacement of fluid in the middle, and the azimuthal profile in the right. Monopole and quadrupole pressure fields are excited, respectively, when two diagonally paired units are operated in the same and opposite polarities. Drive circuits excite the transmitter in the wide frequency band from about 1 kHz to 20 kHz.

Four receiver arrays are mounted on the collar every 90° at a position in line with the transmitter units to receive the borehole quadrupole mode at the most efficient direction. The piezoceramic receiver element converts acoustic pressure into an electrical signal. Four azimuthal receiver positions relative to the borehole quadrupole are illustrated in Fig. 4. The black curve and blue circles, respectively, show the azimuthal pressure profile and four receiver element positions. Receiver elements are connected to amplifiers and digitization circuits near the elements. The time series of signals undergo digital modal decomposition before recording. Modal pressure is the sum of cosine-weighted azimuthal signals, as shown in Eq. 1, where $p_i(t)$ and $pn(t)$ are, respectively, the time series of acoustic signals recorded at i th (i=1,2,3,4) receiver and the resulting modal signal, θi, is the azimuth of the receiver, and n is the borehole mode order. Monopole and quadrupole mode numbers are 0 and 2, respectively.

One receiver array has 12 channels or elements, which are spaced at 100 mm, as illustrated in Fig. 5. Twelve modal pressure waveforms are computed using four receivers at the same transmitter-receiver spacing. When the transmitter is fired in monopole and quadrupole mode, 12 modal signals are recorded and used for slowness computation. Raw waveforms are intermittently stored for quality control.

Fig. 2. LWD sonic tool.

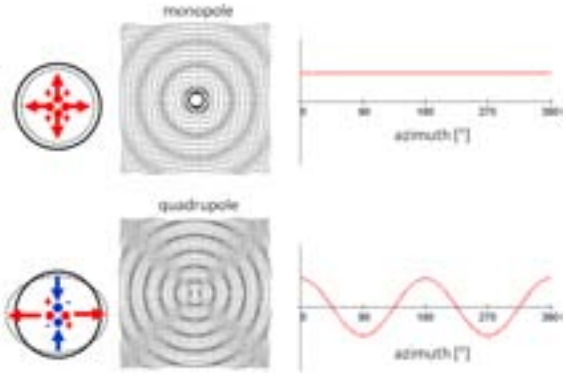

Fig. 3. Monopole and quadrupole mode excitation.

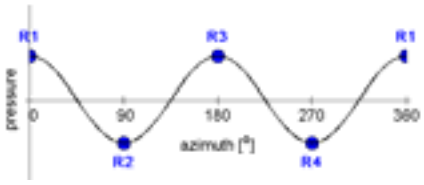

Fig. 4. Quadrupole azimuthal pressure profile and four receivers.

$$pn(t) = \frac{\sum_i p_i(t) \cdot \cos(n \cdot \theta_i)}{\sum_i \cos^2(n \cdot \theta_i)} \qquad \text{(Eq. 1)}$$

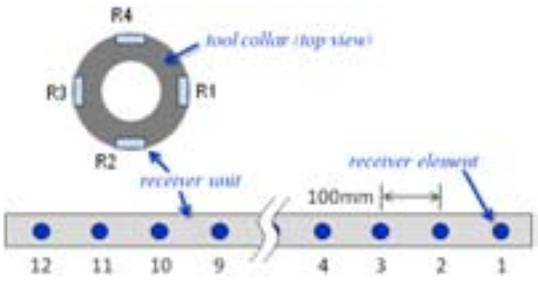

Fig. 5. Receiver array unit.

During drilling, sonic tools may be eccentered in the borehole and, with excitation, may record undesired signals because of this eccentering. In this situation, borehole excitation and received signals are no longer pure modal pressure, even using perfectly matched transmitter units and receiver elements. To minimize tool eccentering, stabilizers are added at the top and bottom of the tool. Transmitter output and receiver sensitivity matching help minimize modal signal contamination by unwanted modes. Below we discuss receiver characterization and evaluation methods using in-house test facilities.

IV. RECEIVER SENSITIVITY MATCHING EVALUATION

Multiple hydrophone and sonar calibration methods have been discussed in the past [6, 7]. Such methods are useful for receiver element characterization but are not always applicable to receivers assembled together with electronics. When elements are mounted on a structure, the sensitivity might vary because of surrounding structures, such as packaging and tool collar. For the multimode sonic tool, relative sensitivity of receivers was evaluated as a receiver array unit assembly, before and after integrating into the tool.

We characterized the sonic tools and receiver unit assemblies in a water pit, a part of the in-house test facilities. The water pit is a 9-m^3 tank that is useful for acoustically characterizing their free-field responses above the frequency of 1 kHz, under ambient pressure and temperature conditions.

A downhole tool is mainly operated under higher pressure and temperature, so environmental tests are important to finalize the design. Sensitivity measurements in such an environment are not trivial because there is no commercially available reference sound source or reference hydrophone for these measurements. Moreover, the electrical connections inside and outside a pressure vessel require special pressure-tight feedthrough with long cables. On the other hand, for the downhole sonic measurements, relative sensitivity matching has always been of primary interest, and methods for calibration or receiver sensitivity equalization have already been developed for the wireline sonic tools [8].

To evaluate sentivity matching, we assemble receiver and transmitter units on the tool and record pipe extensional mode signals in a high pressure and temperature vessel. The transmitter is operated in monopole mode. Pipe extensional mode propagates as the dominant and fastest arrivals at the receiver and is followed by other unwanted modes, including the direct collar arrivals, so that the signal amplitude of this extensional mode is representative of receiver sensitivity compared with other later arrivals. Fig. 6 presents a schematic view of receivers in the pipe and the photo of the vessel. Signals are acquired at six different combinations of pressure and temperature.

Fig. 7 presents recorded pipe-mode signal amplitude versus receiver channels. The horizontal and vertical axes are channel numbers and amplitude in arbitrary units. Curves in four different colors are signals from four azimuthal receiver arrays. From the left to right, we present amplitude recorded at three different pressures of 170, 135, and 100 MPa. Temperature was 150 ^{o}C. From four azimuthal signal amplitudes at the same channel number, we compute their average and azimuthal amplitude deviation from the average. Fig. 8 presents the devitation normalized by the average. We consider this deviation as representative of the sensitivity matching error. This method is not useful for absolute sensitivity measurements, but for characterizing relative azimuthal sensitivity matching.

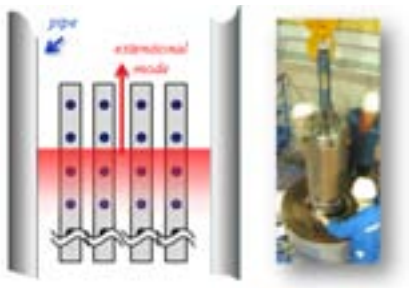

Fig. 6. Sensitivity test at high pressure and temperature.

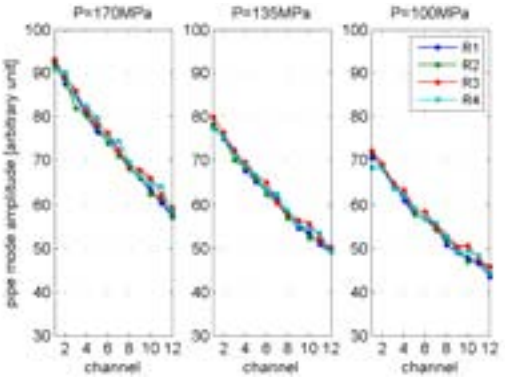

Fig. 7. *Pipe mode amplitude trend of four receiver arrays.*

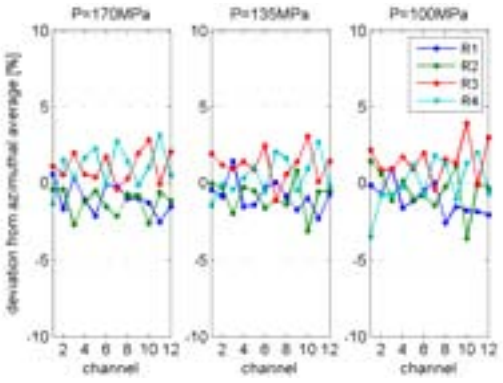

Fig. 8. Normalized amplitude deviation from azimuthal average.

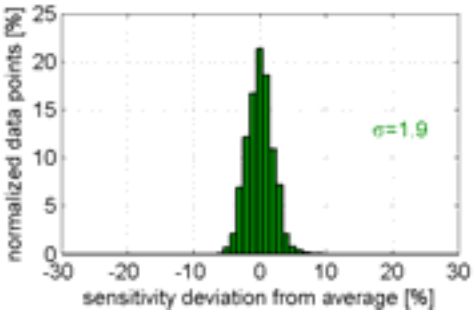

Fig. 9. Relative sensitivity distribution of LWD downhole receivers.

The results may include systematic error, such as submillimeters of tool eccentering in the pipe; however, thanks to the rigid LWD tool structure, mechanical alignment is nearly at the limit of precise tool position control, which is relatively easier than with the wireline tool. We evaluated the sensitivity deviation of the new LWD sonic receivers using 12 different tools at six different pressure and temperature conditions, for a total of 3,456 data points.

Fig. 9 presents the histogram of relative sensitivity distribution of downhole receivers obtained as the result of high pressure and temperature tests. The horizontal and vertical axes are sensitivity deviation from the average and quantity of data points in percentage values, after normalizing them respectively by the average and total data points. Relative sensitivity is distributed smoothly with the standard deviation of 1.9%. This number is satisfactory for sonic slowness computation purposes.

In the past, we applied a sensitivity correction or equalization to some downhole tools, compensating for receiver element sensitivity variation. For the newly developed LWD downhole receivers, we do not require a sensitivity correction.

The tool has been characterized in oil wells while drilling and has been proven to deliver a quality multimode waveform recording and a successful slowness inversion [9].

V. CONCLUSIONS

We successfully developed the latest LWD sonic tool that provides formation slowness from the conventional monopole and the newly developed quadrupole measurements, following our acoustic tool development process. One of the key design elements for quality multimode measurements is receiver sensitivity matching. We designed a new receiver array, developed a methodology for evaluating sensitivity matching at high pressure and temperature conditions, and demonstrated good sensitivity matching using more than 500 receiver elements.

ACKNOWLEDGMENT

We thank Fernando Garcia-Osuna, Alain Dumont, and Tetsuya Tanaka, who initiated new sensor designs and provided valuable advice through development cycle.

***Abstract*—There is a need for on-site and real time detection of organophosphate pesticides in aqueous environments. This work proposes the use of polymer coated shear horizontal surface acoustic wave (SH-SAW) sensors as a sensing platform for detection of organophosphate pesticides in aqueous environments. The chemically sensitive polymer coatings BPA-HMTS and BPA-PDMS, synthesized in-house, and the commercially available polymer PECH, were chosen as sensor coatings for organophosphate detection. The polymers are characterized at various thicknesses (0.25µm and 0.50µm) for their selectivity and sensitivity towards parathion, parathion-methyl, and paraoxon. A sensor array is designed for analyte identification and quantification using both steady-state and transient response information. Analyte identification is performed using a visual pattern recognition technique based on radial plots for the analytes at concentrations from 0.5mg/L to 3.0mg/L. It is shown that using the absorption time constant, which is unique to a given analyte-coating pair, in conjunction with steady-state frequency shifts permits direct identification and quantification of organophosphate pesticides in liquid-phase at low-ppm and sub-ppm concentrations.**

Keywords—shear horizontal surface acoustic wave (SH-SAW), liquid-phase detection, organophosphate pesticides, sensor array, pattern recognition, transient response information

I. INTRODUCTION

Hazardous contaminants in groundwater and surface water can have a serious effect on public health. One of the most common types of contaminants is pesticides, including organophosphate pesticides, which are used by the agro-industry due to their potency and effectiveness to kill insects. Although this class of contaminants is highly efficient as pesticides, they can reside in the environment and seep through the soil, and enter groundwater. Because of their solubility in water, they can easily be absorbed into the human body [1, 2]. Organophosphates have toxic effects on the human body, in particular the brain and nervous system [3]. Due to their high toxicity level, the US Environmental Protection Agency banned the use of organophosphates indoors and continues to monitor their output in industrial and agricultural settings. Current means of detection for organic compounds are time consuming, costly, and require samples to be collected and taken to the lab for analysis [4]. This procedure may also be inadequate because of loss of information during transportation. Therefore, there is a critical need for a portable, low cost sensor for on-site, real time detection of organophosphate pesticides in groundwater and surface water.

In this work, an array of polymer coated shear horizontal surface acoustic wave (SH-SAW) devices is used as sensing platform for identification and quantification of organophosphates in water. SH-SAW is the most promising and sensitive type of acoustic waves for liquid-phase sensing [5]. The polymers used as partially chemically selective coatings on the SH-SAW devices are 2,2'-diallylbisphenol A - 1,1,3,3,5,5-hexamethyltrisiloxane (BPA-HMTS), 2,2'-diallylbisphenol A- polydimethylsiloxane (BPA-PDMS), and polyepichlorohydrin (PECH). These polymers were chosen as effective sorbents for the target analytes, with desirable properties including high sensitivity, short response time, as well as reversible and reproducible response [6, 7]. The chemical contaminants tested are organophosphate-based compounds (parathion, parathion-methyl, and paraoxon).

The most important characteristics of a sensor are its sensitivity and selectivity. A chemical sensor array is used to increase selectivity and allow single analyte identification in multicomponent samples. An array of sensors was designed consisting of devices with different coatings and coating thicknesses (0.25µm and 0.50µm) to identify a target analyte and estimate its concentration. The time responses and steady-state frequency shifts were extracted from the response curves and used as input parameters for data processing to achieve both analyte identification and quantification. The analyte identification was performed using visual pattern recognition techniques and analyte quantification was achieved using the same approach as in Ref. 8.

II. EXPERIMENTS

A. Sensor Design

Fig. 1 shows the SH-SAW device used as a sensing platform in this work [9, 10]. This configuration uses a three-layer geometry: the liquid layer, polymer layer, and substrate. The device is fabricated on 36° rotated Y-cut, X-propagating

This work was supported in part by the NSF/IUCRC Program.

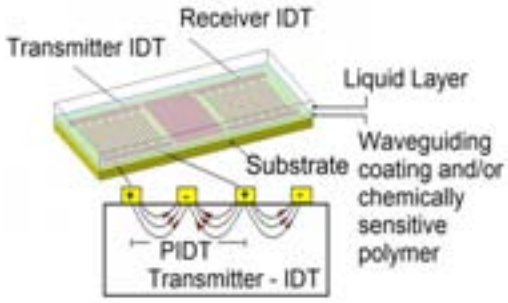

Fig. 1. Three layer acoustic wave sensor geometry

lithium tantalate ($LiTaO_3$) with 10/80nm thick Cr/Au interdigital transducers (IDTs) with a wavelength of 40 μm, giving an operating frequency of 103 MHz. The polymer acts both as a sensing layer and waveguiding layer, trapping the acoustic energy of the SH-SAW to the surface of the device, thus making it more sensitive to surface perturbations. The liquid layer is considered to be a Newtonian fluid and contains the analyte. The particle displacement of a SH-SAW is parallel to the surface and perpendicular to the direction of propagation to avoid acoustic attenuation due to coupling to compressional waves in the adjacent liquid.

B. Materials

Chloroform (99.8%), acetone (99%), methanol (99%), anhydrous toluene (99.8%), 2-propanol, monobasic dihydrogen phosphate, 1,1,3,3,5,5 hexamethyltrisiloxane (HMTS), Platinum(0)-1,3- divinyl-1,1,3,3-tetramethyldisiloxane (Pt-DVTMDS) complex solution in xylene (Pt ~2 %), 2,2'-diallylbisphenol A (BPA), poly(dimethylsiloxane), hydride terminated (PDMS), dibasic monohydrogen phosphate, parathion, parathion-methyl, and paraoxon were purchased from Sigma-Aldrich and used as supplied.

C. Polymer Synthesis

Hybrid organic/inorganic chemically sensitive layers BPA-HMTS and BPA-PDMS were synthesized using a hydrosilyation reaction [6, 7] and making modifications to a procedure reported by Grate et al [7]. BPA is an organic chemical that serves as the functional group for analyte/coating interaction [6]. HMTS and PDMS are inorganic chemicals that provide a porous polymer matrix for rapid analyte absorption [6].

D. Measurement Procedure

Before depositing the film, the devices are first cleaned for 3 min in ultrasonic baths of chloroform, acetone, and 2-propanol, respectively. The devices are then rinsed with Milli-Q de-ionized (DI) water and dried with nitrogen. Afterwards, BPA-HMTS, BPA-PDMS, and PECH solutions were prepared in chloroform and spin coated at using a P6708D spin coater (Specialty Coating Systems) to obtain 0.25 μm and 0.5 μm-thick layers. The coated device was allowed to dry at room temperature 21.7 – 22.5 °C in a dessicator for at least 15 hours. The film thickness was calibrated using an ellipsometer (Gaertner Scientific L2WLSE544). Ellipsometer measurements were performed directly on the sensor device.

A reference solution was created by mixing phosphate buffer solution (PBS) with methanol. Afterwards, a concentrated solution of parathion, parathion-methyl, and paraoxon was prepared and diluted with the reference solution to obtain desired concentrations.

A typical experimental run is started by exposing the coated device to the reference solution at a flow rate of 0.70 mL/min until a stable baseline is obtained. The coated device is then exposed to various analyte concentrations. Between analyte exposures, the sensor response was returned to its initial value by flushing the flow-cell with the reference solution. The differential measurement thus reflects the sensor response due to perturbations caused by only analyte absorption.

III. Data Processing

The response curve (frequency shift) for each sample was modeled using an exponential fit, and the steady-state frequency shift and the response time were extracted [7, 10]. The steady state frequency shift is plotted against analyte concentration and modeled with a linear fit. The slope of the fit represents the sensitivity of the polymer to the analyte. The response times are specific to the polymer/analyte interaction.

For each sample, steady-state frequency shift and response time were extracted for each sensor analyte/coating pair, and the resulting data set was processed using pattern recognition techniques [11]. A sensor array can be created by combining multiple sensors coated with different chemically sensitive polymers on the same wafer. In this case, there are only a limited amount of coatings. Therefore, the coatings available were used at different coating thicknesses (0.25μm and 0.5μm) to provide additional information.

Analyte identification is performed using a visual pattern recognition technique based on radial plots for the analytes, parathion, paraoxon, and parathion-methyl, at concentrations from 0.5mg/L to 3.0mg/L. These specific radial plots are made using the steady-state frequency shifts and time responses of BPA-HMTS, BPA-PDMS, and PECH at a thickness of 0.5μm as the axes, providing a total of six parameters for analyte recognition.

Once the analyte is identified, a level-of-confidence algorithm is calculated to estimate the concentration of an unknown sample by quantifying the similarity between known response patterns and the response pattern of the unknown sample [11]. First, the distance in the six-dimensional space of sensor response parameters is calculated between the known sample and the unknown sample using

$$d(\bar{y},\bar{z}) = \left[\sum_{j=1}^{3}(y_j - z_j)^2\right]^{1/2} \quad (1)$$

If the unknown sample shows a response pattern similar to that of the known sample, the distance between the two samples should be minimal. The certainty of the unknown pattern being identical to the known pattern can be quantified by a level of confidence parameter [11]

$$C_i = \frac{1}{d(\bar{y},\bar{z_i})} \quad (2)$$

The level of confidence is normalized and defined between the values of 0 and 1, corresponding to least certain and most certain, respectively.

IV. Results and Discussion

Fig. 2 shows an example of the frequency response when BPA-HMTS 0.5µm is exposed to various concentrations of parathion-methyl. Data were collected for all three polymers at both thicknesses, exposed to all three analytes. The sensitivities were calculated and recorded in Table I, and the following trends can be observed. The order in the sensitivities of the polymers to the analytes (from highest to lowest) is BPA-HMTS, BPA-PDMS, and PECH; for the analytes, the order is parathion, parathion-methyl, and paraoxon, respectively. In Table I, the sensitivities for PECH follow the (inverse) trend of analytes solubilities [7] as expected. However, for BPA-HMTS, parathion-methyl and paraoxon give similar sensitivities despite their very different solubilities [7]. This can be attributed to the hydrogen-bond interaction between paraoxon and BPA [7]. Such specific interactions between a coating and certain analytes will strongly contribute to the selectivity of the sensor array.

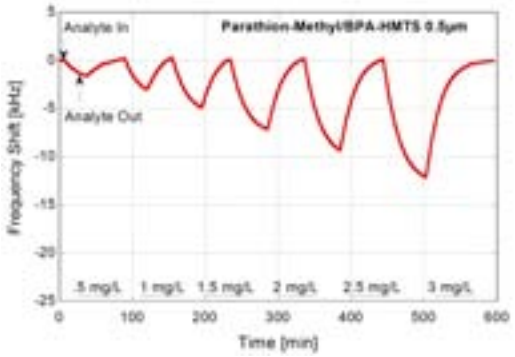

Fig. 2. Measured change in frequency shift upon exposure of the BPA-HMTS 0.5µm coated device to the indicated concentartions of parathion-methyl.

TABLE I. The sensitivities for 0.25µm and 0.5µm thick BPA-HMTS, BPA-PDMS, and PECH when exposed to parathion, parathion-methyl, and paraoxon.

	Sensitivity $\left({}^{kHz}/_{mg/L}\right)$					
polymer / analyte	*BPA-HMTS 0.25µm*	*BPA-PDMS 0.25µm*	*PECH 0.25µm*	*BPA-HMTS 0.5µm*	*BPA-PDMS 0.5µm*	*PECH 0.5µm*
parathion	2.449	1.073	1.491	20.791	9.002	9.093
parathion-methyl	0.572	0.196	0.512	4.246	0.725	2.278
paraoxon	0.450	0.049	0.026	4.413	0.489	0.175

Fig. 3 shows the radial plots for detection of paraoxon at concentrations of 0.5mg/L, 1.0mg/L, 1.5mg/L and 2.0mg/L. The six axes in each plot are the steady state frequency shifts and time responses of BPA-HMTS, BPA-PDMS, and PECH at 0.5µm thickness to paraoxon. When evaluating Fig. 3 it is possible to see the distinct arrow shape pattern with the arrow's point positioned on the BPA-HMTS 0.5µm time response axis. Minor fluctuations in the lower concentration range are due to the error in manually prepared analyte samples. This pattern is specific to paraoxon and it was observed that parathion and parathion-methyl have their own distinct patterns. It is

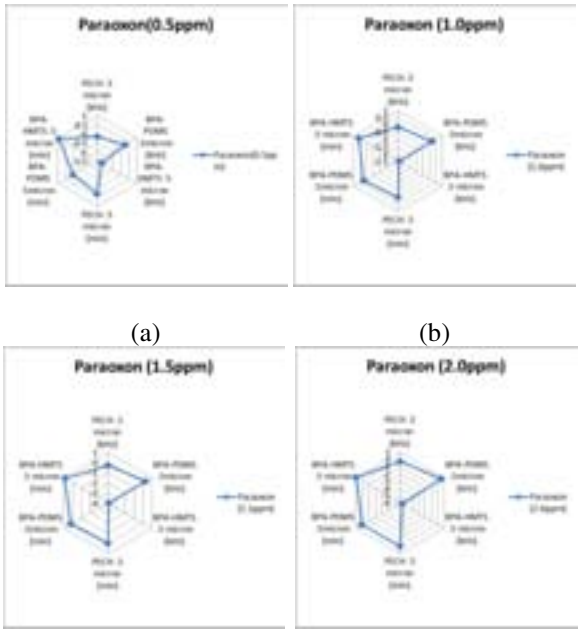

Fig. 3. Radial plots showing the detection of paraoxon at concentrations of (a) 0.5mg/L, (b) 1.0mg/L, (c) 1.5mg/L, and(d) 2.0mg/L using BPA-HMTS, BPA-PDMS, and PECH at a thickness of 0.5µm in an array. The frequency shift and time response serve as the input parameters.

demonstrated that single analyte identification is possible within the above concentration range using this approach.

Fig. 4 shows the level of confidence for the measured test sample 2. It is apparent that the level of confidence for the test sample is maximum for 2.0mg/L of paraoxon, in agreement with its actual concentration and type of analyte. Fig. 5 shows the level of confidence for test sample 5 whose concentration was not measured and recorded within the test database. It was noted that the highest levels of confidence for the latter test sample were found for 1.5mg/L and 2.0mg/L, giving identical level-of-confidence values for these concentrations, thus correctly identifying the test sample as 1.75mg/L of parathion. The accuracy can be improved if more information is added to the data set. Additional tests were conducted, and in all cases the sample analyte concentrations were successfully quantified.

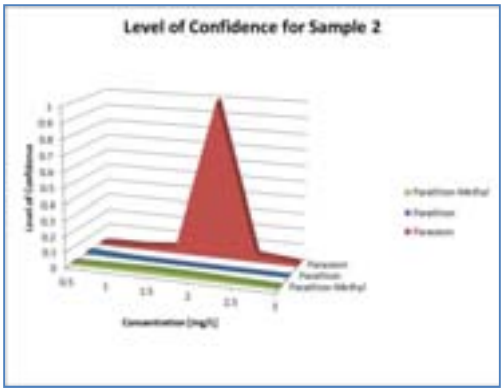

Fig. 4 The level of confidence for test sample 2, points towards 2.0mg/L of paraoxon as predicted by a pattern recognition technique based on an algorithm which computes the distance between the test sample and the known patterns in the 6-dimensional response data space.

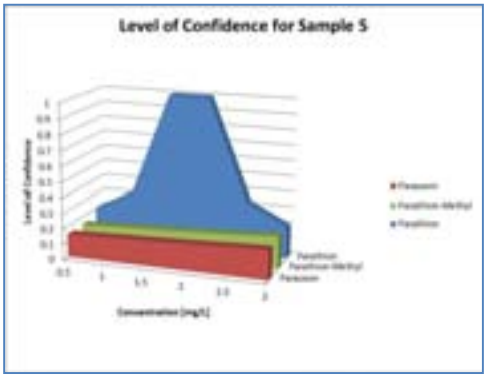

Fig. 5. The level of confidence for test sample 5, points towards 1.75mg/L of parathion as predicted by a pattern recognition technique based on an algorithm which computes the distance between the test sample and the knownpatterns in the 6-dimensional response data space.

V. Conclusion

A chemical sensor array has been designed, using the partially selective coatings BPA-HMTS, BPA-PDMS, and PECH, for the successful rapid identification and quantification of organophosphates in aqueous solutions. These coatings, exhibited very different sensitivity levels, with parathion generally giving the highest sensitivity and paraoxon the lowest. This trend largely reflects the different solubilities of the analytes in water. However, despite the very different solubilities of the analytes parathion-methyl and paraoxon, their sensitivities are very similar for the coatings containing BPA. This is due to the strong hydrogen bond that occurs between the oxygen atom from the paraoxon with the hydroxide groups in BPA, while the sulfur atom in parathion and parathion-methyl does not show particularly strong interaction with BPA.

The polymers at a thickness of 0.5µm exhibited a higher sensitivity and therefore were chosen over the 0.25µm-thick polymers for the radial plots and level of confidence algorithm. The radial plots successfully indicated three different patterns for the three analytes and the level of confidence algorithm successfully estimated the concentrations of measured test samples (e.g. 2.0mg/L of paraoxon) and extrapolated response patterns for sample concentrations that were not included in the pattern recognition design database (e.g. 1.75mg/L of parathion).

These findings have important implications for the in-situ, real-time detection of organophosphate pesticides in groundwater. The described chemical sensor array can form the basis for a sensor system for the monitoring of groundwater and surface water for harmful chemicals and thus make a significant contribution to the protection of public health.

***Abstract*—The resonant characteristics of laterally vibrating rectangular hammerhead microcantilevers in viscous liquid media are investigated. The rectangular hammerhead microcantilever is modeled as an Euler-Bernoulli beam (stem) and a rigid body (head). A modified semi-analytical expression for the hydrodynamic function in terms of the Reynolds number, *Re*, and aspect ratio, *h*/*b*, is proposed to rapidly evaluate the sensing characteristics. Using this expression, the resonance frequency, quality factor and normalized surface mass sensitivity are investigated as a function of the dimensions of the microcantilever and liquid properties. Guidelines for design of hammerhead microcantilever geometry are proposed to achieve efficient sensing platforms for liquid-phase operation. The improvement in the sensing area and characteristics are expected to yield higher sensitivity of detection and improved signal-to-noise ratio in liquid-phase chemical sensing applications.**

I. Introduction

Dynamically driven rectangular prismatic microcantilevers excited in the in-plane direction have been investigated and used in liquid-phase sensing applications due to their relatively high frequency stability and mass sensitivity [1-2]. However, in bio-chemical sensing applications, the performance of rectangular prismatic microcantilever-based sensors is restricted due to their limited surface sensing area. Thus, to increase the surface sensing area and improve sensing characteristics, it is proposed to investigate rectangular hammerhead microcantilevers driven in the in-plane flexural vibration mode in viscous liquid media.

For a rectangular hammerhead microcantilever laterally vibrating in a vacuum, the resonance frequency has been obtained in a close-form analytical expression by assuming the head as a point mass at the tip of the stem [3-4]. However, when the vibrating microcantilevers are immersed in viscous liquids, the liquid will impose hydrodynamic forces on the stem and head, which are not accounted for. Thus, it is no longer appropriate to model the head as a point mass. In this work, the stem and head are modeled as an Euler-Bernoulli beam and a rigid body, respectively. As a result, both translational and rotational motions of the head must be taken into account. In viscous liquids, the hydrodynamic forces exerted on the stem and head must be evaluated separately due to the difference in dimensions. Since the cross-section of either part is still rectangular, the semi-analytical expression for the hydrodynamic function in [1] can still be applied. However, in Ref. 1, the discrepancy between analytical and numerical results is relatively large for small thicknesses and high *Re*. As a result, it is necessary to obtain a new analytical expression for the hydrodynamic function to accurately determine the sensing characteristics.

In this work, a theoretical model of laterally vibrating rectangular hammerhead microcantilevers in viscous liquids is presented. A modified semi-analytical expression for the hydrodynamic function in terms of *Re* and *h*/*b* is proposed and compared with the numerical results. The sensing characteristics are investigated as a function of the geometrical parameters of the rectangular hammerhead microcantilevers and liquid properties, and compared with those of the rectangular prismatic beams. Guidelines for the design of hammerhead microcantilevers for sensor applications are proposed.

II. Theoretical Analysis

A. Equation of Motion

The geometry of a rectangular hammerhead microcantilever, with dimensions on the order of microns, is shown in Fig. 1. To model the stem as an Euler-Bernoulli beam, it is generally assumed that its length is much larger than its width (L_1>>b_1). The equation of motion for a laterally vibrating stem in viscous liquids is given by

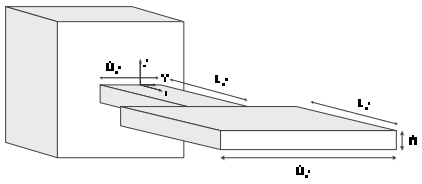

Figure 1: A rectangular hammerhead microcantilever with length and width of the stem being L_1, b_1, respectively; length and width of the head being L_2, b_2, respectively and thickness being h.

This work is supported in part by NSF Grant No. ECCS-1128992 and NSF Grant No. ECCS-1128554.

$$EI_{stem}\frac{\partial^4 v_{stem}(x,t)}{\partial x^4}+\rho_b b_1 h\frac{\partial^2 v_{stem}(x,t)}{\partial t^2}=F_{stem,liquid}(x,t), \quad (1)$$

where E is the Young's modulus, I_{stem} the second moment of area of the cross-section of the stem, ρ_{b} the mass density of the microcantilever; v_{stem} is the displacement in the y-direction. The hydrodynamic force on the stem, $F_{stem.liquid}$, is force per unit length, and is given by

$$F_{stem,liquid}(x,t)=-g_{1,stem}\frac{\partial v_{stem}(x,t)}{\partial t}-g_{2,stem}\frac{\partial^2 v_{stem}(x,t)}{\partial t^2}, \quad (2)$$

In equation (2), $g_{1,stem}$ and $g_{2,stem}$ are coefficients associated with the viscous damping and the effective mass coming from the liquid, respectively [1].

B. Boundary Conditions

In order to solve equation (1), four boundary conditions are needed. Two boundary conditions are defined at the fixed end. One of them states that the stem is perfectly fixed at the support end, and is given by

$$v_{stem}(0,t)=0 \quad , \quad (3)$$

The exciting force is assumed and modeled by an equivalent, harmonic support rotation [5]. The bending slope at the support end of the hammerhead microcantilever is given by

$$\frac{\partial v_{stem}(x,t)}{\partial x}\Big|_{x=0}=\theta_0 e^{j\omega t} \quad , \quad (4)$$

In equation (4), θ_0 and ω are the amplitude and angular frequency of the effective support rotation. The remaining two boundary conditions represent the moment and force balances at the junction between the stem and head (x=L_1). The width of the head is assumed to be much larger than that of the stem, i.e., b_2>>b_1. Thus, the head is modeled as a rigid body, and translational motion and rotational motion of the head are taken into account. In viscous liquids, the inertial and damping forces contribute in the moment and force balance equations, which are given by

$$\sum M_{moment}\Big|_{x=L_1}=0, \quad (5)$$

$$\sum S_{force}\Big|_{x=L_1}=0. \quad (6)$$

C. Hydrodynamic Function

The hydrodynamic function (Γ= Γ_R+jΓ_I) is defined as a normalized hydrodynamic force per unit length [1]. It consists of two components: the viscous damping force, which is associated with Γ_I, and the inertial force, which is associated with Γ_R:

$$g_1\left[\mathrm{Re}(x),h/b(x)\right]=\frac{\pi}{4}\rho_f b^2(x)\Gamma_I\left[\mathrm{Re}(x),h/b(x)\right]\omega, \quad (7)$$

$$g_2\left[\mathrm{Re}(x),h/b(x)\right]=\frac{\pi}{4}\rho_f b^2(x)\Gamma_R\left[\mathrm{Re}(x),h/b(x)\right], \quad (8)$$

Modified analytical expressions for Γ_R and Γ_I are developed to minimize the discrepancy between numerical and analytical results. The mathematical forms of Γ_R and Γ_I are proposed as shown in equation (9a-b).

$$\Gamma_R\left(\mathrm{Re},\frac{h}{b}\right)=\Gamma_{R1}(\mathrm{Re})\Gamma_{R2}\left(\frac{h}{b}\right), \quad (9a)$$

$$\Gamma_I\left(\mathrm{Re},\frac{h}{b}\right)=\Gamma_{I1}(\mathrm{Re})\Gamma_{I2}\left(\frac{h}{b}\right), \quad (9b)$$

In equation (9a-b), $\Gamma_{R1}(Re)$ are $\Gamma_{I1}(Re)$ are expected to depend on the boundary layer thickness, and are functions of $Re^{-0.5}$ [6]. $\Gamma_{R2}(h/b)$ and $\Gamma_{I2}(h/b)$ can be expanded into a summation of multiple h/b terms (similar to Taylor series expansion). The proposed real and imaginary parts of the hydrodynamic function are as follows:

$$\Gamma_R\left(\mathrm{Re},\frac{h}{b}\right)=\left[\frac{1}{\sqrt{\mathrm{Re}}}\sum_{m=0}^{m_{\max}}C_m\left(\frac{h}{b}\right)^{\frac{m}{2}}\right]+\left[\sum_{n=0}^{n_{\max}}D_n\left(\frac{h}{b}\right)^{\frac{n}{2}}\right] \quad (10a)$$

$$\Gamma_I\left(\mathrm{Re},\frac{h}{b}\right)=\left[\frac{1}{\mathrm{Re}}\sum_{p=0}^{p_{\max}}E_p\left(\frac{h}{b}\right)^{\frac{p}{2}}\right]+\left[\frac{1}{\sqrt{\mathrm{Re}}}\sum_{q=0}^{q_{\max}}F_q\left(\frac{h}{b}\right)^{\frac{q}{2}}\right] \quad (10b)$$

Using the surface fitting tool in Matlab, each coefficient and power index in equation (10a-b) is determined simultaneously to obtain the optimum fitting results. The coefficients (C_m, D_n, E_p, F_q) and power indices (m_{max}, n_{max}, p_{max}, q_{max}) are determined to minimize the differences between the numerical data and the proposed analytical expression. The power indices and coefficients are determined as m_{max}=2, n_{max}=4, p_{max}=1, q_{max}=4, C_0=0.9003, C_1=0.6105, C_2=2.1722, D_0=0, D_1= -0.0021, D_2= -0.1459, D_3=0.8255, D_4= -1.3388, E_0=2.5758, E_1= -1.3388, F_0=0.9003, F_1= -0.7121, F_2=1.6845, F_3=0.8236 and F_4=0.4178.

D. Frequency Response

Based on the boundary conditions, the equation of motion can be solved and the normalized frequency response at the tip of the stem is obtained as

$$\left|\frac{X(L_1)}{L_1\theta_0}\right|= \left|\frac{A_1(\cosh KL_1-\cos KL_1)+A_2(\sinh KL_1-\sin KL_1)+\frac{\theta_0}{K}\sin KL_1}{L_1\theta_0}\right|. \quad (11)$$

In equation (11), K, A_1 and A_2 are functions of the properties of the hammerhead microcantilever and surrounding liquid medium. A_1 and A_2 also depend on θ_0. Using equation (11), the resonance frequency and quality factor can be extracted from the frequency spectrum.

III. RESULTS AND DISCUSSIONS

A. Results of the Semi-analytical Expression

Real and imaginary parts of the hydrodynamic function obtained analytically and numerically are compared. The ranges of the percent differences between the analytical and numerical results of the real and imaginary parts are [-3.8%,

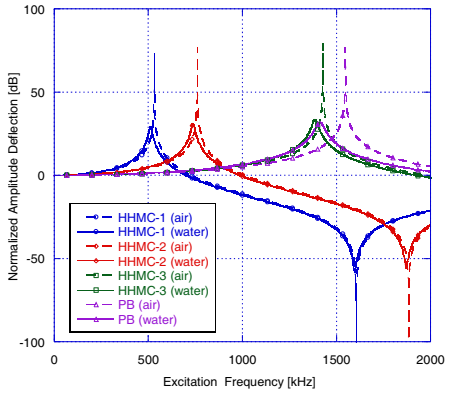

Figure 2: Calculated frequency spectra of three hammerhead microcantilevers (HHMC) of dimensions [(200×45×12) + (50×200×12)] µm^3 (HHMC-1), [(150×45×12) + (50×200×12)] µm^3 (HHMC-2), [(200×90×12) + (50×200×12)] µm^3 (HHMC-3) and a rectangular prismatic beam (PB) of dimensions (200×45×12) µm^3 laterally vibrating in air and water.

6.1%] and [-2.0%, 2.8%], respectively, for Re ~ [10, 10000] and h/b ~ [1/56, 1].

B. *Frequency Spectrum*

Using equation (11), the simulated frequency spectra of four microcantilevers of different dimensions vibrating laterally are shown in Fig. 2. For the investigated geometries, the resonance frequency is highest for the prismatic rectangular beam, because no additional mass is attached at the end of the beam. Percent change of the resonance frequency from air to water for the prismatic beam, 8.8%, is larger than those of rectangular hammerhead microcantilevers, 1.8%~4.9%. It is also found that the 3-dB bandwidths for the hammerhead microcantilevers are narrower than that of the prismatic beam.

C. *Resonance Frequency*

The resonance frequency is investigated as a function of liquid properties and dimensions of the rectangular hammerhead microcantilevers. Fig. 3 (top) shows the resonance frequency as a function of glycerol concentration in water. As viscosity increases, the resonance frequency will decrease. Fig. 3 (bottom) shows the resonance frequency with respect to length (L_2) and width (b_2) of the head for three different stems at a thickness of 12µm. As the length or width of the head increases, the resonance frequency decreases for hammerhead microcantilevers, and it is due to the increase in the mass of the head. For hammerhead microcantilevers with stiffer stems (smaller L_1/b_1), the resonance frequency is higher.

D. *Quality Factor*

The quality factor is investigated as a function of liquid properties and dimensions of the rectangular hammerhead microcantilever. Fig. 4 (top) shows the quality factor as a function of glycerol concentration in water. As viscosity increases, the quality factor will decrease. Fig. 4 (bottom) shows the quality factor with respect to the length (L_2) and width (b_2) of the head for three different stems at a thickness of 12µm. As the length of the head increases, the quality factor decreases (because the increase in damping exceeds the increase in mechanical energy), and the mass center of the head moves away from the tip of the stem. As the width of the head increases, for shorter heads, the quality factor increases because the increase in mechanical energy exceeds the increase in damping. Note that the distance between the mass center of the head and the tip of the stem remains fixed at $L_1+L_2/2$.

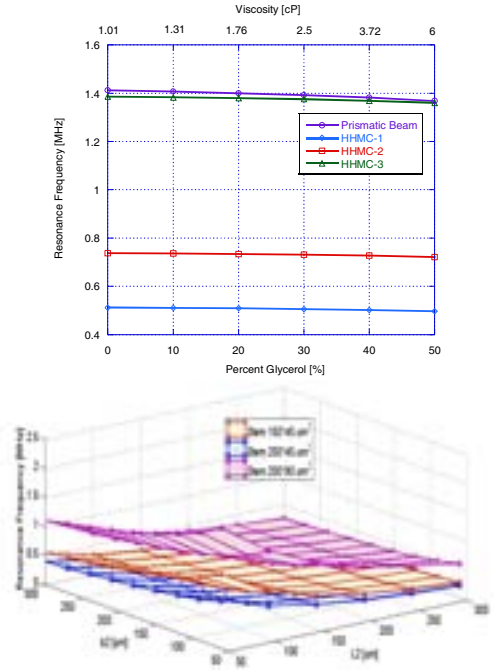

Figure 3: Calculated resonance frequency as a functions of glycerol concentration in water (top: microcantilever dimensions as in Fig. 2) and of the dimensions of the head (bottom).

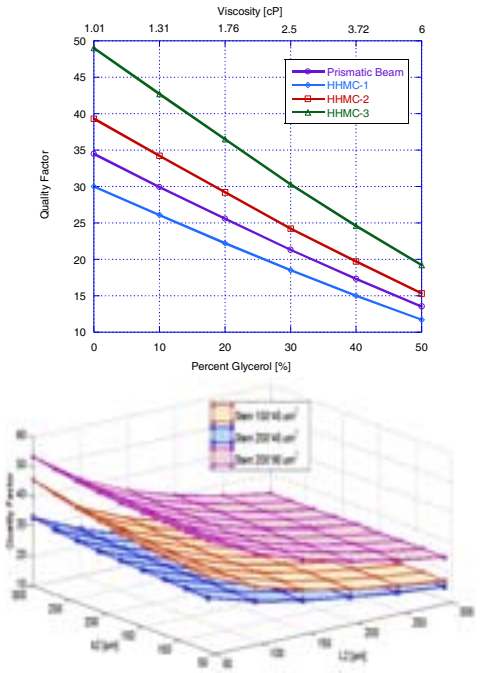

Figure 4: Calculated quality factor as a functions of glycerol concentration in water (top: microcantilever dimensions as in Fig. 2) and of the dimensions of the head (bottom).

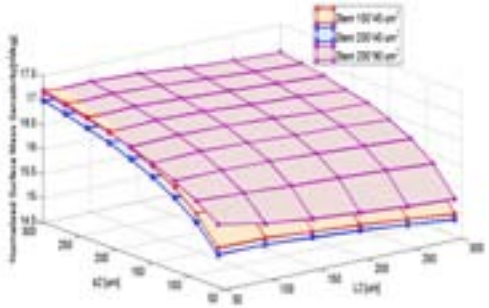

Figure 5: Calculated normalized surface mass sensitivity as a function of the dimensions of the head.

E. Normalized Surface Mass Sensitivity

Normalized surface mass sensitivity is defined and used for comparison between the microcantilevers with different resonance frequency and surface sensing area, and is given by

$$S_n = \frac{\Delta f_{res} / f_{res}}{\Delta m / A}. \qquad (12)$$

In equation (12), Δf_{res} is the shift of the resonance frequency due to added mass, Δm (sorption of target molecules), on the microcantilever surface; A is the surface sensing area of the microcantilever. It is assumed that Δm is dominated by the change in the effective density.

The normalized surface mass sensitivity, S_n, is investigated as a function of the dimensions of the rectangular hammerhead microcantilever. Fig. 5 shows S_n as a function of the length (L_2) and width (b_2) of the head for three different stems at a thickness of 12μm. As the width of the head increases, S_n increases, because the decrease in Δf_{res} is smaller than that of the resonance frequency.

F. Comparison between the Prismatic Beam and Hammerhead Microcantilever

The sensing characteristics of rectangular and prismatic microcantilevers are analyzed and compared in Table I. It is found that the decrease in the resonance frequency from air to water is smaller for the hammerhead microcantilevers. It indicates that a laterally vibrating hammerhead microcantilever will have high chemical sensitivity in both air and viscous liquids. The resonance frequency and quality factor of prismatic beams are larger than those of the hammerhead microcantilevers with the dimensions of the stem being identical to those of the prismatic beams. Although the resonance frequency for a hammerhead microcantilever of dimensions $L_1 \times b_1 \times h + L_2 \times b_2 \times h$ with a wider and shorter head is lower compared to a prismatic beam of dimensions $(L_1+L_2) \times b_1 \times h$, the quality factor for the hammerhead microcantilever is higher. It indicates that a microcantilever with a lower resonance frequency may yield higher quality factor due to geometrical effects.

TABLE I. SENSOR CHARACTERISTICS PREDICTED FOR TWO PRISMATIC BEAMS AND THREE HAMMERHEAD MICROCANTILEVERS

Geometry $[\mu m^3]$	f_{air} [MHz]	f_{water} [MHz]	**Percent Change**	Q_{water}	$S_{n,water}$ [$\mu m^2/ng$]
200×45×12	1.548	1.412	8.8%	36	14.9
200×90×12	3.095	2.944	4.9%	59	15.8
200×90×12+ 50×200×12	1.428	1.386	2.9%	49	15.5
150×45×12+ 50×200×12	0.761	0.738	3.0%	40	16.8
150×45×12+ 50×300×12	0.564	0.554	1.8%	46	17.2

IV. CONCLUSIONS

The sensing characteristics of laterally vibrating rectangular hammerhead microcantilevers in a viscous liquid were analyzed in terms of the microcantilever geometry and the properties of the liquid and compared to those of laterally vibrating prismatic beams. A modified analytical expression for the hydrodynamic function was presented for the purpose of rapid evaluation of the sensing characteristics.

For the range of dimensions investigated, if only the length of the head increases, the mass center of the head will move away from the tip of the stem and the resonance frequency and quality factor will decrease due to the increase in the mass attached at the end of the stem. In contrast, if only the width of the head increases, the mass center of the head will not move and the resonance frequency will decrease, but the normalized surface mass sensitivity will increase; the quality factor will increase rapidly for shorter heads. This is because the increase in mechanical energy exceeds the increase in damping. Such trends can be used to optimize device geometry and maximize the frequency stability in sensing applications. In general, to obtain an efficient hammerhead microcantilever-based sensor platform, the stem of the microcantilever can be designed stiffer and the head can be made wider and shorter. For appropriately designed hammerhead microcantilevers, the improvement in the sensing area and quality factor are expected to yield much lower limits of detection in (bio) chemical sensing applications.

***Abstract*—To address the need to protect public health from contamination of drinking water and water for recreational use, a compact sensor system for in-situ detection of fuel and oil components in water is being investigated. The system makes use of shear-horizontal surface acoustic wave (SH-SAW) sensors coated with thin chemically sensitive polymer films. For this work, the BTEX compounds (benzene, toluene, ethylbenzene, and xylenes) were selected as target analytes because they are good indicators of fuel and oil releases, but also because they include known carcinogens (benzene, ethylbenzene). Chemical selectivity is achieved by combining sensors with various polymer coatings into a sensor array, and by evaluating both steady-state and transient response information. This work focuses on the influence of interdigital transducer (IDT) design on signal distortion and rms (root-mean-square) noise level. It is demonstrated that for suitable IDT design and experimental approach, it is possible to detect all BTEX compounds at concentration levels of 100 ppb or below, and to quantify benzene concentration in binary analyte mixtures at concentrations well below 1 ppm.**

Keywords—groundwater, surface acoustic wave sensors, liquid-phase sensing, benzene, rms noise level, multi-electrode interdigital transducer design

I. INTRODUCTION

The processing, storage and transport of fuel and oil are often associated with potential environmental hazards. In particular, places where large amounts of fuel or oil are stored, such as gas stations, present significant potential threats to public health through unintentional releases into groundwater and surface water [1]–[4]. Timely detection of such releases can minimize the impact on public health and reduce clean-up costs. However, current monitoring practice is largely based on collection of samples in the field, transport and subsequent analysis in the laboratory [3], procedures which can become very time-consuming for high monitoring frequencies. To enable frequent or continuous, *in-situ* monitoring of groundwater and surface water at critical sites, a number of suitable sensor systems are under development [5].

Sensor systems based on SH-SAW (shear-horizontal surface acoustic wave) sensor platforms represent a promising approach for this application. SH-SAWs combine the advantages of high surface confinement of the acoustic energy (which facilitates high sensitivity to the analyte) and the ability to propagate along a solid-liquid interface without suffering excessive acoustic wave attenuation [6]. In our previous studies, the performance of the sensors and various coating materials was investigated under varying environmental conditions, including changes in temperature, acidity, and salinity [7]. It was demonstrated that by evaluating both steady-state and transient response information, this type of sensor can be used to quantify the concentration of benzene in binary analyte mixtures in the low ppm concentration range [8].

The BTEX compounds (benzene, toluene, ethylbenzene, and xylenes) were selected as target analytes for this study because they are good indicators of fuel and oil releases [3], [4], [9], but also because they include known carcinogens (benzene, ethylbenzene) [10]. Due to their hazard potential for public health, legal concentration limits for the BTEX compounds in drinking water are low, with MCL (maximum contaminant level) values in the US ranging from 5 ppb (µg/L) to 10 ppm (mg/L) [5], [11]. Detection of these contaminants at ppb levels is a challenging task, especially if the concentration of one BTEX compound has to be quantified in the presence of similar aromatic compounds.

The BTEX detection challenge is addressed in our work by evaluating both the steady-state frequency shift and the time-dependent behavior of the sensor response. We investigated various polymer materials (≤ 1 µm thick) as sensor coatings based on their partial selectivities for the analytes of interest [8]. In order to achieve detection limits for BTEX compounds in the ppb range, every aspect of the sensor design has to be evaluated for its potential to minimize rms (root-mean-square) noise and signal distortion. For this study, 36°-rotated YX-$LiTaO_3$ was selected as piezoelectric substrate because of its high dielectric constants [12], permitting immersion of the entire device surface—including the polymer-coated interdigital transducers (IDTs)—in water, thus obviating the need for a gasket on the acoustic delay line, which could lead to signal distortion. $LiTaO_3$ also has high piezoelectric constants [12], restricting the number of electrode fingers per

IDT if overcoupling (and consequent signal distortion) is to be avoided. One solution would be to use a wideband IDT, but this could lead to overlap between the SH-SAW and neighboring bulk modes with further adverse consequences for signal distortion. Therefore, another approach is investigated here, based on the use of multi-electrode IDTs [13]. In this way, overcoupling can be avoided by placing many electrode fingers in antiphase with the acoustic wave. It is demonstrated that a suitable multi-electrode IDT design leads not only to better bulk mode suppression and lower phase distortion, but also has a beneficial effect on rms noise, resulting in lower detection limits and higher accuracy in analyte quantification in binary mixtures. In addition, multi-electrode IDTs can be designed to generate multiple SH-SAWs at different frequencies in a single delay line, permitting investigation of frequency-dependent contributions in sensor responses.

II. Experimental

The first of the SH-SAW sensor platforms used in this work has been described previously [14], [15]. The sorbent polymers selected as sensor coatings are poly(ethyl acrylate) (PEA), poly(epichlorohydrin) (PECH), and poly(isobutylene) (PIB) (all from Sigma-Aldrich). Sorbent polymers were deposited from solution by spin coating and baked for 15 min at 55 °C, resulting in thicknesses ranging from 0.55 to 1.0 µm as indicated below. All sensor platforms utilize a dual-delay-line design, with the second line coated with poly(methyl methacrylate) (Scientific Polymer Products) and baked for 120 min at 180 °C, resulting in a glassy, non-sorbent coating. The purpose of this reference line is to compensate for the influence of temperature drifts and other secondary effects. All BTEX analytes had purities of 98.5% or higher.

The experimental set-up used a network analyzer (Agilent E5061B; the 16-fold data averaging function was activated) and a switch/control system (Agilent 34980A) to switch between the two SH-SAW delay lines. The sensor was placed inside a flow cell made in-house, and the peristaltic pump (Ismatec Reglo Digital MS-CA4/12-100) was set to a sample flow rate of 7 µL/s. Switching between different samples was accomplished without interruption of sample flow in order to avoid any resulting signal distortions. The flow cell and samples were set up inside a box, simulating an environment similar to a groundwater monitoring well, and measurements were conducted at room temperature (22.0 ± 0.1 °C). All data shown are corrected for linear baseline drift.

III. Results and Discussion

In previous studies, a 103-MHz SH-SAW sensor device has successfully been used to detect BTEX compounds in the ppm concentration range [7], [8], [14], [15]. This device used an IDT pattern with four electrode fingers per electrical period (S_e = 4), schematically illustrated in the inset of Fig. 1a. Two versions of this device were fabricated which differed in their bandwidths; one used an IDT length of 29 electrical periods (L_{IDT} = 29P), the other design used L_{IDT} = 44P. While the former shows relatively low phase distortion and good bulk mode and sidelobe rejection, the large bandwidth leads to larger overlap between the SH-SAW and adjacent bulk modes and results in a significant asymmetry of the SH-SAW passband. The latter design has a lower bandwidth, but the larger number of electrode fingers leads to stronger acoustic wave reflections and phase distortions, and the coupling of unwanted bulk modes is also enhanced. The mode spectrum of the L_{IDT} = 44P design is shown in Fig. 1a for a polymer-coated device. The highest peak (at 103 MHz) is the SH-SAW; it is followed by a series of bulk modes.

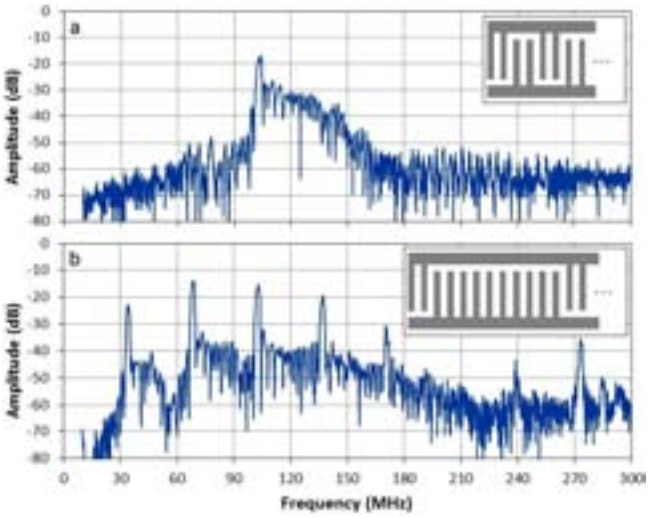

Fig. 1: Mode spectra (in air) for SH-SAW sensors with S_e = 4 (a) and S_e = 12 (b). Sensors were coated with 0.5 µm PMMA. Insets are schematics of the IDT electrode patterns (only part of the IDT is shown).

A solution of the above dilemma is offered by multi-electrode IDT designs [13] where a number of the electrode fingers are deliberately placed in anti-phase with the acoustic wave in order to reduce overall mode coupling. This allows the combination of a narrow IDT bandwidth with low bulk mode coupling and modest acoustic reflections. As an example, Fig. 1b shows the mode spectrum and IDT pattern for a SH-SAW device with S_e = 12. In this case, a series of SH-SAW modes is obtained with frequencies which are multiples of 34 MHz. This IDT design also leads to a lower wave reflection and better triple-transit echo suppression, a more symmetrical passband, and lower phase distortion. The latter is illustrated in Fig. 2.

While the relationship between phase linearity and rms noise level is not a straightforward one, it was experimentally observed that the IDT design giving the lowest phase distortion also gave the lowest rms noise level. This is shown in Fig. 3.

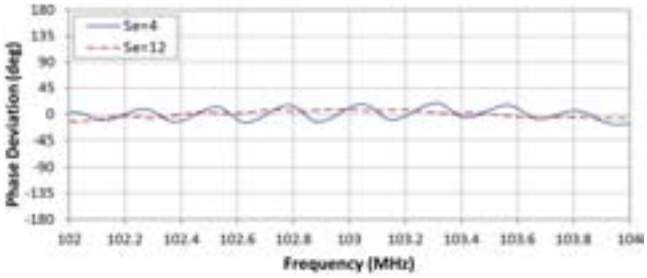

Fig. 2: Phase deviation (from linear phase) for SH-SAW sensors with S_e = 4 (—) and S_e = 12 (- -). Sensors were coated with 0.5 µm PMMA and immersed in water.

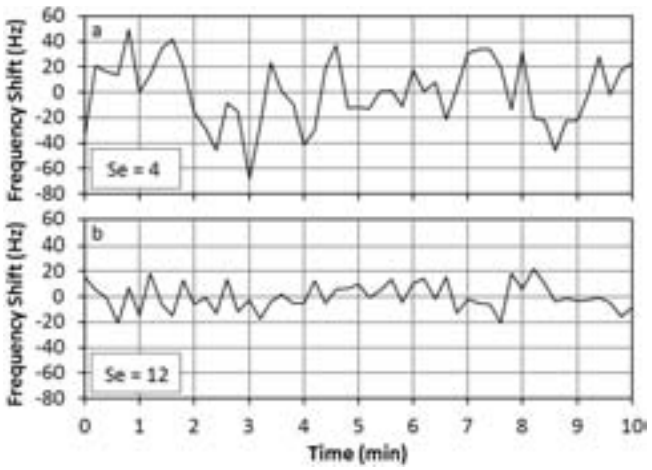

Fig. 3: Baseline noise levels for the 103-MHz SH-SAW mode for devices with S_e = 4 (a) and S_e = 12 (b). Sensors were coated with 1.0 µm PEA and immersed in water (flow rate: 7 µL/s).

For the S_e = 4 IDT design, a rms noise level of 25.9 Hz was calculated for a 1.0 µm PEA coating and the same flow rate used in BTEX detection. (Note that such a relatively thick coating of a rubbery polymer will slightly increase the rms noise level but also will enhance the quantity of BTEX sorbed). For the S_e = 12 IDT design, under the same conditions an rms noise level of only 10.7 Hz was found. For a 0.6 µm PECH coating and S_e = 12 IDT design, the rms noise level was further reduced to 7.1 Hz (data not shown).

In order to evaluate the performance of the improved SH-SAW sensor devices in BTEX detection, measurements were conducted on detection of single analytes and binary analyte mixtures in the concentration range of 100 ppb to 1 ppm. Sample data are shown in Fig. 4; it clearly demonstrates that benzene can be detected at a concentration as low as 200 ppb. From these measurements, the detection limits listed in Table I have been calculated using the relation: detection limit = 3 × rms noise / sensitivity. Note that xylene and ethylbenzene are chemical isomers and thus will give nearly identical sensitivities; therefore, only ethylbenzene is listed. As expected, the detection limits approximately follow the trend in analyte solubilities. In all cases, analytes can be detected at less than 10^{-4} of their saturation concentration in water.

Fig. 4 also shows several responses to binary mixtures. Assuming the sensor responses to multiple analytes in a sample

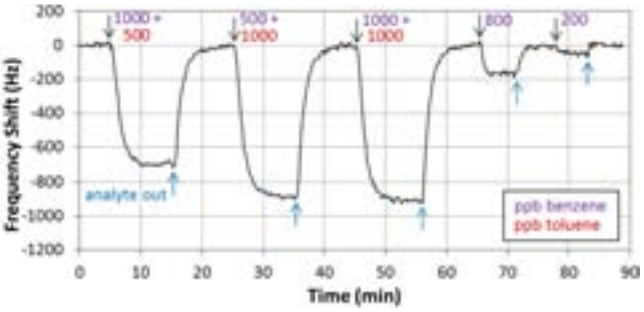

Fig. 4: Response of a SH-SAW device (103-MHz mode) with S_e = 4 and a 0.6 µm PECH coating to various benzene samples and binary mixtures. Analyte concentrations are given in the graph.

TABLE I. EXPERIMENTALLY DETERMINED DETECTION LIMITS (3 × RMS NOISE LEVEL / SENSITIVITY) FOR SH-SAW SENSORS WITH S_E = 12 FOR SIX COATING/ANALYTE COMBINATIONS.

Analyte	Solubility (ppm) [16]	Detection Limit (ppb)	
		1.0 µm PEA	*0.6 µm PECH*
Benzene	1780	100	100
Toluene	531	35	33
Ethylbenzene	161	11	9

are additive in the concentration ranges investigated [8] and that the transient response to a step change in analyte concentration is approximately exponential with time, the response to a binary mixture can be modeled using a dual-exponential fit, whereby the response times and sensitivities for the two analytes in the mixture can be taken from single-analyte measurements. This allows an estimation of the concentrations of two analytes in a mixture using a single sensor device simply by evaluating the transient response information. As an example, for the responses to binary mixtures in Fig. 4, analyte concentrations estimated using dual-exponential fits of the measured data are presented in Table II and compared to nominal (actual) concentrations. Note that the manual sample mixing procedure will introduce slight error in analyte concentrations. Nevertheless, there is a good agreement between nominal and estimated concentration for benzene. Even better agreement is observed for toluene (because of the higher sensitivity for this analyte).

The above results illustrate the detection limit in single-analyte detection and the accuracy in binary mixture analysis that can be achieved using the multi-electrode sensor platform designs. Another advantage of multi-electrode IDT designs is the presence of multiple SH-SAW passbands [13], which can be used for analysis of frequency-dependent effects in a single measurement with a single device. As an example, Fig. 5 shows the response of a SH-SAW device with S_e = 20 to 5 ppm benzene. The basic SH-SAW frequency for this device is 41 MHz; the responses of the 2nd to 4th SH-SAW harmonics to the same sample are shown at 82, 123, and 164 MHz.

To facilitate a more detailed analysis, the exact steady-state frequency shifts for this measurement are listed in Table III. The dependence of the observed frequency shifts on mode frequency contains a contribution from Sauerbrey-type mass loading [17]. Since all SH-SAW modes are propagating along the same delay line and will be exposed to the same amount of mass loading, this contribution is expected to give a $\Delta f \propto f^2$ dependence, where f is the device operating frequency. But the last column of Table III reveals significant additional contributions for the higher harmonics. This can be explained

TABLE II. NOMINAL ANALYTE CONCENTRATIONS FOR THE FIRST THREE SENSOR RESPONSES (TO BINARY MIXTURES) IN FIG. 4, AND CONCENTRATIONS ESTIMATED USING DUAL-EXPONENTIAL FITS.

Sample	Benzene Conc. (ppb)		Toluene Conc. (ppb)	
	nominal	*fit*	*nominal*	*fit*
# 1	1000	1200	500	690
# 2	500	810	1000	1110
# 3	1000	1280	1000	990

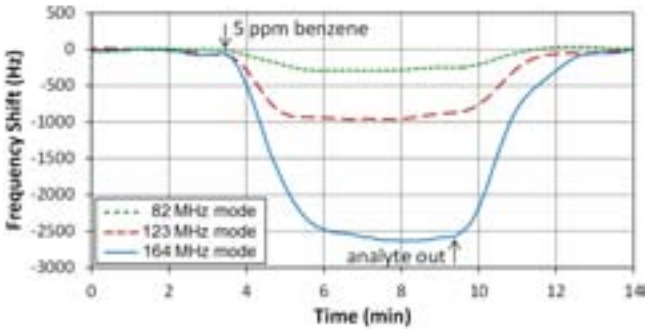

Fig. 5: Response of a SH-SAW device with S_e = 20 to 5 ppm benzene, shown for three different SH-SAW modes with frequencies indicated in the graph. The device was coated with 0.55 µm PEA.

by the higher ratio of waveguide thickness to wavelength for the higher modes, resulting in more efficient waveguiding and a corresponding increase in mass sensitivity for SH-SAW devices [15], [18]. Another contribution is from viscoelastic effects, which would also be expected to result in increased frequency shifts for higher ratios of waveguide thickness to wavelength [7], [14], [19].

IV. Conclusions

In chemical sensor applications, for a high-coupling piezoelectric material like $LiTaO_3$, use of the standard double-finger (S_e = 4) IDT leads to a dilemma: use of a wideband IDT will result in significant overlap of adjacent mode passbands; use of a narrowband IDT will lead to overcoupling and increased acoustic wave reflections. Thus, both alternatives will lead to significant signal distortions. It was demonstrated that the use of multi-electrode IDTs solves this issue, and narrowband SH-SAW modes can be obtained with high phase linearity, low acoustic wave reflection, and good sidelobe and bulk mode suppression.

It was observed that properly designed multi-electrode IDTs also result in significantly lower rms noise levels, with beneficial effects for BTEX detection in water including lower detection limits and higher accuracy in binary mixture analysis, as well as improved reproducibility. In addition, multi-electrode IDTs produce spectra of SH-SAW harmonics which permit investigation of frequency-dependent contributions in sensor responses using a single device in a single measurement. This option can also be useful in a sensor array since it permits collection of information from a larger number of input parameters using a compact sensor platform.

TABLE III. Steady-State Frequency Shifts, $-\Delta f$, for the Sensor Responses Shown in Fig. 5. A Frequency Dependence Stronger than $\Delta f \propto f^2$ is Observed.

Mode	$-\Delta f$ (Hz)	$(f/f_2)^2$	$\Delta f/\Delta f_2$
f_2 = 82 MHz	280	1	1
f_3 = 123 MHz	930	2.25	3.32
f_4 = 164 MHz	2600	4	9.29

***Abstract*— The Time Transfer by Laser Link (T2L2) experiment aims to synchronize remote ultra stable clocks over very long distances using the Satellite Laser Ranging (SLR) technique. T2L2 was launched in July 2008, on board the Jason2 satellite; from 5-6 stations ranging T2L2 during the first months of the mission, around 22 stations of the worldwide SLR network are now participating in the tracking. In addition to the permanent data acquisition and processing (accessible from our website https://t2l2.oca.eu/), several field experiments have been conducted to alternatively demonstrate the ultimate time transfer capability of T2L2, in terms of stability, exactness, comparison with the GPS and Two-Way microwave techniques.**

This paper synthetizes the best performances that T2L2 allows us to achieve, as a result of recent improvements made in the data reduction. The time stability of the T2L2 ground to space time transfer is established at 6-8 ps at 75 seconds, for SLR systems equipped with an H-maser as the reference clock. The ground to ground time transfer stability between 2 SLR stations (in Common View) is estimated at 11 ps rms (average) over one passage and better than 50 ps over several days. We present also the advantages and drawbacks of this unique time transfer technique based on an optical link.

Keywords—Space technique, time transfer, Laser ranging

I. INTRODUCTION

The Time Transfer by Laser Link (T2L2) instrument is passenger of the oceanographic space mission Jason2, that was launched in June 2008 at an altitude of 1335 Km. On board the Jason2 satellite, T2L2 consists of an optical system (detection) and an electronic device for the timing [1]. The principle of the experiment is based on the Satellite Laser Ranging (SLR) technique; thanks to the laser reflector array located on the satellite Jason2 in support of the precise orbitography, T2L2 benefits from the 2-way ranging, whose repeatability error and accuracy reach a few millimeters and less than 1 centimeter, respectively [2]. At ground level, T2L2 relies on the International Laser Ranging Service (ILRS) network [3], whose stations are tracking the satellite for 5 to 6 times per day maximum of 10 to 15 minutes each.

Actually, T2L2 is a technology demonstrator and also a platform permitting to realize some scientific experiments in metrology and fundamental physics. Its performances are in the range of 100 ps of accuracy, and in the range of a few ps at 1000 s. Apart from a few interruptions in 2009, 2010 and 2013 (a few days each time), the instrument is working properly and continuously since 2008.

Since 2009, we have conducted several field experiments, implementing very different configurations to: *i*) properly measure the performances of the time transfer by laser link (for short and long term stability), *ii*) progress in the measurement (method and hardware) of the ground links (delay, cables, etc.) including the time distribution of pulses between equipment such as clock, SLR system, and GPS and Two-way antennas (for exactness), *iii*) compare the T2L2 time transfer to existing microwave techniques such as GPS. In addition, we used the French mobile laser station (300 kg) [4] to conduct some field experiments at the Observatoire de Paris (2010), Tahiti (2011) and Grasse (2012) [5] [6] [7].

We present the most significant events and results of the T2L2 mission that have been obtained so far — ground and onboard characteristics, noise, available data — in Section II. The advantages and drawbacks of the T2L2 technique based on laser technology are discussed in Section III. Finally, some scientifical applications (current and future) are overviewed in Section IV.

II. THE CHARACTERISTICS OF T2L2

T2L2 receives an average of 100,000 optical events (t_B dates) per day. From 5 to 6 SLR participating stations in 2008, T2L2 implies today 22-24 stations (see Fig. 1).

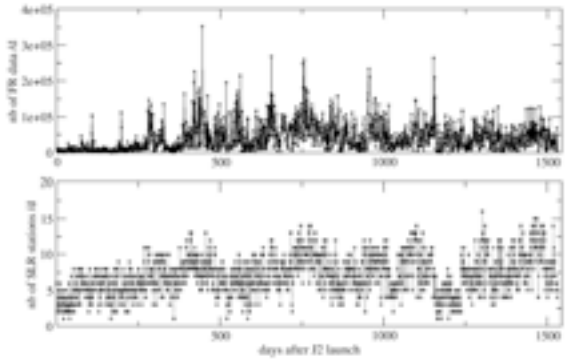

Fig. 1. Number of SLR Full Rate data, from 2008 to 2012, and number of SLR stations per day particiting in the T2L2/Jason2 tracking.

They send their data (t_e dates in UTC and 2-way distances dt_{2w}) regularly to the European Data Center (located in

Germany) and to the Crustal Dynamics Data Information System (US) that specialize in the geodetic space techniques.

Given the very high reliability of T2L2 over time (5 years in space), we developed a data reduction scheme that operates on a daily basis. In parallel, we have developed an interactive website (https://t2l2.oca.eu/) to describe the data over time: ground and board data and statistics. For the web user, it's possible to compute a given ground to space time transfer (from a selected set of SLR stations) or to obtain a history over several days. Actually, the website serves primarily to calculate the ground to ground time transfer ($\Delta t_{B\text{-}S}$ - $\Delta t_{B\text{-}S'}$) between the two reference clock systems of two selected SLR stations (S) and (S'). The basic equation that has been implemented corresponds to the following:

$$\Delta t_{B\text{-}S} = t_B + Corr_{\text{Instrum}} - [\, t_e + (dt_{2w} - Corr_{\text{Sagnac}})/2 \,] \qquad (1)$$

where:

$Corr_{\text{Instrum}}$: is the sum of the instrumental corrections; correction of time walk of the T2L2 non linear diode, and geometrical correction between the locations of the reflector array and the T2L2 optics (around 10 cm or 0.3 ns) on the platform.

$Corr_{\text{Sagnac}}$: Sagnac effect (due to both Earth's and satellite rotations) that is necessary to use when computing the equivalent time travel of the light between the station on the ground and the satellite, from the 2-way measurement (dt_{2w}).

Outside the expected performances mentioned earlier, we can establish a budget error of the ground to space time transfer (Eq. 1) according to Table I [8]. Here, the amounts shown are from recent analyzes from a SLR station equipped with an H-maser as reference clock.

Given the wide variety of clock systems and laser stations, we built a data reduction scheme based on the robust estimation (mathematical and numerical meaning). Statistically, we can say that the estimated noise at 1 s ranges from 45 to 65 ps. The average stability achieved in today's data processing is 4-8 ps at 75 s (see Fig. 2, the Time Variance obtained from many passages of ground to space time transfer for 2 laser stations).

TABLE I. A priori noise of the laser link for ground to space time transfer (in picosecondes).

Items	***Noise by type***		
	Ranging (dt_{2w})	***Board***	***$\Delta t_{B\text{-}S}$***
Timing at ground : t_e	5-10		
Return	5-10		
Laser pulse width	15-35		
Detector at ground	10-15		
Target signature	10-15		
Calibration	1-5		
Timing onboard : t_B		2-3	
Detector onboard		5-35	
Instrument Correct.		1-8	
Sub-total	20-45	5-35	
Total			20-55
Stability (σ_x)	1-5 / 15 s		4-8 / 75 s

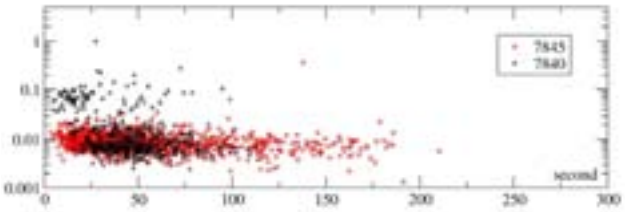

Fig. 2. Time Variance (in ns) of the ground to space time transfer, for each satellite passage, during 4 years; 7845: SLR Grasse, France; 7840: SLR Herstmonceux, UK.

The onboard timing of all optical events (laser pulses coming from ground stations) is referenced by an Ultra Stable Oscillator (USO, quartz) which is the heart of the Doppler tracking technique DORIS (Doppler Orbitography and Radiopositioning Integrated on Satellite) [9]. From recent improvements made in the data reduction, the estimate of the USO frequency from a T2L2 passage above a SLR station reaches 6-8.10^{-14} Hz at best. Thus, we are able to compare the USO frequency as estimated by the T2L2 time transfer and the one resulting from the DORIS orbit determination process. The a priori DORIS performance (in support of the orbitography) being of 0.3 mm/s it roughly corresponds to 3.10^{-12} Hz. As a matter of fact, the quality of the DORIS space technique partly depends on the ability to permanently monitor the USO frequency at least at that level. According to several T2L2 passages, we have established an empirical model describing the frequency variations of DORIS over 30 days; the residuals are in the range of 1-2.10^{-13} Hz. The next step will consist of introducing this model in the estimation process of the Jason2 orbit. Note that at this level of accuracy, we must take into account the relativity corrections: frequency "red shift" and second order Doppler.

Data processing for ground to ground time transfer consists of calculating the differences ($\Delta t_{B\text{-}S}$ - $\Delta t_{B\text{-}S'}$). As laser measurements between two (or more) stations are not synchronized on board (CV), we determine separately each synchronisation (Eq. 1); after filtering (white noise) an interpolation procedure permits to compute ($\Delta t_{B\text{-}S}$) for each second in the onboard time scale. Finally, the search for common seconds (between S and S') led us to calculate directly the difference between the ground clocks. The signal obtained depends essentially on the frequency difference between the two clocks; this difference of 1-3.10^{-13} Hz is due to the frequency error of each clock, and also to the altitude difference between the stations if any (the "red shift" is of ~1.10^{-13} Hz every 1,000 m). The resulting signal has a duration between 250 and 600 s, with an average 300 dots. After removing a linear fit, the ground to ground stability reach 11 ps over one passage (see examples Fig. 3). The time evolution of the mean value of the phase difference present a repeatibility error of ~50 ps.

Finally, great efforts have been made on the ground in order to: *i*) improve the measurement of the time delays in the cables (principle, methods and hardware), *ii*) determine the best point of reference of the time and frequency laboratory (PPS and its distribution to devices: GPS, laser, etc.) [10], *iii*) calibrate each time transfer technique, optical and microwaves.

Several have been conducted to this purpose, notably in Grasse (F), Herstmonceux (UK), and Wettzell (G).

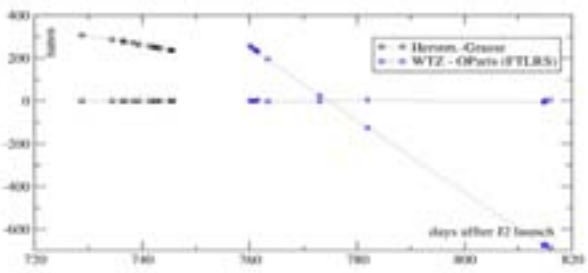

Fig. 3. Ground to ground time transfer (June to September 2010), signals and residuals after quadratic fit; 2 couples of SLR's (FTLRS is the French Transportable Laser Ranging Station, Herstm. in the UK, and WTZ in G).

III. THE POTENTIAL OF T2L2

The a priori potential of the T2L2 experiment is very important (see Table II). There is a good geographical coverage of the Jason2 satellite orbit from the ILRS network, the reliability of the onboard instrument for many years, the principle of the 2-way laser ranging is very simple and the quality of the measurements is very high. The satellite orbit has an altitude of 1335 km and the field of view of the optics of T2L2 being of ±55°, Common View (CV) passes are possible between remote ground stations at 6000 km. The acquisition of measurements on board is possible up to 5,000 Hz, the dead time of the electronic device being of 200 µs. This is more than enough since the SLR stations emit laser pulses usually in the green at 10 Hz. Finally, the onboard detector has been working on a multi-photon mode at 532 nm, this permits us to acquire data from all the SLR stations; heavy and complicated developments or tuning are then avoided.

On the other hand, the T2L2 experiment is constrained by several aspects. Since 2008, only some SLR stations are equipped with a highly stable clock (like a H-maser clock): 1 in China, 4+1 mobile in Europe, 1 in Japan, and 1 in the USA. The measurement dates (t_e) are provided at 1 ps resolution by these stations; other stations use less stable clock system and they provide data with a resolution of 100 ns sometimes. For its part, the onboard USO has a stability < 4 10^{-13} at 10 s but with a decreasing in terms of $t^{3/2}$ giving around 300-350 ps at 1000 s. Finally, the time-frequency laboratories (including those participating in the Atomic Time) are not close to laser stations and vice versa.

In summary, we can expect to "read" very accurately the onboard USO during Jason2 passes of 10 to 15 minutes, assuming that SLR stations use H-maser. For example, with favorable weather over Europe, it is possible to make ground to ground time transfers (CV) several times a day for several days. We must of course admit that with the orbital period of the satellite (almost 2 hours), the vagaries of weather, stops and breakdowns of the SLR stations, it is necessary to focus on a strict organization of field experiments; a planned organization and monitoring of operations on the ground; it has a lot of influence on the outcome.

TABLE II. Current status of T2L2 experiment: expected performances and results; the 2013-2014 follow-on mission shall allow to fulfill the remaining objectives (σ_x in picosecondes; tt: time transfer, gr.: ground).

Objectives		*Status*

IV. APPLICATIONS AND PERSPECTIVES

T2L2 is an instrument available to the scientific community involved in the field of time-frequency, space geodesy and fundamental physics (Table II). Planned for two years at the start of the mission, it was extended for two years (2011-2012) in 2010, and again for two years (2013-2014) in 2012 by the Centre National d'Etudes Spatiales (CNES). We continue to propose field experiments, including synergy with GPS and the Two-way technique, with a view to studying the long-term stability and accuracy of links. Some important effects are also done to improve time stability and time accuracy of laser ranging stations involved.

The applications of the T2L2 time transfer that will be pursued are: *i*) a study of the Lorentz Invariance (the anisotropy of the speed of light should be estimated at 10^{-9} to 10^{-10} [11]), *ii*) a monitoring of the USO frequency at 1-2.10^{-13} Hz should improve the orbit of Jason2 and especially the ground positioning, *iii*) an ultimate validation of T2L2 at the best possible performance, *iv*) a synchronization at 5-10 ns of the reference clocks of the SLR stations permitting improve the orbit determination of several geodetic satellites (now, the dates of SLR measurements differ from a station to another station of a few microseconds, see Fig. 4), *v*) a very accurate

link budget based on the analysis of both energy received at ground and onboard.

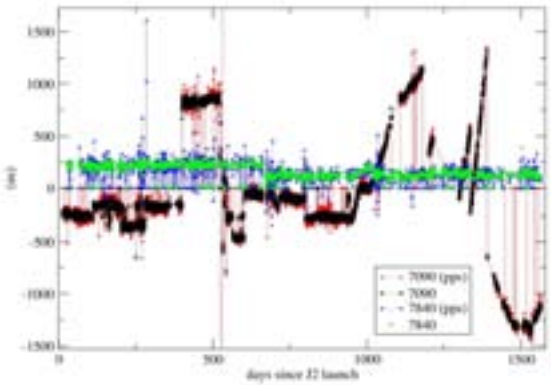

Fig. 4. Synchronisation of the reference clock systems of 2 SLR stations thanks to T2L2 on board Jason2 (7090: Yarragadee, AUS, and 7840: Herstmonceux, UK).

ACKNOWLEDGMENT

The authors wish to thank ILRS and SLR station that are participating to the T2L2 experiment. They wish to thank also the Centre National d'Etudes Spatiales for its support.

***Abstract*— In December 2012, ESA inaugurated their third Deep Space Antenna tracking station near Malargüe, Argentina. Due to the nature of the deep space operations, exigent requirements for stability of reference signals and low phase noise characteristics were necessary on the ground station equipment. In order to fulfill the requirements, new concepts and hardware development were carried out, resulting in an improvement of the performance of the frequency and timing reference system.**

Keywords: maser; cryogenic sapphire oscillator; deep space

I. INTRODUCTION

ESA's Deep Space Antenna 3, with its 35m dish antenna, was succesfully installed in a remote area near Malargüe in Argentina. This antenna follows the two previous Deep Space Antennas installed in New Norcia, Australia, in 2002 and Cebreros, Spain, in 2005. These three antennas are situated at about 120° with respect to each other making possible global coverage. This station profits, in addition, of minimum impact from the atmosphere as a consequence of its strategic location, which results in an enhancement of its performance [1].

New concepts and techniques to improve the overall performance of the Frequency and Timing (F&T) subsystems were developed and applied to ESA's third Deep Space Antenna. In contrast to previous stations, the clocks were not installed in the antenna, but in a distant building 100m away. Preservation of the performance along the long distribution path while maintaining the simplicity of the system as much as possible was not an easy task and was the main motivation during the design of the system. The performance achieved after adaptation and optimization of the key elements of the F&T subsystem and the reduction of the thermal sensitivity, allowed distribution to the antenna site, without degradation of the performance.

Figure 1. DSA3 antenna in Argentina – 35m dish

Independent and well environmentally-controlled clocks room, together with an improved short term stability and phase noise lead the way into the introduction of a 100 MHz frequency distribution system, in spite of the distance. Lower frequencies, such as 5 MHz and 10 MHz, were locally generated in each building out of the 100 MHz distributed signals. Timing signals, on the other hand, were regenerated and synchronized to the remote end.

Furthermore, the introduction of a cryogenic cooled sapphire oscillator (CSO) as a third source, in addition to the two redundant active hydrogen masers, accomplished to combine the CSO's good short term stability together with the better long term stability of the masers by locking the CSO to one of the available masers.

The system design, architecture, key aspects and the results of the tests carried out are presented on this paper.

II. Deep Space Antenna 3 applications

ESA's deep space antenna station incorporates a 35m dish equipped with a Cassegrain Beam Wave Guide feed RF system operated with dichroic mirrors and low noise amplifiers. Ka-band reception and X-band transmission and reception are already supported. Ka-band transmission, and K-band reception are planned to be supported in the near future [1].

The station is prepared to provide telemetry and telecommand functions, as well as serve for other purposes such as satellite tracking and ranging, Radio Science research, and support future scientific missions like LISA Pathfinder [9], Gaia [10] or BepiColombo [11]. ESA's deep space antennas already provide support to Venus express [12], Mars Express [13], Herschel [14] and Planck [15] missions.

While spacecraft tracking for orbit determination requires stable reference frequencies in the medium term and accurate time to obtain positions of satellites with sufficient precision (0.1mm/s). Some Radio Science missions impose, at the same time, high stability in the short term so that once per second events can be measured properly [2][6][7]. All these demanding requirements, added to the difficulty of having the clocks far away from the antenna made the design of the frequency and timing generation and distribution system a continuous challenge.

III. System design and Architecture

The F&T system for the Deep Space Antenna 3 station is distributed among three main locations; Clocks Room, Main Equipment Room (MER) and Antenna Equipment Room (AER). The clock room, is, in turn, subdivided into three smaller rooms, one room for the two Active Hydrogen Masers (Maser room), one room for the cryogenic sapphire oscillator (CSO room) and an Optical Clock room prepared for housing an optical clock in the future. Having the clocks so distant from the antenna results in a critical distribution, however, it has an advantage from the station level point of view. Ka-band transmission and K-band reception equipment, as well as future front-ends can be easier added, keeping the references in the main building and implementing a star topology to distribute the necessary signals to the different antennas. At the moment, reference frequency and timing signals from the clocks are distributed to the MER, and from the MER distributed to the AER, located 100m away from the Operations Building. A simplified block diagram with the different locations of the F&T system is presented in Fig. 2.

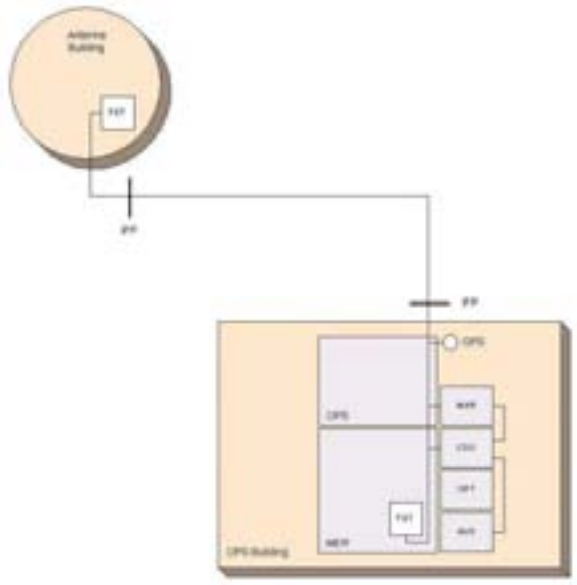

Figure 2. Simplified diagram of DSA3 locations with F&T equipment.

The system is prepared to store all data and measurements available from the system in order to provide long-term analysis of the frequency and timing signals' performance. Additionally, the system uses 3-corner hat ADEV post-processing software to determine the performance of each individual clock. Temperature and magnetic field in the maser room are continuously controlled. Undesired events are also logged for problem detection and troubleshooting activities.

A. Reference Clocks

Three high performing clocks are available at the station. The different rooms comprising the Clocks Room, are all environmentally controlled to avoid temperature variations of more than ± 0.5°C, assuring a stable thermal environment in which the clocks can perform at their best.

Figure 3. The two masers inside the Maser Room (MAR)

The two redundant Active Hydrogen Masers (AHM), see Fig. 3, manufactured by T4Science in Neuchâtel, Switzerland,

exhibit an improved thermal design and high performance. For DSA3, the masers were modified to improve the phase noise of the 100 MHz maser frequency signal at frequency offsets below 100 Hz from the carrier, eliminating the need of external clean-up oscillators and/or Phase Locked Loops (PLL) outside of the maser. To do so, an Oven Controlled Crystal Oscillator (OCXO) manufactured by Pascall, United Kingdom, with a performance at 100 MHz of –138 dBc/Hz at 100 Hz offset was used instead of the original Voltage Controlled Crystal Oscillator (VCXO). The Pascall oscillator is locked to a 5 MHz BVA-type Ultra Stable Oscillator (USO) model 8607 from Oscilloquartz, Neuchâtel, Switzerland, which provides the good phase noise at lower frequency offsets. The OCXO is located outside of the ovenised maser electronics compartment due to heat dissipation concerns and supplied with regulated stable power supply. In addition to these modifications, the number of available 100 MHz signal outputs in the PLL board of the maser was duplicated from two to four, and distributed from the Maser interface directly to the units in MER.

Fig.4 shows the phase noise performance of the modified maser at 100 MHz. The figure represents one maser against the other. Assuming that both perform similarly, 3 dB can be subtracted from the values shown in the plot. For frequency offsets very close to the carrier (until about 30 Hz) one can appreciate the performance of the BVA, whilst, for instance, at 100 Hz, the signal already benefits from the phase noise of the Pascall OCXO, as a result of the selected PLL bandwidth .

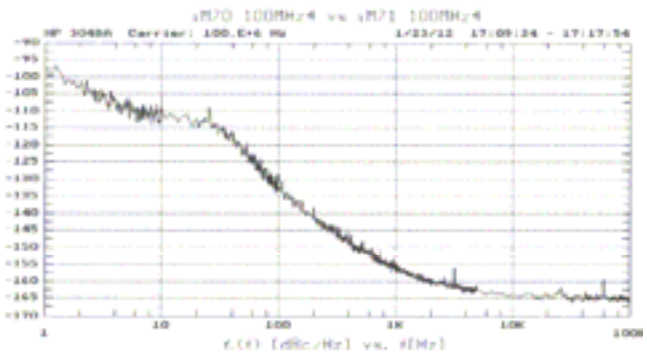

Figure 4. Maser 1 vs. Maser 2 – 100 MHz phase noise

Table 1 shows the improvement gained with respect to previous systems in terms of phase noise performance. Significant improvement can be seen at high frequency offsets.

TABLE I. MASER IMPROVEMENT WITH RESPECT TO PREVIOUS STATIONS

Phase Noise in dBc/Hz of the 100 MHz signal at the Maser interface		
Frequency Offset	***Previous Stations***	***DSA3***
1 Hz	-102	-102
10 Hz	-115	-115
100 Hz	-125	-136
1 kHz	-148	-160
10 kHz	-156	-164
100 kHz	-160	-165

In addition to the two AHM, ESA backed the design and implementation of a third clock to be used in DSA3. This clock is a Cryogenic Sapphire Oscillator prototype manufactured by Femto-ST in Besançon, France (See Fig. 5).

Figure 5. CSO in DSA3

The CSO consists of a high-Q sapphire whispering gallery mode resonator [5]. The resonator is thermally regulated by means of a cryocooler which sets the temperature close to 6K, so that any first order variation due to temperature cancels out. Electronics are comprised by amplifiers and filters belonging to the oscillator loop, and work at room temperature [5]. Finally, a synthesizer is needed in order to [6]:

- Perform the down-conversion from the CSO reference output frequency 9.989 GHz to 100MHz, 10 MHz and 5 MHz.
- Lock the CSO to the selected maser. The CSO counts with its own dedicated phase comparator which measures the phase difference between the masers and the CSO. By means of this phase comparator it is possible to lock the CSO to a maser with a long time constant (around 1000s). The result of this practice is an output frequency which profits from the good short term stability of the CSO and benefits from the good long term stability of the maser to which is locked to.

Fig. 6 shows the phase noise of the synthesizer measured during Factory Acceptance Tests. Two equal synthesizers were manufactured and measured against each other. As a result, and assuming that both units contribute the same amount to the measured phase noise, one can subtract 3 dB to obtain the real performance of one single synthesizer.

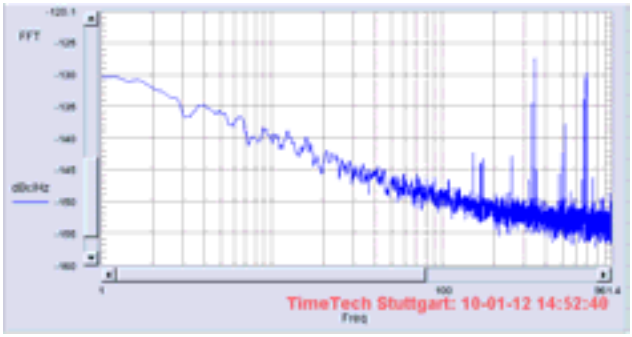

Figure 6. CSO synthesizer phase noise up to 1kHz at 100 MHz.

Moreover, having three clocks has further advantages. It is possible to measure the performance of each individual clock. Fig.7 shows the performance of the three clocks in DSA3 measured by means of the three-corner-hat method up to 1000s. One can see the better short-term performance of the CSO compared to that of the masers.

B. Frequency Distribution System

DSA3 F&T subsystem is based on a 100 MHz distribution system. Active distribution units to compensate for internal losses were equipped with low temperature coefficient (150 fs/K), standard high performance buffer amplifiers and low noise figure Monolithic Microwave Integrated Circuits (MMIC) set in parallel. 5 MHz and 10 MHz signals are also provided by the system, generated by division of the 100 MHz reference frequency signal. This state-of-the-art high performing low phase noise divider and distribution board shows improved phase noise characteristics (see Fig. 8) and was developed during the design of the F&T system for DSA3.

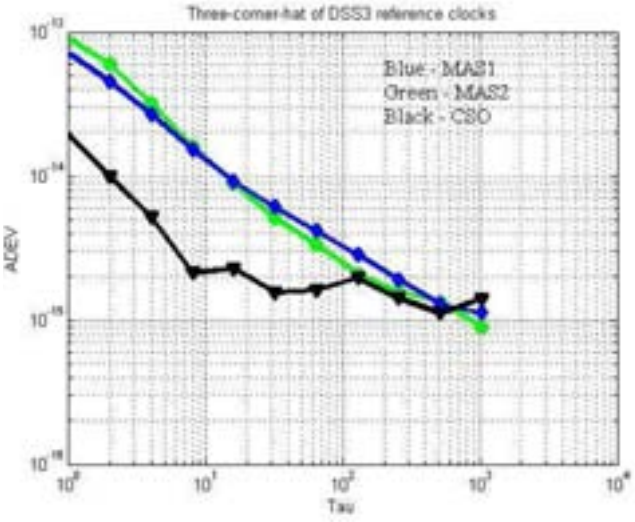

Figure 7. Individual Allan deviation performance of each clock

To assure a successful design, appropriate cables were selected to transmit the 100 MHz signals from the Clocks room to the MER and from the MER to the AER, without degrading the performance of the signal. In fact, implementing a long cross-site link, such as that between MER and AER, at frequencies below 100 MHz would have degraded the maser/CSO performance due to the very high thermal sensitivity of all coaxial cables at low frequencies [3]. Consequently, LDF4 50Ω cables with foam dielectric from Andrew, and presenting an extremely low thermal coefficient (0.6 ppm/K at 100 MHz), were selected for the cross-site link. In addition, cable ducts were buried 80 cm deep to attenuate the temperature variations as much as possible.

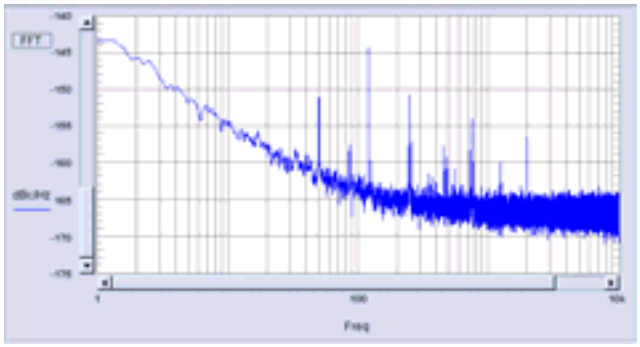

Figure 8. Divider phase noise at 100 MHz (*)

For the transmission of the 100 MHz from the Masers and CSO to the F&T rack inside the MER, and for the cables between the Maser room and the CSO room, FSJ-4 and FSJ-1 cables were used, respectively. These high quality cables have a greater thermal coefficient than LDF-4 50Ω, but, sufficient for adjacent rooms and short distances. A trade-off between thermal characteristics and cost had to be conducted.

Concerning performance at system level, Fig. 9 shows the performance achieved at the furthest point from the clocks (i.e. AER). The setup consisted of using one redundancy chain distributing the signals from one maser, against the second redundancy chain distributing the frequency of the second maser. (3 dB to be subtracted)

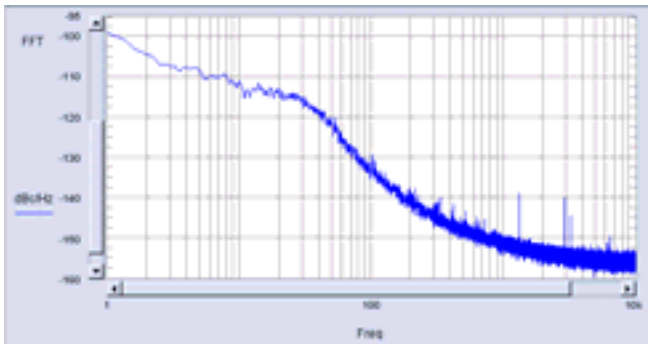

Figure 9. Phase Noise: Maser 1 through chain 1 vs Maser 2 through chain 2 at 100 MHz

* 3 dB to be subtracted to get phase noise of single unit

C. *Timing Distribution System*

Timing signals are generated using the derived 5 MHz signal from the masers (or CSO). The generated 1pps is constantly monitored against UTC (GPS) and maintained within 100ns. Moreover, the GPS comparison also allows long-term frequency accuracy analysis.

There is no distribution of timing signals as such, but regeneration of these signals on the remote side out of a 1pps two-way measurement. An optical link with active delay compensation assures that the remote 1pps signal is aligned to less than 1ns to the transmitted one [4]. IRIG-B timing signals also follow this 1pps and will therefore also appear aligned.

IV. Summary and Conclusions

Designing a well-performing F&T subsystem for DSA3 was a challenge. The requirement of locating the clocks at a substantial distance of 100 m from the antenna imposed applying new concepts to the F&T system design. In this paper, we have presented the motivation, architecture, design process, developments and results from the F&T system installed in DSA3, Argentina.

Main differences and new developments with respect to previous stations were, among others:

- Special configuration of the AHM with improved phase noise performance to avoid the use of external clean-ups.
- Design of a 100 MHz distribution system to profit from the reduced temperature coefficient at high frequencies.
- Selection of thermally stable cables running on deep cable ducts to decrease temperature variations.
- Low phase noise, high performing dividers to provide lower frequencies out of the 100 MHz distributed signal.
- Introduction of a third clock with excellent short term performance which could be locked to an AHM at integration times of around 1000 s.
- Improved optical link for time synchronization with active delay compensation and uncertainty below 1ns.

In this paper, we have presented the motivation, architecture, design process, developments and results from the F&T system installed in DSA3, Argentina.

***Abstract*— Estimation instead of feedback loops is recommended to obtain a composite clock. Wiener filtering approach to clock ensembling is introduced and demonstrated on the simplest case of two clocks. Design procedure dealing with clock system non-stationarity, non-observability and numerical issues, is given. Impact of causality to unexpected performance degradation is discussed.**

I. Introduction

Composite clock, or clock ensembling, i. e. calculation of best time estimate given readings from multiple clocks, is a must for state-of-art timekeeping. There are two distinct tools for clock ensembling: (i) feedback; (ii) estimation. Using (i), a phase- or frequency-locked loop or loops (PLL, FLL) are formed, containing clock and a controller. The controller corrects clock's time (by tuning, modulation, phase stepping, etc.), and the corrected signal is fed back into the controller. On the other hand, in case of (ii) an estimator senses clocks' reading without any modification, and produces estimate of clocks' state, applicable as a correction to time reading. The corrected signal is not fed back into the estimator.

Realizations of (i) are e. g. Network Time Protocol (NTP), and Atomic Clock Ensemble in Space (ACES [1]). Suppose the controller (i) is constrained to be linear (what is the common case). Then, following separation principle [2], even the optimal controller (minimum variance controller) will give worse or same performance, as an optimal linear estimator (ii); the limit case of the same performance requires zero control noise. Therefore, we claim that use of (i) is justified only when implementation of estimator is not feasible (e. g. in case of specific analogue circuitry). Otherwise, including ACES and NTP in our opinion, the estimator (ii) is the right way to choose.

II. Clock modelling

The essential prerequisite for design of ensembling is a clock model, describing statistical properties of phase evolution over time $x(t)$. A clock is described as a linear stochastic system, defined by phase spectrum $\mathcal{S}_{xx}(f)$. The system is marginally stable: it contains one or more integrators in cascade, corresponding to $f^{-n}, n = 2, 4, \ldots$ terms in $\mathcal{S}_{xx}(f)$. In addition, it may contain stable modes as well. Within estimation approach to ensembling, clocks are not disciplined, the system is purely stochastic, no deterministic input (tuning).

A discrete-time processing is assumed further. Estimates are calculated digitally from sequence of measurements. For convenience, these shall be acquired at equidistant time instants $t_k, t_k - t_{k-1} = T_s = const.$. This can be fulfilled only approximately, because T_s is perturbed by clock noise as well. Although considered by [3], we follow the conclusion of [4], that the effect is negligible for the purpose of ensembling.

Confinement to a class of linear discrete-time systems, containing stable and marginally stable modes, is sufficient for estimator design procedure (Sec. III). Assumption of clock process linearity implies that properly designed linear estimator is optimal in sense of mean squared error (MSE). It also implies, that spectrum $\mathcal{S}_{xx}(f)$ is sufficient description of the process – possibly different clocks with equal $\mathcal{S}_{xx}(f)$ are indistinguishable, regardless of their internal structure (Spectral factorization theorem [2], [5]).

Assumption of linearity works well for f^{-2}, f^{-4}, f^{-6} spectrum terms, which indeed origin from cascaded integration of error. A more peculiar component of the spectrum is $1/f$-noise (flicker), constituting f^{-3}, f^{-5} terms [6]. Works on deterministic chaos suggest an inherently non-linear behavior as a cause of $1/f$-noise [7]. The $1/f$-noise can not be generated by linear system of finite order. However, for a given frequency band of interest and required fidelity, the spectrum may be approximated by a linear system of some finite order. The interesting question follows, whether a linear estimator designed for such an approximate system may approach the optimal estimator even for a process, containing non-linear (chaotic) $1/f$-noise. The answer is not known to us, so we follow [3], approximating $1/f$-noise terms by finite-order, linear, discrete-time model.

A single-input, single-output (SISO) discrete-time linear system can be described by its transfer function $G(z)$: $x(t) = G(z)u(t)$ (input signal u transformed to output y; z is a forward shift operator). In our case of purely stochastic system (no control input) $u(t)$ is a unit variance white noise. For finite-order systems $G(z) = B(z)/A(z)$ where B, A are polynomials. A spectrum of x ($S_{xx}(z)$ or $\mathcal{S}_{xx}(f)$) is given by:

$$S_{xx}(z) = G^*(z)G(z)S_{uu} = \frac{B^*(z)B(z)}{A^*(z)A(z)}S_{uu}, \qquad (1)$$

$$\mathcal{S}_{xx}(f) = S_{xx}(e^{j\theta}), \quad \theta = 2\pi f T_s,$$

where $G^*(z) = \overline{G(1/z)}$. If x is real-valued, $S_{xx} = S^*_{xx}$. Given S_{xx} can be always factored as product of G, G^* (1) so that roots of B, A lie inside the unit disc. The step is called spectral factorization, denoted $G(z) = \mathrm{spf}(S_{xx}(z))$, producing stable, minimum-phase model G [2], [5]. $\mathrm{spf}(\cdot)$ allows to create clock model out of a given phase spectrum. A state-space clock model $\mathbf{x}(t+1) = \mathbf{\Phi x}(t) + \mathbf{u}(t)$ [4], [8], [3], [9], [10] can be converted to SISO $G(z)$ by standard means [2].

The model of single clock has been given. Ensemble is a set of N clocks (Fig. 1a). Using any meaningful physical means of time signal processing (counters, phase comparators, mixers, etc.), only time differences between the clocks may be measured. There is no clue about an "absolute" time offset. With any number of mutual measurements, we end up with only $N-1$ degrees of freedom in data: measurement matrix is singular.

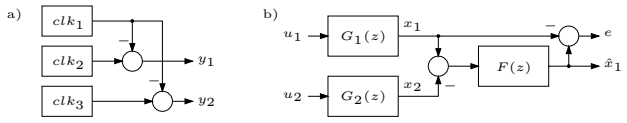

Fig. 1. (a) Clock ensemble (b) Composition of two clocks

Two important consequences follow, whose conjunction makes the estimation task non-trivial one: (i) time offset (error) of each individual clock grows without bounds; (ii) clock ensemble system is not completely observable. Therefore, any possible time estimator produces time estimate whose error grows without bounds as well. The goal is to achieve the lowest possible error within finite horizon. It is probably this specialty, why the topic of clock ensembling is still in active research [9], [10].

III. Estimator design

The most general form of MSE optimal linear estimator is Kalman filter (KF [2]). The mentioned clock ensemble's non-stationarity and non-observability cause difficulties to practical KF computation due to unbounded covariance growth. This problem gave rise to KF variants with specific covariance treatment [4], [8], [3], [10]. We have chosen another way, leading to a simple, closed-form estimator: Wiener filter (WF [5], [2]). The only limitation of WF for clock applications is that time-invariant processes are assumed, i. e. clock spectra supposed to be constant during estimation. In the simplest case of only two clocks [1], the WF becomes SISO, and the expressions are very simple.

The ensemble of $N = 2$ clocks $G_{1,2}(z)$ thus produces only one $(N-1)$ measurement y, Fig. 1b. $G_{1,2}$ are assumed SISO, i. e. $\mathrm{spf}(\cdot)$ performed if necessary. The time difference y is fed into estimator $F(z)$, which is designed to estimate output of one of the two clocks, $\hat{x}_1$. The $\hat{x}_1$ samples constitute corrections of x_1 signal, reducing effectively an uncertainty of composite time to that of residual signal e. The task is symmetrical, after exchanging $G_1 \leftrightarrow G_2$, the estimator becomes $F'(z) = 1 - F(z)$. Optional measurement noise may be incorporated into G_2 model.

The design of linear, MSE optimal estimator following Wiener formalism is based on two spectra: spectrum S_{yy} of the measured signal y, and cross-spectrum between y and signal to be estimated x, designated S_{xy}. In our case $y = x_1 + x_2$ and $x_{1,2}$ are uncorrelated ($x_1 \perp x_2$) therefore simply $S_{xy} = S_{xx}$.

There are three different variants of resulting estimators: non-causal $F_{nc}(z)$, causal $F(z)$ and finite-lag $F_T(z)$ WF. $F_{nc}(z)$ is best (lowest MSE), but requires to process future samples $y(t+1) \ldots y(+\infty)$. It can not be used in real-time, only offline in batch processing (smoothing). $F(z)$ is designed to deliver estimates without any lag, within the measurement cycle, possibly in real-time. Because of the lack of future y development information, its MSE is worse. A gap between $F_{nc}(z)$ and $F(z)$ is filled with $F_T(z)$, allowing to trade performance vs. filter lag T (number of future samples to wait for). The non-causal solution is simple [5], [2]: $F_{nc} = S_{xy}/S_{yy}$; in our specific case:

$$F_{nc} = \frac{S_{xx}}{S_{yy}} = \frac{S_{11}}{S_{11} + S_{22}},$$

where $S_{kk} = G^*_k G_k$ are clock spectra; the residual error is:

$$e = x_1 - \hat{x}_1 = \frac{1}{w_1 + w_2}(w_1 x_1 + w_2 x_2), w_k = \frac{1}{S_{kk}}.$$

Residual spectrum is easily plotted, or even sketched:

$$S_{ee} = \frac{S_{11} S_{22}}{S_{11} + S_{22}}$$

.

Considering $\mathcal{S}_{xx}(f) = \sigma^2_x(f)\mathrm{d}f$, we see that estimator averages input signals $x_{1,2}$ weighted by inverse of their respective variances at given frequency. If both clocks have a spectrum of the same shape $S_{11} \propto S_{22}$, estimator reduces to mere static weighted average $F_{nc}(z) = const.$, and it is also the only case when $F_{nc}(z) = F(z)$ is causal.

If both processes $x_{1,2}$ (or the output y), are filtered by common transfer function $G'_1(z) = G_c(z)G_1(z)$, $G'_2(z) = G_c(z)G_2(z)$, then $F_{nc}(z)$ remains unchanged. Thanks to this property, $F_{nc}(z)$ is equally optimal for estimation of time (phase), as for estimation of frequency.

$F(z)$ is not allowed to weight future data so its impulse response must be zero in negative time, $h(t<0) = 0$. Operation to truncate $H(z)$ to its causal part is denoted $[H(z)]_+$. A naïve approach to $F(z)$ might be to take $[F_{nc}(z)]_+$. This resembles a common practice of block data processing: samples outside of a dataset are expected to be zero. Despite of that, $[F_{nc}(z)]_+$ is not the MSE optimal $F(z)$. The right solution is derived with help of a notion of whitening filter $W(z)$ [5]:

$$W(z) = \mathrm{spf}(1/S_{yy}), \qquad F(z) = [S_{xy}W^*]_+ W.$$

Compare $F_{nc}(z) = (S_{xy}W^*)W$ – only a part of $F_{nc}(z)$ underwent the causal truncation. $F(z)$ is no longer invariant to multiplication by common factor G_c. Therefore, MSE

optimum for time generally differs from MSE optimum for frequency in case of causal estimator. $F_T(z)$ is similar to $F(z)$, only the $(S_{xy}W^*)$ is allowed to look T samples into the future: $F_T(z) = z^T[z^{-T}S_{xy}W^*]_+W$. The properties are similar to that of $F(z)$, performance compares as follows: var $e_{causal} \geq$ var $e_T \geq$ var e_{nc}.

Design procedure begins with clock models in form of polynomial fractions $G_1(z) = B_1(z)/A(z)$, $G_2(z) = B_2(z)/A(z)$, common denominator $A(z)$ is assumed. Models may be safely expanded to common $A(z)$ if required. Spectrum of measured signal is:

$$S_{yy} = (U_1^*G_1^* + U_2^*G_2^*)(G_1U_1 + G_2U_2)$$

Since $u_1 \perp u_2$, var $u_1 =$ var $u_2 = 1$, $U_1^*U_2 = 0, U_1^*U_1 = U_2^*U_2 = 1$:

$$S_{yy} = G_1^*G_1 + G_2^*G_2 = \frac{B_1^*B_1 + B_2^*B_2}{A^*A} = \frac{C^*C}{A^*A}$$
$$\text{where} \quad C = \mathrm{spf}(B_1^*B_1 + B_2^*B_2). \tag{2}$$

Note $C(z)$ is obtained by $\mathrm{spf}(\cdot)$ (2). Cross-spectrum of $x = x_1 \rightarrow y$ is:

$$S_{xy} = (U_1^*G_1^*)(G_1U_1 + G_2U_2) = G_1^*G_1 = \frac{B_1^*B_1}{A^*A}$$

.

Giving the non-causal WF:

$$F_{nc} = \frac{S_{xy}}{S_{yy}} = \frac{B_1^*B_1}{C^*C}.$$

Causal WF follows:

$$W = A/C, \text{ so that } S_{yy} = 1/(W^*W)$$
$$F = [S_{xy}W^*]_+W = \left[\frac{B_1^*B_1}{AC^*}\right]_+ \frac{A}{C} = \left[\frac{D_+}{A} + \frac{D_-}{C^*}\right]_+ \frac{A}{C}$$

$$B_1^*B_1 = D_+C^* + D_-A \tag{3}$$

$$F(z) = \frac{D_+(z)}{C(z)}. \tag{4}$$

The polynomials $D_{+,-}$ result from (3). Their orders should be constrained so that D_+/A is causal (and possibly containing absolute term $z^0 \equiv h(0)$), while D_-/C^* is strictly anti-causal, non-containing the absolute term. Such a constraint assures unique solution to (3) [11].

IV. Specific problems

The central problem of clock ensembling is the non-stationarity and non-observability of the system (Sec. II). The non-stationarity manifests itself as a marginally-stable $(z-1)^m$ factor: $A(z) = (z-1)^m\tilde{A}(z)$, where $\tilde{A}(z)$ are stable factors (possibly $\tilde{A}(z) = 1$ for pure integrator models). Some of the WF formulations disallow marginally stable factors at all; others [11] do allow them, but they require at least the residual error e variance to be bounded. In our case, this condition is not satisfied. To overcome problems caused by $(z-1)^m$ ($\mathcal{S}_{..}(f \rightarrow 0) \rightarrow \infty$), we employ following notional alteration $A(z) = (z-(1-\epsilon))^m\tilde{A}(z)$.

Integrators were substituted by 1^{st}-order low-pass filters with cutoff $f_c \rightarrow 0$ smaller than any interesting frequency in the system. An important feature of this workaround is that the infinitesimally displaced factor $(z-(1-\epsilon))$ is interchangeable with pure $(z-1)$ in actual computation: $A(z)$ does not enter (2) at all, and there are no roots close to $(z-1)$ in (3) except $A(z)$ itself. The only purpose of said alteration is to determine that $A(z)$ is a stable, or causal (4) polynomial, and $A^*(z)$ is an unstable, anti-causal one. Observe also that $A(z)$ cancels out of both $F_{nc}(z)$ as well as $F(z)$ result.

Another design difficulty is due to a huge range of interesting frequencies to be modelled in clock ensembles. E.g., in [1] two-clock ensemble, a key area of interest lies around band from 5×10^{-6} Hz to 1 Hz. Suppose system sampling frequency is $f_s = 10$ Hz. A filter requested to emphasize or suppress signal in given band needs to contain poles located near $z = 0.54$, $z = 0.999997$. This makes (2) hard or impossible to solve by means of root-finding in ordinary double-precision floating point arithmetics (64b FP). Therefore, we have switched to arbitrary-precision arithmetic software (Maple 9.5). The $\mathrm{spf}(\cdot)$ (2) has been solved by addition, multiplication, root-finding, and discarding all $|z| > 1$ roots.

The second step consists in solving (3), leading to a system of linear algebraic equations. We have not noticed numerical difficulties here using 64b FP, but anyway we continued to solve the linear system in arbitrary-precision domain as well. For the examples described below, a precision of hundred(s) of decimal digits always yielded plausible results.

The design procedure yields an estimator as a polynomial fraction such as $F(z) = D_+(z)/C(z)$ in the causal variant. It is an infinite impulse response (IIR) filter, whose modes correspond to roots of $C(z)$. The $C(z)$ should be stable by definition of $\mathrm{spf}(\cdot)$, unless (2) fails to compute due to insufficient arithmetic precision.

Filter coefficients come from (2,3) in overly large precision, unjustified for practical implementation. Implementation of the filter using chosen word length and calculation structure, stability and performance might be degraded by means of: (i) signal round-off error and its propagation; (ii) filter coefficient displacement. Respective countermeasures belong to field of DSP expertise [12]. Good tool to asses implementation performance shift due to (ii) is residual spectrum S_{ee}. In our examples, we have used 64b FP and direct form IIR structure.

It should be stressed that the stability of whole clock composition system lies in the estimator. Therefore, if the IIR filter implementation is stable on finite wordlength arithmetic level, the whole system is guaranteed to be stable. This is a remarkable difference from the ensembling systems relying on feedback loops (PLL, FLL, etc.), where an improper matching of system model to physical clocks or tight stability margin may cause instability.

V. Examples

First example is artificial; both clocks follow the same model $x_k(t) = (r_{k,1}/(z-1)^2)u_{k,1} + r_{k,2}u_{k,2}$, but different parameters. S_{11}, S_{22}, and S_{ee} for both $F(z)$, $F_{nc}(z)$ is shown in Fig. 2. $F(z)$ is apparently worse than $F_{nc}(z)$, interestingly, in small region it is worse than any of the two input clocks. Still, it remains optimal by means of S_{ee} integral over f.

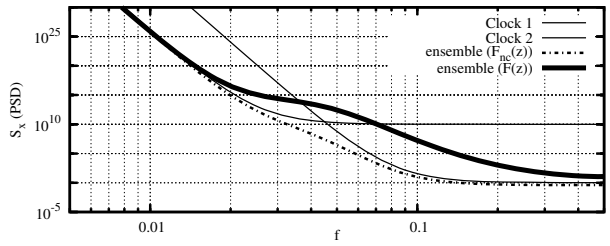

Fig. 2. Comparison of non-causal vs. causal WF for artificial clocks

Second, WF has been applied to two-clock (Cs clock "PHARAO", H-maser "SHM") ensemble model, as published [1]. $1/f$-noise of SHM has been approximated by 3^{rd}-order model, Fig. 3. While $F_{nc}(z)$ acts as expected, $F(z)$ is a real surprise: the time (phase) MSE-optimal causal estimator almost completely discards the SHM reading, weighting it up to $|F(z)|_{max} = 0.063$. S_{ee} is nearly identical to spectrum of PHARAO.

Is it correct? For MSE optimum in time ($\equiv$ phase), yes. By intuition, this probably is not the desired solution. We suppose, that the best way to get the most of the two clocks is to employ $F_T(z)$, in the graph plotted for chosen lag $T = 10^4\,\mathrm{s}$.

Recall, that any (linear) feedback system, as the present PLL&FLL solution [1], must be same or practically worse than even $F(z)$ by means of MSE. Performance of $F(z)$ and $F_{T=10^4\,\mathrm{s}}(z)$ is compared to PLL&FLL in Allan variance graph, Fig. 4. It is worth mentioning that PLL&FLL implementation is much more complex than that of IIR WF in this case.

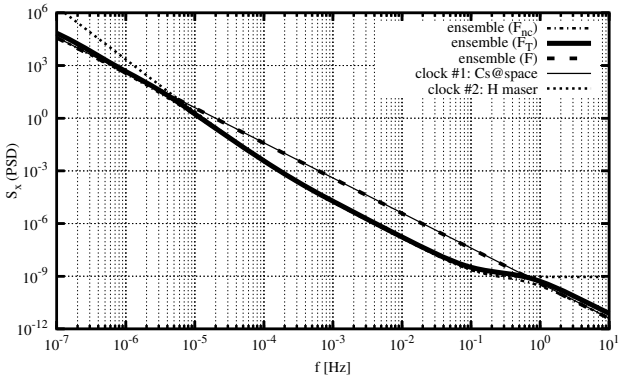

Fig. 3. Clock and residual phase spectra of ACES clocks and WF

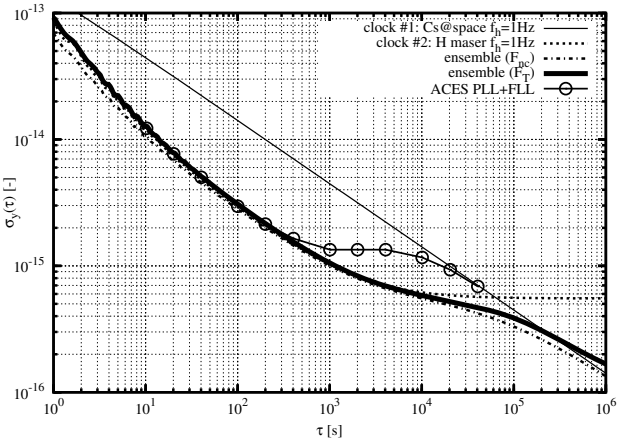

Fig. 4. Allan deviation of ACES clocks and WF residuals

VI. Conclusion

Use of estimation approach to clock composition instead of feedback loops is encouraged, wherever estimator implementation is possible. Design of WF for two-clock ensemble has been provided, dealing with non-observability of the system. Practical example of the ACES project model shows, how WF outperforms current PLL&FLL-based solution in performance as well as simplicity. Besides this, it shows how significant may be an advantage of finite-lag over causal WF.

***Abstract*—The stability of an atomic clock changes with time due to several factors, such as mechanical vibrations, temperature, and radiations. To represent this time variation, we introduced the dynamic Allan variance (DAVAR). The DAVAR is a surface function of time and the observation interval. This surface is stationary with time when the clock follows the specifications, whereas it changes with time when an anomaly occurs. We derive the exact analytic DAVAR for a series of common anomalies, namely, a sinusoid, a phase jump, and a frequency jump. These anomalies are of fundamental interest in space clocks. Our results establish a clear connection between the nature and properties of the anomalies and the corresponding shape of the DAVAR.**

I. Introduction

Atomic clocks play a fundamental role in global navigation satellite systems (GNSSs), such as GPS, GLONASS, and the future European system Galileo. In GNSSs, atomic clocks are employed both onboard satellites and in ground stations. Monitoring the quality of the atomic clocks is an essential task, since an error in time generates an error in position. Although atomic clocks are ultra-stable oscillators, they do experience anomalous behaviors, especially onboard satellites. These anomalies are caused by several factors, such as temperature, radiations, and aging.

In this article we analyze the most common anomalies, namely, oscillations, phase jumps, and frequency jumps. These anomalies are deterministic variations in the trend of the clock time and frequency deviations. In a future work we will consider variations in the statistics of the clock noise. For each of the considered anomaly we obtain the exact analytic dynamic Allan variance (DAVAR). The DAVAR is a surface function of time and the observation interval, which represents the variation with time of the clock stability [1], [2]. When the clock follows the specifications, the DAVAR is stationary with time. When an anomaly occurs, the DAVAR changes with time, its shape being a function of the occurred anomaly. By observing the DAVAR surface we can better monitor the clock behavior [3], [4], and by setting detection surfaces we can also reveal anomalous behaviors automatically [5]. The obtained analytic results clarify how the clock stability changes when an anomaly occurs.

The article is organized as follows. In Sect. II we establish our notation for the key clock quantities, as well as for the Allan and dynamic Allan variance. Then, in Sect. III we obtain the analytic DAVAR for an oscillation, a phase jump, and a frequency jump.

II. Notation

We indicate by $x(t)$ the time deviation of the clock with respect to a reference time. The corresponding normalized frequency deviation is given by [6]

$$y(t) = \frac{dx(t)}{dt}. \tag{1}$$

The standard definition of clock stability is the Allan variance [7]-[10]

$$\sigma_y^2(\tau) = \frac{1}{2}\left\langle \Delta^2(t,\tau) \right\rangle, \tag{2}$$

where

$$\Delta(t,\tau) = \bar{y}(t+\tau) - \bar{y}(t), \tag{3}$$

and the average frequency deviation is defined as

$$\bar{y}(t) = \frac{1}{\tau}\int_{t-\tau}^{t} y(t')dt'. \tag{4}$$

Writing the time average explicitly,

$$\sigma_y^2(\tau) = \frac{1}{2}\lim_{T\to\infty}\frac{1}{T}\int_{-T/2}^{T/2}\Delta^2(t,\tau)dt. \tag{5}$$

It is convenient to rewrite $\Delta(t,\tau)$ through a convolution operation

$$\Delta(t,\tau) = h_\tau(t) * y(t), \tag{6}$$

where

$$h_\tau(t) = \frac{1}{\tau}[P_\tau(t+\tau/2) - P_\tau(t-\tau/2)] \tag{7}$$

and $P_\tau(t)$ is a rectangular window defined as

$$P_\tau(t) = \begin{cases} 1, & |t| < T/2, \\ 0, & |t| \geq T/2. \end{cases} \tag{8}$$

The DAVAR is defined as [1]

$$\sigma_y^2(t,\tau) = \frac{1}{2(T-2\tau)}\int_{t-T/2+\tau}^{t+T/2-\tau} E[\Delta^2(t,t',\tau)]dt', \tag{9}$$

where E is the expected value, T is the analysis window, the observation interval τ is subject to $0 < \tau < T/2$,

$$\Delta(t,t',\tau) = \bar{y}_T(t,t'+\tau) - \bar{y}_T(t,t'), \tag{10}$$

the average frequency deviation is defined by

$$\bar{y}_T(t,t') = \frac{1}{\tau}\int_{t'-\tau}^{t'} y_T(t,t'')dt'', \tag{11}$$

and

$$y_T(t,t') = y(t')P_T(t-t'). \tag{12}$$

We see that

$$\bar{y}_T(t,t') = \bar{y}(t'), \tag{13}$$

for $t-(T/2-\tau) \le t' \le t+T/2-\tau$. Replacing this result in (10),

$$\Delta(t,t',\tau) = \Delta(t',\tau), \tag{14}$$

for $t-(T/2-\tau) \le t' \le t+T/2-\tau$, and then in (9),

$$\sigma_y^2(t,\tau) = \frac{1}{2(T-2\tau)} \int_{t-T/2+\tau}^{t+T/2-\tau} E[\Delta^2(t',\tau)]dt'. \tag{15}$$

For a deterministic frequency deviation $y(t)$ it is

$$\sigma_y^2(t,\tau) = \frac{1}{2(T-2\tau)} \int_{t-T/2+\tau}^{t+T/2-\tau} \Delta^2(t',\tau)dt'. \tag{16}$$

This simplified form is extremely useful for the analytic evaluation of the DAVAR.

III. Analysis of Clock Anomalies

We have obtained the exact analytic DAVAR for an oscillation, a phase jump, and a frequency jump. We show the details of these calculations for the case of the oscillation, whereas the phase and frequency jumps will be discussed in a future publication.

A. Oscillation

We consider the sinusoid

$$y(t) = A\cos(2\pi f_0 t + \varphi). \tag{17}$$

We first obtain its Allan variance. From (4), it is

$$\bar{y}(t) = \frac{1}{\tau}\int_{t-\tau}^{t} A\cos(2\pi f_0 t + \varphi)dt, \tag{18}$$

which integrates to

$$\bar{y}(t) = A\frac{\sin \pi f_0 \tau \cos[\pi f_0 (2t-\tau)+\varphi]}{\pi f_0 \tau}. \tag{19}$$

Similarly,

$$\bar{y}(t+\tau) = A\frac{\sin \pi f_0 \tau \cos[\pi f_0 (2t+\tau)+\varphi]}{\pi f_0 \tau}. \tag{20}$$

Substituting in (6),

$$\Delta(t,\tau) = -2A\frac{\sin^2 \pi f_0 \tau}{\pi f_0 \tau}\sin(2\pi f_0 t + \varphi). \tag{21}$$

From (5),

$$\sigma_y^2(\tau) = 2A^2\frac{\sin^4 \pi f_0 \tau}{\pi^2 f_0^2 \tau^2}\lim_{T\to\infty}\frac{1}{T}\int_{-T/2}^{T/2}\sin^2(2\pi f_0 t+\varphi)dt, \tag{22}$$

which integrates to

$$\sigma_y^2(\tau) = A^2\frac{\sin^4 \pi f_0 \tau}{\pi^2 f_0^2 \tau^2}. \tag{23}$$

The corresponding Allan deviation is

$$\sigma_y(\tau) = A\frac{\sin^2 \pi f_0 \tau}{\pi f_0 \tau}. \tag{24}$$

From (16), the DAVAR is obtained by solving

$$\sigma_y^2(t,\tau) = \frac{1}{2(T-2\tau)}\int_{t-T/2+\tau}^{t+T/2-\tau}\Delta^2(t',\tau)dt'. \tag{25}$$

It is

$$\begin{aligned}\sigma_y^2(t,\tau) &= A^2\frac{\sin^4 \pi f_0 \tau}{\pi^2 f_0^2 \tau^2} \\ &\times\left[1-\frac{\sin 2\pi f_0(T-2\tau)}{2\pi f_0(T-2\tau)}\cos(4\pi f_0 t+2\varphi)\right].\end{aligned} \tag{26}$$

We see that the first term is (23), namely, the Allan variance of a sinusoid. Therefore, the DAVAR of a sinusoid can be written as

$$\sigma_y^2(t,\tau) = \sigma_y^2(\tau)\left[1-\frac{\sin 4\pi f_0(\tau-T/2)}{4\pi f_0(\tau-T/2)}\cos(4\pi f_0 t+2\varphi)\right], \tag{27}$$

and the corresponding dynamic Allan deviation (DADEV) is

$$\sigma_y(t,\tau) = \sigma_y(\tau)\sqrt{1-\frac{\sin 4\pi f_0(\tau-T/2)}{4\pi f_0(\tau-T/2)}\cos(4\pi f_0 t+2\varphi)}. \tag{28}$$

We rewrite the DADEV as

$$\sigma_y(t,\tau) = \sigma_y(\tau)\sqrt{1-\alpha(\tau)\cos(4\pi f_0 t+2\varphi)}, \tag{29}$$

where

$$\alpha(\tau) = \frac{\sin 4\pi f_0(\tau-T/2)}{4\pi f_0(\tau-T/2)}. \tag{30}$$

This function is a sine centered in $\tau = T/2$, and

$$\alpha(\tau) = \begin{cases} 1, & \tau = T/2, \\ 0, & \tau = T/2 - \frac{m}{4f_0},\ m = 1,2,\ldots \end{cases} \tag{31}$$

Therefore

$$\sigma_y(t,\tau) = \sigma_y(\tau), \tag{32}$$

when $\tau = T/2 - \frac{m}{4f_0}$, and m is a positive integer, provided that $\tau > 0$, namely, $m < 2f_0 T$. Moreover, for large values of f_0, the denominator $4\pi f_0(\tau - T/2)$ of $\alpha(\tau)$ decays rapidly, and, for small τ values, it is $\alpha(\tau) \approx 0$, and

$$\sigma_y(t,\tau) \approx \sigma_y(\tau). \tag{33}$$

In Fig. 1 we show the DADEV obtained when $f_0 = .2$, $\varphi = 0$, and $T = 100$. (We use dimensionless quantities for simplicity.) For this large f_0 value the approximation (33) holds, and the DADEV basically corresponds to the Allan deviation at any time t. Since f_0 is large, the oscillation period is small, and the main lobe of the DADEV is located at small τ values. Conversely, in Fig. 2 we show the DADEV obtained when $f_0 = .01$, with identical φ and T values. For this small f_0 value the denominator of $\alpha(\tau)$ decays slowly, and the oscillation in time due to the term $\cos(4\pi f_0 t + 2\varphi)$ is clearly visible.

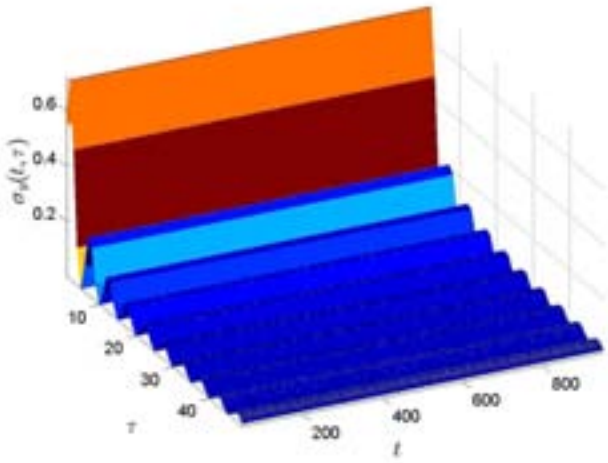

Fig. 1. DADEV of a sinusoid with large oscillation frequency. The plot shows the DADEV obtained when $f_0 = .2$. For this large f_0 value the DADEV is approximately equal to the Allan deviation of the sinusoid at any time interval.

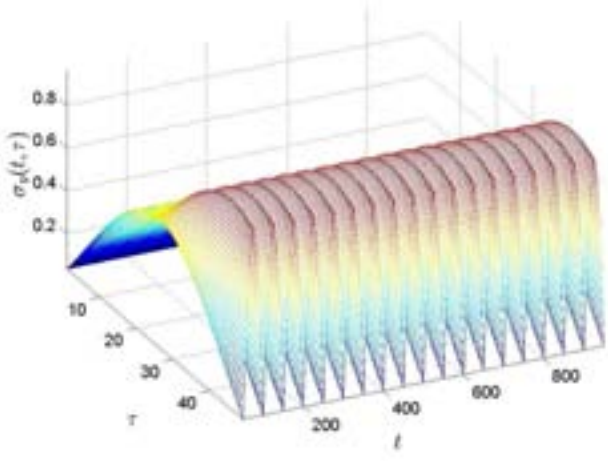

Fig. 2. DADEV of a sinusoid with small oscillation frequency. The plot shows the DADEV of a sinusoid whose oscillation frequency is $f_0 = .01$. For this small f_0 value the oscillation with respect to time is clearly visible. This oscillation is due to the term $\cos(4\pi f_0 t + 2\varphi)$ in (29).

B. Phase jump

We consider the phase jump

$$x(t) = u(t), \tag{34}$$

where $u(t)$ is the Heaviside step function, defined as

$$u(t) = \begin{cases} 1, & t \geq 0, \\ 0, & t < 0. \end{cases} \tag{35}$$

By using (1), we have

$$y(t) = \delta(t). \tag{36}$$

Consequently

$$\Delta(t,\tau) = h_\tau(t), \tag{37}$$

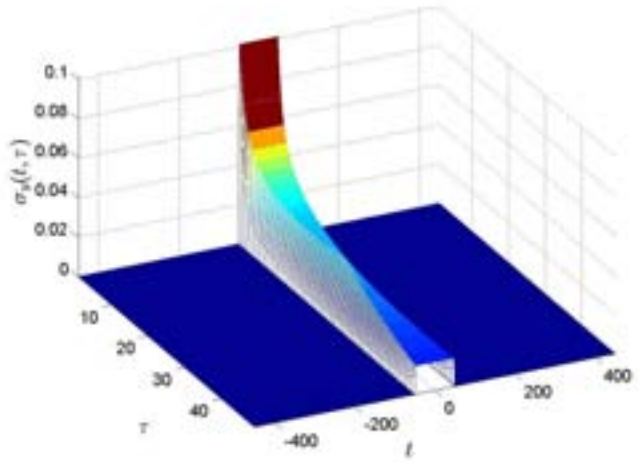

Fig. 3. DADEV of a phase jump. The plot shows the DADEV for a phase jump located at $t = 0$. This anomaly produces a local degradation of the clock stability concentrated in the interval $-T/2 \leq t \leq T/2$. The surface decreases with τ because the anomaly is averaged out at large τ values.

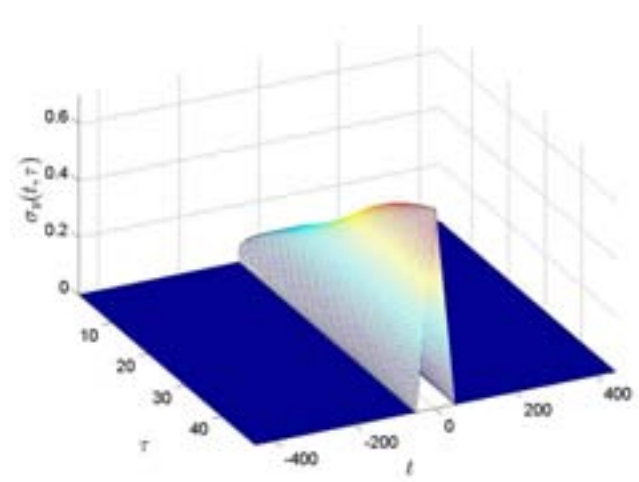

Fig. 4. DADEV of a frequency jump. The plot shows the DADEV of a step variation in the frequency deviation. This anomaly causes a degradation in the local clock stability concentrated in the interval $-T/2 \leq t \leq T/2$. In this interval, the DADEV increases with τ because the step change in the frequency deviation is tracked more often by the incremental average frequency deviation $\Delta(t,\tau)$.

and

$$\Delta^2(t,\tau) = \frac{1}{\tau^2} P_{2\tau}(t). \tag{38}$$

The corresponding analytic DAVAR, obtained by solving (16), can be computed exactly. In Fig. 3 we show the DADEV. Since the frequency deviation is a delta function, the instability is more visible at low observation interval values, whereas it is averaged out at large observation interval values. Consequently, the DADEV is a surface decreasing with τ. Moreover, it is concentrated about the $-T/2 \leq t \leq T/2$ interval. Therefore, as expected, a phase jump produces a local degradation of the clock stability.

C. Frequency jump

We consider the frequency jump

$$y(t) = u(t). \tag{39}$$

It is

$$\Delta(t,\tau) = \left(1 - \frac{|t|}{\tau}\right) P_{2\tau}(t). \tag{40}$$

Therefore

$$\Delta^2(t,\tau) = \left(1 - 2\frac{|t|}{\tau} + \frac{t^2}{\tau^2}\right) P_{2\tau}(t). \tag{41}$$

By solving (16) we can compute the exact analytic DAVAR. In Fig. 4 we show the corresponding DADEV. The frequency jump generates a local degradation in the clock stability, concentrated in the interval $-T/2 \leq t \leq T/2$. In this interval, the DADEV surface increases with τ. For small τ values, in fact, the incremental average frequency deviation $\Delta(t,\tau)$ is zero for most of the time values. Conversely, at large observation interval values $\Delta(t,\tau)$ captures the step variation in the frequency deviation more often, resulting in a larger instability.

IV. Conclusions

We have obtained the exact analytic DAVAR for an oscillation, a phase jump, and a frequency jump. These anomalies are common for space clocks in GNSSs, and cause a local degradation in the positioning error performances. Understanding their impact on the clock stability is hence of fundamental interest. The obtained results clarify the variation in stability produced by each of the considered anomaly.

***Abstract*—The new realization of UTC(OP) is described. The steering algorithm and the prediction of UTC(OP) are presented in details. The results of the first semester of operation are reported.**

I. Introduction

The generation of a timescale by steering a H-maser signal to the average of all SYRTE commercial clocks has been tested for a few years [1]. After running this time scale in parallel with the official UTC(OP), which was based on one single commercial Cs clock, we concluded that the performances were not justifying the complexity of the system. Instead, we have developed a very new algorithm for the steering of a H-maser signal to the SYRTE atomic fountain ensemble [2] (comprising 3 Cs primary frequency standards and one Rb fountain). Preliminary tests of the new algorithm started in December 2011. For these tests we used a new 100 MHz phase micro stepper developed by SKK Electronics in collaboration with SYRTE [3]. The results were promising. Hence in October 2012 we implemented the new algorithm to generate the official realization of UTC(OP).

At SYRTE all fountains share the same cryogenic oscillator which is phase locked to a H-maser. This way, all fountains measure the frequency of the same H-maser. Automatic fountain data processing provides preliminary data corrected of all systematic frequency shifts, hourly. At the present stage, the daily steering to this data-stream is sufficient to drive the timescale with a stability in the low 10^{-16}.

Where previously a few tens of ns were observed, the difference between UTC(OP) and UTC has not exceeded 5 ns since the implementation of this new UTC(OP).

II. Scientific background

In common meaning a UTC(k) is the physical realization of a (independent) prediction of UTC. The word independent is often forgotten and a number of UTC(k) is realized by using as reference some other UTC(k) or GPStime with a short time constant phase lock.

Although not officially required, in order to guarantee the independence of a UTC(k), one can only use the *Circular T* to assess the position of his own UTC(k) with respect to UTC, and to estimate the adequate steering planning which is valid until the publication of the following *Circular T*. This is roughly equivalent to stating that a UTC(k) can only be phase locked to UTC with a time constant longer than 40 days (30 or 35 days of span of the circular plus a few days for the TAI data collection and calculation by the BIPM). It is evident that for times up to of forty days the stability of the local oscillator is the key element for the performances of an independent UTC(k).

The commercial Cs beam frequency standards traditionally used in the generation of UTC(k)'s have a flicker floor of about 10^{-14} or slightly better. Hydrogen masers have a short term stability that is two orders of magnitude better than a Cs beam standard, but the flicker floor is reached earlier and at 40 days one can expect a stability only in the low 10^{-15}. It is straightforward to infer that the frequency of the maser can be predicted only at the level of its expected stability. Therefore using a maser allows a gain of about one order of magnitude on the stability of a UTC(k). As rule of thumb an error of 10^{-15} over 40 days can lead to a time error of 4 ns.

Practically this error is only a component of the uncertainty of the prediction because the frequency stability of UTC itself and the link instabilities have to be considered also. If an atomic fountain is used as local reference oscillator this term can be reduced well below 1 ns, as the frequency stability of a fountain over such period is in the low 10^{-16}. In this case it is evident that the stability is no longer the limiting factor in the realization of a UTC(k).

Nevertheless a time scale requires an oscillator that is running uninterruptedly and this is not the case with atomic fountains. In some cases, as for the LNE-SYRTE, the fountains does not produce a continuous physical signal but they allow to calibrate (almost continuously) a free-running fly-well oscillator, typically a H maser. In this case the steering of the maser frequency is evaluated by adding two components, the bigger one, daily adjusted, is the opposite of the frequency error of the maser as measured from the atomic fountain. If only this correction is applied to the phase micro stepper used to steer the maser, the generated timescale will be a realization of the SI second by the fountain. To better predict UTC a second coefficient is introduced. This coefficient is evaluated monthly using the *Circular T*.

III. UTC(OP) implementation

A simplified schematic of the hardware used for the generation of UTC(OP) is shown in fig. 1. The figure represents the actual situation but we plan the replacement of some hardware components to fulfill the requirements for hosting a ground station for ACES space project. The flywheel clock is currently the H-maser 1400889 operated free-running. The 100 MHz output of the maser is used as reference for the frequency lock of the cryogenic oscillator that drives the three SYRTE atomic fountains. In near future the same output will also drive

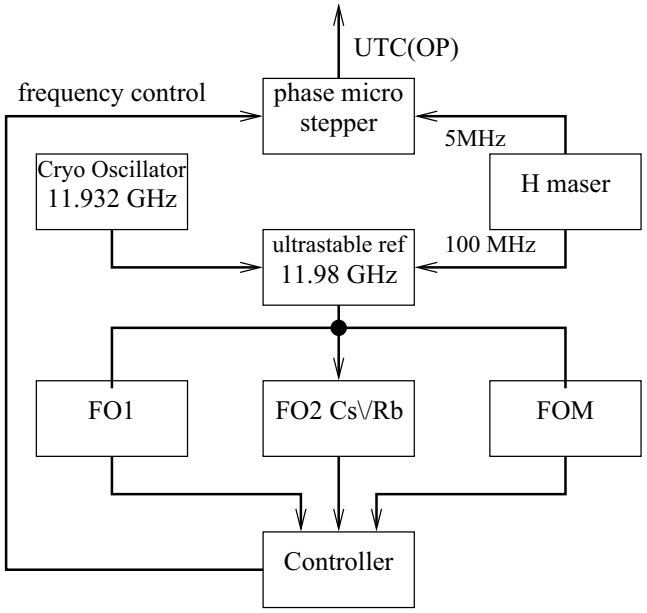

Fig. 1. Simplified block schematic.

the newly developed phase micro stepper [3], but at present the 5 MHz commercial phase micro stepper , historically used in time comparison is still in use. A detailed description of the maser frequency distribution, filtered by the cryogenic oscillator can be found in [2].

For the mobile fountain FOM, a post-processing of data has been running for many years in quasi real time. Cleaned and shifts corrected data are made available within about 1 hour latency. A similar but more sophisticated post-processing was also implemented a couple of years ago for FO2Cs FO2Rb and FO1 fountains. The quasi real time data have to be approved and eventually reprocessed before the generation of TAI reports, but they are largely sufficient to guarantee a stability at 10^{-16} level for the daily steering of the H maser.

The generation of a time scale by combining several low performances clocks is a complicate task that belongs to the art domain more than the basic science. In the case of UTC(OP), where at the starting point there are fountains with accuracy (not only stability) in the low 10^{-16}, there is no need of sophisticated statistic tools. The choice of the algorithm has been oriented to obtain robustness of the system instead of the ultimate optimization of performances. For instance, the frequency of the maser is measured simultaneously by all the available SYRTE fountains (at present FOM is in Toulouse), but only data of one fountain are used for the automated steering. The decision of which fountain is used depends on the operating planning. Typically we commute from one to another when a fountain is expected to interrupt regular operation for a few days for planned experiment or maintenance. We plan to use the data of the other fountains to rise a warning in case of non coherent measurement. We believe that setting up an automated switch in case of bad or missing data is too sophisticated for the purpose. Owing to the stability of the maser, a few days of missing fountain data have negligible impact on the realization of UTC(OP). In the normal data post-processing of SYRTE fountains all the systematic are corrected every one cycle. Nevertheless those files are too big and difficult to manipulate for the purpose of fountain comparison. For routine fountain comparison, and UTC(OP) generation, the original data files are converted (in quasi real time) to files with a reduced set of data averaged over 0.1 day. These "pack" files contain ten frequency values per day dated at pre-established times, notably 0.05 0.15 etc. Each point is obtained after filtering some period of the original file due to eventual problems in fibers link or in the lock of the cryogenic oscillator. A further cleaning is performed by fitting each 0.1 day period with a straight line and removing eventual outlier exceeding 5 sigma. The value of the fit at the middle of the interval is used to generate the pack file.

The steering software once a day predicts the maser frequency for the next day by extrapolating the linear fit of pack files covering the last 20 days. The correction to be applied at the phase micro stepper for the next day is the sum of the predicted maser frequency and the monthly coefficient that finely adjust the frequency of UTC(OP) to UTC. When the steering algorithm has been implemented in October 2012 the coefficient using the data in the last *Circular T* was calculated manually by adding 2 terms. The first one was the average of the frequency difference between UTC(OP) and UTC calculated over the *Circular T* period. The second term was calculated to compensate the last known time offset between UTC(OP) and UTC within 60 days. Since a few months this steering procedure has been implemented in quasi automated software. At that occasion the calculation of the frequency of the previous month has been modified to take into account the fact that the corrections of the previous month are applied with a delay of at least 10 days.

The same software is also used to generate a prediction of the difference of UTC(OP) and UTC for the next month. The quality of the prediction can be verified a posteriori when a new *Circular T* is published.

IV. Results

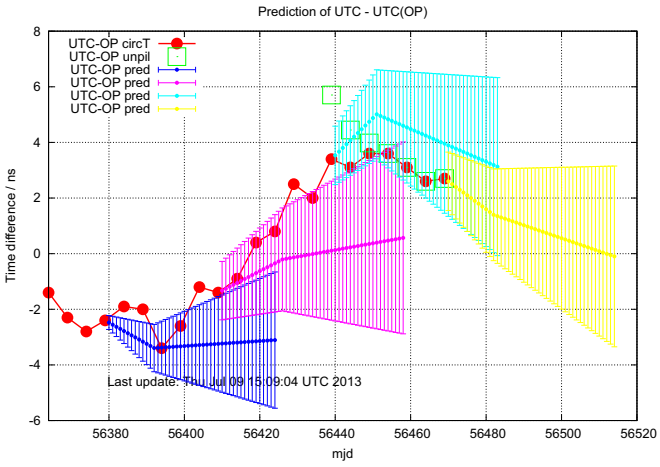

Fig. 2. The red line shows UTC-UTC(OP) using the new algorithm, the other data are explained in the text.

Since the beginning of operation of the new algorithm in Oct 2012, the difference between UTC and UTC(OP) did never reach the limit of 5 ns with an rms value of less than 3 ns.

In figure 2 the red line with circles shows the difference between UTC and UTC(OP) during the last four months, while the green big square are the point actually used to calculate the frequency of UTC(OP) over the period of *circular T306*. The differences between the green squares and the red dots at the beginning of the period are due to the fact that we have to take in account the impact of the previous applied steering in order to estimate the actual frequency difference between UTC and UTC(OP). Indeed the previous correction was applied at some time near the middle of the BIPM interval, corresponding to the date of publication of the *Circular T*. The same correction must be applied backward in order to estimate the actual frequency of UTC(OP), averaged over the entire interval. The points with error-bars in colors blue, lilac, cyan and yellow represents the predicted value with the associated uncertainty after publication of *Circular T303* to *T306*.

As we do not have long experience in this field we miss statistical data for the evaluation of error-bars. Therefore we have arbitrarily chosen a realistic (conservative) uncertainty of 10^{-15} on the frequency. The second component of the total uncertainty is due to the estimation of the starting point of the prediction. After the first month where this therm has been set at 0.3 ns, deduced by the statistical uncertainty published in *circular T*, we had the feeling that the term was too small and therefore it has been fixed arbitrarily at 1 ns, that is half way between the published uncertainties of type A and B of the dime difference between UTC and UTC(OP). The plot of the following months confirms that this choice is more realistic and eventually ask for a further increase. In fact the cyan data set has an evident offset of 1 ns, almost constant over the entire period.

ACKNOWLEDGMENT

The authors would like to thank the technical staff of Réferences Nationales de Temps of LNE SYRTE for the continuous support and monitoring. We also acknowledge the precious support of Service d'Electronique for improving the reliability of the frequency distribution and measurement systems.

A New Weighting Procedure for UTC

Gianna Panfilo, Aurélie Harmegnies
International Bureau of Weights and Measures (BIPM)
Pavillon de Breteuil, 92312, Sèvres, France
aharmeg@bipm.org

***Abstract*—This paper deals with the new weighting procedure studied and developed at the BIPM Time Department for the calculation of the Coordinated Universal Time (UTC). After the implementation of the quadratic prediction model in UTC algorithm, no effect has been observed on the clock weight distribution. To optimize the use of atomic clocks in order to improve the stability of UTC, a proposed review of the weighting algorithm is described.**

Time scale; UTC; TAI; weight; algorithm; frequency drift;

I. INTRODUCTION

To generate UTC, three main algorithms are used: the prediction and the weighting algorithms used to calculate the free atomic time scale (EAL) from about 400 free-running clocks spread worldwide, and the steering algorithm to steer the EAL frequency on the SI frequency provided by the Primary Frequency Standards.

The clock frequency prediction method has been reviewed and the clock prediction model has been changed from a linear to a quadratic model [1] adapted for clocks presenting frequency drift (case of H-masers and ageing caesium clocks). The new version of the prediction algorithm was implemented in September 2011 with significant effects in terms of improvement of the EAL stability. As aimed, the frequency drift of -1.3×10^{-17}/day affecting EAL has almost completely disappeared after the introduction of the new prediction algorithm and no additional steering has been applied to obtain the International Atomic Time (TAI) since last months of 2012.

II. CLOCK WEIGHTS STATUS

After the introduction of the new prediction algorithm in the UTC generation, the distribution between H-masers and caesium clocks on the total weight did not change because the frequency prediction does not influence the weighting procedure [2, 3] which considers the difference [EAL- clock] as the relevant weighting parameter. In particular in the current weighting algorithm the inverse of the variance of the frequency of [EAL – clock] over one year is used to estimate the performance of the atomic clocks and to assign a weight. The long term performance of the time scale is guaranteed by de-weighting those atomic clocks presenting a frequency drift (case of H-masers) or an ageing. One consequence of this procedure was the low impact of the contribution of the H-masers in the time scale ensemble: indeed, H-masers which represent about 100 out of the 400 clocks used in TAI computation, contribute only at about 10% of total weight and only few of them (less than 10) reach the maximum weight. Considering that to ensure its extreme reliability and its long-term frequency stability, UTC should rely on the largest possible number of atomic clocks of different types and spread worldwide then the need for a weighting procedure revision comes clear.

III. REVIEWED WEIGHTING PROCEDURE

The new version of the weighting algorithm is supported on the concept of weighting the clocks according to their predictabilities, instead of their frequency stability as in current version [2, 3]. In this new weighting procedure, the difference between the frequency of the atomic clocks y[EAL-clock] and its prediction $\hat{y}$[EAL-clock] is used. The main idea is that a clock with strong signature like frequency drift or ageing can be correctly used in the timescale ensemble if well predicted. In the new weighting algorithm the difference between the predicted and the real frequency of the atomic clocks is evaluated.

$$\epsilon_{i,I_k} = |\, y(i,I_k) - \hat{y}(i,I_k)| \qquad (1)$$

where the index i identifies the clock and I_k the calculation interval.

In time scale algorithm, a statistical quantity characterizing frequency stability of a clock is generally used to compute the corresponding clock weight. A filter over one year of these data is applied to evaluate the weights and to guarantee the long term stability of the clock ensemble. This filter gives a predominant role to the new measurements:

$$\sigma_i^2 = \frac{\sum_{j=1}^{M}\left(\frac{M+1-j}{M}\right)\epsilon_{i,j}^2}{\sum_{j=1}^{M}\left(\frac{M+1-j}{M}\right)} \quad (2)$$

and a temporary weight is calculated:

$$\omega_{i,TEMP} = \frac{1/\sigma_i^2(12,T)}{\sum_{i=1}^{N} 1/\sigma_i^2(12,T)} \quad (3)$$

The new weight ω_i of clock H_i is equal to $\omega_{i,TEMP}$ except in two cases:

1. Clock H_i satisfies the requirement set for the limitation of weight as for the current algorithm [2, 3].

2. Clock Hi shows abnormal behavior during the interval of computation so it cannot contribute. In this case the current value of the difference between the real frequency and the predicted one is checked. If the value is larger than a fixed threshold the clock is temporarily excluded from the ensemble.

IV. Effect of the new clock weighting

The effect of the new weighting model on the EAL stability seems to be satisfactory. A frequency stability improvement of the time scale at short and long term is observed. Moreover a better clock weight distribution is obtained which allows the H-masers to play a significant role on the time scale (about 30% of the total weight and 40 H-masers having the maximum weight) and limits the preponderance of caesium clocks in the EAL generation (from about 85% of the total weight in the current procedure to about 65% when using new weighting algorithm).

V. Conclusion

This new weighting algorithm is planned to be implemented in the procedure of TAI calculation before the end of 2013. Time laboratories contributing to the computation of the Rapid UTC at the BIPM [4] provide daily clock data; these data will serve for studying the impact of this new algorithm at shorter term stability.

Beijing, China
Email: zhangam@nim.ac.cn

***Abstract*—NIM has reconstructed UTC (NIM) since 2010 at new campus, and the official UTC (NIM) was switched to the new campus in October 2012. The new clock ensemble includes 6 Hydrogen masers and 7 Cesium clocks, with 1 Hydrogen maser and 2 Cesium clocks placed at the old campus. The master clock is a Hydrogen maser at new campus, and UTC (NIM) is generated from a micro phase stepper steered by a new algorithm and UTC, the frequency of the Hydrogen maser is predicted and rapid UTC data is used to steer UTC (NIM). A dual mixer time difference measurement system is used to measure the time difference between the clocks and UTC (NIM) at new campus, the clocks at old campus are linked to UTC (NIM) by GPS. GPS and TWSTFT data are reported to BIPM everyday automatically. The GPS receivers at new campus are calibrated with reference to one GPS receiver calibrated by BIPM. The UTC (NIM) has been operated normally at new campus; the accuracy and stability are improved. In this paper the generation of new UTC (NIM) is described and the performance of UTC (NIM) is presented.**

***Key words*-- UTC, UTC(NIM), UTCr, GNSS, TWSTFT, algorithm**

I. INTRODUCTION

The Coordinated Universal Time (UTC) is the universal standard time and it is the paper time implemented by the definition of the atomic second, Local representations of UTC is commonly called UTC(k) time scales, where k is a acronym representing an organization or a country[1]. UTC (NIM) is one of the physical realization of UTC, and it is also the time and frequency primary standard in China, it plays a very important role in time and frequency system in China. National Institute of Metrology (NIM) is responsible to construct and maintain UTC (NIM).

In the year of 2008, NIM has realized an independent time scale TA(NIM) which is generated from a Hydrogen maser steered by the cesium fountain clock[2], and UTC(NIM) is generated from TA(NIM) steered by UTC.

In the year of 2009, NIM's new campus, a 56-hectare advanced experimental base was put in use, it is approximately 40 kilometers northwest of the old Campus and it can provide tightly controlled laboratory conditions to maintain the integrity of the measurements.

Since 2010, new UTC (NIM) was under construction at the new campus. The clock ensemble, internal measurement system and the international comparison system were reconstructed. A new algorithm was developed to generate UTC (NIM), we still use a stable Hydrogen maser as the master clock, its frequency is predicted, and UTC (NIM) is generated from a micro phase stepper steered by the UTC together with the predicted value. UTC（NIM）is traced to UTC based on GNSS (Global Navigation Satellite System) time and frequency transfer and TWSTFT (Two-way Satellite Time and Frequency Transfer) system. The GNSS receivers working at the new campus were calibrated by differential method with reference to the receiver calibrated by BIPM. The UTC (NIM) was switched to the new campus officially on October 14, 2012. Since then, UTC (NIM) works normally. The data from BIPM *Circular T* shows that the maximum time difference between UTC (NIM) and UTC is within ±10ns, the time stability is less than 0.6 ns/5d, and the frequency stability is less than 3×10^{-15}/5d.

II. GENERATION OF UTC(NIM)

A. Setup of UTC(NIM)

Fig. 1 shows the block diagram of the UTC (NIM). The whole system consists of atomic clock ensemble, internal measurement system, UTC (NIM) algorithm and international comparison system.

The new atomic clock ensemble consists of 6 hydrogen masers (MHM2010) and 7 Cesium clocks (HP5071A, high-performance cesium beam tube) including 1 Hydrogen maser and 2 Cesium clocks located at the old campus. All the atomic clocks run in the temperature controlled and shielding chambers at both campus, with dual AC power supplies and DC UPS power supplies for protection. The temperature variation of the clock chamber at the new campus is within ±0.5°C.

The internal comparison system is used to measure the time difference between the clocks, the reference time is UTC (NIM). The internal comparison system at the new campus contains a time difference measurement system (multi-channel switch 3499A and time interval counter SR 620) and a dual-mixer time difference (DMTD) measurement system (MMS). The DMTD system has much higher resolution than the counter.

The 1 PPS (Pulse per Second) output of UTC (NIM) is produced by a controlled phase micro stepper (HROG-5). The input reference signal of the micro phase stepper comes from the frequency output of a stable hydrogen maser which is chosen as the reference clock (master clock). And the frequency deviation adjustment of the controlled phase micro stepper is determined by the UTC (NIM) algorithm. A backup UTC (NIM) is also realized at the same time.

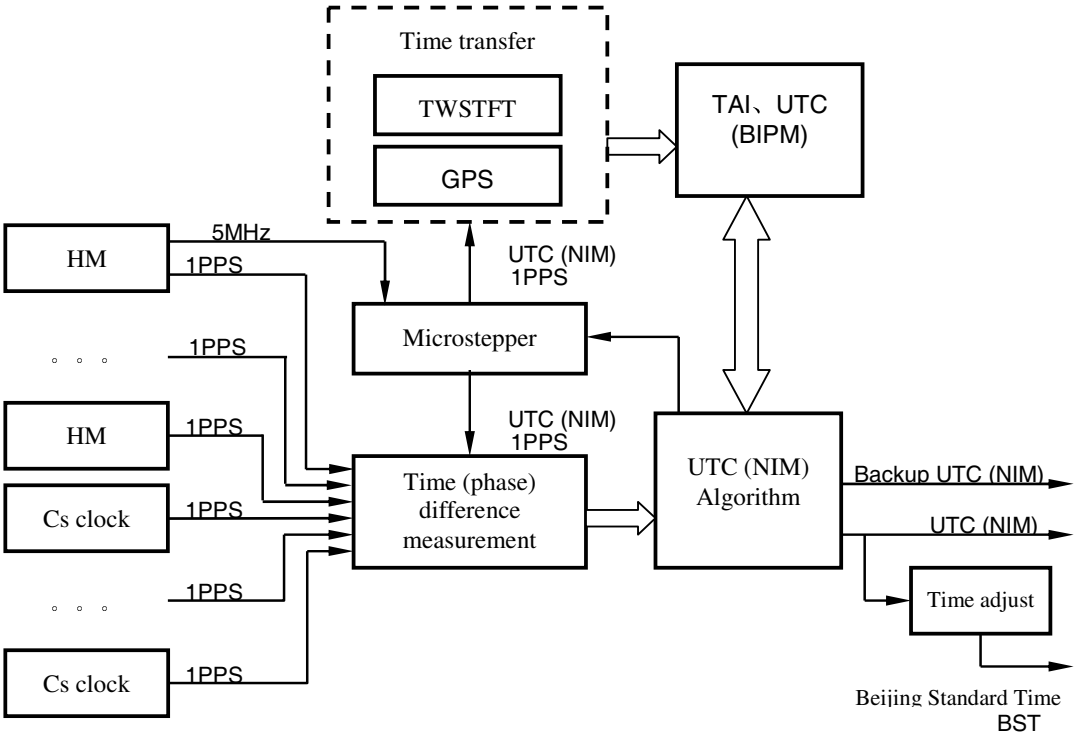

Figure 1. The block diagram of UTC (NIM)

B. Algorithm of UTC(NIM)

Each month the time differences between the UTC and the UTC (*k*) are reported at 5-day intervals together with the uncertainty u_A and u_B in BIPM *Circular T.*

In the generation of a time scale UTC (k), prediction of atomic clock behavior plays an important role and it is inserted in all time scale algorithms [3]. Based on the *Circular T*, extrapolation of values over 10 to 45 days based on prediction models is necessary to many applications.

A rapid realization of UTC named UTCr was realized by BIPM in January 2012; it is published every week and based on daily data reported daily by contributing laboratories. It is disseminated through daily values of [*UTC*r – *UTC* (*k*)] [4]. We can access UTC more frequently by the rapid UTC; UTCr data are used in Algorithm of UTC (NIM).

The UTC (NIM) algorithm has 3 functions, the first function is to make the UTC (NIM) and UTC remain in phase, and implementation steps are as follows.

(1) Get the [UTC - UTC (NIM)] time difference value from *Circular T*;
(2) Get the [UTC(NIM) – the master clock] time difference value from the internal measurement system;
(3) Calculate the [UTC- the master clock] time difference value by step(1) (2), then we will be able to calculate the frequency difference between TAI and the master clock $\Delta f_{TAI\text{-}masterclock}$;
(4) Predict the next $\Delta f_{TAI\text{-}masterclock}$ value through linear fitting and Kalman filtering;
(5) Obtain [UTCr- UTC(NIM)] time difference value;
(6) Work out [UTCr – the master clock] time difference value by the step (2) (5), then calculate the frequency difference between UTCr and the master clock $\Delta f_{UTCr\text{-}masterclock}$;
(7) Estimate the next $\Delta f_{UTCr\text{-}masterclock}$ by linear fitting;
(8) Combine the predicted $\Delta f_{UTCr\text{-}masterclock}$ and $\Delta f_{TAI\text{-}masterclock}$ and used it as the estimated hydrogen maser frequency deviation;
(9) Obtain the final frequency adjustment value by adding the estimated hydrogen maser frequency deviation and the frequency deviation adjustment derived from [UTC- UTC (NIM)] data in *Circular T*;
(10) The frequency of the master clock is steered with the final frequency adjustment value by the phase micro stepper to generate UTC (NIM).

In order to ensure the safety of the time scale, a backup UTC (NIM) is also realized at our new campus. A second Hydrogen maser is used as back up master clock; it is connected to another micro phase stepper which is steered by the UTC (NIM) algorithm.

Thus the second function of the algorithm is to generate the backup UTC (NIM). It is realized in two steps. The first step is to steer the hydrogen maser and make its frequency to be consistent with UTC, which is similar with above (1) to (8). The second step is to make its phase to be consistent with

UTC (NIM), which is similar with the above (9) and (10). At present, the time difference between backup UTC (NIM) and UTC (NIM) is less than 5 ns.

The third function of the algorithm is to monitor the phase and frequency hopping in the system. This function is achieved by measuring the time and frequency difference between the UTC (NIM) and every clock in the clock ensemble.

C. *Time and frequency transfer system*

UTC time transfer is based on two basic techniques: TWSTFT and GNSS [5]. Both GNSS and TWSTFT system were set up at the new campus. GNSS code-based and GPS carrier phase (GPSCP) methods are used to do the time and frequency transfer. At the old campus, GNSS method is used. The 2 Cesium clocks and 1 Hydrogen maser at old campus are linked to UTC (NIM) by GPS, the clock data are also reported to BIPM.

Before Oct.14, 2012, UTC (NIM) is generated at the old campus. One GNSS receiver (IMPR: Septentrio PolaRx2eTR) located at the old campus which contributed data to BIPM was calibrated in the end of 2009 by BIPM. Since then the uncertainty u_B of UTC-UTC (NIM) in *circular T* is approximately 5ns instead of 20ns.

In order to calibrate the GNSS receivers working at the new campus with the differential calibration method, IMPR is used as the reference receiver. A self-developed GPS receiver IMEU was first calibrated with the reference receiver IMPR at the old campus. Shortly After that, IMEU was used as a traveling receiver and moved to the new campus; two GNSS time and frequency transfer receivers including IMEJ (Dicom GTR50) and BJNM (Septentrio PolaRx3eTR) were calibrated reference to IMEU. The calibration setup is shown as in Fig. 2.

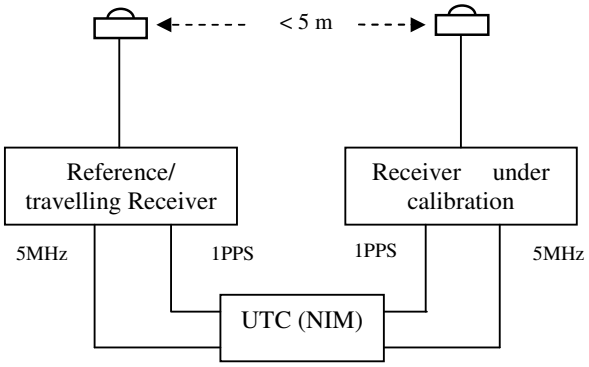

Fig. 2. Setup of receiver calibration

The calibration was finished in April 2012, and the results were reported to BIPM. After the switching, the uncertainty u_B of UTC-UTC (NIM) in *circular T* remains approximately 5ns, and in the same time the uncertainty u_A is reduced to (0.3-0.5) ns.

NIM established TWSTFT station at the new campus in the year 2008 and participated the Europe-Asia TWSTFT link, now the communication satellite is AM2 and the participant laboratories of Europe-Asia TWSTFT link include PTB, TL, NICT, NIM, NTSC, SU and NPLI. According to the measurement results, the 1-day frequency stability between NIM and PTB is less than 3×10^{-15}. The time transfer result between NIM and PTB during MJD56050-56200 by TWSTFF and GPSCP is shown as in Fig 3.The two time transfer results are consistent.

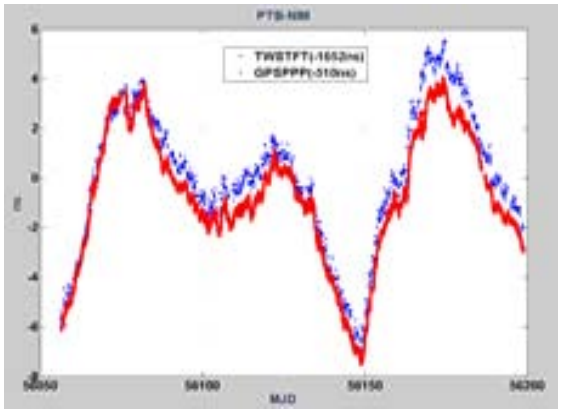

Fig. 3. TWSTFT and GPSCP comparison result between NIM and PTB

III. PERFORMANCE OF UTC(NIM)

The time scale at the new campus was put into test running in the end of 2010, and it was synchronized to the UTC (NIM) at the old campus in May of 2012. UTC (NIM) was switched to the new campus officially on October 14, 2012, since then, the clock data, GPS data and the TWSTFT data are reported to BIPM from the new campus every day.

Figure 4 shows the performance of the UTC (NIM) before and after the switching compared with other 7 UTC (k), including UTC (USNO), UTC (SU), UTC (PTB), UTC (IT), UTC (NIST), UTC (NICT) and UTC (UTSC). Before switching（2012.1.3-2012.10.13）, UTC(NIM) is generated from the old campus, the maximum variation from UTC is within ±15 ns, the time stability is 0.74ns/5d. After switching (2012.10.14-2013.6.26), the maximum variation from UTC is within ±10 ns, the time stability is 0.54ns/5d.

The 5-day time stability and frequency stability of these laboratories are listed in table 1.

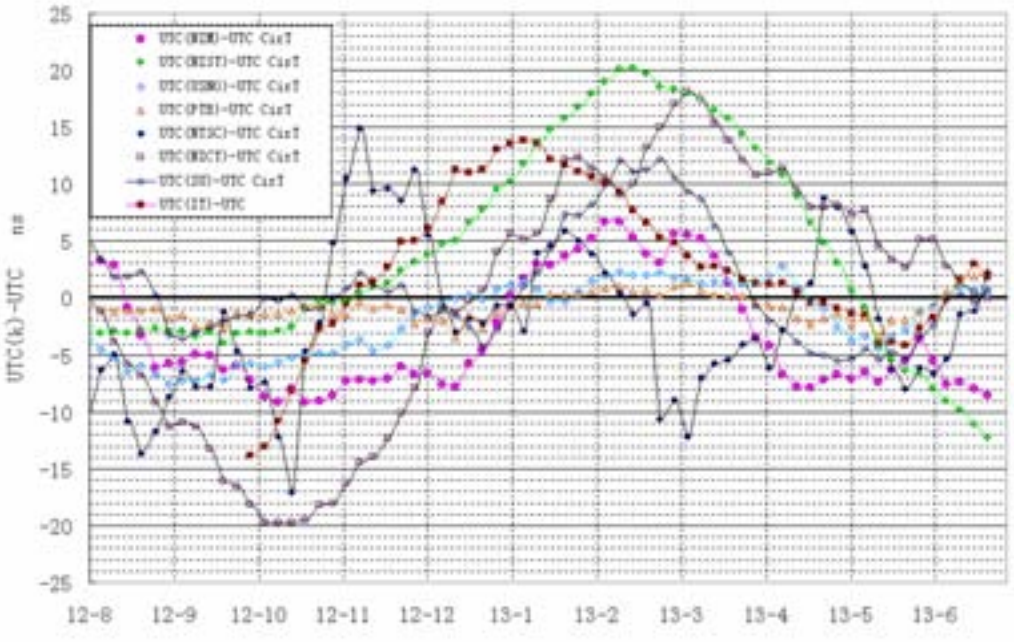

Fig. 3. Performance of UTC (NIM) compared with other 7 labs

Table1
Time and frequency stability comparison(2012.10.14-2013.6.26）

NMI	Time Deviation/5d	Allan Deviation/5d
NIST	0.29 ns	1.2e-15
USNO	0.34 ns	1.5e-15
PTB	0.46 ns	2.0e-15
IT	0.46 ns	1.9e-15
NIM	0.54 ns	2.2e-15
SU	0.61 ns	2.4e-15
NICT	0.68 ns	2.7e-15
NTSC	1.93 ns	7.9e-15

IV. CONCLUSION

UTC (NIM) has been reconstructed at NIM's new campus and the data has been reported to BIPM officially since Oct.14, 2012, a stable Hydrogen maser is selected as the master clock, and UTC (NIM) is generated from a micro phase stepper steered by a new algorithm and UTC, a backup UTC (NIM) is also realized. The data in BIPM Circular T shows that the time deviation of UTC (NIM) from UTC is within ±10 ns. In order to increase the reliability of UTC (NIM), at present an algorithm based on a Hydrogen maser ensemble is under development at NIM.

Predicting The Polish Timescale UTC(PL) Based On The Corrections Designated By The UTC And UTCr Scale

Łukasz Sobolewski
Institute of Electrical Metrology
University of Zielona Góra
Zielona Góra, Poland
e-mail: L.Sobolewski@weit.uz.zgora.pl

Abstract— **The article presents the results of research on the prediction of the Polish timescale UTC(PL) based on the corrections designated according to UTC and UTCr scale. In both cases for prediction the GMDH neural networks and time series analysis method were used. For predicting the UTC(PL) the influence of the input data preparation method for the GMDH neural network was examined. The obtained results were compared with the predictions designated using linear regression method. Better results of predicting the UTC(PL) were obtained using GMDH neural network. The most preferred results have been obtained for the input data containing only the corrections designated by the UTCr scale.**

Keywords-GMDH neural networks; Polish timescale UTC(PL); Rapid UTC; atomic clock

I. INTRODUCTION

In Poland, the organization responsible for maintaining the national time scale UTC(PL) is the Central Office of Measures (GUM, *pl.* Główny Urząd Miar). It uses a 5071 A cesium atomic clock and a device (Microstepper Austron 2055), which enables corrections to be made to ensure the maximum compatibility of the UTC(PL) with the UTC [3, 6].

The problem of maintaining the highest compliance of the UTC(PL) with the UTC is due to a delay in publication of the corrections designated for a given month with a five-day interval by the International Bureau of Weights and Measures (BIPM, *fr.* Bureau International des Poids et Mesures). These corrections defines the divergence of the national timescales in relation to the UTC and are generally published between the 8^{th} and 12^{th} day of the following month. Therefore, the problem of maintaining the highest compliance of the UTC(PL) with the UTC in the current month can be solved only by predicting the corrections.

The GUM uses the laborious procedure of predicting the corrections based on the analytical linear regression method, which requires a lot of metrological experience form the person who performs the analysis [3]. For predicting the corrections for the UTC(k) can also be used other analytical methods such as linear regression method with stochastic differential equations [11], an analytical method using Allan deviation [1], or a method based on Kalman filter [4].

Other approach for creating simulated time scale is shown in [7]. It involves the prediction of the simulated scale NRT (neural-fuzzy reference timescale), based on the 48 clocks of four laboratories (Japan, China, Korea, and Taiwan) compared with TWSTFT method, using ANFIS system (adaptive network-based fuzzy inference system). Results show that the difference between UTC and NRT do not exceed ±5 ns.

Institute of Electrical Metrology of the University of Zielona Góra, in collaboration with GUM has been running research on the application of neural networks in predicting the corrections for the UTC(PL). The obtained results of the research suggest the possibility of using the MLP and RBF networks [6, 8] for predicting the corrections for the UTC(PL). A disadvantage of this type of neural networks is the long duration in obtaining a result for the prediction. This stems from the need to match the appropriate network structure and number of neurons to the nature of the data provided on its entry in the training process.

In order to eliminate this problem in further research the GMDH neural network were used, which uses the group method of data handling and belong to the self-organizing networks. GMDH network structure is formed automatically on the basis of prepared training and testing data sets. In the course of the training process, the network expands and evolves until the enhanced efficiency of its operation has been achieved [5]. Until a new layer of neurons is attached to the current structure of the network, elements of the new layer are subjected to selection for accuracy of processing. Neurons that do not meet the criterion for assessing the condition imposed, i.e., the processing error is too large, are eliminated from the structure of the network.

The first obtained results shows that the corrections designated by the GMDH neural network provide better compatibility of the UTC(PL) with the UTC, than the corrections received in the GUM. The results of these research are presented in [9]. It decided to carry out further research on predicting the corrections for the UTC(PL) using GMDH neural network.

The results shown in the article concern on predicting the Polish timescale UTC(PL) based on the corrections designated by the UTC and UTCr scale. In both cases of predicting the corrections for the UTC(PL) the commercial tool GMDH Shell 2.2 and time series analysis method was used

II. Predicting The UTC(PL) Based On The Corrections Designated By The UTC Scale

The basis for preparation of the input data set for the GMDH neural network, as in the linear regression method used in the GUM, were the two groups of historical data available from 1 January 2006 (MJD 53736) to April 2010 (MJD 55299) (MJD - Modified Julian Date). The first of these were the results of measurements of phase time $x\_a(t)$ between the 1pps signals (pulse per second) of the UTC(PL) and atomic clock realizing the UTC(PL) scale [6], determined for each day according to relation

$$x\_a(t) = UTC(PL) - clock. \quad (1)$$

The second group of data were the corrections $x\_b(t)$ determined by the BIPM for the UTC(PL), which are designated on the MJD days ending with the digit "4" or "9", according to the relationship

$$x\_b(t) = UTC - UTC(PL). \quad (2)$$

Using MATLAB's polynomial interpolation function PCHIP (Piecewise Cubic Hermite Interpolating Polynomial) for the data set from the BIPM, a mathematical model was determined, which permitted an extension of the training data set by calculating the values of the corrections for the UTC(PL) relative to UTC for each day of the analysed period of time. This action made it possible to increase the number of data provided at the input of the GMDH neural network.

The final data set, which is the basis for determining at each day the input data for the GMDH neural network, was calculated according to the formula

$$x(t) = x\_a(t) + x\_b(t) = UTC - clock. \quad (3)$$

The data set calculated from relation (3), called time series (ts1), was the first set of data for which the training process of GMDH neural network and prediction of correction values for the UTC(PL) was performed. Time series ts1 contains a linear trend component $x_r(t)$ and a variable component. Therefore, for the training process of the GMDH neural network and predicting the corrections for the UTC(PL), also the second time series (ts2) was prepared. Such an approach was dictated by the small values of deviations from trend, which may cause that the neural network will adopt the trend as an important piece of information in the training process, and this may affect the deterioration of the prediction results of the UTC(PL). However inputting data represented by time series ts2 to the GMDH neural network will cause the network training process to adopt a model that describes the deviation from the trend. The final form of time series ts2 was obtained via elimination from the time series ts1 a long-term trend of the phase-time changes $x_r(t)$ described with the linear regression equation. The various components of time series ts2, formed by the values of the deviations from the trend, were calculated from the relation

$$xd(t) = x(t) - x_r(t). \quad (4)$$

A detailed description of the time series ts1 and ts2 preparation is shown in [8, 10].

Predicting the corrections for the UTC(PL) was made on the 15th day of the month for 28 consecutive months from January 2008 (MJD 54479) to April 2010 (MJD 55299). In course of the research at the input of the GMDH neural network the data vectors were given prepared on the basis of time series ts1 and ts2. At the output of the neural network a prediction was obtained, on the same day as in the GUM. In the predicting process the prediction value x_p for the time series ts1 was designated, and on this basis in the next step the correction value $(\text{UTC-UTC(PL)})_p$ was calculated. This prediction represents the value of correction needed to correct the UTC(PL) in order to ensure the best compatibility of the UTC(PL) with the UTC. In the case of time series ts2 the first step, using GMDH neural network, was to designate the prediction value of the deviation from the trend xd_p, which was next added to the prediction value of the trend calculated using a regression equation. The obtained result was the sought value of the prediction x_p. Further calculations aimed at achieving the value of predicted correction were carried out similarly as for the time series ts1 [10].

The research results shown in the article are presented as the prediction error (Δ_1), determined according to the relationship

$$\Delta_1 = (UTC - UTC(PL))_p - (UTC - UTC(PL))_{CIRT}. \quad (5)$$

It is the difference between the predicted value of the UTC(PL) correction relative to the UTC, and the value of the correction read from the "Circular T" bulletin for the day of determining the prediction.

For each of the predicting methods the parameters of the GMDH neural network were selected individually for each day of prediction, so that the obtained prediction error Δ_1 was as small as possible.

Fig. 1 shows the prediction errors obtained for time series sc1 and sc2, which were compared with the values of prediction errors obtained in the GUM using linear regression method.

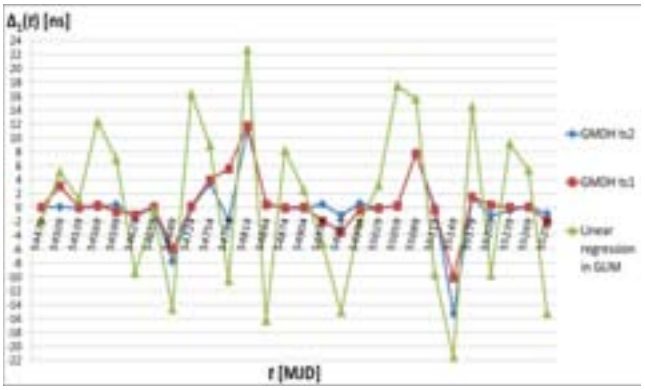

Fig. 1. Prediction errors in predicting the corrections for the UTC(PL).

In the case of determining the corrections for the UTC(PL) it can be noted that the method of preparation of both time series (ts1 and ts2) has little effect on the results of predicting. The obtained prediction errors in the analyzed period of 28 consecutive months are much smaller than the prediction errors obtained in the GUM. In the worst cases i.e., for the prediction day MJD 54814 for time series ts1 and MJD 55149 for time series ts2, the prediction error using time series analysis method, for times series ts1 was 11.73 ns, and for times series ts2 -15.23 ns. For the same days of prediction the prediction error obtained in the GUM using linear regression method, was also the highest and was respectively 22.7 ns and -21.5 ns.

Predicting the corrections for the UTC(PL) using GMDH neural network can also be performed using regression method. The results presented in [10] shows that using GMDH neural network and a regression method generates prediction errors of greater value than the time series analysis method.

III. Predicting The UTC(PL) Based On The Corrections Designated By The UTCr Scale

As already mentioned the problem of maintaining the best compliance of the UTC(PL) with the UTC is due to a delay in publication of the corrections designated by the BIPM. To remedy this situation on the 1st of January 2012 the BIPM has launched a pilot project called a Rapid UTC. The main idea is to expedite the transfer of information about the differences between national timescales, including UTC(PL) and UTC. Based on data transmitted daily from clocks and time transfer systems to the BIPM it is possible to designate a weekly sub-scale UTC Rapid (UTCr). Based on a designated scale UTCr every Wednesday on the BIPM ftp server the corrections for the last week defined for each day are published for each clock which realizes the UTC(k) scale [2]. Analysis of the published corrections for the Polish timescale UTC(PL) according to UTCr scale (UTCr-UTC(PL)) and UTC scale (UTC-UTC(PL)), showed little differences between received corrections, of a few ns. This meant a more accurate prediction of the corrections for the UTC(PL) and, consequently achieves better stability and compatibility of the UTC(PL) with the UTC. The advantage of this solution is also a smaller, three-day, delay in the publication of the corrections according to the UTCr scale. These facts were decisive in the initiation of research on predicting the corrections for the UTC(PL), using GMDH neural networks, based on previous known values of UTCr-UTC(PL) corrections.

In order to ensure the sufficient training data set for the GMDH neural network a basic set of data containing values of UTC-UTC(PL) corrections for the period from 1 February 2012 (MJD 55958) to 31 August 2012 (MJD 56170) was prepared. For the prepared data set, similarly as in predicting the UTC(PL) based on the corrections designated by the UTC scale, the PCHIP function was used to obtain the values of UTC-UTC(PL) corrections for each day of the analysed period of time. The rest of the training data for the GMDH neural network, attached to a basic set of data, were prepared in two ways. The first method of data preparation assumed adding to the basic set of data, after 31 August 2012, only the UTCr-UTC(PL) corrections. In the second case, added to the basic training data set of corrections were the UTC-UTC(PL) corrections for the last month, after the publication of the BIPM, and the UTCr-UTC(PL) corrections available in the month of determination of the correction for the UTC(PL). For the UTC-UTC(PL) corrections too, the PCHIP interpolation function was used to obtain the values of corrections for each day of the analysed period of time. Preparing two additional sets of data was aimed to examine how preferable will be the use of the UTC-UTC(PL) corrections in relation to the UTCr-UTC(PL) corrections.

At the input of the GMDH neural network, data vectors were given prepared according to the first or the second method. At the output of the neural network the $(UTCr-UTC(PL))_p$ predicted correction was obtained. However, presented results represent the prediction error determined according to the relationship

$$\Delta_2 = (UTCr - UTC(PL))_p - (UTC - UTC(PL))_{CIRT}. \quad (6)$$

This error is the difference between the predicted value of the (UTCr-UTC(PL))p correction, and a value of the UTC-UTC(PL) correction read from the "Circular T" bulletin.

BIPM designate the UTC-UTC(PL) corrections on the MJD days ending with the digit "4" or "9", so it was assumed that the predictions will be determined on the same days.

For comparison, there are also calculated the prediction errors designated according to the formula

$$\Delta_3 = (UTCr - UTC(PL)) - (UTC - UTC(PL))_{CIRT}. \quad (7)$$

They define the difference between the UTCr-UTC(PL) correction read from the BIPM's ftp server, with the value of the UTC-UTC(PL) correction read from the "Circular T" bulletin on the same day of the prediction.

On fig. 2 and fig. 3 are presented the obtained prediction errors (Δ_2 and Δ_3) for the first and the second method of input data preparation. Also the prediction errors (Δ_1) obtained in the GUM using linear regression method are presented.

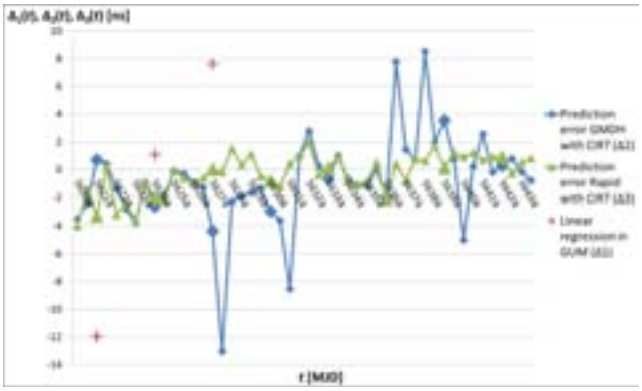

Fig. 2. Prediction errors in predicting the corrections for the UTC (PL) according to the first method of data preparation.

The obtained results (Fig. 2) indicate a correct prediction of the corrections by the GMDH neural network. The obtained prediction error values in the most cases are at the level of prediction error values Δ_3 calculated from the formula (7). The maximum prediction error obtained for the prediction day MJD 56279 is -13.03 ns. The value of this error results from a large

change in trend direction of the UTCr corrections. In other cases, the prediction errors are in the range of ±10 ns.

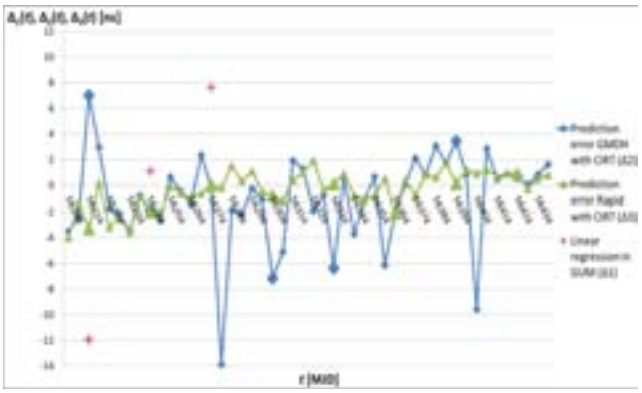

Fig. 3. Prediction errors in predicting the corrections for the UTC (PL) according to the second method of data preparation.

Fig. 3 presents the prediction errors (Δ_2) obtained for the second method of input data preparation for the GMDH neural network. In this case the obtained prediction error values cover a much greater range than the prediction error values Δ_3 obtained from the data from the BIPM. The highest value of the prediction error, equal to -13.9 ns, was also obtained at MJD 56279. The value of this error is also due to the large change in trend direction of the UTCr corrections.

On fig. 2 and fig. 3 shown with enlarged markers are presented the prediction errors occur on the 15th day of the month, so on the same day as the predictions obtained in the GUM using linear regression method. In the case of the first method of data preparation the prediction errors are in the range of ±5 ns, and for the second method ±8 ns.

IV. CONCLUSIONS

Carried out a series of first studies on the prediction of the Polish timescale UTC(PL) based on the corrections designated by the UTC and UTCr scale, indicates that the lower values of prediction error were obtained using the prediction based on the corrections designated by UTCr scale for the first method of input data preparation for the GMDH neural network. This is due to the fact that the publication of the UTCr corrections is delayed by up to three days, compared to the dozen days delay in publication of the corrections in the "Circular T" bulletin. This means the better quality of prediction of the Polish timescale UTC(PL) based on the corrections designated by the UTCr scale, because it is made for shorter period of time, than in the case of predicting the UTC(PL) based on the corrections designated by UTC scale. In the case of using UTCr scale the first prediction of the correction for the UTC(PL) in the following month could be designated between 1st and 10th day. Further predictions of the corrections for the UTC(PL) are designated based on new training data for the GMDH neural network. However, in the case of application of the UTC scale the first result of the prediction is available on the 15th day of the following month. Predictions of the corrections for the UTC(PL) for the consecutive days are designated based on the same training data set for the GMDH neural network.

In addition, an advantage of the Rapid UTC project is the fact that the UTCr corrections are calculated for each day. Thus there is no need to use the PCHIP functions to extend the data set for each day of the analysed period of time, as in the case of UTC-UTC(PL) corrections.

The obtained results showed that the GMDH neural networks can be used to predict the Polish timescale UTC(PL). The application of the commercial tools GMDH Shell version 2.2 allows to obtain lower values of prediction error, than when using linear regression method used in the GUM.

Abstract—**In order to produce collective SC-cut quartz resonators on 4’’ wafers, we use a Finite Element Analysis software to model and simulate new resonator design. The modeling allowed us to optimize the geometrical and the physical parameters of the prototypes. These resonators are encapsulated under vacuum to not damage their performances. Knowing that a structure with radius of curvature is hardly compatible with collective fabrication, we have realized plano-plano structure working at 14 MHz.**

Keywords: Quartz, Piezoelectric resonator, Bulk Acoustic Wave, Finite Element Method, Quality factor

I. INTRODUCTION

In the light of modern computer modeling, innovative processes and a multidisciplinary approach of research and industry, our project (for more details, see [1]) has been proposed to revisit designing low-cost miniaturized quartz resonators without compromising on the performance characteristics. A lower cost of manufacturing induces collective processes. So, we achieved 4’’ wafers (standard of microelectronics) in which our prototypes will be cut. To insure the best of them, each of these resonators will be encapsulated under vacuum thanks to a procedure of wafer bonding (quartz on quartz). Our study focuses on a flat plate vibrating at 14 MHz on the 3rd overtone of the C-mode. Thanks to Finite Element Method (FEM) software, we are able to find optimal geometrical and physical parameters of the resonators, as well as their characteristics (motional parameters, Q factor …).

II. QUARTZ WAFER SPECIFICATION AND CHARACTERISATION

A. Required physical parameters

The cutting process of 4 inches quartz wafers, SC-cut oriented, requires very big blocks of quartz crystal. If we want to cut the wafers only in pure Z-zone (i.e. on each side of seed), we have to initiate the growth from seeds with its dimension along X-axis equal at least to 100 mm. In the contrary, we must settle for smaller seeds and some resonators defined partially in “+X” and “–X”-zones. But, in all cases, we must avoid the seed which crosses the middle of the wafer. So, we have worked on wafers extracted from blocks whose the dimensions are the following:

100, 120 and 86 mm along X, Y and Z respectively
(corresponding to the blue square on the Fig. 1).

The red rectangle, meanwhile, defines the seed whose the length should be greater than 180 mm if we do not want to obtain truncation on the parallelepiped.

Fig. 1: Quartz block for 4 inches wafer

So, in the first “blue” parallelepiped, we cut another quasi-cube defined by the first angle Phi with a rotation around the Z-axis (as indicated in the Fig. 2). Its dimensions are about: 85, 106 and 86 mm along X’, Y’ and Z respectively.

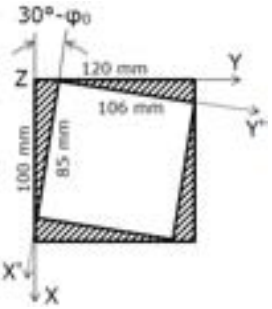

Fig. 2: First block set from the first cutting angle

Finally, a maximum of 20 to 25 slices are cut into the last block (see Fig. 3), and then cut circularly (with a diameter of 100 mm) without forgetting the orientation marks determining the directions of X’’ and Z’’.

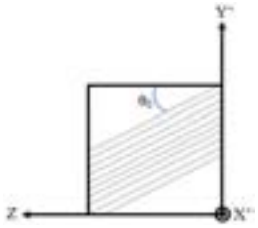

Fig. 3: Cutting process of the slices (second angle)

For these beveled wafers, we ask for physical parameters as:

- thickness of 380 µm +/- 10 µm
- TTV (Total Thickness Variation) better than 5 µm
- and surface roughness corresponding to a polish state (with Ra of the order of 10 nm).

B. Orientation checking and influence on the frequency curve temperature of the C-mode, 3rd overtone

The orientation of such a wafer is directly linked to the position of the turnover point (TOP) of the frequency temperature curve of the C-mode, 3rd overtone (i.e. the operating temperature of the oscillator). It is generally fixed to 75 +/- 5°C. So, we need the accuracy with which each area (corresponding to the vibrating zone of each resonator) is oriented, better than +/- 1'. Indeed, as shown in the following Fig. 4, a variation of 1' of the θ angle induces a variation of about 8°C (it means +/- 4°C around 75°C) of the first TOP of the frequency versus temperature curve.

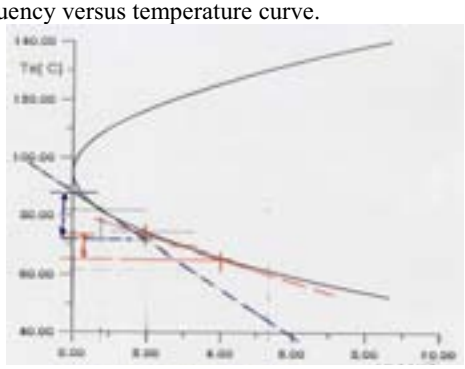

Fig. 4: Influence of the cutting angles on the TOP
1' of θ-angle corresponds to 8°C around 75°C

After cutting one wafer in 16 squared samples, we have checked the orientation of each small area. For the θ-angle, we obtain a range of measures of +/- 1'10'' around θ_0 and +/- 1' around φ. Such an angular deviation between 2 consecutive resonators corresponds to a deflection of about 5 µm. So, our requirements are achieved.

III. Finite Element Analysis

A. Physical description

The resonator is a plano-plano disc whose the vibrating part can be isolated from the dormant one by "bridges" (adequately oriented) or by a groove as shown in the Fig. 6a and 6b. Its dimensions are 15.75 x 15.75 mm and its thickness 1.14 mm (3 times 380 µm). The diameter of the active part is 13.55 mm.

The caps, dug in the center, are bonding around on each side of the resonant plate. The bonding processes are realized at different temperatures, the first one at the higher temperature (about 430 °C) while the second one is sealed at 350 °C. The applied pressure is estimated at about 150 N.

The following figure (Fig. 5a and 5b) are photographs of the glass frit deposition on one caps-wafer defining the 16 resonators and a detail of one resonator on which we see the drilling of the via and the digging of the cap.

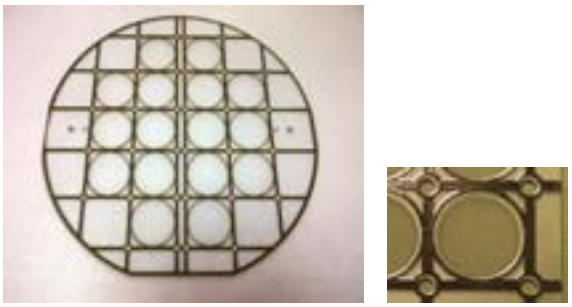

Fig. 5: 4'' caps-wafer and detail of one cell

Once the resonator encapsulated, it is clamped by 2 clips in opposite corners, corresponding to the metallization.

B. Modeling

The Finite Element Method software used is COMSOL Multiphysics®. Part of computations have been performed on the supercomputer facilities of the "Mésocentre de calcul de Franche-Comté". The squared resonator, as described in Fig. 6a, is meshed as shown below (Fig. 6b):

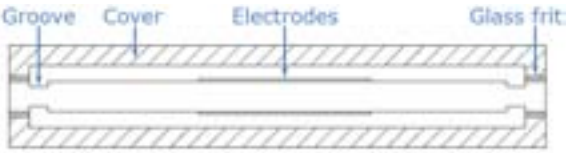

Fig. 6a: Schematic diagram of the resonator

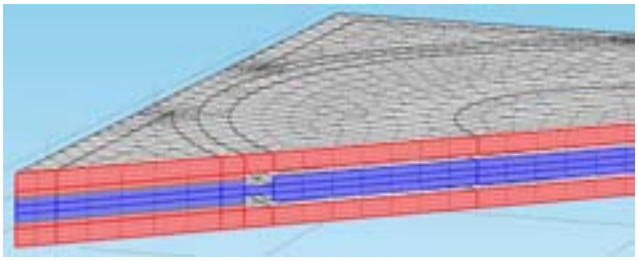

Fig. 6b: Mesh of the complete resonator with groove

The electrical potential is applied by the mean of circular gold electrodes with a diameter of 6.4 mm and a thickness of 185 nm. It is very small compared to that of the resonator. So, they are replaced by boundary load conditions in order to avoid a possible discontinuity of mesh. They are:

$$\sigma_i\ [N.m^{-2}] = \rho.h.\omega^2.u_i$$

where ρ is the density, h the thickness of the electrodes, ω the angular frequency and u_i the displacements.

We introduce the tensor of viscosity constants η_{ij} measured by Lamb and Richter [2] in the elasticity matrix of the blank to evaluate the acoustic losses.

$$C_{ij} + j\omega.\eta_{ij}$$

As for electrodes, the thin layers of glass frit between the central wafer and the 2 covers are not meshed. And so, the dissipation of energy through the glass frit and the covers is replaced by Rayleigh damping [3 - 4] in the caps, inducing imaginary part on the constitutive constants.

$$\xi = \frac{1}{2}\left(\frac{\alpha_{dM}}{2\pi f} + \beta_{dK} 2\pi f\right)$$

$$\alpha_{dM} = \omega/Q_R \text{ and } \beta_{dK} = 0$$

where ξ is the damping factor, α_{dM} and β_{dK} are the mass and stiffness damping parameters, respectively and Q_R is the estimated quality factor. Otherwise, we decide to neglect the clamping of the resonator in 2 opposite corners because they are far from the vibrating area.

IV. Determination of the Quality Factor

To visualize the electrical response of the system, an harmonic analysis is performed. The table 1 presents the frequency spectrum of the resonator in the range 14 to 14.5MHz, together with the motional resistance of each anharmonics.

	C300	C320	C302	C340	C322	C304
f [kHz]	14.233	14.263	14.271	14.321	-	14.330
Rm (Ω)	30	4,280	760	35,000		39,500

Table 1: Frequencies of the anharmonic modes

whereas the resonant frequency of the B300 (which is B-mode 3rd overtone) is 15,620 kHz with a motional resistance of 18 Ω. The C322 mode of vibration has been not found.

This modal spectrum allows us to observe the existence of several vibration modes at different resonant frequencies. We note the presence of modes, called anharmonic or sometimes spurious, after the "main" resonance. All of these modes depend on the geometry of the resonator and its orientation in the crystal frame. We note, at least, that the fastest thickness-shear mode (the B one) is 9.7% higher than the slowest one (named C), which is close to the experience (9-10%).

A. Method of calculation

The determination of the quality factor is performed by computing the electrical parameters of the resonator. This step is done with the method reported in [5]. To calculate the quality factor of a tuning fork resonator, the authors used the equivalent electrical model of quartz resonator (Fig. 7) and the complex admittance. The top electrode is set to 1 V while the bottom electrode is grounded. In this way, the value of the admittance of the system will be equal to the value of the current at the top electrode.

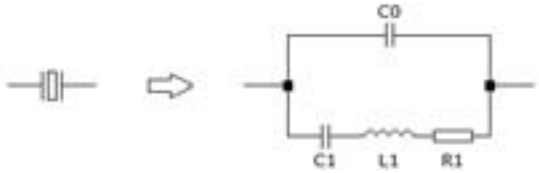

Fig. 7: Butterworth-Van Dyke model of quartz resonator

The conductance (noted G), is the real part of the admittance, while the imaginary part (noted B), is the susceptance.

$$Y = G + jB$$

The electrical parameters of the equivalent model are determined by solving the following equations:

$$B_1 = B - \omega C_0$$

$$R_1 = \frac{G}{G^2 + B_1^2} \quad ; \quad X_1 = \frac{-B_1}{G^2 + B_1^2}$$

$$\left[\frac{dX_1}{df}\right]_i = \frac{[X_1]_{i+1} - [X_1]_{i-1}}{f_{i+1} - f_{i-1}}$$

$$L_1 = \frac{1}{4\pi}\frac{dX_1}{df}\bigg|_{f=fs}$$

$$C_1 = \frac{1}{4(\pi f_s)^2 L_1} \quad ; \quad Q = \frac{1}{2\pi f_s C_1 R_1}$$

In these equations, B_1 is the susceptance of the motional branch and X_1 its reactance. The value of the static capacitance C_0 is obtained by performing an electrostatic analysis of the quartz plate.

As the parameters R_1, L_1, C_1 and Q slightly vary with the frequency, a large spectrum and small frequency increments are not necessary. So, the time and the quantity of memory used for the frequency response analysis are low.

B. Results

Firstly, we focus our study on the 3rd overtone of the C-mode, vibrating at about 14 MHz. The variations of Q and R_1 versus Q_R have presented in the following figure (Fig. 8) and compared to those of the B-mode (Fig. 9).

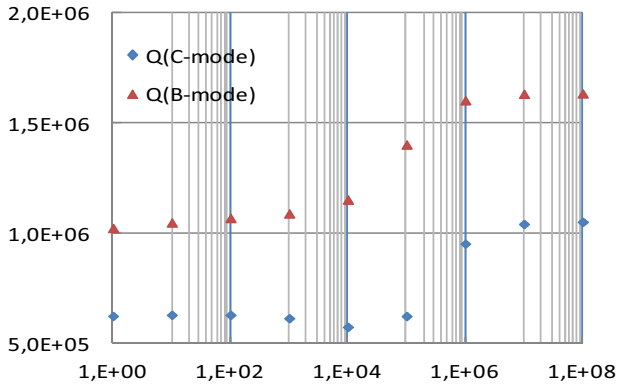

Figure 8: Variations of Q-factor vs. Q_R for B and C-modes

On each curve of the Fig. 8, we observe 2 levels at their 2 ends. For small values of Q_R (corresponding to the clamping infinitely rigid), the Q-values are the smallest. In contrast, it tends to the Q-value yet calculated without damping and equal to 1.05 million for the C-mode. In this case, the model based on the use of the Rayleigh damping is less than 1% of the calculated value without damping.

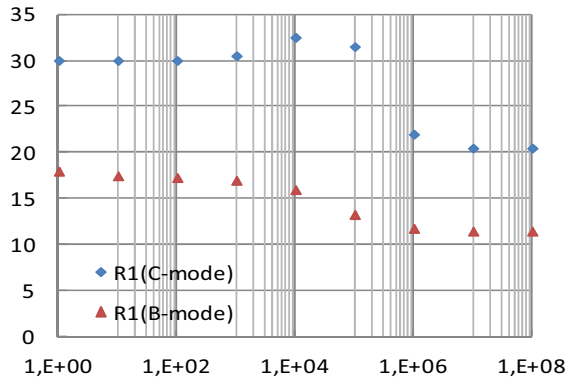

Fig. 9: Variations of R_1 (in Ω) vs. Q_R for B and C-modes

The mean values for L_1 and C_1 of the C- and B-modes are, respectively: L_1 = 220 mH, C_1 = 0.57 fF and L_1 = 190 mH, C_1 = 0.55 fF.

V. Comparison with Measures

Sixteen prototypes were realized on a 4" wafer (as shown in the Fig. 10). Only 6 of them have been sealed without defects or leaks due to the bonding process, not yet completely achieved. One, the number 2, has been broken. The measurements on the C-mode for the 5 others numbered as indicated below are summarized in the Table 2:

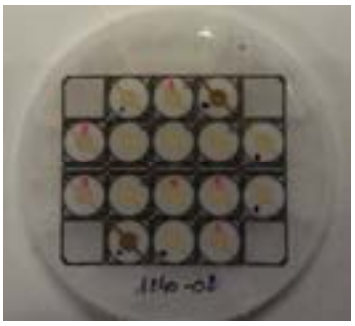

Fig. 10: Prototypes on 4" wafer

Piece	1	3	4	5	6
R_1 [Ω]	25.6	32.6	31.2	31.5	32.6
L_1 [mH]	196	225	200	197	197
Q [k]	686	622	576	559	541
C_1 [fF]	0.64	0.56	0.62	0.64	0.63

Table 2: Electrical parameters for C-mode

where C_1 is calculated with: $L_1.C_1\,\omega^2 = 1$

The same measurements were realized on the B-mode for the five prototypes. The results are summarized in the following table:

Piece	1	3	4	5	6
R_1 [Ω]	22	24.1	31.2	24.2	22.5
L_1 [mH]	174	170	200	185	175
C_1 [fF]	0.60	0.61	0.52	0.56	0.60
Q [k]	773	691	576	750	762

Table 3: Electrical parameters for B-mode

The number 1 is largely better than the others (Q-value close to 0.7 million for C-mode). With reference to the C-mode, the clamping is well modeled when Q_R is less than 10^{+5}. In contrary, the mean Q-value measured for the B-mode 3rd overtone is lower than the worst calculated value. We suppose that other damping cause can affect the B-mode, more than the C-mode, and particularly the damping due to the surface roughness under the electrodes.

At least, we can see that the experimental values of the inductance L_1 and the capacitance C_1 are very close to the computations: difference of 8% for C-mode (4% when Q_R is less than 10^{+5}) and 5% for B-mode.

VI. Conclusion

In the goal to realize collective SC-cut quartz resonators, Finite Element Method help us to find the optimal characteristics of the prototypes such as motional parameters, Q factor … After checking that the SC-cut 4 inches wafers are consistent with our requirements, we have implemented a manufacturing process that allowed us to get resonators whose the specifications are also consistent to our model. Indeed, on the C-mode, we have observed a good agreement between the experimental results and those obtain with FEM software (difference less than 10%). However, the results obtained for the B-mode show a discrepancy on the Q factor, probably due to parameter which is not taken into account in our model. The inclusion of other factor (like surface roughness) will allow us to improve our model, especially for the B-mode.

Acknowledgment

This work was funded by the "Agence Nationale de la Recherche" in the framework of a French research project entitled "FREQUENCE2009".

We thank KRYSTALY, a Czech company for delivery the SC-cut 4" wafers.

***Abstract*—As part of the current drive to engineer minitureized monolithic high performance microelectromechanical enabled oscillators there is a need for further study of frequency fluctuations in microelectromechanical resonators. To facilitate this we consider the measurement of frequency fluctuations using a vector network analyzer and demonstrate the utility of this approach using an aluminum nitride contour-mode resonator. We examine a generalized quasi-static model as well as a more detailed dynamic model and compare one- and two-port measurement setups.**

***Keywords*—Frequency fluctuation, phase noise, vector network analyzer, aluminum nitride contour-mode resonator.**

I. Introduction

In order to engineer high performance and low phase noise oscillators it is essential to understand the frequency fluctuations present in the resonator. These fluctuations contribute directly to the phase noise of the closed-loop oscillator and set the lower bound of achievable phase noise levels in any oscillator where the resonator serves as the frequency reference [1], [2]. Unlike phase noise arising in the amplifier, resonator frequency fluctuations cannot be evaded by employing bending in the frequency response found in Duffing and similar nonlinear resonators.

Frequency fluctuations in quartz acoustic resonators have been studied in great detail [3]. The stability of microelectromechanical (MEMS) resonators has also been studied [5], though to a lesser extent. As part of the present drive to engineer miniturized and monolithic high performance MEMS enabled oscillators there is a need for further study of frequency fluctuations in MEMS resonators. To facilitate this we consider the measurement of frequency fluctuations using a vector network analyzer (VNA) and demonstrate this method using an aluminum nitride contour-mode resonator.

Interferometric techniques for measuring resonator frequency fluctuations, such as the single and dual resonator bridges, have long been standard practice [2], [4]. High performance tools designed for this purpose (e.g. R&S FSUP OR NXA-26) are application specific and can be costly. The VNA, however, is a general purpose interferometric measurement tool that is commonly already a part of any RF laboratory's toolset. The VNA can be used in lieu of more specialized equipment provided it is equipped with continuous wave or time-domain measurement capability. The precision of the VNA measurement naturally depends on the instrument's noise floor. This can controlled to some extent by adjusting the bandwidth of the intermediate filter (IF). The tradeoff is that lowering the IF bandwidth decreases the measurement noise but also decreases the highest offset frequency that can be reached with the measurement.

The remainder of this paper is arranged as follows. In section II we discuss the principle of the measurement using a general quasi-static model. In section III we examine the measurement using a more detailed, but less general, dynamic model; an RLC series resonator. In section IV we demonstrate the measurement of frequency fluctuations in an aluminum nitride contour-mode resonator and follow up with conclusion in section V.

II. Quasi-Static Measurement Analysis

In this section we present a general, although simplistic, quasi-static analysis of frequency fluctuation measurement using the VNA. We consider the one-port measurement of a resonator with reflection coefficient Γ. This analysis can easily be generalized to a two-port measurement by replacing Γ with the s_{21} scattering parameter. The VNA port emits an outward traveling wave with complex amplitude a. The received wave will have complex amplitude b given by

$$b = \Gamma a. \tag{1}$$

When the device is driven near resonance we can expand the reflection coefficient in the frequency detuning

$$\Gamma = \Gamma_0 + \Gamma_1(\Omega - \omega_0), \tag{2}$$

where Ω is the drive frequency and ω_0 is the resonant frequency. The phase of the reflection coefficient is

$$\angle\Gamma = \tan^{-1}\left(\frac{\mathrm{Im}[\Gamma_0 + \Gamma_1(\Omega - \omega_0)]}{\mathrm{Re}[\Gamma_0 + \Gamma_1(\Omega - \omega_0)]}\right), \tag{3}$$

$$\approx \angle\Gamma_0 + \frac{\mathrm{Im}[\Gamma_0^*\Gamma_1]}{|\Gamma_0|^2}(\Omega - \omega_0), \tag{4}$$

This material is based on work supported by the Defense Advanced Research Project Agency under the MTO-DEFYS program, award # FA86501217264.

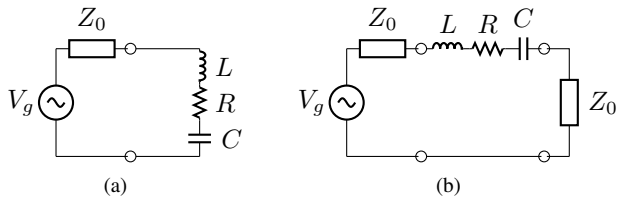

Fig. 1: One- (a) and two- (b) port RLC measurement models.

where we have expanded to leading order in $\Omega - \omega_0$. The sensitive of the phase to the frequency detuning $(\Omega - \omega_0)$ is

$$\frac{\mathrm{Im}[\Gamma_0^* \Gamma_1]}{|\Gamma_0|^2} = \frac{\partial \angle\Gamma}{\partial\Omega}\bigg|_{\omega_0}. \tag{5}$$

Now we suppose that both the drive frequency and the resonant frequency fluctuate in time. In addition, we assume that the fluctuations in the drive frequency and resonant frequency are uncorrelated. Using the VNA in continuous wave mode to drive the resonator at resonance ($\langle\Omega\rangle = \langle\omega_0\rangle$) and measure the reflection coefficient as function of time provides us with $\Gamma(t)$. Calculating the power spectral density of $\angle\Gamma(t)$ for small fluctuations in Ω and ω_0 gives

$$S_{\angle\Gamma}(\omega) = \left(\frac{\partial \angle\Gamma}{\partial\Omega}\bigg|_{\omega_0}\right)^2 \Big(S_\Omega(\omega) + S_{\omega_0}(\omega)\Big) + S_m(\omega), \tag{6}$$

where S_Ω is the power spectral density of the drive frequency fluctuations, S_{ω_0} is the power spectral density of the resonator frequency, and S_m is the measurement noise spectrum. Provided the measurement noise and the source frequency fluctuations are sufficiently small, the measurement of the reflection coefficient phase as a function of time will give the frequency fluctuations of the resonator.

III. Dynamic RLC Model

The analysis in the previous section captures the principle of the measurement. However, a more detailed analysis reveals some interesting points. Accordingly, in this section we consider the measurement using a more detailed model that includes additional noise sources and the resonator dynamics. The model we consider is series RLC resonator with additive and parametric noises. We consider this resonator model in both a one-port and a two-port configuration, see figure 1. In this analysis we assume that Z_0 is real. The series RLC model is a valid model of an aluminum nitride contour-mode resonator near resonance. The resonator equation is

$$L\ddot{q} + \big(R + 2L\zeta_r(t)\big)\dot{q} + \left(\frac{1}{C} - 2\sqrt{\frac{L}{C}}\zeta_i(t)\right) q = V_0\big(1+\alpha(t)\big)\cos\big(\Omega t + \theta(t)\big) + n(t), \tag{7}$$

where q is the charge in the capacitor, $\zeta_r(t)$ and $\zeta_i(t)$ are parametric noises that produce quality factor and resonant frequency fluctuations, $\alpha(t)$ and $\theta(t)$ are the amplitude and phase noise of the VNA drive signal, and $n(t)$ is addtive noise. The additive noise can be approximated as white since the resonator is sensitive only to the spectrum in a narrow band around the resonant frequency. Thus we assume $\langle n(t)n(t')\rangle = D\delta(t-t')$. When $n(t)$ is thermal noise $D = 2Rk_BT$ where k_B is Boltzmann's constant and T is the temperature. When the noise and damping are weak $q(t)$ follows a nearly harmonic orbit. Thus we make the change of coordinates

$$q = a_0 u(t) e^{i\Omega t + i\theta} + \text{c.c.}, \tag{8}$$

$$\dot{q} = i(\Omega + \dot{\theta}) a_0 u(t) e^{i\Omega t + i\theta} + \text{c.c.}, \tag{9}$$

where $u(t)$ is the complex amplitude of the resonator motion, $a_0 = V_0/4iL\Omega$ is the characteristic amplitude, and c.c. stands for the complex conjugate of the preceeding terms. The resonator admittance is conveniently expressed in terms of the resonator complex amplitude,

$$Y = \frac{2i\Omega a_0 u}{V_0(1+\alpha)}. \tag{10}$$

The reflection and transmission coefficients,

$$\Gamma_r = \frac{1 - Z_0 Y}{1 + Z_0 Y} = \frac{1 + \alpha - u\mu_r}{1 + \alpha + u\mu_r}, \tag{11}$$

$$\Gamma_t = \frac{2Z_0 Y}{1 + 2Z_0 Y} = \frac{2u\mu_t}{1 + \alpha + 2u\mu_t}, \tag{12}$$

where Γ_r is the reflection coefficient for a one-port measurement, Γ_t is the s_{21} scattering parameter for a two-port measurement, $\mu_r = Z_0/2L$, and $\mu_t = Z_0/L$.

Applying the method of averaging to the resonator equation in the new complex coordinate, u, gives the approximate resonator equation

$$\dot{u} \approx -\big(\Lambda + \xi(t)\big)u + 1 + \eta(t), \tag{13}$$

where $\Lambda = \lambda + i\sigma$, $\lambda = R/2L$, $\sigma = \Omega - (LC)^{-1/2}$, $\xi(t) = \zeta_r(t) + \ddot{\theta}/2\Omega + i\zeta_i(t) + i\dot{\theta}$, and $\eta(t) = \alpha(t) + 2e^{i\Omega t + i\theta} n(t)/V_0$. The complex parametric noise ξ is a combination of the resonator parametric noise and the source frequency noise. Through measuring the reflection coefficient we can extract the power spectra of the real and imaginary parts of ξ, but we will be able to measure the frequency fluctuations of the resonator, ζ_i, only if they are larger than the frequency fluctuations of the source. If this is not the case a dual resonator bridge measurement is required [2], [4]. Solving equation (13) in the weak noise limit gives

$$u = \int_{-\infty}^{t} dt_1 \exp\left[-\int_{t_1}^{t} dt_2 \big(\Lambda + \xi(t_2)\big)\right]\big(1 + \eta(t_1)\big), \tag{14}$$

$$\approx \int_{-\infty}^{t} dt_1 e^{\Lambda(t_1 - t)} \left(1 - \int_{t_1}^{t} dt_2 \xi(t_2) + \eta(t_1)\right). \tag{15}$$

From equation (15), the mean value of the resonator's complex amplitude and the reflection coefficient are

$$\langle u\rangle = \frac{1}{\Lambda}, \qquad \langle\Gamma_r\rangle = \frac{\Lambda - \mu_r}{\Lambda + \mu_r}, \qquad \langle\Gamma_t\rangle = \frac{\mu_t}{\Lambda + \mu_t}. \tag{16}$$

With the VNA in continuous wave mode we measure Γ_r or Γ_t as a function of time with a fixed driving frequency. We then consider the fluctuations in Γ,

$$\gamma \equiv \Gamma - \langle\Gamma\rangle \approx -\beta\Lambda^2(u - \langle u\rangle) + \beta\Lambda\alpha(t), \tag{17}$$

$$\beta = \begin{cases} \frac{2\mu_r}{(\lambda+\mu_r)^2} & \text{one-port reflection,} \\ -\frac{\mu_t}{(\lambda+\mu_t)^2} & \text{two-port transmission,} \end{cases} \tag{18}$$

where γ has been expanded in Taylor series to leading order in terms of $u - \langle u\rangle$ and α. For notational convenience the

subscripts have been dropped. It is understood that when considering a one-port or a two-port transmission measurement the appropriate definition of β, given in equation (18), is to be used.

It was shown in [6] that the complex power spectral density of $\langle\gamma(t)\gamma(t+t_1)\rangle$ can be used to average out the additive noise and extract the frequency fluctuations of the resonator. We emphasize that this is the Fourier transform of $\langle\gamma(t)\gamma(t+t_1)\rangle$ and not $\langle\gamma(t)\gamma^*(t+t_1)\rangle$. Indeed, this gives

$$S_\gamma(\omega) = \int_{-\infty}^{\infty} dt_1 \langle\gamma(t)\gamma(t+t_1)\rangle e^{-i\omega t_1}, \tag{19}$$

$$= \frac{\beta^2\Lambda^2\big(S_\xi(\omega)+\omega^2 S_\alpha(\omega)\big)}{(\Lambda^2+\omega^2)}, \tag{20}$$

where $S_\xi(\omega)$ is the complex power spectral density of ξ given by $S_\xi(\omega) = S_{\xi_r}(\omega) - S_{\xi_i}(\omega) + 2i\,\mathrm{Re}[S_{\xi_r,\xi_i}(\omega)]$ and S_{ξ_r}, S_{ξ_i}, and S_{ξ_r,ξ_i} are the power spectra and cross-sprectum of the real and imaginary parts of ξ. For small offset frequencies, ω, equation (20) gives the complex power spectral density of the parametric noise. Unfortunately there are two potential issues with this approach. The first is that the measurment of S_ξ is not sufficient to extract S_{ξ_r} and S_{ξ_i} separately. This approach is most useful when one knows, for example, that $S_{\xi_r} = 0$. The second issue is that even if $S_{\xi_r} = 0$, we will not measure zero because of the measurement noise. This can lead to erroneously large measured values for S_γ. If these issues cause a problem we must calculate the power spectral densities of $\mathrm{Re}[\gamma]$ and $\mathrm{Im}[\gamma]$ separately. These spectra are much more cumbersome to express analytically and so we will give only their expression at resonance, $\sigma = 0$,

$$S_{\mathrm{Re}[\gamma]}(\omega)\Big|_{\sigma=0} = \frac{\beta^2\lambda^2\big(S_{\xi_r}(\omega)+\omega^2 S_\alpha(\omega)+2\lambda^2\frac{D}{V_0^2}\big)}{\lambda^2+\omega^2}, \tag{21}$$

$$S_{\mathrm{Im}[\gamma]}(\omega)\Big|_{\sigma=0} = \frac{\beta^2\lambda^2\big(S_{\xi_i}(\omega)+2\lambda^2\frac{D}{V_0^2}\big)}{\lambda^2+\omega^2}, \tag{22}$$

$$S_{\mathrm{Re}[\gamma],\mathrm{Im}[\gamma]}(\omega)\Big|_{\sigma=0} = \frac{\beta^2\lambda^2 S_{\xi_r,\xi_i}(\omega)}{\lambda^2+\omega^2}, \tag{23}$$

If we fix R and L and vary Z_0 we find that β^2 is maximized when $Z_0 = R$ for a one-port reflection measurement and $2Z_0 = R$ for a two-port transmission measurement. The optimal values of β^2 are $\beta^2 = L^2/R^2 = Q^2/\omega_0^2$ for a one-port reflection measurement and $\beta^2 = L^2/4R^2 = Q^2/4\omega_0^2$ for a two-port transmission measurement. This result suggests that high frequency resonators with modest Q are more difficult to measure. Yet, we might consider that the spectrum of frequency fluctuations should scale with ω_0^2 if time-keeping ability is kept fixed. This should cancel the ω_0^2 in the denominator of β^2 and so the measurement sensitivity comes down to the unloaded Q of the resonator. In addition, it is interesting to note that the reflection measurement is four times more sensitive assuming ideal matching conditions in both cases and identical measurement noise.

IV. Contour-Mode Resonator Measurements

In this section we demonstrate the measurement outlined above. We consider a 473 MHz one-port aluminum nitride contour-mode resonator [7] measured by an Agilent N5230A vector network analyzer. The reflection coefficient of the resonator is shown in figure 3. The figure shows the measured reflection coefficient in blue and the least squares fit to the modified Butterworth Van Dyke (MBVD) model in red. The MBVD equivalent circuit is shown in figure 2 and the model parameters are shown in table I.

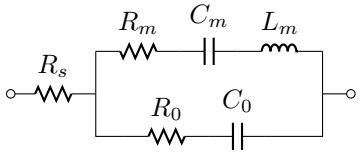

Fig. 2: Modified Butterworth Van Dyke (MBVD) circuit model.

$L_m = 81.666\ \mu\mathrm{H}$	$C_m = 1.3841$ fF	$R_m = 122.039\ \Omega$
$C_0 = 241.67$ fF	$R_0 = 168.49\ \Omega$	$R_s = 14.09\ \Omega$

TABLE I: MBVD resonator parameter values.

In order to measure the intrinsic frequency fluctuations of the resonator, the resonator was driven in continuous wave (CW) mode at resonance, 473.4125 MHz. The CW measurement point is shown as a black dot in figure 3. Linearizing the phase curve about this point, we find

$$\left.\frac{\partial\angle\Gamma}{\partial\Omega}\right|_{\omega_0} = 1.1279\times10^{-4}\ \text{rad/Hz}. \tag{24}$$

In order to characterize the VNA the VNA source phase noise was measured using the Agilent E5052B signal source analyzer. The phase noise spectrum is shown in figure 4 in green. In addition a passive attenuator was measured using the VNA. The attentuation was similar to the loss in the resonator reflection coefficient and so the phase fluctuations of the attenuator measurement should provide a valid measure of the VNA measurement noise floor. Moreover, if we compare the VNA measurement noise to the phase noise of the VNA source we find the VNA phase noise is much lower and thus negligible.

Next we measured the resonator, performing 9 CW sweeps of 16001 points with a sampling frequency and IF banwidth of 200 Hz. The power spectral density of the frequency fluctuations was then calculated using equation (6), ignoring

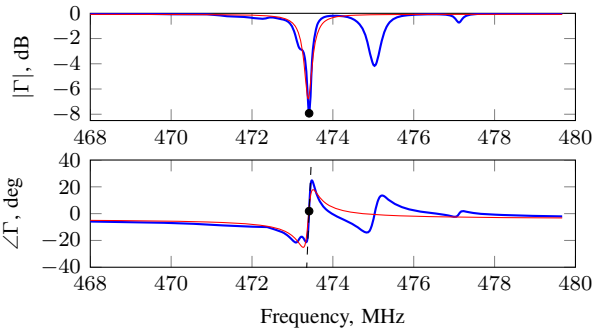

Fig. 3: Resonator reflection coefficient. The measured reflection coefficient is in blue and the MBVD model fit is in red. The MBVD coefficients were fit via least squares regression.

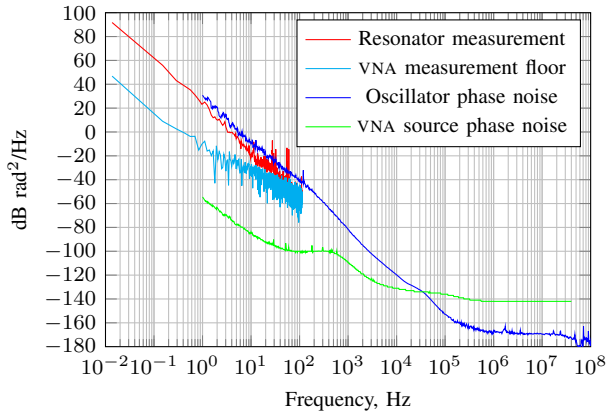

Fig. 4: Spectrum of phase noise for the oscillator, the resonator measured in open-loop, the VNA source, and a passive attenuator used to determine the measurement noise floor.

the source frequency fluctuations and the measurement noise, and averaging over the multiple CW sweeps. As a point of comparison, the same oscillator was placed into an oscillator and the phase noise of that oscillator was measured using the E5052B. The oscillator was constructed with a simple Pierce amplifier circuit on a printed circuit board and wirebonded to the resonator. In order to compare the oscillator phase noise and the measured frequency fluctuations it is necessary to divide the frequency fluctuations by ω^2. The reason is that frequency fluctuations in the resonator contribute directly to the frequency fluctuations of an oscillator because the resonator serves as the frequency selective component (*i.e.* frequency reference) of the oscillator. Figure 4 shows both the oscillator phase noise and the resonator frequency fluctuations, referred to phase by division by ω^2. The VNA measurement floor was also referred to the oscillator phase by dividing by ω^2. In figure 4 it is clear that the measurement noise floor (cyan) is well below the measured resonator noise (red). The resonator noise (red) is matched in slope and only 5-10dB below the closed-loop oscillator phase noise (blue). This comparison supports the validity of the proposed measurement technique.

V. Conclusion

In this work we have discussed the principles of measuring resonator frequency fluctuations with a vector network analyzer. By consider a simple RLC model we have discussed the issues invovled with measuring the frequency fluctuations via the complex spectrum of the reflection or transmission coefficient. This measurement averages out the additive noise, but has difficulty distinquishing frequency and damping fluctuations in the resonator. In addition, we have shown that the reflection measurement is four times more sensitive than the transmission measurement if the measurement noise is equal in both cases. Finally, we have demonstrated the measurement with a 473 MHz aluminum nitride contour-mode resonator. By comparing the measurement to a closed-loop phase noise measurement using the same resonator and to noise floor measurements we comfirmed the validity of the proposed measurement technique.

***Abstract*— This paper deals with experimental studies of nonlinear behavior of Bulk Acoustic Wave (BAW) devices, in a Solidly Mounted Resonator (SMR) structure. The purpose is to extend the Modified Butterworth Van Dyke model to a complete non-linear model of a BAW resonator, which takes into account all nonlinear effects. Frequency shifts were studied when high Radio Frequency (RF) power (up to 5W) is applied to the resonators. We have focused on the W-CDMA frequency standards, for resonators of emission filters of a front-end module in mobile phones. To stabilize the input power, we have developed a new calibration method, which is able to match the data correction between a high and small signal at any frequencies. With this method, we have access to the power waves, and we recalculate the S-parameters externally as a function of the frequency sweep.**

Keywords—Bulk Acoustic Wave; Calibration; VNA; High RF Power;Non Linearities.

I. INTRODUCTION

The race industry to improve the integration and performance of the components used today is fraught with more complex technological problems. It leads to the emergence of new structures such as acoustic wave devices, and more particularly to Bulk Acoustic Wave (BAW) [*1*] devices, which have the capacity to meet the needs of filtering and local oscillators.

Current solutions to meet these needs will be presented first, integrating in the current context of increasing speed of transmission of digital data. The different causes of nonlinearities in BAW devices will be presented and we quantify their preponderance. Finally, we show the tester in automated power has been achieved and we will describe the measurement results. Finally, we see that the full non-linear study of a piezoelectric device may require the study of the acoustic aspect of the phenomenon.

II. CONTEXT OF THE STUDY

A. Filters and oscillators in mobile phones

The filtering function is one of two main applications achieved by bulk acoustic wave devices in mobile devices (figure 1).

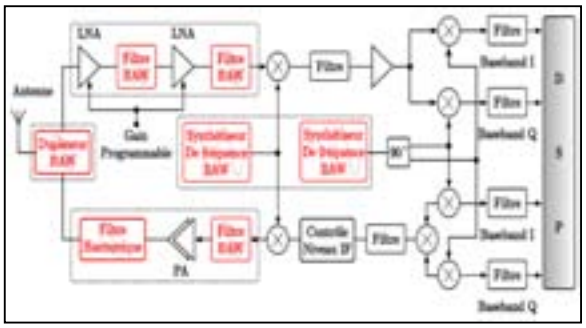

Fig. 1. Front-end multistandard architecture of mobile phones

RF filters used in the European Mobilis project are BAW narrow-band filters which may be used as filters or duplexers [*2*][*3*]. Mobilis project has been initiated by the IMS Laboratory [*4*].

They are further characterized by an input and output impedance level, input / output (single or differential) type, maximum acceptable level of input power (especially for Tx filters for signal transmission), a temperature range of operation which does not generate an excessive drift, characterization and quantification of non-linear effects due to the filter design and the critical parameter which is the integration of the component in a mobile phone [*5*] .

On of the aim is to develop a technology platform based on mobile applications for Ambient Intelligence, and improve performance to check the requirement of mobile telephony [*5*].

The aim is the following: study and model BAW filters subjected to a strong signal. The purpose is to identify the main effects that may impact the reliability of the component, including the effect of high power RF bandwidth on SMR BAW filter, ie the insertion losses, frequency shift and possible damage on different resonators (according to their position in the filter and the power distribution in the circuit).

By these criteria we performed measurements; results should enable the development of a nonlinear electrical model valid around the resonance. So we will first focus on different non-linear effects caused by high power RF in the following

section, before describing the test bench used and discuss the results.

B. High RF power main effects on BAW devices

The direct consequence of high power is the heating of the component. We must therefore take into account the effects of heat on the center frequency shift. Thermal effects have also consequences on the elastic stiffness. The electrostriction effect is also very important. The mechanical constraint is quadratic response of the electric field applied on the device. It is quite hard to analyze non linearities due to heating effects because these variations evolve simultaneously in time and space[*6*][*7*][*8*][*9*] [*10*] [*11*].

III. HIGH POWER MEASUREMENTS

S-parameters at high RF powers are difficult to measure and require a special test bench. Measurement results obtained with the reflection tester (figure 3) were supplemented with the tester in transmission (figure 5). This one has been built with conventional RF equipment, and has been carefully calibrated to determine precisely the power injected in the device at any frequency value, without any post-computation [*6*].

A. High Power Reflection Test Bench

The used test-bench in reflection is shown figure, it does not allow direct access to the value of the incident power. It is necessary to make a classic S parameter measurement, small signal, and discretize the frequency points.

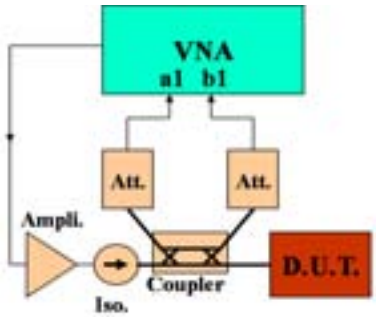

Fig. 2. High Power Reflection Test Bench

Value for each selected frequency, a measure of power is carried out. With a computation process one can obtain the value of the input impedance. Then the electrical response of the resonator is obtained, for small and high signals (figure 3).

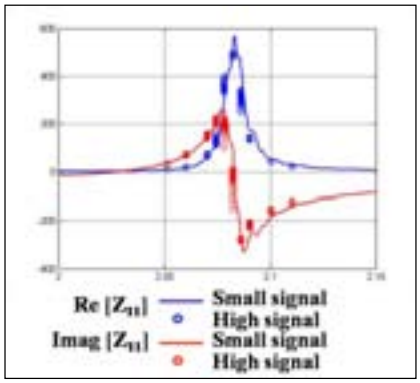

Fig. 3. Power parametrization of the input impedance

Due to variations of the amplifier and due to the attenuation, it is necessary to adapt for each point of the frequency shift of the impedance of the BAW resonator as a function of the input power Pe. The curve of variation of the impedance of the device is obtained after correction for a frequency band. It is then possible to evaluate an approximation of the BAW resonator impedance versus frequency for each value of input power Pe as shown figure 4.

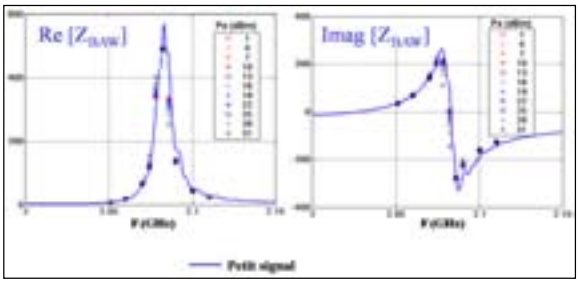

Fig. 4. Real and Imaginary parts of the impedance of the resonator for each input Power Pe

We have seen that it is possible to extract the values of the localized equivalent model MBVD around resonance. It can therefore highlight from the approximation made of these measurements the change in capacitor Cm and resistance Rm according to the power. The most significant results by this method are:

• A relative shift of Cm close to 0.2% (0.15% for loaded resonators) and a shift on the resistance Rm of 17% (27% for loaded resonators) have been observed.

• A relative shift of the resonant frequency close to 0.1% in both cases.

• A shift of the anti-resonance frequency close to 0.1% in both cases, and a resonant frequency shift lower than 0.3%.

The contribution of the effect of power on the value of the resonant frequency remains weak.

B. High Power Transmission Test Bench

A 4-port Vectorial Network Analyzer (VNA) is used both as measuring device and RF source. It delivers -20dBm power, swept around 2GHz. The signal is amplified by a Power

Amplifier (PA) (40dB gain) previously characterized as sufficiently linear for the used frequency range. All used devices for the test bench, including attenuators and couplers, have been chosen to be functional in the frequency band (figure 5).

Finally, the test bench is connected to a probe station to overcome various effects such as landslides, claw arks on the wafer or apparatus damage. In addition, the set up has a power sensor connected to the resonator's input, in order to manage the input power, which enables a power feedback loop. This is a particularly delicate step that requires the establishment of an original procedure of double calibration (frequency/power).

This calibration method simplifies the equipment and locates the input power measurement very close to the resonator. Initially, a calibration is performed on the power level output of the coupler, so that the VNA corrects the power supplied simultaneously: the power is well known in the DUT plane and it is fixed, and we also take into account losses in probe cables. In a second step, a standard S-parameters calibration is carried out under the probes (Short Open Load Thru), so low power and high power are enabled. The choice of the maximum power value was studied taking into account return wave limits of the measuring devices and power densities available on the resonators that are being evaluated for future use as the input stage of mobile phone emission filters.

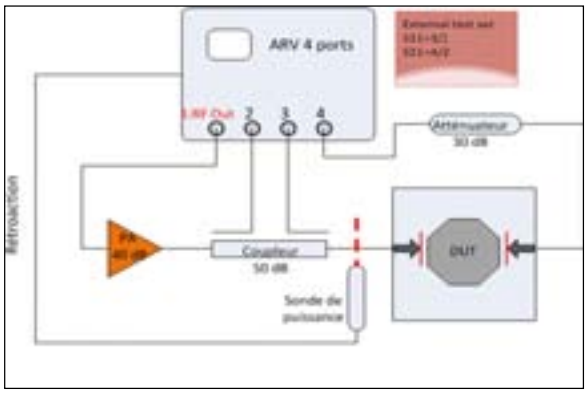

Fig. 5. High Rf Power Measurement Transmission Test Bench

C. Results

We performed measurements on small resonators ($100*100\mu m^2$ and $50*50\mu m^2$), with rectangular and apodized shape, wich have been designed by EPCOS [*12*] and XLIM [*13*]. The maximum input power value is 34 dBm, above which we observe device breakage (deterioration of the top electrode, undesirable resistive effects on the access pads). The power density varies between $36dB/mm^2$ and $60dB/mm^2$. In particular, a frequency shift is observed on the resonant frequency, which decreases by 5% from its initial value from 20 dBm to 34 dBm.

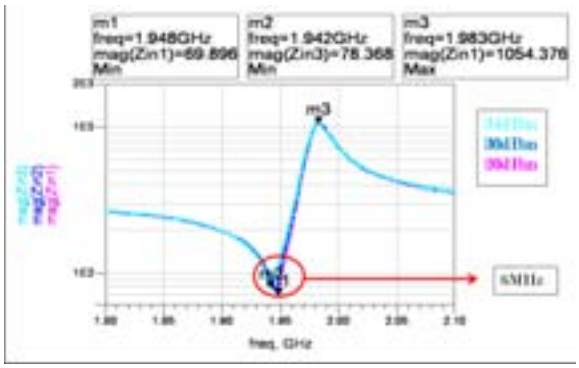

Fig. 6. Electric Response for the apodized resonators

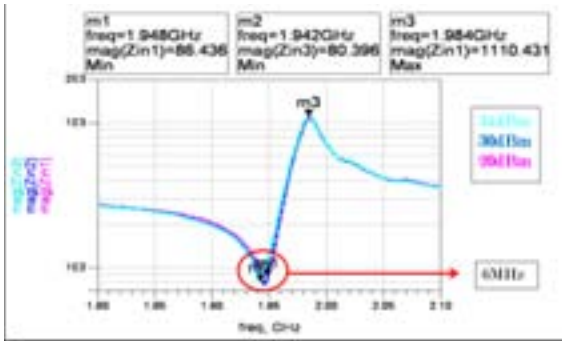

Fig. 7. Electric Response for the rectangular resonators

D. Discussion

When the incident power increases, the shifts in geometric parameters of the resonator is small compared to the variations of parameters in the piezoelectric material. To accurately model the nonlinear behavior of a BAW resonator, it is then necessary to consider elastic, dielectric and electro-acousticof the piezoelectric layer.

IV. CONCLUSION

The European Mobilis project aims to develop a filtering solution based on BAW SMR technology, suitable for mobile multistandard applications. This context creates a thorough study of the possibilities of these devices in terms of linearity and reliability when subjected to high power. Indeed, the BAW resonators are integrated in WCDMA duplexers, and should not be damaged by the signals of high power transmission.

It is therefore necessary to determine the possible causes of non-linearity in the BAW resonators, and identify phenomena related to nonlinear piezoelectricity. The electrostriction, the variation of the MIM capacitor and thermal effects appear to be the main causes of nonlinearities in BAW devices.

These preliminary studies allowed us to highlight the existence of localized elements shifts and propose parametric linear models. We performed several measurement campaigns on the power handling on transmission Tx resonators.

A bench of specific measurement was performed. This bench is used to find the input power fed into the device under

test and to monitor the frequencies of resonance and anti-resonance according to the power. For this, it was required to perform a double careful calibration to take into account simultaneously all the parameters. The results showed a weak shift of the resonant frequency. We then extracted the localized components potentially variables by comparing the results obtained in transmission and reflection.

The contribution of the power on the value of the resonant frequency is low, so this shows that the BAW devices are reliable and have good power handling [*14*].

Evolution of the test bench is being considered, specifically to further knowledge on mechanical and spectral aspects.

ACKNOWLEDGMENT

This work was carried out within the European project Mobilis with the support of the French National Scientific Research Center CNRS. All the measurements have been performed in XLIM Institute, Limoges, France.

***Abstract*—This paper presents a numerical study of the impact of process-induced variations on the achievable motional resistance R_x of one-dimensional, cyclic and cross-coupled architectures of electrostatically transduced MEMS resonators operating in the 250 kHz range. Monte Carlo numerical simulations which accounted for up to 0.75% variation in critical resonator feature sizes were initiated on 1, 2, 3, 4, 5 and 9 coupled MEMS resonators for three distinct coupling architectures. Improvements of 100X in the spread of R_x and 2.7X in mean achievable R_x are reported for the case of 9 resonators when implemented in the cross-coupled topology, as opposed to the traditional one-dimensional chain.**

I. Introduction

The demand for high performance and reduced size wireless communication devices has pushed research interests towards the design and development of low power, small footprint and single chip CMOS integrated wireless-transceiver solutions. The potential of Micro Electro Mechanical Systems (MEMS) technology to meet some of these requirements has led to the recent development and adoption of miniaturized, silicon micro-machined mechanical resonators for operation as timing references [1]. Such micro-resonators, unlike their traditional quartz crystal counterparts, are manufactured using silicon micro-fabrication techniques and offer considerably smaller form factor as well as shorter lead times. Electrostatically transduced silicon MEMS resonators have also been shown to provide a number of advantages including - high mechanical quality factors (Q), low static power dissipation and CMOS manufacturing compatibility making them attractive alternatives to quartz based timing references. However, such silicon micro-resonators are still limited by their high motional resistance (R_x) that consequently hinders direct deployment in RF front-end applications.

Although one-dimensional (1D-κ) mechanical coupling of micro-resonators (see discrete element model in Fig. 1) has been suggested as a potential route to help reduce the R_x of such devices [2]-[3], weakly coupled micro-mechanical devices are highly prone to structural asymmetries induced by manufacturing tolerances. The presence of small imperfections in an array of identically designed resonators leads to a distortion in the vibratory mode shape from the case of a structurally symmetric system [4]. The vibration energy becomes spatially localized and does not extend throughout the structures anymore. This effect often results in non-uniform reductions in R_x from the case of perfect symmetry [5]. While it is possible to tune the structural symmetry and consequently improve conformity in R_x reduction [3][5], this method still remains impractical for larger 1D-κ arrays.

Alternative design methodologies have been investigated to help improve the immunity of such coupled arrays to the impact of manufacturing tolerances in the context of their application to micro-electro-mechanical filters. More specifically, two-dimensional coupling [6] as well as cyclic coupling architectures [7] have been shown experimentally and numerically to provide improved insertion loss and ripple characteristics, indicating an enhancement in robustness to vibration localization effects relative to their 1D-κ counterparts.

In an attempt to obtain better scalability and more predictable R_x reduction of such weakly coupled arrays, this paper presents a numerical study of the impact of manufacturing tolerances on the achievable R_x for three classes of mechanical coupling topologies: one-dimensional coupling 1D-κ (Fig. 1a), cyclic-coupling C-κ (Fig. 1b) and cross-coupling X-κ (Fig. 1c). The numerical study is based on a flexural mode Si MEMS double-ended-tuning fork (DETF) resonator operating at 250 kHz (Fig. 2) where the normalized inter-resonator spring coupling is experimentally quantified as $\kappa = k_c/k = 5\text{x}10^{-3}$. In order to assess the robustness to process-induced variations, Monte Carlo numerical simulations, which accounted for up to $\pm$ 0.75% random variations in resonator beam widths (with nominal value of 6 μm), were initiated to produce R_x estimates of the three coupling schemes for N = 1, 2, 3, 4, 5 and 9 coupled resonators.

II. Theory

A. System modelling

The degree of vibration energy confinement in a mechanically coupled array depends on the magnitude of the structural perturbations as well as the strength of the internal coupling spring constant κ. One possible approach to improving device immunity to structural perturbations is to increase the number of paths for the vibration energy to flow within the system.

Three distinct coupling schemes with different degrees of internal coupling are investigated in this paper:

1) The traditional one dimensional chain 1D-κ (Fig. 1a) with adjacent coupling k_c and free-ends at the edges
2) Cyclic-coupling C-κ (Fig. 1b) with adjacent coupling k_c throughout the array

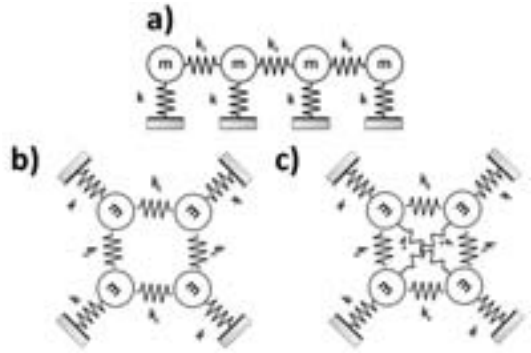

Fig. 1. Schematics of the equivalent mechanical models of the a) 1D-κ one dimensional coupled chain, b) C-κ cyclic-coupling and c) X-κ coupled confugration, respectively, for the special case of N = 4 resonators.

3) Cross-coupling X-κ (Fig. 1c) with adjacent coupling k_c and non adjacent coupling k_x

The N resonators composing a particular coupled-system are represented by a single-degree-of-freedom system with nominal mass m, stiffness k and damping coefficient c.

Combining the N equations of motion in matrix form with sinusoidal forcing yields to

$$\underline{M}\ \underline{\ddot{X}} + \underline{C}\ \underline{\dot{X}} + \underline{K}\ \underline{X} = \underline{F} \tag{1}$$

The three mechanical coupling schemes investigated in this paper differ from each other by their stiffness matrices $\underline{K}_{1D}$, $\underline{K}_{C-\kappa}$ and $\underline{K}_{X-\kappa}$ for the 1D-κ, C-κ and X-κ topology, respectively.

The complex valued amplitude response vector $\underline{X}$ of the system is computed as

$$\underline{X}(j\omega) = [-\omega^2\underline{M} + j\omega\underline{C} + \underline{K}]^{-1}\underline{F} \tag{2}$$

In the case of electrostatically transduced MEMS resonators, the driving force f_i is given by

$$f_i = \frac{\epsilon A_i}{g_i^2} v_{ac} V_{DC} \tag{3}$$

where ϵ, A_i, g_i are the vacuum permittivity, effective transduction area and nominal transduction gap, respectively, v_{ac} and V_{DC} are the small signal drive voltage and DC-polarization voltage, respectively.

The N-DOF spring-mass system yields to N fundamental modes of vibrations $\underline{u}_k$ at N distinct natural frequencies ω_k.

As the resonators vibrate at the kth mode of vibration ω_k, the sense electrodes of the N resonators generate a total motional current i_{out} expressed as

$$i_{out} = j\omega_k \epsilon V_{DC} \sum_{i=1}^{N} \frac{A_i}{g_i^2} \underline{X_i} \tag{4}$$

The overall R_x of the coupled-resonator device is then numerically computed as

$$R_x = \frac{v_{ac}}{max(|i_{out,\omega=\omega_k}|)} \tag{5}$$

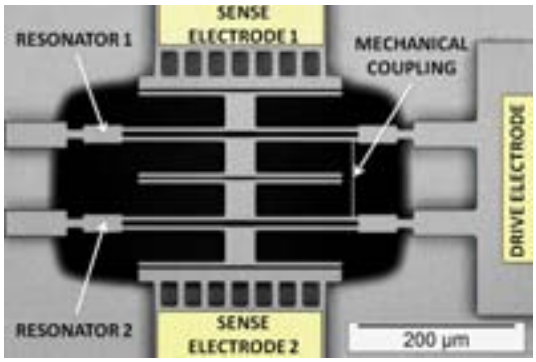

Fig. 2. Optical micrograph of two mechanically coupled double-ended tuning fork (DETF) silicon resonators.

TABLE I. DESIGN PARAMETERS

Beam width b_0	6 μm
Beam length l_0	300 μm
Device thickness t_0	25 μm
Gap g_0	2 μm
$Q = \sqrt{mk}/c$	30000
$\kappa = k_c/k$	5x10^{-3}

For the three topologies considered, we choose the fundamental mode $\underline{u}_1$ of vibration for comparison occurring at the lowest eigenfrequency ω_1 which is defined as

$$\underline{u}_1^T = \frac{1}{\sqrt{N}}[1 \ldots 1] \tag{6}$$

B. Robustness to process-induced variations

In order to quantify the robustness of the distinct coupling schemes in the face of process-induced variations, numerical simulations were based on DETF resonators shown in Fig. 2 operating at the fundamental in-phase tuning fork mode at 250 kHz. The tines of the DETFs are 300 μm long, 6 μm wide and 25 μm thick. The gap between individual tines is 6 μm while the coupling rod is 94 μm long. The electro-mechanical transduction is conducted through two parallel plate electrodes attached to each tine of the DETF with an air-gap spacing g_0 of 2 μm. The devices were manufactured using a standard Silicon-On-Insulator (SOI) process. These nominal values are summarized in Table I.

The value of the mechanical coupling spring κ is experimentally quantified using the coupled device of Fig. 2. This is done using the curve-veering phenomenon [8] by electrostatically tuning the mechanical stiffness of one of the resonators, while keeping all other structural parameters constant.

The negative spring constant k_e achieved with this tuning is given by

$$k_e(V_{DC}) = -\frac{\epsilon A}{g_0^3} V_{DC}^2 \tag{7}$$

Figure 3 shows the plot of the squared eigenfrequencies ω_i^2 as a function of the induced stiffness perturbations $\delta k \propto V_{DC}^2$.

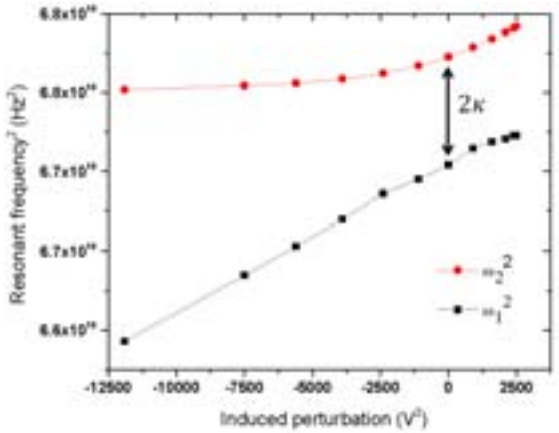

Fig. 3. Experimentally measured variations in the eigenvalues as a function of the induced stiffness perturbations on the DETF resonator.

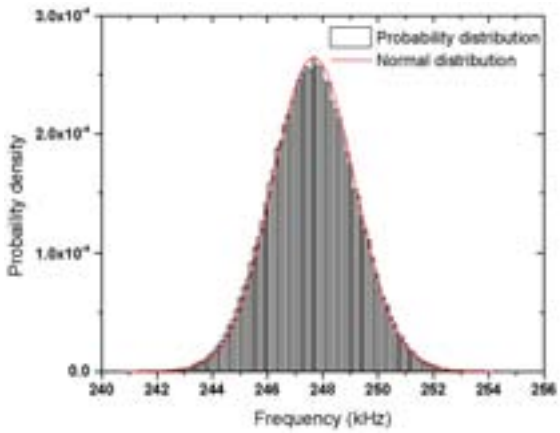

Fig. 4. Simulated probability density of the DETF frequency for random variations in the beam widths.

This enables us to quantify the spring coupling κ (Table I) between the two DETF resonators when the loci of the two eigenmodes achieve a minimum frequency separation.

C. Numerical simulations

Monte Carlo numerical simulations, which accounted for up to 0.75% random variations in resonator beam widths, were initiated to produce R_x estimates of the three coupling schemes for N = 1, 2, 3, 4, 5 and 9 resonators. These random variations were achieved numerically by setting the beam width b_i of the ith resonator as

$$b_i = b_0\left(1 + \mathcal{N}(0,\sigma)\right) \tag{8}$$

where b_0 is the nominal value of the beam width, $\mathcal{N}(0,\sigma)$ is the normal distribution with zero mean and standard deviation 3σ = 7.5x10^{-3} (i.e. 99.7% of the random beam widths generated are within 45 nm from their nominal value b_0 = 6 μm).

Choosing these values allows for 2.25% of random variations in the resonator stiffness k which can considerably affect the vibration dynamics of such high-Q, weakly coupled resonator systems. Randomly modifying the beam widths of the DETF tines allows us to simulate breaks in structural symmetry due to both mass and stiffness perturbations. The normalized distribution of the natural frequency for a single DETF with these parameters is shown in Fig. 4.

The distribution of the frequency follows approximately a normal distribution with a mean $\mu_0 = 247.6$ kHz and standard deviation σ_0 = 770 Hz.

D. Choosing the right eigenmode

Since there are N modes of vibrations, the recording of the amplitude of vibration vector $\underline{X}$ as a function of the input frequency, will yield to N distinct peaks corresponding to the N eigenmodes. To evaluate the R_x of the whole system, we would then have to specifically find the maximum amplitude corresponding to the particular vibration mode of interest (i.e. in our case the $\underline{u}_1$ mode). These random trials are then repeated until satisfactory convergence is achieved (in this case 2x10^5 experiments).

In order to correctly identify the frequency range for which we should perform the frequency sweep to record the vibration response of mode $\underline{u}_1$ around ω_1, we first consider the undamped eigenvalue problem, given the initial random distribution of the geometrical parameters.

This is done by solving

$$\underline{K}\ \underline{u}_i = \lambda_i \underline{M}\ \underline{u}_i \tag{9}$$

where $\underline{u}_i$ and λ_i are the ith eigenvector and corresponding normalized eigenvalue $\left(\lambda_i = \omega_i^2/\left(k/m\right)\right)$.

Once the N eigenvalues are identified, we choose the lowest eigenvalue which will always correspond to the $\underline{u}_1$ eigenmode. Using the solutions of the undamped eigenvalue problem to identify the correct frequency range of the damped system is used to speed up the simulation times and improve the accuracy of the measurements as a greater number of points can be taken around the particular frequency of interest. Furthermore, we can easily modify the algorithm to track another mode of vibration simply by adjusting the range of frequency sweep.

In order to return motional resistance values which we would expect from experimental measurements, we specify the small signal driving voltage v_{ac} = -20 dBm and polarization voltage as V_{DC} = 10 V.

III. Results

Fig. 5 and Fig. 6 are plots of the probability distribution (normalized to have unit area) of the R_x for the three coupling schemes when N = 4 and N = 9, respectively. The X-κ topology is chosen such that $\kappa = \kappa_x$. For the case N = 4, we see a clear improvement in the mean value as well as spread for higher order coupling. For N = 9, there is a clear advantage of the X-κ topology against the other two topologies as it achieves an improvement by one order of magnitude in σ as compared to the 1D-κ and C-κ schemes.

The results for the other array lengths N are summarized in Table II where the mean (μ) and standard deviation (σ)

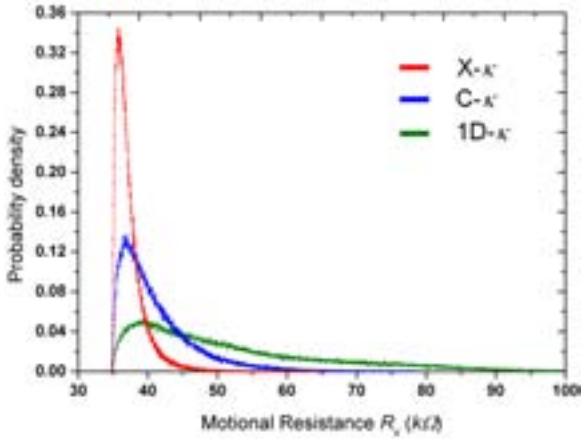

Fig. 5. Simulated probability distributions of the R_x for the 1D-κ, C-κ and X-κ configurations, respectively, for the case of N = 4 coupled resonators.

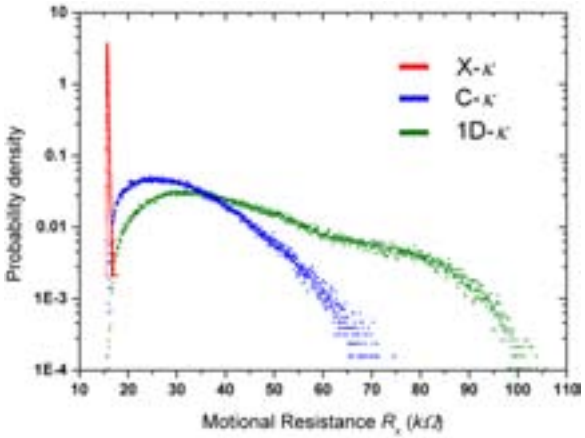

Fig. 6. Simulated probability distributions of the R_x for the 1D-κ, C-κ and X-κ configurations, respectively, for the case of N = 9 coupled resonators.

of the R_x distribution for the different coupling schemes are reported. From Table II we see that for the 1D-κ and C-κ configurations, the spread in R_x increases as N is increased. Using mechanically coupled topologies remains beneficial for an R_x reduction purpose as the achievable mean value of R_x drops with increasing N at the cost of a larger spread for the 1D-κ and C-κ schemes. However, for the case of the X-κ, increasing the number of resonators significantly decreases the spread in the R_x value from σ = 2.11 at N = 4 to σ = 0.14 at N = 9.

TABLE II. DISTRIBUTION OF THE MOTIONAL RESISTANCE R_x FOR THE DIFFERENT COUPLING SCHEMES AND ARRAY SIZE N

Array size N		1	2	3	4	5	9
1D-κ	μ (kΩ)	140	77.17	59.1	51.48	47.54	42.28
	σ (kΩ)	0.63	7.24	11.0	13.27	14.67	16.43
C-κ	μ (kΩ)	X	X	50.89	41.06	36.0	30.76
	σ (kΩ)	X	X	4.04	5.20	6.31	9.04
X-κ	μ (kΩ)	X	X	X	37.30	29.31	15.79
	σ (kΩ)	X	X	X	2.11	1.11	0.14

IV. CONCLUSION

This paper presents a numerical study of the impact of process variations on the motional resistance of three distinct mechanical coupling topologies of MEMS resonators. The numerical trends, based on Monte Carlo simulation methods, suggest an improvement in the mean and spread of R_x as the number of coupled resonators N is increased for the X-κ scheme as opposed to the traditional 1D-κ linear chain and the cyclic C-κ configuration. For the special case of N = 9, we expect a 2.7X improvement in mean R_x and more than 100X decrease in R_x spread as we go from the 1D-κ to the X-κ topology. A fully cross-coupled topology where $\kappa = \kappa_x$ can be challenging to achieve in practice. Further numerical studies are necessary to evaluate the optimal cross-coupling spring constant for a given resonator topology, manufacturing variability and number of coupled resonators N in order to achieve good performance. The numerical scheme presented in this paper is an efficient design procedure to evaluate the structural immunity to process variations of resonator performance metrics (in this case the R_x). These numerical results motivate in-depth studies of alternative coupling topologies, in the case of weakly coupled resonators, towards designing process tolerant, highly scalable resonator arrays.

Unwanted Transverse Modes in SAW Resonators Caused by Stitching Errors And Stripe Nonlinearities

Pierre Dufilie, Raymond Zeitler, Jim Jacobs, Merle Yoder
Phonon Corporation
Simsbury, CT, USA

Abstract — **High Q SAW and STW resonators utilize interdigital transducers with transverse weighting. This weighting is fit to the fundamental mode (M0) of the resonator cavity, so the transducer should not couple to the higher order transverse modes (M1, M2, ...). Errors in the actual resonator pattern caused by stitching errors in laser generated photomasks will introduce an asymmetry which can excite both higher order symmetric (M2, M4, ...) and antisymmetric (M1, M3, ...) transverse modes. Non-uniformities due to processing can also contribute to these higher order modes. Higher order modes in oscillators are undesirable because they degrade linearity or induce frequency popping.**

The majority of high resolution (0.5um or better) 1X photomasks are fabricated using laser mask-making machines. This approach is adequate for most SAW devices; however SAW resonators are very sensitive to small variations in linewidths and line positions -- variations that cannot be detected by normal optical examination. A typical resonator pattern (2mm x 2mm active area) is too large to be exposed in a single laser stripe.

The objective of this study is to determine the photomask fabrication method which can minimize the higher order transverse modes. A 695MHz STW resonator was designed and realized in an array of 26 rows and 16 columns on multiple 1x dark field quartz masks exposed with different photomask tools. The tools were Etec Alta 3500 and 3900 laser pattern generators, Micronic laser writer and an ASET 645 15" Image Repeater used with a 10x reticle.

Multiple wafers were contact-printed from each mask, and all dies on the wafers were RF-probed to acquire S11 over a span of 40MHz centered at 695MHz. The data was converted to admittance, and the main response was fitted to a lumped-element model, which was then removed. The residual data, which contained the extraneous modes, was then analyzed for correlation to: position in the array of dies; mask technology; wafer number.

Electrical measurements of STW resonators fabricated with different photomask tools do exhibit differences in transverse mode levels, the newer pattern generators having lower high order modes. Those fabricated with mask generated with the 10X stepper exhibited the best performances.

Keywords – SAW Resonator, photomask, fabrication

I. INTRODUCTION

Over the years, manufacturing methods for photomasks, used to pattern SAW devices, have dramatically evolved. In the 1960's photomasks were created by manually cutting Rubylith films and then reducing the pattern size using a large reduction copy camera. Rubylith was then replaced with a layer of photographic emulsion on a Mylar film patterned by an optical plotter.

With the development of optical pattern generators such as the GCA 3600, masks with features as small as 2um could be written directly. These patterns were composed of individual rectangles rotated at various angles.

Raster scanning led to additional advancements in photomask printing. Ebeam pattern generators using raster scanning were developed to obtain submicron features. Later, many ebeam systems were replaced with faster laser pattern generators where the stage moves at a constant speed while the laser beam scans perpendicular to the stage motion using either a rotating mirror or an acousto-optic modulator. The Micronic Laser writer is an example of a single beam system while the Alta systems use 32 parallel beams created by a beam splitter.

Even with the abovementioned advancements in photomask patterning, manufacturing masks for SAW resonators still presents a challenge. In most cases the size of the resonator is such that the critical features must be split up into two or more stripes. The resulting butting errors at the boundaries of adjacent stripes have a strong effect on device performance.

II. 1-PORT STW RESONATOR

For this study a 695MHz STW resonator was used. The resonator is shown in fig 1 (a). It consists of a transducer and two reflective gratings. The resonator is asynchronous with 55 transducer fingers that have a period of 3.57um and 1.86um linewidth and two 300-strip grating reflectors with 3.608um period and 1.88um linewidth. The acoustic aperture is 900um and the total resonator length is 2360um. The die size for the resonator is 3000um x 1900 um. The transducer is transversely weighted to excite only the fundamental transverse acoustic cavity mode 0.

Photomasks were made with a 16 x 26 array of resonator patterns. 38° yx quartz wafers were processed using the lift-off

process. The wafers were first coated with photoresist and then patterened using contact printing with each photomask. Then the patterned wafers were reactive ion etched [5] to a depth of 1500Å. Next, the wafers were metalized with 3000Å of 2% Cu doped aluminum. After liftoff wafer probe measurements were made on the resonators.

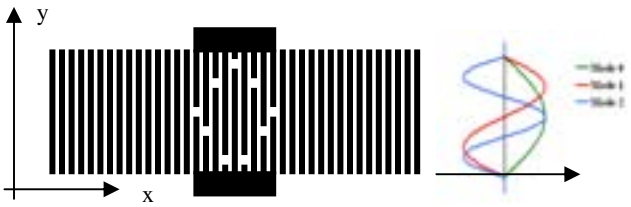

Fig 1 – (a) One-port STW resonator consisting of a transverse weighted transducer and two reflective gratings and (b) transverse mode profiles for modes 0, 1, and 2 .

The resonator has an effective cavity length of 895um and a nominal Q of 16500. The equivalent group delay τ of the resonator is related to the unloaded Q by equation 1, where f_R is the resonance frequency.

$$Q = \pi f_R \tau \qquad (1)$$

The nominal Q corresponds to a delay of 7.56us which corresponds to an effective acoustic path length L_{eff} of 38mm.

The transducer is transversely weighted to excite only mode 0 (M0). Seven transverse modes can exist with an acoustic aperture of 900um. Using the parabolic velocity approximation, the relative mode frequencies in table 1 are obtained for modes 0-5.

Mode	0	1	2	3	4	5
f-f_{R0} (kHz)	0.000	-0.044	-0.117	-0.219	-0.350	-0.510

Table 1 – Relative transverse mode frequencies for modes 0-5 computed using the parabolic velocity approximation.

The conductance of two measured resonators is plotted in fig 2. One resonator (blue) excites only the fundamental mode. This is the desired resonator characteristic. The resonator conductance in red is a defective resonator which excites all of the transverse modes. The parabolic approximation gives accurate results for the M1 and M2 mode frequencies and has reduced accuracy for the higher order modes.

III. TRANSVERSE MODES AND MASK ERRORS

Transverse modes in a single-mode resonator design can be excited when the acoustic velocity is not constant in the acoustic aperture (y-axis).

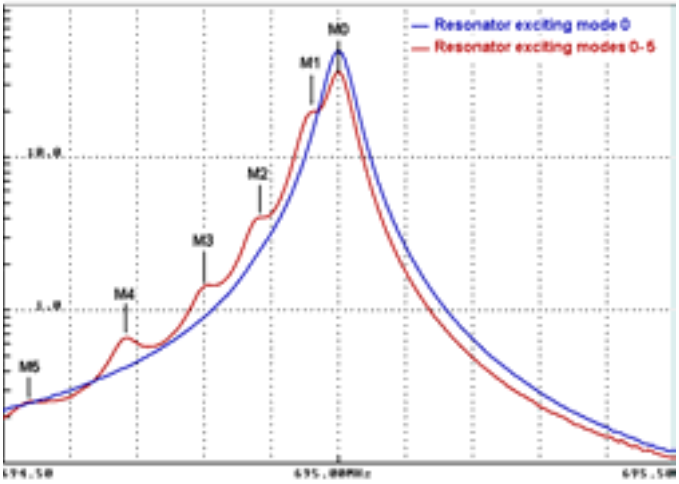

Fig 2 – Conductance plots of two measured resonators. The conductance in blue has only the fundamental mode M0. The conductance in red exhibits transverse modes M0-M5.

An example of the mode conversion mechanism is shown in fig 3. As the acoustic wave exits the transducer only the fundamental mode M0 exists. As the wave propagates over the effective path length some of the wave is converted into the antisymmetric mode M1.

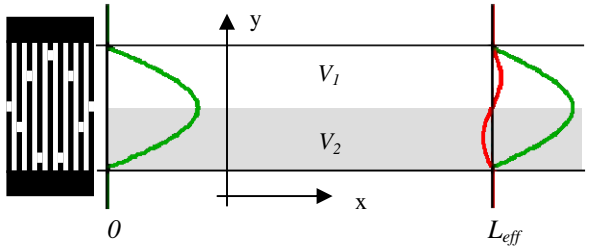

Fig 3 – Mode conversion due to a stepped velocity variation over the acoustic aperture of the transducer.

A second way in which unwanted transverse modes may be excited is when stripe butting errors (in x or y) exist in the resonator pattern.

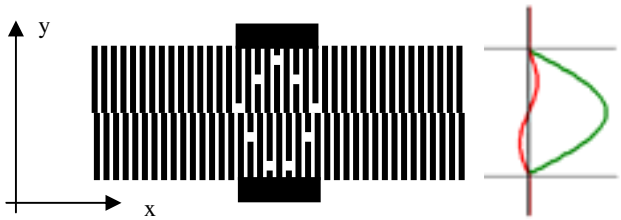

Fig 4 – Unwanted transverse mode generated due to stripe offset errors in the propagation direction (x-axis butting errors).

Both e-beam and laser mask generators write the mask patterns in a series of stripes. Linewidth differences between adjacent stripes will result in a difference in velocity. For the 695MHz resonator a 0.01um difference in linewidth results in a 28º phase difference at L_{eff} (fig 3). Butting errors at the stripe boundaries can also occur. An x-offset butting error of 0.01um corresponds to a 0.25° error and is large enough to affect the higher order modes M4, M5, …. These effects, along with nonlinearities within the stripes, will contribute to unwanted transverse modes in the resonator.

IV. PHOTOMASK TOOL EVALUATION

Photomasks were made using the Etec Alta 3500 and 3900 laser pattern generators, Micronic laser writer and an ASET 645 15" Image Repeater used with a 10x reticle. Note that the results which follow may not represent the optimum performances of the photomask tools. The x-axis of the resonator pattern is in the direction of stage motion and the y-axis is the direction of the raster scan. All but one of the Alta 3900 photomasks will have this orientation. The criteria for a useful resonator is that the mode 1 is suppressed. This will insure that, when used in an oscillator, frequency "popping" will not occur.

A photomask made using the Micronic laser writer was used to fabricate resonators. The conductance for the 16 resonators in row 6 are superimposed in fig 5. For this wafer the wafer yield is less than 8%.

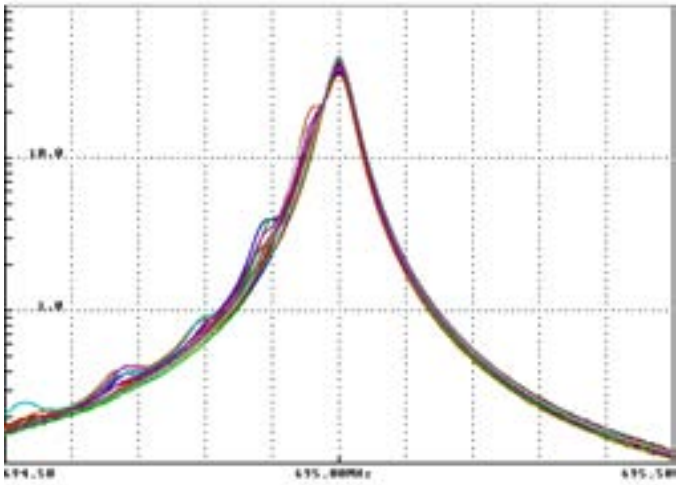

Fig 5 – Conductance plots for row 6 of wafer manufactured with a Micronic laser writer. Vertical scale in mS.

Two photomasks were made using the Alta 3500. One was made using 2-pass mode where the stripe is written twice. The second was made using 4-pass mode. Although using more passes increases the total write time, the stripe uniformity is improved. Measured conductances on a wafer manufactured with the 2-pass mode mask are shown in fig 6. In the figure there are 25 plots, one for each row on the wafer. The y-axis boundary positions of the stripes in the acoustic aperture are different for rows 1-5, however they repeat every 5 rows. These measurements demonstrate that stripe uniformity and butting errors can have a strong effect on resonator performance.

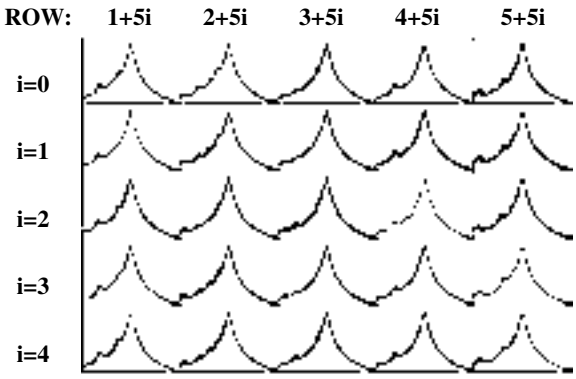

Fig 6 – Conductance plots of resonators in 25 rows on a quartz wafer manufactured with an Alta 3500 in 2-pass mode. Transverse mode patterns repeat every 5 rows.

The effect of going from a 2-pass mode to a 4-pass mode for mask generation is shown in fig 7. The extra passes suppress the high order transverse modes M3-M5 and reduce the M2 mode. The stitching errors do not appear to be effected.

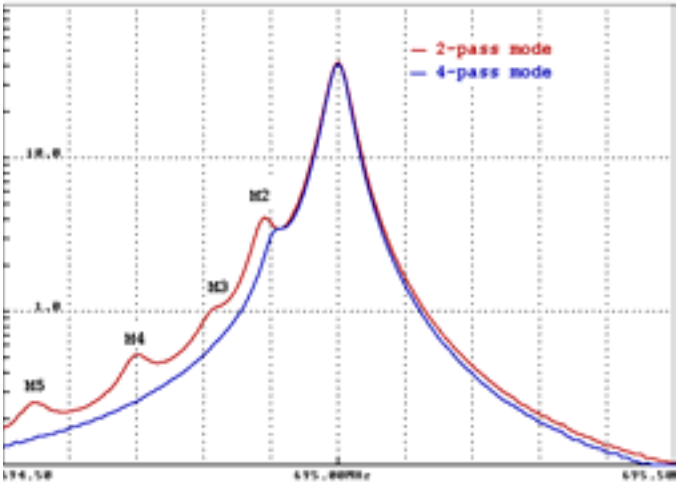

Fig 7 – Conductance plots of resonator in row 7, column 9 manufactured with an Alta 3500 in 2-pass mode (red) and 4-pass mode (blue). Vertical scale in mS.

Two photomasks were made using the Alta 3900, both in 2-pass mode. The first photomask has the standard pattern orientation (0° mask). For the second photomask (90° mask), the entire mask pattern was rotated 90° such that the acoustic aperture of each resonator is not split into stripes. A plot of 8 resonators fabricated with each photomask is given in fig 8.

The wafer yield is 28% for the wafer fabricated with the 0° mask. The yield increases to 45% with the 90° mask.

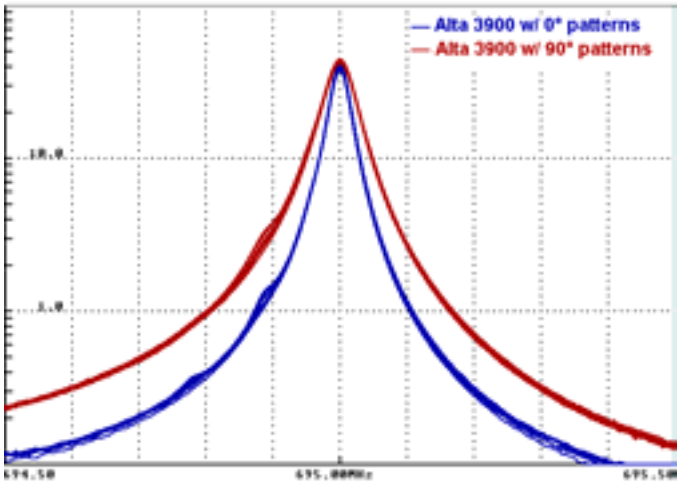

Fig 8 – Conductance plots of resonators in wafer row 17 manufactured with an Alta 3900 in 2-pass mode with a 0° pattern (blue) and with the 90° pattern (red). Vertical scale in mS.

The final photomask was made by first making a 10X reticle using an Alta 3900 and then stepping the pattern in a 16X26 array using a ASET 645 15" Image Repeater. This photomask will not have the types of errors which occur with laser pattern generators. Measurements of 44 resonators on a wafer are superimposed in the plot of fig 9, showing excellent repeatability.

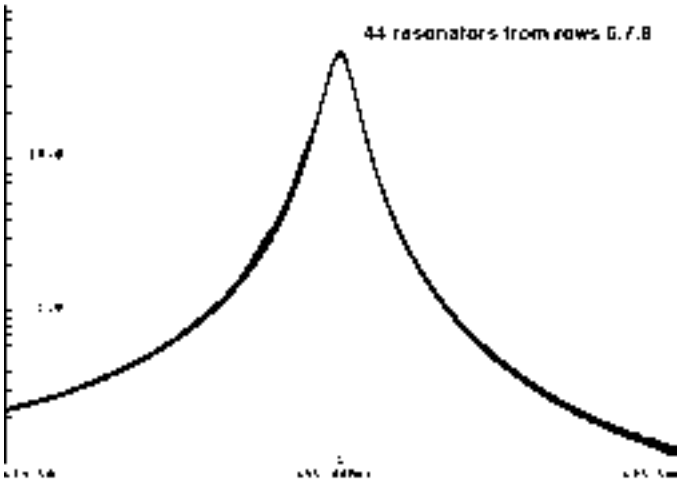

Fig 9 – Conductance plots of resonators wafer rows 6-8 fabricated with the ASET 645 15" Image Repeater. Vertical scale in mS.

An alternate method for testing for good resonators is to examine only a single parameter, motional resistance RM0 of mode M0 or 1/Gmax, where Gmax is the peak conductance of the resonator. When we compare two resonators (see fig 2) the resonator with unwanted modes will exhibit a smaller peak conductance or a larger value for RM0. By plotting the distribution of RM0 on a wafer we can estimate the wafer yield. The RM0 distributions for the six wafers are plotted in fig 10.

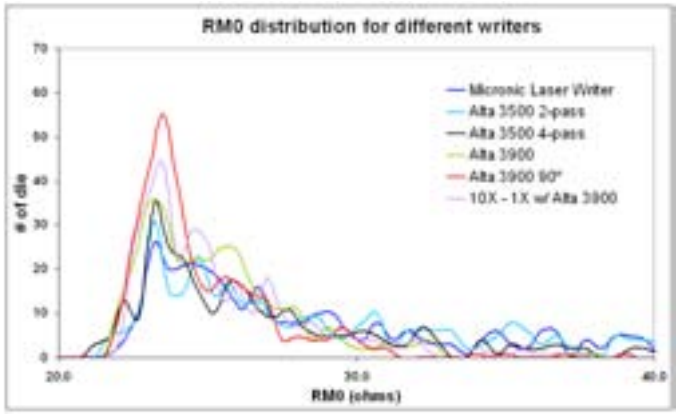

Fig 10 – Measured motional resistance distributions of mode 0 for 38° yx quartz with a 16 x 26 array of 1-port STW resonators fabricated with six different photomasks using 0.5Ω increments in RM0.

V. CONCLUSIONS

It has been shown that high order transverse modes in a STW resonator can be attributed to nonuniformities in the photomask. Variations in mask uniformity smaller than 0.01μm are detectable electrically using this method. This effect has been used to evaluate different photomask tools.

Tests have shown that newer generations of laser pattern generators are achieving better mask uniformity. Increasing the number of writing passes significantly reduces the higher order mode strengths.

The choice of pattern orientation (0º vs 90º) has an impact on the yield for resonators.

Finally, a photomask generated with a 10X stepper results in the best resonator performance.

***Abstract*—Direct imaging of a 10 μm surface acoustic wave (SAW) propagation in a $La_3Ga_5SiO_{14}$ (LGS) crystal was obtained on the ESRF synchrotron radiation source in the saggital diffraction geometry using the Talbot effect. Imaging of the SAW wave field with the period 10 μm was observed at a distance corresponding to the Talbot distance. It is shown that the presence of the growth banding in the crystal does not influence on the propagation of acoustic wave-fields in the crystal nor does it cause a distortion of the SAW wave front.**

Keywords-surface acoustic waves; $La_3Ga_5SiO_{14}$ crystal; X-ray diffraction; ssynchrotron radiation; Talbot effect

I. INTRODUCTION

Recent progress in modern telecommunication systems and sensors based on SAW-devices urges the development of methods to study the SAW propagation in solids. Most interesting and promising for the analyses of acoustic wave field in solids are scanning electron microscopy (SEM) and X-ray diffraction and topography. Scanning electron microscopy in the mode of low-energy secondary electron registration permits the visualization of surface and bulk, traveling and standing acoustic waves and makes it possible to study diffraction phenomena in acoustic beams and interaction of acoustic waves with crystal structure defects [1-5]. However, this method is efficient for the investigation of acoustic wave propagation only in piezoelectric crystals. The method gives only qualitative information on the acoustic wave propagation and allows measuring the wavelength of acoustic waves. Unlike scanning electron microscopy, X-ray diffraction and topography are the methods of quantitative analysis and permit studying acoustic wave fields both in piezoelectric and non-piezoelectric materials. Using high-resolution X-ray diffraction, amplitudes and wavelengths of acoustic wave can be determined, acoustic waves attenuation in the crystal depth and along their propagation direction can be measured by the analysis of their X-ray diffraction spectra [6-10]. Stroboscopic X-ray topography, like SEM, permits direct imaging of an acoustic wave field in the real time mode [6, 11-14]. Direct imaging of traveling SAW by stroboscopic X-ray topography is based on focusing of X-ray radiation by the SAW minima. In this case the image of a traveling SAW can be observed in the focal plane at a distance D from an acoustically modulated crystal surface. Since a SAW length consists of one minimum and one maximum, the period of an observed image is equal to one wavelength. Distance D is determined from the expression [11]

$$D = \sin\Theta_B / 2hK^2 \left(\sin^2\Theta_B \sin^2\beta + \cos^2\beta\right), \qquad (1)$$

where Θ_B is the Bragg incidence angle of X-ray radiation onto the modulated crystal surface, h is the SAW amplitude, $K = 2\pi/\Lambda$, Λ is the SAW wavelength, and β is the angle between the projection of incident X-ray radiation onto the crystal surface and SAW propagation direction. As is seen from (1) the focal distance D is directly proportional to the square of the SAW wavelength Λ and inversely proportional to the SAW amplitude h. However, it should be noted that imaging of a traveling SAW by stroboscopic X-ray topography is only possible at temporal synchronization of SAW excitation and inherent temporal structure of the synchrotron radiation source, which considerably limits the application of the method for the investigation of acoustic wave fields.

As to X-ray topography, it has no limitations for the analysis of standing SAW fields where an acoustic wave image is formed through focusing of X-ray radiation by antinodes of a standing wave and the period of image observation is two times smaller than the SAW wavelength [15].

The aim of this work is to study the traveling SAW propagation in the $La_3Ga_5SiO_{14}$ crystal by X-ray topography on a synchrotron radiation source.

Russian Foundation for Basic Research

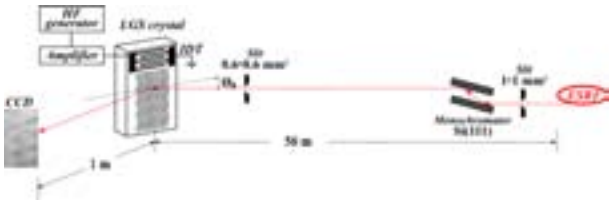

Figure 1. Experimental setup.

II. Experimental Setup

X-ray diffraction on the acoustically modulated $Y-$cut of the LGS crystal (reflecting planes (100) are parallel to the crystal surface) was studied in the saggital diffraction geometry in the scheme of a double-crystal X-ray diffractometer on the optical beamline ID06 of the ESRF synchrotron radiation source. The experimental scheme is shown in Fig. 1. The X-ray wavelength $\lambda = 1$ Å was selected with a Si(111) double-crystal monochromator which diffracts X-ray in vertical plane. The LGS crystal modulated with a $\Lambda = 10$ μm SAW was positioned at 56 m off the X-ray source. X-rays at the Bragg incidence angle Θ_B to the studied LGS crystal diffract on the SAW serving as diffraction grating for normal incidence. A CCD-camera was placed at 1 m from the acoustically modulated crystal to register a diffracted image of the crystal. The CCD-camera pixel was 0.645 μm.

III. SAW Device

LGS is a piezoelectric crystal of the 32 space group symmetry. The crystal lattice resembles the quartz crystal lattice with unit cell parameters $a = 8.170$ Å and $b = 5.128$ Å [9]. The LGS crystal was grown along the growth axis {11.0} by the Czochralski method in the "FOMOC Materials Co".

The $Y-$cut of the LGS crystal was used in the experiment. An interdigital transducer (IDT) was fabricated on the crystal surface by the photolithography method to excite the SAW. The IDT consists of 20 pairs of electrodes with a 5 μm period, which corresponds to a SAW with a wavelength of $\Lambda = 10$ μm. The velocity of SAW propagation in the $Y-$cut along axis X is $V = 2340$ m/s. This crystallographic orientation of SAW propagation in the LGS crystal obviates the power flow angle, which considerably simplifies the experiment. The resonance frequency of a $\Lambda = 10$ μm SAW excitation is $f_0 = V/\Lambda = 234$ MHz. The propagation of the traveling SAW leads to a strictly periodic sinusoidal deformation of a crystal lattice. The SAW amplitude can be varied from zero to several Å by varying the IDT high-frequency input signal.

IV. Experimental Results

Figure 2 presents an X-ray topograph of the $Y-$cut of the LGS crystal excited by the SAW. The image was registered at a distance of 1 m from the crystal. Reflection from the (100) planes at $\Theta_B = 4.175°$ was used. The topograph exhibits the growth banding which appear during the LGS crystal growth

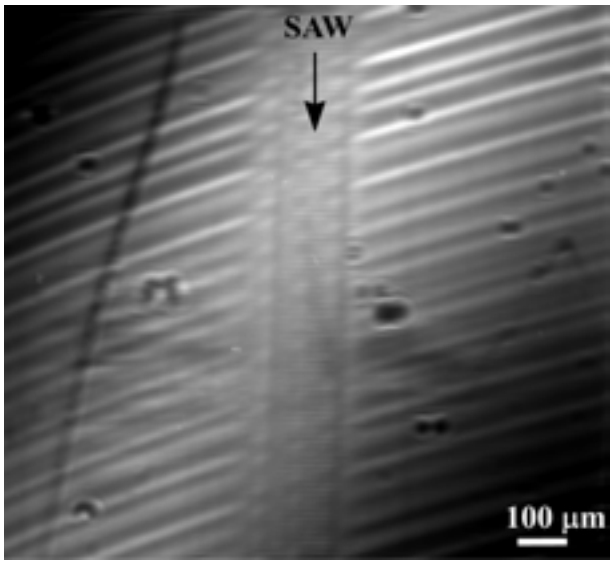

Figure 2. X-ray topograph of the $Y-$ cut of an LGS crystal excited by SAW. $\lambda = 1$ Å; $\Lambda = 10$ μm; $f_0 = 234$ MHz; reflection (100); $\Theta_B = 4.175°$.

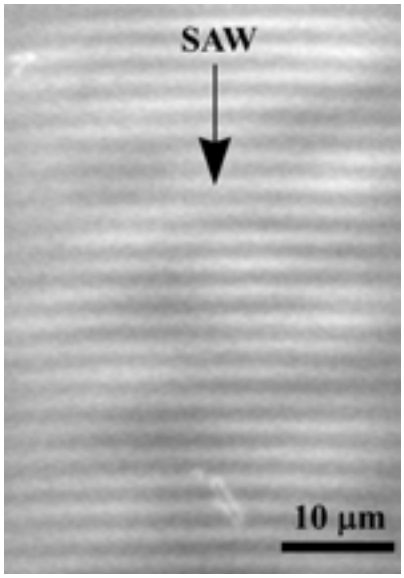
by the Czochralski method. An image of the SAW acoustic wave field is clearly seen in the topograph center. It is also seen that no diffraction divergence occurs in the acoustic beam.

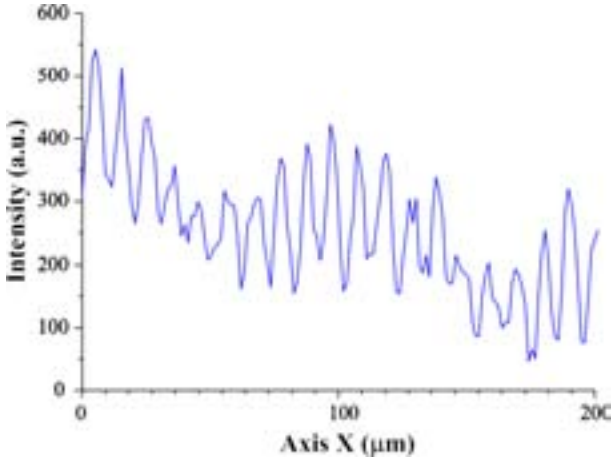
At higher magnification, the image of the acoustic wave fields appears as a periodic structure with a 10 μm period, which is equal to the $\Lambda = 10$ μm SAW wavelength (Fig. 3a). Figure 3b shows the corresponding distribution of the diffracted X-ray intensity in the SAW propagation direction along the X axis. The distribution of the diffracted X-ray intensity is a periodic structure with a 10 μm period.

The topographs in Figs. 2 and 3 show that the growth banding in the crystal do not influence the SAW propagation and do not cause a distortion of the acoustic wave front. Modulation of the diffracted X-ray intensity in the acoustic beam is a result of summation of the images of SAW and growth banding in the crystal. The distribution of the diffracted X-ray intensity (Fig. 3b) also exhibits modulation with a ~100 μm period, which corresponds to the period of growth banding in the crystal.

The possibility of SAW imaging is directly connected with the Talbot effect [16-17]. The effect consists in that the grating image is restored if the periodic grating is illuminated with a coherent radiation from a certain distance (the Talbot distance). A SAW can be regarded as a stationary diffraction grating because the velocity of SAW propagation is by five orders of magnitude slower than that of X-ray photons. In our case, SAW is stationary with respect to X-ray radiation. The synchrotron radiation at ESRF is, in part, coherent and this is one of the conditions for the realization of the Talbot effect. If an X-ray wavelength λ is much smaller than that of SAW, the Talbot distance is determined as [18-19]



(a)



(b)

Figure 3. Acoustic wavefield in the Y – cut of an LGS crystal: (a) SAW image; (b) distribution of the diffracted X-ray radiation along direction of SAW propagation. $\lambda = 1$ Å; $\Lambda = 10$ μm; $f_0 = 234$ MHz; reflection (100); $\Theta_B = 4.175°$.

$$Z_T = \frac{2\Lambda^2}{\lambda}. \qquad (2)$$

In our experiments at $\lambda = 1$ Å and $\Lambda = 10$ μm, the Talbot distance is $Z_T = 2$ m. The X-ray topographs in Figs. 2 and 3 were registered at the distance 1 m, which is two times smaller than the Talbot distance. At this distance $(Z_T/2)$ as at the Talbot distance (Z_T), the period of an image observed should be equal to the SAW wavelength [18-19]. In our experiment, a periodic structure of acoustic wave field with a 10 μm period was observed, which is equal to the SAW wavelength $\Lambda = 10$ μm.

Any changes in the distance to the crystal (large or smaller deviation from $Z_T/2$ distance) cause the disappearance of acoustic wave field image on the LGS crystal surface. Note that changes in the amplitude of the IDT input signal (hence, in the SAW amplitude) do not cause changes in the acoustic wave field image on the crystal surface.

V. Conclusion

The possibility of direct imaging of an acoustic wave filed on the crystal surface in the real time mode was demonstrated on an acoustically modulated LGS crystal in the saggital geometry of X-ray diffraction. It is shown that the formation of an acoustic wave field image is connected with the Talbot effect that can be realized on a synchrotron radiation source under the conditions of a partially coherent X-ray radiation and strongly periodic modulation of the crystal lattice with a surface acoustic wave.

Note that this method is optimal for direct imaging of acoustic wave field on the crystal surface since it does not require synchronization of acoustic wave excitation and X-ray irradiation of the crystal surface.

The analysis of the acoustic filed image on the LGS crystal surface showed that presence of crystal growth banding formed during the crystal growth by the Czochralski method does not cause a distortion of the acoustic wave field even if the SAW wavelength is smaller than the growth banding width.

Thus, the Talbot effect is an ideal instrument for direct imaging of acoustic wave fields and for investigation of acoustic wave interaction with the crystal structure defects.

***Abstract* — X-ray diffraction on the $La_3Ga_5SiO_{14}$ (LGS) crystal modulated by surface (SAW) and pseudo-surface acoustic waves (PSAW) with wavelength of Λ=6 μm was studied using a double axis X-ray diffractometer at the BESSY II synchrotron radiation source. The propagation of SAW and PSAW leads to sinusoidal modulation of the crystal lattice and gives rise to diffraction satellites on the rocking curve, with the intensity and angular divergence between the diffraction satellites depending on the wavelength and amplitude of the crystal lattice acoustic modulation. The analysis of diffraction spectra enables the determination of the amplitude and acoustic wavelengths, and power flow angles of acoustic energy propagation. The investigation of acoustic wave fields showed that PSAW is a flowing back wave.**

I. INTRODUCTION

Acoustoelectronic devices based on SAW are widely used in telecommunication systems for information processing and data transfer. Such devices are also efficient in sensor devices, wireless ones included. In recent years, novel piezoelectric materials promising for acoustoelectronics have been extensively searched. Much attention has been given to crystals of lanthanum-gallium silicate group which possess both good piezoelectric and thermal properties [1-4]. Note that SAW velocities in these crystals are small, which makes the crystals attractive for the fabrication of miniature acoustoelectronic devices.

Methods of X-ray topography and diffraction are of special interest in the studies of the crystal acoustic properties because they enable the visualization of acoustic wave fields in the crystals in the on-line mode. The X-ray topography method used in the region of Fresnel diffraction provides the visualization of acoustic wave fields on the crystal surface [5-8]. The acoustic wave fields were visualized in the main acoustic cuts of the langasite $La_3Ga_5SiO_{14}$ crystal, and power flow angles were measured by X-ray topography, because in this crystal the direction of the SAW wave vector does not coincide with the direction of the power flow vector [8]. The SAW propagation in the crystals can also be studied by X-ray diffraction which permits the SAW amplitude to be measured by the analysis of the diffraction spectra [9-12].

The aim of this work was to study the PSAW excitation and propagation in the LGS crystal. PSAWs are now an interesting object of investigation because PSAW, like SAW, can be excited using an IDT. SAW and PSAW have the same wavelength but different velocities and, consequently, are excited at different frequencies. In this work the double axis X-ray diffractometer was used to study SAW and PSAW excitation and propagation in the $Z-$cut of the LGS crystal.

II. EXPERIMENTAL SETUP

Figure 1 displays the schematic drawing of a double axis X-ray diffractometer setup on the KMC2 optical beamline at the BESSY II synchrotron radiation source. The energy of X-ray radiation near the $K-$edge of Ga was $E=12.5$ keV, which corresponds to kinematical diffraction. The energy was selected with a Si(111) double-crystal monochromator, and X-ray radiation was collimated with a 60×60 μm^2 entrance slit. The incident angle of X-ray radiation was the Bragg angle. Acoustic modulation of the crystal lattice gives rise to diffraction satellites on the rocking curve with the angular divergence between the satellites

$$\delta\Theta = d/\Lambda, \qquad (1)$$

where d is the interplanar spacing, and Λ is the acoustic wavelength. The angular divergence between the diffraction satellites is determined from expression (1) and the intensity of

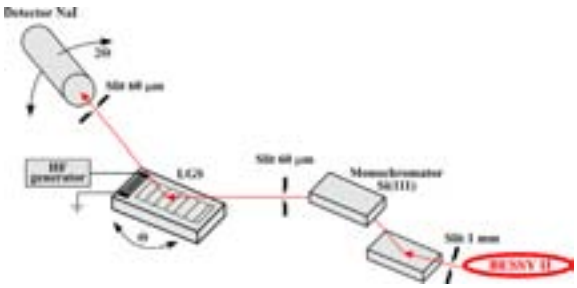

Figure 1. Experimental setup.

diffraction satellites depends on the amplitude of the crystal lattice acoustic vibrations [11-12]. A standard NaI scintillation detector with a 60 μm entrance slit was used to recorder the diffracted X-ray intensity.

III. SAW Device

LGS is a piezoelectric crystal of the point group symmetry 32. The crystal was grown along the {110} axis by the Czochralski method at the FOMOS Materials Co.

The $Z-$ cut of the LGS crystal (the (001) planes are parallel to the crystal surface) was used to study the SAW and PSAW propagation. On the crystal surface an interdigital transducer (IDT) was formed by e-beam lithography technique to excite the SAW and PSAW. The IDTs were formed on the crystal surface so that the wave vectors of the acoustic wave are along the $(X+30°)$ and $(X+60°)$ directions. The IDT consisted of 50 pairs of metallic electrodes with a 3 μm period, which corresponds to the SAW wavelength of $\Lambda = 6$ μm. The acoustic wave amplitude could be varied linearly from zero to several angstroms by changing the amplitude of the input high-frequency signal supplied to the IDT. The propagation of SAW and PSAW in the $Z-$cut of the LGS crystal is characterized by the power flow angle, i.e. the direction of power flow vector (PFV) does not coincide with the direction of the acoustic wave vector.

IV. Experimental Results

To study the SAW and PSAW propagation in the $Z-$cut of the LGS crystal along the $(X+30°)$ and $(X+60°)$ directions at various acoustic amplitudes, rocking curves were measured at X-ray energy $E=12.5$ keV (X-ray wavelength $\lambda = 1.03$ Å). The reflection from the (001) planes at the Bragg incidence angle $\Theta_B = 5.619°$ was used in the experiment.

Fig. 2 shows the maps of acoustic wave field distribution of SAW (a) and PSAW (b) on the $Z-$cut surface of LGS in the case of acoustic wave propagation along the $(X+30°)$ direction. The resonance frequency of $\Lambda = 6$ μm SAW excitation was $f = 416$ MHz, which corresponds to SAW velocity of $V = 2496$ m/s, while in the case of PSAW excitation the resonance excitation frequency is $f = 496$ MHz at the velocity of $V = 2976$ m/s. Thus SAW and PSAW have

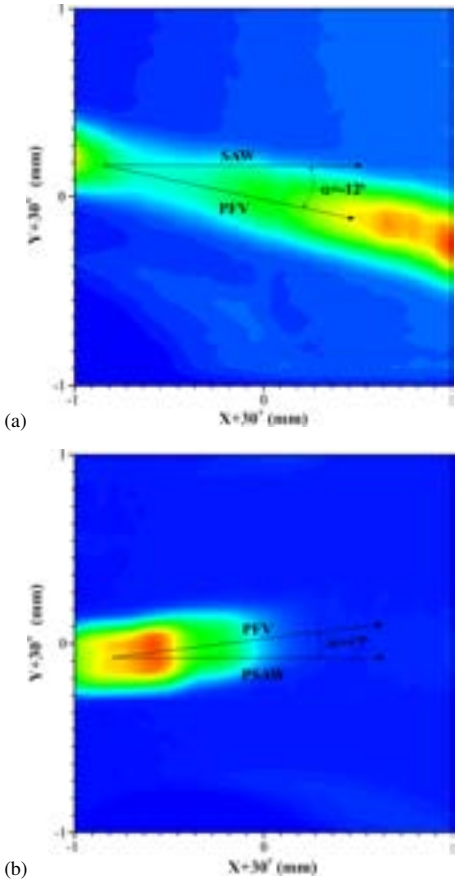

Figure 2. Maps of the diffracted X-ray intensity: (a) SAW, (b) PSAW. E=12.5 keV; reflection (001); Θ_B=5.619°; Λ=6 μm; SAW propagation along direction (X+30°).

the different velocities. The data in Fig. 2 were obtained at the amplitude of the input signal on an IDT $U = 15$ V and present the distribution of X-ray intensity on the crystal surface, which was diffracted to the first diffraction satellite. It is clearly seen from the maps that the direction of the SAW and PSAW wave vectors does not coincide with the PFV directions, i.e. the power flow angle occurs. Moreover, SAW and PSAW propagations differ by the direction and signs of the power flow angle. For SAW the power flow angle is $\alpha = -12°$, for PSAW it is $\alpha = +7°$. It is also seen in the figure that the PSAW acoustic wave field on the $Z-$cut surface of LGS can be observed only near the IDT, whereas the SAW acoustic wave field can be observed on the whole surface of the piezoelectric substrate. This means that PSAW is a flowing-back wave which propagates from the IDT into the crystal depth at an angle to the crystal surface. X-ray diffraction on the PSAW-modulated crystal can be observed only near the IDT.

Fig. 3 displays the rocking curves of the $Z-$cut of LGS crystal modulated by the SAW and PSAW with the wavelength $\Lambda = 6$ μm. The rocking curves were measured at the amplitude of the input signal on an IDT $U = 15$ V. The angular divergence between the diffraction satellites on the rocking curve is $\delta\Theta \approx 0.0051°$, which corresponds to the value

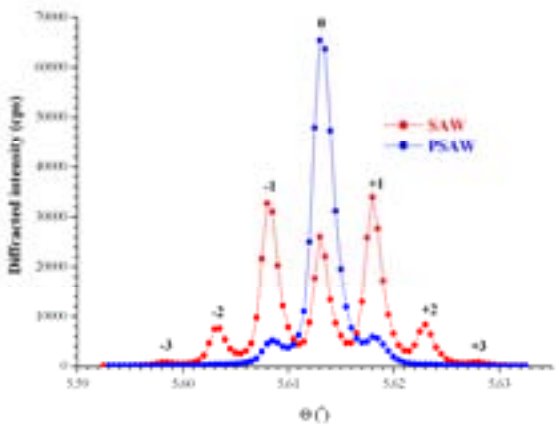

Figure 3. Rocking curves of the *Z*-cut of an LGS crystal modulated by SAW and PSAW propagating along (*X*+30°) direction. *E*=12.5 keV; reflection (001); Θ_B=5.619°; Λ=6 μm.

calculated from eq. (1) for the acoustic wavelength $\Lambda = 6$ μm. This similar divergence between diffraction satellites in the cases of SAW and PSAW suggests that these wave processes have similar wavelengths. As can be seen from Fig. 3, the rocking curves of the $Z-$cut of LGS crystal modulated by SAW and PSAW differ from each other. In the case of SAW modulation, the large number of the diffraction satellites can be seen on the rocking curve, which corresponds to more high acoustic amplitude than in the case of PSAW. In the case of diffraction on PSAW, the X-ray radiation first diffracts on the near-surface non-modulated crystal lattice and then diffracts on deeper PSAW-modulated layers of the crystal lattice. This results in that the intensity of the zero diffraction satellite exceeds the diffracted intensities of the rest orders.

Fig. 4 shows the maps of SAW (a) and PSAW (b) propagation along the $(X+60°)$ direction in the $Z-$cut of LGS crystal. It is seen that the power flow angle for SAW propagation is $\alpha = -6°$, while the power flow angle for PSAW is $\alpha = +5°$. Therefore the SAW and PSAW have the different excitation frequencies and velocities. The SAW with wavelength of $\Lambda = 6$ μm was excited at resonance frequency $f = 396$ MHz and propagated on the crystal surface with a velocity of $V = 2376$ m/s. The PSAW was excited at resonance excitation frequency $f = 516$ MHz and propagated with a velocity of $V = 3096$ m/s.

Fig. 5 presents the dependences of diffraction satellite intensities versus amplitude of the input signal supplied to the IDT for SAW (a) and PSAW (b). The character of the dependences is similar for SAW and PSAW. As the amplitudes of SAW and PSAW increase, the intensity of the zero diffraction satellite decreases. The intensities of the first diffraction satellites increase with increasing of the amplitude of acoustic wave. It is clearly seen in Fig. 5 that the diffraction satellites appear on the rocking curves at different amplitudes for SAW and PSAW. For SAW the first satellites appears on the rocking curve at $U = 1$ V, the second satellites appears at $U = 7$ V, while for the PSAW the first diffraction satellites appears at $U = 4$ V and the second satellites appears at $U = 14$

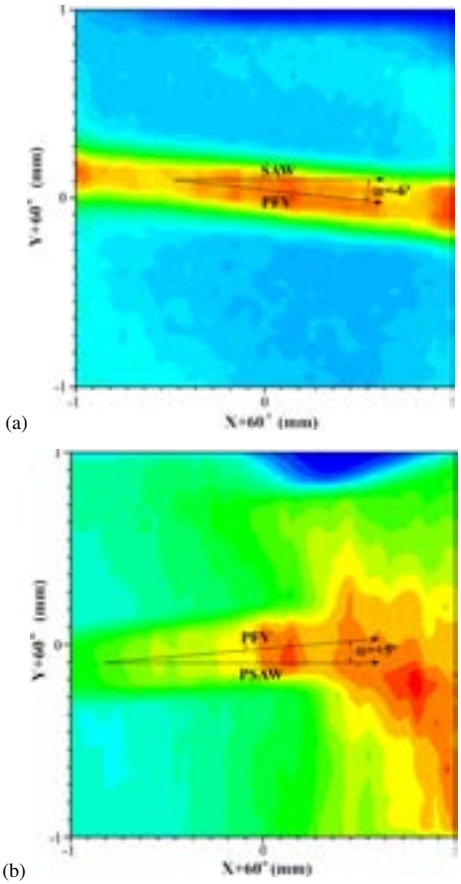

Figure 4. Maps of the diffracted X-ray intensity: (a) SAW, (b) PSAW. *E*=12.5 keV; reflection (001); Θ_B=5.619°; Λ=6 μm; SAW propagation along direction (*X*+60°).

V. Therefore in the case of PSAW in the LGS crystal the intensity of the zero diffraction satellite exceeds the intensity of the rest diffraction satellites because PSAW is excited by the IDT and tends to crystal depth at an angle to the surface.

V. Conclusion

X-ray diffraction on SAW and PSAW in the $Z-$cut of the LGS crystal was studied for the first time. The analysis of the diffraction spectra enabled the determination of the propagation velocities and power flow angles of the SAW and PSAW. It was shown that the velocity of PSAW exceeds that of SAW and the power flow angles of SAW and PSAW are of different values and signs. It was also found that SAW and PSAW are excited by the IDT although at different resonance frequencies. The Rayleigh SAW was found to propagate in the crystal subsurface whereas the PSAW propagates from the IDT towards the crystal depth at an angle to the crystal surface. Fig. 6 exhibits schematically the cross-section of the LGS crystal, the SAW (a) and PSAW (b) propagations, and X-ray diffraction on SAW and PSAW. In the case of PSAW, the X-ray radiation first diffracts on the crystal subsurface non-modulated by the acoustic wave and then part of the penetrated radiation diffracts deeper on the

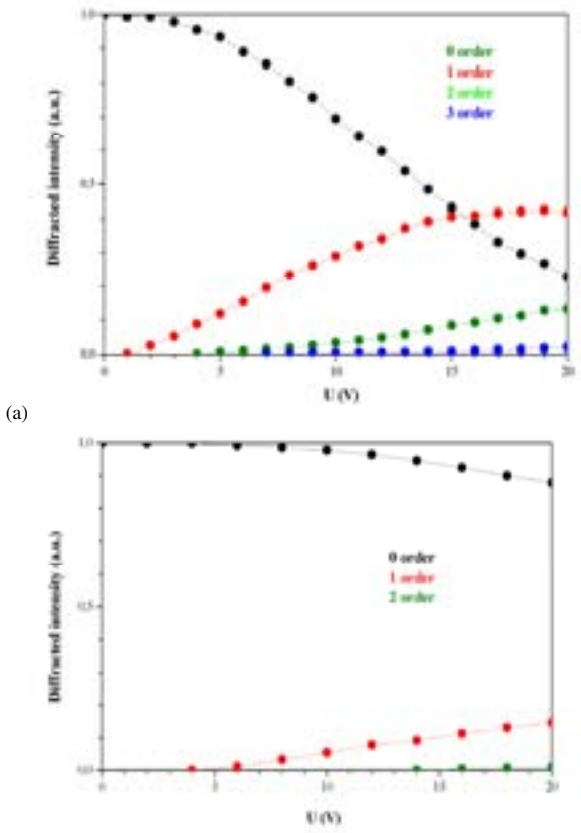

Figure 5. Intensities of the diffraction satellites in the *Z*-cut of an LGT vs. amplitude of the input signal supplied to the IDT *U*: (a) SAW; (b) PSAW. *E*=12.5 keV; reflection (001); Θ_B=5.619°; Λ=6 μm; SAW propagation along direction (*X*+60°).

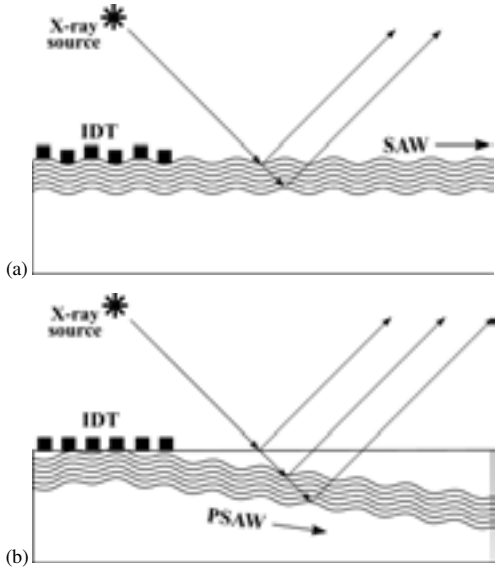

Figure 6. Schemes of SAW (a) and PSAW (b) propagation in the *Z*-cut of an LGS crystal.

crystal lattice modulated by PSAW (fig. 5b). This sequence of diffraction processes leads to a greater intensity of the zero diffraction satellite.

The difference in the power flow angles of SAW and PSAW looks promising from the viewpoint of creation of multifunctional multifrequency acoustoelectronic devices which can operate in various frequency ranges using one source of generation of various acoustic waves (e.g. an interdigital transducer).

Further development of the X-ray diffraction model and employment of the X-ray diffraction on a PSAW modulated crystal would enable the angle between the crystal surface and PSAW propagation direction to be determined.

Abstract— **The article observes the calculation technology of the surface specific gravity current in the contoured quartz resonators. And besides the authors of the article offer the construction of the electrodes optimized for the functional relation of the current distribution. Besides the article regards the calculation of the SC resonator's resistence- a SC - cut at various parameters of the surface's curves for optimized electrodes. The calculations' results are compared with the results for the electrodes of a standard construction.**

Keywords-component;quartz rezonator, calculation of the rezonator's resistance, rezonator's electrodes construction.

Double-rotated resonators of the SC-cut are widely spread in quartz generators because they possess robustness for the heat stress and changes. However they have a drawback- high activity of the temperature mode at a standard electrodes' construction. This work is aimed to calculate the optimized electrodes construction at which the activity of the temperature mode lowers and on the contrary the activity of the fundamental mode rises.

Practically, all data sources offer the following formula for the calculation of a surface electric current density in the sphere of electrode's covering:

$$Is = \omega \cdot \left(e_{22} \cdot Ay + e_{24} \cdot Az + e_{26} \cdot Ax\right) \cdot 2 / h, \quad (1)$$

where *Ax*, *Ay*, *Az* –are the components of the particle's displacement's phasor at vibrations, ω –angular rate of the present vibration mode, *h* –rezonator's thickness of a plate,

e_{2p} (p = 2, 4, 6) – the index of piezoelectric quartz rates in the system of coordinates of the resonator's plate. Besides, as it will be shown below, a formula (1) doesn't allow to optimize the electrodes' construction for the double- rotated cut resonators. Let's regard the processes of polarized currents' origin in quartz resonator electrodes more detailed than it is presented in classical literature. In this case let's take the following hypothesis:

- The gradients of displacements along the surface's plate are less than relevant gradients along the thikness.
- The distribution of amplitude's displacement obeys the sinusoidal manner.

Let's take the following identification marks for the coordinates: x z – coordinates along long and short sides of resonator, y – coordinate along the thickness of a plate (this is a standard system of coordinates for double-rotated cut resonators), the zero of coordinate system is in the centre of resonator; in some cases we will use indexes 1, 2 and 3 instead of letters to identify the coordinates (for coordinates x, y and z the indexes will be relevant), in this case the coordinates themselves will be marked as x_1, x_2 and x_3.

Let's write the data of the component's displacements:

$$U_i = A_i \cdot \sin\left(\frac{n \cdot \pi \cdot x_2}{h}\right) \cdot \sin\left(\frac{n \cdot \pi}{2}\right), \quad (2)$$

where i = 1 … 3. The components of the amplitudes' displacements A_i depends on the coordinates along the surface of the plate. (x_1 and x_3). Additional constant multiplier, depended on the number of a mode n, is inserted for the independence of the displacement mark on the surface of resonator from the number of a mode. Let's mark the components of deformations :

$$S_{ij} = \frac{1}{2}\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right), \quad (3)$$

Let's pass to single-index identifications from double-indexe ones:

$$\begin{cases} S_p = r_{ij}, & i = j,\ p = i \\ S_q = 2S_{ij},\ i \neq j,\ q = 9 - i - j \end{cases} \quad (4)$$

Let's express the components of polarization through deformations:

$$D_i = e_{ip} S_p \quad (5)$$

Here and after Einstein's law will be used, according to which in the expressions the summation by repeated indexes is made.

The presence of gradients of polarization means the origin of the volume charges. Let's write the Poisson's equation (with account for correlation (5)):

$$\rho = div(\bar{D}) = \frac{\partial D_i}{\partial x_i} = \frac{e_{ip} \partial S_p}{\partial x_i} \quad (6)$$

Let's mark the normal component of the electric field:

$$E_2 = \frac{1}{\varepsilon_{22}} \int \rho dy + C1 = \frac{1}{\varepsilon_{22}} \int e_{ip} \frac{\partial S_p}{\partial x_i} dx_2 + C1 \quad (7)$$

According to (7) we can express the amount of current potential.

$$V = -\int E_2 dy + C2 = -\int\left(\frac{1}{\varepsilon_{22}}\int e_{ip}\frac{\partial S_p}{\partial x_i}dx_2 + C1\right)dx_2 + C2 \quad (8)$$

The amount of a constant $C1$ in (7) and $C2$ in (8) for the area under electrodes can be determined according to conditions:

$V(h/2) = 0$, $V(-h/2) = 0$. (9)

For calculation of constanta $C2$ let's write the expression for the sum of potentials on the upper and lower plate: $V(h/2) + V(-h/2) = 0$. If we put here (8) with regard to (2...7), than we will have: $2 \cdot C2 = 0$, whence it follows that $C2 = 0$.

For determination of the amount of $C1$ lets write the expression for the contrast of the potentials on the upper and lower sides of a plate: $V(h/2) - V(-h/2) = 0$. The substitution of expressions here (2...8) gives the following result:

$$C1 = \frac{2h}{\varepsilon_{22} n^2 \pi^2}\left(\frac{\partial^2\left(e_{11}Ax + e_{16}Ay + e_{15}Az\right)}{\partial x^2} + \frac{\partial^2\left(\left(e_{15}+e_{31}\right)Ax + \left(e_{14}+e_{36}\right)Ay + \left(e_{13}+e_{35}\right)Az\right)}{\partial x \partial z} + \frac{\partial^2\left(e_{35}Ax + e_{34}Ay + e_{33}Az\right)}{\partial z^2}\right) - \frac{e_{22}\cdot Ay + e_{24}\cdot Az + e_{26}\cdot Ax}{h\cdot\varepsilon_{22}} \quad (10)$$

The formula evaluation (2...8) due regard to (10) gives the following result:

$$Is = \omega \cdot e_{ip} K_{ip}, \quad (11)$$

where wheight multipliers K_{ip} are expressed through the components of the amlitude's changes according to the table 1.

Table 1.

p	***i* = 1**	***i* = 2**	***i* = 3**
1	$\frac{-2h}{n^2\pi^2}\cdot\frac{\partial^2 Ax}{\partial x^2}$	$-\frac{\partial Ax}{\partial x}$	$\frac{-2h}{n^2\pi^2}\cdot\frac{\partial^2 Ax}{\partial x \partial z}$
2	$-\frac{\partial Ay}{\partial x}$	$2\frac{Ay}{h}$	$-\frac{\partial Ay}{\partial z}$
3	$\frac{-2h}{n^2\pi^2}\cdot\frac{\partial^2 Az}{\partial x \partial z}$	$-\frac{\partial Az}{\partial z}$	$\frac{-2h}{n^2\pi^2}\cdot\frac{\partial^2 Az}{\partial z^2}$
4	$\frac{-2h}{n^2\pi^2}\cdot\frac{\partial^2 Ay}{\partial x \partial z} - \frac{\partial Az}{\partial x}$	$2\frac{Az}{h} - \frac{\partial Ay}{\partial z}$	$\frac{-2h}{n^2\pi^2}\cdot\frac{\partial^2 Ay}{\partial z^2} - \frac{\partial Az}{\partial z}$
5	$\frac{-2h}{n^2\pi^2}\cdot\left(\frac{\partial^2 Ax}{\partial x \partial z} + \frac{\partial^2 Az}{\partial x^2}\right)$	$-\left(\frac{\partial Az}{\partial x} + \frac{\partial Ax}{\partial z}\right)$	$\frac{-2h}{n^2\pi^2}\cdot\left(\frac{\partial^2 Az}{\partial x \partial z} + \frac{\partial^2 Ax}{\partial z^2}\right)$
6	$\frac{-2h}{n^2\pi^2}\cdot\frac{\partial^2 Ay}{\partial x^2} - \frac{\partial Ax}{\partial x}$	$2\frac{Ax}{h} - \frac{\partial Ay}{\partial x}$	$\frac{-2h}{n^2\pi^2}\cdot\frac{\partial^2 Ay}{\partial x \partial z} - \frac{\partial Ax}{\partial z}$

The parameters in the table 1 are given for that side of a resonator that corresponds to the positive y-direction (at $y = h/2$). For the other side of a resonator (at $y = -h/2$) the amount of the multiplying parameters are resulted from the relevant expressions of the table 1 through multiplication of every expression component by $(-1)^{n+1}$, where n – is the order of coordinate derivative.

It's easy to assure oneself, that the expression (11) turns to (1) if all derived amplitudes of vibrations with respect to coordinates of the surface plate are equal to zero.

The formula of the calculation of functions on the surface of a resonator is given in [1]. The realization of the calculation's program of these functions in a format of a descriptor file FlexPDE is given in [4] and the calculation of the current's surface density according to the formula of the table 1 is given in [5].

Fig. 1 shows the calculation's results of the current's surface density of the mode f_{300} according to formula of the Table 1 for the plane-convex contoured SC – cut resonator (*yxbl*/22°20'/34°06') with the frequency of 10 MHz with contour radius of 100 mm.

The results of the calculations show that there are areas with the opposite signs of the charge destiny on the surface of the SC-cut resonator. Optimal electrode's design must take into consideration this phenomenon. In [2] and [3] the constructions of the resonator electrodes are described, where only the attempt is made without calculations.

Schematic sketch of a resonator and the electrodes constructions with account for the surface distribution of a current density show at fig 2. At this drawing the borders 1 and 2 corespond the electrodes at upper side of resonator, the borders 3 and 4 – at the lower. Y' axis is directed away from the observer, so the visible side of the resonator - the bottom. Electrode 1 is connected with electrode 4, and electrode 3 is connected with electrode 2. So an electrode is divided on two segments of different amount on every side of a plate and also there is a gap between them. The gap spreads along the border division of the polarization area with different signs. The gap's parameter is an angle with the X-axis (φ), and the amount of a shift of its centre from the centre of a resonator (S).

Electrodes' diameter is equal to 5mm in all cases.

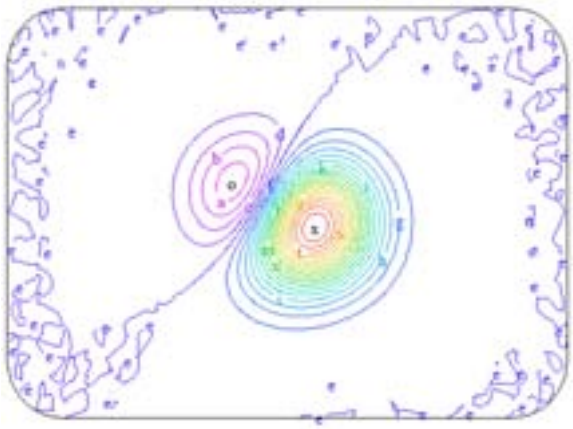

Fig.1. The distribution of a surface current density in the SC – cut resonator on top side (y=+h/2), view from bottom side through the plate.

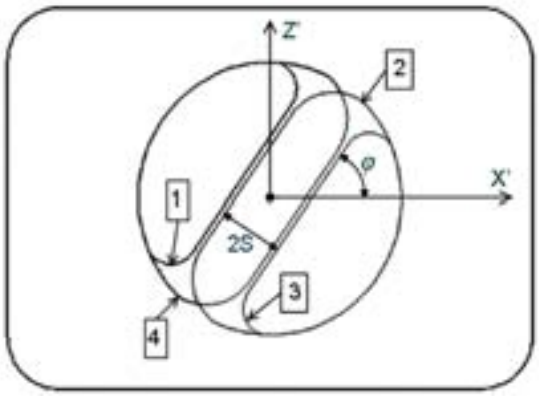

Fig.2. Scheme representation of a resonator and an electrodes

The results of calculations for resonator with the parameters mentioned above under exciting a mode C are given in the fig. 3 ... 5. Fig. 3 shows the lines of the vibration amplitude's level distribution for mode C. Picture 4 demonstrates the lines of the of a surface current density level (normalized in relation to the ordinary amplitude of vibration). It may be seen from the picture that the electrodes' construction is optimized for the distribution of surface charges. Picture 5 shows the same lines of the charges' distribution level but this time on the other side of resonator. (sight through resonator). Distributions shown on the pictures 4 and 5 are centrally symmetrical, so electrodes on the upper and lower sides must be mirror symmetrical. The same calculations for the mode B are given on the pictures 6 … 8. These pictures demonstrate that these electrodes are not more optimal for surface current of a mode so the resistance for this mode must rise essentially. The calculation results of the C and B's modes' resistance for different curve's values of resonator's surface are given in the Table 3.

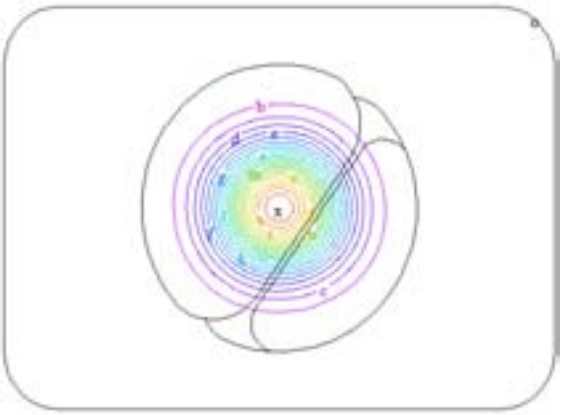

Fig.3. Lines of vibration amplitude's level distribution on the surface of a resonator for C-mode.

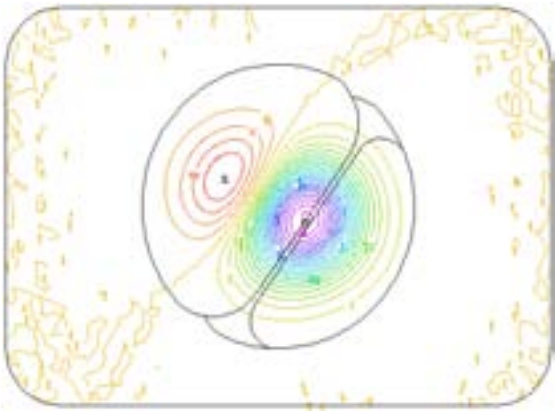

Fig.4. Lines of the current density level on the upper surface of a resonator for mode C (sight through the plate on the part of upper surface of a resonator)

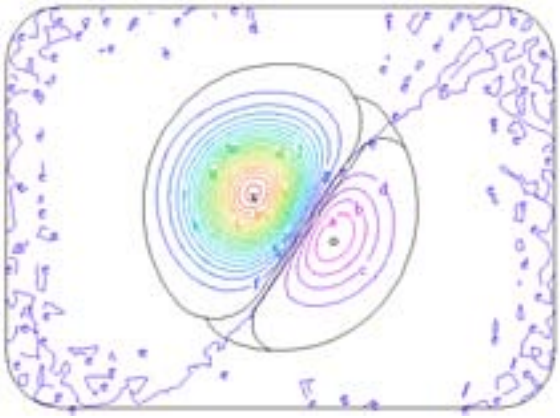

Fig.5. Lines of low surface-charge density level for mode C

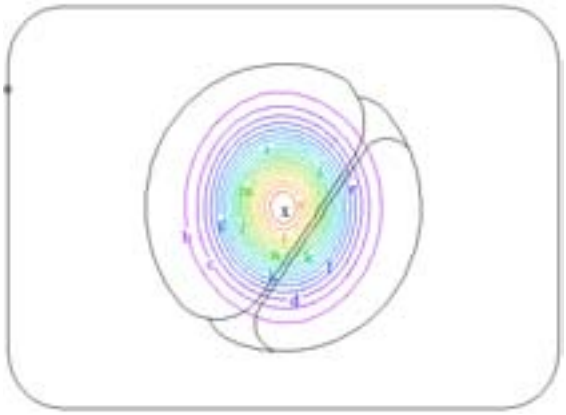

Fig.6. Lines of vibration amplitude's level distribution on the surface of a resonator for mode B.

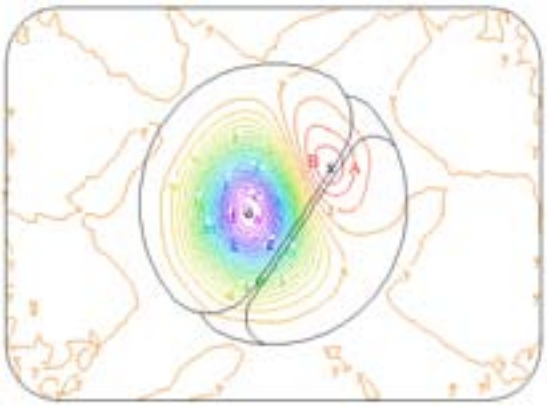

Fig.7. Lines of upper surface-charge density level of a resonator for mode B (sight through the plate on the part of resonator's upper surface)

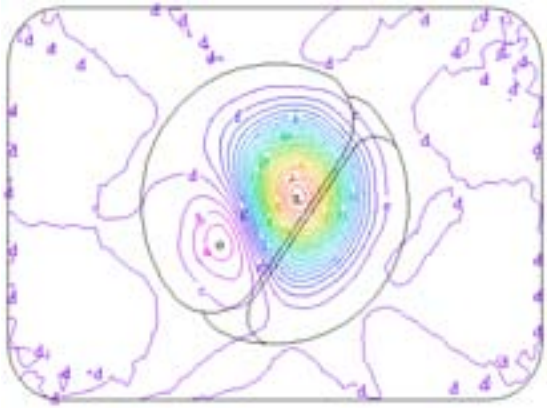

Fig.8.Lines of lower surface-charge density level for mode B

Table 3.

Contour radius, mm	300	200	150	100
Gap azimuth φ, degree	77	57	57	55
Gap shift S, mm	1	0.8	0.7	0.6
Mode C resistance (Rc), Ohm	68	70	72	76
Mode B resistance (Rb), Ohm	328	629	1007	1737
Rb/Rc	4.8	9.1	14.1	23.0

To compare the given results with the classical ones the Table 4 proposes the calculation results of a mode resistance for standard electrode's construction (entire electrodes) for the same resonator with the same electrode's diameter parameters.

Table 4.

Contour radius, mm	300	200	150	100
Mode C resistance (Rc), Ohm	91	107	120	144
Mode B resistance (Rb), Ohm	111	133	154	190
Rb/Rc	1.22	1.25	1.28	1.32

As it may be seen from the table above, for an standard electrode's construction the resistances Rb/Rc ratio lies within the range from 1.22 to 1.32, and for the offered construction within the range from 4.84 to 23.02. In a case of a standard construction it's quiet difficult to use a resonator in a generator because of the danger of a temperature mode excitement, so it's necessary to use special schemotechnical variants to reject an unwanted mode.

In case of electrodes' optimization, the correlation of resistances scales up till the parameter when it's possible to go without any additional instruments (as frequency-selective circuits). This method will allow to improve the stability of generator's frequency and to lessen its noises.

So, the presentation of electrodes improves the quality parameters of quartz resonator and leads to elevation of the safety of its functioning and also to reduction of the unwanted mode's vibration influence.

Abstract—The Mindlin plate theory has been widely used for the study of high frequency vibrations of quartz crystal plates for resonator design and analysis. To improve the accuracy, the plate equations have to be corrected for the exact thickness-shear frequencies which in turn ensure the accurate results for other coupled modes. The correction procedure was suggested by Mindlin and the correction factors for the first-order equations have been available. Lately, a systematic procedure for the correction factors up to the fifth-order has been established and two correction schemes with different correction factors have been adopted for the higher-order vibrations. These results have expanded applications of the Mindlin plate equations to the overtone vibration analysis which is required for the overtone resonators. One critical issue concerning the applications of the Mindlin plate with correction factors are the effect of electrodes, which are essential part of resonators and complications are resulted. With this objective in mind, we start from the Mindlin plate equations with a full set of vibration modes for the consideration of electrode mass and stiffness effects as a continuation of our earlier studies which only considered the mass effect in terms of mass ratios. The analysis regarding to the AT-cut of quartz crystal plates show that the consideration of electrode stiffness and mass will change the correction factors, thus making the equations more accurate in the calculation of frequency spectra and mode shapes. For very thin electrodes, the correction factors should be the same as suggested by earlier studies. The procedure is implemented to the SC-cut quartz crystal plates which have more enhanced couplings of vibration modes due to the material anisotropy. Correction factors for both AT- and SC-cut quartz crystal plates with consideration of electrode stiffness are given in polynomials of mass ratios for different metals.

Keywords—Mindlin; plate; vibration; quartz; crystal; resonator

I. INTRODUCTION

The Mindlin plate theory was developed for analysis thickness-shear vibrations of quartz crystal resonators without considering complication factors in the beginning [1, 2]. Since electrodes are important parts of quartz crystal resonators with great influence on the frequency and other properties, they should not be neglected when analyzing vibrations for practical applications. Mass effect of electrodes as the dominant feature has always been taken into consideration through mass ratio [3, 4, 5, 6, 7, 8], because thicknesses of electrodes are much thinner but heavier compared with crystal plates. While crystal blanks in resonators are shrinking in size and the electrodes remaining constant, the relative increase of influence of electrodes on the performance of plate resonators should be considered. In this case, it is natural that both stiffness and mass effects of electrodes are taken into consideration simultaneously. The stiffness and mass effects of electrodes can be considered through the ratio of thickness, density, and elastic constants of electrodes to those of quartz crystal plates, as demonstrated in an earlier study [9].

For the analysis with the Mindlin plate theory, Wang [5, 10, 11] have the plate equations corrected without and with mass effect of electrodes considered. The inclusion of stiffness effect was demonstrated before and the calculation is carried out in this study as part of the continued refinement of plate equations for the analysis of quartz crystal resonator.

II. MINDLIN PLATE EQUATIONS WITH THE CONSIDERATION OF STIFFNESS AND MASS EFFECTS OF ELECTRODES

From the higher-order Mindlin plate equations, the two-dimensional stress equations of motion for electroded quartz crystal plates are [9]

$$\begin{Bmatrix} T_{1,1}^{(n)} \\ T_{6,1}^{(n)} \\ T_{5,1}^{(n)} \end{Bmatrix} + \begin{Bmatrix} T_{5,3}^{(n)} \\ T_{4,3}^{(n)} \\ T_{3,3}^{(n)} \end{Bmatrix} - n \begin{Bmatrix} T_{6}^{(n-1)} \\ T_{2}^{(n-1)} \\ T_{4}^{(n-1)} \end{Bmatrix} = \sum_{m=0}^{N} \rho B_{mn} \left[1 + (m+n+1) R \right] \begin{Bmatrix} \ddot{u}_1^{(m)} \\ \ddot{u}_2^{(m)} \\ \ddot{u}_3^{(m)} \end{Bmatrix}, \quad (1)$$

where

$$B_{mn} = \begin{cases} \dfrac{2b^{m+n+1}}{m+n+1}, & m+n = \text{even}, \\ 0, & m+n = \text{odd}, \end{cases} \quad (2)$$

and $T_p^{(n)}$, R and $u_j^{(n)}$ are the nth-order stresses, mass ratio of electrodes and crystal plate, and displacements. Further details on this and following equations can be found in references listed in this paper.

The two-dimensional strain components with higher-order displacements in the abbreviated notations [2] are

$$S_1^{(m)}=u_{1,1}^{(m)},S_2^{(m)}=(m+1)u_2^{(m+1)},S_3^{(m)}=u_{3,3}^{(m)},$$
$$S_4^{(m)}=u_{2,3}^{(m)}+(m+1)u_2^{(m+1)},S_5^{(m)}=u_{3,1}^{(m)}+u_{1,3}^{(m)},\quad(3)$$
$$S_6^{(m)}=u_{2,1}^{(m)}+(m+1)u_1^{(m+1)},m=0,1,2,3\cdots.$$

We consider the electrodes are symmetric, then [9]

$$T_p^{(n)}=\sum_{m=0}^{N}B_{mn}c_{pq}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{pq}}{c_{pq}}\right]S_q^{(m)},\quad(4)$$

where c_{pq},c'_{pq} are constants of quartz crystal plate and electrodes.

The *n*th-order constitutive equations of symmetric correction are [10]

$$T_p^{(n)}=\sum_{m=0}^{N}B_{mn}c_{pq}\kappa_p^{(m)}\kappa_q^{(n)}S_q^{(n)}.\quad(5)$$

The correction factors are needed in maintaining the cut-off frequency of the thickness-shear and other important modes accurate in comparison with the three-dimensional solutions.

Substituting (3) into (4), with (5) we can obtain the full constitutive relation in terms of displacement components and electrode stiffness as

$$\begin{aligned}T_p^{(n)}=\sum_{m=0}^{N}B_{mn}\kappa_p^{(n)}\Bigg\{&c_{p1}\kappa_1^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p1}}{c_{p1}}\right]u_{1,1}^{(m)}+\\&c_{p2}\kappa_2^{(m)}(m+1)\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p2}}{c_{p2}}\right]u_2^{(m+1)}\\&c_{p3}\kappa_3^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p3}}{c_{p3}}\right]u_{3,3}^{(m)}+\\&c_{p4}\kappa_4^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p4}}{c_{p4}}\right]\left[u_{2,3}^{(m)}+(m+1)u_3^{(m+1)}\right]+\\&c_{p5}\kappa_5^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p5}}{c_{p5}}\right]\left(u_{3,1}^{(m)}+u_{1,3}^{(m)}\right)\\&c_{p6}\kappa_6^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p6}}{c_{p6}}\right]\left[u_{2,1}^{(m)}+(m+1)u_1^{(m+1)}\right]\Bigg\}.\end{aligned}\quad(6)$$

We focus on the cut-off frequency at zero wavenumber and assume straight-crested waves in crystal plates, then we can have (6) reduced to

$$\begin{aligned}T_p^{(n)}=\sum_{m=0}^{N}B_{mn}\kappa_p^{(n)}\Bigg\{&c_{p2}\kappa_2^{(m)}(m+1)\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p2}}{c_{p2}}\right]u_2^{(m+1)}\\&+c_{p4}\kappa_4^{(m)}(m+1)\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p4}}{c_{p4}}\right]u_3^{(m+1)}\\&+c_{p6}\kappa_6^{(m)}(m+1)\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p6}}{c_{p6}}\right]u_1^{(m+1)}\Bigg\}.\end{aligned}\quad(7)$$

Similarly, the *n*th-order constitutive equations of natural correction, in comparison with (5), are

$$T_p^{(n)}=\sum_{m=0}^{N}B_{mn}c_{pq}\kappa_p^{(m)}\kappa_q^{(m)}S_q^{(m)}.\quad(8)$$

Substituting (3) into (4), with (8) we can obtain

$$\begin{aligned}T_p^{(n)}=\sum_{m=0}^{N}B_{mn}\kappa_p^{(m)}\Bigg\{&c_{p1}\kappa_1^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p1}}{c_{p1}}\right]u_{1,1}^{(m)}+\\&c_{p2}\kappa_2^{(m)}(m+1)\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p2}}{c_{p2}}\right]u_2^{(m+1)}+\\&c_{p3}\kappa_3^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p3}}{c_{p3}}\right]u_{3,3}^{(m)}+\\&c_{p4}\kappa_4^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p4}}{c_{p4}}\right]\left[u_{2,3}^{(m)}+(m+1)u_3^{(m+1)}\right]+\\&c_{p5}\kappa_5^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p5}}{c_{p5}}\right]\left(u_{3,1}^{(m)}+u_{1,3}^{(m)}\right)+\\&c_{p6}\kappa_6^{(m)}\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p6}}{c_{p6}}\right]\left[u_{2,1}^{(m)}+(m+1)u_1^{(m+1)}\right]\Bigg\}.\end{aligned}\quad(9)$$

We focus on the cut-off frequency at zero wavenumber and assume straight-crested waves. Since electrodes are always isotropic, $T_p^{(n)}$ can be reduced with the elastic constants to

$$\begin{aligned}T_p^{(n)}=\sum_{m=0}^{N}B_{mn}\kappa_p^{(m)}\Bigg\{&c_{p2}\kappa_2^{(m)}(m+1)\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p2}}{c_{p2}}\right]u_2^{(m+1)}\\&+c_{p4}\kappa_4^{(m)}(m+1)\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p4}}{c_{p4}}\right]u_3^{(m+1)}+\\&c_{p6}\kappa_6^{(m)}(m+1)\left[1+(m+n+1)\frac{2b'}{b}\frac{c'_{p6}}{c_{p6}}\right]u_1^{(m+1)}\Bigg\}.\end{aligned}\quad(10)$$

III. Correction Factors with the Consideration of Stiffness and Mass of Electrodes

With the known exact thickness-shear vibration frequency obtained in an electroded quartz crystal plate [7] and the approximate solutions from the Mindlin plate equations with the consideration of stiffness and mass effect in constitutive equations and stresses equations of motion above, we can determine the correction factors through numerical solutions of the algebraic equation.

A. Symmetric Correction of Plate Equations for AT-cut Quartz Crystal

A.1. Correction of the First-order Plate Equations

With the two-dimensional constitutive equations, we can obtain stress $T_p^{(n)}$, and substitute the zeroth-order stresses (7) into first-order equations of motion (1) with parameters

$$s_{22}=\frac{2b'}{b}\frac{c'_{22}}{c_{22}},\quad s_{44}=\frac{2b'}{b}\frac{c'_{44}}{c_{44}},\quad s_{66}=\frac{2b'}{b}\frac{c'_{66}}{c_{66}}.\quad(11)$$

then we have

$$\left[\kappa_6^{(0)}\kappa_6^{(0)}(1+s_{66})-\frac{\Omega^2}{3}(1+3R)\right]A_1^{(1)}=0,$$
$$\left[\frac{c_{22}}{c_{66}}\kappa_2^{(0)}\kappa_2^{(0)}(1+s_{22})-\frac{\Omega^2}{3}(1+3R)\right]A_2^{(1)}+\frac{c_{24}}{c_{66}}\kappa_2^{(0)}\kappa_4^{(0)}A_3^{(1)}=0,$$

$$\frac{c_{42}}{c_{66}}\kappa_4^{(0)}\kappa_2^{(0)}A_2^{(1)}+\left[\frac{c_{44}}{c_{66}}\kappa_4^{(0)}\kappa_4^{(0)}\left(1+s_{44}\right)-\frac{\Omega^2}{3}\left(1+3R\right)\right]A_3^{(1)}=0. \tag{12}$$

Substituting the exact cut-off frequencies into (12), for non-zero solutions, determinant mush vanish, we can obtain correction factors. After obtaining correction factors with different thickness and mass ratios, for practical applications we have an empirical formula for correction factors as function of the mass ratios

$$\begin{aligned}\kappa_2^{(0)}&=0.9069+0.9122R-1.3865R^2+1.2484R^3,\\ \kappa_4^{(0)}&=0.9069+0.9361R-1.3670R^2+1.2240R^3,\\ \kappa_6^{(0)}&=0.9070+0.3850R-1.2796R^2+1.7362R^3.\end{aligned} \tag{13}$$

A.2. Correction of the Third-order Plate Equations

Substituting the second-order stresses (7) into third-order equations of motion (1) we can obtain

$$\begin{aligned}&\left[\kappa_6^{(0)}\kappa_6^{(0)}\left(1+s_{66}\right)-\frac{\Omega^2}{3}\left(1+3R\right)\right]A_1^{(1)}+\\&\left[\kappa_6^{(0)}\kappa_6^{(2)}\left(1+3s_{66}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]b^2A_1^{(3)}=0,\\&\left[\frac{c_{22}}{c_{66}}\kappa_2^{(0)}\kappa_2^{(0)}\left(1+s_{22}\right)-\frac{\Omega^2}{3}\left(1+3R\right)\right]A_2^{(1)}+\\&\frac{c_{24}}{c_{66}}\kappa_2^{(0)}\kappa_4^{(0)}A_3^{(1)}+\frac{c_{24}}{c_{66}}b^2\kappa_2^{(0)}\kappa_4^{(2)}A_3^{(3)}+\\&\left[\frac{c_{22}}{c_{66}}b^2\kappa_2^{(0)}\kappa_2^{(2)}\left(1+3s_{22}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]A_2^{(3)}=0,\\&\left[\frac{c_{22}}{c_{66}}\kappa_2^{(0)}\kappa_2^{(0)}\left(1+s_{22}\right)-\frac{\Omega^2}{3}\left(1+3R\right)\right]A_2^{(1)}+\\&\frac{c_{24}}{c_{66}}\kappa_2^{(0)}\kappa_4^{(0)}A_3^{(1)}+\frac{c_{24}}{c_{66}}b^2\kappa_2^{(0)}\kappa_4^{(2)}A_3^{(3)}+\\&\left[\frac{c_{22}}{c_{66}}b^2\kappa_2^{(0)}\kappa_2^{(2)}\left(1+3s_{22}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]A_2^{(3)}=0,\\&\left[\kappa_6^{(2)}\kappa_6^{(0)}\left(1+3s_{66}\right)-\frac{\Omega^2}{3}\left(1+5R\right)\right]A_1^{(1)}+\\&\left[\frac{9}{5}\kappa_6^{(2)}\kappa_6^{(2)}\left(1+5s_{66}\right)-\frac{\Omega^2}{5}\left(1+7R\right)\right]b^2A_1^{(3)}=0,\\&\left[\frac{c_{22}}{c_{66}}\kappa_2^{(2)}\kappa_2^{(0)}\left(1+3s_{22}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]A_2^{(1)}+\\&\frac{c_{24}}{c_{66}}\kappa_2^{(2)}\kappa_4^{(0)}A_3^{(1)}+\frac{9}{5}\frac{c_{24}}{c_{66}}b^2\kappa_2^{(2)}\kappa_4^{(2)}A_3^{(3)}+\\&\left[\frac{9}{5}\frac{c_{22}}{c_{66}}b^2\kappa_2^{(2)}\kappa_2^{(2)}\left(1+5s_{22}\right)-\frac{\Omega^2}{7}\left(1+7R\right)\right]A_2^{(3)}=0,\\&\frac{c_{42}}{c_{66}}\kappa_4^{(2)}\kappa_2^{(0)}A_2^{(1)}+\frac{9}{5}\frac{c_{42}}{c_{66}}b^2\kappa_4^{(2)}\kappa_2^{(2)}A_2^{(3)}+\\&\left[\frac{c_{44}}{c_{66}}\kappa_4^{(2)}\kappa_4^{(0)}\left(1+3s_{44}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]A_3^{(1)}+\\&\left[\frac{9}{5}\frac{c_{44}}{c_{66}}b^2\kappa_4^{(2)}\kappa_4^{(2)}\left(1+5s_{44}\right)-\frac{\Omega^2}{7}\left(1+7R\right)\right]A_3^{(3)}=0.\end{aligned} \tag{14}$$

Substituting the exact cut-off frequencies into (14), for non-zero solutions the determinant must vanish. After obtaining correction factors with different thickness and mass ratios, we have symmetric correction factors fitted into curves for different mass ratios as

$$\begin{aligned}\kappa_2^{(0)}&=0.9480+0.9164R-2.2725R^2+3.3899R^3,\\ \kappa_4^{(0)}&=0.9480+0.9415R-2.2689R^2+3.3868R^3,\\ \kappa_6^{(0)}&=0.9480+0.3632R-2.0880R^2+3.8494R^3,\\ \kappa_2^{(2)}&=0.7635+0.9104R-8.4394R^2+14.0294R^3,\\ \kappa_4^{(2)}&=0.7635+2.0148R-8.3618R^2+13.6602R^3,\\ \kappa_6^{(2)}&=0.7637+1.4842R-8.5784R^2+15.4158R^3.\end{aligned} \tag{15}$$

B. Natural Correction of Plate Equations for AT-cut Quartz Crystal

B.1. Correction of the First-order Plate Equations

Substituting the zeroth-order stresses (10) into the first-order equations of motion (1), we obtain the same equations as (12), and the results of correction factors are obtained as given in (13).

B.2. Correction of the Third-order Plate Equations

Substituting the second-order stresses (10) into the third-order equations of motion (1) we can obtain

$$\begin{aligned}&\left[\kappa_6^{(0)}\kappa_6^{(0)}\left(1+s_{66}\right)-\frac{\Omega^2}{3}\left(1+3R\right)\right]A_1^{(1)}+\\&\left[\kappa_6^{(2)}\kappa_6^{(2)}\left(1+3s_{66}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]b^2A_1^{(3)}=0,\\&\left[\frac{c_{22}}{c_{66}}\kappa_2^{(0)}\kappa_2^{(0)}\left(1+s_{22}\right)-\frac{\Omega^2}{3}\left(1+3R\right)\right]A_2^{(1)}+\\&\frac{c_{24}}{c_{66}}\kappa_2^{(0)}\kappa_4^{(0)}A_3^{(1)}+\frac{c_{24}}{c_{66}}b^2\kappa_2^{(2)}\kappa_4^{(2)}A_3^{(3)}+\\&\left[\frac{c_{22}}{c_{66}}b^2\kappa_2^{(2)}\kappa_2^{(2)}\left(1+3s_{22}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]A_2^{(3)}=0,\\&\frac{c_{42}}{c_{66}}\kappa_4^{(0)}\kappa_2^{(0)}A_2^{(1)}\frac{c_{42}}{c_{66}}b^2\kappa_4^{(2)}\kappa_2^{(2)}A_2^{(3)}+\\&\left[\frac{c_{44}}{c_{66}}\kappa_4^{(0)}\kappa_4^{(0)}\left(1+s_{44}\right)-\frac{\Omega^2}{3}\left(1+3R\right)\right]A_3^{(1)}+\\&\left[\frac{c_{44}}{c_{66}}b^2\kappa_4^{(2)}\kappa_4^{(2)}\left(1+3s_{44}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]A_3^{(3)}=0,\\&\left[\kappa_6^{(0)}\kappa_6^{(0)}\left(1+3s_{66}\right)-\frac{\Omega^2}{3}\left(1+5R\right)\right]A_1^{(1)}+\\&\left[\frac{9}{5}\kappa_6^{(2)}\kappa_6^{(2)}\left(1+5s_{66}\right)-\frac{\Omega^2}{5}\left(1+7R\right)\right]b^2A_1^{(3)}=0,\\&\left[\frac{c_{22}}{c_{66}}\kappa_2^{(0)}\kappa_2^{(0)}\left(1+3s_{22}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]A_2^{(1)}+\\&\frac{c_{24}}{c_{66}}\kappa_2^{(0)}\kappa_4^{(0)}A_3^{(1)}+\frac{9}{5}\frac{c_{24}}{c_{66}}b^2\kappa_2^{(2)}\kappa_4^{(2)}A_3^{(3)}+\\&\left[\frac{9}{5}\frac{c_{22}}{c_{66}}b^2\kappa_2^{(2)}\kappa_2^{(2)}\left(1+5s_{22}\right)-\frac{\Omega^2}{7}\left(1+7R\right)\right]A_2^{(3)}=0,\end{aligned}$$

$$\frac{c_{42}}{c_{66}}\kappa_4^{(0)}\kappa_2^{(0)}A_2^{(1)}+\frac{9}{5}\frac{c_{42}}{c_{66}}b^2\kappa_4^{(2)}\kappa_2^{(2)}A_2^{(3)}+$$
$$\left[\frac{c_{44}}{c_{66}}\kappa_4^{(0)}\kappa_4^{(0)}\left(1+3s_{22}\right)-\frac{\Omega^2}{5}\left(1+5R\right)\right]A_3^{(1)}+ \quad (16)$$
$$\left[\frac{9}{5}\frac{c_{44}}{c_{66}}b^2\kappa_4^{(2)}\kappa_4^{(2)}\left(1+5s_{22}\right)-\frac{\Omega^2}{7}\left(1+7R\right)\right]A_3^{(3)}=0.$$

Substituting the exact cut-off frequencies into (16), for non-zero solutions the determinant must vanish. Then we have natural correction factors fitted into curves for different mass ratios as

$$\begin{aligned}
\kappa_2^{(0)} &= 0.9408+1.0243R-3.2428R^2+5.4746R^3,\\
\kappa_4^{(0)} &= 0.9369+1.0603R-3.0354R^2+4.8909R^3,\\
\kappa_6^{(0)} &= 0.9370+0.4817R-2.8695R^2+5.4039R^3,\\
\kappa_2^{(2)} &= 0.7736+1.8259R-7.9338R^2+13.1607R^3,\\
\kappa_4^{(2)} &= 0.7725+1.9270R-7.8163R^2+12.6678R^3,\\
\kappa_6^{(2)} &= 0.7727+1.3951R-8.0023R^2+14.3097R^3.
\end{aligned} \quad (17)$$

IV. Conclusions

For practical applications, it is more convenient to have an empirical formula for correction factors as functions of mass ratios. Correction factors with stiffness and mass effects of electrodes considered are more useful in actual applications for the analysis of thickness-shear vibrations of miniaturized quartz crystal resonators with the Mindlin plate equations. While the correction factors with natural approach can be used in analytical solutions, the symmetric correction factors can also be implemented in the finite element analysis based on the Mindlin plate theory for numerical solutions. With the correction factors for thicker electrodes on the SC-cut quartz crystal substrates, we now have the full set of correction factors for both AT- and SC-cut quartz crystal blanks for vibration analysis needed in the design and optimization of quartz crystal resonators. Since accurate analysis can only be done with the finite element method, the new set of correction factors from this paper will enrich the capability and functions of our existing finite element software for quartz crystal resonator design.

***Abstract*— A 1 GHz AT-cut quartz thickness shear mode resonator is modeled for the first time with thermally induced bonding stresses and their effect on the device frequency-temperature (*f-T*) characteristic. Without the details of the bonding configuration, modeling indicates the *f-T* characteristic slightly rotates as a function of the change in stiffness of a simplified absorbing mount. However, if details of the bonding configuration are included, our modeling predicts the potential for a significant distortion in the *f-T* curve. High or varying stress over temperature in the device active region is found to lead to an undesirable increase in the *f-T* slope. The origin of the active region stress can be varied, but in practice it frequently originates from a temperature dependent bonding stress, or from fabrication steps such as metal depositions. In this paper we highlight the magnitude of the thermal stress effect on the *f-T* curve, and offer design methods that mitigate the thermally induced bonding stress by de-coupling the active resonator area from high stress regions of the quartz device.**

Keywords- Quartz MEMS, oscillators, resonators, frequency stability, stress, thickness shear mode.

I. Introduction

Frequency stability of oscillators used in timing applications is of paramount importance. It is well known that one dominant source of frequency instability in quartz oscillators relates to the mounting stresses incurred during wafer bonding[1]. A resonator bonded to a substrate at elevated temperature and subsequently cooled can experience significant residual stress in the device active region. As the operating temperature of the device varies, so does the magnitude of the residual stress. This stress acts to perturb the device resonant frequency thereby compromising frequency stability. Mounting stress relaxation over time can also lead to device hysteresis. As the need for higher frequency and smaller devices has developed for many new commercial applications, these effects are exacerbated in smaller packages. This paper discusses how ~1 GHz ultra-high-frequency (UHF) MEMs thickness-shear quartz resonator designs[2] can be optimized for improving thermal frequency stability via reduced residual stresses.

A newly developed 3-D FEA simulation technique which includes mounting stresses[3] is applied to optimize UHF device designs for high thermal stability. One of the effects of stress is to produce a rotation of the *f-T* characteristic. Very small stresses can produce significant frequency shifts, especially for fundamental mode UHF devices. This rotation can often mask the true quartz *f-T* characteristic and results in resonator thermal instability.

II. Mounting Stress Analysis

As an example of the effect of mounting stresses on device resonant frequency, Fig. 1 shows a simulation of frequency perturbation versus stress in the active region for a 770 MHz 2-µm-thick AT-cut quartz resonator. The inset of Fig. 1 shows a simulation of the thermally induced stress for a ΔT = +75°C of a single-thickness quartz resonator rigidly bonded to a silicon substrate with zero stress at T = 25°C. A mounting stress of 130 MPa near the mounts produces a stress of 1 MPa in the active region and a resulting resonator frequency shift of 21 ppm. We determine a sensitivity of 1 ppm/50 kPa stress in the active region which represents a significantly higher frequency sensitivity than for larger, thicker, lower frequency designs. In this paper, new UHF resonator designs are explored for mitigating this effect in sub-mm-size UHF quartz resonators.

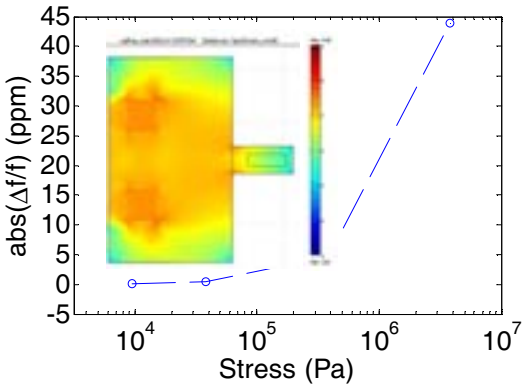

Figure 1. Frequency perturbation of a 2-µm-thick 770-MHz AT-cut resonator versus stress in the active electrode region.

At 1 GHz the effect of resonator frequency shift from residual stress becomes more pronounced. Here we explore the effect of varying mounting stiffness of a simplified resonator model. Fig. 2 presents a resonator model where

the mounting condition is initially an absorbing soft rubber strip with Young's Modulus, E = 2 x 10^{-8} Pa, which is fixed in space along its back surface to represent the anchor of the device. The AT-cut quartz resonator has plate dimensions 235 x 1.5 x 105 µm, and aluminum electrodes 150 x 0.04 x 50 µm. A thermally induced stress profile is calculated in COMSOL for this simplified quartz resonator and mount geometry for a ΔT = 75°C. In this model, bonding stress is assumed to be zero at T = 25°C. When elevated to T = 100°C, the residual stress in the center of the resonator active region (under the electrodes) is found to have increased to 319 kPa. Fig. 3 presents a corresponding linear cross section of the stress in the device along the quartz crystal x-axis.

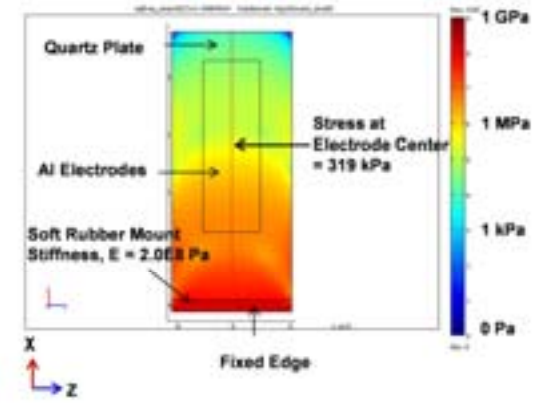

Figure 2. Simplified resonator design with ideal (soft) rubber mounts of Young's modulus E=2.0E8 Pa. Thermally induced stress at the mounts from a ΔT=75°C increase results in a Von Mises stress of 319 kPa in the active electrode region.

Consider the *f-T* characteristic of the simple resonator case as illustrated by the red curve in Fig. 4. This represents the unperturbed or unrotated *f-T* characteristic for soft mounts of stiffness E = 2 x 10^{-8} Pa. The absolute frequency shift for a temperature excursion from -40°C to 85°C corresponds to a 22 ppm change from the frequency observed at 25°C. Using COMSOL we calculate the device admittance parameters as f_0 = 1.05 GHz, R_1 =10.5Ω, L_1 = 2.1 x 10^{-5} H, C_1 = 1.1 fF, C_0 = 0.17 pF, and Q = 13.5K. The $f \times Q$ product for this design is $f \times Q$ = 1.42 x 10^{13}. As the stiffness of the fixed mount is stepped toward a more rigid condition (E = 2 x 10^{12} Pa), the corresponding *f-T* curves in Fig. 4 exhibit a slight counterclockwise rotation. While the absolute frequency at T = 25°C is maintained for all three stiffness cases, the frequency shifts to lower values

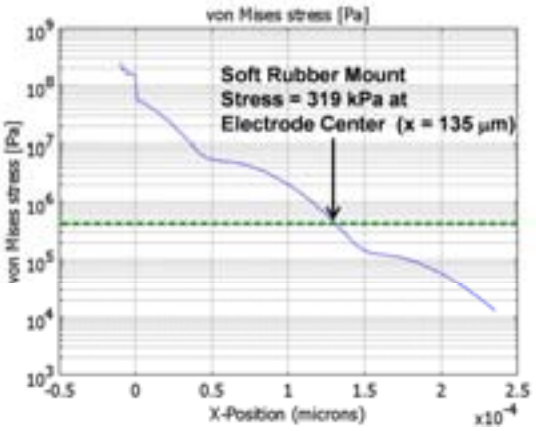

Figure 3. Plot of thermally induced Von Mises stress along the length of the resonator for a ΔT=75°C. The residual stress is 319 kPa at the center of the electrode.

below 25°C and higher values above this temperature as the mounts become more rigid. At 1GHz, this result is consistent with the theoretical analysis performed at 500 MHz by Y.K. Yong et al [3].

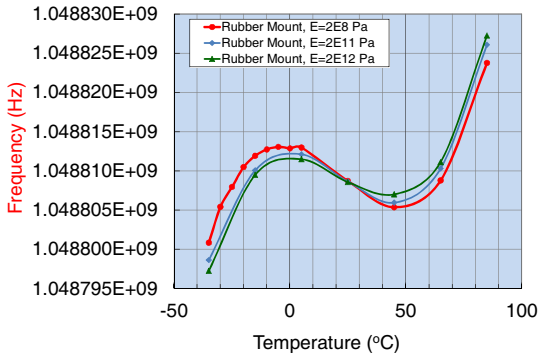

Figure 4. Variation of frequency over temperature for a simplified resonator design with zero mounting stress defined at T = 25°C.

For comparison, consider the case of a more detailed model that includes the mounting configuration with rigid (epoxy) bonds attaching the resonator to a silicon substrate as in Fig. 5. For a mount stiffness of E = 2.0 x 10^{11} Pa and the same ΔT = 75°C, the Von Mises stress is found to be significantly higher (σ = 731 kPa) in the active electrode region than for the simplified case (σ = 319 kPa). Fig. 6 shows the corresponding linear cross section of the stress along the x-axis of the crystal for this more detailed analysis.

The revised predicted *f-T* characteristic for varying stiffness of the bond regions (mounts) is presented in Fig. 7. For the rigid mount case where E = 2 x 10^{11} Pa, we calculate the admittance parameters of the device as f_0 = 1.05 GHz, R1 = 7Ω, L1 = 1.4x 10^{-5} H, C_1 = 1.6 fF, C_0 = 0.17 pF, and Q = 13.5K. The $f \times Q$ product remains high at $f \times Q$ = 1.42 x 10^{13}. If we replace the rigid mounts to the silicon substrate with a soft rubber like material of stiffness E = 2.0 x 10^{8} Pa, the *f-T* characteristic remains fairly unchanged from the simplified case. However, for stiffer mounts with a Young's

Modulus closer to that of quartz (E = 2.0 x 10^{11} Pa), the *f-T* characteristic becomes severely compromised. The *f-T* behavior takes on a more parabolic form, rapidly deviating in frequency above the simplified case as we depart from the zero bonding stress temperature of T = 25°C. This is consistent with empirical data for non-optimized devices which exhibit a high positive *f-T* slope above room temperature.

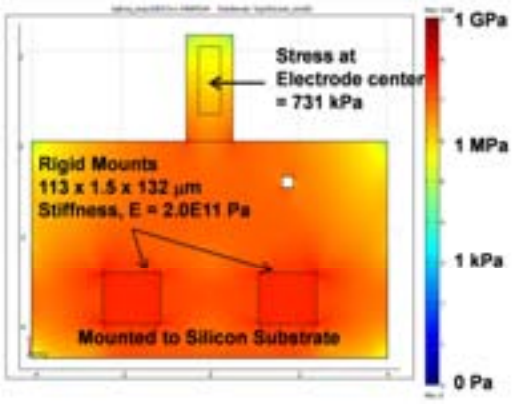

Figure 5. Von Mises stress of more detailed resonator design with mounts bonding the quartz to a silicon substrate. Stress is computed for ΔT = 75 °C.

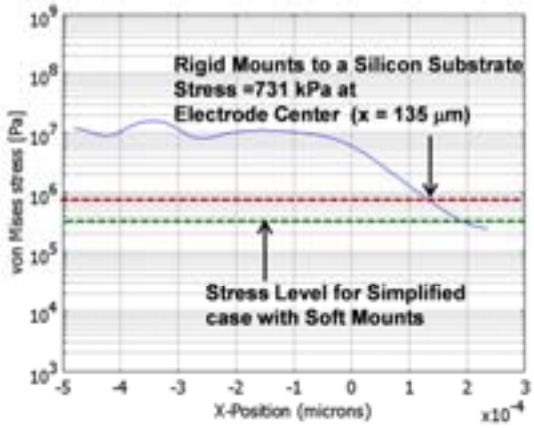

Figure 6. Plot of thermally induced Von Mises stress along the length of the resonator for a ΔT = 75°C. The resonator is bonded to a silicon substrate with rigid mounts. The residual stress magnitude is 731 kPa at the center of the electrode.

III. DESIGNS WITH IMPROVED FREQUENCY-TEMPERATURE CHARACTERISTIC

We determine that in order to correct the distorted *f-T* behavior of Fig. 7, one must de-couple the resonator mechanically from high stress regions. As an example, we incorporate stress relieving springs in the mounting configuration as shown in Fig. 8. The springs of width = 30µm efficiently relieve in-plane stress from the bonding sites (mounts) in both the x- and z-axes. The resonator is then effectively

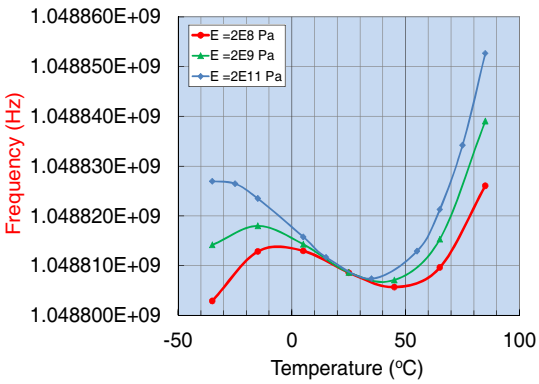

Figure 7. Variation in the f-T characteristic when residual stress from a more detailed mounting configuration is included. The f-T curve for soft mounts (red) is unrotated. High f-T distortion occurs as the stiffness of the mounts is increased to a rigid, epoxy like material (blue).

mechanically de-coupled from the high stress mounting areas. The calculated admittance parameters for this design are f_0 = 1.05 GHz, R_1 = 9.8Ω , L_1 = 2.0 x 10^{-5} H, C_1 = 1.2 fF, C_0 = 0.17 pF, and Q = 13.5K. For this design we maintain the $f \times Q$ product of 1.42 x 10^{13}.

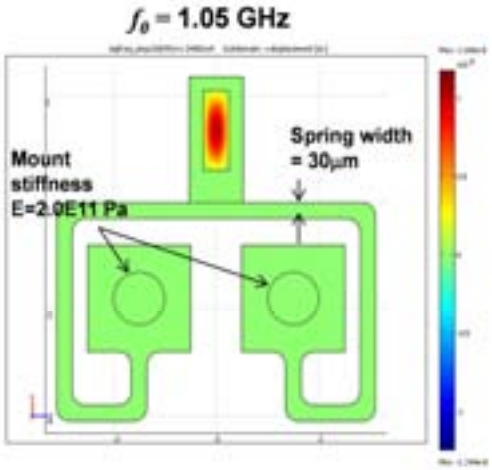

Figure 8. Schematic of improved 1GHz design with springs for stress relief in the active electrode region.

The resulting stress profile for a ΔT = 75°C is presented in Fig. 9 where we calculate a high stress in the mounting area but a low stress value of 21 kPa in the electrode region. The corresponding linear cross-section of stress across the resonator is presented in Fig. 10. Clearly, the spring mounting configuration predicts significantly lower stress in the electrode area over the simplified resonator case, therefore we anticipate an improved unrotated *f-T* characteristic.

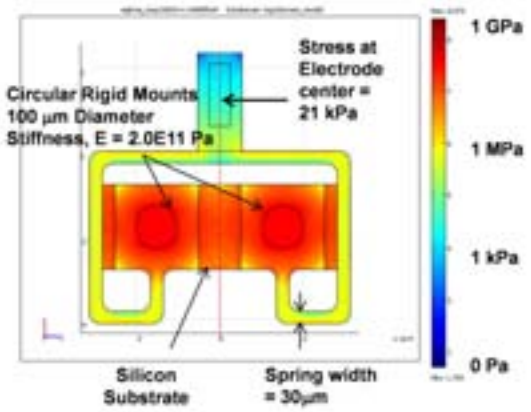

Figure 9. Springs provide stress isolation reducing the residual thermally induced stress in the active region to 21 kPa. ΔT=75°C.

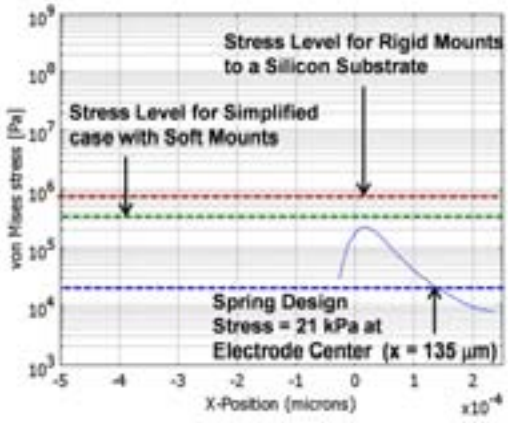

Figure 10. Stress isolation of the resonator from the bonding region significantly reduces residual stress in the active region to σ = 21 kPa.

The theoretical improvement in frequency stability over temperature is confirmed in the simulation result of Fig. 11. In this Figure, the *f-T* results are compared for (i) a resonator mounted via a quartz base to a silicon substrate (standard mount), and (ii) the same resonator mounted to the silicon substrate but isolated from the mounts by stress relieving springs (spring mount). The predicted *f-T* performance for soft versus rigid mounts is calculated for each case. Recall, for case (i) we observed a higher residual stress in the electrode region and rigid mounts showed the large frequency instability over temperature. However, implementation of stress isolation of the resonator with springs, e.g. case (ii), dramatically reduces frequency deviation from the soft mount case. The *f-T* characteristic maintains the classic S-shaped AT-cut quartz profile. The improvement in the *f-T* profile with springs corresponds to a 25 ppm improvement in thermal frequency stability for a ΔT = 50°C.

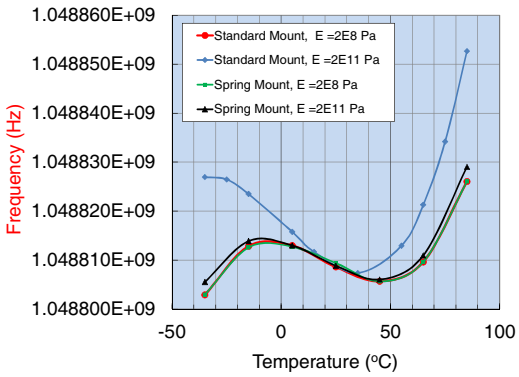

Figure 11. Distortion of the fT curve of the resonator with mounts bonded to a silicon substrate is significantly reduced for designs incorporating stress isolation in the form of spring elements.

CONCLUSIONS

Thermally induced mounting stresses in UHF quartz resonators has been modeled and its effect on frequency-temperature stability analyzed. The mounting condition plays an important role in the frequency stability of UHF devices over temperature. A detailed model shows that as the stiffness of mounts is increased from soft rubber to rigid mounts, the *f-T* curve rotates counterclockwise and can result in highly compromised frequency stability over temperature.

1GHz AT-cut quartz thickness shear mode resonators have been designed and analyzed offering significantly improved thermal frequency stability via a de-coupling of variable mounting stresses from the active electrode region. We have shown that implementation of stress relieving elements such as springs can greatly reduce the stress in the active electrode region and thereby eliminate the *f-T* instability caused by thermally and time varying mounting stress. We will apply this analysis method to future UHF oscillator designs for improved thermal frequency stability.

Abstract— **We have observed a phenomenon of high precision MEMS quartz resonators to change their frequency-temperature characteristics when they are mounted or bonded onto a substrate. This is due to the difference in thermal expansion coefficients between the quartz and substrate. When the temperature is changed, the mounting points between the quartz resonator and substrate become a source of mounting stress/strain in the resonator. We have defined a zero-stress temperature as the temperature at which the mounting stress is zero. We could determine the zero-stress temperature from the aging data of the resonator.**

We have derived a set of incremental equations for small vibrations superposed on mounting stress/strain that included the zero-stress temperature. The equations were employed in a COMSOL model of a UHF quartz resonator. The resonator frequency versus temperature profile was calculated by the change in eigenfrequency of the thickness shear mode as a function of the temperature. The eigenvalue problem of the resonator was modeled in COMSOL. The frequency-temperature curve of the resonator was shown to rotate counter-clockwise with the mounting stiffness and zero-stress temperature with respect to the frequency-temperature curve of the same resonator with no bonding stress. Furthermore the frequency-temperature curve of a bonded resonator will intersect the frequency-temperature curve of the same resonator without bonding stress at the zero-stress temperature.

Keywords- Quartz MEMS, frequency-temperature behavior, -zero-stress temperature, -bonding stress/strain, -COMSOL model.

I. INTRODUCTION

Bonding and mounting stress in quartz resonators is known to produce frequency shifts which can also modify the frequency-versus-temperature (f-T) profiles [1]. This stress/strain is produced by two events. First, when the quartz plate is initially bonded into the final package, the bonding process may require high temperature annealing or processing. When the package is cooled, the difference in thermal expansion coefficients between the quartz and the package produces stress that can partially relax to yield an initial stress condition at room temperature. Second, when the package is then varied over temperature during use, this initial stress is modified by the same thermal expansion coefficient differences. Depending on the thermal history of the device, the mounting stress can be minimized or reduced to zero at a particular temperature (T_{ref2}) as evidenced by a very low relaxation or aging rate. Previous numerical models for quartz f-T profiles [2] have not included this zero stress condition nor the variations in the stress and strain in the quartz due to the mounts in calculating the f-T profiles. In this paper, we describe a method within a COMSOL finite element analysis to include these effects for the first time.

II. GOVERNING EQUATIONS

A. *Definition of T_{ref2}, the zero-stress temperature*

It is necessary for our discussion of bonding stress to define the idea of a zero-stress-temperature T_{ref2}. Furthermore, it is also necessary for us to differentiate the zero-stress-temperature T_{ref2} from another reference temperature T_{ref} =25°C which is the reference temperature of the crystal material properties and the temperature at which the resonator is both stress and strain free.

The resonator is bonded to the substrate at some temperature above the reference temperature T_{ref}=25°C, and annealed at a higher temperature. At some point the mounts are "hardened". The wafer is brought back to room temperature and the mounting stress relaxes slowly over time. If the wafer sits at room temperature for several hours or days, the mounting stress/strain settles to some value. If the wafer is then increased in temperature to T_{ref2}, the mounting stress is found to be zero (based in aging data). We call T_{ref2} the zero-stress temperature. Note that while the resonator is stress-free at both T_{ref} and T_{ref2} it is strain free only at T_{ref}. While T_{ref} is equal to 25°C the value of T_{ref2} depends on the resonator bonding and processing

B. *Four states of the resonator*

For modeling the bonding stress and its effects on the frequency-temperature behavior of the resonator it is necessary to describe the resonator in four states in order to derive the governing equations.

Figure 1 shows the four states of the resonator and its respective material displacement vectors $\underline{\mathbf{U}}^{(a)}$, $\underline{\mathbf{U}}^{(b)}$, $\underline{\mathbf{U}}^{(c)}$, and $\underline{\mathbf{U}}^{(d)}$. State 0 is the initial reference frame at temperature T_{ref} = 25°C for the material properties, resonator geometry, and a stress-strain free state. The next state is State 1 when at temperature T_{ref2} the resonator is stress-free but *not* strain-free as explained in the previous section on the zero-stress

This work was sponsored in part by DARPA'S MTO office under the DEFYS program, issued by DARPA /CMO under contract No. HR0011-10-C-0109. The views and conclusions contained in this document are those of the authors and should not be interpreted as representing the official policies, either expressly or implied, of DARPA or the U.S. Government.

temperature T_{ref2}. State 2 of the resonator is at any operating temperature T wherein the resonator experiences both stress and strain due to bonding stress and thermal strain. Finally State 3 is when the resonator is excited and experiences small vibrations superposed on the previous State 2. In the next section, we derive the governing equations for small vibrations of the resonator superposed upon the strains and deformation of State 2.

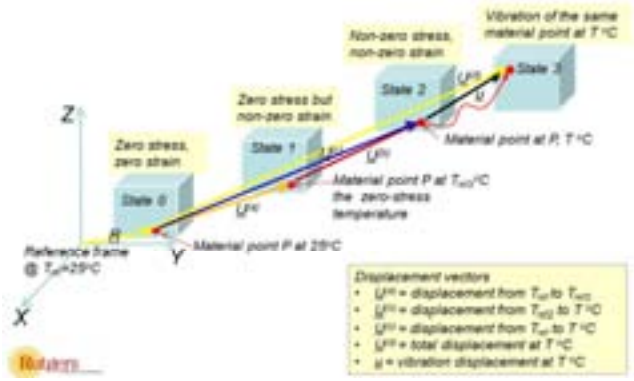

Figure 1. Four states of the resonator.

C. *Nonlinear Lagrangean governing equations for the resonator at State 2 and State 3*

The following are the governing nonlinear Lagrangean equations for the resonator at States 2 and 3.

Nonlinear strain-displacement relations:

$$E_{ij}^{(s)} = \tfrac{1}{2}\left(U_{i,j}^{(s)} + U_{j,i}^{(s)} + U_{k,i}^{(s)} U_{k,j}^{(s)}\right) \qquad \text{Eq(1)}$$

Nonlinear constitutive relations:

$$T_{ij}^{(s)} = C_{ijkl} S_{kl}^{(s)} + \frac{1}{2} C_{ijklmn} S_{kl}^{(s)} S_{mn}^{(s)} \qquad \text{Eq(2)}$$

Nonlinear stress equations of motion:

$$\begin{aligned} &(T_{ij}^{(s)} + T_{jk}^{(s)} U_{i,k}^{(s)})_{,j} = \rho \ddot{U}_i^{(s)} \quad \text{in V} \\ &\text{Specify } P_i^{(s)} = n_j (T_{ij}^{(s)} + T_{jk}^{(s)} U_{i,k}^{(s)}) \text{ or } U_i^{(s)} \text{ on S} \end{aligned} \qquad \text{Eq(3)}$$

$U_i^{(s)}$ is the displacement and the "s" superscript in parenthesis represents the state at which the displacement is defined, that is, s = c for State 2, and s = d for State 3. $E_{ij}^{(s)}$, $T_{ij}^{(s)}$, and $P_i^{(s)}$ are respectively the strain, stress and stress traction. C_{ijkl} and C_{ijklmn} are respectively the linear elastic constants and nonlinear elastic constants.

D. *Incremental equations for small vibrations superposed on thermal stress-strain in a resonator*

It is very difficult to solve computationally the set of nonlinear equations Eq(1), Eq(2) and Eq(3). However for small <u>*linear*</u> vibrations u_i superposed on State 2 we could derive a set of incremental equations that are linear if the displacements, stain and stress at State 2 are known a priori. We take the difference between the displacements, strain and stress at States 3 and 2, respectively, to obtain their incremental displacements, strain and stress:

$$\begin{aligned} u_i &= U_i^{(d)} - U_i^{(c)} \\ e_{ij} &= E_{ij}^{(d)} - E_{ij}^{(c)} \\ t_{ij} &= T_{ij}^{(d)} - T_{ij}^{(c)} \end{aligned} \qquad \text{Eq(4)}$$

We used the definition of incremental quantities in Eq(4), and a methodology similar to reference [3] to derive the incremental equations for small vibrations superposed on State 2:

Incremental strain-displacement relations:

$$e_{ij} = \frac{1}{2}(u_{j,i} + u_{i,j} + U_{k,i}^{(c)} u_{k,j} + U_{k,j}^{(c)} u_{k,i}) \qquad \text{Eq(5)}$$

Incremental stress-strain relations:

$$t_{ij} = (C_{ijkl} + C_{ijklmn} E_{mn}^{(c)}) e_{kl} \qquad \text{Eq(6)}$$

Incremental stress equations of motion:

$$\begin{aligned} &(t_{ij} + t_{jk} U_{i,k}^{(c)})_{,j} = \rho \ddot{u}_i \quad \text{in } V \\ &p_i = n_j (t_{ij} + t_{jk} U_{i,k}^{(c)}) \quad \text{in } S \end{aligned} \qquad \text{Eq(7)}$$

In the derivation of Eq(7) we have neglected the stress $T_{jk}^{(c)}$ because it was shown in reference [3] using variational analysis and Hamilton's equation that the initial stress $T_{jk}^{(c)}$ is a second order quantity that could be neglected in the incremental equations. Hence in Eq(5) to (7), only the deformation gradient and strain of State 2 are assumed known a priori in order for the governing incremental equations to *be linear*.

E. *Displacement and strain in the resonator at State 2*

It is necessary that we know the deformation gradient and strain at State 2 of the resonator in order to solve linearly the incremental governing equations (Eq(5) to (7)). From Fig. 1 we see that:

$$\begin{aligned} U_i^{(c)} &= U_i^{(a)} + U_i^{(b)} \\ E_{ij}^{(c)} &= E_{ij}^{(a)} + E_{ij}^{(b)} \end{aligned} \qquad \text{Eq(8)}$$

Hence, the displacement and strain in the resonator at State 2 are dependent on their respective quantities at State 1.

1) Thermal strains under stress-free and steady-state uniform temperature at T_{ref2}: State 1

The constitutive equations for an elastic material with thermal expansion are:

$$\sigma_{ij} = C_{ijkl}(E_{kl}^{(a)} - \alpha_{kl}\theta_a) \quad \text{Eq(9)}$$

where σ_{ij} is the stress tensor, C_{ijkl} elastic constants, $E_{kl}^{(a)}$ strain tensor at State 1, α_{kl} thermal expansion coefficients and $\theta_a = (T_{ref\,2} - T_{ref})$. The thermal expansion coefficients for quartz were measured by Bechmann, Ballato and Lukaszek [4]. Since at State 1 the resonator is stress-free, that is $\sigma_{ij} = 0$, Eq(9) implies that $E_{kl}^{(a)} = \alpha_{kl}\theta_a$. Therefore at State 1 the resonator has thermal strains:

$$E_{kl}^{(a)} = \alpha_{kl}\theta_a . \quad \text{Eq(10)}$$

2) Thermal strains at temperature T: State 2

Resonator not bonded: If the resonator is *not bonded* to any substrate it will have negligible stress at any temperature T. The resonator remains stress free, therefore the thermal strains will be like Eq(10) by a similar argument:

$$E_{kl}^{(c)} = \alpha_{kl}\theta \quad \text{where} \quad \theta = (T - T_{ref}) \quad \text{Eq(11)}$$

Eq(11) can also be written as $E_{kl}^{(c)} = \alpha_{kl}\theta_a + \alpha_{kl}\theta_b$

where $\theta_a = (T_{ref\,2} - T_{ref})$ and $\theta_b = (T - T_{ref\,2})$

Or

$$E_{kl}^{(c)} = E_{kl}^{(a)} + E_{kl}^{(b)} \quad \text{Eq(12a)}$$

$$\text{where} \quad E_{kl}^{(a)} = \alpha_{kl}\theta_a \quad \text{Eq(12b)}$$

$$\text{and} \quad E_{kl}^{(b)} = \alpha_{kl}\theta_b \quad \text{Eq(12c)}$$

$E_{kl}^{(a)}$ is the thermal strain at State 1 induced when the temperature changed from T_{ref} to T_{ref2} while $E_{kl}^{(b)}$ is the thermal strain induced in the stress-free resonator when the temperature changed from T_{ref2} to T.

Resonator bonded: If the resonator is *bonded* to a substrate the resonator will have stresses at temperature T, and Eq(12c) is then not valid because with the bonding stress $E_{kl}^{(b)} \neq \alpha_{kl}\theta_b$. It is necessary then to calculate $E_{kl}^{(b)}$ by a finite element software such as COMSOL. Eq(12c) must be amended for the bonded resonator to read:

$$E_{kl}^{(b)} = \text{thermal strains calculated by COMSOL} \quad \text{Eq(12d)}$$

Eq(12b) is still valid since by definition the resonator is stress-free at both temperatures T_{ref} and T_{ref2}.

III. Frequency-Temperature Curves of the Bonded Resonators

The resonator frequency versus temperature profile is calculated by the change in eigenfrequency of the thickness shear mode as a function of the temperature. The eigenvalue problem of the resonator is modeled in COMSOL where Eq(12a) to Eq(12d) are first solved, and followed by the solution of the eigenvalue problem of Eq(5) to (7). We show in Fig. 2 a COMSOL model of a 526 MHz, AT-cut quartz resonator. The resonator is bonded to a silicone strip at the bottom end, and the silicone strip is fixed. The resonator plate is hence mounted like a cantilever plate.

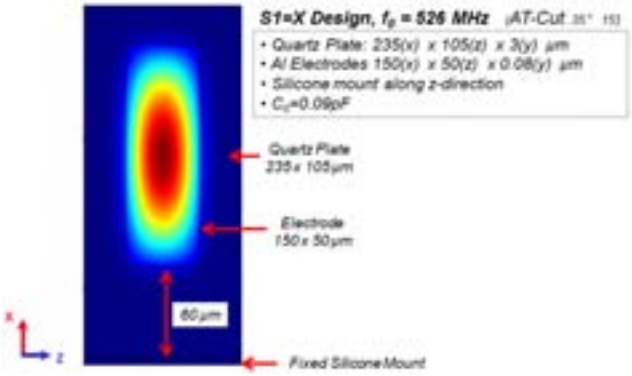

Figure 2. COMSOL of a 526 MHz, AT-cut quartz resonator.

A. *Effects of the mounting stiffness on the frequency-temperature curves.*

The effect of bonding stress on the frequency versus temperature profile (f-T curve) of the resonator is studied by changing the elastic stiffness constant of the silicone strip mount (mounting stiffness) from $2.0\text{x}10^8$ Pa to $2.0\text{x}10^{11}$ Pa and $2.0\text{x}10^{12}$ Pa, respectively. The bonding stress in the resonator depends on the mounting stiffness relative to the elastic stiffness constants of the quartz plate (quartz stiffness). Since the quartz stiffness are in the order of 10^{11} Pa, the bonding stress is negligible when the mounting stiffness is $2.0\text{x}10^8$ Pa. The bonding stress when the mounting stiffness is $2.0\text{x}10^{12}$ Pa will be greater than when the mounting stiffness is $2.0\text{x}10^{11}$ Pa. Figure 3 shows the effect of mounting stiffness on the f-T curves of the AT-cut resonator. The zero-stress temperature T_{ref2} was kept at 25°C. We observe that at higher bonding stress

(higher mounting stiffness), the f-T curves rotate counter clockwise about the 25°C reference temperature point. The f-T curve for mounting stiffness=2.0x10^{12} Pa does not quite cross the other curves at 25°C due to a spurious mode at about -5°C.

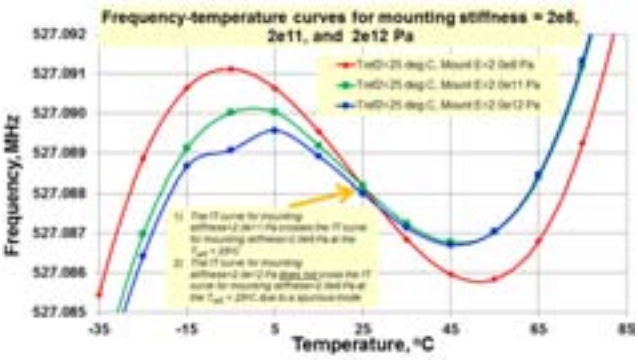

Figure 3. Effect of the bonding stress and mounting stiffness on the f-T curves of the AT-cut resonator.

B. *Effects of the zero-stress temperature T_{ref2} and mounting stiffness on the f-T curves.*

The effects of both the zero-stress temperature and mounting stiffness on the f-T curve of the AT-cut resonator are studied. Figure 4 shows the effect of the zero-stress temperatures 25, 35 and 45°C on the f-T curves when the mounting stiffness is set to 2.0x10^{8} Pa. We see that the three f-T curves mutually coincide. Since the mounting stiffness is about a thousand times smaller than the quartz stiffness there is negligible bonding stress in the resonator. Therefore, there is negligible effect from the change of the zero-stress temperature from 25 to 45°C

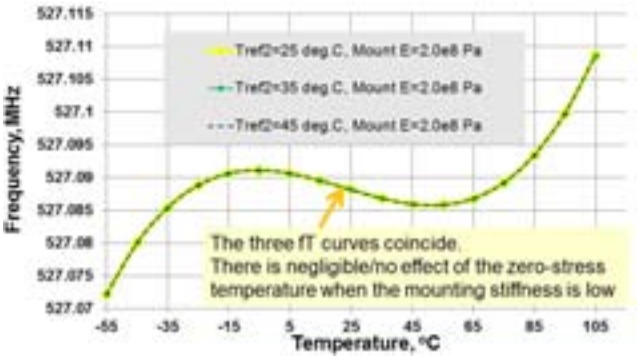

Figure 4. Effect of the zero-stress temperature on the f-T curves when the mounting stiffness = 2.0x10^{8} Pa.

When the mounting stiffness is increased to 2.0x10^{11} Pa we see the presence of bonding stress in the resonator. Figure 5 shows the counter clockwise rotation of the f-T curves for increasing zero-stress temperature when the mounting stiffness is set to 2.0x10^{11} Pa. Also we observe in the figure that the f-T curves for the zero-stress temperatures 25, 35 and 45°C cross the curve for mounting stiffness=2.0x10^{8} Pa at 25, 35 and 45°C, respectively. Since the f-T curve when the mounting stiffness = 2.0x10^{8} Pa represents a resonator without bonding stress, the temperature at which the other frequency-temperature curve intersects it would represent the zero-stress temperature of the resonator with bonding stress. This validates our concept and definition of the zero-stress temperature of a resonator.

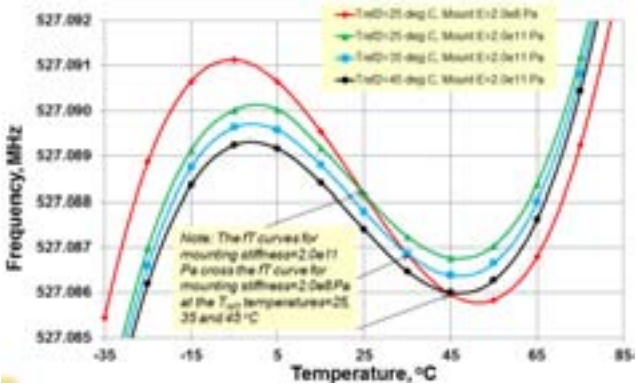

Figure 5. Effect of the zero-stress temperature on the f-T curves when the mounting stiffness = 2.0x10^{11} Pa.

When the mounting stiffness is increased to 2.0x10^{12} Pa the bonding stress is greater than when the mounting stiffness was 2.0x10^{11} Pa. Figure 6 shows the effect of this increased bonding stress on the f-T curves with zero-stress temperatures 25, 35, and 45°C, respectively. There are counter clockwise rotations of the f-T curves. In addition we observe that the increased bonding stress has induced an unwanted mode (spurious mode) at about -5°C which in turn has affected the f-T curves so that they do not cross the f-T curve with mounting stiffness=2.0x10^{8} Pa at their respective zero-stress temperatures. Instead, the f-T curves cross at higher temperatures than their respective zero-stress temperatures. For example the f-T curve of the resonator with mounting stiffness=2.0x10^{12} Pa and zero-stress temperature 45°C crosses the f-T curve with mounting stiffness=2.0x10^{8} Pa at about 50°C

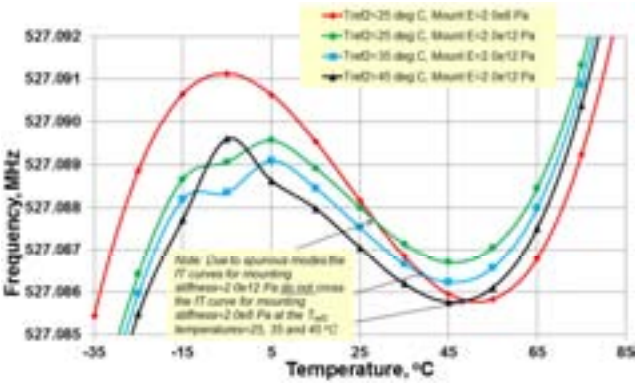

Figure 6. Effect of the zero-stress temperature on the f-T curves when the mounting stiffness = 2.0x10^{12} Pa.

IV. CONCLUSIONS

A set of incremental equations for small vibrations superposed on initial thermal strains, including the zero-stress temperature, was derived and employed to study the effects of mounting stiffness and zero-stress temperature on the frequency-temperature behavior of a UHF quartz resonator. The zero-stress temperature T_{ref2} is the temperature at which the plate resonator is stress-free but *not* strain-free. The zero stress point will be governed by the bonding of the plate, and relaxation after bonding. The mounting supports will create inhomogeneous thermal strains and stresses in the plate as the temperature is changed from T_{ref2}. These strains are a function of the stiffness of the mounting material, mounting geometry and resonator geometry.

The resonator frequency versus temperature profile was calculated by the change in eigenfrequency of the thickness shear mode as a function of the temperature. The eigenvalue problem of the resonator was modeled in COMSOL. With increasing mounting stiffness and zero-stress temperature the frequency-temperature curve of a quartz resonator was shown to rotate counter-clockwise with respect to the frequency-temperature curve of the same resonator with no bonding stress. Furthermore the frequency-temperature curve of a bonded resonator will intersect the frequency-temperature curve of the same resonator without bonding stress at the zero-stress temperature

Relaxation of the inhomogeneous stresses over time can create hysteresis if the resonator is not sufficiently isolated from the mounts. Compared to soft mounts such as rubber or epoxy, hard mounts can create larger rotations of the f-T profiles. Our general analysis can be applied to any resonator geometry and mounting design to optimize the predictability of the f-T curve and minimize hysteresis and aging. This is particularly important for UHF shear-mode device designs where micron-thick quartz plates are utilized.

***Abstract*—Single-bit Nyquist-rate quantization of sinewaves with amplitude dithering using a sequence of independent and uniformly distributed random variables has been proposed for all-digital RF frequency synthesis generation. This work demonstrates how we can improve the Dynamic Range using non-uniformly distributed dithering by selectively allowing some of the harmonics to be present in the spectrum (vs. the spurs-free output of the uniform distribution.). MATLAB simulation examples illustrate the results of the proposed approach.**

Keywords—Digital-to-frequency converter, direct digital synthesis, frequency spurs, quantization

I. INTRODUCTION

Over the past few years all-digital frequency synthesis has attracted the attention of the R.F.I.C. industry [1]-[3]. This was motivated by the increasing challenge in the design of R.F., analog and mixed-signal related circuit blocks, compared to alternative digital ones, as technologies downscale. Interestingly, efforts towards all-digital frequency synthesizers can be traced at least thirty years back [4]-[6].

Fully digital architectures have been proposed for generating synchronous single-bit digital outputs of sinewave-like spectrum which can be used as local-oscillator signals in RF chains and be amplified for transmission without distortion and with very high efficiency using a switching amplifier.

Here we consider a single-bit-output Nyquist-rate sinewave quantization scheme, discussed in [7]-[8], which is practically realized by a Direct Digital Synthesizer (DDS) with a 1-Bit output Nyquist-rate Digital to Analog Converter (DAC). Dithering is added to the output of the Look-Up-Table (LUT) before the single-bit quantization to alleviate the frequency spurs by breaking the periodicity of the truncation error.

It has been shown in [7]-[8] that uniform dithering of appropriate range completely eliminates the spurs. This paper illustrates that by selectively allowing some output harmonics we can reduce the noise floor level and improve the dynamic range of the output.

II. ABSTRACT ARCHITECTURE AND DEFINITIONS

It is a common practice to use random dithering to suppress the frequency spurs of quantization in DDS [9]-[10] and data converters [11]. Here we consider the extreme case of a DDS with Nyquist-rate single-bit output quantization and amplitude dithering as shown in Figure 1. Sequence $\cos(\Omega k)$ can be generated by a phase accumulator and a LUT. The Zero Order Hold (ZOH) provides the continuous-time single-bit digital waveform output and all blocks are clocked by a reference clock of frequency $f_S = 1/T_S$.

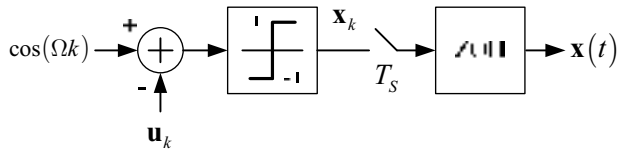

Figure 1: Dithered single-bit quantization of a sinewave

Let $\Omega = 2\pi w/q$ for some integers w and q such that $0 < w < q/2$. It is not necessary that q is a power of 2. Random dithering sequence $\{\mathbf{u}_k\}$ is subtracted from $\cos(\Omega k)$ resulting in the discrete-time single-bit (± 1) signal

$$\mathbf{x}_k = \operatorname{sgn}\left(\cos\left(2\pi wk/q\right) - \mathbf{u}_k\right). \tag{1}$$

We assume that $\{\mathbf{u}_k\}$ is composed of independent and identically distributed (IID) random variables of cumulative density function (CDF) $G:[-1,1]\to[0,1]$ with continuous second derivative. It is of course $\Pr(\mathbf{u}_k \le u) = G(u)$. Also, it is convenient for our analysis to express the CDF G as a series of Chebyshev polynomials of the first kind, i.e.,

$$G(u) = \frac{1}{2} + \frac{1}{2}\sum_{j=0}^{\infty} a_j T_j(u). \tag{2}$$

where the summand and multiplier $1/2$ are used to simplify the algebra. Coefficients a_j are derived according to [8], [12].

Inversely, CDF G can be defined using Eq. (2). Assuming the series in (2) converges appropriately and is term-by-term differentiable, G is a CDF if and only if $G(-1)=0$, $G(1)=1$ and $G'(u)\geq 0$ for every $u\in[-1,1]$. These three conditions can be expressed as

$$\sum_{j=0}^{\infty}(-1)^j a_j=-1 \quad , \quad \sum_{j=0}^{\infty}a_j=1 \tag{3}$$

and

$$\sum_{j=1}^{\infty} j a_j U_{j-1}(u)\geq 0 \qquad \forall u\in[-1,1] \tag{4}$$

using the fact that $T_j(\pm 1)=(\pm 1)^j$ for every $j=0,1,2,...$, and $T_j'(u)=j\cdot U_{j-1}(u)$, for $j=1,2,3,...$, where U_j is the j-th Chebyshev polynomial of the 2nd kind [12].

III. Output Spectrum

Under the assumption that the dithering sequence $\{\mathbf{u}_k\}$ is composed of IID random variables, the discrete-time sequence $\{\mathbf{x}_k\}$ is formed of independent but not identically distributed random variables. The distribution of $\mathbf{x}_k$ is a periodic function of $k\in\mathbb{Z}$ of period equal to q or a divisor of it. Therefore $\{\mathbf{x}_k\}$ is cyclostationary of period q. In this case it is common [13]-[14] to define the *period-average* autocorrelation function $\overline{r}_x(k)=\left(\sum_{m=0}^{q-1} r_x(k+m,m)\right)/q$, where $r_x(n,m)=E\{\mathbf{x}_n\mathbf{x}_m\}$; then, use $\overline{r}_x(k)$ to define the PSD of $\{\mathbf{x}_k\}$ as the discrete-time Fourier Transform of it, i.e., $s_x(\omega)=\sum_{k=-\infty}^{\infty}\overline{r}_x(k)e^{-ik\omega}$.

The ZOH in Figure 1 converts the discrete-time sequence $\{\mathbf{x}_k\}$ into the continuous-time signal

$$\mathbf{x}(t)=\sum_{k=-\infty}^{\infty}\mathbf{x}_k p(t/T_S-k) \tag{5}$$

where $T_S=1/f_S$ is the sampling period and $p(t)$ is the pulse equal to 1 for $t\in[0,1)$ and zero otherwise corresponding to ZOH's operation. The PSD of the continuous-time signal $\mathbf{x}(t)$ can be expressed [8] using $s_x(\omega)$ as

$$S_x(f)=T_S\cdot\mathrm{sinc}^2(f\cdot T_S)\cdot s_x(2\pi f T_S). \tag{6}$$

The following Theorem, [8], based on the above definitions provides the means to calculate analytically the PSD $S_x(f)$.

Theorem: Based on the aforementioned definitions and assumptions, if $\gcd(w,q)=1$ then the PSD of $\mathbf{x}(t)$ is

$$S_x(f)=\mathrm{sinc}^2\left(\frac{f}{f_S}\right)\cdot\left(\ S_{HA}(f)+S_N(f)+S_{DC}(f)\ \right) \tag{7}$$

where the HArmonics, Noise and DC components are

$$S_{HA}(f)=\frac{1}{4}\sum_{h=1}^{\infty}b_h\left(\delta\left(f-\frac{h}{q}f_S\right)+\delta\left(f+\frac{h}{q}f_S\right)\right), \tag{8}$$

$$S_N(f)=\frac{1}{f_S}\cdot\left(1-a_0^2-\frac{1}{2}\sum_{j=1}^{\infty}a_j^2\right), \tag{9}$$

and

$$S_{DC}(f)=\frac{b_0+3a_0^2}{4}\delta(f) \tag{10}$$

respectively. The power of the frequency components at $\pm(h/q)f_S$, $h=0,1,2,...$ in Eq. (8) is $b_h/4$ and

$$b_h\triangleq\sum_{r=-\infty}^{\infty}a_{I(h,r)}^2 \tag{11}$$

where $I(h,r)=|j_1 h+qr|$; constant j_1 (and k_1 which is not used in the expression) is derived solving the Diophantine equation $wj_1+qk_1=1$. Specifically, coefficient b_w of the frequency components at $\pm(w/q)f_S$ is $b_w=\sum_{r=-\infty}^{\infty}a_{|1+qr|}^2$. □

The application of the Theorem is illustrated in the following sections.

IV. DR and the Trade-Off With Spectral Clarity

In most practical cases the desirable frequency component is the one at $\pm(w/q)f_S$ with amplitude $\mathrm{sinc}^2(f/f_S)\cdot b_w/4$, captured by $S_{HA}(f)$ in Eq. (8). The output noise level has PSD $\mathrm{sinc}^2(f/f_S)\cdot S_N(f)$ captured by Eq. (9). We define the Dynamic Range (DR) as the ratio of the desirable signal's power to noise's PSD, $DR=10\log_{10}\left(\frac{\mathrm{sinc}^2(f/f_S)\cdot b_w/4}{\mathrm{sinc}^2(f/f_S)\cdot S_N(f)}\right)$, in (dB), which replacing the values of b_w and $S_N(f)$ becomes

$$DR=10\log_{10}\left(\frac{\sum_{r=-\infty}^{\infty}a_{|1+qr|}^2}{1-a_0^2-\sum_{j=1}^{\infty}\frac{a_j^2}{2}}\right)+10\log_{10}(f_S)-6.02 \quad \text{(dB)} \tag{12}$$

Note that the summand $10\log_{10}(f_S)$ in Eq. (12) should be expected because the power of the sinewave's quantization error is spread over the whole frequency bandwidth which is proportional to the sampling frequency.

A. Case 1: Uniformly Distributed CDF G

We consider first the case of dithering sequence $\{\mathbf{u}_k\}$ with *uniformly distributed* IID random variables, i.e. constant probability density $G'(u)=1/2$ in $[-1,1]$ and CDF given by $G(u)=(u+1)/2$. Observing Eq. (2) and using the fact that $T_1(u)=u$ we get $a_0=0$, $a_1=1$ and $a_k=0$ for $k=2,3,4,...$.

Now we apply the Theorem for a pair of integers w and q with $0 < w < q/2$ and $\gcd(w,q) = 1$. Since only $a_1 = 1$ is nonzero, for b_h, $h = 0,1,2,...$ to be nonzero there must exist an integer $r \in \mathbb{Z}$ such that

$$I(h,r) = |j_1 h + qr| = 1 \qquad (13)$$

Since (j_1, k_1) is a solution of the Diophantine equation $wj_1 + qk_1 = 1$ the general solution of Eq. (13) is

$$(h,r) = \pm(w,k_1) + \rho(q,-j_1),\ \rho \in \mathbb{Z} \qquad (14)$$

and since $0 \le w < q$, the nonnegative values of h are $h = w + \rho q$ for $\rho = 0,1,2,...$ and $h = -w + \rho q$ for $\rho = 1,2,...$. We conclude that the only nonzero coefficients b_h, $h = 0,1,2,...$ are b_w and $b_{\eta \cdot q \pm w}$ for $\eta = 1,2,3,...$ giving

$$S_{HA}(f) = \frac{1}{4} \sum_{\substack{h=w,\ \eta \cdot q \pm w \\ \eta = 1,2,3,...}} \left(\delta\left(f - \frac{h}{q} f_S \right) + \delta\left(f + \frac{h}{q} f_S \right) \right),$$

$S_N(f) = 1/(2f_S)$ and $S_{DC}(f) = 0$ respectively. So the only two frequency components in the frequency range $[0, f_S]$ are at $(w/q) f_S$ and its image at $(1 - w/q) f_S$. This is true in general for integers w and q satisfying our assumptions. Therefore uniform CDF G leads to spurs-free output.

For example if $w = 25$ and $q = 64$ then the only nonzero coefficients are b_{25} and $b_{\eta \cdot 64 \pm 25}$ for $\eta = 1,2,3,...$. Moreover $b_{25} = b_{\eta \cdot 64 \pm 25} = 1$, $\eta = 1,2,3,...$ .The results are confirmed by the PSD in Figure 2 derived using simulation, where the weighting factor $\text{sinc}^2(fT_S)$ is ignored.

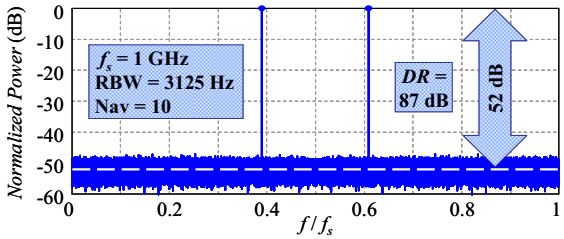

Figure 2: Spectrum of single-bit quantized sinewave with uniformly distributed dither when $w = 25$ and $q = 64$; the weighting factor $\text{sinc}^2(f/f_S)$ is ignored. $f_S = 1\,GHz$, Resolution BW = 3125 Hz and waveform averaging Nav=10 runs.

Two more cases of simulated PSD when $a_0 = 0$, $a_1 = 1$ and $a_k = 0$ for $k = 2,3,4,...$ are shown in Figures 3 and 4 for different values of w, q, f_s and waveform averaging runs Nav. As expected from the Theorem the spectra are spurs-free.

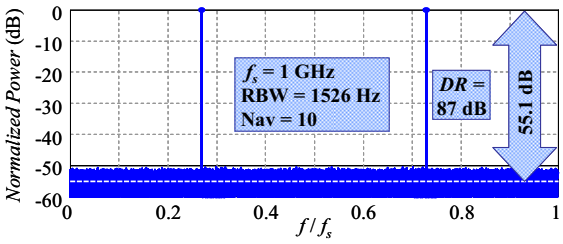

Figure 3: PSD of simulated random sequence $\{\mathbf{x}_k\}$ when $a_0 = 0$, $a_1 = 1$ and $a_k = 0$, $k = 2,3,4,...$; $w = 17723$, $q = 2^{16}$; $f_S = 1\,GHz$, Resolution BW = 1526 Hz and waveform averaging Nav=10 runs.

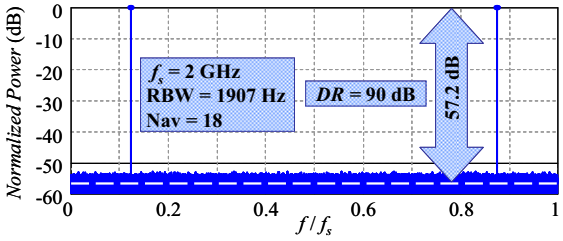

Figure 4: PSD of simulated random sequence $\{\mathbf{x}_k\}$ when $a_0 = 0$, $a_1 = 1$ and $a_k = 0$, $k = 2,3,4,...$; $w = 2^{16} - 1$, $q = 2^{19}$; $f_S = 2\,GHz$, Resolution BW = 1907 Hz and waveform averaging Nav=18 runs.

The dynamic range for the case of $a_0 = 0$, $a_1 = 1$ and $a_k = 0$ for $k = 2,3,4,...$, is derived from Eq. (12) to be

$$DR = 10\log_{10}(f_S) - 3.01 \text{ dB} \qquad (15)$$

In the PSD of the case $w = 25$ and $q = 64$ in Figure 2 the dashed white line indicates the averaged noise floor power. For $f_S = 1\,GHz$ we get $DR \cong 87$ dB. Subtracting $10\log_{10}(RBW)$ dB, where $RBW = 3125\,Hz$, to account for the resolution BW used for the simulation we get a very good match to the simulated 52 dB (Figure 2). Similarly for the case $w = 17723$ and $q = 2^{16}$ in Figure 3 where again Eq. (15) gives $DR \cong 87$ dB and after subtracting $10\log_{10}(RBW) \cong 32$ we get about 55 dB (Figure 3). Similarly in the case in Figure 4.

B. *Case 2: $a_1, a_3 \neq 0$ & All Other Coefficients a_k are Zero*

Suppose now that $a_1, a_3 \neq 0$ and all other coefficients a_k are zero then since $T_1(u) = u$ and $T_3(u) = 4u^3 - 3u$ we have $G(u) = \frac{1}{2} + \frac{a_1}{2}u + \frac{a_3}{2}(4u^3 - 3u)$ from Eq. (2). For G to be a CDF Eqs. (3) and (4) must hold implying $a_1 + a_3 = 1$ and $2G'(u) = a_1 + a_3(12u^2 - 3) \ge 0$ for every $u \in [-1,1]$.

Note that function $2G'(u)$ achieves its minimum either at $u = 0$ or at $u = \pm 1$ so $G'(u) \ge 0$ for every $u \in [-1,1]$ if and only if $a_1 - 3a_3 \ge 0$ and $a_1 + 9a_3 \ge 0$. Therefore G is a CDF if and only if $a_1 + a_3 = 1$, $a_1 + 9a_3 \ge 0$ and $a_1 - 3a_3 \ge 0$. The solution is $a_1 = (6 + 3\rho)/8$ and $a_3 = (2 - 3\rho)/8$, $\rho \in [0,1]$.

Assuming $q>4$ implies $\sum_{r=-\infty}^{\infty} a_{|1+qr|}^2 = a_1^2$ and Eq. (12) gives $DR = 10\log_{10}\left(\frac{2a_1^2}{2-\left(a_1^2+a_3^2\right)}\right)+10\log_{10}\left(f_S\right)-6.02$ dB. Using the expressions of a_1 and a_3 above, DR becomes a strictly increasing function of ρ with maximum value $DR = 10\log_{10}\left(f_S\right)-0.55$ (dB) for $\rho=1$, corresponding to $a_1 = 9/8$ and $a_3 = -1/8$. In this case the DR is about 2.5 dB higher than in Case I but the 3rd harmonic is present here as shown in the following.

For $w=25$ and $q=64$ the simulated PSD is shown in Figure 5. Applying the Theorem again we conclude that the only frequencies in the spectrum $(0, f_S)$ are at $(25/64)f_S$ and $(1-25/64)f_S$ corresponding to the fundamental and its image as well as $(-1+3\cdot 25/64)f_S$ and $(2-3\cdot 25/64)f_S$ corresponding to the 3rd harmonic and its image. Moreover for $h=0,1,2,...,63$ the only nonzero b_h are $b_{25}=(9/8)^2$, $b_{39}=(9/8)^2$, $b_{11}=(1/8)^2$ and $b_{53}=(1/8)^2$ corresponding to frequencies above. Results agree with simulation in Figure 5.

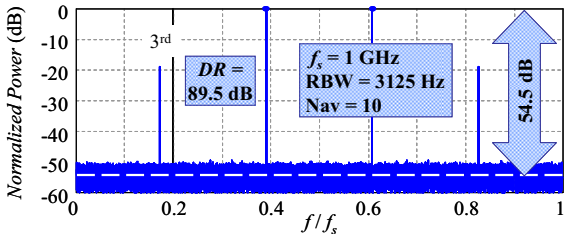

Figure 5: PSD of simulated random sequence $\{\mathbf{x}_k\}$ when $a_1 = 9/8$, $a_3 = -1/8$ and all other coefficients $a_k = 0$; $w=25$ and $q=64$

C. *Case 3: $a_1, a_3, a_5 \neq 0$ & All Other Coefficients a_k are Zero*

The case of $a_1, a_3, a_5 \neq 0$ with all other coefficients a_k zero implies $G(u) = \frac{1}{2}+\frac{a_1}{2}T_1(u)+\frac{a_3}{2}T_3(u)+\frac{a_5}{2}T_5(u)$ which is a CDF if and only if $a_1+a_3+a_5=1$ and $2G'(u) = 80a_5u^4+(12a_3-60a_5)u^2+a_1-3a_3+5a_5 \geq 0$ for all $u\in[-1,1]$.

The derivation of (a_1, a_3, a_5) maximizing DR is more involved than before. It turns out that the maximum is achieved for $a_1 = 1.1906$, $a_3 = -0.2375$, $a_5 = 0.0469$ and all other coefficients a_k zero; $DR = 10\log_{10}\left(f_S\right)+1.31$ (dB), i.e. about 4.3 dB higher than with uniformly distributed dither in Case I.

For $w=25$ and $q=64$ the simulated PSD is shown in Figure 6. The fundamental the 3rd and the 5th harmonics and their images are the only components in the spectrum, which can be shown using the Theorem as well.

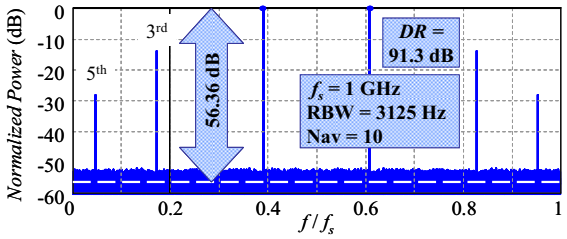

Figure 6: PSD of simulated random sequence $\{\mathbf{x}_k\}$ when $a_1 = 1.1906$, $a_3 = -0.2375$, $a_5 = 0.0469$, all other coefficients $a_k = 0$; $w=25$, $q=64$

V. CONCLUSIONS

Single-bit, Nyquist-rate quantization of sinewave with additive random dithering formed of independent and identically distributed random variables has been discussed as a means for all-digital frequency synthesis. Using the uniformly distributed dither, resulting in spurious free output, as a reference, other distributions have been considered in an effort to increase the dynamic range by trading-off the presence of selected harmonics in the output for lower output noise floor. An improvement of about 4.3 dB has been shown when the third and fifth harmonics are allowed to be present. Examples based on MATLAB simulation have been discussed illustrating the presented theory.

lbuczek@agh.edu.pl

***Abstract*—Currently a number of electronic components capable of processing multi-GHz electrical signals are available on the market. This allows building a system for measuring the difference of optical frequencies of two semiconductor lasers, exploiting high-speed photodiode and frequency prescalers and based on coherent detection and down-conversion.**

Keywords—semiconductors laser; coherent detection; down-conversion; high-speed frequency prescalers

I. INTRODUCTION

There is a group of applications useing semiconductor lasers with optical frequencies separated by tens of GHz [1-5]. In these cases, we usually need a method for precise measurements of the difference of optical frequencies. Using of high-speed electronic components allow building a system for measuring the difference of optical carrier frequencies of two semiconductor lasers, exploiting photodiode and frequency prescalers and base on coherent detection and down-conversion. The proposed system may be used for measuring of difference of the optical frequency semiconductor laser in fiber optic time and frequency dissemination system exploiting two closely spaced laser transmitters [5,6]. This system may be useful also for characterizing ultra-dense WDM laser sources [2,3]. Analysis of the measurement results would be helpful to determine the difference of optical frequencies and its fluctuation.

II. THE MEASUREMENT SYSTEM

The block diagram of proposed system is presented in Fig. 1. Two optical signals from distributed feedback (DFB) semiconductor lasers are supplied to a high-speed photodiode. State of polarization (SOP) of the optical signal of one of them may be controlled. Resulting beat-note with the frequency equal to the difference of the laser carriers is further processed by a set of high-speed prescalers. They divide the frequency of signal to the value low enough for counting by the system based on a field programmable gate array (FPGA) and a microcontroller. In the first stage prescaler divides by 8 and operates up to 18GHz. Prescaler in the second stage may be slower than in the first stage and its division ratio may be programmable.

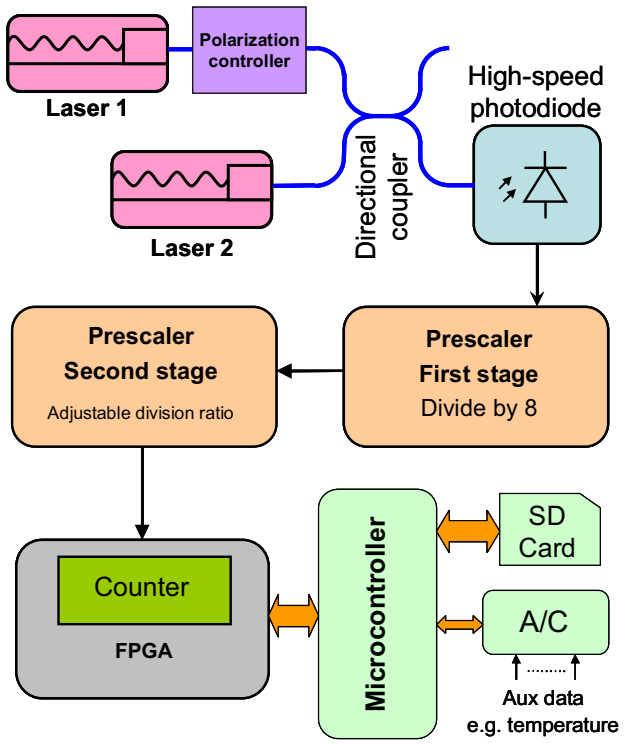

Fig1. Idea of measuring the difference of semiconductor lasers carrier frequencies using high-speed prescalers.

A frequency counter and communication interface with a microcontroller is implemented in FPGA circuit. Microcontroller supports typical SD memory card and multi-channel analog to digital converter. Measurements results of the difference of optical frequencies are recorded onto standard SD memory cards. At the same time it is possible record any analog signal, other parameters as laser current and ambient temperature and so on. Described measurement system allows taking up to some hundred measurements per second for a period determined by capacity of the memory card.

The efficiency of the beating process is directly affected by the state of polarization (SOP) of optical signals that beat in the photodiode. In the worst case of orthogonal polarization the output signal will disappear. Thus the SOP should be controlled to ensure the robust operation of the system.

The prototype system was designed to operate with the frequencies up to 18 GHz that corresponds to the wavelength difference of the lasers up to 0.14 nm. Using currently available technology this difference may be easily extended to 26 GHz (i.e. 0.2 nm).

III. Verification of the Presented System

A verification was performed by comparing results obtained using presented system with results from a real time spectrum analyzer. The block diagram of the verification method is presented in Fig. 2.

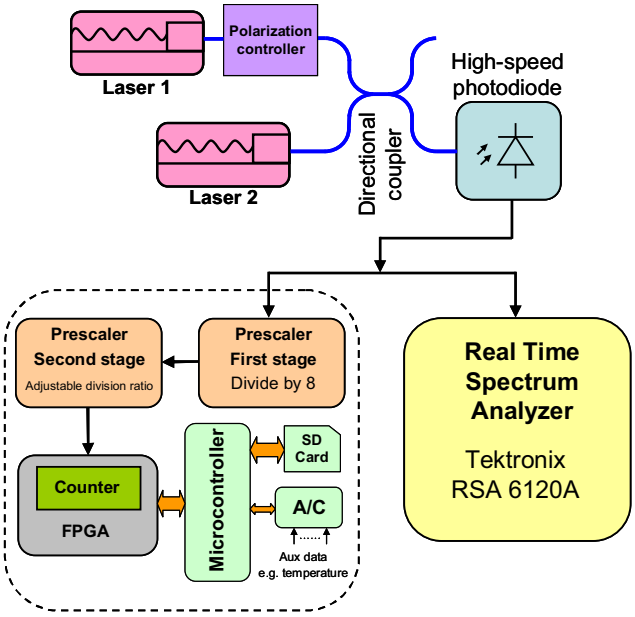

Fig2. Block diagram of the verification method of the presented system

In the presented method of verification, electrical signal from the photodiode is simultaneously supplied to system with prescaler and to the real time spectrum analyzer Tektronix RSA 6120A. Obtained result of measurement should by same on both measurement methods. During the verification lasers were stabilized using simple method based on internal thermistor. Measurement results obtained using real time spectrum analyzer is presented in Fig. 3. Measurement results obtained using described system is presented in Fig. 4. Comparison of the measurements results confirm usefulness of the described system for measuring difference of the optical frequencies of the semiconductor lasers.

This work was supported by Faculty of Computer Science, Electronics and Telecommunications under the decision 15.11.230.079

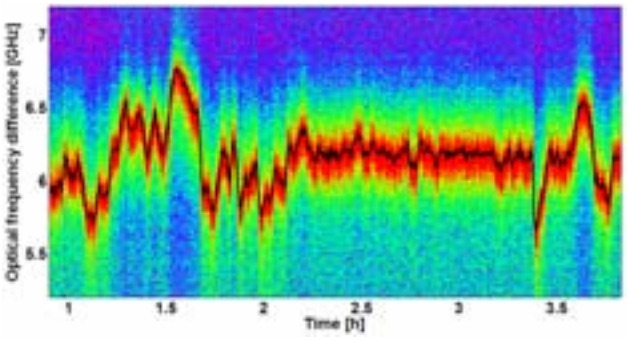

Fig3. Measurement results obtained using real time spectrum analyzer (black line is peak of spetrogram)

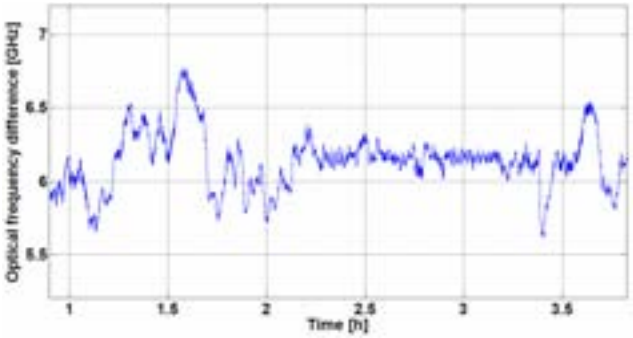

Fig4. Measurement results obtained using presented system based on prescaler and down-conversion

IV. Exmple Measurement

An example of 10-day record showing the relative stability of two telecommunication-grade DFB lasers stabilized using Fabry-Perot etalons and fluctuations of ambient temperature are presented in Fig. 5

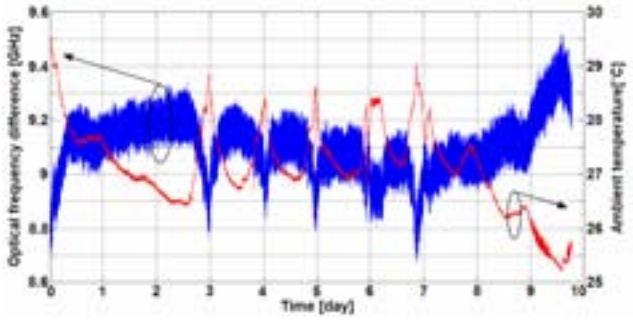

Fig5. The record of 10-days measurement of frequency difference of two DFB lasers stabilized using Fabry-Perot etalons.

In this measurement one can observe a strong correlation between difference of optical frequencies of the two semiconductor lasers and fluctuations of the ambient temperature.

V. CONCLUSION

Advantages of the presented system are simplicity, small size and relatively low cost. Small size allow to use the system as part of another system such as fiber optic time and frequency dissemination system. Comparison of the measurements method confirm usefulness of the described system for measuring the difference of the optical frequencies of the semiconductor lasers.

***Abstract*—In this paper, we present the characterization results of an optimized 4.6 GHz frequency synthesizer ASIC targeted for miniature atomic clock applications. Fabricated into a 130 nm RF CMOS process, the circuit occupies an active area of 2 mm^2 and consumes 15 mW of power. The measured phase noise is about -85 dBc/Hz in the range of 2 kHz to 100 kHz frequency offset from the carrier. The circuit was used as RF synthesizer in an experimental cesium atomic clock setup. The obtained clock stability of 5×10^{-11} at $\tau = 1$ second corresponds to the stability obtained with a laboratory synthesizer on the same setup, and is limited by the signal-to-noise ratio of the detected CPT signal. The theoretical stability limit due to the ASIC phase noise is $2\times10^{-11}\,\tau^{-1/2}$, which is not limiting the measured clock stability.**

Keywords—microwave, synthesizer, ASIC, PLL, low power, low phase noise, atomic clock.

I. INTRODUCTION

We have previously reported on the preliminary development and evaluation of a 4.6 GHz frequency synthesizer CMOS ASIC for miniature atomic clocks based on Coherent Population Trapping (CPT) in micro-fabricated Cs vapor cells [1]. The circuit consumes around 15 mW and features a frequency resolution better than 10^{-13}.

For guaranteeing the lowest power consumption and the smallest dimension for miniature atomic clock systems [2], an application specific integrated circuit (ASIC) is the best choice for frequency synthesis, compared to commercial frequency synthesizers. In [1], the frequency synthesizer ASIC is built around a fractional-N phase-locked loop (PLL). It consists of a low power, low phase noise voltage-controlled oscillator (LC-VCO). The VCO is buffered by a high-efficiency power amplifier (PA) with programmable output power level. A programmable divider controlled by a 3rd-order, 40-bit MASH sigma-delta modulator (SDM) is used to provide sub-mHz frequency tuning steps at the 4.6 GHz carrier output.

A 20 MHz voltage-controlled quartz oscillator (VCXO) provides the PLL reference frequency. The PLL bandwidth is typically 300 kHz. The chip is implemented in a 130 nm RF CMOS process, and is powered at 1.2 Volt. Fig. 1 shows the block diagram of the PLL ASIC.

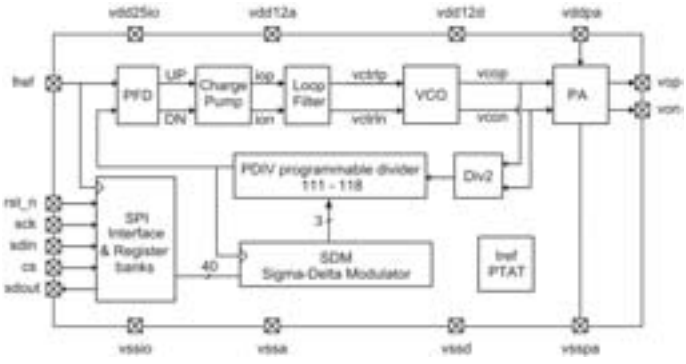

Figure 1. Schematic block diagram of the PLL ASIC [1].

II. DESIGN OPTIMIZATION

Compared to the initial design [1], the ASIC in this paper was optimized at the layout level. Since the on-chip digital switching noise was verified to be an important noise source in the initial design, resulting in degraded PLL phase noise by substrate coupling, efforts were made in this current circuit to reduce the effect of on-chip digital noise. Three techniques were applied:

1. Guard rings around all the digital blocks, including the SDM, programmable divider, phase/frequency detector and charge pump.

This work was funded by the EU 7th framework program FP7, under contract no. 224132 (MAC-TFC project www.mac-tfc.eu). Work at LTF was also supported by the Swiss National Science Foundation (grants no. 200020_140681 and Sinergia CRSI20_122693).

2. Increased decoupling capacitors on the digital power supply, to filter switching peaks.
3. Improved reference frequency input pad. In the first design, a digital input buffer was used, with a dynamic level shifter for conversion between IO voltage (2.5 Volt) and core voltage (1.2 Volt). This circuit showed poor noise performance, and was adding jitter on the reference clock signal. It was then replaced by an analog-wire pad with no level-shifter.

III. Phase Noise Measurement

The phase noise performance of the optimized ASIC synthesizer was measured using a phase noise measurement system (model NMS by Spectradynamics inc. [3]). A commercial laboratory-type frequency generator was used as a noise reference, showing a phase-noise performance of less than -100 dBc/Hz at 1 kHz offset from the 4.6 GHz carrier and down to -123 dBc/Hz in the frequency band of 10 kHz to 100 kHz, which is our frequency range of interest for atomic interrogation.

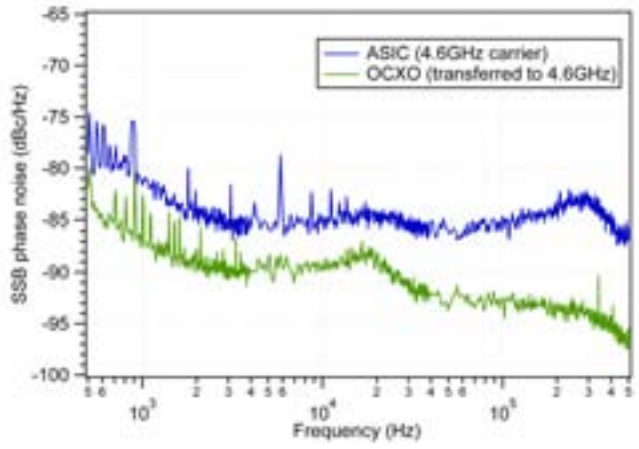

Figure 2. Measured phase noise of the ASIC at 4.6 GHz carrier (blue upper trace) and of the 20 MHz VCXO (transferred to 4.6 GHz, green lower trace).

Fig. 2 reports the measured single-sideband phase-noise of the ASIC synthesizer at 4.6 GHz, reaching ≈ -85 dBc/Hz in the band of interest from 2 kHz to 100 kHz (upper, blue trace). This phase-noise level is only slightly higher (4 to max 10 dB higher) than the phase-noise of the 20 MHz thermally-compensated quartz oscillator (TCVCXO) transferred to 4.6 GHz carrier (lower, green trace). This result proves the good phase-noise performance of the synthesizer ASIC, and especially the improvement compared to the initial circuit, which showed a phase noise of -77 dBc/Hz @ 2 kHz offset and -83 dBc/Hz @ 100 kHz offset from the carrier.

IV. Clock Stability Tests

The performance of the ASIC used as RF frequency synthesizer in an atomic clock was evaluated on an experimental atomic clock setup based on coherent population trapping (CPT) [4] as described in [5]. A distributed feed-back (DFB) laser diode was used, emitting laser radiation at 894.6 nm, in resonance with the Cs D1 optical transition. A fiber-coupled electro-optical modulator (EOM) driven at half of the Cs hyperfine splitting (i.e. at 4.6 GHz) was used to create modulation sidebands, of which the positive and negative first-order sidebands were used to induce the CPT effect in a thermal Cs vapor contained in a micro-fabricated cell [6]. The Cs cell was held in a physics package providing a stable temperature, and well-controlled magnetic field conditions. The signal from a photo-detector placed behind the physics package was demodulated at $f_m \approx 1$ kHz using a lock-in amplifier and subsequently used to steer the frequency of a 20 MHz TCVCXO that serves as frequency reference for the microwave synthesizer providing the 4.6 GHz frequency driving the EOM.

Two configurations of quartz oscillator and microwave synthesizer were used in this study. The reference configuration consists of a laboratory-type low-noise frequency synthesizer (spectradynamics inc., model CS-1) including both a 5 MHz quartz oscillator and the 4.6 GHz synthesizer itself [3]. This synthesizer shows a phase noise at 4.6 GHz carrier of -113 dBc/Hz at 1 kHz offset and -126 dBc/Hz at 10 kHz to 100 kHz offset, which is well below the phase-noise performance of the ASIC synthesizer. However, as a laboratory instrument this reference synthesizer has several orders of magnitude higher mass, volume, and power consumption than the ASIC synthesizer discussed here. The ASIC test configuration consists of a commercial 20 MHz quartz TCVCXO and the ASIC synthesizer chip. In the ASIC test configuration, an additional RF amplifier was connected to amplify the -5 dBm output power of the ASIC to the +3 dBm power level used to drive the EOM. Note that in a final miniature atomic clock realization using direct modulation of the VCSEL laser current, the -5 dBm output power of the ASIC synthesizer is in the power range required for appropriate clock operation [7, 8]. In both the reference and test configurations, an external frequency generator was used to produce the $f_m \approx 1$ kHz modulation frequency for the microwave signal, while the modulation depth was set in the respective microwave synthesizer used.

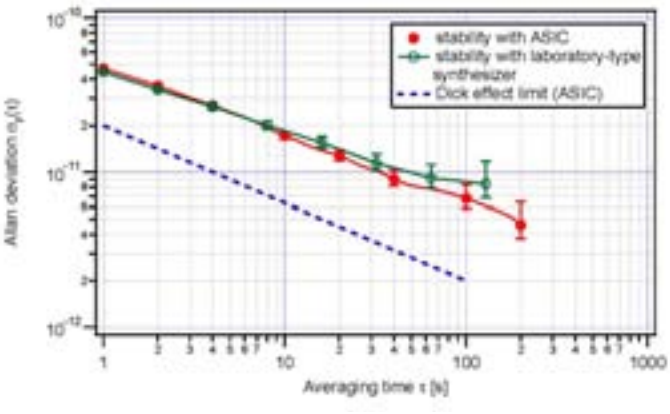

Figure 3. Clock stabilities recorded with the experimental clock setup, using the reference synthesizer (green, open symbols) and the ASIC synthesizer chip (red, filled symbols). The blue dashed line gives the Dick-effect stability limit due to the ASIC phase noise.

Fig. 3 shows the clock stabilities recorded with the two synthesizer configurations. Both the clock stability obtained with the laboratory-type reference synthesizer (green, open symbols) as well as the clock stability obtained with the ASIC synthesizer chip (red, filled symbols) show a stability of 5×10^{-11} at $\tau = 1$ s and down to $\approx 8\times10^{-12}$ at $\tau = 100$ s, in good agreement with the theoretical stability limit of $\approx 7\times10^{-11}\,\tau^{-1/2}$ calculated from the signal-to-noise ratio of the CPT signal on the photo detector. Small differences between the two stabilities measured are within the error bars and can also be attributed to slightly different loop settings. These results show that the performance of the ASIC synthesizer chip is well suited for realizing miniature atomic clocks with excellent frequency stabilities.

Fig. 3 shows also the theoretical stability limit of an atomic clock in which the ASIC phase noise would represent the highest contribution to clock stability limitation. Due to the Dick effect [9], the phase noise of a synthesizer at higher order harmonics of the modulation frequency f_m (applied to the microwave signal in order to obtain an error signal for stabilization of the microwave frequency to the center of the atomic reference line) results in a limit to the clock frequency stability given by:

$$\sigma_y(\tau) = \sqrt{\sum_{n=1}^{\infty} C_{2n} \cdot S_\varphi(2nf_m)} \cdot \tau^{-1/2} \qquad (1)$$

where n is the harmonic number, S_φ is the phase noise measured at even harmonics of the modulation frequency, and C_{2n} is the coefficient of sensitivity given by:

$$C_{2n} = \frac{2n}{(2n-1)(2n+1)} \frac{f_m}{\nu_{\mathrm{Cs}}} \qquad (2)$$

where $\nu_{Cs} = 4.6$ GHz is the synthesizer output frequency (half of the Cs hyperfine splitting). Using $f_m = 1$ kHz and the measured phase-noise of Fig. 2, we obtain a short-term stability limit due to the Dick effect of $\sigma(\tau) = 2\times10^{-11}\,\tau^{-1/2}$. This stability limit is well below the typical short-term stability specification of $6\times10^{-10}\,\tau^{-1/2}$ for miniature atomic clocks [2,10].

V. Conclusion

We have presented the characterization results of an optimized version of a microwave synthesizer ASIC chip capable of providing 4.6 GHz output frequency with full modulation capabilities required for interrogation of a miniature atomic clock. The optimized ASIC is fabricated in a 130 nm RF CMOS process, occupying an active area of 2 mm^2 and consuming about 15 mW. The measured phase noise of the ASIC is around -85 dBc/Hz in the 2 kHz to 100 kHz frequency band of relevance for atomic clock interrogation. This is only up to 10 dB higher than the phase noise of the 20 MHz VCXO reference used in our studies.

Measurement of the clock stability obtained with an experimental clock setup (using a micro-fabricated Cs cell) shows that using the ASIC synthesizer does not result in any degradation of clock stability compared to using a reference laboratory-type microwave synthesizer. Both clock stabilities obtained are limited to the same level of $\leq 7\times10^{-11}\,\tau^{-1/2}$, by the signal-to-noise ratio of the clock signal obtained from the micro-fabricated Cs cell, but not by the Dick-effect limit which is calculated to be $2\times10^{-11}\,\tau^{-1/2}$ for the ASIC synthesizer.

The obtained results prove that the realized ASIC design is well suited for the realization of state-of-the-art miniature atomic clocks, while having very attractive size and power consumption, and good perspectives for low-cost mass production.

***Abstract*—In this work we present a newly designed compensating module, which reduces the delay mismatch between two integrated delay lines used in time transfer system. In this work we show the measured results of the compensation efficiency, both in nominal temperature, and for ± 5°C temperature excursions. We find the remaining mismatch as no greater than 3 ps. After applying the compensation module, the problem of the delay lines mismatch go below other factors limiting the overall system performance.**

Keywords—fiber network, frequency distribution, optical fibers, time transfer, delay lines, mismatch compensation

I. INTRODUCTION

In last years our group is developing the fiber optic system for accurate time and frequency (T&F) dissemination [1][2][3]. The main idea is to actively stabilize the propagation delay of the link by organizing a delay locked loop (DLL) system, using the feedback signal from remote side of the system. The core element of the hardware is a set of two precisely matched electronic delay lines, fabricated as an application-specific integrated circuit (ASIC). Without the proposed compensation module the mismatch of the tuning characteristics of the delay lines may be as much as 150 ps, and it affects the overall T&F dissemination accuracy and stability [1][2].

In our system (see Fig. 1) the reference frequency signal after passing through one of the electronic delay lines and after reaching remote destination point is then returned. After passing through the second delay line, its phase is being compared with the phase of the primary reference signal. Then the error signal from the phase comparator controls the line's delay so as to minimize variations of the signal propagation time. Compensating module, which is the subject of discussion in this article is circled in Fig. 1. Its purpose is to minimize the impact of the mismatch of the two delay lines, caused by fabrication process impairments.

II. CONCEPT OF COMPENSATING MODULE

The block diagram of the presented solution is shown in Fig. 1. It is known that it is not possible to produce two delay lines which would have the same parameters even in the integrated circuit. Between the lines, there is always some very little mismatch. Without any actions undertaken to reduce it, the mismatch has magnitude up to about 150 ps (see Fig. 6). The main idea of the compensating module is to measure output voltage from phase comparator, make some modifications according to the relevant characteristics and add

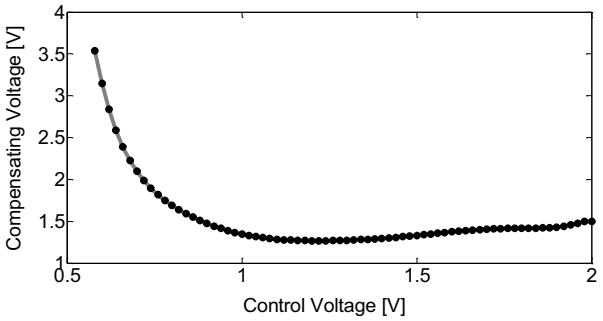

Fig. 2. Example characteristic of compensating voltage versus phase comparator output voltage.

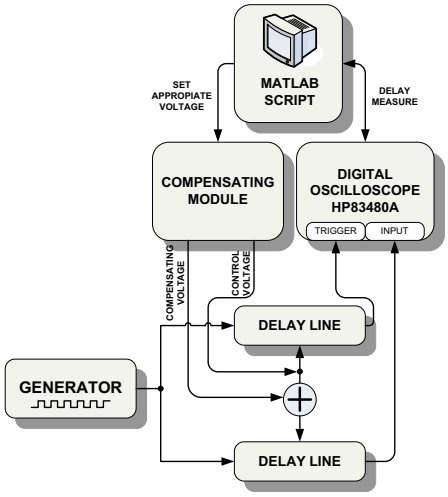

Fig. 3. Test bench to determine the LUT content.

compensating voltage to one of the delay lines. Unfortunately the mismatch is a non-linear function of the control voltage, and is different for each particular chip, therefore it is necessary to also develop algorithm for determining characteristics of compensating voltage. After that, data points are written to the LUT (*Look-Up-Table*). Because the module uses precise *a/d* and *d/a* converters, it is possible to apply the changes of a control voltage of the order of a few microvolts. The example characteristic of the compensating voltage (correction points stored in LUT table) is shown in Fig. 2.

Due to the LUT implemented in the microcontroller memory, there is an ability to save any characteristics of the compensating voltage against the control voltage. In the target system, the module continuously measures output voltage from phase comparator and corrects the control voltage of one of the lines thereby reducing the mismatch to acceptable level.

This is the main function of the module but not the only one. As mentioned before, each newly fabricated delay line will have slightly different characteristics of the mismatch. It is therefore reasonable to develop an algorithm which quickly and accurately allow as to determine the correction factors, thus filling up the LUT table with appropriate values.

Script running under Matlab environment sends commands and data to the presented module and also to the digital oscilloscope HP83480A. The scope measures the delay between trigger signal slope position and current signal slope position and return this value to Matlab script via GPIB. Block diagram of the hardware configuration to determine the LUT coefficients is shown in Fig. 3. The algorithm of the Matlab script is presented as a block diagram in Fig. 4.

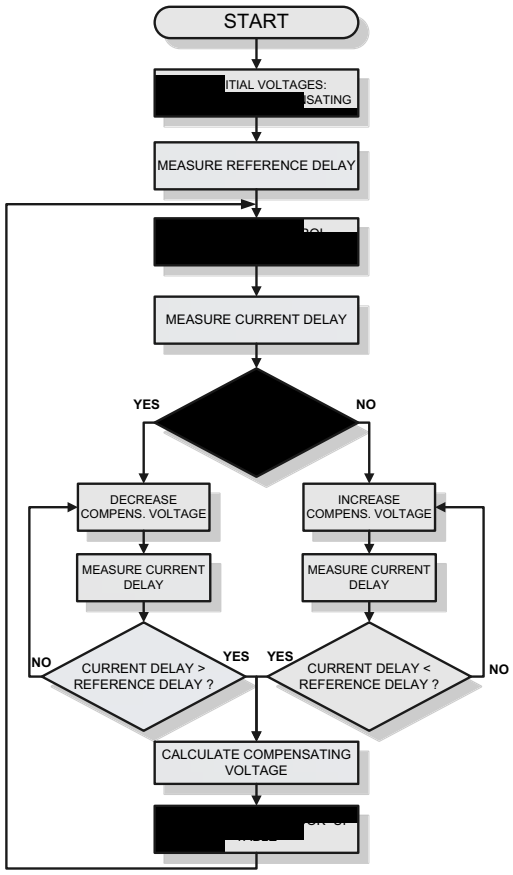

Fig. 4. Algorithm block diagram for determining LUT correction coefficients.

III. OBTAINED RESULTS

After fulfilling the LUT table with relevant correction coefficients the module was tested in the target system. Fig. 5 shows summary comparison between mismatch without active compensating module and with this solution. We can see that without any compensation, the mismatch would reach level of about 150 ps. Fig 6 shows measured mismatch for different temperatures. Curve for 28°C is a reference one as LUT coefficients were determined exactly in such temperature. We can see that residual mismatch do not exceed 3.1 ps peek-to-peek. It is less than other factors limiting overall accuracy. Despite the variations of the mismatch caused by temperature changes, we can see that for 32°C mismatch does not exceed

4 ps peek-to-peek which value is still acceptable. Only for lower ambient temperatures the mismatch is increasing, reaching 10 ps (Fig. 6, curve for 23°C).

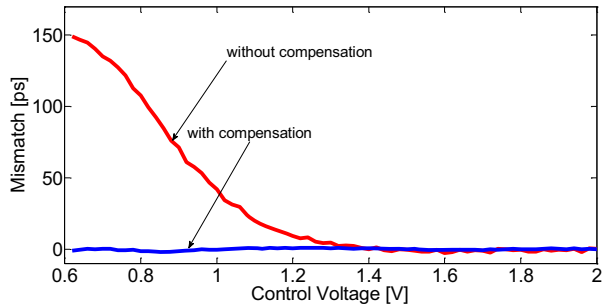

Fig. 5. Delay line mismatch with and without compensating module (measures at 28°C).

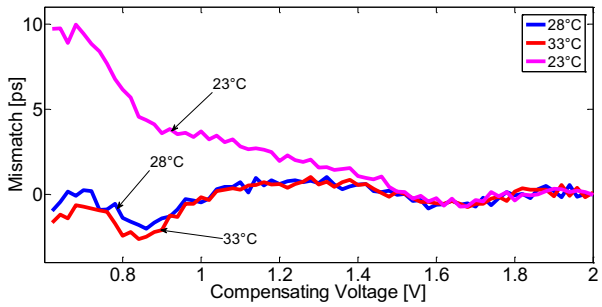

Fig. 6. Residual mismatch for different temperatures.

IV. Conclusion

In summary, the described circuit performed its main task. As a further improvement of the module it seems to be reasonable to determine and save in the module memory more LUT tables of the compensating voltages for some temperature range. Signal from the local temperature sensor would allow the module to change the characteristic of the compensating voltage on an ongoing basis.

***Abstract*—Temperature compensated crystal oscillator (TCXO) is widely used in GPS receiver for its small size and low cost, but the g sensitivity of TCXO decrease the frequency stability and deteriorate the performance of GPS receiver when suffering from serious vibration. To reduce the g sensitivity, the way used prevalently is mechanic cushion but it is not efficient at low frequency vibration. This paper proposed hybrid-compensation which is made up of electronic compensation and mechanic cushion. The electronic compensation aims at low frequency vibration while mechanic cushion aims at high frequency. The method proposed can reduce the g sensitivity and improve reliability of TCXO by adding extra devices to the original TCXO. Experiments show that, the using of hybrid-compensation technology can effectively reduce the phase noise of crystal oscillator and extend the applicability of TCXO, for maintained more than 15dB decay at 4g@1kHz vibration.**

Keywords—TCXO; acceleration effect; hybrid-compensation; electronic compensation; mechanic cushion

I. INTRODUCTION

TCXO is widely used as frequency source in aircraft, missile, navigation instruments and timing devices for its small size, high precision and low aging rate [1]. But both aircraft and missile suffer from serious vibration, because the stress frequency effect of crystal, the crystal oscillator's stability is extremely poor [2-4]. As frequency source, the frequency drift of crystal oscillator will directly lead to a decline in the whole system performance, such as poor missile hit rate, bad communication and not accurate of GPS vehicle positioning.

In order to improve the stability of TCXO and keep small size, reference [5] proposed a method, which using two crystal oscillators of same characteristics parallel connected can counteract acceleration sensitivity, to improve the crystal oscillator frequency stability. But it is hard to find matching crystal oscillators in practice. This paper presents a hybrid-compensation technology combined with electronic compensation technology and mechanic cushion. The electronic compensation technology to obtain the real time acceleration of TCXO through the MEMS sensor which has small size, and then compensate the frequency drift of TCXO by digital controller, while the mechanic cushion to reduce the phase noise by mechanical snubber. The combined hybrid-compensation technology will effectively reduce the TCXO acceleration sensitivity, and extend the applicability of TCXO.

II. VIBRATION & PHASE NOISE

The crystal oscillator is an oscillation circuit based on quartz crystal, so the performance of quartz crystal directly determines the performance of the oscillator. As quartz plate has stress relaxation effect [2], TCXO will produce frequency jitter due to the stress relaxation effect of wafer in vibration environment, commonly known as the acceleration effect of crystal oscillator. In the experimental study, usually use phase noise of crystal oscillator to measure the influence caused by the vibration. More details about the theory of phase noise please refer to classic reference wrote by the Filler [4].

A. *The acceleration effect of TCXO*

The relatively rigorous output signal of the TCXO model can be rewrite as

$$V(t)=[V_0+\varepsilon(t)]\cos[2\pi f_0 t+\upsilon(t)] \qquad (1)$$

Where V_0 is the nominal amplitude, f_0 is the nominal frequency, $\varepsilon(t)$ is the amplitude jitter, also call as the amplitude noise, $\upsilon(t)$ is phase drift, visibly, both $\varepsilon(t)$ and $\upsilon(t)$ closely related to vibration a. Rewrite the phase of equation (1) as a function of f as

$$S_f=\vec{\Gamma}\cdot\vec{a}=\frac{f(\vec{a})-f_0}{f_0}=\frac{\Delta f}{f_0} \qquad (2)$$

Where $\vec{\Gamma}$ means acceleration sensitivity vector of crystal oscillator, $\vec{a}$ means vibration vector, S_f represents frequency drift rate. From equation (2) can be seen, the vibration impact on the crystal oscillator is strict related to vibration direction. Fig.1 shows two kinds of frequency drift of crystal oscillator caused by vibration of different directions.

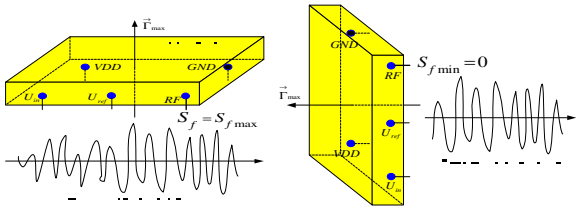

Fig. 1. Frequency drift caused by vibration of different directions

B. The phase noise of TCXO

When TCXO suffers from vibration of harmonic vibration, the output signal can be given by

$$V(t)=[V_0+\varepsilon(t)]\cos[2\pi f_0 t+\beta\sin(2\pi f_v t)] \quad (3)$$

Where $\beta=\frac{\Delta f}{f_v}$ is the modulation coefficient, f_v is the harmonic vibration frequency. So we can get

$$V(t)=[V_0+\varepsilon(t)]\sum_{n=-\infty}^{+\infty} J_n(\beta)\cos[2\pi(f_0+n\cdot f_v)t] \quad (4)$$

$$\varepsilon(t) << V_0$$

It is obvious that the energy on both sides of the sideband is equal. When the modulation index β<0.1 , then the modulation caused by vibration is mainly manifested in the first sideband, so we can get

$$L_v^1=20\log\frac{J_1(\beta)}{J_0(\beta)}=20\log\frac{(\vec{\Gamma}\cdot\vec{A})f_0}{2f_v} \quad (5)$$

When in experiments, in order to make a quantitative test of the influence caused by external vibration, the ratio with the first sideband energy and the baseband energy is calculated in general, viz. phase noise, show as Fig.2.

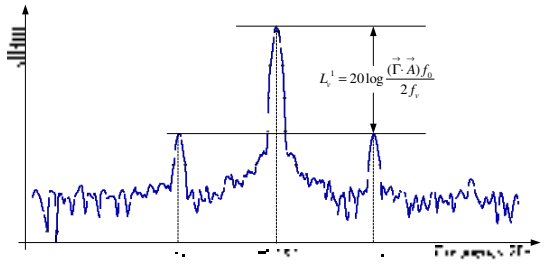

Fig. 2. The modulation effect of TCXO caused by external vibration

III. HYBRID-COMPENSATION TECHNOLOGY

To reduce the g sensitivity, the way used prevalently is mechanic cushion but it is not efficient at low frequency vibration. In fact the frequency drift in crystal oscillator caused by lower frequency vibration is still great, and it cannot be tolerated especially in precision equipments. The result of reference [6] shows that digital compensation technology can effectively reduce the influence of low-frequency vibration on the crystal oscillator. Therefore, the combination of mechanical cushion and electronic compensation technology can effectively improve the frequency stability of crystal oscillator.

A. Electronic compensation technology

With the piezoelectric effect of crystal plate, design an additional voltage control terminal for crystal oscillator circuit use the variable capacitance diode is meaningful. Then the signal frequency can be adjusted in a certain range through applying voltage to the voltage control terminal, so to achieve the precise compensation of crystal oscillator can use the method with an certain compensation algorithm.

Suppose the piezoelectric coefficient of crystal oscillator is k_v, there is

$$V_c(t)=\frac{[f(t)-f_0]\cdot k_v}{f_0}=k_v\cdot\vec{\Gamma}\cdot\vec{a} \quad (6)$$

Where $V_c(t)$ is compensation voltage, $f(t)$ is the instantaneous output frequency. $V_c(t)$ can be calculated by measuring the g sensitivity and the acceleration of crystal oscillator. The electronic compensation system is shown as Fig.3.

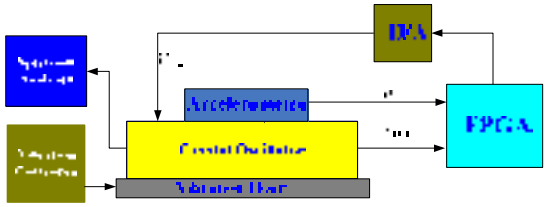

Fig. 3. Diagram of electronic compensation system

As there is only a small range of frequency through voltage compensation, and there still have compensate time delay [1]. So the electronic compensation technology applied at low frequency vibration environment is of better effect, but it is not efficient at high frequency vibration.

B. Mechanic cushion

In industrial applications usually adopts mechanic cushion to isolate external vibration, for mechanic cushion performs excellent in high frequency vibration environment [7,8]. In order to achieve the required spectrum of crystal oscillator output signal, a mechanic cushion device is designed, the simple structure model is shown as Fig.4.

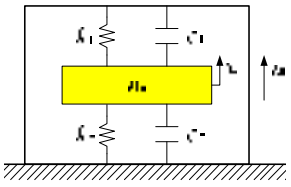

Fig. 4. Diagram of mechanical cushion structure

In Fig.4 *m* means the mass of crystal oscillator; *k1*, *k2* means the stiffness coefficient of each level; *c1*, *c2* means the

damping coefficient of each level. x means the vertical displacement of each level; u means the vertical displacement of the base.

Therefore the differential equations of mechanical motion can be obtained by the following

$$m\ddot{x}+(c_1+c_2)\dot{x}+(k_1+k_2)x=(k_1+k_2)u+(c_1+c_2)\dot{u} \quad (7)$$

Then transfer function can be rewritten from equation (7).

$$G_T=\sqrt{\frac{(c_1+c_2)^2w^2+(k_1+k_2)^2}{(k_1+k_2-mw^2)^2+(c_1+c_2)^2}} \quad (8)$$

Using MATLAB to make a simulation, here assuming that the damping coefficient of each level is c_1=c_2=0.01Ns/m, the stiffness coefficient of each level is k_1=k_2=200N/m, the mass of crystal oscillator is m=0.12kg. The simulation result is shown in Fig.5. It is obviously that when the vibration frequency is lower than 231.1Hz the mechanical cushion device cannot compensate effectively.

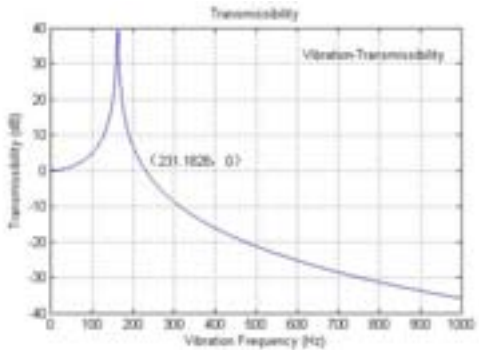

Fig. 5. The transfer function of mechanical cushion

IV. EXPERIMENTAL PERFORMANCE

Based on the theory analysis above, firstly experiment with voltage control terminal under static conditions. Result of the relationship between the control voltage and the output frequency of the crystal oscillator (V_c—f) is shown in Fig.6, it can be seen from the figure that the control voltage and the frequency of the crystal oscillator is a linear correlation. So it is doable to compensate the frequency drift of crystal oscillator by applying voltage to the voltage control terminal of crystal oscillator.

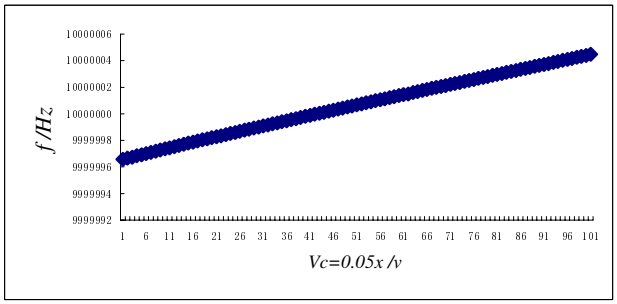

Fig. 6. The relationship between the control voltage and output frequency

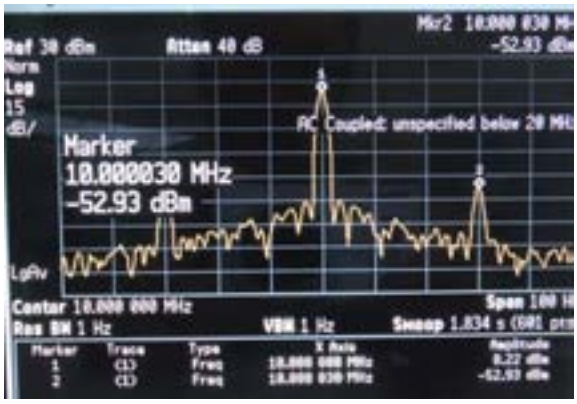
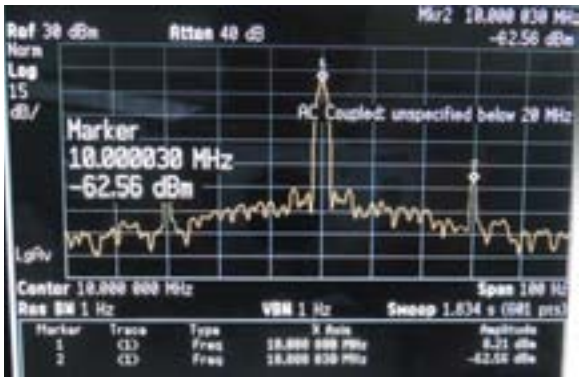
The experimental platform is mainly composed of vibration controller, vibration platform, mechanical buffer, crystal oscillator, spectrum analyzers and DC power supply. During the experiment the crystal oscillator is fixed on the vibrating table, through advance setting the vibration environment, using the spectrum analyzer can observe the spectrum of crystal oscillator output signal real time.

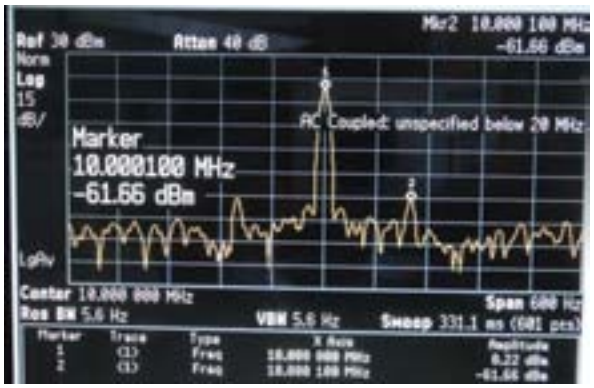
Experiment makes crystal oscillator test in multi-frequency point for 4g in amplitude. Considering the electronic compensation technology functions more efficient than mechanic cushion in low frequency vibration, while mechanic cushion functions more efficient than electronic compensation technology in high frequency vibration, apply mechanic cushion at first and then add electronic compensation technology in low frequency vibration (f<300Hz) , and in turn in high frequency vibration environment (f>300Hz) . The test results as shown in Fig.7.



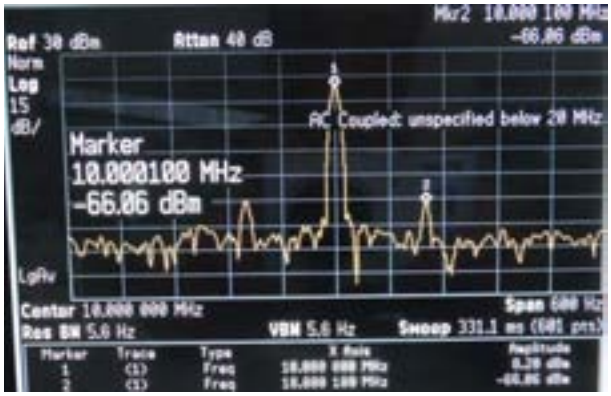
(a) With mechanical cushion no electronic compensation (4g, 30Hz)



(b) With mechanical cushion and electronic compensation (4g, 30Hz)

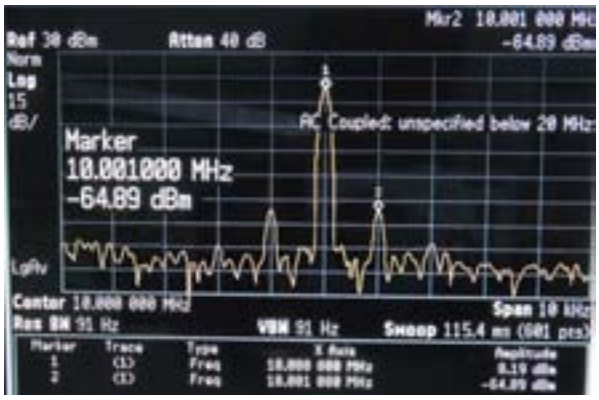


(c) With mechanical cushion no electronic compensation (4*g*, 100Hz)



(d) With mechanical cushion and electronic compensation (4*g*, 100Hz)

(e) With electronic compensation no mechanical cushion (4*g*, 1kHz)



(f) With electronic compensation and mechanical buffer (4*g*, 1kHz)

Fig. 7. Experimental results in multi-frequency at 4*g*

Conclusion can be made from the experimental results is that the mechanic cushion makes negligible compensation on the crystal oscillator when at low frequency vibration, and the same to electronic compensation technology at high frequency vibration. Combine the different compensation characteristics of mechanic cushion and electronic compensation technology, the applying of hybrid-compensation technology performs excellent especially in high frequency vibration environment. So the using of hybrid-compensation technology which is based on electronic compensation technology and mechanic cushion has a very important significance.

V. CONCLUSION

The paper first analysis the relationship between vibration and phase noise, and briefly discusses the basic principle of digital compensation method and mechanic cushion. Then make a simulation of two-level mechanic cushion by MATLAB, the results show that the mechanic cushion performance excellent when the vibration frequency is higher than 231Hz, even the parameters of the isolate system is not rigorous, the results can prove the mechanical cushion is beneficial for high frequency vibration. On the basis of these works, then verified in experiments, the experimental results show that control voltage and the frequency of crystal oscillator is linear correlation. And electronic compensation technology only effective in low frequency vibration while the mechanic cushion effective in high frequency vibration. The combination of electronic compensation technology and mechanic cushion can effectively improve the phase noise of the crystal oscillator in wide frequency range. Experimental results show that the applying of hybrid-compensation technology can reach about 15dB improvement in 4g@1kHz. It is obvious that the research of hybrid-compensation technology has very important significance.

***Abstract*—This paper describes the finite element method analysis of (XY*lt*) −35°/−1° rotated X-cut quartz oscillators vibrating in the length-extensional mode and the experimental data of the sample processed monolithically by the wet etching. The oscillator consists of the resonator with a slot and an integral mounting system and has the first order temperature frequency coefficient $\alpha = -0.6 \times 10^{-6}$ /°C, the second order temperature frequency coefficient $\beta = -3.5 \times 10^{-8}$ /°C^2, and the parameters of the electrical equivalent circuit in the air: the series inductance L_1 = 2.70 H, the capacitance ratio r = 192, the series resistance R_1 = 1080 Ω, and Q = 19000.**

Keywords—quartz oscillator; X-cut; length extensional mode; slot structure; wet etching

I. INTRODUCTION

X-cut quartz rod oscillators vibrating in length extensional mode (LE) were fabricated for 1 MHz oscillators[1]. A singly rotated (XY*t*) −5° X-cut quartz plate was used for this type oscillator because it has a zero first order temperature frequency coefficient α when an aspect ratio $R_{ZY} = w/l$ (w: resonator width, l: resonator length) is less than 0.1[2]. To obtain a smaller series resistance R_1 and a smaller capacitance ratio r, the rectangular resonators with R_{zy} in a range from 0.3 to 0.5 using a singly rotated X-cut quartz plate with a rotation angle from (XY*t*) −5° to (XY*t*) −25° have been investigated[3-4]. The resonators, however, cannot be mounted on its sides because they have a node located in the center.

This paper describes theoretical analysis by a finite element method of a doubly rotated X-cut quartz oscillator composed of a resonator with a slot and a monolithical mounting system among rotation angles ranging from (XY*lt*) 0°/0° to (XY*lt*) −60°/−10°. The paper also describes the experimental data of the fabricated doubly rotated (XY*lt*) −35°/−1° X-cut resonator, such as frequency-temperature characteristics and electrical properties measured and comparison with the theoretical values.

II. STRUCTURE OF A X-CUT QUARTZ CRYSTAL RESONATOR WITH A SLOT

A designed doubly rotated X-cut oscillator consists of a resonator with a slot, a folk type mounting system and two supports. Figure 1 shows a schematic diagram of the designed LE mode X-cut oscillator. The overall size of the resonator is 2000 μm long and 920 μm wide. The mount with two arms connected to supports enables a cylinder type packaging of the fabricated oscillator. Metal electrodes Au(150 nm)/Cr (50 nm) were sputtered on both X″-surfaces. The (XY*lt*) 0°/−5° X-cut rectangular resonator has zero α for R_{ZY} ranging from 0 to 0.2 or from 0.28 to 0.60[2]. The gap occurred because when R_{ZY} = 0.23 the coupling of the second-order flexural mode of the X-cut rod couples the LE mode. Thus, we determined R_{ZY} for the single rod composing the resonator to be 0.2.

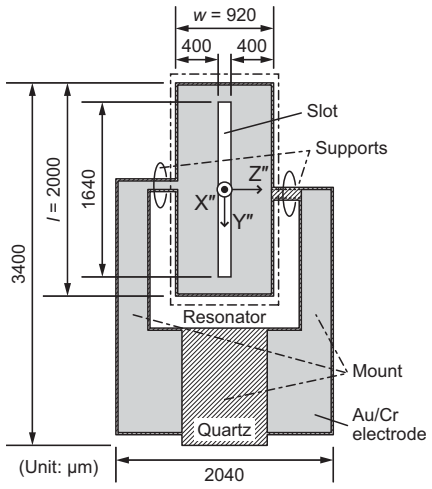

Figure 1. Schematic diagram of the designed quartz resonator. The X″, Y″, and Z″ axes means doubly rotated X, Y, and Z axes of a quartz crystal.

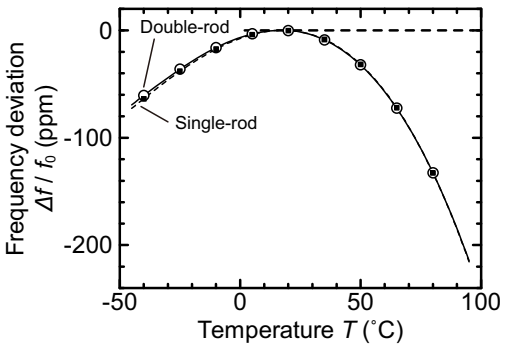

Figure 2. Temperature-frequency characteristics of the X-cut quartz resonators with a single rod and double rods with R_{ZY}= 0.20. The resonant frequencies of both resonators were f= 1.32 MHz at a reference temperature of 20°C

III. A X-CUT QUARTZ CRYSTAL OSCILLATORS WITH THE DOUBLE-ROD QUARTZ RESONATOR ANALIZED BY FEM

The frequency-temperature characteristics of a single-rod and a double-rod quartz resonators with R_{ZY} = 0.2 were calculated by the ANSYS (ANSYS Inc. PA, USA). The simulated resonant frequency f_0, α, and the second order frequency coefficient β of the double-rod resonator was 1.33 MHz, -1.59×10^{-7} /°C, and -2.73×10^{-8} /°C^2, respectively (Fig. 2). The simulated frequency f_0 agreed well with the one derived from the LE mode frequency equation, f_0 = 1.36 MHz. The frequency f_0 and temperature coefficients of the resonator hardly changed by mounting. These results indicate that the temperature character of the resonator with a slot is similar to that of the resonator which has two rods connected at both ends.

The conventional tuning-fork type quartz resonator is fabricated using Z-cut plate by the wet etching process. Z-cut quartz LE mode rod oscillators with sidewall electrodes on the X planes were also fabricated by wet etching[5]. Although the etching speed in the X-axis direction is rather slow, the rotation around the Y axis of the X-cut plate increases the etching speed normal to the surface and allows to process complex structure monolithically. To design a zero temperature coefficient double-rod resonator and a tuning-fork type mount, a doubly rotated X-cut (XY*lt*) φ_Y /θ_X quartz plate was analyzed by FEM. As shown in Fig. 3(a), α of the double-rod resonator became positive for $\varphi_Y < -35°$. We designed the LE mode double-rod resonator with $\varphi_Y = -35°$ where the wet etching speed is fast enough. With decreasing θ_X, α of the doubly rotated X-cut double-rod resonator increase (Fig. 3(b)), which allows to compensate the possible decrement of α by mounting the resonator[3].

As shown in Fig. 4, the root mean square displacement d of the element on the side along the +Z″-axis of the double-rod resonator was minimum at Y = 40 μm and the minimum d became smaller than that of the single rod resonator. When the aspect ratio R_{ZY} = 0.2 , d of the resonator on the side along the +Z″-axis became small enough for the double rod resonator to be supported not at the midpoint but the 40-μm offset point from the midpoint of side (Fig. 5). The height of the support was designed so that the vibration modes of the mount do not

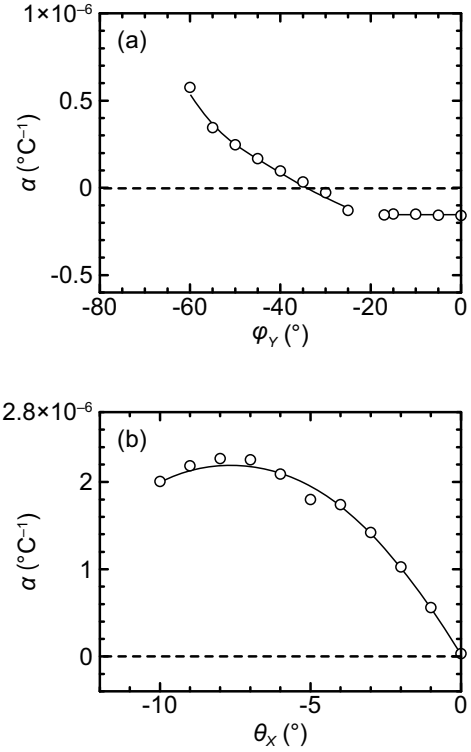

Figure 3. First order coefficient α of the doubly-rotated X-cut quartz resonator with a double-rod structure. (a) Rotation around the Y-axis. (b) Rotation around the X-axis.

couple with the LE mode shown in the displacement field images calculated by the FEM analysis. With increasing the support width W_1 from 60 μm to 320 μm, α decreased (Fig. 6). As there was a little change for W_1 < 180 μm, W_1 was determined at 120 μm to remain α almost zero and positive.

IV. FABRICATION OF THE DOUBLY ROTATED X-CUT QUARTZ OSCILLATOR BY THE WET ETCHING PROCESS

The (XY*lt*) −35°/−1° double-rod quartz resonator was fabricated by the wet etching process in 20% buffered HF (BHF) at 50°C for 14 h and 30% BHF at 50°C for 1 h. Table 1 shows the size of a fabricated sample. The sample has a temperature coefficient α of -0.6×10^{-6} /°C (Fig. 7). The little difference from the calculated α indicates the vibrating mode of the double-rod resonator in the oscillator did not coupled with the vibrating mode of the supports and the mount.

Because of the anisotropical etching of the quartz crystal, the sample with the etch residue and undercut had the longer length of the oscillator along the Y″-axis than the designed length and the narrower width along the Z″-axis than the design width. Substituting parameters in the FEM model with the measured size α was calculated to be -0.4×10^{-6} /°C, which agreed better with the measured value than the calculated value α of 0.2×10^{-6} /°C based on the design values did. A series resistance R_1, a series inductance L_1, a capacitance ratio r, and Q were 1080 Ω, 2.46 H, 187, and 19000, respectively.

TABLE I. DESIGNED AND MEASURED SIZES OF THE NEWLY FABRICATED X-CUT QUARTZ RESONATOR. DESINED AND MEASURED SIZES OF THE NEWLY FABRICATED X-CUT QUARTZ RESONATOR.

	Resonator size		Support width		Slot size	
	Length [μm]	Width [μm]	Left side [μm]	Right side [μm]	Length [μm]	Width [μm]
Designed value	2000	920	120	120	1640	120
Measured value	2045	904	153	154	1553	134

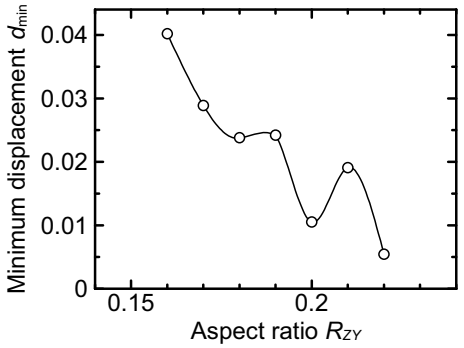

Figure 5. RMS minimum displacement of the element on the +Z″-axis direction side of the (XY*lt*) −35°/−1° cut resonator vs. R_{ZY}.

V. CONCLUSION

The LE mode X-cut quartz oscillator consists of the resonator with a slot and a fork type mount was analyzed by FEM to reduce the series resistance and capacitance ratio. The resonator structure is regarded as the double-rod resonator connected at both ends and mounted at effective nodes of the rod resonator. By using (XY*lt*) −35°/−1° cut quartz plate the oscillator fabricated had $\alpha = -0.6\times10^{-6}$ /°C, $R_1 = 1080\ \Omega$, $L_1 = 2.70$ H, $r = 192$, and $Q = 19000$ by the wet etching process.

Investigation into Spectrum Shape Fluctuations of Oscillators and Signal Sources

Michael Underhill
Underhill Research Limited
Lingfield, UK
E-mail: mike@underhill.co.uk

***Abstract*—A standard SDR receiver with digital FFT type spectrum analysis software and a time waterfall display is used to investigate spectrum shape and 'spur' fluctuations in LC and crystal oscillators. Oscillator start-up spectra are found to narrow exponentially in time towards the expected Leeson model 'bell' shape, with a time constant inversely proportional to the resonator bandwidth. Spurs can be seen most prominent around the 3dB bandwidth frequencies of the oscillator resonator. The spur frequencies in general are a constant fixed offset from the carrier frequency and do not drift. Spur amplitude fluctuations appear to be random but with an average periodicity inversely proportional to spacing from the carrier. Some theory for the fluctuations is under development.**

Keywords—oscillator time spectra; digital FFT spectrum analyser; spectrum time waterfall; oscillator fluctuation theory.

I. INTRODUCTION

Spurious 'spikes' or 'spurs' can be observed in the spectra of oscillators and signal sources using both analogue and digital spectrum analyzers Some tentative explanations for the occurrence of such spurs and related phase and frequency jumps have been put forward [1-3]. The fluctuations of these in time need further investigation so that theory may be constructed. The RF Space ™ Software Defined Radio shown in Fig. 1 is the measurement equipment used for this investigation.

II. SOFTWARE DEFINED RADIO (SDR) AS DIGITAL SPECTRUM ANALYSER

Fig. 1. RF Space ™ Software Defined Radio, SDR-IQ, used as a FFT Spectrum Analyzer. ADC of 14 bits, clocked at 66.6 MHz. I and Q format data signals from a **direct** digital converter (DDC), with a bandwidth of 192 kHz anywhere within the range 0 to 30 MHz to 1 Hz precision. SpectraVue software provides SDR control and a selectable time waterfall display. Power is supplied via the USB port connection. Size is 3×10×12 cm.

Fig. 1 shows the RF Space ™ Software Defined Radio, SDR-IQ, used as a FFT Spectrum Analyzer. SpectraVue freeware is used for the time waterfall and other time plotted displays in the following figures.

Because of the parallel processing of the FFT the spectrum samples are available at a sampling rate that is typically more than a thousand times faster than is possible with a traditional swept frequency spectrum analyser.

Also the sideband noise dynamic range of a 14 bit DAC clocked at 66.6MHz as in the SDR-IQ is $14\times6 + \log 3.33\times10^7 = 84 + 75 = 159$dBC/Hz. This performance is well in excess of what can be achieved with the best swept frequency analogue spectrum analysers by about 40dB typically.

III. SOFTWARE SPECTRUM OF LC OSCILLATOR WITH SPURS

Fig. 2 shows the spectrum of a 9.728MHz LC oscillator in a Malden Electronics model 754 signal generator. A varactor has been placed across the LC tuned circuit to allow externally applied frequency modulation. Spurious 'spikes' or 'spurs' can be observed in the snapshot spectrum at the top. And amplitude fluctuations of the spectrum and spectrum spurs can be seen in the time waterfall at the bottom. Time markers are at the left of the waterfall. Colour amplitude calibration in dBs is to the left of the waterfall.

In Fig. 2 there are visible spurs at ±38kHz, ±19kHz, and –9.5kHz and +51kHz. Note that the periodicity of the ~2dB fluctuations are approximately inversely proportional to the spacing from the carrier. The reason for this needs further investigation. But it provides evidence that the coupling between the energy in different parts of the frequency spectrum is a function of sideband frequency, or level above thermal noise kT, or oscillator resonator bandwidth, or a combination of these.

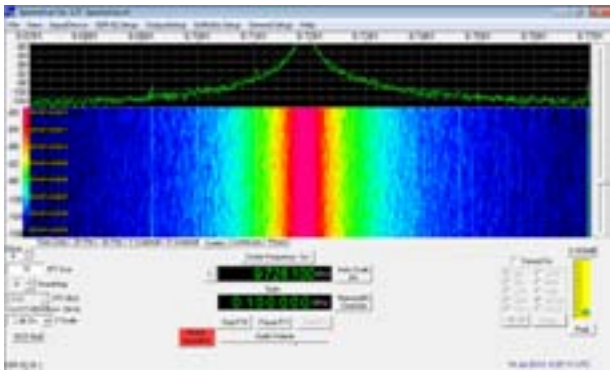

Fig. 2. Spectrum of LC Oscillator at ~9.728MHz over a 100kHz FFT analyser bandwidth, with LC Q ~120, and 3db bandwidth of ~80kHz. Vertical scale steps of 4dB. Plateau noise at ~-104dB and carrier at ~0db level. Waterfall time markers are at one second intervals.

IV. Spur Fluctuation over Time

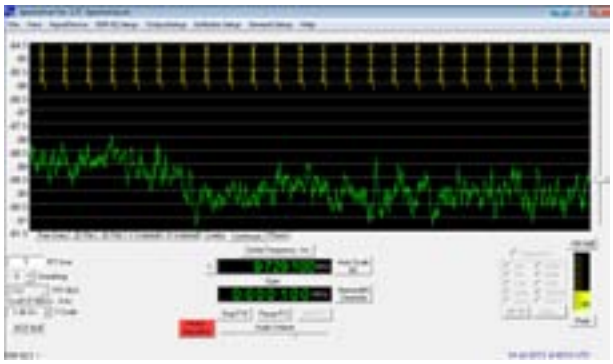

Fig. 3. Slow time variation of single spur at +2.3kHz from 9.728MHz carrier. Vertical scale steps of 0.5dB. Plateau noise at ~-104dB level and carrier at ~0db level. Horizontal time scale markers are at ten second intervals. .

Fig. 3 is a four minute duration right-to-left amplitude measurement of a single spur. Note that these slow fluctuations averaged over 5 sampling periods have a typical amplitude excursion of about 2dB.

V. Spur Fluctuations in 20MHz Crystal Oscillator

Fig. 4 shows the spectrum of a CMAC IQXO-22 20MHz crystal oscillator. The supply was a 3×1.4 = 4.2v NiMH rechargeable battery of three cells. Prominent 100Hz harmonic mains sidebands at −70 to −90dBC can be seen. The oscillator and supply were not sufficiently screened or decoupled from mains interference. However ~2db amplitude fluctuations can be seen on most of the interlaced 50Hz harmonics. It might have been supposed that injection locking by mains interference might have had the effect of suppressing these fluctuations.

In this case the 'Blackman-Harris' windowing function available in Spectra Vue gave the very good FFT adjacent signal selectivity performance needed to separate the weak 50Hz harmonic components from the relatively strong 100Hz components. This windowing function gives the best adjacent FFT bin selectivity at the cost of a peak response widened to two or three FFT bins.

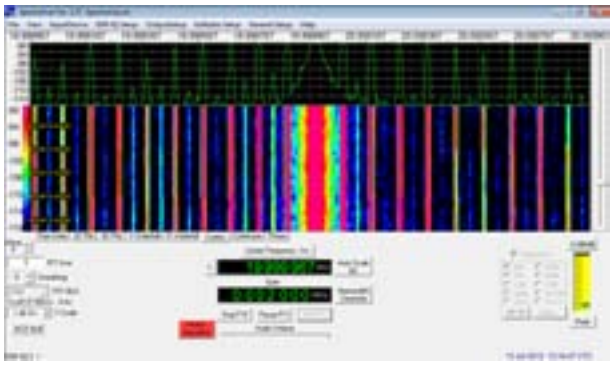

Fig. 4. Spectrum of 20MHz Crystal Oscillator with prominent 100Hz mains harmonic sidebands at about 70 to 90dBc. Time markers are at ten second intervals.

VI. Start-Up and Shock Spectrum Shape Transients of a 20MHz Crystal Oscillator.

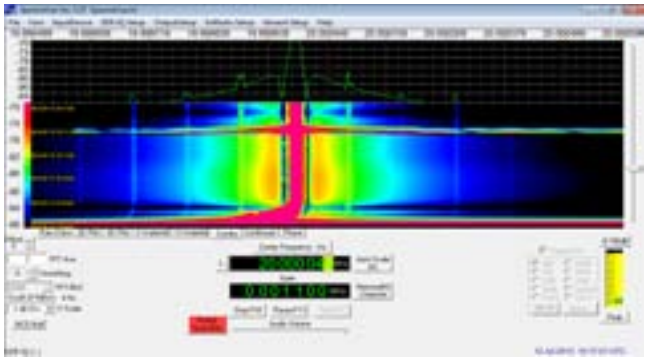

Fig. 5. Crystal mechanical shock spectrum shape transient at top of waterfall. Start-up transient at bottom of waterfall. 1.1kHz display bandwidth and 10sec spaced time markers. Blackman windowing was used.

Fig.5 compares the spectrum shape transient of a 20MHz crystal oscillator (CMAC IQXO-22) on start-up (at the bottom of the waterfall) with what occurs after a mechanical shock applied to the crystal. In both cases the spectrum shape narrows with a time constant that is inversely proportional to te resonator bandwidth. Start-up drift from a lower than final frequency is apparent. In the mechanical shock case the spurs can also be seen to be initially widened.

Here the Blackman windowing algorithm was used. It has less effective far-out selectivity but has two close-in nulls to improve close-in filter selectivity. These can be seen in Fig. 5 either side of the central carrier. However the orange and green 'blooming' of the spectrum seen between the two transients was found to be an unwanted artefact of the Blackman windowing algorithm. Long term variations (~20min) of up to 20dB were observed in this part of the spectrum. When Blackman-Harris windowing was applied better wide plateau selectivity was achieved, the close-in nulls disappeared and the long-term variations also disappeared. Thus the use of 'Blackman-Harris' windowing, rather than

'Blackman' windowing, appears to be essential in this application and this is used elsewhere in this paper.

VII. Strobe Measurement of LC Oscillator Switching Transients

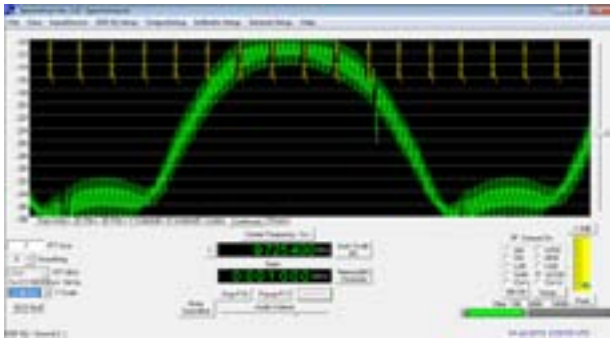

Fig. 6. Strobed time transients for 9.73MHz LC oscillator. Frequency jumpsTime markers at 1sec intervals. Strobe frequency of 18.51Hz. .

The 9.73MHz LC oscillator used for Fig. 6 and Fig. 7 has a resonator Q of ~120 and a bandwidth of ~800kHz. This means that the spectrum settling time constant is ~1.2µs. Depending on the 'RBW' bandwidth of the SpectraVue FFT the spectrum sampling rate will typically be no more than 2 to 4Hz. This is not sufficient for direct sampling of the spectrum transient in this case. However repetitive 'strobing' was found to be possible and to give a much expanded in time, albeit sampled, display of switching transients of this oscillator.

In Fig. 6 and Fig. 7 the oscillator frequency is being 'jumped' by a 18.51Hz square wave applied by a varactor across the tuned circuit. In Fig 6 the time scale has been expanded by the strobing from 1/18.51 to ~12s or ~200 times. In Fig. 7 the time expansion is ~40 times. The strobing expansion depends on there being a stable small fractional frequency offset from a whole number ratio between the FFT sampling frequency and the switching frequency stimulating the oscillator transient.

Fig. 6 is a right-to-left time display of the total lower sideband energy in response to the frequency switching at 18.51kHz. Fig. 7 shows the time decay of the lower sideband power as a spectrum.

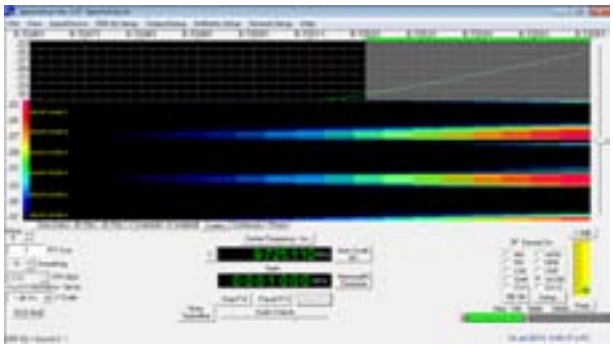

Fig. 7. Strobed Spectrum transients for 9.73MHz LC oscillator. Time markers at 1sec intervals. Strobe frequency of 18.51Hz.

VIII. Qualitative Theory of Spectrum Fluctuations

The Leeson model of an oscillator is as shown in Fig. 8 and its spectrum is shown in Fig. 9 [4]. The problem to be addressed is that the idealised 'bell-shaped' spectrum is only true as a long term time average. In practice we find that in the short term the spectrum shape is noisy and it fluctuates in amplitude and in the phase of its sideband components.

The fluctuations are found to be greatest when the sideband power density is comparable to the thermal noise and this occurs in the regions around the oscillator resonator 3dB bandwidth points.

We also find that the small amount of external discrete signal noise electromagnetically coupled into the oscillator resonator will cause 'spurs' which are constant in frequency but can fluctuate in amplitude. The process is one of partial injection locking [2] as indicated in Fig. 9.

Even if all external sources of interference can be filtered out then such low level spurs can still occur, but in this case their frequencies are less predictable and more random. It could then be regarded as a case of random self-injection locking. Such a concept needs further investigation.

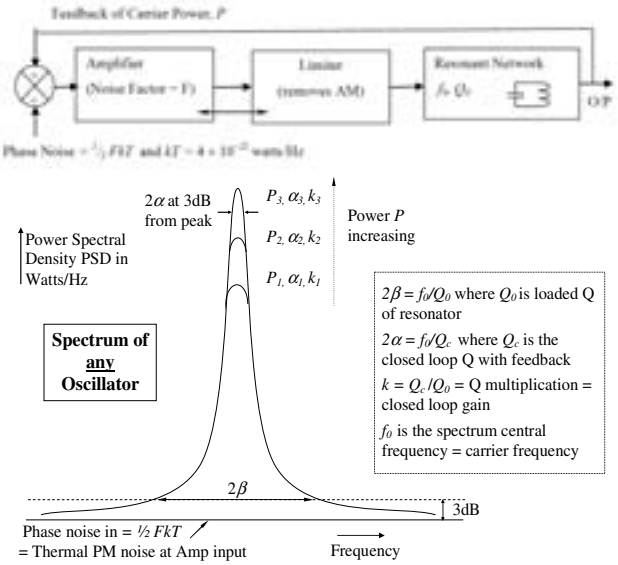

Fig. 8. Leeson Oscillator model at top with spectrum as a function of oscillator power below.

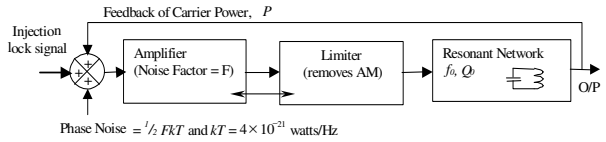

Fig. 9. Injection locking in the Leeson oscillator model.

The underlying assumption for spectrum fluctuations is that the total power of the oscillator remains constant, but power

can be temporarily transferred from one part of the spectrum to another to cause local spectrum fluctuations.

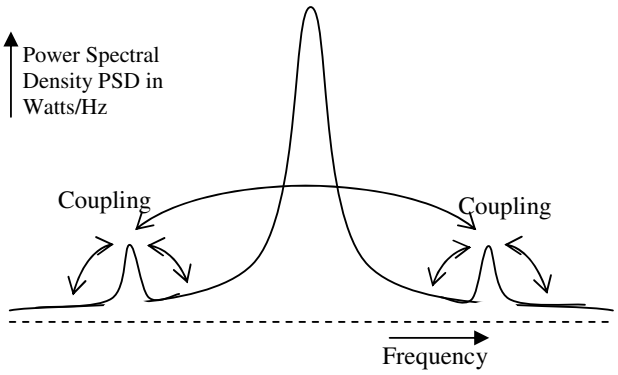

Fig. 10. A pair of oscillator spectrum noise components shown with exaggerated amplitude and coupling to other parts of the spectrum.

A more quantitative model of spectrum fluctuations can be envisaged on the basis that the power *coupling* factors for different parts of the spectrum determine the fluctuation periodicity and statistical time constants as shown in Fig. 10.

At present the coupling factors need to be observed and calibrated empirically. This is a step towards extracting a predictive theoretical model of oscillator fluctuations. However on the basis of the experiments and results so far we can deduce the following:

1. Coupling is strongest to adjacent parts of the surrounding spectrum and between opposite sideband pairs.

2. Coupling is strongest between components of almost the same spectral density. Otherwise the strongest component dominates and partially suppresses all weaker components.

3. The coupling factors are dependent on some inverse power of sideband frequency. The power could be $1/f^2$ or $1/f$ or $1/f^{½}$. More measurements are needed.

4. For stability when there are a multiple of coupled components the strongest component should exceed in power the sum of the powers of all the weaker components. When this is not the case the stronger component can be suppressed randomly by the ensemble of weaker components.

5. This is thought to be the main mechanism that can cause fluctuations in the shape of the spectrum, particularly around the 3dB resonator bandwidth points where the oscillator sidebands are not much stronger than the thermal noise.

IX. Conclusions

SDR Digital Spectrum Analyser techniques have made it possible to measure spectrum shape time fluctuations of crystal oscillators and LC oscillator signal sources for the first time with good accuracy.

Thus theory for oscillator spectrum shape fluctuations is being developed based on the measurements made so far. A second order Leeson model [4], with an energy constraint on the total spectrum power, is being considered. The coupling factor for transfer of energy between different parts of the spectrum appears to be inversely proportional to a (fractional) power of the frequency spacing. Further measurements are needed.

***Abstract*— This paper presents a fully-digital analog-television RF transmitter realized on a small FPGA. Phase Alternating Line (PAL) encoding algorithms have been implemented along with digital filters and a Direct Digital frequency Synthesizer, for generating the carrier signal, achieving RF transmission of greyscale image captured from an onboard video camera.**

Keywords—Direct digital synthesis, frequency spurs, quantization, Digital-to-Analog converter

I. INTRODUCTION

Direct digital synthesizers (DDS) or numerically controlled oscillators are important in many digital communication systems [1], [2]. Quadrature synthesizers are used for constructing digital up and down converters, demodulators, and implementing various types of modulation schemes, including PSK (phase shift keying), FSK(frequency shift keying), and MSK (minimum shift keying) [3].

A common method for digitally generating a complex or real valued sinusoid employs the use of a phase accumulator and a sine/cosine lookup table. The lookup table stores samples of a sinusoid whereas the phase accumulator is used to generate a suitable phase argument that is mapped by the lookup table to the desirable output waveform. The average frequency of the DDS is defined by the frequency control word *w* and the system clock, $f_{clk.}$ The desirable frequency generated by the DDS is given by the following equation [4]:

$$f_{out} = \frac{W}{2^n} \cdot f_{clk}$$

Often a quantizer [5] is introduced between the phase accumulator and the LUT. The quantizer receives high precision phase angle and generates a lower precision representation of the angle in order to reduce the size of the LUT. This process decreases the size of the LUT from $2^n \cdot M$ to $2^t \cdot M$ but as an aftereffect introduces phase noise and unwanted spurious spectral components in the DDS output signal.

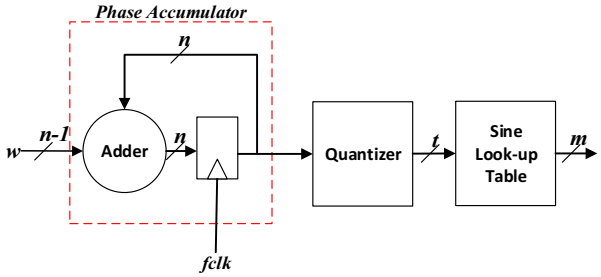

Figure. 1. Direct digital synthesizer core

Amplitude quantization is often employed in the output of the LUT, decreasing the world length of the amplitude to m bits. Amplitude quantization has an important effect on the spectral fidelity of the output signal introducing noise which decreases the signal-to-noise ratio. An approximation of the SNR in the output is given by [4]:

$$SNR = -6.02 \cdot m - 1.76\ dB$$

The maximum frequency output is given by the uniform sampling theorem $f_{outMAX} = \frac{Fs}{2}$ although a maximum frequency of $\frac{Fs}{4}$ is often preferred.

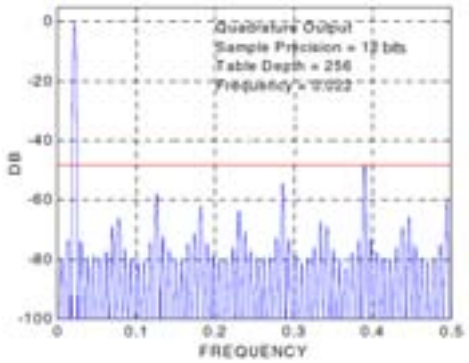

Figure. 2. Typical spectrum of the DDS core used with table depth = 256 and 12-bit precision samples [3]. Here it is $f_{out} = 0.022 \cdot f_{clk}$

The output of DDS is not perfectly periodic for most of the values of w resulting in an output signal with deterministic timing irregularities and a spectrum full of possibly strong and undesirable frequency spurs [6],[7]. Both phase and amplitude quantization techniques used in the process result in spectral artifacts. The depth of the look-up table affects the phase angle resolution and width affects the amplitude resolution of the signal. These resolution constraints are equivalent to time base jitter [8] and amplitude quantization of the signal and add spectral modulation lines and a broad-band noise floor to the signal's spectrum as shown in Fig. 2.

II. Phase Alternating Line (PAL) Analog Television Encoding System

A fully digital PAL television signal transmitter has been designed and implemented. PAL, short for Phase Alternating Line, is one of the three color encoding systems for analogue television and has been popular in most European countries. The other two analogue systems are NTSC and SECAM [9].

PAL encoding system has some advantages compared to the other two encoding systems. In contrast to NTSC, PAL does not require tint control circuit in order to perform color correction. In contrast to NTSC, the PAL standard automatically cancels hue errors by phase reversal, so tint control is unnecessary. This causes lower saturation, which is much less noticeable to the eye than NTSC hue errors. SECAM on the other hand uses Frequency Modulation with alternative transmission of the chrominance vectors. Although this technique solves the hue errors, the signal is more sensitive to cross-color intermodulation and a delay line is required at the receiver.

A frame in PAL encoding system (576i) consists of 625 lines, with 610 visible lines divided into two interlaced frames and 15 synchronizing lines.

Vertical synchronizing sequence for field 1, starts from scanline 623 and ends in scanline 5 inclusive. It consists of 6 pre-equalizing pulses, 5 long sync pulses and 5 post-equalizing pulses.

The synchronizing sequence for filed 2 starts from line 311 and ends in line 317 inclusive. It consists of 5 pre-equalizing pulses, 5 long sync pulses and 4 post-equalizing pulses. During the transmission of vertical sync pulses, teletext data can also be transmitted.

A typical PAL encoder consists of a complex system, where the chrominance components (U and V) are quadrature amplitude modulated and then added to the luminance signal (Y) in order to produce a complex baseband composite signal.

Then this signal is amplitude modulated to the desirable frequency and passed through a vestigial filter. Along with the visible components of the signal, horizontal and vertical synchronizing pulses and color subcarrier bursts are transmitted. The audio signal is Frequency Modulated and transmitted on a different carrier frequency in the same channel. The total bandwidth of the channel, including the picture and audio signal cannot extend more than 8 MHz as shown in fig. 5.

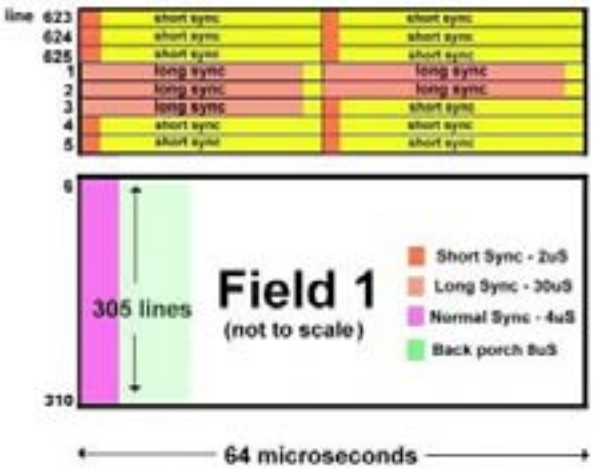

Figure. 3. Field 1 in PAL consisting of picture and synchronizing scanlines

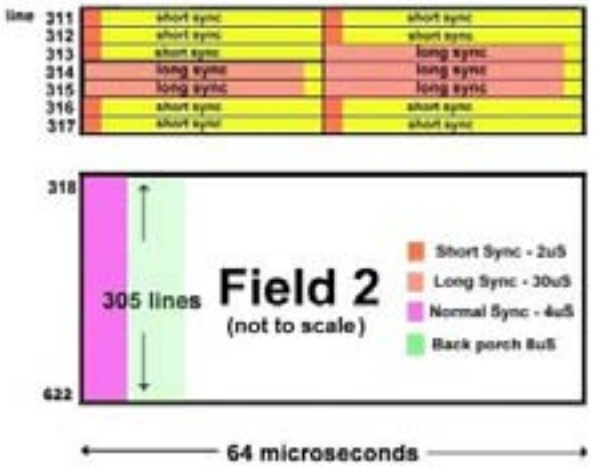

Figure. 4. Field 2 in PAL consisting of picture and synchronizing scanlines

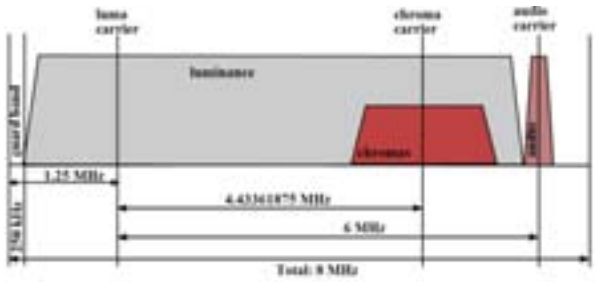

Figure. 5. Spectrum of a television channel with PAL

In order to implement a PAL encoder, a specially designed Finite State Machine and visual encoding algorithms have been created Fig.6. The image transmitted can be provided from another system, using a digital interface (ie. a PC using USB) or captured directly from a

video camera. For the purpose of the live demo we selected the second approach.

Image is live captured from an onboard inexpensive VGA camera module. Due to the different timings of VGA and PAL protocols, a RAM-based frame buffer is used to store the contents of a frame. The image is then encoded to the phase alternating line system and filtered in order to meet the bandwidth limitations. We have to note that due to limitations of RAM blocks on this entry level FPGA board, only a black and white picture is transmitted, whereas in a bigger FPGA board or an ASIC, a color transmitter can be implemented with minor modifications in the architecture.

In order to modulate the encoded baseband data stream, an n-bit wide Direct Digital Synthesizer is needed. Using multi-bit-output phase-dithered DDS we generate a 9-bit wide carrier sinusoid. The amplitude modulation is digitally implemented by directly multiplying the binary carrier and the DC-shifted composite data stream. Finally using digital amplitude dithering the multi-bit modulated signal is converted to 4-bit digital stream which is converted to analog trivial DAC realized with a resistor network.

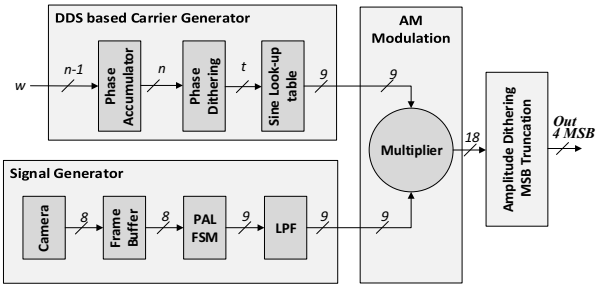

Figure. 6. DDS-based all-digital PAL video RF transmitter architecture using 4 bit random dithering DAC

III. Random Number Dithering And 4-Bit Quantization

Although many techniques are proposed in order to convert the multi-bit digital signal to a single-bit analog one, many of them require the use special or accurately matched analog components and detailed and time consuming analog design.

The proposed architecture requires the minimal use of analog components and can be easily implemented on any FPGA or ASIC integrated circuit. Instead of driving the multi-bit signal to the output DAC, amplitude dithering is employed and the most significant bits are driven to a low resolution DAC. This technique eliminates most of the unwanted spurs generated in all the stages of the signal path with the cost of the increased noise floor. The noise floor at the output is given in relationship to process gain and SNR by the following equation:

$$NF = 10 \cdot log_{10}\left(\frac{f_{clk}}{2}\right) + 6.02 \cdot log_2\left(\frac{output\ levels}{2}\right)\ dBc/Hz$$

Where the first term represents the process gain and the second term represents the gain due to the use of more than one output bits.

There are two techniques proposed for quantization of a fully digital multi-bit signal into an analog single-bit one. In both techniques a source of random a uniform noise is used [10], [11]. The multi-bit uniform noise generated by a random number generator is added to the AM modulated signal fig.7 and fig.8. and then the three or four most significant bits are kept.

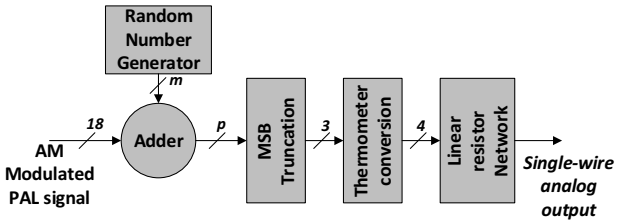

Figure. 7. Birary resistor network

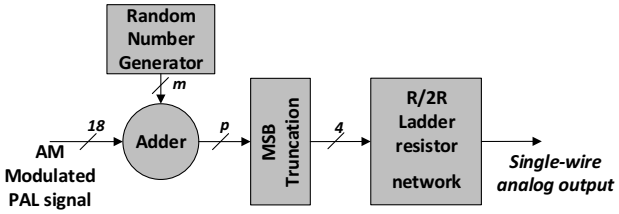

Figure. 8. R/2R Ladder resistor network

In the case we use a binary resistor network, the three MSBs are thermometer coded and then driven to a binary resistor network fig. 9a.

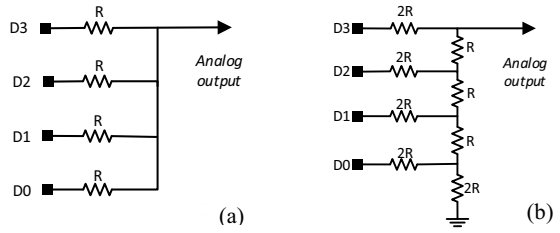

Figure. 9. (a) Birary resistor network,
(b) R/2R ladder resistor network

The second technique employs the use of an R/2R ladder resistor network. This technique improves the precision with the use or the same number of components fig. 9b.

IV. FPGA Implementation/Live Demo

Based on the proposed architecture in section II, and for the purpose of a live demonstration, the demo board in fig.10 was built. It is based on Papilio One [12], an entry level FPGA board, using Xilinx's Spartan 3E XC3S250E FPGA. This entry level FPGA has an equivalent of 250K gates and

only 216Kbits of Block RAM. A phase dithered DDS of n = 9 bits has been selected.

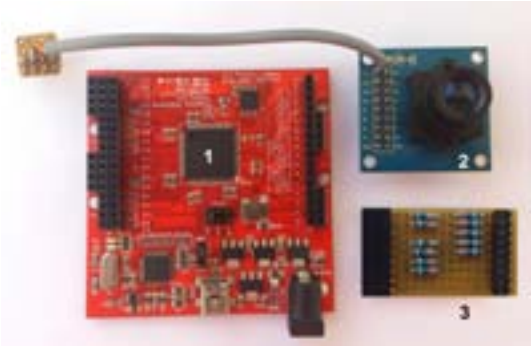

Figure. 10. Board built fot the purpose of the Live Demo

1. Papilio One/ Spartan 3E FPGA Board
2. OV7670 VGA Video Camera Module
3. R/2R ladder resistor network

For the analog-to-digital conversion, a random-dithering DAC was used. The only analog components are eight resistors, avoiding the use of active analog components.

The FPGA utilization of this implementation is presented in fig.11. Despite the use of a small FPGA chip, the whole project, including the camera module, PAL encoding algorithms, AM modulation and dithering module, occupies only 14% of the total chip resources.

The implementation operated at 200MHz achieving noise floor of about 88dBc/Hz (within the desirable frequency range) fig.13.

Device Utilization Summary			
Logic Utilization	Used	Available	Utilization
Number of Slice Flip Flops	352	4,896	7%
Number of 4 input LUTs	495	4,896	10%
Number of occupied Slices	365	2,448	14%
Number of bonded IOBs	20	66	30%

Figure. 11. Device utilization of the implemented Video RF transmitter

Figure. 12. Footage from the FPGA-based PAL Video RF transmitter

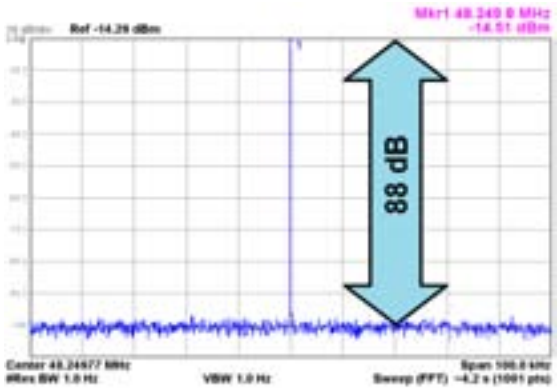

Figure. 13. FPGA Implementation (spectrum analyzer measurement of DDS output) using binary resistor network. Resolution BW = 1 Hz and waveform averaging Nav=10 runs

V. CONCLUSIONS

A versatile purely digital analog video transmitter architecture, that results in minimum chip-area, low-power and low-cost implementations, has been presented, including a nearly all-digital DAC. Measurements have demonstrated a dynamic range of over 88dBc/Hz. Random number dithering can reduce the size of the DAC, finally resulting in a single-bit output analog circuit. Through this work, it has been shown that the fabrication of traditionally analog circuits is possible, using only digital design techniques.

***Abstract*—Fluctuation dissipation theorem allows to recover a 1/*f* noise spectral density at low frequency. The level of this 1/f noise is governed by a single fitting parameter that can be connected to the onset frequency of this 1/*f* regime. It constitutes the fundamental intrinsic limit of quartz crystal. Some preliminary considerations on the physical origin of this parameter in terms of microscopic processes in the crystal are given. Experimentally, quartz crystal resonators have been cut from a quartz crystal block supplied specifically for this study on 1/f noise. The short-term stabilities of several resonators have been measured to be lower than $8{\cdot}10^{-14}$. A comparison of these resonators is given and the results are discussed according to the position of the resonators inside the crystal block.**

Keywords-1/f noise; quartz resonator; fluctuation-dissipation theorem; short-term stability.

I. INTRODUCTION

The Centre National d'Etudes Spatiales (CNES), Toulouse, France and the FEMTO-ST Institute, Besancon, France, have initiated investigations on the origins of noise in bulk acoustic wave resonators together with several European manufacturers [1]. Theoretical and experimental works are reported in this paper. We first improve on our previous study using fluctuation dissipation theorem (FDT) by adding a term for internal damping [2] to the classical wave equation already studied [3]. This allows us to recover a 1/*f* noise spectral density at low frequency. The level of this 1/*f* noise is governed by a single fitting parameter that can be connected to the onset frequency of this 1/*f* regime. It constitutes the fundamental intrinsic limit of quartz crystal. Some preliminary considerations on the physical origin of this parameter in terms of microscopic processes in the crystal are given.

Experimentally, quartz crystal resonators have been cut from a quartz crystal block supplied specifically for this study on 1/*f* noise. The reader is reminded of the description of the blank realization and the topology of the resonator prototype is exposed. The resulting resonators are SC-cut with a 5 MHz resonant frequency. Then, we report noise measurements made on these quartz crystal resonators using a passive phase noise measurement system. The short-term stabilities of several resonators have been measured to be lower than $8{\cdot}10^{-14}$. A comparison of these resonators is given and the results are discussed according to the position of the resonators inside the crystal block.

II. THEORETICAL APPROACH

A. Fluctuation-Dissipation Theorem

The fluctuation-dissipation theorem (FDT) as formulated in [4] and [5] is used to estimate the power spectral density of thermal noise coming from fluctuations in the thickness (2*h*) of quartz resonators (cf. Fig. 1).

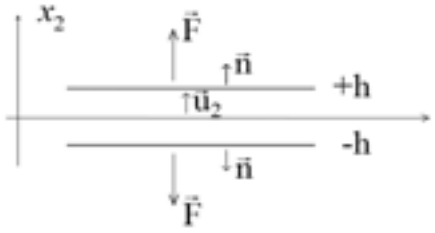

Figure 1 : Resonator design.

In a previous paper [3], we described these fluctuations by a 1D viscoelastic model of the longitudinal vibrations along the thickness of the quartz resonator (axis x_2). The level of white noise was found to be far below what is measured, meaning that viscoelastic damping of thickness fluctuations is not the dominant noise process. Here, an internal friction term, φ, is added in the formulation, in order to obtain a 1/*f* spectrum at low frequencies. Indeed, for this mode (characterized by the mechanical displacement inside the resonator $u_2(x_2,t)$), the strain S_2 and stress T_2 are then respectively given by:

$$S_2 = \frac{\partial u_2}{\partial x_2} \tag{1}$$

$$T_2 = c_{22}(1 + j\varphi)S_2 + \eta_{22}\frac{\partial S_2}{\partial t} \tag{2}$$

with c_{22} the elastic constant and η_{22} the viscoelastic damping constant of quartz crystal. φ is an internal friction coefficient [2], [5].

The fundamental principle of dynamics for continuum media can then be written as:

$$\rho \frac{\partial^2 u_2}{\partial t^2} = c_{22}(1 + j\varphi) \frac{\partial^2 u_2}{\partial x_2^2} + \eta_{22} \frac{\partial^3 u_2}{\partial x_2^2 \partial t} \quad (3)$$

with ρ the quartz mass per unit volume.

Searching for solutions of the type:

$$u_2(x_2, t) = [a \sin(kx_2) + b \cos(kx_2)]e^{j\omega t} \quad (4)$$

with limit condition given by:

$$T_2(\pm h, t) = F \cdot e^{j\omega t}/S \quad (5)$$

with F the modulus of the harmonic mechanical force applied to the surface S of the electrodes (perpendicular to x_2), gives:

$$k^2 = \frac{\rho\omega^2}{(c_{22}+j(c_{22}\varphi+\eta_{22}\omega))} \quad (6)$$

$$a = \frac{F/S}{(k\cos(kh)(c_{22}+j(c_{22}\varphi+\eta_{22}\omega))} \quad (7)$$

$$b = 0 \quad (8)$$

The complex mechanical admittance of the system is defined by:

$$\bar{Y}(\omega) \equiv \frac{\frac{\partial u_2(\pm h,t)}{\partial t}}{\pm F \cdot e^{j\omega t}} = \frac{j\omega a \sin(kh)}{F} \quad (9)$$

The FDT then states that the spectral power density of the thickness fluctuations can be computed by [4] and [5]:

$$u_2^2(\pm h, \omega) = \frac{4k_B T}{\omega^2} Re\left(\bar{Y}(\omega)\right) \quad (10)$$

with T the absolute temperature (in K) and k_B the Boltzmann constant (in J/K).

Inserting (7) into (9), then the result into (10) with the assumptions $\varphi \ll 1$ and $\omega \ll c_{22}/\eta_{22}$ gives:

$$u_2^2(\pm h, \omega) \approx \frac{4k_B T h}{S\omega c_{22}^2}(\eta_{22}\omega + c_{22}\varphi) \quad (11)$$

Moreover, we can consider that the circular frequency at resonance $\omega_r \sim 1/h$, thus:

$$S_y(\omega) = \frac{\langle(\partial\omega_r)^2\rangle_\omega}{\omega_r^2} = \frac{u_2^2}{(2h)^2} \quad (12)$$

then:

$$S_y(\omega) \approx \frac{1}{\omega} \times \frac{2k_B T}{V c_{22}} \left(\frac{\eta_{22}}{c_{22}}\omega + \varphi\right) \quad (13)$$

where V is the volume of the resonator. One can then see from the previous expression that for circular frequencies lower than $\varphi\, c_{22}/\eta_{22}$, the internal friction becomes dominant and gives a $1/f$ spectrum. Hence, φ could, in principle, be determined by the corner frequency between 1/*f* noise and white noise in the bare resonator (Fig. 2).

For 1/*f* (flicker) noise, the standard deviation of the difference of the average fractional frequencies measured for two consecutive samples is given by the expression [6]:

$$\sigma_{y\_flicker} = \sqrt{2\ln(2) S_y(1Hz)} \quad (14)$$

This is the square root of the Allan variance [7]. It is commonly used to compare the short-term stabilities of various resonators, since it is the noise at low frequencies floor in terms of relative frequency fluctuations.

Provided the corner frequency is bigger than 1 Hz, $\sigma_{y\_flicker}$ would be given by:

$$\sigma_{y\_flicker} = \sqrt{2\ln(2) \frac{2k_B T}{V c_{22}} \varphi} \quad (15)$$

We note that φ could depend upon the temperature and that no assumption where made about this possible dependence.

B. Numerical application

We consider here numerical values typical for a 5 MHz oscillator equipped with an SC-cut quartz crystal resonator. Due to the rotation of the axis, the 2 axis is not the usual one, so that the constants must be evaluated in the rotated basis: c_{22} = 115 GPa, η_{22} = 1.36·10^{-3} Pa·s, $T = 350$ K and $V = 0.104$ cm^3. This gives:

$$\sigma_{y\_flicker} \approx 1.06 \cdot 10^{-12} \sqrt{\varphi} \quad (16)$$

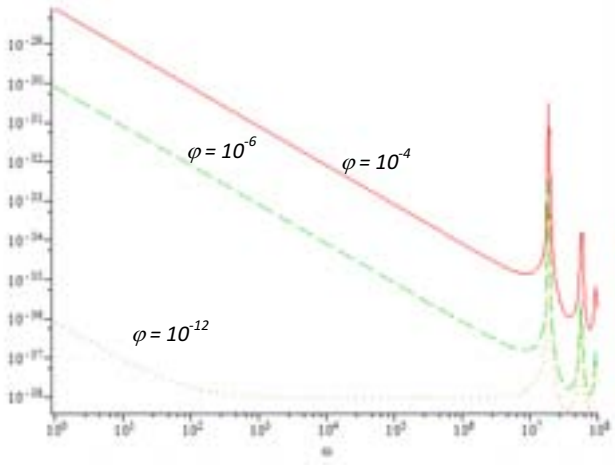

Figure 2 : Behavior of $S_y(\omega)$ for various values of φ. The transition frequency between the $1/\omega$ regime and the white noise regime is proportional to φ.

Unfortunately, in present measurements, the white noise of the amplifier is masking the white noise of the resonator, so that we cannot estimate the maximum possible value of φ from our measurements.

In order to recover measured values of $\sigma_{y\_flicker}$ with this expression, we would need to have φ between 10^{-2} and 10^{-4}, which would mean that even at resonance the internal damping would be dominant over viscoelastic damping…

III. EXPERIMENTAL RESULTS

A. Short term stability definition

The passive technique using carrier suppression is used to characterize the inherent phase stability of the ultra-stable resonators [6]. The noise results are usually measured in term of $\mathcal{L}(f)$, the one-sided power spectral density (PSD) of the phase fluctuations. If the two resonators can be considered reasonably identical, then, half of the total noise is attributed to each resonator. In that case, $\mathcal{L}(1Hz)$ is equal to $S_\phi(1Hz)$, which can be used to compute the PSD of relative frequency fluctuations $S_y(f)$, using [6]:

$$S_y(1Hz) = \left[\frac{F_L^2+1}{f_{res.}^2}\right] S_\phi(1Hz) \qquad (17)$$

with $f_{res.}$ the resonant frequency of the resonator. Finally, for $1/f$ (flicker) noise, the standard deviation of the difference of the average fractional frequencies measured for two consecutive samples is given by (14).

B. Resonator realization

The crystal block is presented in Fig. 3. This crystal block is obtained from a seed cut in a previous synthetic crystal which was grown using a natural seed. Its dimensions were approximately 220 mm along the Y-axis, 36 mm along the Z-axis and 110 mm along the X-axis. Two Y-cut slices have been cut before and after an oriented block used to achieve ten quartz bars. The Y-cut slices are used to obtain for dislocations evaluation by X-ray topographies. The red marks show how the crystal is cut in order to get SC-cut blanks from 14 initial bars. First, Fourteen quartz bars pre-oriented on the first rotation angle have been achieved. The length of the bars was about 70 mm. Taking into account the width of the cutting saw, about 24 resonators can be obtained in each bar.

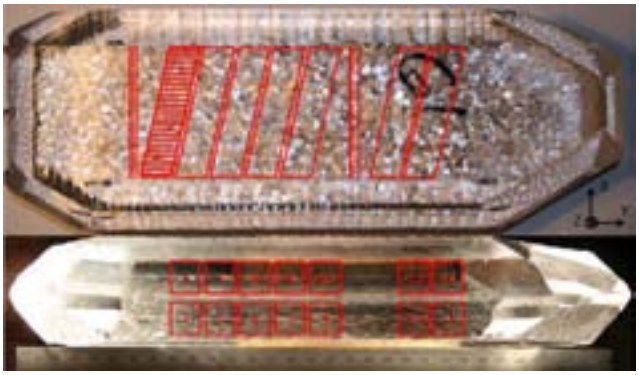

Figure 3 : Quartz crystal resonators according to their positions in the mother block.

The final prototype of the resonator is a typical 5 MHz SC-cut resonator. The diameter of the resonator is 14 mm for a thickness of 1.09 mm. A plano-convex shape allows the energy trapping for the 3rd overtone of the slowest thickness shear mode (C-mode). A radius of curvature of 130 mm has been chosen to optimize this energy trapping according to the Tiersten-Stevens model [8]. Electrodes diameter is 8 mm. The temperature turn over point of the resonator is chosen between 80 °C and 85 °C by adjusting the cutting angles.

C. Noise results

Fig. 4 and 5 give the short-term stability floors of resonators obtained in bars 12 and 14. They span approximately two orders of magnitude. The best resonators have a short-term stability (Flicker floor) below $8{\cdot}10^{-14}$, whereas the worst are above 10^{-12}. Although the positions of the blanks are known, no clear correlation between the noise results and the blanks positions (e.g. center or edges) can be found for these bars.

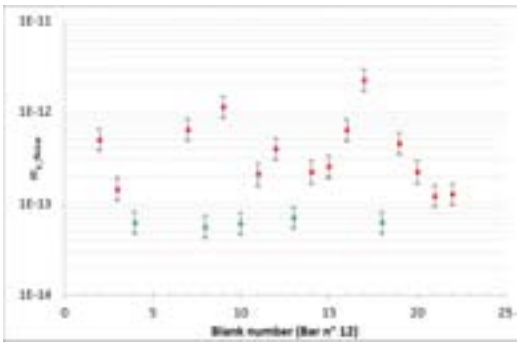

Figure 4 : Noise measurements from resonators cut in bar 12.

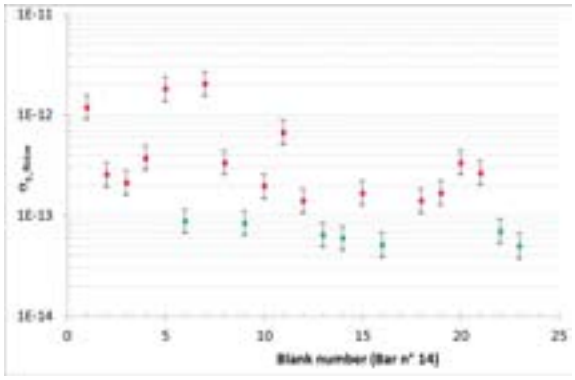

Figure 5 : Noise measurements from resonators cut in bar 14.

Fig. 6 presents the standard deviation of the noise floor of all the resonators measured so far, including those from bar 12 and 14. Resonators from bar 1 to 11 are not precisely localized along the bar. No clear effect of the bar position can be seen in these preliminary results. Other measurements are under way.

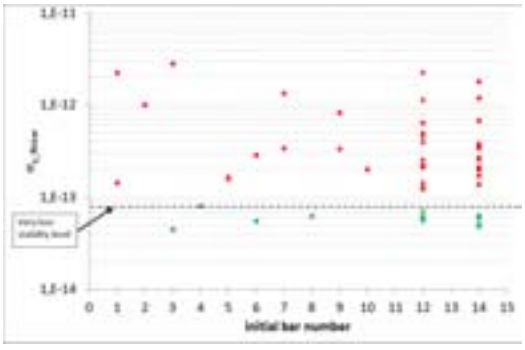

Figure 6 : Short-term stability of quartz crystal resonators according to the position in the mother block.

IV. Conclusion

Using a damping force proportional to strain and independent of frequency, naturally allows to get a $1/f$ noise spectrum at low frequencies. Indeed, we could get the noise limit of measured resonators, a few 10^{-14} [9-11], with $\varphi > 10^{-4}$. However, this would mean that the effective value of Q at the resonance would be dominated by internal damping (addition of losses: $1/Q_{eff} = (1/Q_{viscous} + \varphi)$ and lower than what is measured by at least 2 orders of magnitude. We therefore conclude that internal damping of thickness fluctuations by any force proportional to strain and independent of frequency, may not be the dominant noise mechanism for the best SC-cut quartz resonators.

The short-term stability of ultra-stable resonators has been studied according to the position of the blanks in the mother crystal. The short term stability of several resonators has been measured lower than $8 \cdot 10^{-14}$. No clear correlation between the blank position and the quality of the resonator can be seen in these preliminary data. Results coming from the other blanks are expected in a near future and may give some more indications.

***Abstract*—An RF switching down-converting mixer with an embedded single-bit-output all-digital frequency synthesizer is proposed. The output spectrum of the mixer is derived analytically based on that of the synthesizer as well as with simulation. A test setup using an FPGA implementation of the synthesizer and a discrete-component switching mixer has been built. Measurements are presented confirming the theoretical derivations.**

Keywords—switching mixer; frequency synthesizer;

I. INTRODUCTION

The interest in all-digital architectures has been intensified in the RFIC industry over the past few years due to the increasing challenge in the design and the extra cost of fabrication of RF analog and mixed-signal IC versus standard digital ones in modern nano-scale IC technologies. Digital circuit design has the advantage of portability, reconfigurability, automated checking and verification.

This paper proposes a switching RF down-converting mixer whose Local Oscillator (LO) input is driven by an embedded single-bit output all-digital frequency synthesizer, offering some of the aforementioned advantages compared to traditional analog mixer architectures.

Switching mixers are popular blocks in discrete-component designs and have been implemented in RFICs [1][1]. However, they are typically driven by classical PLLs or complex mixed-signal frequency synthesizers.

The proposed mixer architecture is shown in Fig. 1 below and is based on digital transmission gates which are driven directly by the single-bit output stream of the embedded all-digital frequency synthesizer. Certain dithering techniques are also used to make the synthesizer's spectrum sinewave-like and convert spurs to continuous noise floor.

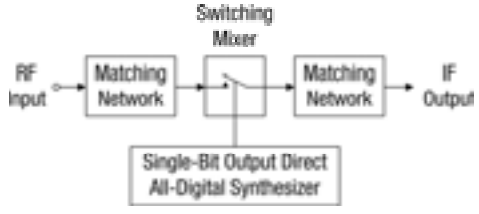

Fig. 1. Proposed switching mixer with embedded all-digital synthesizer.

First we discuss the embedded all-digital frequency synthesizer in Section II and state analytically its output spectrum. Then, the switching mixer architecture is described in Section III and its output spectrum is mathematically derived using that of the synthesizer. Finally the test setup is discussed and the measurements derived are presented and compared to the theoretical ones in Section IV.

II. EMBEDDED ALL-DIGITAL FREQUENCY SYNTHESIZER

The proposed mixer, shown in Fig. 1, comprises of a transmission gate which is digitally controlled by the all-digital frequency synthesizer. The synthesizer architecture and its output spectrum are described in the following sections.

A. Frequency Synthesizer's Architecture

The LO signal is provided by a Pulse Direct Digital Synthesizer (PDDS). It consists of a phase accumulator (n-bits wide), the Most Significant Bit of which is used as the output signal.

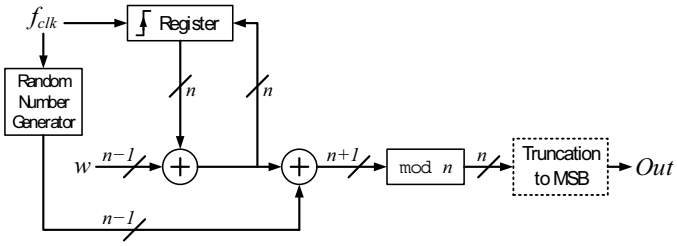

Fig. 2. Block diagram of single-bit output frequency synthesizer with phase dithering implementation.

PDDS is an extreme case of a single-bit DDS. Thus, especially when no oversampling is used, the output of the PDDS has deterministic timing irregularities and a spectrum full of strong and undesirable frequency spurs. Although the strongest frequency component is typically at the desirable average frequency, the spectral quality is unacceptable for analog and RF applications, unless a spurs-suppression technique is used.

Here we use phase dithering to randomize the synthesizer's output (otherwise) deterministic jitter and break any periodicity of it, spreading the power of the frequency spurs over the sampling bandwidth $[0, f_{clk}]$. As a drawback, a continuous noise floor is formed.

Dithering is implemented by generating a digital random sequence formed of independent and identically distributed random variables and adding it to the output of the Phase Accumulator (just before truncation) [2]. The cumulative distribution function of the random variables is of the form

$$F(u)=\left(1+\sin\left(\frac{\pi u}{2^{n-1}}-\frac{\pi}{2}\right)\right) \text{ with } u=0,1,2,\ldots,\left(2^{n-1}-1\right) \quad (1)$$

It has been demonstrated [1] that the PDDS in Fig. 1 with such a dithering sequence results in spurs-free output.

B. Frequency Synthesizer's Output Spectrum

The average output frequency of the synthesizer, based on the clock frequency f_{clk}, is equal to $f_{LO}=\left(w/2^n\right)f_{clk}$ where the Frequency Control Word w (n-1 bits wide) ranges within $0<w<2^{n-1}$ and so f_{LO} takes values within $\left[0, f_{clk}/2\right]$ with step $f_{clk}/2^n$.

It can be shown that the output of the considered PDDS is equivalent to that of the uniformly dithered single-bit Nyquist-rate quantized sinewave [3]. So the Power Spectral Density (PSD) of the synthesizer's output $v(t)$, considered as a ±1 signal (and *not* as a digital 0/1 one) is given by

$$S_v(f)=\operatorname{sinc}^2\left(\frac{f}{f_{clk}}\right)\left[\frac{1}{4}\delta\left(f\pm\frac{w}{2^n}f_{clk}\right)+\frac{1}{2f_{clk}}\right] \quad (2)$$

where $f\in\left[-f_{clk}, f_{clk}\right]$ and the spectrum is f_{clk} - periodic except the envelop function $\operatorname{sinc}^2\left(f/f_{clk}\right)$.

III. Mixer Architecture & Output Spectrum

The mixer, shown in Fig. 1, has a simple single-ended switching structure with passive networks on the RF input and IF output ports for impedance matching. The switch, controlled by the PDDS's output acts essentially as 0/1 multiplier.

A. Mixer Output Spectrum

In this section we derive expressions of the output spectrum of the mixer. We denote the RF input signal as $g(t)$. The output of the mixer is essentially the multiplication result $y(t)=g(t)x(t)$ where $x(t)$ is the 0/1 single-bit output of the frequency synthesizer. We write $x(t)=\left(v(t)+1\right)/2$ to relate it with the ±1 signaling used for the expression of the spectrum in Eq. (2).

To determine the power spectral density of the mixer output $y(t)$ we calculate the autocorrelation function of the output[1] which is given by

$$R_y(t,t+\tau)=\frac{1}{4}E\left\{\left[v(t)+1\right]g(t)\left[v(t+\tau)+1\right]g(t+\tau)\right\} \quad (3)$$

[1] Recall that the output of the mixer is a random signal due to the dithering.

Although $g(t)$ can be any signal, we consider it to be deterministic, e.g. a sinewave. The above equation becomes

$$\begin{aligned}R_y(t,t+\tau)&=\frac{g(t)g(t+\tau)}{4}E\left\{v(t)v(t+\tau)+v(t)+v(t+\tau)+1\right\}\\&=\frac{g(t)g(t+\tau)}{4}E\left\{v(t)v(t+\tau)+1\right\}\\&=\frac{g(t)g(t+\tau)}{4}\left[1+R_v(t,t+\tau)\right]\end{aligned}$$

where we used the fact $E\left\{v(t)\right\}=0$ for all values of t.

Since $y(t)$ is not a Wide-Sense Stationary (WSS) signal, instead of R_y we have to use the more general average-autocorrelation function defined as

$$\bar{R}_y(\tau)=\lim_{T\to\infty}\left[\frac{1}{2T}\int_{-T}^{T}R_y(t,t+\tau)\,\mathrm{d}t\right] \quad (4)$$

To simplify the algebra we assume that $g(t)=A\sin\left(2\pi f_g t\right)$, implying after a few steps that[2]

$$\bar{R}_y(\tau)=\frac{A^2}{8}\cos\left(2\pi f_g\tau\right)\left[1+\bar{R}_v(\tau)\right] \quad (5)$$

The power spectral density of $y(t)$ is the Fourier transform of $\bar{R}_y(\tau)$ [4], which is the convolution of the Fourier transforms of $\cos\left(2\pi f_g\tau\right)$ and $\left[1+\bar{R}_v(\tau)\right]$. The latter becomes $\left[\delta(f)+S_v(f)\right]$ where S_v is given by (2). Therefore,

$$\begin{aligned}S_y(f)&=\frac{A^2}{16}\left[\delta\left(f-f_g\right)+\delta\left(f+f_g\right)\right]\otimes\left[\delta(f)+S_v(f)\right]\\&=\frac{A^2}{16}\left[\delta\left(f-f_g\right)+\delta\left(f+f_g\right)+S_v\left(f-f_g\right)+S_v\left(f+f_g\right)\right]\end{aligned} \quad (6)$$

Combining it with Eq. (2) we derive

$$\begin{aligned}S_y(f)=&\frac{A^2}{16}\left[\delta\left(f-f_g\right)+\delta\left(f+f_g\right)\right]\\&+\frac{A^2}{16}\operatorname{sinc}^2\left(\frac{f-f_g}{f_{clk}}\right)\left[\frac{1}{4}\delta\left(f-f_g\pm\frac{w}{2^n}f_{clk}\right)+\frac{1}{2f_{clk}}\right]\\&+\frac{A^2}{16}\operatorname{sinc}^2\left(\frac{f+f_g}{f_{clk}}\right)\left[\frac{1}{4}\delta\left(f+f_g\pm\frac{w}{2^n}f_{clk}\right)+\frac{1}{2f_{clk}}\right]\end{aligned} \quad (7)$$

Since the mixer is used for down-conversion, the desirable component at the output is at frequency[3] $f=\left(w/2^n\right)f_{clk}-f_g$ and of amplitude $A^2\operatorname{sinc}^2\left(w/2^n\right)/64$ (see Eq. (7)). Again, from Eq. (7) the continuous noise power spectral density at the same frequency is given by

[2] Under some minor assumptions on the relationship between w, n and f_g.

[3] It is assumed that $f_{LO}\equiv\left(w/2^n\right)f_{clk}>f_g\equiv f_{RF}$.

$$\frac{A^2}{32 f_{clk}}\left[\operatorname{sinc}^2\left(\frac{w}{2^n}-\frac{2f_g}{f_{clk}}\right)+\operatorname{sinc}^2\left(\frac{w}{2^n}\right)\right].$$

Therefore, the noise level with respect to the carrier equals

$$NPower = 10\log_{10}\left(1+\frac{\operatorname{sinc}^2\left(\frac{w}{2^n}-\frac{2f_g}{f_{clk}}\right)}{\operatorname{sinc}^2\left(\frac{w}{2^n}\right)}\right)+3-10\log_{10}\left(f_{clk}\right)\ (\text{dBc})$$

If $w/2^n$ and f_g / f_{clk} are smaller than 0.3 or so then one can approximate the sinc functions with one and derive the simplified expression

$$NPower = 6-10\log_{10}\left(f_{clk}\right) \qquad (8)$$

IV. Measurements & Results

Our test setup consists of the mixer architecture in Fig. 1 with the all-digital frequency synthesizer implemented in a mini FPGA board (XuLA-50 / Xilinx Spartan-3A). Both the low-cost off-the-shelf transmission gate (with on/off switching time ~5ns) and the low-cost FPGA limit the frequency of operation of the mixer to a few tens of MHz.

Case 1: The clock frequency of the PDDS is $f_{clk} = 10\,\text{MHz}$ and its synthesized output frequency is set to $f_{LO} = 3$ MHz. The RF signal is a sinewave at $f_{RF} \cong 2.7$ MHz. The mixer's output spectrum centered at the desirable output frequency component $f_{LO} - f_{RF}$ is shown in Fig. 3.

From Eq. (8) we derive that the noise floor in this case is about $-64\,\text{dBc}$. This is exactly what the measurement in Fig. 3 below shows.

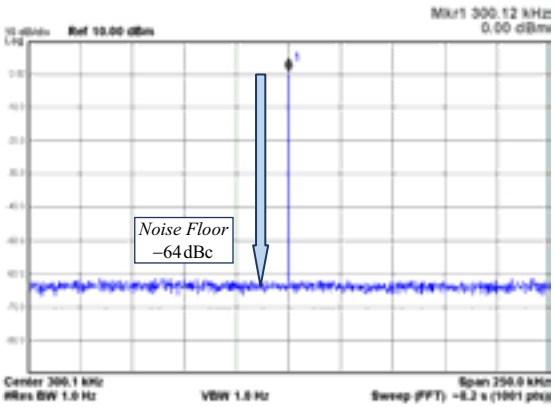

Fig. 3. Output of the switching mixer, with $f_{clk} = 10\,\text{MHz}$, $f_{RF} = 2.7$ MHz, $f_{LO} = 3$ MHz (centered at 300 kHz).

Case 2: The clock frequency of the PDDS is $f_{clk} = 200\,\text{MHz}$ and its synthesized output frequency is set to $f_{LO} = 21.2$ MHz. The RF signal is a sinewave at $f_{RF} \cong 20$ MHz. The mixer's output spectrum $0-50$ MHz is shown in Fig. 4 as well as in Fig. 5 which is centered at the desirable frequency component $f_{LO} - f_{RF}$. The gradient of the noise floor near zero frequency is probably due to the lack of calibration of the spectrum analyzer below 10MHz.

Again, using Eq. (8) we derive that the noise floor level should be about $-77\,\text{dBc}$. The estimate is confirmed by the measurement in Fig. 5 below.

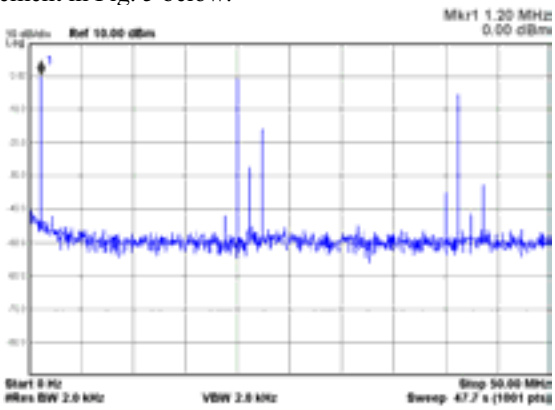

Fig. 4. Output (0-50 MHz) of the switching mixer, with $f_{clk} = 200\,\text{MHz}$, $f_{RF} = 20$ MHz, $f_{LO} = 21.2$ MHz.

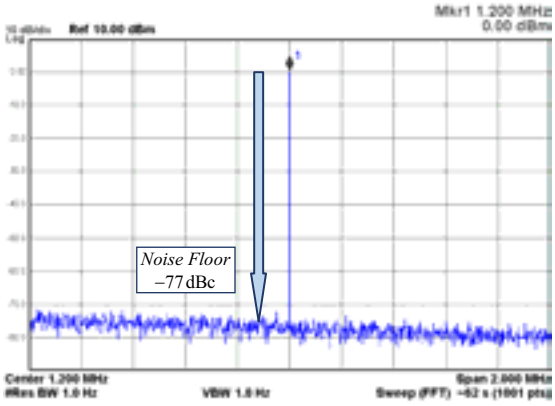

Fig. 5. Output of the switching mixer, with $f_{clk} = 200\,\text{MHz}$, $f_{RF} = 20$ MHz, $f_{LO} = 21.2$ MHz (centered at 1.2 MHz).

V. Conclusions

A switching RF down-converting mixer with an embedded all-digital frequency synthesizer has been proposed and its output spectrum has been derived mathematically. The measurements with our test setup agree with the theory. Future directions include balanced switching architectures and VLSI implementations of this approach in order to illustrate results in higher frequencies.

Abstract— **In this paper, we have made a 433 MHz dual-T SAW oscillator. The oscillator is made of an amplifier, variable gain amplifiers, phase shifters and dual-T SAW resonator circuit. Oscillation frequency can be changed by controlling the gains of variable gain amplifiers. The effective quality factor of the oscillator is enhanced by adjusting phase shifts of phase shifters. Frequency tunable range is about 1,200 ppm, exceeding the limit restricted by used SAW resonators. The effective quality factor of the oscillator is about 30,000, about three times of the unloaded Q of SAW resonators. Phase noise of the oscillator is estimated from the measured spectrum. Above 6 dB improvement of phase noise is obtained at 1kHz offset frequency compared to that of a colpitts oscillator.**

Keywords—SAW resonator; SAW oscillator; VCSO; VCXO; crystal resonator; crystal oscillator; quality factor; dula-T circuit; resonator; oscillator;

I. INTRODUCTION

Quartz crystal and SAW resonators are widely used in high precision voltage controlled oscillators. Recently, demand for wide tunable range and reduction of phase noise has been increasing for VCOs. But the frequency tunable range is limited by the capacitance ration of a crystal resonator or SAW resonator within a few hundred ppm. And the phase noise is limited by the effective quality factor of a VCO. To overcome these restrictions, a variety of piezoelectric material resonators and oscillator circuits have been developed. But, reported results were not sufficient for recent demands. To attain the demand for wide tunable range, a dual-T quartz crystal resonator circuit was proposed [1]. The resonance frequency of a dual-T crystal resonator circuit can be changed a several thousand ppm exceeding the limit determined by the piezoelectric coupling factor of a crystal resonator. We have been studying the properties of the dual-T crystal resonator circuit[2]-[4]. Omori et al. proposed a widely tunable dual-T SAW band elimination filter and its application to wideband UHF VCO[5].

In this paper, we have investigated a dual-T SAW oscillator. At first, we explain the circuit of a dual-T SAW oscillator. Then we show the simulation and measurement results of a dual-T SAW resonator circuit. Finally, we show the characteristics of the dual-T SAW oscillator.

II. DUAL-T SAW OSCILLATOR CIRCUIT

Fig. 1 shows the schematic diagram of a dual-T SAW oscillator circuit. A dual-T SAW resonator circuit is composed of two T circuits. Each T circuit is composed of an inductor and a capacitor in a series arm and a SAW resonator in a shunt arm. Each SAW resonator has different resonance frequency. The inputs of two T circuits are connected to the output terminal of the amplifier via different variable gain amplifier VGA1 and VGA2. The output terminals of two T circuits are connected and fed back to the amplifier. In order to cancel out the parallel capacitance C_0 of a SAW resonator, the values of L_S and C_S are determined so that the resonance frequency of L_S and $C'_S=C_S+C_0$ is approximately equal to the resonance frequency of a SAW resonator. The same value C_S is used for C_{S1} and C_{S2} because the difference of the resonance frequencies of the two series arms is small. The values of L_{S1} and L_{S2} are set to equal value L_S by the same reason. A phase shifter is inserted in series with each T circuit to improve the effective quality factor.

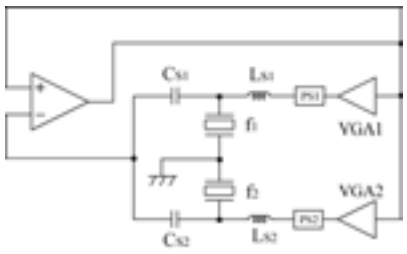

Figure 1 Dual-T SAW oscillator circuit.

III. FREQUENCY RESPONSE OF DUAL-T SAW RESONATOR CIRCUIT

We have made the simulation of frequency response of a dual-T resonator circuit. Table 1 shows the equivalent parameters of SAW resonators. Fig.2 shows the simulated frequency response. The solid line shows the frequency response for 10.6 degree phase shift and the dotted line for 0 degree phase shift. By insertion of phase shift, the notch depth and the slope of phase increase. This result suggests the increase of the effective Q of a dual-T resonator circuit. The notch at 433.59MHz represents the spurious response of lower

* He joined AISIN COMCRUISE Co., Ltd. on 1 April, 2013.

resonance frequency SAW resonator. This response is considered explaining the measured frequency response.

Tabel 1 Equivalent parameters of SAW resonators

Parameters	No.1	No.2
Resonance frequency [MHz]	433.42	433.92
R1 [Ohm]	26.1	16.0
L1 [uH]	101	61.6
C1 [fF]	1.32	2.18
C0 [pF]	2.3	2.2
Q	10600	10500

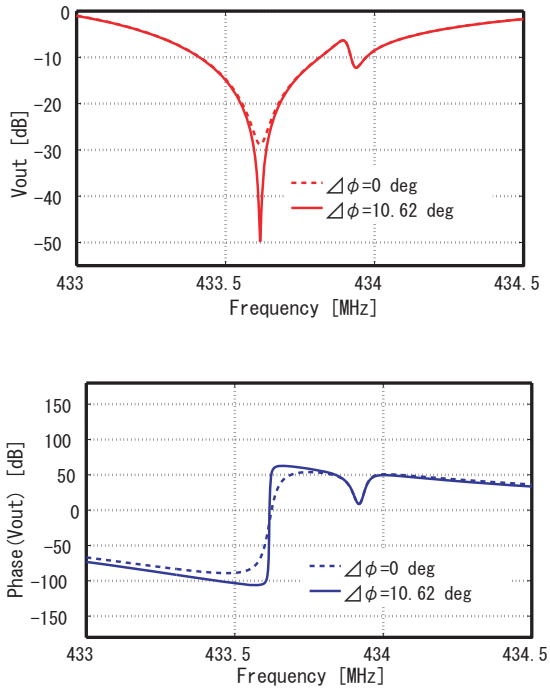

Figure 2. Frequency response of dual-T SAW resonator circuit. (simulation)

Fig.3 shows the measured frequency response. The solid line shows the frequency response for 10 degree phase shift and the dotted line for 0 degree phase shift. The measured result is similar to the simulation result.

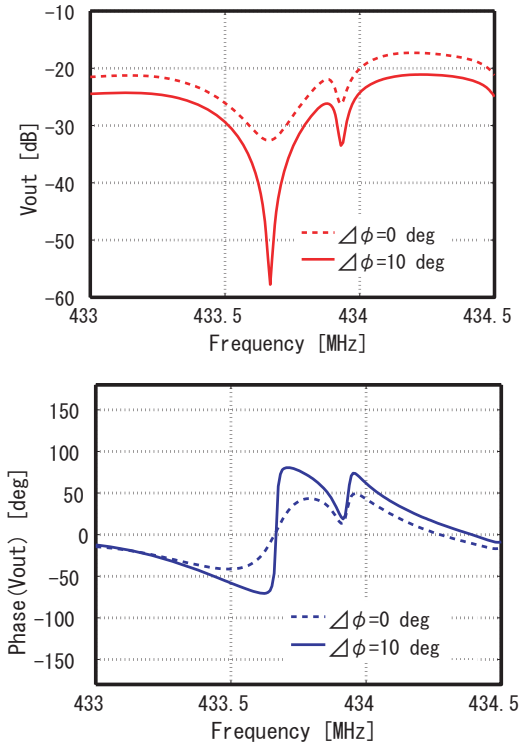

Figure3. Frequency response of Dual-T SAW resonator circuit. (measurement)

IV. OSCILLATOR CHARACTERISTICS

Fig. 4 shows the simulated relation between oscillation frequeny and control voltage of variable gain amplifier. This result suggests about 1200 ppm frequency variation range.

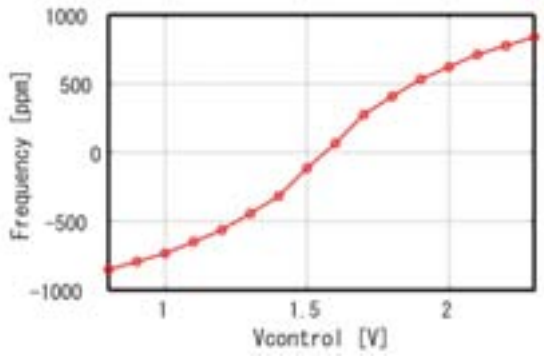

Figure 4. Relation between oscillation frequency and control voltage.

Then, we measured the characteristics of the oscillator. Fig. 5 shows the measured open loop gain of the oscillator when the oscillation frequency is set to be the center of tunable range. Effective Q values evaluated from both the voltage and phase transfer characteristics are about 33,000. These values are around three times of unloaded Q of SAW resonators.

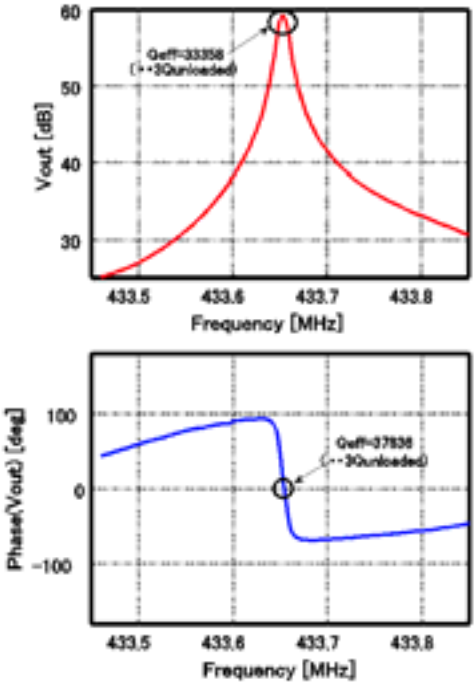

Figure 5. Open loop gain.

Fig. 6 shows the measured spectrum of the output voltage. We estimated the phase noise from the measured spectrum. Fig. 7 is the phase noise at 1kHz offset frequency. The phase noise at the frequency 600ppm higher from the center frequency is -92 [dBc/Hz] The phase noise at the center frequency is -97 [dBc/Hz]. About 6 dB improvement is observed. This value suggests that the effective Q of the oscillator becomes two times of the unloaded Q of a SAW resonator. From this result, we think the Q enhancement method is effective. The evaluated effective Q is small compared to that of the value evaluated from the measured open loop gain of the oscillator. The reason of this difference is the limit of our measurement system. In Fig.7, we shows the measured phase noise of the coplitts oscillator made using the same SAW resonator, for comparison. The phase noise of the colpitts oscillator is almost same with that of the dual-T oscillator at the upper end of frequency tunable range. This means that the effective Q of the dual-T oscillator is almost equal to that of the colpitts oscillator. This fact is reasonable because the dual-T resonator behaves as the single resonator at the upper or lower end of the frequency tunable range.

V. SUMMARY

In this paper, we investigated a dual-T SAW oscillator. It was shown that the frequency tunable range beyond the resonator limited value can be attained. Effective Q enhancement is observed from both the frequency response of the dual-T resonator circuit and the open loop gain of the oscillator. The phase noise estimated from measured spectrum supported the effective Q enhancement effect.

Tracking DDS in Time and Frequency Metrology

Claudio E. Calosso

***Abstract*— It is possible to implement a real-time phasemeter/frequencymeter, by simply using a Direct Digital Synthesizer (DDS) in a Phase Locked Loop. Data written into the DDS to track the input is the output of this instrument. This scheme is compact, low noise, cheap, wide input range, real time and can be used in many applications both in RF and in Optical Frequency metrology.**

Keywords— aliasing; digital frequency divider; phase noise; white noise; flicker

I. INTRODUCTION

The Phase-Locked Loop (PLL) in electronics was introduced in early 1930s to surpass the superheterodyne technique in radio receiver [1]. Since then, its diffusion has been very wide: in telecommunication, in digital electronics, in motor controls… and also in time and frequency: indirect frequency synthesis, clean-up and tracking oscillators, phase noise measurement, but also comb stabilizations, laser locks or even fiber link compensation.

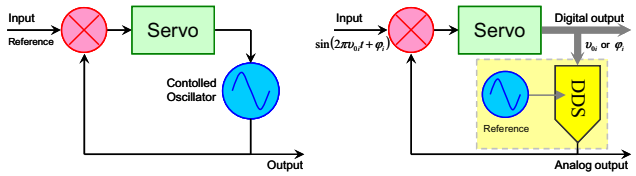
Here I will consider the case where the Voltage Controlled Oscillator (VCO) is replaced with a Direct Digital Synthesizer (DDS) [2] clocked by a good reference. Even if the equations that rule the new scheme and the classical one are the same, the meaning and the use of the tracking DDS is completely different.

II. ANALOG PLL VS TRACKING DDS

In a PLL the phase of the controlled oscillator is compared with the phase of the input and an error signal is generated and fed to a servo. When the loop is closed, the latter applies a correction to the controlled oscillator to null the phase error and consequently to align the output phase to the input one. In this condition, within the loop bandwidth, the output phase is equal to the input one (Fig. 1).

This is true for the analog implementation and for the tracking DDS. The difference is in the noise level of the controlled oscillator with respect to the input. In the classical analog PLL, the phase noise of input is better than the one of the VCO for low Fourier frequency. Usually, the loop bandwidth corresponds to the cross-point of the two spectrums, in order to get the best of both. At the output of the PLL we can find a filtered replica of the input. In this sense, the classical PLL is a filter.

In the Tracking DDS scheme, instead, the controlled oscillator is represented by a DDS clocked by a good quality oscillator i.e. an OCXO, a rubidium, an hydrogen maser… whose phase noise is better than the input one for the entire spectrum. In this case, by closing the loop, the output is degraded to the level of the input phase noise. To do this, within the bandwidth *D*, the servo writes into the DDS a sequence of data that is the digital representation of the input phase. So the Tracking DDS is a phase or frequency meter, depending on which one the loop is closed.



a) b)

Fig. 1. Fig. 1. Classical PLL (a) and Tracking DDS (b) block diagrams

III. IMPLEMENTATION

The implementation of a trancking DDS is very similar to the one of a digital PLL. The difference is that we have to drive a DDS instead of a VCO.

In general a VCO has an imprecise relation between the input voltage and the output frequency, due to the poor medium-long term stability of the oscillator, to the variability of the VCO constant, to the temperature sensitivity… With DDS, instead, the relation between the digital number at the input and the output is well defined. For this reason we can use the data written in the DDS and state that it is the digital representation of the output. In this manner, by putting the DDS in the loop, we can reverse its function and use it to implement an instrument instead of a generator.

In some particular applications, the same can be done with traditional PLL, but only for high Fourier frequency, where the VCO is better than the input. With DDS, this can be extended even for low Fourier frequency and, that is the same, for longer integration time.

Another big difference, is that the only accessible variable in VCO is the frequency. With DDS, we can write both the

phase and the frequency. In many cases, having a direct access to the phase has significant advantages.

An important point is the digital delay of the loop that limits the tracking bandwidth. This has to be considered according to the application requirements. The delay induced by the DDS is of the order of 100 ns that theoretically limits the bandwidth to 2.5 MHz. In addition, we have also to consider the delay induced by the Analog to Digital Converter (ADC) and to the servo. A 1 MHz bandwidth is an achievable goal.

If the application does not require such a bandwidth, it is possible to use serial components, with great reduction of the required PCB area.

The mixer usually does not represent a limit, being a low noise component. The same for the ADC, because it is preceded by an amplifier. The servo can be implemented into and FPGA, with no practical limitation about speed, resolution and functionalities.

IV. Applications

The tracking DDS has plenty of applications both in Radio Frquency (OF) metrology and in Optical Frequency (OF) metrology.

A. RF applications

In the first case, the noise in the input signals is low and the design is devoted to fully exploit the low residual phase noise of the DDS. To get the best, a direct clock is recommended, being not negligible the noise of the internal multiplier. On the opposite, the required tracking bandwidth is low. Infact, typical applications concern the measurement of frequency standards, where the information is for Fourier frequencies below 1 Hz.

By applying the tracking DDS scheme, we can implement high resolution phase/frequency meters with many channels. In this case, the information can be sent to a PC that stores them for further analysis.

By considering that tracking DDS works in real-time, it is possible to think to other applications where this information is used to close a loop. [3] describes an OCXO ensemble, where the measurement of several OCXOs with respect to a local one is processed to steer the local OCXO. This is done by driving a DAC. The same principle can be extended and used to generate a time scale in real-time.

B. OF applications

The optical frequency metrology is an emerging field. A common characteristic is the high noise level of the electronic signals.

The existing electronics was developed to deal with very low noise signals as the ones encountered in RF. It many cases there are problems when this kind of electronics is used in OF domain. By example, in the beat-note between two lasers, the noise power is higher than the signal and a classical frequency meter cannot be directly used, because the input trigger cannot "see" the signal. In this case, the use of a tracking DDS is advantageous, due to the fact that the out-of-bandwidth noise is filtered out the scheme. In this sense, it can be considered as a robust phase/frequency meter.

In case of high level coloured phase noise, the required tracking bandwidth has to be high, in order to be able to track the big amount of noise and to avoid cycle slips.

By considering the real-time facility, it is possible to approach many applications. Here I report two examples. The first one concerns phase data stream that fed to a DDS to drive an Acousto-Optic Modulator. In this case it is possible to implement the complete electronics for a coherent fiber link [4].

The second case is when phase data is sent to a DAC to drive a piezo. This can be used for comb and laser locking.

V. Results

I tested the tracking DDS by measuring a 161.000001 MHz signal generated by a second DDS that shares the same 10 MHz clock. For simplicity, I used the internal multiplier of the DDSs. In case of direct clock, the results are 10 time better.

The tracking bandwidth is 10 kHz, the measurement bandwidth is 100 Hz and the sample-rate after the decimator is 200 Hz.

Fig. 2 reports the overlapping Allan deviation of data saved into the monitoring PC.

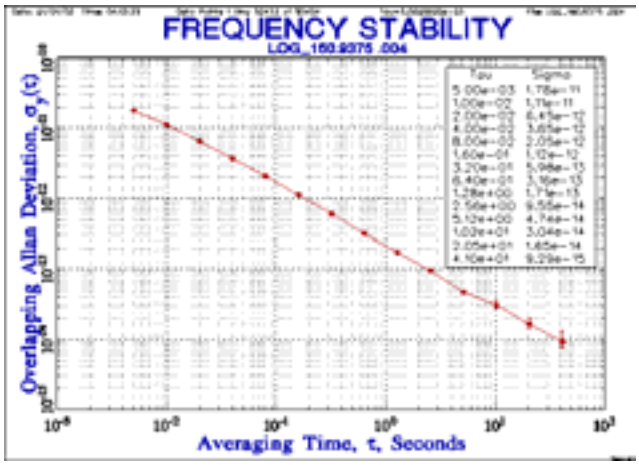


Fig. 2. Fig.2. Overlapping Allan deviation of the tracking DDS residual noise.

The plot is dominated by flicker phase noise. The stability is 2×10^{-13} at 1 s. Even if the goal of the experiment was to demonstrate the principle of the tracking DDS, the residual phase noise is low enough to be used to characterize and active hydrogen maser for measurement time longer than few seconds.

VI. Conclusions

I demonstrated that it is possible to implement a new type of phase/frequency meter by using a DDS in a PLL. The scheme is very flexible and can be used in a wide range of applications, thanks to the digital and real-time nature of the

scheme. The preliminary results are promising and demonstrates that this scheme is suitable to be used both in RF and in Optical Frequency Metrology.

***Abstract*— This paper presents a miniature timing microsystem based on a pair of co-integrated low and high frequency silicon resonators -430kHz or 522kHz and 26MHz respectively- so as to implement a µW-level accurate, low power, temperature-compensated real time clock (RTC) and to generate low noise, low jitter clocks at any frequency between 1-50MHz in a reconfigurable way at less than 10mW power dissipation.**

Keywords - Silicon resonators, TCMO, hybrid integration, CMOS, timing, RTC, programmable clocks, TSV, 3-D integration

I. INTRODUCTION

Over recent years the several decades long quartz-dominated timing industry has been continuously challenged by the introduction of new products or demonstration of prototypes based on MEMS resonators (see [1] for a comprehensive survey). Temperature compensated MEMS oscillators (TCMO) are now rivaling in stability with XTALs despite their much larger temperature sensitivity which mandates accurate high resolution temperature sensors for efficient compensation [2]. On the other hand, they offer interesting miniaturization perspectives with eased packaging done at wafer or chip-scale level using silicon manufacturing lines [3]. This paper address such challenges with the demonstration of co-integrated AlN-actuated silicon resonators used to derive both a low power, low frequency clock to generate a real time clock (RTC) and low jitter programmable clocks between 1-50MHz in a reconfigurable way.

II. CONCEPT AND ARCHITECTURE

A. *Hybrid integration for more than Moore*

Fig. 1 shows a schematic cross-section illustrating the timing microsystem concept that is currently under development. Two packaging approaches are being pursued in parallel. In both, CMOS wafers are used as part of the package to reach extreme miniaturization. In a first scenario, light post-CMOS processing is applied on top of the active circuits to deposit an Al redistribution layer (RDL), Au/Sn electro-plated sealing rings and bumps and Au stoppers. Then, 150µm-thick co-integrated AlN-actuated silicon resonators know good dies (KGD) built over buried cavities in SOI, are soldered directly atop the CMOS wafer thinned down to 100µm using a die to

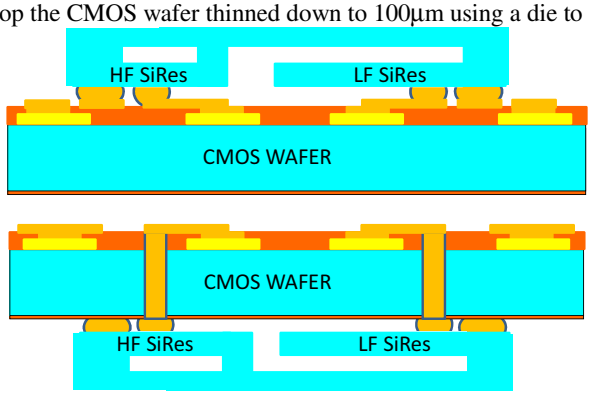

Figure 1. Schematic cross-section of the timing microsystem

wafer attach approach forming a vacuum sealed cavity around the resonators. The resulting housing that is immune to moisture and further nearly eliminates any temperature gradient between the resonator and active circuitry can then merely be wire-bonded on the application board or further overmolded in a DFN plastic package. In a more post-CMOS processing intensive approach, through silicon via (TSV) are first etched and Cu-filled within the CMOS wafer. The silicon resonators are then assembled at the backside of the CMOS wafer after deposition of the appropriate layers. Resulting chip-scale packaged components are then amenable for direct soldering on board using flip-chip bonding. Early validation of the combination of the sealing and TSV technologies applied to the packaging of miniature XTALs in a mostly similar way has been demonstrated in [4].

B. *System architecture*

Fig. 2 shows a detailed block diagram of the timing microsystem. A low frequency 430kHz or 522kHz silicon resonator-based oscillator combined intermittently to a temperature sensitive 10MHz RC oscillator is used to derive a temperature-compensated 32,768Hz clock after fractional

division (÷R) for coarse or long term frequency adjustment (~1ppm over 2s) in a fully digital manner without impacting the oscillator. Short term fine adjustment over a limited frequency range can be obtained using interpolation by switching part of the oscillator loading capacitance in an on/off way with a controllable duty cycle to reach sub-ppm resolution over 1s. Digitally controlling the oscillator between only two frequencies eliminates analog varactors, a DAC and most of the non-linearity inherent to pulling a MO over a large range. Both techniques can advantageously be combined to compensate the temperature sensitivity of the silicon resonator over an arbitrary large temperature range [5]. The 32,768Hz signal then merely drives the real time clock (RTC) sub-circuit implementing clock, calendar, timer and alarm functions. Any of the above clocks as well as 1024Hz and 1Hz ones obtained from the RTC division chain can be made available externally

Besides the RTC, HF clocks re-programmable between 1 to 50MHz via a serial interface can be generated on demand using a 26MHz silicon resonator-based oscillator combined to a fully integrated fractional PLL (divider N, Phase Frequency Detector, Charge Pump and Loop Filter). Up to two independent temperature compensated clocks with low noise and jitter performances, such as required for radio applications or high DR converters are obtained after integer (÷M) or fractional division (÷P) of the LO signal that is compensated by adjusting the N division ratio in a temperature dependent way. Two output pads are available to multiplex the HF clocks.

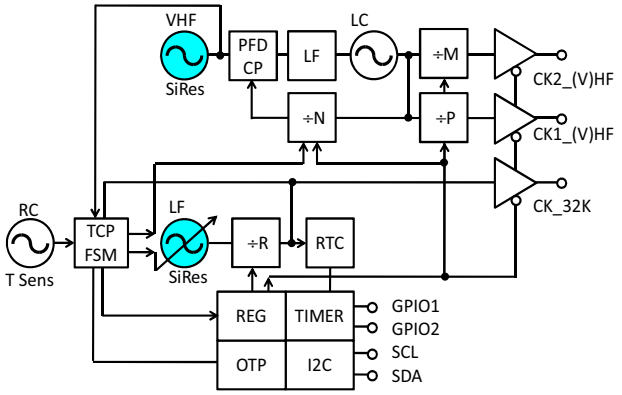

Figure 2. Block diagram of the timing microsystem

III. CHARATERIZATION

A. *Resonators performances*

Table 1 shows the co-integrated silicon resonators electro-mechanical parameters obtained from measurements on a vacuum prober. Moderate Q-factors of 11k and 18k are obtained at 26MHz and 500kHz respectively. The impedance levels of the HF and LF, AlN-actuated resonators reach 130 to 200Ω and 60 to 75kΩ respectively, much closer to the motional resistance of XTAL counterparts compared to that reached with parallel-plate actuated resonators. This is obtained owing to a better coupling coefficient (k^2). The measured resonator FOM (Q times coupling product) are however still worse than that of equivalent quartz XTALs lagging by a factor 5 when taking into account that the LF resonator one is degraded by half by the process dependent large pad capacitance. A further advantage of piezoelectric resonators is that no DC biasing is required allowing standard transconductance XO topologies, such as that presented in [6], to be reused in a straightforward way.

TABLE I. MEASURED CO-INTEGRARED RESONATORS PARAMETERS

High Frequency Resonators

	Rm	C0	f	Q	K2	FOM
HF01	214 Ohm	3,47 pF	27,0 MHz	5600	0,175%	9,8
HF02	134 Ohm	3,45 pF	26,3 MHz	10900	0,149%	16,2

Low Frequency Resonators

	Rm	C0	f	Q	K2	FOM
IN12	59 kOhm	1,64 pF	430,4 kHz	17.2k	0,028%	4,8
IN14	74 kOhm	1,45 pF	522,0 kHz	18.4k	0,024%	4,4

B. *Temperature compensation of the LF SiRes*

Fig. 3 shows a measurement of the uncompensated (blue and red curves spanning -3000ppm over -40 to 85°C) and temperature compensated (green, ±20ppm) LF silicon resonator using both frequency interpolation and variable division for fine (~50ppm range) and coarse adjustments respectively. Calibration was done at three temperature points by measuring the MO frequencies (f_H and f_L) at two loading capacitance values and reading via the serial interface the output of a counter clocked by the 10MHz highly temperature-sensitive, mostly linear RC oscillator and enabled during a given number of the MO periods. As the RC oscillator temperature sensitivity is 100x larger than that of the MO, a digital representation of the system temperature is obtained in a very simple way without requiring complex and energy/area consuming analog to digital conversion. Polynomial coefficients of the corresponding function $f_{MO}(f_{RC})$ are then stored in the non-volatile one time programmable (OTP) memory embedded on the ASIC. During operation, the on-chip temperature compensation state machine then periodically turns on the RC oscillator to get a new temperature measurement, calculates and updates the compensation to be applied to the MO and divider using the stored coefficients. The average current consumption in this mode is 1µA. The HF MO is temperature compensated through the frequency synthesizer by adjusting the N divider value. Up to 4^{th} order compensation using a 5 temperature trim can be applied to both the RTC and HF clocks.

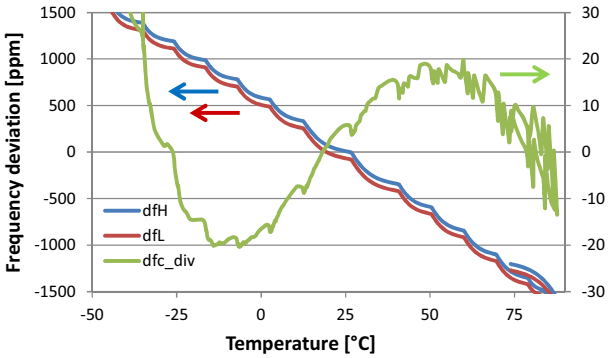

Figure 3. LF (TC)MO temperature stability measurements

C. *Clock generation with HF SiRes*

Fig.4 shows a measurement of the phase noise of the HF clock generation circuit. The 26.36MHz MO clock is plotted together with the LC VCO divided clock exhibiting the characteristic Δσ modulator induced quantization noise shaping towards higher frequencies. The LC PLL is locked via the fractional-N divider at 2.16GHz from which a low noise 48MHz clock is obtained by integer division by M=45. Apart in the vicinity of the loop filter bandwidth (200-300kHz), the generated clock phase noise tracks that of the reference with a scaling of 20 log(N/M) as expected.

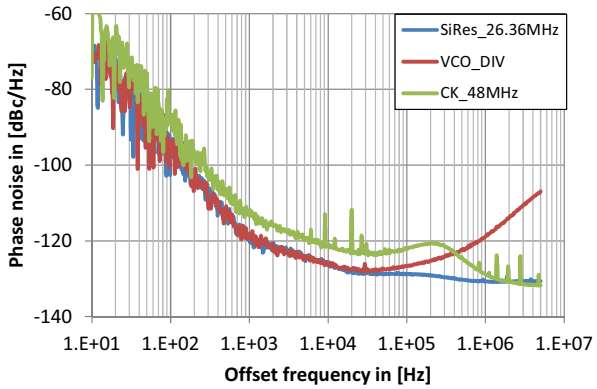

Figure 4. Phase noise plot of the HF clock generation circuit

Fig.5 shows a measurement of thepower consumption breakdown in the clock generation mode when a 48MHz clock is generated. The current consumption is 5.6mA at 1.6V (9mW) shared quite evenly between the 2.16GHz LO, the two N and M dividers including the PFD/CP, ΔΣ modulator and 26MHz MO reference and the on-chip buffer driving an on-board 50Ω driver.

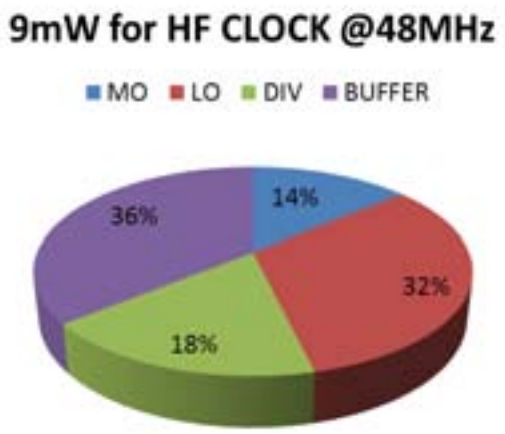

Figure 5. Power consumption breakdown of the HF clock generation circuit

D. *Components and die photograph*

Fig. 6 shows a picture of the LF and HF silicon resonators co-integrated on a die measuring 660x1480μm^2 together with an ASIC die photo highlighting its floor plan (size is 1100x1500μm^2). The ASIC has been integrated in a 180nm 1P6M CMOS generic technology first using MPW service and eventually using a MLM approach to allow post-CMOS processing. Resonators are also being packaged at wafer scale in a housing compliant with direct assembly on the ASIC using thermo-compression on Au stud-bumps. As such tasks are still ongoing, early system level characterization was performed using unpackaged HF resonators and more pressure sensitive LF resonators sealed in vacuum in standard ceramic packages.

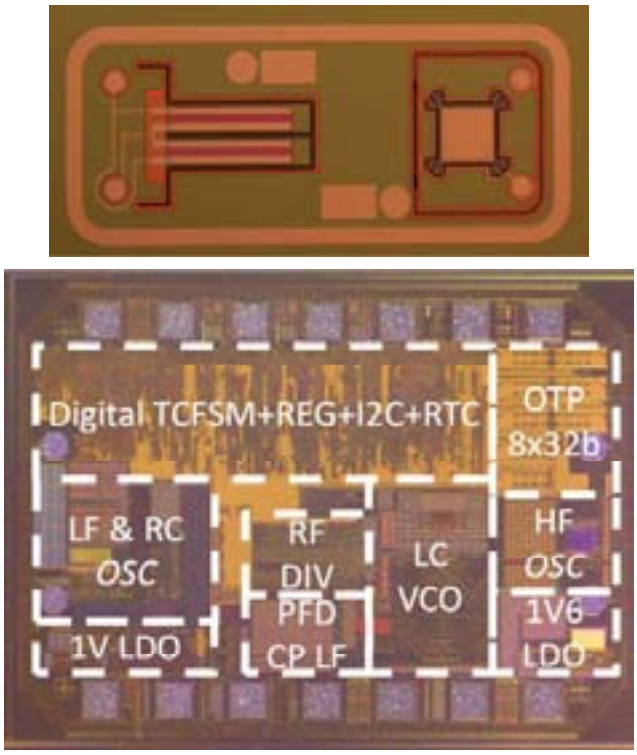

Figure 6. Die photographs at same scale

IV. Summary and Conclusions

A 1.5x1.1mm^2 timing microsystem relying on two co-integrated 430kHz and 26MHz AlN-actuated silicon resonators and capable of generating both a 1µW-level RTC with calendar and alarm functions and on-demand low jitter reprogrammable clocks between 1 to 50MHz at a power dissipation below 10mW was presented. A direct KGD to CMOS wafer packaging approach minimizing the overall microsystem thickness to 250µm but that is still under development was introduced and early system level measurements using standalone packaged resonators were given demonstrating ±20ppm accuracy after a trim at three temperatures. Better stability performances are expected using a 5-point trim and intimate contact between the resonators and the ASIC temperature sensor once the final system is implemented.

A Comparison of FBAR Oscillators with Standard Resonators and Stress Relieved Resonators

R. Ruby[1], S. Sridaran[1], S. Ortiz[1], K.G. Oppermann[2]
[1]Avago Technologies, San Jose, CA
[2]Avago Technologies, Munich, DE

Abstract— **One of the issues facing many types of oscillators is the transference of stress from the external world through the die to the resonator. Typically, resonators are clamped at more than one location. Integrated FBAR oscillators (referred to as FMOS[1,2]), uses a resonator that is clamped on all sides and integrated into an all-silicon, chip-scale package with integrated circuits. For filter applications, this is quite reasonable, but, for oscillators this may not be acceptable. Mounting FBAR oscillators (epoxy die attach, over-molding and soldering) onto a customer board exposes the FBAR oscillator to stresses that occur during the assembly, plus additional stresses that occur during the wear and tear (as well as temperature induced stresses) that the customer board experiences. Although intuitively, applied stress will change frequency of the resonator, this is hard to quantify. This paper does a first cut model of the stresses and then matches that to the changes in the measured frequency. Next, we discuss several designs that help mitigate the effect of external stresses on the resonator.**

I. INTRODUCTION

We are attempting to make production-worthy, commercially viable chip-scale oscillators and VCOs. The all-silicon packaged die uses wafer-level packaging techniques to create both a hermetic package for the resonator and circuit as well as hermetic vias connecting the resonator/circuit to outside pads. We refer to this integrated platform of circuit and resonator, FMOS (FBAR, Metal Oxide and Silicon). And if successful, will be one of the smallest commercially available products of their kind on the market.

The first generation all-silicon package consists of 6 pads on the top surface (Fig. 1) with 6 vias to a resonator (FBAR) located in the base wafer and a IC in the lid wafer as shown in Fig. 2.

One concern for this device as used for XO applications (precision timing) would be any change in frequency as a function of customer assembly. In crystal oscillators, the crystal is attached to the IC via conductive silicone connections that provide both electrical contact and compliance and isolation to any external stresses applied to the package housing the IC and crystal. In Fig. 2, it can be seen that the FBAR resonator is attached on all sides. For any external stress applied to the package (for example when it is soldered to a pcb during customer assembly into a module), the frequency will shift.

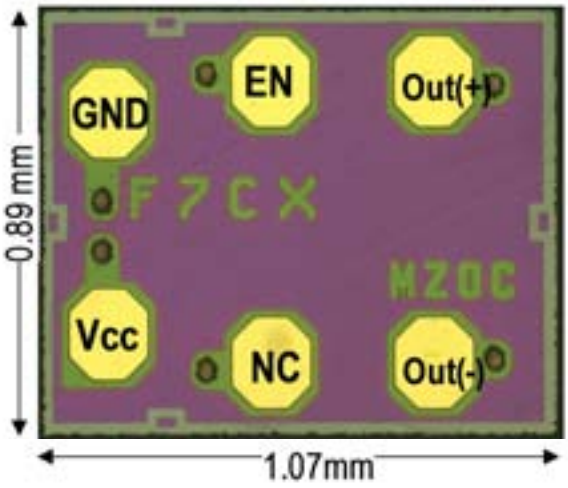

Fig.1; Optical micrograph of the top view of a FMOS die. The copper pads are labeled. Besides a differential output, the die has an enable pin, a Vcc pin and Ground pin. The sixth pin can be used in a VCO as a tuning pin.

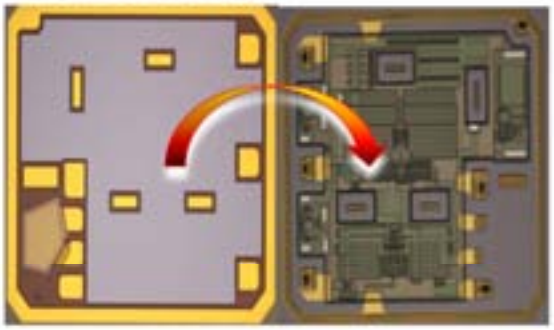

Fig.2; Optical micrograph of the base wafer containing the FBAR resonator and the lid wafer containing the circuitry.

Figure 3a shows a COMSOL model of our device. Typical values for the geometries, material constants were assumed. Figure 3b shows the simulated stresses across the resonator shown in Figure 2. The stresses shown in Figure 3b are created by simulating a net 125°C change in temperature of a FMOS die (as shown in Fig 1) attached to a pcb (via a standard solder mount). The die in this simulation assumes an

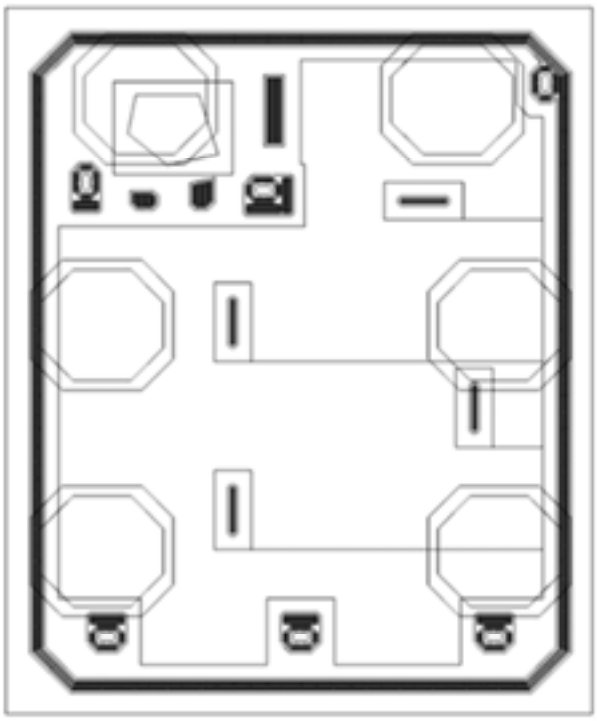

Fig.3a; COMSOL layout used to simulate in-plane forces on the resonator (upper right – apodized shape polygon)

over mold as well as an under fill. Although both over mold and under fill affect the values of the amount of stress, it is important to note that there is a stress. Associated with this stress, one can expect both a strain on the resonator and a frequency shift.

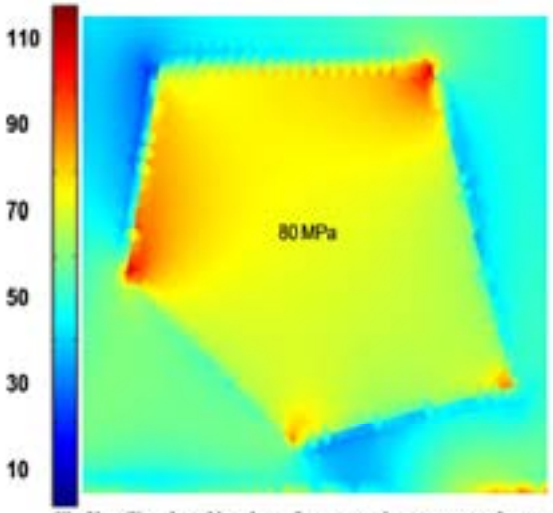

Fig.3b; Simulated in-plane forces on the resonator due to externally applied stresses when a die is soldered to a pcb.

II. DISCUSSIONS

To quantify the amount of frequency shift one might expect from externally applied in-plane stress, the following experiment was done. A wafer consisting of thousands of oscillators on a 6" wafer is mounted on a vacuum chuck and frequencies of individual oscillators are measured. The wafer is removed and then re-mounted on the vacuum chuck and the same dies are measured again. From this, we determine a base line of the spread and median of the ensemble of measured oscillators. Next, the wafer was removed and then placed on top of a thin (13 um) Mylar substrate 57 mm in diameter – all on the same vacuum chuck. The Mylar spacer lies inside the vacuum rings of the chuck and thus the wafer is pulled down under vacuum, the wafer is held fast to the chuck –with a slight bending of the wafer due to the Mylar spacer. This bending approximates real life stress applied by external forces.

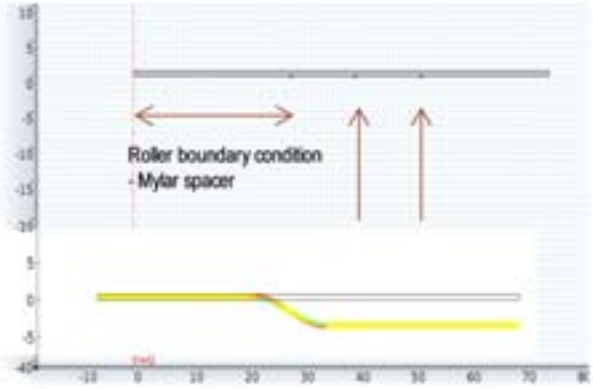

Fig.4; Drawing of the wafer (75 mm rad.), location of the edge of the Mylar spacer (27.5 mm rad.) and the location of the two vacuum rings on the vacuum chuck. Below is a COMSOL simulation of the bending moments.

Figure 4 shows the COMSOL model of the stresses on the silicon wafer as it bends due to the Mylar spacer. A simplifying assumption was made that the silicon was solid and that the resonator, ~600 to 680 um above the bottom edge and surrounded by an air gap is seeing a similar stress as the hypothetical device surrounded by silicon. Because the lid wafer is only 80 to 100 um thick, we believe that the neutral plane lies well below the resonator. Hence, as the wafer bends down at the Mylar edge, the resonator is seeing a tensile stress and when the wafer bends up at the contact point of the vacuum chuck, the resonator is in compression.

Figure 5a is a plot of the calculated in-plane stresses on individual resonators as a function of radius on a wafer. Figure 5b is a plot of the change in frequency (δ f) in ppm as a function of radius. From this, we conclude that we are getting about 0.8 ppm/MPa shift in frequency due to in-plane stresses. From COMSOL modeling of the stresses applied to the resonator in Fig. 3b, one can see that a 125 ^{o}C shift in temperature can cause up to about ~80 MPa of in-plane stress. This is due to the fact that the pcb will grow (shrink) faster than the silicon die.

When a die is soldered down to a pcb substrate, the part sits on a liquidus of solder (eutectic between 205 ^{o}C and 220 ^{o}C) at the ~230 ^{o}C maximum IR reflow temperature. As the die/board cool down, the solder passes its eutectic and solidifies. After which, further cooling down to room temperature will create stresses due to the larger pcb thermal coefficient of expansion (relative to the silicon). One can easily argue that the resonator modeled in Fig. 3a will see up to 125 MPa of external stress. Thus, one might expect frequency shifts on the order of 100 ppm. As a sanity check,

serialized oscillators whose frequencies were measured before and after bonding to a pcb showed a median 140 ppm shift.

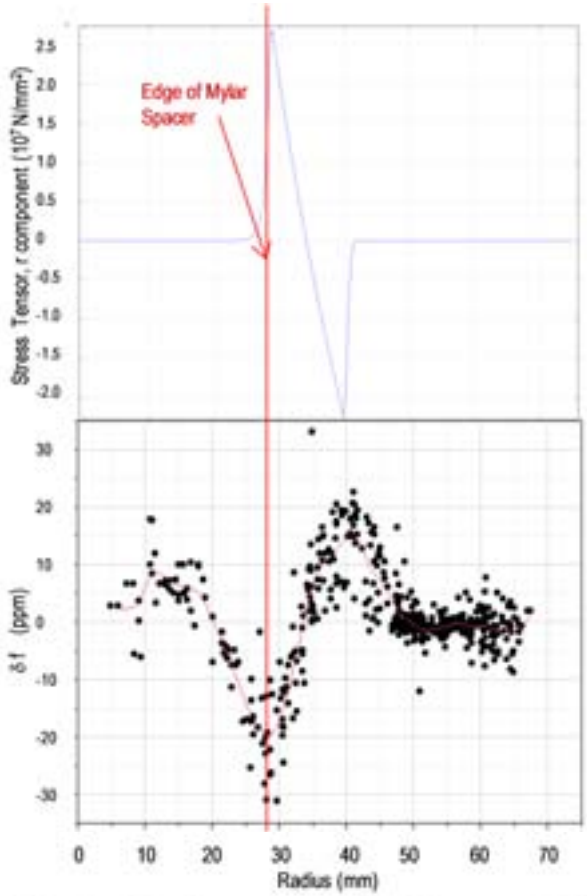

Fig.5a; The simulated stress across a wafer as it is traverses a Mylar spacer. Fig. 5b; The measured change in oscillators across the wafer as plotted on a radius (~1000 oscillators)

III. STRESS RELIEVED RESONATORS

Figure 6a is an SEM micrograph taken of a novel FBAR device on a pedestal [3]. The electrical leads to and from the resonator go under the resonator (in the cavity formed under the active area of the resonator) and up the sides of the pedestal. The actual resonator active area forms a disc around the pedestal and hence, no part of the acoustically active area 'sees' the pedestal. Figure 6b highlights an important modification of this device. With the pedestal centered with respect to the FBAR disc, lateral modes based on Bessel type eigen modes can and will create sub resonances. These resonances are problematic for both filters and oscillators. In the latter case, these modes can 'walk' thru the main resonance due to changes in temperature (the main, 'desired' mode having one temperature coefficient of frequency and the parasitic mode have a different coefficient). This issue is dealt with by apodizing the resonator [4]. In the case of a single mount with nominal radial symmetry, the resonator is laid out to be off-center with respect to the pedestal. Figure 7 shows two superimposed, measured Q-circles of the devices shown in Fig. 6a and 6b.

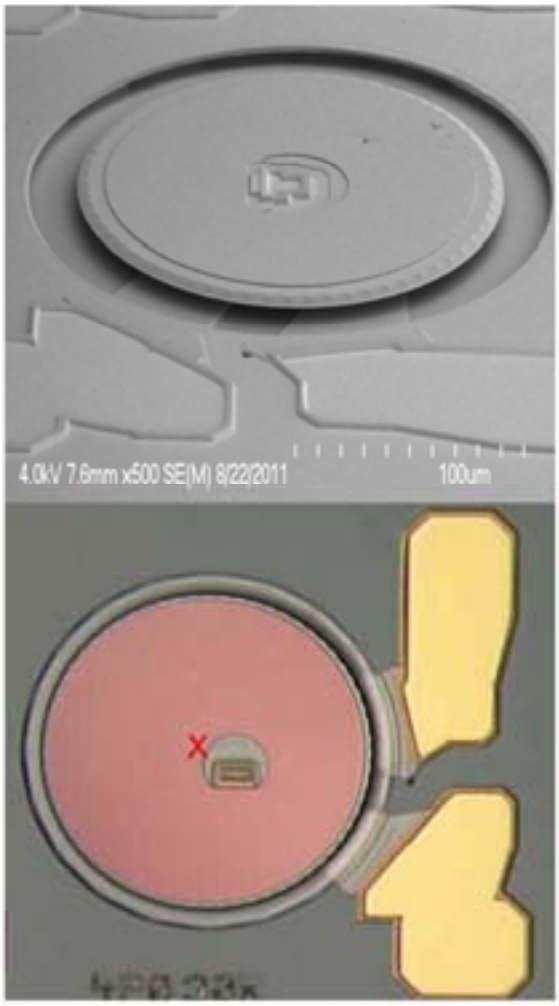

Fig.6a; SEM Micrograph of a center mounted resonator. Here the pedestal is in the center of the disk. Fig. 6b; an Optical micrograph of a similar resonator, but here, the pedestal is offset from the center (the center of the resonator is marked with an X).

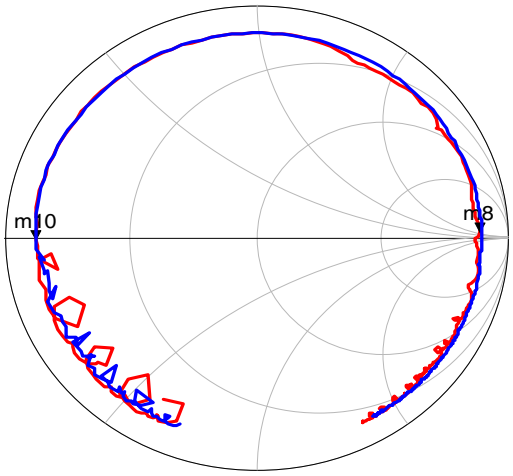

Fig.7; Measured Q-circles of the two kinds of resonators shown in Fig. 6. The Red curve highlights the issues of lateral modes when using a symmetrical device and the blue curve shows the effect of apodization by moving the pedestal off-center.

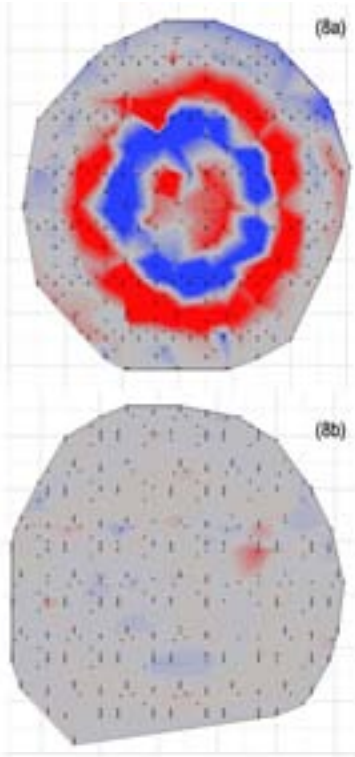

Fig.8; Wafer maps of the change in oscillator frequency as measured before and after a Mylar spacer is placed under the center of the wafer. There is roughly an equal distribution of non-stress relieved devices (8a), to stress relieved devices described in Fig. 6 (8b). The color coding matches Fig 5b, blue – -20 ppm, red – +20 ppm.

The major point of this new design for an FBAR resonator is that any external forces applied to the pedestal are not significantly applied to the resonator. Hence, there are no frequency offsets due to externally applied forces. Highlighting this point; Figure 8 shows wafer maps of the frequency change of two kinds of oscillators distributed over a wafer. Oscillators using the POR resonator shown in Fig 3b are plotted in Fig. 8a. Oscillator using stress released resonators shown in Fig. 6 are plotted in Fig 8b. Both oscillators use the same IC circuitry in the lid. In the former case, one can clearly see the effect of the Mylar spacing under those POR resonators, while in the latter case; there is no evidence of the Mylar spacer.

IV. Conclusion

One issue, the sign of the frequency change vs. applied external stress, remains unresolved. From simple 'string' theory (as in a violin string); it is intuitive that as one increases the tension of the string, the frequency goes up with the square root of the increased stress. Instead, we see that the frequency goes down with frequency and up with added compression. We are now investigating the root cause of this. Secondly, we see differing amounts of frequency shift as a function of a fixed stress. We attribute this to better die design and some confounding effects due to resonators that are bowed due to internal residual stress.

***Abstract*— We proposes a method for measuring the transient oscillation frequency observed when Coherent Population Trapping is excited by means of optical pumping radiation fields whose frequency difference is detuned slightly from the ground state hyperfine frequency of the atom used. Using narrow-band simulation filter and phase matching techniques this measuring method can provides a measurement precision of about 0.5Hz. Based on this reading accuracy the DCPT atomic clocks frequency instability can be better than 5e-11 (t=100s) and tend to more stable at longer integration time. According to our experimental results, we demonstrate that a DCPT atomic frequency standard could give good short and long term frequency stability.**

During the last decade, coherent population trapping (CPT) has been widely used in miniaturized atomic clocks. And in traditional CPT atomic clocks, a circuit loop is applied to lock the microwave frequency to the ground state hyperfine splitting. This servo circuit influences the volume and brings in instability to the clock system. In 2009, our team proposed an atomic clock based on the transient detuned CPT phenomenon, which does not require a phase-locking-loop to lock the microwave frequency to the hyperfine splitting frequency, and enables us to directly read the two ground states' transition frequency. In this design, CPT is excited by two optical pumping fields and their frequency difference is detuned slightly from the ground state hyperfine splitting of 85Rb. The pumping optical fields are created by modulating the frequency of a laser. After the laser passes through the rubidium atom cell, a oscillation signal will be detected whose frequency is equal to the detuning frequency, as is shown in Fig.1. We call it transient oscillation of detuned coherent population trapping (DCPT). The DCPT atomic clocks' output standard frequency can be achieved by directly adding/subtracting the transient oscillation frequency of DCPT to/from the microwave frequency used for modulating the pumping laser. Meanwhile, this scheme eliminates the PLL that locks the microwave frequency to the ground state hyperfine splitting in traditional atomic clocks. And in this scheme, the stability of the atomic clock is mainly limited by measurement precision of the detuning frequency.

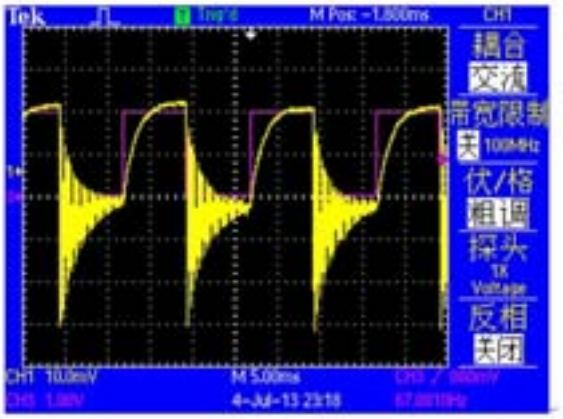

Fig. 1. The yellow line is the transient oscillation signal, and the blue line is the modulation signal of RF.

In this paper we proposed a method for measuring the transient oscillation frequency, as well as an improved design for the DCPT atomic clock. According to our experiment results, this method provided a measurement precision better than 1Hz, and the expected frequency instability will be in the order of 10-10-10-11. We have also experimentally proven the validity of the theoretical result using this more precise method. With its advantages in digits, signal analysis and system simplification, there are great potentials in its further integration and miniaturization as well.

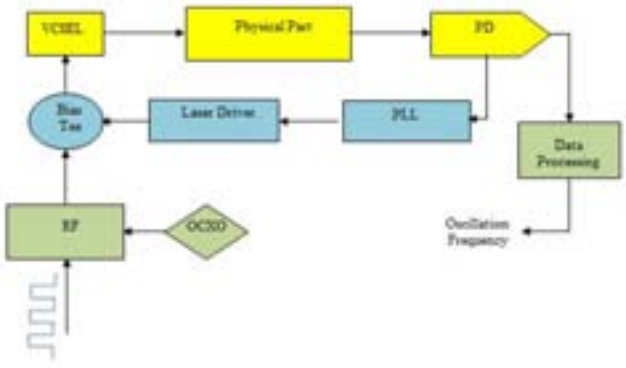

Fig. 2. Experimental setup of the scheme. The data processing module is used to extract the oscillation signal.

Fig.2 shows our experimental system of this atomic clock. The microwave signal was generated by a frequency synthesizer, and modulated by a 60Hz square wave with the lower and higher levels corresponding to the frequency of the dark resonance and a positive 1.3KHz detuning, respectively. According to the linewidth data in our experiment, the detuning can be set within the range of 1K Hz to 10K Hz. Fig.3 shows that the oscillation occurs at the edge of square wave, and it was observed in the oscilloscope that was connected to PD.

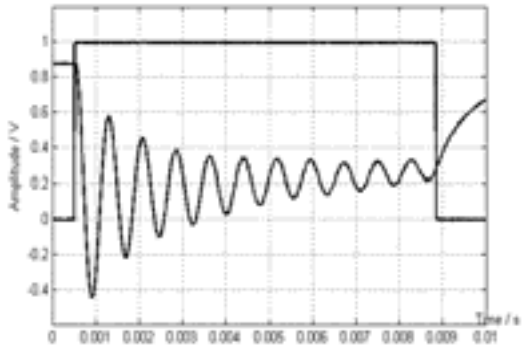

Fig. 3. Optical signal modulated by the square wave.

In the data processing part, the DCPT oscillation frequency is extracted by a filter which is a simulation filter generated by MATLAB tools. After the FFT transformation, we will get the spectrum of the oscillation signal, as is shown in Fig.4. As there exists a picket fence effect in the Fourier transform from the time domain to the frequency domain, we use the narrow-band simulation filter and scan the period of the square wave simultaneously, when 1/2 of the period is equal to integer multiple of the DCPT oscillation period, the spectral line intensity of oscillation frequency will be the maximum, as is shown in Fig.5.

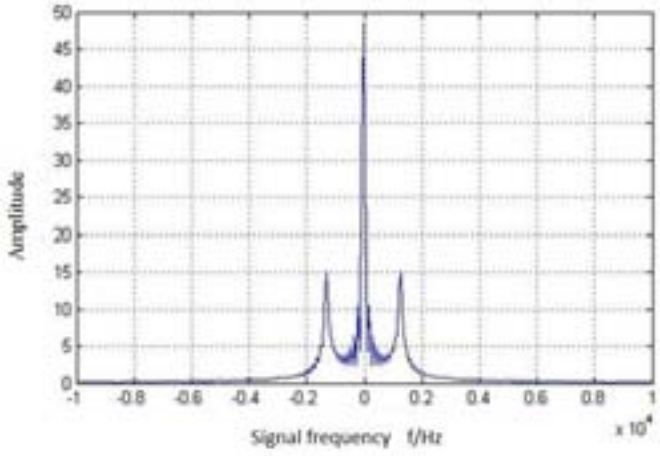

Fig. 4. The light spectrum of the transient oscillation

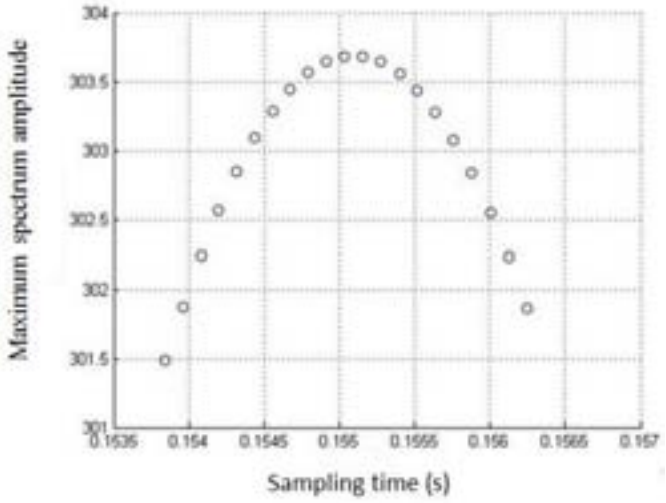

Fig. 5. We scan the period of the square wave to get the largest spectrum amplitude.

Using this method, the spectrum leakage can be decreased and the oscillation frequency can be extracted accurately.

Since the oscillating frequency equals the detuning frequency theoretically, we can obtain the output standard frequency by adding or subtracting the oscillation frequency and microwave frequency without an extra frequency-locking-loop.

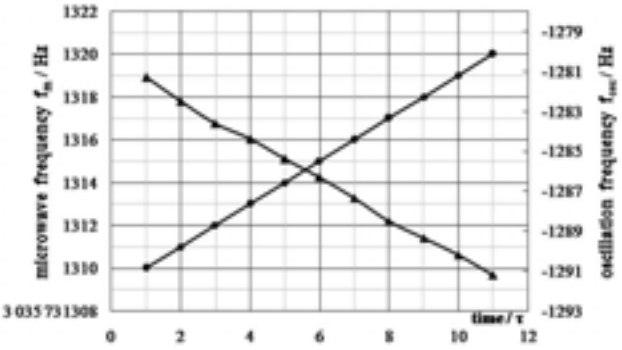

Fig. 6. Ascending microwave frequency at a sample rate of 1Hz/s is marked with dots, and correspondingly changing oscillating frequency is represented by a series of triangles. τ is the time interval of sampling, which was 20 seconds here. In our experiment, $f_m > f_h$, so we added a minus sign in front of f_{osc}.

Based on the theories and analysis demonstrated above, we used the experimental setup shown in Fig. 1 to measure the changing DCPT oscillating frequency, following the shift of fm. We manually changed the microwave frequency fm every 20 seconds, and measured corresponding DCPT oscillating frequency. The results are shown in Fig.6.

From Fig.6, it is observed that the DCPT oscillating frequency fosc and microwave frequency fm changed correspondingly by same magnitude, but in opposite directions. This result concurs with the theory that the oscillation frequency fosc changes as a consequence of the detuning frequency fd. Compared to the related prior research, the

Identify applicable sponsor/s here. If no sponsors, delete this text box (*sponsors*).

precision was greatly improved, which makes it more probable to achieve this atomic clock with an average stability(a standard stability). Using the fm and fosc data from Fig. 3, we can achieve a stable output frequency, as seen in Fig. 7.

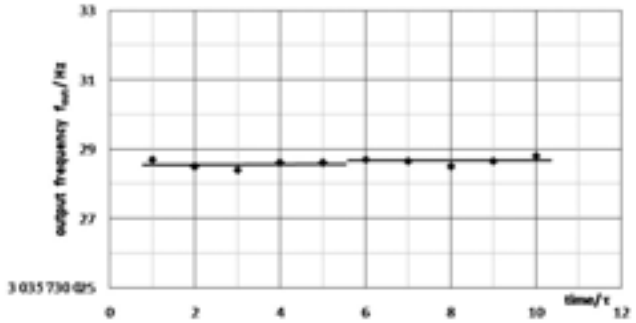

Fig.7. Output frequency results. Scattered dots and the black line jointed by three square dots indicate corresponding results before and after the averaging process, respectively.

In Fig. 6, the scattering data represent the output standard frequency fout derived by subtracting measured oscillation frequency fosc from microwave frequency fm,. The precision of the output frequency instability was about 0.5Hz, leading to a short-term instability of around 2×10-10.

Since the measurement error of fosc was mainly caused by random noise, in order to further improve the precision, we averaged every 5 data and increased the averaging time to 100 seconds. This averaging result is demonstrated by two lines in Fig. 6, which represent the numerical result of averaging the first 5 data and the following 5 data respectively. It is shown that the measurement precision was increased to about 0.2Hz, and the long term stability was about 5×10-11, which also suggest the possibility to be better. In addition, here the sampling rate was limited by the computing rate.

Therefore, if the performance index of data processing device is increased and the averaging method is implemented, the short-term and long-term stability will be further improved. In our experimental setup, the frequency synthesizer as the microwave source has a hundred-second-frequency instability better than 5×10-11, which makes our results reasonable. In addition, properly chosen relative facilities, such as a steadier square wave generator, can be used to optimize the precision and stability as well.

In comparison with traditional atomic clocks, this DCPT atomic clock makes it unnecessary to use the circuit for locking the microwave frequency, which eliminates the instability and loose locking probability brought in by the phase locking loop, especially when the scheme is used in harsh environments. And the transient signal has an amplitude 3 to 4 times that of the CPT signal, which further benefits observation and analysis. In addition, this data processing section can be easily digitalized and integrated. As a result, this scheme has great potential in the design and manufacture of miniature atomic clocks.

In conclusion, we have proposed and implemented a method which allows us to obtain the transient oscillating frequency with a relatively high stability for the DCPT atomic clock, and we have experimentally proven that the transient oscillation frequency is equal to the detuning frequency on the scale of 0.2Hz. We have supplemented our prior research with increased precision which further indicates the possibility to achieve a DCPT atomic clock with good short-term and long-term stability. This DCPT atomic clock also provides great advantages to both integration and miniaturization, which make it a potential scheme for CSACs in the future.

Microwave Cavity Design for an Optically-Pumped Rubidium Atomic Beam Clock

Chang Liu, Yanhui Wang
Institute of Quantum Electronics,
School of Electronics Engineering and Computer Science, Peking University
Beijing, China
wangyanhui@pku.edu.cn

Abstract—**We design a microwave cavity for our developing compact optically-pumped rubidium beam frequency standard. For clock transition of ^{87}Rb (F=2, m_F=0 to F=1, m_F=0), the central frequency is 6.8347GHz. The cavity made of WR90 waveguide in previous cesium beam clocks no longer works. In our design, we follow the method of Ramsey-type cavity in cesium beam clocks but change the cross section of waveguide. Some related modifications have to be made such as the lengths of waveguide. Unfortunately one is not likely to obtain analytical results on these values. Finite element analysis software helps to numerically solve the electromagnetic field based on arbitrary boundary conditions. Therefore, the resonant frequency and other characters of a cavity are computable when its dimensions are given. As a result, suitable dimensions can be determined to get a resonant frequency of 6.8347GHz. Considering other effects, e.g. end-to-end phase difference, more optimizations and requirements are proposed.**

Keywords-rubidium beam clock; microwave cavity; resonant frequency; frequency stability

I. INTRODUCTION

A. Optically-pumped Beam Clocks

Manufactured atomic beam clocks, especially cesium clocks, free of collision frequency shift and first-order Doppler shift, have good performance on long-term stability. The restrictions of beam clock's short-term stability lie in the limited time period of atom-microwave interaction and the low utilization of atoms. The former is solved by the use of cold atoms, i.e. in fountain clocks, but the system becomes so complicate that the fountain clocks is more likely to operate in laboratories. On the other hand, optical pumping and detection, which increase prominently the utilization rate of atoms, are quite suitable for a beam device, where the pumping, microwave interrogation and detection are separate in space, making the disturbance between the interactions relatively small. However, unexpected effects, such as the light shift, still exist, of which extra care should be taken. Research on compact optically-pumped cesium and rubidium clocks are reported [1-3].

We are working on an optically-pumped rubidium beam clock, schematic of which is shown in Fig.1. One problem we are facing is the long-term working of laser diodes. A method using rubidium lamps instead of laser diodes was proposed [4]. The advantage of lamps is their stability while the shortcomings are the wide span in spectrum and weak intensity, which influence the pumping and detection rate. To make a comparison, we will test both laser diodes and lamps as light sources in experiment.

B. Microwave Cavity in Atomic Frequency Standards

A microwave cavity is a vacuum space surrounded by conducting boundaries. According to Maxwell equations, the modes of standing electromagnetic field inside are fixed when boundary condition is given. Most of the time, the fundamental mode is used. The characters of a cavity are described by its resonant frequency and quality value. Basic theories about microwave cavity can be found in many related materials such as [5].

The microwave cavity provides the environment for atom-microwave interaction, because in fundamental modes, direction, amplitude and phase of magnetic field are all uniform along particular lines in the cavity, which are just suitable trajectories for atoms to traverse the cavity.

In beam frequency standards, a long atom-microwave interaction time indicates a narrow line width, which improves the short-term stability. The atoms' velocity distribution is dependent on the oven temperature, whose variation's range is quite little, less than 10% during experiment. Hence, the line width is mainly determined by the length of the cavity, measured along the atoms' trajectory. However, the cavity is not as long as good, for the uniform of field is hard to ensure if the cavity is too large. Moreover, the total size of a commercial clock is usually limited.

The separated field method, proposed by N. F. Ramsey [6], adopts a U-shaped cavity, which is traversed twice, at the ends, by atoms, as seen in Fig.1. For atoms, there is a long drift distance between the two traversing. The Ramsey line width is inversely proportional to this microwave-free distance and independent on the traversing distance. The drift distance could be very long, from 10cm to several meters, depending on the design.

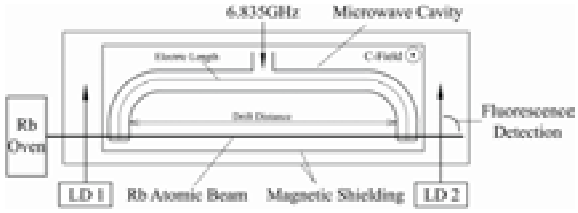

Figure 1. The schematic diagram of our rubidium beam tube.

Some methods and improvements on U-shape cavities in cesium beam clocks are given in [7-8].

II. METHODS

A. Simulation of Field in the Cavity

For a straight cavity, all characters can be given theoretically. But it is not so easy for a U-shape cavity, taking into account the bends, apertures that enable atoms to cross, T-junction for energy input and so on. Finite element analysis software, HFSS ANSYS in our design, which is able to numerically calculate the field inside a model, is used to calculate the resonant frequency, intrinsic quality value (quality value without regard to the energy input), and field pattern of a given cavity shape. Fig.2 is an example of the simulated magnetic field distribution in our U-shape cavity.

B. Requirements

The resonant frequency of the cavity, denoted by ν_c, is the peak location of the power-frequency line. That is to say, if the microwave is at the resonance frequency of the cavity, the power input is at maximum. As a result, to get sufficiently large microwave power, ν_c should be, in our device, close to 6.8347GHz, which is the frequency the microwave signal tends to be, i.e. the frequency of clock transition of ^{87}Rb. Besides, cavity pulling effect, as a cause of frequency shift, again requires ν_c to be close to the clock transition frequency. The corresponding frequency shift is [9]

$$\Delta\nu_c \propto \frac{T_c^2}{T_i^2}\cdot(\nu_c-\nu_0), \tag{1}$$

where T_c is equal to $Q_L/\pi\nu_0$, T_i is a characteristic time of flight during drift distance and ν_0 is the clock transition frequency. One can see that the frequency shift is proportional to the mistuning of the cavity. Consequently, instead of WR90 in cesium clocks, the type of waveguide is chosen to be WR112, whose cross section is $28.499\cdot12.624\text{mm}^2$, for it is applicable for the clock transition frequency, 6.8347GHz. On the other hand, the cavity pulling is also proportional to the square of loaded quality value Q_L (quality value considering energy input). If Q_L is sufficiently small, e.g. less than 1000, the cavity pulling effect may be negligible.

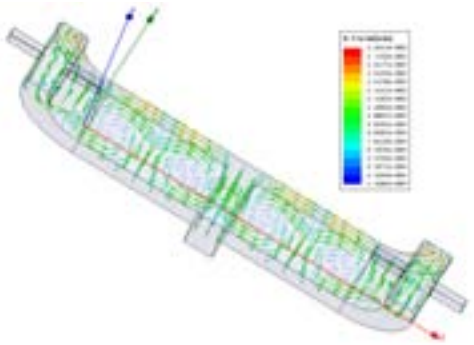

Figure 2. An example of simulated magnetic field (vector).

III. THEORIES AND NUMERICAL SIMULATIONS

A. Rectangular Cavity as an Approximation

Properties of isolated, straight cavities made of shorted rectangular waveguide are given [5]. Under TE_{10n} mode, the relation between resonant frequency and the electric length of a straight cavity, which is denoted by c, is

$$c = n\cdot[(\frac{2}{\lambda})^2-(\frac{1}{a})^2]^{-1/2} \tag{2}$$

where λ is the wavelength in vacuum and a is the long side of the cross section of waveguide. Note that c/n is the so-called waveguide wavelength, which is 68.67mm for waveguide WR112 and microwave frequency of 6.8347GHz. Considering the size of the clock, we use TE_{106} mode of the cavity, i.e. n=6, leading to the total length to be 206.02mm. If bends, apertures and energy input are added, the total length has to be slightly adjusted to meet the frequency. It is worth noting that theoretically the cavity's resonant frequency decreases linearly with the increase of the total electric length.

B. Field Simulation

An example of the simulation of magnetic field inside the U-shape cavity has been shown in Fig.2. With the simulation, we get the resonant frequency with different lengths of the cavity. By this means, the suitable lengths can be found, when the resonant frequency is equal to the clock transition frequency, as mentioned in Section II. The simulation result of the resonant frequency depending on drift length of the cavity is shown in Fig.3, where the variation tendency, as can be seen, is quite in accordance with the theory. The drift distance is thus determined to be 151.33mm, and the total electric length to be 207.26mm correspondingly, a little different with the theoretic result mentioned before. The other variable lengths are determined in the similar way.

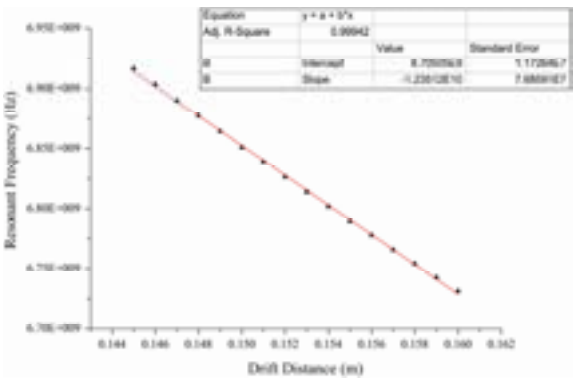

Figure 3. Simulation result of resonant frequency varying with drift distance.

IV. Results and Discussion

A. Configuration of the Cavity

The final configuration of the U-shape cavity is shown in Fig.4. The apertures that allow atoms to pass are $3.6 \cdot 6\text{mm}^2$ in size. Sections of cutoff waveguide are attached to the apertures where atoms traverse, preventing microwave leakage.

Beyond the U-shape cavity (not shown), the microwave signal is transferred by coaxial. A coaxial-to-waveguide transducer is used to couple the signal into the cavity. Posts of variable heights are on the transducer's wall, to tune the total resonant frequency and quality value. Besides, a ceramic window isolates the U-shape cavity from the transducer, which is the usual method for a sealed cavity. The total loaded quality value of the cavity is about 1000, which is also obtained from the simulation result.

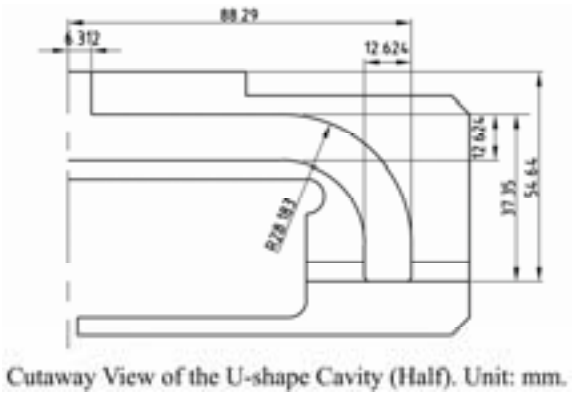

Figure 4. The final result of U-shape cavity.

B. Estimation on the Ramsey Line Width

In optically-pumped frequency standard, the Ramsey line width is calculated by [10]

$$\Delta\nu = \frac{\Delta_L}{2\pi T_i}. \tag{3}$$

Here $T_i=\alpha/L$, where α is the most probable velocity and L is the drift length. Δ_L is value which depends on the velocity distribution, 3.02 in the cycling transition detection scheme. Assuming the oven temperature is 400K, the most probable velocity is then 283m/s. Thus the Ramsey line width is estimated to be approximately 900Hz. This width is about two times larger than what we measured in our previous cesium clocks, because both the drift distance is shorter, and the most probable velocity is higher here than in cesium tube. Besides, actual operating conditions will influence this width.

V. Conclusion

A method based on field simulation of microwave cavity design for a compact rubidium beam clock is presented. The simulation result is quite in accordance with the theories. The final performance of the cavity is a resonant frequency of 6.8347GHz and a loaded quality value of 1000. The drift distance is 151.330mm and the total electric length of the cavity is 207.26mm. The Ramsey line width is a little larger than what we expect. Improvement on the drift length or atoms' velocity control may be proposed in the future.

***Abstract*—A preliminary calculation of the frequency shifts resulting from the distributed phase of a rectangular cavity is used to model frequency measurements of the fountain clock NRC-FCs1. The calculation is based on a numerical evaluation of the cavity field made with a finite element EM solver. The frequency shift is obtained by solving the Bloch-equations numerically along the path of the atoms on the free-fall trajectories through the cavity. We study the frequency shifts as a function of the launch direction, the tilt of the physics package and offsets in the position of the MOT relative to the axis defined by the state-selection cavity and the Ramsey cavity.**

I. Introduction

The evaluation of frequency offsets arising in a Ramsey interrogation require a careful experimental evaluation of a fountain clock supported by numerical modeling of the electromagnetic field of the Ramsey cavity. The frequency of a fountain clock is dependent on phase variations in the rf-field and various geometrical factors. Phase variations arise from losses in the cavity walls and coupling to the antennas, all of which create traveling waves. The atomic motion through the phase variations produce first order Doppler shifts which are position dependent. As a result, distributed cavity phase (DCP) frequency shifts are often the leading contribution to the uncertainty of many fountain clocks [1]. Decades of work have resulted in a good understanding of DCP. However most atomic fountain clocks use TE_{011} cylindrical cavities while NRC-FCs1's design is based on a rectangular cavity and transversal C-field configuration borrowed from laboratory beam clocks. DCP calculations require three-dimensional solutions of the cavity field, a process which requires intensive computing resources. Simplifications to a two-dimensional problem exist for cylindrical cavities [2] but the symmetry of the system cannot be exploited advantageously for a rectangular cavity. However, decreasing costs of computer resources and improved performance of computers have reduced the time required to obtain results from a finite element model.

FCs1's Ramsey cavity is designed with conical below-cutoff waveguides in order to keep atoms away from the high fields near sharp edges and minimize phase shifts [3]. This configuration also gives a computational advantage since the atoms do not interact with the field where dense meshing calculations would be required. Our first partial numerical results show a behaviour consistent with the frequency shifts measured in NRC-FCs1 as a function of the launch direction, the tilt of the physics package and the choice of the antenna used to feed the Ramsey cavity. Measurements showed that a significant frequency difference exists between operation of the fountain clock with one antenna or the other. This difference may be a result of a misalignment of the MOT with respect to the axis defined by the state-selection and Ramsey cavities.

II. The physics package

The fountain clock NRC-FCs1 operates with a MOT loaded in $825\,\text{ms}$ and a launch cycle of $1575\,\text{ms}$ [4]. The atoms are trapped, accelerated and cooled with six $\sigma^+ - \sigma^-$ beams in the 110-configuration. They leave the MOT region in the $|F = 4, m_F\rangle$ states and are pumped to the $|F = 3, m_F = 0\rangle$ state by the state-selection cavity. The states remaining in the $|F = 4, m_F \neq 0\rangle$ are removed by a σ^+ polarized $4-5'$ pusher beam. Ramsey pulses are provided by a rectangular cavity

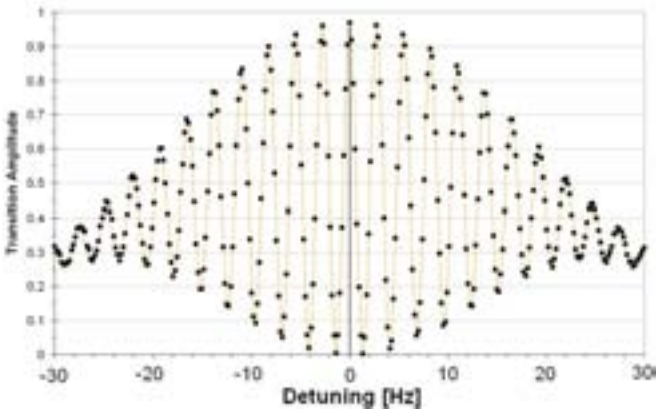

Fig. 1. Ramsey fringes for a 25cm fountain, one measurement per point.

operating in the TM_{210}-mode and fed with two magnetically-coupled antennas. A transversal C-field is generated by four linear electrodes. Because of a longer interaction between the atoms and the rf-field, the rectangular cavity produces a narrower Rabi pedestal than obtained with cylindrical cavities. In addition, it does not have field reversals in the neighborhood of the ends of the below-cutoff waveguides which could produce potentially large frequency shifts. Since the C-field is transversal the configuration takes advantage of a higher shielding from the inner cylindrical magnetic shield. The best short-term frequency stability is achieved at the optimal fountain height of 25 cm above the Ramsey cavity. The microwave signal is generated with a synthesizer chain synchronized with the NRC-SM1 maser which offered the best stability ($\sigma_y(\tau = 1s) < 2 \times 10^{-13}$). After Ramsey interrogation, the population in the $F = 4$ and $F = 3$ states is measured from the fluorescence signals obtained from four state-selecting beams: the $|F = 4\rangle$ detection beam, the pusher beam, the repumper beam, and another $|F = 4\rangle$ detection beam. Figure 1 shows the measured Ramsey fringes with a 96% contrast. An Allan deviation of $\sigma_y(\tau) = 3 \times 10^{-13}\,\tau^{-1/2}$ was obtained for $\tau < 10^5$ s. Changes to laser polarization in the detection system and the light shift contribute to the uncertainty by $< 10^{-15}$. The sample deviation of the frequency measurements show a repeatability $\sigma = 1.8 \times 10^{-15}$ over weeks of operation.

Six circular apertures can clip the atomic cloud during their free-flight. The lowest aperture, 162 mm above the MOT and 5.0 mm in diameter, is part of the lower light-shutter. The the cut-off waveguide of the state-selection cavity is located 186 mm above the MOT and has a diameter of 5.0 mm. A second light shutter has an aperture located 187 mm below the Ramsey cavity with a 10.5 mm diameter. The Ramsey cavity, located 768 mm above the MOT, has 10.5 mm diameter apertures at the ends of the cut-off waveguides each located 62 mm below and above the center of the cavity. The geometry of the system also includes detection beams having a 20 mm diameter. However, the intensity profile of these beams is not included in the current simulation.

III. Cavity field

The numerical evaluation of the field in the cavity is made using of a full-wave finite element EM solver (Ansoft HFSS finite element method solver). The precise shape of the cavity ($d_x = 39.2$ mm, $d_y = 26.67$ mm and $d_z = 18.0$ mm, and rounded internal corners) was reproduced in a CAD drawing in the solver. The dimension d_y was varied until the resonance frequency matched 9.192 GHz with $d_y = 26.84$ mm. The resonant frequencies of the model cavity are compared with the measured values in Table I. The RMS difference between theory and measurements for the remaining five modes is 45 MHz.

The Ramsey cavity is made of two identical copper halves held together symmetrically about the XZ-plane. The microwave signal is coupled into the cavity via two magnetic antennas (rectangular loops 2.6 mm $\times$0.5 mm) through 2.0 mm-wide slits located on the sides of the cavity (Fig. 2). The cutoff waveguides have cylindrical symmetry, with a conical shape near the cavity center in order to keep the atoms away from the high fields at the edges and minimize phase shifts. The cavity has a measured loaded $Q_{\text{measured}} = 4600$ and a numerically estimated unloaded $Q = 10000$.

TABLE I. Frequencies of the modes

Mode	Measured	Calculated
TM_{110}	7.036 GHz	6.999 GHz
TM_{210}	9.192 GHz	9.192* GHz
TE_{011}	9.262 GHz	9.280 GHz
TE_{111}	10.691 GHz	10.637 GHz
TM_{111}	11.019 GHz	10.967 GHz
TE_{211}	11.711 GHz	11.658 GHz

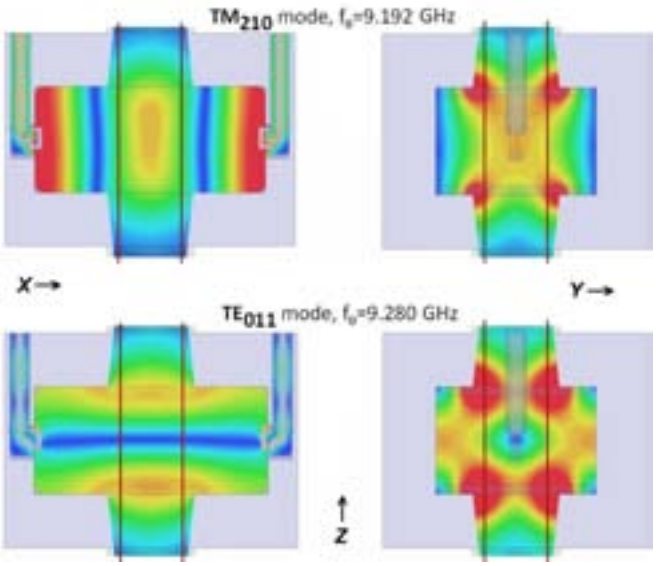

Fig. 2. Magnetic field amplitude for the TM_{210} and TE_{011} modes. The atoms are confined inside the space limited by the vertical lines.

The forward transmission plotted in Fig. 3 shows the resonances of the various modes. Two sharp dips occur at 9.2 GHz and 10.8 GHz. These are the result of destructive interference between three coupling fields (the two adjacent modes and the direct coupling from one antenna to the other) which occur when the first index l of the adjacent modes TM_{lmn} or TE_{lmn} have the same parity. The model gives a loaded $Q_{\text{model}} = 1000$. It is suspected that the exact position of the antennas is not modeled correctly which results in a larger coupling.

Although the finite element model includes in its solution every mode of the cavity, it is convenient to think of the field as the sum of many fields [1]. This could be useful to distinguish the small phase and amplitude variations generated by the solver from the errors generated by the calculations. Here we write the cavity field as the sum of a large amplitude standing wave $\mathbf{H}_0(\vec{r})$ representing the resonator's TM_{210} mode and other small amplitude fields representing an expansion of the non-resonant modes of the cavity and the field from the antennas:

$$\vec{H}(\vec{r}) = \vec{H}_0(\vec{r}) + \sum_k \left[\beta_k(\Delta\omega_k)\vec{h}_k(\vec{r})\right] + \vec{a}(\vec{r}),$$

where $\vec{H}_0(\vec{r})$ and $\vec{h}_k(\vec{r})$ are real and $\vec{a}(\vec{r})$ is the field from

the antennas. The fields $\vec{h}_k(\vec{r})$ are from other cavity modes and each factor $\beta_k(\Delta\omega_k)$ contains the phase and amplitude of the standing wave k relative to the phase and amplitude of the large standing wave at a detuning $\Delta\omega_k = \omega_{\mu\text{wave}} - \omega_k$. Using this expansion, it is possible to accurately evaluate the phase contributions of the non-resonant fields $\vec{h}_k(\vec{r})$ by calculating each one with the solver tuned on the resonant frequency of each mode k. The solutions for each field can be added differentially (with the factor $\beta_k(\Delta\omega_k)$) to the resonant solution for TM_{210} to study the effect on the phase.

IV. Frequency shift

The frequency shift is calculated by simulating the path of the atoms along the free-fall trajectories through the cavity while solving numerically the Bloch equations using the differential form:

$$\begin{aligned} \delta u &= +\Delta\, v\, \delta t \\ \delta v &= -\Delta\, u\, \delta t + \Omega\, w\, \delta t \\ \delta w &= -\Omega\, v\, \delta t \end{aligned}$$

where $\Delta = 2\pi(f_{\text{mw}} - f_0)$, Ω is the Rabi frequency, f_{mw} is the frequency of the microwave field and f_0 is the atomic resonance frequency [5]. For this work, the Rabi frequency is derived from the Y component (parallel to the C-field) of the cavity field.

The calculation proceeds as follows. Initial positions and launch velocities of an atom are used to generate a set of trajectories $\vec{r}(t)$ through the physics package. Only trajectories which do not stop on any of the apertures are kept in the set. For each position along the trajectory intersecting regularly spaced constant-z planes inside the Ramsey cavity, $\vec{r}(nz_0)$, the field H and its phase Φ are sampled from the results of the finite element solver. A bilinear interpolation along the X- and Y- axes is made to obtain a list of field values $H(nz_0)$ and $\Phi(nz_0)$ at the locations $\vec{r}(nz_0)$. The lists are converted to time dependent values and smoothed using a spline fitting function. Starting with the Bloch vector $(u = 0, v = 0, w = -1)$, the Bloch equations are integrated along the trajectory with time intervals $\delta t = t(nz_0) - t((n-1)z_0)$.

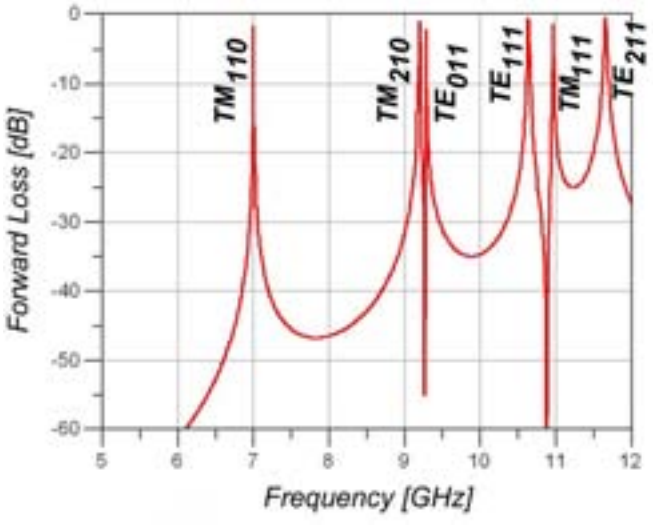

Fig. 3. Forward loss through Ramsey cavity. Canceling interference produces sharp dips between modes for which the parity of their first index is the same.

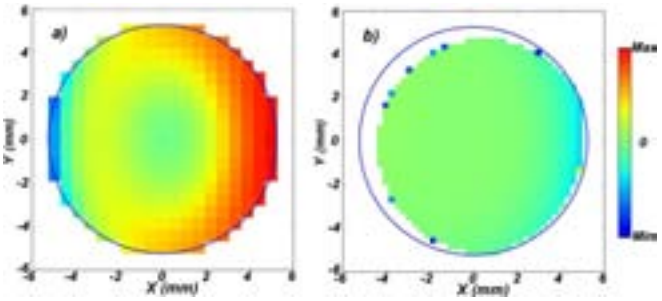

Fig. 4. Atomic population after Ramsey interrogation. The colour code represents the value w of the Bloch vector plotted as a function of the position of the atom at the exit of the Ramsey cavity. The antennas, located on the left- and right-hand side of the image, are labeled W and E respectively.

The initial launch velocities used for the calculation are selected according to a Gaussian velocity distribution representing the measured distributions along the three axes. Launching with a 110-configured MOT results in three different velocity distribution in the X-, Y- and Z-directions with equivalent temperatures $15.0\,\mu$K, $2.1\,\mu$K and $6.0\,\mu$K respectively [6]. For each trajectory a probability is assigned representing the probability of finding an atom within a velocity space element. A graph representing the population of the atoms (w component of the Bloch vector) as a function of the exit position after Ramsey interrogation is obtained from an average of the w values weighted by the probability of the trajectory. Two examples of the results are given in Fig. 4 for (a) two antennas and a tilted physics package and (b) one antenna and misaligned MOT. Atoms launched with a faster velocity are blocked at the edge of the apertures, resulting in a different excitation value seen as a dark pixel at the periphery of the disk. The frequency offset is found from the total population calculated at microwave frequencies $+f_m$ and $-f_m$ at half maximum on the Ramsey fringe.

V. Results and discussion

The experimental conditions were reproduced numerically, with the physics package tilted ± 1 mrad from the vertical along the x and y directions. A perfect alignment of the MOT along the axis defined by the center of the state-selection and Ramsey cavities was used as well as as a MOT offset by $x = -1.8$ mm and $y = 0.9$ mm. In all cases, antenna-E, antenna-W (see caption of Fig. 4) and both antennas were tested. In order to simulate the use of the antenna-W, the field from antenna-E was used with the geometry rotated by $180°$ about the z-axis. The results are shown in Table II. The table shows the offsets normalized by $\sqrt{Q_{\text{model}}/Q_{\text{measured}}} = 0.47$ to compensate for the weaker antenna coupling of the measurement system.

The first block in the table lists results obtained with one antenna and a perfectly centered MOT. The relative frequency shift dy of the clock as a function of tilt varies by $dy/d\theta_x = 2.7 \times 10^{-15}$/mrad while $dy/d\theta_y < 0.1 \times 10^{-15}$/mrad. The effect does not change significantly when the MOT is misaligned ($x_0 = -1.8$ mm and $y_0 = 0.9$ mm), as shown in the second block of Table II. In this case, the frequency shift as a function of tilt is $dy/d\theta_x = 2.1 \times 10^{-15}$/mrad

TABLE II. CALCULATED FREQUENCY SHIFTS

Number of Antennas	Initial position x_0, y_0[mm]	v_x, v_y [mm/s]	Tilt θ_X, θ_Y [mrad]	Frequency Offset $\left[10^{-15}\right]$
1	0, 0	0, 0	0, 0	-5.0
1	0, 0	0, 0	-1, 0	-8.0
1	0, 0	0, 0	$+1$, 0	-2.7
1	0, 0	0, 0	$0, -1$	-5.1
1	0, 0	0, 0	$0, +1$	-5.1
1	$-1.8, +0.9$	$+16, -8$	$-4, +2$	-5.6
1	$-1.8, +0.9$	$+16, -8$	$-5, +2$	-7.7
1	$-1.8, +0.9$	$+16, -8$	$-4, +1$	-5.8
1	$+1.8, -0.9$	$-16, +8$	$+4, -2$	-1.8
1	$+1.8, -0.9$	$-16, +8$	$+5, -2$	$+1.7$
1	$+1.8, -0.9$	$-16, +8$	$+4, -1$	-2.3
2	0, 0	0, 0	0, 0	-4.9
2	0, 0	0, 0	± 1, 0	-5.2
2	0, 0	0, 0	$0, \pm 1$	-5.0
2	$\mp 1.8, \pm 0.9$	$\pm 16, \mp 8$	$\mp 4, \pm 2$	-3.6
2	$-1.8, +0.9$	$+16, -8$	$-5, +2$	-3.0
2	$-1.8, +0.9$	$+16, -8$	$-4, +1$	-4.0

and $dy/d\theta_y = 0.2 \times 10^{-15}$/mrad. However, the misaligned MOT produces an asymmetry in the system and the frequency difference $\Delta f = 3.8 \times 10^{-15}$ arises when the other antenna is used. In the last case, when both antennas are used, the frequency offset has a weak dependence on tilt remaining $dy/d\theta < 0.2 \times 10^{-15}$/mrad for small angles (third block in Table II. However a constant offset is present due to a quadratic dependence of the DCP not canceled by the two antennas. A change in the launch direction does not cause a significant effect, mostly as a result of the velocity selection made by the apertures of the Ramsey cavity.

The measured frequency shifts as a function of tilt are: for antenna-E $dy/d\theta_x = 1 \times 10^{-15}$/mrad and $dy/d\theta_y = 5 \times 10^{-15}$/mrad; for antenna-W $dy/d\theta_x = 3 \times 10^{-15}$/mrad and $dy/d\theta_y = 3 \times 10^{-15}$/mrad. All measurements have an uncertainty of 1.8×10^{-15}/mrad. The measured frequency are comparable to the calculated values. However, the measured frequency shift between the two antennas is 18×10^{-15} which seems to indicate that the misalignment of the MOT is even greater than the numbers used in the model. This could also explain some of the variations in the measured $dy/d\theta$.

It is possible that the position of the MOT is shifted away from the symmetry axis due to the asymmetric construction of the electrostatic shutters [4]. The shutter enclosures are 20 cm diameter disks installed off-axis. When under vacuum, the compressed disks may flex in a way to produce a misalignment. Correction coils were added for the added possibility of centering the MOT (X and Y directions) and shift the launch location. The model helps in determining the direction the MOT has to be moved to correct the offset.

VI. CONCLUSIONS

The numerical method presented in this work produces consistent evaluations of the DCP frequency shifts in a rectangular Ramsey cavity and are consistent with the measured results obtained with NRC-FCs1. The model brings a better understanding of the causes of the frequency shifts. Two principal contributions arise from a misalignment of the MOT and a strong coupling of the antennas resulting in an important flux from antenna to the other.

Further work is required to complete this evaluation. A model with the correct $Q_{\text{loaded}} = 4600$ is necessary and the field of the state-selection cavity can be added to the simulation. Contributions from phase gradients of other modes should be calculated separately and added as a perturbation to the field. This would provide a good check of the results of the finite element solver. The coupling of the antennas can also be separated from the unloaded cavity modes by using the eigenmode solver. One can thus verify that the frequency offsets are mainly due to the coupling between the antennas. Finally, the intensity distribution of the laser beams can be accounted for, but this is not expected to change the results significantly.

ACKNOWLEDGMENT

L.M. would like to thank Ph. Laurent (Observatoire de Paris) and K. Szymaniec (NPL) for useful discussions and advice on the distributed cavity phase shift. The computations were made in the Python computing language with the Numpy, Scipy and Matplotlib extensions and IPython interactive computing [7].

Abstract — **Frequency stability of passive frequency standard is associated with the figure of merit of a quantum discriminator. The method of the discriminator figure of merit measuring and the lowest achievable short-term frequency stability in the passive hydrogen maser are presented. Results of theoretical and experimental research are compared. The result of investigation shows that with increase in a excitation signal power, spectral line shape can be considered as the sum of several lines.**

Keywords - passive hydrogen maser; figure of merit; stability; spectral line shape.

I. INTRODUCTION

Frequency stability of any passive frequency standard is associated with the figure of merit of a quantum discriminator (physics package), characterized by the ratio of signal/noise to the width of the atomic transition spectral line during indicating the atomic resonance. The larger this parameter, the higher is short-term frequency stability of the maser [1]:

$$\sigma(\tau) = \frac{\Delta f_l}{F_{\text{s-n}}} \times \frac{const}{f_l \sqrt{\tau}} \quad ,$$

where $F_{s\text{-}n}$ – signal-to-noise ratio (SNR), Δf_l – width of the atomic spectral line, f_l – frequency of the atomic transition, *const* – coefficient dependent on line detection method, τ – averaging time.

II. THEORETICAL ESTIMATION OF A PASSIVE HYDROGEN MASER STABILITY

Let us consider a passive hydrogen maser (PHM) with single frequency modulation [2]. Block diagram of PHM is given in Fig.1. Expression can be concretized for the quantum discriminator:

$$\sigma(\tau) = \sqrt{\frac{S_n(\Omega)}{2 f_l^2 S_d^2 \tau}},$$

where $S_n\ (\Omega)$ – noise spectral density at the output of the selective amplifier; S_d – the slope of discriminator curve at frequency offset excitation signal from spectral line centre by Δf.

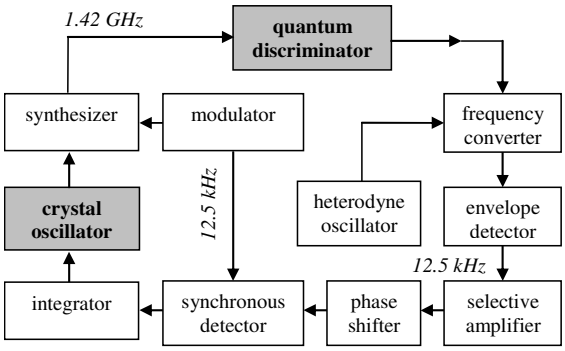

Fig. 1. Block diagram of Passive Hydrogen Maser.

If a selective voltmeter with a pass-band ΔB_{sel}, is used, S_d can be measured as the effective voltage U_{sel} of a first harmonic signal at the output of the selective amplifier, which appears as a result of detuning. U_{n} can be measured as effective noise voltage U_{n} when there is no signal at input. Frequency stability of passive frequency standard can be estimated from the following expression:

$$\sigma(\tau) = \frac{U_n \Delta f}{2\pi\ f_l U_{sel}} \frac{1}{\sqrt{\Delta B_{sel} \tau}} \quad .$$

Experimental dependence of PHM CH1-76A stability at time of averaging 100 sec upon the SNR during frequency offset $\Delta f = 0.1$ Hz is given in Fig. 2.

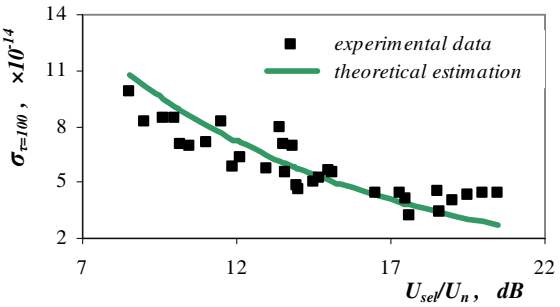

Fig. 2. Dependence of CH1-76A stability at time of averaging 100 sec upon the SNR during frequency offset $\Delta f = 0.1$ Hz.

The SNR was measured by means of the selective microvoltmeter with $\Delta B_{sel} = 300$ Hz. Also estimated value calculated by means of the given formula is shown in figure. The analysis of the figure plot shows close agreement of a theoretical estimation and experimental results up to signal/noise values equal to 19 dB, and then there comes limitation on stability improvement.

III. Investigation of Stability Limitation

For investigation of stability limitation we will refer to the slope of discriminator curve S_d. The expression received by us is based on the solution of the equation of PHM [3, 4] in a "steady-state" approximation:

$$S_\partial \approx \frac{2J_1(m)}{J_0(m)\sqrt{1+q}} \frac{\alpha S_0}{T_1 T_2 (1+S_0)}, \qquad (1)$$

where $q = \Omega/\gamma_c$; γ_c – the halfwidth band of the microwave cavity of the hydrogen discriminator; m, Ω – the index and the angular frequency of the phase modulation; $J_n(m)$ – the Bessel function of the first kind of the n order from the argument m; α и S_0 – the hydrogen discriminator excitation and saturation factor; T_1 и T_2 – longitudinal and transverse relaxation time of the atomic ensemble. The expression shows (Fig. 3) that at small saturation the slope of discriminator curve is proportional to S_0 (therefore, to an excitation signal power), and at $S_0 >> 1$ the slope of discriminator curve tends to a limit. But the results of the experiment given in Fig. 4 show that after achievement of a maximum reduction S_d begins at increase of a excitation signal power P_{ex}.

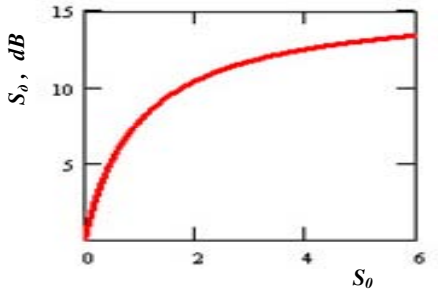

Fig. 3. Theoretical dependence of the slope of discriminator curve upon the hydrogen discriminator saturation factor.

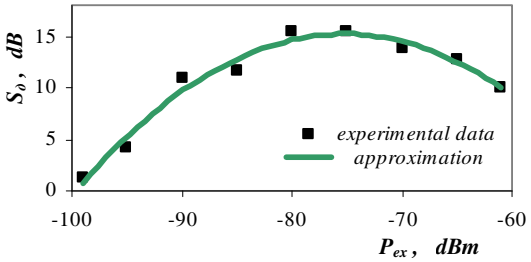

Fig. 4. Experimental dependence of the slope of discriminator curve upon the power of a excitation signal power during frequency offset $\Delta f = 0.1$ Hz.

Amplitude characteristics of the quantum hydrogen discriminator were experimentally investigated for verification of theoretical model. According to the conventional representations the atom spectral line has a Lorentz line shape. For example, such result is obtained due to the solution of the equation of a hydrogen maser in a "steady-state" approximation [3].

For verification the equipment with accumulation of data was used. It allowed to increase the accuracy of measurements. As a source of a signal the Anritsu MG3642A signal generator was used. As the receiver the spectrum analyzer E4402B-COM of Agilent Technologies was used. The generator and the spectrum analyzer were synchronized by a highly stable signal of 10 MHz from the active hydrogen standard of frequency CH1-75A. Between the generator and the quantum discriminator the ferrite isolator with the return losses more than 100 dB was placed, and between the discriminator and the receiver the variable attenuator was placed for improvement of wave impedance matching and reduction of signal distortion [5]. We increased attenuation at increase in a signal of the generator.

Experimental data in a form of the hydrogen line shape are given in Fig. 5. Parameter is the power of a excitation signal. The result of investigation shows that the spectral line shape corresponds to Lorentz line shape only at small ($\approx -90...-100$ dBm) excitation signal power. With increase in a excitation signal power it is observed not only broadening, but also strong distortion of the spectral line. The line shape can be considered as the sum of several (possibly three) spectral lines detuning from each other.

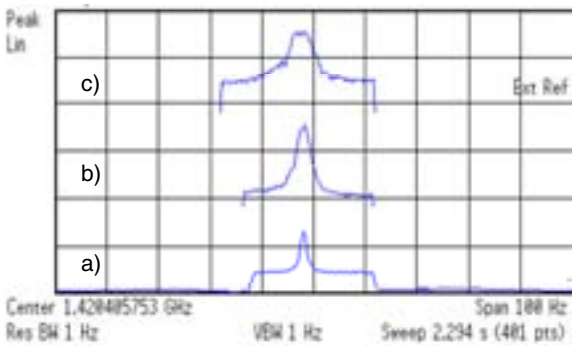

Fig. 5. The PHM spectral line shape at a different excitation signal power P_{ex}: a) – 94 dBm; b) – 74 dBm; c) – 67 dBm.

IV. Discussion

In a "steady-state" approximation it is considered that all atoms give quantum of energy and after that leave the microwave cavity. Actually the quantity of the atoms which have given quantum of energy is defined by induced atom transition rate. The transition rate depends on the power of a excitation signal power. Quantity of atoms which can give and again receive energy quantum grows at increase of signal power.

In these conditions Stark – Zeeman dynamic effect has to be apparent. It is the effect of splitting of the spectral line that

appears in strong alternating electromagnetic fields [6, 7]. Splitting of satellites is equally to the Rabi frequency:

$$b_R = \mu_{12}\mu_0 H/\hbar$$

where H – intensity of magnetic microwave field component, μ_{12} – magnetic dipole moment of transition, μ_0 –magnetic constant, $\hbar$ – Planck constant. According to our theoretical estimates at an excitation signal power equal to – 70 dBm we have $b_R/2\pi \approx 2$ Hz.

At a low excitation signal power the Rabi frequency is small and shift of satellites from the central peak is also small in comparison with line width. In this case satellites in Fig. 5 are not observed. Then summation of several lines leads to a flat top of the line. At further increase in Rabi frequency there is an observed splitting of the line.

The analysis shows that there are two main factors defining behavior of the slope of discriminator curve in Fig. 4. The first factor leads to increase in S_d. According to the expression 1 at the small saturation factor S_0 the slope of discriminator curve is proportional to excitation signal power. The second factor is associated with broadening and line splitting, it contributes to S_d reduction. The broadening and splitting leads at the beginning to emergence of a plateau on a discrimination curve near zero frequency offset. After that the general reduction of a tilt angle of the discrimination curve occurs.

V. Conclusion

- The larger figure of merit of a quantum discriminator, the higher is short-term frequency stability of the maser.
- At small ($\approx -80...-100$ dBm) excitation signal power the experimental slope of discriminator curve increases. At further increase of a excitation signal power S_d begins to decrease. The experimental spectral line shape can be considered as the sum of several spectral lines. We explain the spectral line splitting by Stark – Zeeman dynamic effect that appears in strong alternating electromagnetic fields.
- The discovered effect limits short-term stability of passive hydrogen maser.

***Abstract*—A pulsed RADAR approach is investigated to probe acoustic delay lines used as passive sensors. In order to comply with the requirements of compact, low power receiver electronics, a stroboscopic equivalent time sampling approach is demonstrated. A strategy for generating high resolution time delays while allowing for long interrogation durations (up to 5 μs) is implemented by combining an FPGA-based delay generator with commercially available programmable digital delay lines. The measurement sequence of generating interleaved combs is due to the long delay line reconfiguration duration (SPI communication) with respect to the coarse comb (FPGA based counter). The response of the sensor is recorded and processed to acquire the coarse acoustic velocity information through magnitude measurement, and an accurate physical quantity estimate is computed thanks to the phase information. We demonstrate an improved software measurement strategy which prevents the slow process associated with a stroboscopic approach and allows to reach refresh rates of up to 20 kHz when probing an acoustic tag for a physical property measurement, while keeping the hardware to a bare minimum.**

I. Introduction

Acoustic delay lines are well know transducers used as passive sensors interrogated through a wireless link. The inverse piezoelectric effect converts the energy of an incoming electromagnetic pulse, trough the interdigitated transducer (IDT) connected to the antenna, to an acoustic wave propagating on a piezoelectric substrate. Mirrors patterned on this substrate reflect a fraction of this wave back and the direct piezoelectric effect converts these acoustic pulses to electromagnetic signals detected by the receiver. The interrogation unit design is given by the characteristics of the sensor response. As part of this study, we will be interested in probing a commercially available acoustic delay line provided by the Carinthian Tech Research (CTR, Villach, Austria) whose spectral and time response is displayed in Fig. 1.

The delay line is probed with an excitation signal whose spectral characteristics lie in the 2.4 to 2.454 GHz range, hence complying with the industrial, scientific and medical (ISM) band regulations. The time-domain response of this line for a 54 MHz bandwidth excitation signal exhibits eight echoes between 994 ns and 2.19 μs. Two of these echoes partially overlap due to the reduced bandwidth, but are still separated by a gap exhibiting a 17 dB dynamic range.

Multiple electronic reader units have been presented in the literature, most of which are based on the Frequency Modulated Continuous Waves (FMCW) RADAR approach [1],

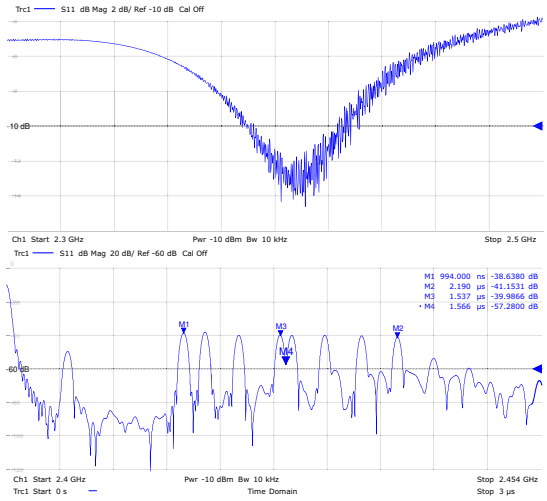

Fig. 1. Top: S_{11} spectral response of a CTR delay line between 2.3 GHz and 2.5 GHz. Bottom: 3 μs time response with an excitation signal of 2.427 GHz and a bandwidth of 54 MHz. The 8 echoes are visible, with insertion losses of 40 dB, due to mirror efficiency, with an additional parasitic echo due to the back edge of the device at 350 ns after the excitation signal.

[2] whose control of the spectrum use and radiofrequency synthesis circuit is most basic, although requiring significant computational power (periodic audio-frequency rate sampling and Fourier transform) to extract the electrical properties of the acoustic delay line acting as cooperative target. Furthermore, FMCW requires a well linearized voltage controlled oscillator or linear digital synthesis for the Fourier transform components to coherently sum throughout the frequency excursion over the transfer function of the transducer [3], [4].

Another complementary approach is the pulsed RADAR method in which the frequency band, rather than being continuously swept, is probed by a wideband pulse. Echoes in the time domain are returned by reflectors following a delay proportional to their distance. In such a configuration, the challenge no longer lies in the signal source but on the wideband receiver whose sampling rate must be high with respect to the occupied bandwidth. One well known solution, best suited in the case of RADAR in which the environment is probed by a signal generated by the instrument and acting as a trigger signal, is the stroboscopic method as used for example in Ground Penetrating RADARs (GPR). Such an instrument has been demonstrated to be compatible with recovering the time domain response of acoustic transducers acting as passive cooperative targets [5], [6].

Before discussing the operation of the proposed reader unit, we first explain the reasons for choosing a pulsed RADAR approach rather than the classical FMCW RADAR method. Secondly, we explain the principle of equivalent time sampling and our system requirements. Details and implementation of this method are then discussed. Finally, measurements and results are reported with a discussion of the reader improved sampling rate.

II. Pulsed Radar

We assess the use of a pulsed RADAR approach in which the instantaneous power reaching the target is greatly increased with respect to a continuous emission, even though the average power consumption (depending on pulse repetition rate) is of the same order of magnitude than those found in FMCW. We assume that the emitted power must comply with ISM band regulations [7, Annex 1H] – 10 dBm emitted power in the 2.4 to 2.483 GHz ISM band – since common acoustic sensors do not occupy wide enough bandwidths to be considered as ultra-wideband devices.

Both FMCW and pulsed RADAR propagation characteristics are governed by the RADAR equation which will be used to assess the maximum interrogation range of acoustic transducers acting as cooperative targets. The one-way propagation equation relates the received power P_r to the instantaneously transmitted power P_t through

$$P_r = \frac{P_t G^2 \lambda^2}{(4\pi R)^2} \tag{1}$$

assuming that both the transceiver and the sensor are fitted with an antenna exhibiting a gain (G) equal to 1. λ is the signal wavelength and R the range between the RADAR and the sensor.

Once the sensor is loaded, the reflected power P_r' must account for the insertion loss IL of the device. We thus estimate the interrogation range R of a sensor by considering that the returned signal power S is given following

$$R = \frac{G \cdot \lambda}{4\pi} \sqrt[4]{\frac{P_t}{S \cdot IL}} \tag{2}$$

Hence, the range limitation is given by the P_t to S ratio and we consider S_{min} the minimum detectable power on the receiver defined as the minimum acceptable signal to noise ratio $(S/N)_{min}$ multiplied by the thermal noise injected into the low noise amplifier (LNA) $k_B T_0 B F$ with k_B the Boltzmann constant, T_0 the antenna and LNA temperature, B the receiver bandwidth and F the amplifier noise factor.

The relationship providing an estimate of the acoustic device interrogation range as a function of the instantaneously transmitted power is:

$$R_{max} = \frac{G \cdot \lambda}{4\pi} \sqrt[4]{\frac{P_t}{S_{min} \cdot IL}} \tag{3}$$

The receiver bandwidth defines the thermal noise level on the receiver and hence the detection limit: in the case of FMCW, typical sweep rates of the frequency source spanning 50 MHz is in the 10 ms range, yielding beat frequencies when probing an acoustic delay line with echoes delayed by up to 5 μs of $50 \times 10^6 \times 5.10^{-6}/10^{-2} = 25$ kHz. We will thus consider and FMCW recording bandwidth of 30 kHz, much lower than the pulsed RADAR receiver bandwidth of a few hundred MHz.

Assuming an FMCW system continuously transmitting 10 dBm and fitted with a receiver with 30 kHz bandwidth characterized by a noise figure of 3 dB, a signal to noise ratio of 3 dB and 40 dB of insertion losses in the acoustic device, then the maximum interrogation range is about 1.5 m. Such an interrogation range is achieved by instantaneously emitting 43 dBm (20 W or 32 V in a 50 Ω load) pulses by a pulsed RADAR setup designed with a receiver bandwidth of 54 MHz. For such a device to comply with ISM regulation and emit the same average power, the 20 ns long pulses must be emitted no faster than once every 34 μs. In this context, the pulsed RADAR refresh rate can reach 29.4 kHz. A tradeoff aimed at reducing the time interval between pulse emission is achieved by lowering peak power, at the cost of reduced range. In the next part, we will assume a pulse repetition rate interval of 5 μs (with a peak power of 34 dBm providing an interrogation range of 93 cm following the previous calculation).

The general pulsed-RADAR system architecture is shown in Fig. 2. A carrier frequency generated by a continuous source centered around 2450 MHz is chopped by a fast (<30 ns rise time) switch to load energy in an acoustic delay line. The returned echoes are translated to baseband by a wideband I/Q demodulator, feeding the dual-channel acquisition system which will be the topic of the next section.

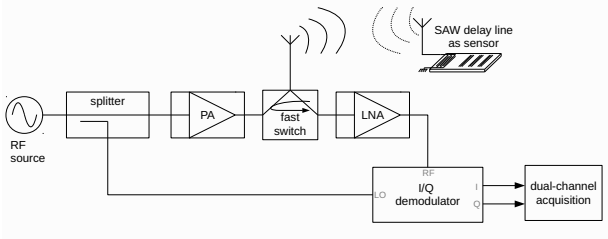

Fig. 2. Schematic of a passive wireless acoustic sensor interrogation unit

In order to comply with the requirements of compact, low power receiver electronics, a stroboscopic equivalent time sampling approach is used. The two values representative of the physical quantity detection by the transducer are the returned power magnitude and phase, as provided by an I/Q demodulator. This demodulator provides an output signal of up to 100 MHz bandwidth, which involves digitizing a signal at 200-1000 MSamples/s to obtain a sufficient number of points to extract magnitude and phase with the targeted resolution aimed at only being limited by the local oscillator phase noise. The equivalent-time sampling approach provides a trade-off between reducing the demand for fast electronics components and increasing the acquisition time.

III. Equivalent Time Sampling

Equivalent time sampling (ETS) is based on repeating the probe signal and recording at each iteration a single sample at various time delays with respect to the emitted pulse. This measurement strategy is best suited when actively probing the medium, as done in RADAR systems, since the emitted pulse

acts as a synchronization trigger to define the recording time delay.

Considering the time reference, common to all measurements, defined as T_0, then at each iteration the ETS system record a sample at $T_0+n\cdot\delta T$ with sample index $n \in [1:N]$, N being the number of samples in the reconstructed signal. The time step δT yields an equivalent sampling rate $f_s = 1/\delta T$. The two main disadvantages of this technique are the duration of the acquisition which depends on the number of samples and the repetition rate since N individual measurements are needed, and the need for a reproducible signal during the N measurements. These drawbacks are considered here to be overcome by the simple hardware setup made solely of a fast track and hold controlled by a programmable delay line while only low bandwidth analog to digital converter and memory access are needed otherwise.

In order to perform post-processing calculation on echoes characterization with at least 10 samples during each echo lasting about 10 ns, a sampling rate of at least 1 GS/s is targeted. Commercially available programmable delay lines suiting our needs exhibit delay resolutions between 1 ns and 100 ps. Acquisition of a time response between 500 ns and 5 μs at a rate of 1 GS/s involves 4,500 measurements. When acquiring one measurement point, it is necessary to wait 5 μs to avoid temporal aliasing and allowing for all returned signal from the acoustic sensor to fade out: hence yielding an incompressible measurement duration between 22.5 ms. Obtaining the same result while complying with ISM regulations requiring repetition rates no faster than 34 μs yields an acquisition time of at least 153 ms.

IV. Experimental setup

The challenge in using such commercially available delay lines is the range of accessible delays: an 8-bit programmable delay line such as Maxim DS1023-25 providing a resolution of 250 ps only generates a maximum delay of $2^8 \cdot 250$ ps $= 63.75$ ns, much below the targeted 5 μs. Two delay lines are thus cascaded, one for coarse delay generation and another for high resolution delay generation. The coarse delay line must exhibit low jitter (necessarily less than the accurate line delay, in this case 250 ps): in our case, the delay generator is provided by a Programmable Logic Device (PLD) clocked at 100 MHz which ensures a time resolution of 10 ns. This device also generates the trigger signal of the switch.

The duration for programming a Maxim DS1023-25 delay line through a SPI link is also taken into account for the total measurement time estimate. Although the fastest clock rate on the SPI bus is 10 MHz, we secure communication by clocking the bus at 1 MHz. For each measurement, the delay line must be programmed by an 8-bit word, so the programming duration 8 μs. In addition, some latencies is associated with the delay line programming, requiring an additional 530 ns, and measurements can only be repeated after the acoustic sensor response has faded out after 5 μs. Thus, the total duration for a 4,500 point dataset is $4500\times(8+0.53+5+0.02) = 60975$ μs $\simeq 61$ ms. Fortunately, thanks to an optimized scanning strategy of the response, it is possible to reduce the programming time.

Considering a 10 ns resolution coarse delay, and a 1 ns fine delay equal to 4-delay line steps, 10 measurements are needed between two coarse delays to achieve a 1 GS/s sampling rate. The programming time of a PLD is at most two periods of the core clock. Rather than continuously reprogramming the slow (SPI bus) fine delay, an optimized approach consists in setting the fine delay and sweeping the coarse delay over the whole acoustic sensor response range (0 to 5 μs). Having acquired this first dataset, the fine delay line is set again (requiring a 8.53 μs lag) and the system retrieves a second dataset. The operation is repeated 10 times to get the full response. This stroboscopic acquisition using interleaved coarse and fine delay combs (Fig. 3) allows a theoretical acquisition time of 22.7 ms in the same conditions of the previous calculation, or a threefold update rate improvement with respect to the basic strategy described above.

So far no assumption is made on the acoustic sensor echo position. However, once the measurement has been performed, a strong assumption is that the echoes will be located close to their last identified position. Hence, rather than scanning the whole acoustic sensor delay of 0.5 to 5 μs by 1 ns steps, we focus solely on a feedback loop approach requiring 3-measurements on each echo. The central delay is then computed using a parabolic fit and feeds the next measurement step. The total measurement duration is then reduced by limiting from 4,500 to $3 \times 8 = 24$ samples for an acoustic sensor encoding 8 bits. The associated measurement duration is $24\times(8+0.53+5+0.02) = 325.2$ μs. If furthermore only the central delay needs fine tuning and the two other measurements before and after the central delay only require reprogramming the coarse delay (10 ns steps), then the measurement duration is further reduced to $8\times(8+0.53+5+0.02)+16\times(5.02) = 189$ μs or a 5.3 kHz refresh rate.

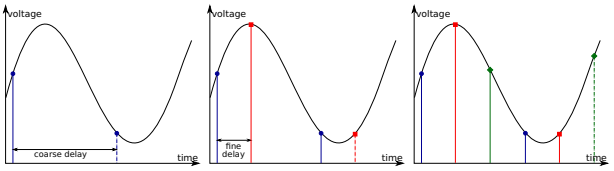

Fig. 3. Example of a sine-wave reconstruction with stroboscopic acquisition interleaving coarse and fine delay combs. Each case represents a coarse comb of recorded samples. The transition from one case to another requires setting the fine delay line.

V. Results

This acquisition system scans the output of the I/Q demodulator to calculate the physical quantity to be measured in a post-processing step. Fig. 4 shows the I and Q data recorded from 500 ns to 3 μs and the resulting $|I+iQ|$ magnitude, favorably compared to the measurement performed using a network analyzer (Fig. 1).

Beyond the acoustic tag identification based on the magnitude calculation, extracting a velocity information associated with a physical quantity measurement is achieved by computing $\arg(I+iQ)$. A differential measurement only requires the estimate of the phase difference between two echoes: only two acquisition points of both I and Q signals with a dual analog-to-digital converter are needed. Using the afore mentioned 3-point strategy for each echo, only 6 measurements are performed requiring a total measurement duration of $2\times(8+0.53+5+0.02)+4\times(5.02) = 47$ μs. Circles on Fig. 4 display the delay at which these 6 measurements are performed in order to characterize the first two echoes in the context of

a temperature measurement, thus providing a refresh rate of about 20 kHz. While such an update rate is still 10 times lower than the maximum achievable measurement speed of a 5 μs delay acoustic sensor, it optimizes an embedded electronics approach requiring only a few high-bandwidth components (track and hold, switch, I/Q demodulator).

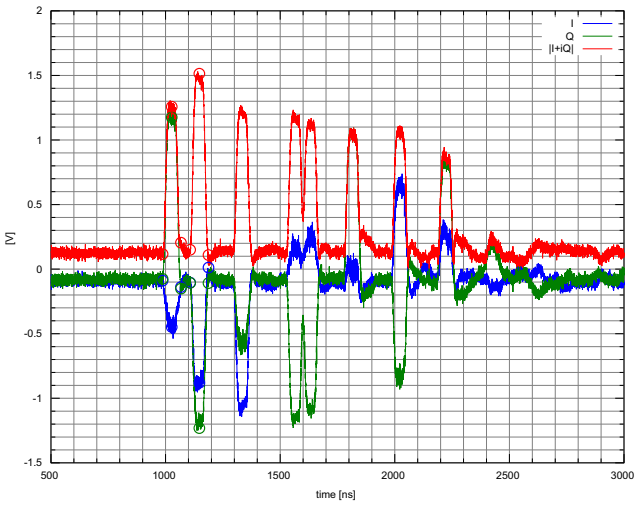

Fig. 4. Acoustic delay line response sampled by a stroboscopic interrogation unit. Six circles are highlighted on each trace over the first two echoes, representing the minimum number of samples recorded for a temperature measurement.

VI. Conclusion

A pulsed mode RADAR optimized for minimizing the number of high-bandwidth components and fast sampling rate is demonstrating for probing wideband acoustic transducers acting as passive wireless sensors. Compliance with ISM regulation and reaching the same range than an FMCW approach nevertheless allow a pulsed RADAR approach to improve at least 10-fold the refresh rate assuming a wideband receiver (fast radiofrequency analog to digital converter).

A stroboscopic strategy reducing the number of wideband components to a switch, a fast track and hold and I/Q demodulator associated with an optimized algorithm of interleaved coarse and fine time delays provides tag identification at 5.3 kHz refresh rate while measuring a physical quantity using acoustic phase computation on two echoes is performed at 20 kHz.

***Abstract*—For an increasing number of application (energy production, car industry, space, etc.), hydrogen appears as a solution of the future as it is the most common body in the Universe (and therefore on Earth). However, due to its unstable properties, a particular care must be dedicated to control possible gaseous leaks close to facilities using this resource. Here we propose surface acoustic wave sensors for detecting gaseous hydrogen in standard environmental conditions (atmospheric pressure and room temperature). The proposed SAW sensors consists in two Rayleigh-wave delay lines built on Quartz. One equipped with a Palladium overlay and the other exhibiting a free path between the two interdigitated transducers. A dedicated hermetical gas test cell has been developed to test the efficiency of the sensor when exposed to hydrogen-composed atmospheres. A particular care was paid to avoid hydrogen leakage in the working environment and to perform the regeneration of the gas absorbing layer. The developed SAW devices exploiting hydrogen absorption capabilities of palladium layers exhibiting different thicknesses have been here used to make the detection and the identification of hydrogen concentrations (in the 0.25-2% range) diluted in nitrogen and is also able to make detection in current atmosphere. The effect of the palladium thickness variations along with the influence of an Yttrium doping of the palladium layer on the sensor behavior will be studied here.**

I. Introduction

The raising shortage of fossil energy resources added to the increasing concern towards environmental issues have led to consider hydrogen as one of the most promising energy resource. This odorless and colorless gas being highly explosive over 4% concentration in air, the availability of a fast and accurate detection system close to storing facilities and equipping hydrogen-operated machines is mandatory for obvious security reasons. Such a system must exhibit a significant selectivity as it must detect the presence of gaseous hydrogen in air with concentrations smaller than the above-mentioned critical limit at standard conditions (room temperature and atmospheric pressure) as well as in harsher environment (very low or significantly high temperature). Besides some solutions have been proposed [1] [2] [3] [4] [5] [6] [7]. The current availability of such a detection system meeting modern specifications of hydrogen use and storage is still questionable. The mains improvements for such sensors are their sensitivity, their selectivity and their reliability together with sensor size, cost reduction, energetic needs and response time [8]. Many methods of detection of hydrogen and a comprehensive review can be found in the literature [9], providing a substantial material base to try and address the above challenges. Among the possibilities, SAW (Surface Acoustic Wave) sensors have been widely studied in the last decades because of their attractive capabilities. Indeed, SAW devices exhibit high sensitivity to surface perturbation since the quasi totality of the energy propagates in a region that thickness is a few times the wavelength of the propagating acoustic wave. It is also a mature technology, SAW device do exhibit limited size (less than 1 cm²) and they allow for wireless use [10]. Initial works were made by D'Amico et al. [11] using the properties of palladium layer to trap the targeted gas. Since this pioneer work, innovations concerning the selectivity and stability of sensitive layers versus external parameter have been proposed to improve hydrogen detection using SAW devices [12] [13] [14] [15] [16] [17] [18] [19]. In this paper, a SAW sensor is proposed for detecting gaseous hydrogen in standard environmental conditions (atmospheric pressure and room temperature). The proposed SAW sensor consists in two Rayleigh-wave delay lines built on Quartz, one covered with a Palladium (Pd) overlay and the other exhibiting a free path between the two interdigitated transducers (IDTs) used to excite and detect the acoustic wave. These IDTs are built using aluminum electrodes, as this metal is known to be inert versus gaseous hydrogen. An innovative aspect of the proposed sensing system consist in the open-loop strategy for phase changes monitoring [20]. Moreover, delay lines are monitored in parallel using a synchronous detection approach that provides high frequency measurement resolution and that permits a systematic characterization of the device before operated. Along this approach, the impact of changes of intrinsic properties of the devices such as working frequency drift with aging can be minimized. The developed device allows for identifying different concentrations of hydrogen diluted in N_2 and is also able to detect H_2 in current atmosphere. The SAW sensor as well as the exploited monitoring system will be first exposed. Experimental validation of H_2 detection then is reported, with a description of the chemical test bench and detection results for various palladium layer thicknesses. An analysis of the influence of that thickness on H_2 adsorption and its influence on SAW propagation is proposed to provide routes for the device optimization.

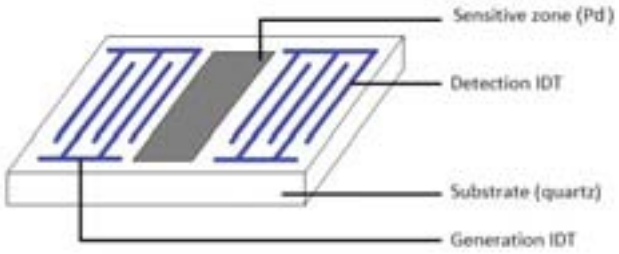

Fig. 1. Scheme of a SAW delay line using Rayleigh surface acoustic wave at 78MHz.

II. SAW SENSOR AND ASSOCIATED MONITORING SYSTEM

Selective detection of hydrogen at room temperature and pressure have been achieved using SAW delay lines exploiting Rayleigh waves on AT-cut Quartz, as the corresponding first order temperature coefficient of frequency (TCF) is close to zero, yielding frequency-temperature compensation for the above-mentioned operating conditions. The configuration of both generation and detection IDTs used for the sensor consist in 50 fingers pairs with a grating period of 10 μm and a center-to-center spacing of 5mm (the reactive surface). The wavelength is 40μm, yielding a frequency operation in the vicinity of 78MHz as the wave velocity approaches 3100m.s^{-1}. The Pd and Y-Pd alloy films were deposited by thermal evaporation on a single run and shaped by a lift-off technique. Its length along the propagation path was 3mm and its thickness varies from 15 nm to 300 nm. The device configuration is shown on Fig. 1.

Using a network analyzer, the transfer function of the device can be easily determine and hence the phase shift induced by gas absorption has been first monitored that way. However, the use of a dedicated electronics has been implemented and delivers similar information. That is represented on Fig. 2. This system includes two separated phase measurement schemes: a rough characterization stage using the AD8302 phase and magnitude detector, and a high sensitivity phase measurement using dedicated phase detectors and variable gain, low noise operational amplifiers as presented in another work [20]. The sensitivity of the set-up allows for some tens mill-degrees resolution and is easily transportable. The response of the bare device and the functionalized one are respectively measured. This configuration has been used so as to make a systematic characterization of each new device used for H_2 detection. Fig. 3 illustrates the way the phase shift measurement is achieved.

III. SIMULATION RESULTS

A crucial part of the developement of such a sensor consists in the improvement of its sensitivity and its response time. Simulation results are expected to provide informations on the way the sensing layer has to be designed in order to optimize its efficiency. In that purpose, a theoretical study of the influence of the palladium layer thickness on the sensor response upon the hydrogenation is here exposed.

Accurate calculations have been achieved, based on a set of programmes dedicated to the analysis of stratified structures

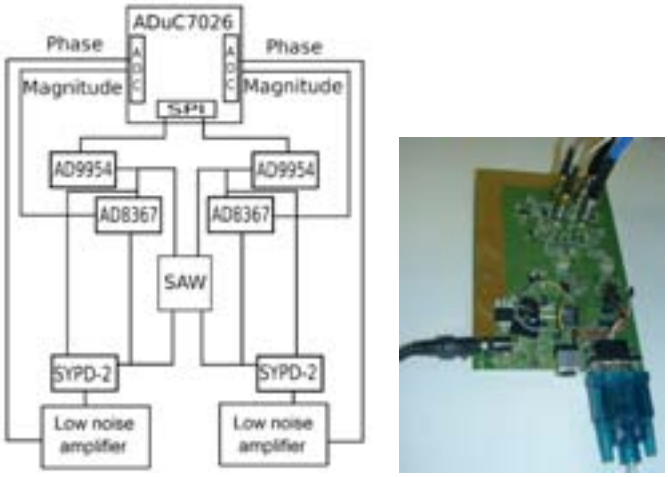

Fig. 2. Scheme and photograph of the SAW devices probing card.

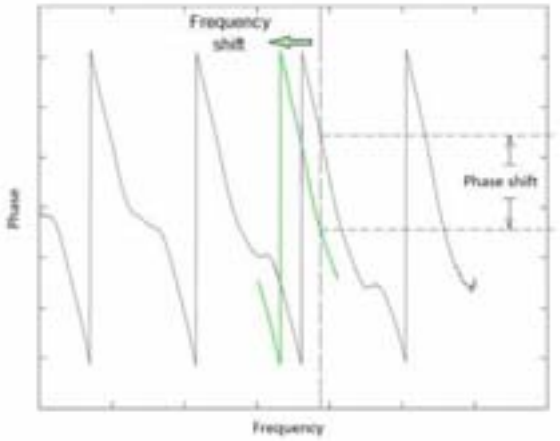

Fig. 3. Phase shift measurement principle using a dedicated instrumentation.

used as elastic wave guides. The fundaments of the corresponding developments have been presented in [21] [22]. The calculation principle is based on the derivation of a surface or interface effective permittivity yielding numerous information about the wave propagation characterictics such as the wave velocity, the mode coupling and possible propagation losses. The model accounts for all the known linear properties of the materials constitutive of the layered structure which directly condition the accuracy of the results as no assumption is made on the device operation (provided flat interfaces). Moreover, since only devices composed of Quartz substrates have been used here, changes in electrodes conductivity are not consider as a possible origin of the observed phase velocity drift and therefore were not taken in account in the proposed analysis. Electromechanical coupling of Rayleigh waves on Quartz substrates is actually small enough to consider conductivity changes negligible. As shown by Anisimkin and al in [23] the two main phenomena that influence the phase velocity change of elastic waves on Quartz are mass- and elastic-loading. This theoretical study takes into account the contribution of

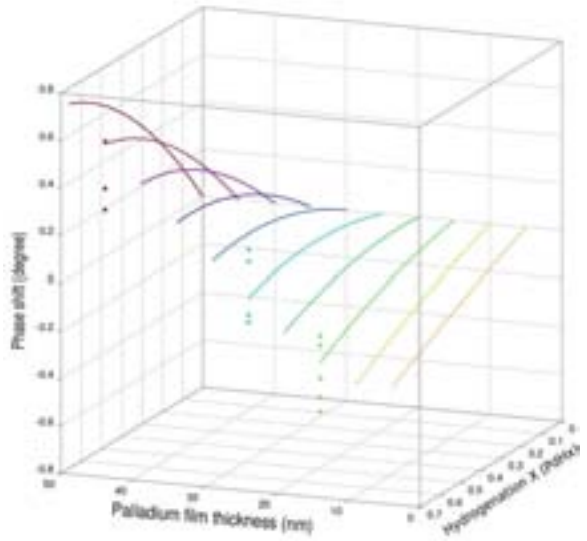

Fig. 4. Simulated phase shift of the Rayleigh wave that propagate through palladium films of different thicknesses upon its hydrogenation.

both phenomena provided some parametric adjustement. It is actually considered here that the finer the sensitive layer is the more important mass-loading effect becomes. Indeed, for Pd layer that thickness is less than 20nm, we consider an expansion of the layer close to zero because of the influence of the substrate. This assumption permits to explain the mass-loading observed for very thin films. Otherwise mass-loading is evidenced by the damping of the transfert function in magnitude which is characterictic of this phenomenon. On an other hand, the Rayleigh wave is more affected by elasticity modification of the Pd layer than mass-loading then the thickness of this one increases. One can see on Fig. 4 the theoretical phase shift upon hydrogenation for different film thicknesses. These calculation are in adequacy with experimental results symbolized by the points. One can notice a difference between the shape of simulation results and the experimental ones exposed in the next section. Actually, calculations don't take into account the absorption dynamics of the hydrogen through the palladium layer. The comparison with experimental data is so made for a total hydrogenation of the palladium layer that corresponds to an hydrogenation coefficient $X = 0.66$ on Fig. 4.

IV. Experimental results

Detection of hydrogen using SAW delay lines exhibiting different thicknesses of palladium as functionalizing films have been achieved at room conditions. Figs. 5 and 7 present experimental results when using nitrogen as carrier gas. The detection of about 2%vol of hydrogen in N_2 at 35% RH and 20°C can be achieved with a minimum response delay of 10 seconds for considering that the determination of the H_2 concentration in the melting gas is derived from the phase shift velocity during the exposure and not from the steady state.

As shown on Fig. 7, the functionalizing film thickness appears as a way of improving the reactivity of our sensor.

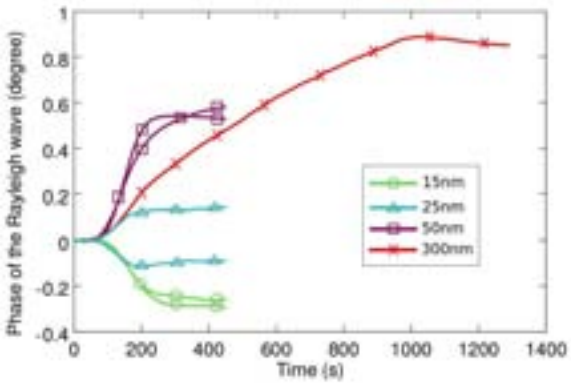

Fig. 5. Experimental Rayleigh wave's phase shift induced within palladium layers of different thicknesses during hydrogenation under 2%vol H_2.

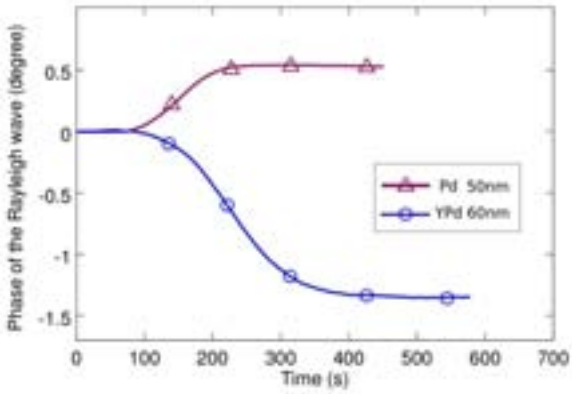

Fig. 6. Experimental Rayleigh wave's phase shift induced within Pd and Y-Pd alloy sensitive layers during hydrogenation under 2%vol H_2.

Indeed, a maximum phase shift velocity of 4±0.7 degree.s^{-1} has been observed for the 50nm palladium functionalized device. Contrary to the others for which the phase shift velocity modulus doesn't exceed 2 degree.s^{-1}. One will notice that the parameter to improve is the phase shift velocity modulus. Actually, depending on either mass- or elastic-loading is the largest effect occuring during the hydrogenation, an decrease or an increase of the phase will be observed. The aim of this work is to maximize the phase shift velocity irrespectively of the direction of change.

As the sensitivity and reactivity of our device depends on the capability of the functionalizing layer to trapp the surrounding hydrogen, a chemical doping of this layer has been made to investigate its influence on the sensor operation. Preliminary result concerning Yttrium doping can be seen on Fig. 6 and 7. It shows that the Yttrium doping allows for increasing the phase shift velocity during the hydrogenation. Indeed, this velocity is -7.62 milidegree.s^{-1} for an exposition to 2%vol H_2 in N_2 that is about twice the largest value reached this undoped palladium. In this case, mass-loading is the most efficient effect that impact the behavior of the wave. We note that this is an encouraging preliminary result that needs to be validated in terms of repeatability and reversibility.

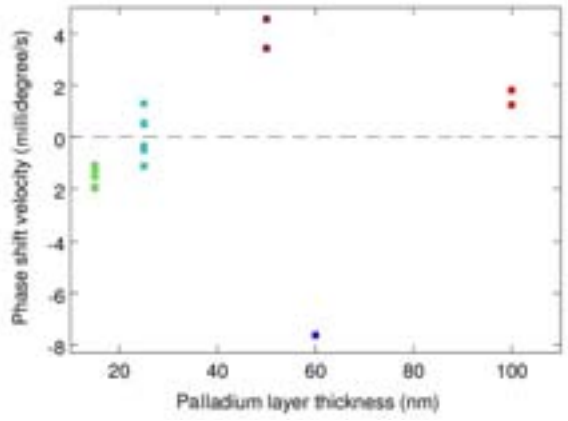

Fig. 7. Experimental phase shift velocity observed with different thicknesses of palladium and Y-Pd alloy under hydrogen 2%vol.

V. Conclusion and further works

Here has been evidenced the capability of our hydrogen sensor to operate in the 0.25-2% range in nitrogen. The influence of thickness variations of the palladium film together with the Yttrium doping of the sensing layer have been studied. It finally appears that the use of a certain sensing layer thickness allows for exploiting either mass- or elastic-loading that both occure during the hydrogenation. Considering the technological restraint, a few thicknesses have been investigated and it has been observed that the use of palladium layer that thickness are less than 300nm allows for minimizing the dependence on the adsorption dynamics of H_2 through Pd of the response time of the device.

Further works will consist in studing the absorbtion dynamics of hydrogen through palladium film and also the ways to promote a faster absorption so as to enhance the sensitivity and reactivity of our sensor. Physical analysis of sensitive layers during hydrogenation will be made in order to explain and improve the parametric adjustment used to simulate the comportment of our devices. The use of different thicknesses of Y-Pd alloy will also be studied in order to reinforce our knowledge concerning this promising way of trapping hydrogen.

Abstract—**The research on surface acoustic wave (SAW) tag has lasted many years. However, the application and promotion are unsatisfactory due to the inherent defects of the manufacturing technology of the large capacity SAW tag. From the perspective of practical production, this paper proposes a novel design of SAW tag to reduce costs. The method is based on the correlation IDT and permutations and combinations theory. At the same time, some ideas about the reader structure for this SAW tag are given.**

Keywords- SAW Tag; large capacity; correlation IDT; anti-collision tag unit; SAW Tag reader.

I. INTRODUCTION

Compared with the integrated circuit (IC) tag, the SAW tag has many advantages, including wireless, passive operation, but the biggest disadvantage is that the capacity is too small especially in the case of the amplitude modulation SAW tag. The capacity of SAW tag based on the simultaneous time position and phase shifting is enough for global application.[1] But in order to ensure the consistent amplitude of reflector echoes and time domain resolution sensitivity, tags with different codes need to be designed and manufactured separately, leading to high manufacturing cost. The correlation SAW devices with phase-shift keying (PSK) method avoid the adverse effects of low SNR [2], and also get the characteristic of anti-collision. [3] This paper presents two types of SAW tag, one is the medium data capacity type consisting of the traditional interdigital transducer (IDT), and the other is the large data capacity type that contains correlation IDT coded by PSK method. Both of them use the pulse position modulation (PPM) and theory of permutations and combinations.

II. MEDIUM CAPACITY SAW TAG

A. Basic PPM SAW Tag

The SAW pulse propagates along the surface of the substrate, which is usually made of a material with strong piezoelectricity, such as lithium niobate (LiNbO3). The SAW pulse is partially reflected and partially transmitted by each of the code reflectors, placed at precisely determined positions on the chip. These reflectors usually consist of one or a few narrow aluminum strips. The reflected SAW pulse returning to the IDT carries a code based on the positions of the reflectors. In other words, this encoding method is based on the time delays of reflected pulses. It is known as time position encoding or pulse position modulation (PPM) in figure 1. When the echo pulses returns to the IDT, the acoustic signal is then reconverted into an electrical form and retransmitted by the tag antenna. The response signal is then detected and decoded by the reader. [4]

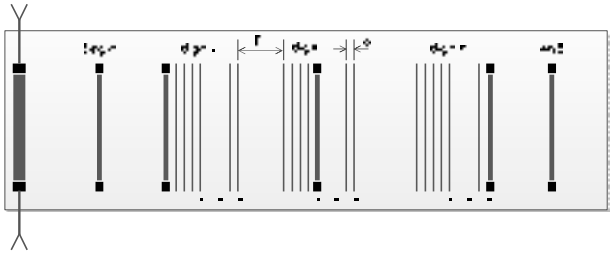

Figure 1. Structure of PPM SAW tag

The tag contains begin and end reflectors used for calibration and several digit areas. In each digit area there is one or more reflectors, and the number of the positions in every digit area is determined by time slots. D is the width of pulse exclusion region, and d is the width of a slot.

In figure 1, the number of the slots in each digit area is x and there is only one reflector in it. The number of digit area is n. So the capacity of this tag is x^n. When the length of the tag is constant value, the larger capacity means bigger x and n, then D and d are smaller, which are determined by the band width of IDT and the time resolution of the reader. The design will be much more difficult because the reader relies on the echoes amplitude and time delay to decode. The situation of each tag is different, so we need to design and manufacture each tag separately to ensure the consistent amplitude of reflector echoes and time domain resolution sensitivity, which is impossible.

B. Mediun Data Capacity SAW Tag

Compared with single acoustic channel, multi acoustic channels SAW tag partly reduced the multiple reflections. [4] Even if the loss is higher in every channel, but it is still a good idea to pre divide the energy of the integration pulse. So we come up with a new type of combined SAW tag. Assume that there are eight reflectors including two calibration reflectors and six digit area reflectors. First they are parity divided into

two tag units, and then in each unit the reflectors are equally distributed on two acoustic channels as shown in figure 2.

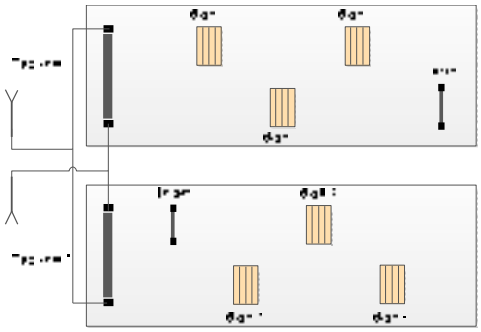

Figure 2. Multi acoustic channels and combination of PPM SAW tag

The two tag units access the antenna in parallel and form a combined tag. Figure 3 shows the Amplitude verse Time of echoes. The calibration reflectors in different units are used to calibrate the fabrication error. tag unit 1 uses the end reflector as reference while tag unit 2 uses the begin reflector as reference. The time delay between digit reflectors and calibration reflectors is used for distinguishing which tag unit an echo belongs to and for getting the code of each tag unit.

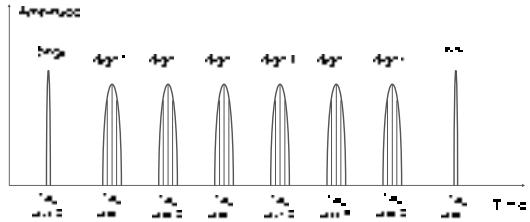

Figure 3. Amplitude verse Time of combined PPM SAW tag choes

The data capacity of this combined tag is the same as the traditional PPM tag, but the echo consistency is much better. The most significant point is that it can greatly reduce the number of photo masks, which are the most expensive during manufacturing. If the number of slots in each digit area is 4, the capacity is 4^6 equals to 2^{12}. To conventional PPM tag, it needs 4^6 photo masks; to this type of SAW tag it only needs $2*4^3$ photo masks. Because tag unit 1 and tag unit 2 can be combined freely. The cost is reduced to one tenth.

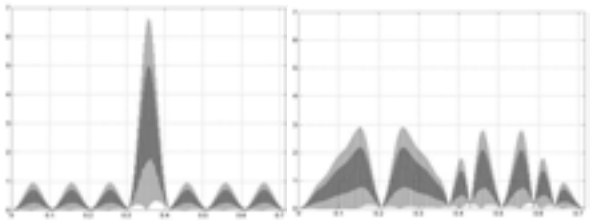
But this combined tag also has drawback; in this example, if the tag operates at 434MHz and IDT bandwidth is 20MHz, we must carefully choose the positions of the first and second reflectors so as to shift the round-trip interference of them to the pulse exclusion region or behind the last digit area. When expanding the data capacity of this type SAW tag, it's necessary to take the round-trip interference of more reflectors into consideration. So it is not suitable for large capacity applications.

III. LARGE CAPACITY SAW TAG

IDT modulated by PSK method can be called Correlation IDT (CIDT). It can only respond to the corresponding PSK modulated carrier pulse, namely the autocorrelation while to the wrong PSK modulated carrier pulse it wouldn't return any response, called cross-correlation. In the case of autocorrelation, the CIDT will generate a typical peak on the substrate while in cross-correlation it won't.

A. *Anti- collision CIDT*

The key of an anti-collision SAW tag unit is the CIDT. By using barker code sequence or Orthogonal Frequency Coding (OFC) method [5] etc., the CIDT obtains coding and anti-collision characteristics. For example, figure 4 shows the simulation result of the coding IDT output when a 7-bit barker code sequence [1110010] is used. Figure 4(a) shows the autocorrelation. Figure 4(b) is the output when input sequence is [1011000], which is the minimum cross-correlation peak value among 7-bit barker codes.



(a)7-bit barker code autocorrelation (b)[1011000] with [1110010] cross- correlation

Figure 4. Simulation result of CIDT output

B. *Structure of anti-collision SAW Tag units*

The structure of the anti-collision SAW tag unit (in figure 5) also contains multi acoustic channels and adapts on PPM. But the position of digit area in each tag unit doesn't have any relevance which is different from the medium capacity SAW tag. When a corresponding PSK carrier pulse loads on the CIDT, it will generate a typical peak that propagates along the substrate. After the peak meets the digit reflector and returns to the CIDT, it will be shifted to PSK code output from antenna.

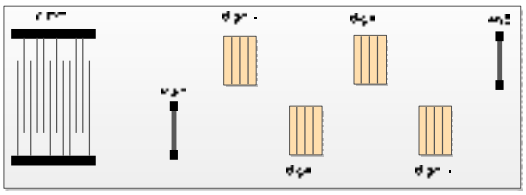


Figure 5. Structure of anti-collision SAW tag units

C. Structure and the capacity of conbined SAW tag

The combined SAW tag (in figure 6) is formed by a number of anti-collision SAW tag units which also access the antenna in parallel.

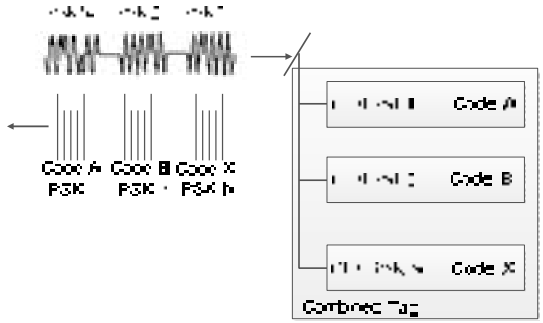

Figure 6. Structure of large capacity SAW tag

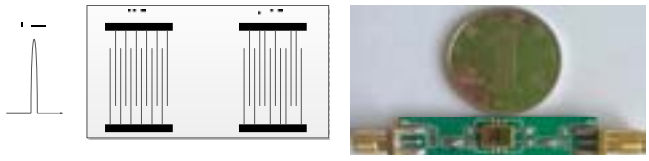
When the reader sends a sequence of PSK code modulation carrier pulses, the tag units with corresponding CIDT respond one by one according to the order of the inquire pulses.

The compatibility N is the number of anti-collision SAW tag units in a combined tag, which is determined by the PSK code group used on the CIDT. Thus, high compatibility of a non-periodic polar code group is necessary in large capacity applications.

Our team recently has found a 13-bit encoding group based on the communications coding theory, the compatibility of which reaches 8. If the number of the digit slots and digit areas in each unit is 6 and 4, the capacity of this combined SAW tag is $(6*6*6*6)^8$equals 2^{83}. It is enough for global applications, and only 6^4*8 photo masks are needed.

D. Some ideas about the reader structure

As the frequency of the carrier is very high (434MHz), how to generate a PSK modulated carrier pulse becomes a problem. The first solution presented in figure 7 (a) is to use a SAW en coding correlator.



(a). Structure of correlator (b). instance of correlator

Figure 7. SAW encoding correlator

When a carrier pulse is loaded on the ordinary IDT, we can get a PSK code modulated signal from the CIDT which can be used as interrogation pulse for the combined tag.

We have built a 8 bit PSK code SAW encoding correlator (in figure 7(b)) for test. Every bit contains 28 carrier cycles and the code is [00101100], the width of the load pulse is 10ns, the result as shown in figure 8.

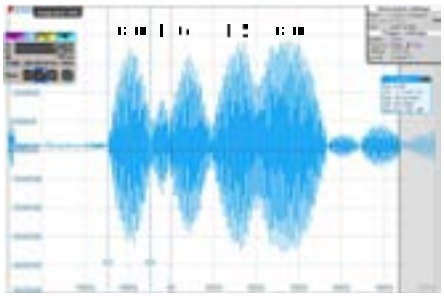


Figure 8. Output of SAW encoding correlator

The result agrees with our design well, every bit last 65ns,which equals 28*(1/434MHz). But there are two defects of this solution. First, the number of the encoding correlators in a reader is the same with the number of the anti-collision SAW tag units in a combined tag, which is very inconvenient for reader switching among encoding correlators when reading a combined tag. Second, when the reader and the tag are in different temperature areas, the reader may not get any response.

According to the definition of Software Defined Radio (SDR), the second solution uses fast switching single pole double throw (SPDT) to switch a differential carrier signal to generate a PSK modulated pulse. Figure 9 shows the structure of this solution and figure 10 shows the test result.

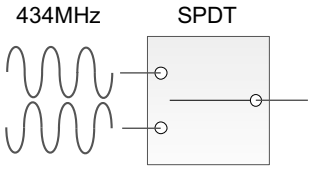

Figure 9. Structure of second solution

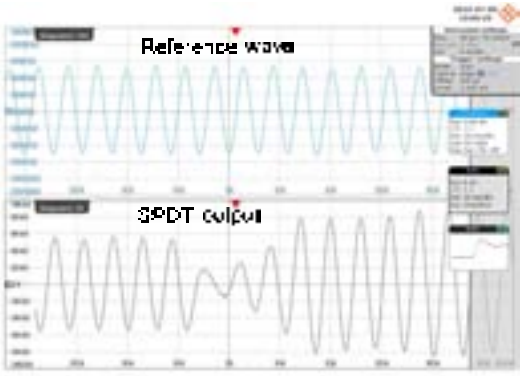

Figure 10. Output of SPDT

Contrast reference with output, the switch time of the SPDT is less than 5ns, which is very fast. The second solution overcomes the two defects mentioned above. By changing the control signal on the SPDT，the output can be any PSK code.

And by sweeping the frequency of the carrier, the center frequency of the combined tag can be found and the max echo amplitude can be obtained no matter what the temperature is.

IV. CONCLUSION

A novel large capacity SAW tag has been presented. The capacity can achieve 2^{83}, which is enough for global applications, and it is suitable for massive production by using correlation IDT and permutations and combinations theory. The reader structure is also discussed and the SPDT solution is much better.

The medium capacity SAW tag is very simple and the reader is easy to realize. It is suitable for some industrial application in a small area.

ACKNOWLEDGMENT (HEADING 5)

***Abstract*—We report a micro-machined Tonpilz hydrophone that uses the piezoelectric thickness mode and is suitable for the audible frequency range (i.e., 20Hz–20kHz). The structure of the sensor is based on the structure of a conventional Tonpilz transducer; however, two different design approaches were investigated to enhance sensitivity and to withstand the high-pressure underwater environment. To improve the sensitivity, the area ratio of the head mass to the piezoelectric body is several hundreds to one, which amplifies the acoustic pressure input of the transduction body. To improve the resistance to the hydrostatic pressure in the deep-water environment, the structure uses a castor oil backing to balance the hydrostatic pressure at the front surface of the acoustic sensing structure. We developed a lumped element model to investigate the design parameters for miniaturized hydrophones. The hydrophone was then fabricated using micromachining, and tested by comparing the device with a commercially available hydrophone in an anechoic bath to assess the feasibility of its use as an effective underwater sound receiver.**

Keywords-Piezoelectric MEMS; Underwater receiver; Acoustic sensor; SONAR

I. INTRODUCTION

Micromachined underwater acoustic sensors have numerous advantages including their small size, practicality, and low-cost due to batch fabrication [1-4]. Micromachined hydrophones may enable a number of new applications if they can be constructed with satisfactory specifications. For example, the hydrophones used as components of towed-array SONAR (TAS) for both civilian and military purposes require high sensitivity, stability to environmental noises, and robustness for deep-sea applications [5]. Low-cost miniaturized hydrophones with the required specifications may allow the realization of usable thin TAS, cost-effective sonobuoys, and compact arrays that can be used as a new type of vector sensor. Miniaturized hydrophones may also find uses in applications such as underwater unmanned vehicles (UUVs) [6].

Conventional hydrophones are typically fabricated using assembly processes with a number of specially designed parts. In recent years, various types of micromachined hydrophones have been reported, including condenser hydrophones and piezoresistive hydrophones [1-4]. These existing devices have shown feasibility for specific applications; however, it should be noted that the reported sensitivities were relatively low at frequencies below several kHz. In this paper, we describe the development of a micromachined Tonpilz hydrophone (hereafter referred to as a micro-Tonpilz hydrophone) for audible frequencies. The basic structure of the sensor, shown in Fig. 1, is based on the structure of a conventional Tonpilz transducer; however, two different design approaches were used to enhance the sensitivity and improve the resistance to the high hydrostatic pressure of the deep-sea environment.

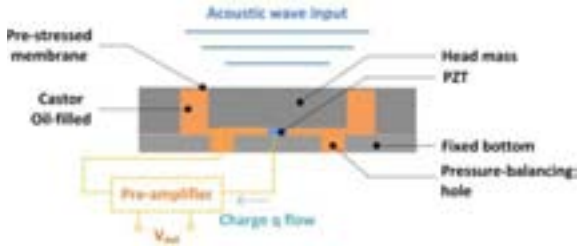

Figure 1. Cross-sectional schematic diagram of the micro-Tonpilz hydrophone. The device is circularly symmetric.

In contrast to conventional Tonpilz transducer, we designed our device with so that the area ratio of the head mass to the piezoelectric body was very large, up to several hundreds to one. This amplifies the input acoustic pressure to the transduction body, and the pressure amplification mechanism is expected to realize high sensitivity with a small device size if a properly designed pre-amplifier is used.

Additionally, the structure used a castor oil backing, which is effective in balancing the hydrostatic pressure of the deep-sea environment. To design the hydrophone for deep-sea applications, we developed a lumped element model to identify

This research was financially supported by a grant to MEMS Research Center for National Defense funded by DAPA/ADD, in the Republic of Korea.

the requirements for the pre-amplifier circuits and to design the miniaturized hydrophones appropriately.

II. Design of the Micro-Tonpilz Hydrophone

A. System model based on a 1-DOF lumped-element model

Figure 2 shows the 1-degree-of-freedom (DOF) lumped element model (LEM) of the micro-Tonpilz hydrophone. The model represents the mechanical impedances of the sensor, and comprises the impedance of the sensor itself Z_m, the radiation impedance applied by medium on the sensor Z_r, and the impedance at the back of the structure Z_b.

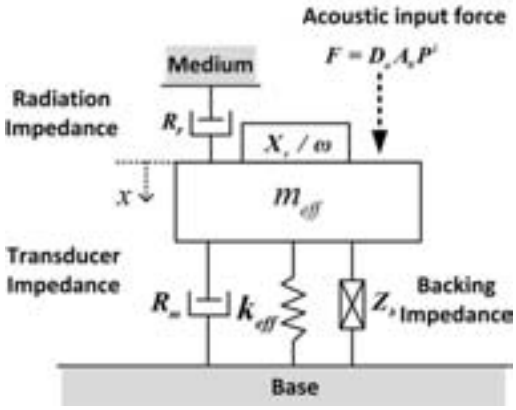

Figure 2. 1-DOF LEM of the micro-Tonpilz hydrophone

The modeling was performed assuming that the sensor is much smaller than the wavelength of the sound. The impedance of the sensor was analyzed as a function of the major parameters of the structure. The mass of the head attached to the central core on the membrane was considered the dominant effective mass. The stiffness was also analyzed by considering the compliance of the lead zirconate titanate (PZT) and the membrane separately. The PZT was assumed to be a bar with one DOF in the LEM; however, the electromechanical coupling was also considered to improve the accuracy of the modeling of the motion of the PZT.

Although the modal analysis of the proposed sensor structure calculates the fundamental mode (PZT thickness mode), the following points should be carefully considered. If the head mass is too large and the membrane is too compliant, an unwanted lateral fundamental mode of the structure can occur. In this case, we cannot expect that pressure amplification will be effective. Even though the membrane surrounding the head mass can be expected to lead the fundamental mode of the structure with motion in the axial direction, if the surrounding membrane is too stiff, which helps to avoid the lateral mode, this can reduce the sensitivity. This implies that membrane stiffness should be carefully chosen. The stiffness of the surrounding membrane was calculated assuming a circular membrane with an attached core. The impedance components are listed in Table I.

TABLE I. Impedance components

Impedance	Component	Description
$Z_m = R_m + j(\omega m_{eff} - k_{eff} / \omega)$	m_{eff}	Effective mass
	k_{eff}	Effective stiffness (PZT stiffness + membrane stiffness)
	R_m	$R_m = Q_m^{-1} \cdot (m_{eff} k_{eff})^{1/2}$, where Q_m is the mechanical quality factor at resonance in a vacuum.
$Z_r = R_r + jX_r$	R_r	Assuming that $kR \ll 1$, R_r can be approximated to $(1/2) \cdot \rho_0 c A_0 \cdot (kR)$, where ρ_0 is the density, c is the speed of sound, k is the wave vector; A_0 is the area and R the radius of a rigid circular piston.
	X_r	$\approx (8/3\pi) \cdot \rho_0 c A_0 \cdot (kR)$
$Z_b = R_b - jX_b / \omega$	R_b	The backing impedance was considered as a resistive element from the flow of the castor oil through backing hole R_b, and the backing stiffness can be determined from the backing chamber dimensions X_b.
	X_b	

Now we consider the open-circuit piezoelectric constitutive equation, i.e.,

$$\begin{pmatrix} F \\ e \end{pmatrix} = \begin{pmatrix} k_{eq} & -1/d_{eq} \\ -1/d_{eq} & 1/C_{eq} \end{pmatrix} \begin{pmatrix} \delta \\ q \end{pmatrix}, \tag{1}$$

where

$$k_{eq} = \left(\frac{1}{1-k_{33}^2} \right) \cdot \frac{A_1}{s_{33}^E t}, \quad \frac{1}{d_{eq}} = \frac{k_{33}^2}{1-k_{33}^2} \cdot \frac{1}{d_{33}}, \quad C_{eq} = (1-k_{33}^2) \cdot \frac{\varepsilon_{33}^T A_1}{t},$$

and

$$k_{33}^2 = \frac{(d_{33})^2}{\varepsilon_{33}^T s_{33}^E}$$

is the electromechanical coupling coefficient and A_1 is the area of the PZT transducer. Taking the mechanical impedances of the 1-DOF LEM, the constitutive equation for the PZT connected to a pre-amplifier that has an electrical input impedance of Z_{in}, we can derive the electromechanical system model and frequency response function by taking the Fourier transformation for the equation of motion.

B. Advantages of the pressure-amplification structure

Using the analytic system model for the micro-Tonpilz hydrophone, we can calculate both the frequency response of the structure and the pressure amplification. The frequency response was simulated using the material properties of PZT based on model C-6 from the Fuji Ceramics Corporation.

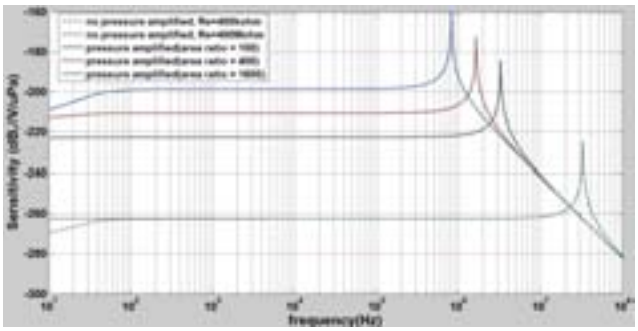

Figure 3. Simulated sensitivity as a function of frequency. The solid line is the amplified pressure, and the dashed line is without pressure amplification (i.e., with an area ratio of 1).

Simulated data are shown in Fig. 3 using a sensor with a diameter of 2 mm. The designation "without pressure amplification" refers to the area of the PZT similar to that of the head, which is typical in ultrasonic applications. "Pressure amplification" corresponds to a relatively small area of PZT compared with the area of the head. The PZT was 3 μm thick, which is consistent with the sol-gel PZT deposition process used in microelectromechanical systems (MEMS) fabrication. The open-circuit sensitivity in the flat-frequency response range is $V / p_i = g_{33} t$, where g_{33} is the piezoelectric constant, and t is the thickness of the PZT. This implies that the sensitivity in the flat-frequency response region of the micromachined hydrophone using the PZT thickness mode may be limited to relatively low sensitivities. This is reflected in the simulated data shown in Fig. 3; without pressure amplification, the sensitivity was relatively low in frequencies below the fundamental resonance, and only frequencies close to the resonant frequency showed acceptable sensitivities. This may explain why most previous applications of micromachined hydrophones using the piezoelectric thickness mode have focused on ultrasonic resonant applications.

Pressure amplification significantly increased the sensitivity in the flat-frequency response range, even with a thin PZT layer and small sensor size, which increased the bandwidth. Assuming a pre-amplifier input impedance of 400 MΩ, a good frequency response with a wide bandwidth is expected. The sensitivity was -200 dB (Ref. V/μPa) without pre-amplification, which is significantly higher than that of a commercially available miniature hydrophone.

III. Fabrication of the Micro-Tonpilz Hydrophone

The fabrication of a number of designs derived from the system model was carried out. The micromachining fabrication of the sensor includes two main elements: the fabrication of the pressure amplification structure (i.e., head mass and surrounding membrane) and the fabrication of the patterned PZT that is electrically connected to the output line. The final step is eutectic bonding to combine the fabricated parts. After bonding, the micro-sensor was diced, assembled, and packaged with a custom pre-amplifier.

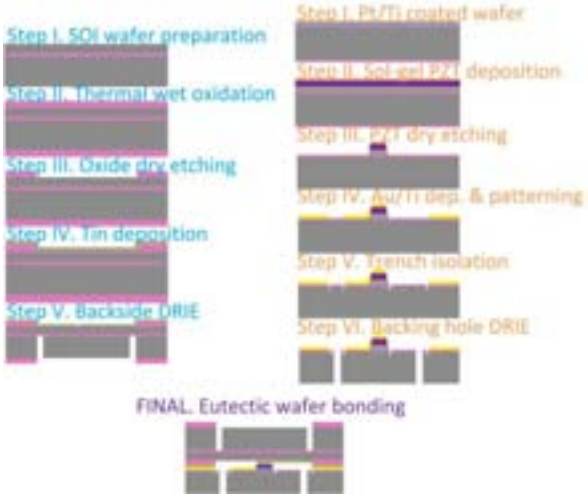

Figure 4. Micromachining process for the micro-Tonpilz hydrophone.

The fabrication process is shown schematically in Fig. 4. A 300-nm-thick layer of thermally grown oxide was prepared on a silicon wafer, and then the Pt/Ti bottom electrode layer was deposited. The PZT film was deposited using the sol-gel process. The Zr/Ti ratio of the PZT layer was 52/48. A Pt top electrode layer was deposited, and a thermal anneal was performed. The PZT layer was then patterned using photolithography and dry etched. To form the signal line, an Au/Ti layer was deposited using an electron-beam evaporator and patterned using photolithography. Shallow trench isolation was performed to suppress the leakage currents. Finally, the backside was etched away using deep reactive ion etching (DRIE) to form the backing hole.

The head-mass part was fabricated from a silicon-on-insulator (SOI) wafer to form a membrane structure. A high-resistivity SOI wafer (>10 kΩ·cm) was used to minimize the leakage current. The head-mass structure surrounded by the membrane was fabricated using DRIE. The final eutectic bonding was performed as a wafer-level process.

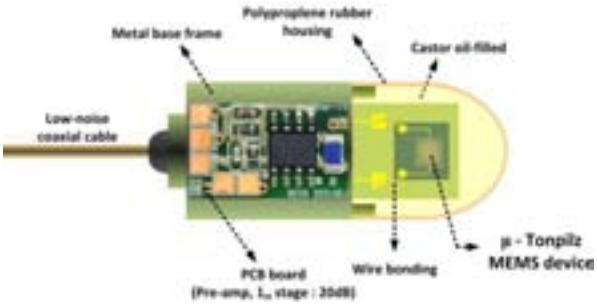

Figure 5. The assembly and packaging of the micro-Tonpilz hydrophone.

The completed micro-Tonpilz hydrophone was diced into chips and packaged as shown in Fig 5. The gain of the first stage pre-amplifier was 20 dB. The second stage pre-amplifier amplified the signal, which was transmitted using low-noise coaxial cable. A metal base frame made from stainless steel

and PCB housed the first stage pre-amplifier and was fixed to the frame. The micromachined sensor was attached on to the PCB and electrically connected using wire bonding. Finally, an acoustically transparent polypropylene rubber cap was placed on the structure, and the assembly was filled with castor oil.

IV. Results and Discussion

The hydrophone was characterized experimentally using small anechoic bath. Using a comparison method in which the micro-Tonpilz hydrophone and a reference hydrophone (B&K 8103) were fixed in similar positions and received the sound generated from an underwater loudspeaker, the micro-Tonpilz hydrophone was characterized. The underwater experimental set-up is shown in Fig. 6.

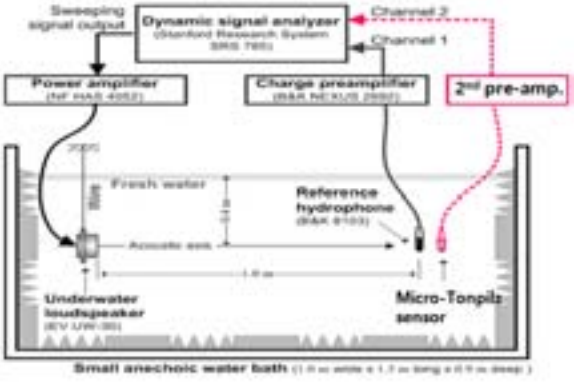

Figure 6. Underwater experimental set-up using a small anechoic bath.

Both the frequency response and the time-domain response were measured; the results are shown in Fig. 7. The sensitivity of the micro-Tonpilz hydrophone was approximately -200 dB (Ref. V/μPa, pre-amplified) in the range 700–4,000 Hz. At low frequencies, the underwater loudspeaker generated a relatively low sound-pressure level, and the measured signal-to-noise ratio was poor. This is attributed to roll-off noise and external electromagnetic interference. Although the fabrication of the micro-Tonpilz hydrophone was successful, some problems can be observed from the measured data. First, more effective shielding to block external electromagnetic noise is required. This seems to be critical, as both the sensor and the pre-amplifier had very high electrical impedance, making the device sensitive to the external noise sources. Second, the pre-amplifier design and sensor design should be optimized more. Although the sensitivity of the micro-hydrophone was not as great as expected, we have demonstrated feasibility for signal transduction at audible frequencies.

Abstract—**Due to its high sensitivity, repeatability and easy connection with electrical measurement systems, Quartz thickness-shear-mode (TSM) resonator is adopted to extract the complex shear modulus of Parylene-C films, which play an important role as both an effective wave-guiding layer and biocompatible interfacial layer in Shear-Horizontal Surface Acoustic Wave Device (SH-SAW, Love Mode). Parylene-C films of different thicknesses were deposited on the surface of AT-cut quartz TSM resonators, and admittance spectrums of these uncoated and coated TSM were measured by an impedance analyzer. Results indicated that the ideal thickness range for extraction was from 2.04 *μm* to 3.55 *μm*, effectively avoiding inadequate acoustic deformation as well as excessive electrical-response attenuation. The storage modulus *G′* and loss modulus *G″* of Parylene-C were 0.155±0.011 *GPa* and 4.78±0.44 *GPa*, respectively.**

Keywords-SH-SAW; TSM; TLM; Parylene-C; shear modulus

I. INTRODUCTION

Shear-Horizontal Surface Acoustic Wave Device (SH-SAW, Love Mode) is considered as one of the most promising probing methods in both fundamental biology and biomedical engineering, detecting behaviors of cells on their surface in a non-invasive, simple and quantitative manner [1-2]. Comparing with the traditional Bulk Acoustic Wave Sensors (BAW), Rayleigh waves excited by surface electrodes in SH-SAW perform extremely sensitivity to certain surface perturbations as well as favorable inertness to other surrounding factors, resulting in an extensive application prospect of SH-SAW in complicate liquid or multiphase circumstances [3-4]. As the key part of SH-SAW, acoustic-wave guiding layer on surface plays a crucial role in improving the device performance. Parylene-C (poly(2-chloro-*p*-xylylene)) has been proven as ideal acoustic-wave guiding layer owing to its good uniformity, compactness and adhesion to the substrate [5]. Meanwhile, of comparative cell compatibility, Parytlene-C films also have preferable effects on the bio-sensitivity interference on SH-SAW surface [6]. Presently, some relevant studies have been explored concerning SH-SAW with Parylene-C guiding layer [5,7]. However, most of them neglected the innovative applications of SH-SAW as cell-based sensors. Besides, based on experimental detail evidences, few researchers have provided further theoretical analysis accordingly. In order to establish a reliable theoretical analysis for Parylene-C-guiding SH-SAW biosensors, a series of physical and mechanical parameters are needed as the initial inputs in algorithm.

Due to its high sensitivity, simple structure, and easy interconnection with electronic measurement systems, quartz thickness-shear-mode (TSM) resonator is adopted to characterize the mechanical properties of Parylene-C [8]. As its surface loading condition varies, for example Parylene-C films deposited on the surface, the electrically-excited acoustic-wave propagation could change accordingly through entire quartz crystal. Two general types of equivalent-circuit models are proposed to describe the TSM resonator: the lumped-element model (Butterworth-Van Dyke, BVK) and the distributed model (Transmission Line Model, TLM), and the former could be derived from reduction of the later in near-resonant circumstances [4]. Because of the zero error between its assumptions and actual TSM electrical response, the distributed model TLM is chosen to provide a comprehensive description for TSM with viscoelastic films in this study [4, 9]. TLM is also widely used in SH-SAW devices studies, which would help optimize the parameter matching between TSM and SH-SAW model analysis in future research. Nevertheless, some problems of coating property extraction in TSM have not been solved completely, including approximately-theoretical measurement and calculation error control. It has also been found that viscoelastic coatings of various thicknesses could induce other resonance effects, leading to incompatible with calculation model [10].

In this study, uniform Parylene-C films of different thickness were prepared on TSM surface by thermal deposition, and admittance spectrums of both uncoated and coated TSM were measured through an impedance analyzer. Based on a modified TLM, corresponding storage shear modulus G' and loss shear modulus G'' of Parylene-C films were extracted. We reported the variation of G', G'' with increasing Parylene-C thickness, proposing the desirable thickness range for complex-shear-modulus extraction as from 2.04 μm to 3.55 μm. Referring to these accurate G', G'' values, reliable theoretical analysis could be established for SH-SAW with Parylene-C films as both an effective wave-guiding layer and biocompatible interfacial layer in future research.

II. THEORETICAL MODEL OF TSM RESONATOR

TLM for TSM has two acoustic ports and one electrical port, and via a transformer the acoustic variables, force F and linear velocity v, are coupled to an electrical port [11].

The acoustic-electrical analogy of TLM could be defined as that,

$$\begin{bmatrix} F_1 \\ F_2 \\ V \end{bmatrix} = -j \begin{bmatrix} Z_C \cot\alpha_q & Z_C(\sin\alpha_q)^{-1} & h/\omega \\ Z_C(\sin\alpha_q)^{-1} & Z_C \cot\alpha_q & h/\omega \\ h/\omega & h/\omega & 1/\omega C_0 \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ I \end{bmatrix} \tag{1}$$

where $F_{1,2}$ and $v_{1,2}$ are the external force and linear velocity at TSM resonator surfaces, respectively; and Z_C, α_q, h and C_0 are defined as follows, with relevant parameters shown in Table 1.

$$\begin{aligned} Z_C &= AZ_q = A\sqrt{\rho_q c_q} \\ \alpha_q &= \omega h_q \sqrt{\rho_q / c_q} \\ h &= e_q / \varepsilon_q \\ C_0 &= \varepsilon_q A / h_q \end{aligned} \tag{2}$$

Letting $Z_1=F_1/v_1$, $Z_2=F_2/v_2$ to represent the surface loading condition of TSM resonator, (1) is rewritten as [12],

$$\begin{bmatrix} V \\ I \end{bmatrix} = [B] \cdot \begin{bmatrix} F_1 \\ v_1 \end{bmatrix} = \frac{1}{\varphi H} \begin{bmatrix} 1 & \frac{j\varphi^2}{\omega C_0} \\ j\omega C_0 & 0 \end{bmatrix} \cdot \begin{bmatrix} \cos\alpha_q + j\frac{Z_2}{Z_C}\sin\alpha_q & Z_C(\frac{Z_2}{Z_C}\cos\alpha_q + j\sin\alpha_q) \\ \frac{j}{Z_C}\sin\alpha_q & 2(\cos\alpha_q - 1) + j\frac{Z_2}{Z_C}\sin\alpha_q \end{bmatrix} \cdot \begin{bmatrix} F_1 \\ v_1 \end{bmatrix} \tag{3}$$

where

$$H = \cos\alpha_q - 1 + j\frac{Z_1}{Z_q}\sin\alpha_q, \varphi = hC_0 \tag{4}$$

Defining $Z=V/I$, $Y=I/V$, then Z and Y are expressed as,

$$\begin{aligned} Z &= \frac{1}{j\omega C_0} - \frac{K^2}{j\omega C_0 \alpha_q} \frac{2\tan(\alpha_q/2) - j(Z_1+Z_2)/Z_C}{(1+Z_1Z_2/Z_C^2) - j(Z_1+Z_2)/Z_C \cot\alpha_q}) \\ Y &= j\omega C_0 + \frac{j\omega C_0(2\tan(\alpha_q/2) - j(Z_1+Z_2)/Z_C)}{\alpha_q / K^2((1+Z_1Z_2/Z_C^2) - j(Z_1+Z_2)/Z_C \cot\alpha_q) - 2\tan(\alpha_q/2) + j(Z_1+Z_2)/Z_C}) \end{aligned} \tag{5}$$

where

$$K^2 = e_q^2 / \varepsilon_q c_q \tag{6}$$

Generally, for uncoated TSM, both surfaces are stress free with two short-circuit acoustic terminations of $F_1=Z_1=F_2=Z_2=0$. However, when extra films (upper/lower electrodes and Parylene-C) are deposited directly on the surfaces, Z_1 and Z_2 are changed accordingly depending on these films' own physical and mechanical properties. For Au/Cr electrodes on both sides are very thin (~100 *nm*), their effects on surface loading Z_1 and Z_2 values are neglected, simplifying the original theoretical model effectively. Thus, Z_1 is only determined by Parylene-C's properties, and Z_2 is always zero. Assuming Parylene-C films as isotropic, homogeneous and uniform coating on Quartz, Z_1 could be calculated as follows, with relevant parameters shown in Table 1 also.

$$Z_1 = jZ_1^C A\tan\alpha_1 \tag{7}$$

where

$$\begin{aligned} Z_1^C &= \sqrt{\rho_1 G_1}, G_1 = G' + jG'' \\ \alpha_1 &= \omega h_1 \sqrt{\rho_1 / G_1} \end{aligned} \tag{8}$$

Substituting the Z_1 and Z_2 into (5) Y expression,

$$Y = j\omega C_0 + \frac{j\omega C_0(2Z_C\tan(\alpha_q/2) + Z_1^c A\tan\alpha_1)}{\alpha_q / K^2(Z_C + Z_1^c A\tan\alpha_1\cot\alpha_q) - 2Z_C\tan(\alpha_q/2) - Z_1^c A\tan\alpha_1} \tag{9}$$

Nevertheless, considering the excluded electrode effect of TSM, other non-uniformity influences and surrounding perturbations, modified TLM model is proposed as shown in Fig.1 (b). Taking these uncertainties into account, the total parallel capacitance C_0^* is defined as that [13],

$$C_0^* = C_0 + C_p \tag{10}$$

where C_0 is TSM static capacitance, and C_p is the external capacitance. With C_0^* as a desirable way of compensation for previous model, (7) (9) are respectively rewritten into (12) (13). This model establishes an explicit relationship between experimental observations (TSM electrical response) and relevant device parameters, which is of great significance in the following algorithm analysis.

$$Y = j\omega C_0^* + \frac{2j\omega C_0\tan(\alpha_q/2)}{\alpha_q / K^2 - 2\tan(\alpha_q/2)} \tag{11}$$

$$Y = j\omega C_0^* + \frac{j\omega C_0(2Z_C\tan(\alpha_q/2) + Z_1^c A\tan\alpha_1)}{\alpha_q / K^2(Z_C + Z_1^c A\tan\alpha_1\cot\alpha_q) - 2Z_C\tan(\alpha_q/2) - Z_1^c A\tan\alpha_1} \tag{12}$$

TABLE I. PARAMETERS OF TSM RESONATORS [14]

Density of Quartz	ρ_q	$2.651\times10^3\ kg\cdot m^{-3}$
Shear Stiffness of Quartz	$c_q = c_{66} + e_{26}^2/\varepsilon_{22} + j\omega\eta_q$	$2.970\times10^{10}\ N\cdot m^{-2} + j\omega\eta_q$
Piezoelectric Constant of Quartz	$e_q = e_{26}$	$9.657\times10^{-2}\ A\cdot s\cdot m^{-2}$
Dielectric Permittivity of Quartz	$\varepsilon_q = \varepsilon_{22}$	$3.982\times10^{-11}\ A^2\cdot s^4\cdot kg^{-1}\cdot m^{-3}$
Surface Area of TSM Resonator	A	$2.047\times10^{-5}\ m^2$
Thickness of TSM Resonator	h_q (theoretical)	165 μm
Density of Parylene-C	ρ_1	$1.289\times10^3\ kg\cdot m^{-3}$
Shear Modulus of Parylene-C	G_1	To be determined
Thickness of Parylene-C Films	h_1	To be determined

III. EXPERIMENTALLY DETAILS AND ANALYSIS METHODS

The admittances of uncoated 10-MHz TSM resonators (International Crystal Manufacturing Co., Oklahoma City, OK) were firstly measured by an Agilent 4294A Precision Impedance Analyzer (Agilent Technologies, Palo Alto, CA), which were recorded for the extraction of effective parameters of TSM. Subsequently, Parylene-C films were deposited on TSM surface by thermal deposition system (SCS PDS 2010 Labcoter 2, SCS Equipment, Dallas, TX). The thicknesses of as-deposited Parylene-C films were analyzed by a profilometer (Dektak3 ST surface profiler, Veeco Instruments

Inc., Woodbury, NY) and surface morphology was observed by Scanning Electron Microscopy (XL-30 FEG SEM, FEI/Philips, Japan). The admittances of TSM resonators with different Parylene-C thickness were recorded also. For getting precise results in succeeding fitting procedure, each sample with certain-thickness films was measured three times under the same conditions.

Based on TLM equivalent-circuit model presented in Section 2, a fitting procedure is introduced to obtain accurate values for both storage shear modulus G' and loss shear modulus G'' [15]. The total parallel capacitance $C_0^* = 6.0874$ pF, which is measured at double fundamental-resonance frequency based on the limiting relationship $Y = j\omega C_0^*$ [16].

IV. Results and Discussions

Fig.1 gives the admittance spectrums of TSM resonators with different Parylene-C thickness. The marked thickness of Parylene-C films is detected by Surface Profiler, and the inset morphology image for TSM with 1.6 μm Parylene-C is obtained by Scanning Electronic Microscopy. It is indicated that as-deposited Parylene-C films are smooth and compact, without any obvious bumps or pores across the surface. Based on the admittance spectrum of uncoated TSM resonator, effective parameters h_q, μ_q, C_0^* and C_p are extracted as Table 2 lists. The fitting process is well-acceptable with the error of 0.0430%, leading to affirmative calibrated parameters of TSM resonator.

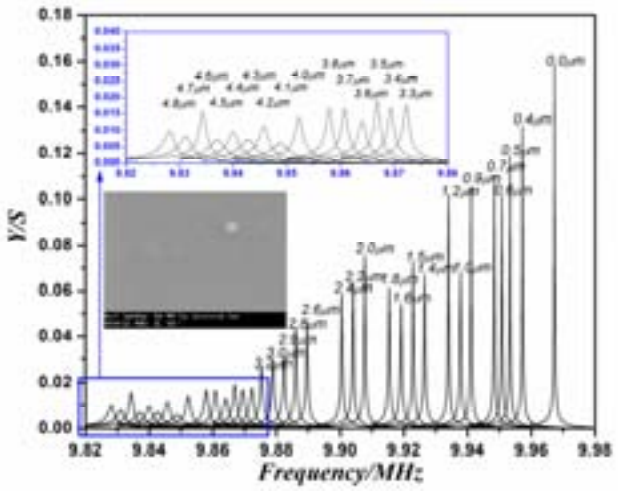

Figure 1. Admittance curves of TSM with different Parylene-C thickness

TABLE II. Calibrated Parameters of TSM Resonator

Effective Thickness of TSM	h_q	166.72 μm
Effective Viscosity of Quartz	μ_q	0.0053 $Pa{\cdot}s$
Effective Static Capacity of TSM	C_0	4.4280 pF
Effective External Capacity of TSM	C_p	1.6594 pF

Fig.2 shows the complex shear modulus (storage modulus G' and loss modulus G'') of Parylen-C films with different thickness. Fitting calculation provides the optimal solution set of G', G'' as well as the corresponding Parylene-C thickness, which are in good agreement with the Surface Profiler analysis. This figure illustrates that G′ and G″ have the similar variation tendency: In the beginning, the shear modulus increase with Parylene-C's thickness increasing from 0.34 μm to 2.04 μm (Range I), and then inclined to be constant relatively as the thickness ascending further (Range II and III). Meanwhile, with no obvious changes observed in Range II, the dispersion of shear modulus is increasing gradually from Range II to III. When the Parylene-C films are thin as in Range I, the entire Parylene-C films tend to move with TSM surface synchronously, and the displacement of films inclines to be uniform. The acoustic phase shift across viscoelastic films is relatively small, constraining the typical deviations of viscoelastic films' behavior from rigid films'. During this range considered as gravimetric region, the films thickness and density contributed mostly to TSM's electrical response other than the mechanical properties. With the thickness' further rising to non-gravimetric region, Parylen-C displacement is not synchronous with TSM surface, resulting in an appreciable acoustic phase shift through the films. Thus, considerable shear deformation is introduced into the films' behavior, causing the viscoelastic contribution in electrical response to be substantial and quantifiable [4]. From this perspective, an appropriate thickness range of Parylene-C films (2.04 μm - 3.55 μm) should be selected to get the accurate characterization of the viscoelastic properties.

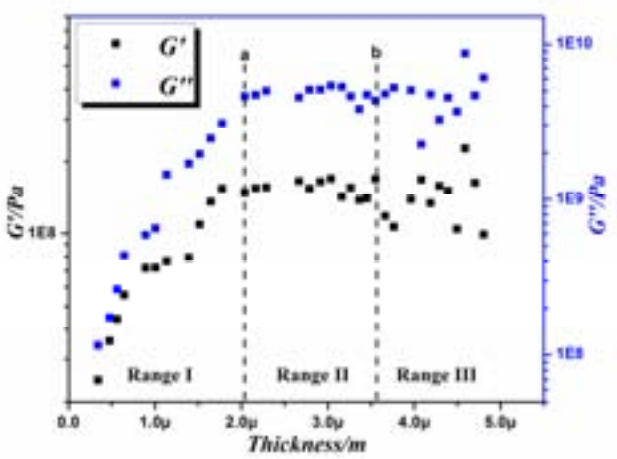

Figure 2. Shear modulus G′ and G″ of Parylene-C with different thickness

As a result, the shear modulus values in Range II (Parylene-C thickness from 2.04 μm to 3.55 μm) are adopted, and storage modulus G' and loss modulus G'' of Parylene-C are 0.155±0.011 GPa and 4.78±0.44 GPa, respectively. Fig. 3 exhibits the fitting-error analysis for Range II. The upper plot is fitting-error curve with the variation of Parylene-C thickness; the lower two are for TSM resonator with 2.91-μm Parylen-C, as the comparison of experimental and fitting curves of Y's real part G and image part B, respectively. The error upper limit is set as 1% in algorithm of shear-modulus

extraction. Much smaller than this setting point, the final fitting error for Range II keep stable under 0.100%, and even for most samples less than 0.050%. Besides, the fitting error for both the real part G and image part B of admittance Y is limited similarly, which proves high reliability and resolution of fitting process further.

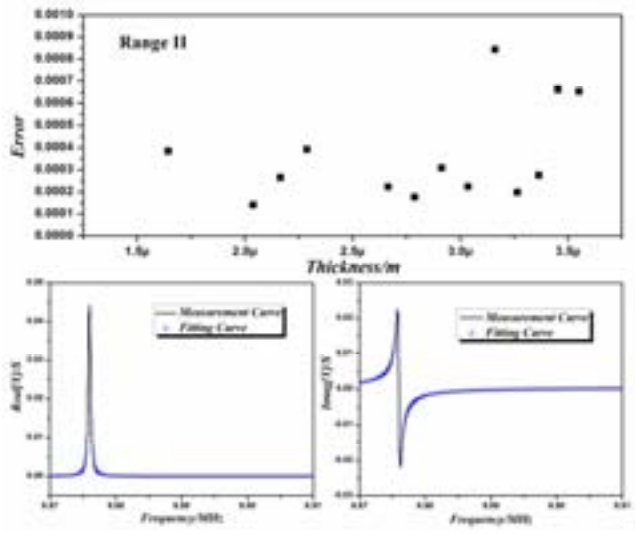

Figure 3. Fitting of TSM resonators with different Parylene-C thickness

V. CONCLUSIONS

In this study, quartz thickness-shear-mode (TSM) resonator is adopted to extract the complex shear modulus of Parylene-C films. Accordingly, with null error between its assumptions and actual TSM electrical response, the distributed model - Transmission Line Model (TLM), which is also widely used in SH-SAW devices analysis, is applied to provide a comprehensive description for TSM with viscoelastic films. Considering the electrode effect, surrounding perturbations and other kinds of non-uniformity, non-certainties influences, total parallel capacitance C_0^* is introduced to substitute static capacitance C_0 in modified TLM. In the meantime, preliminary calibration is conducted to determine the effective parameters of uncoated TSM before extraction of complex shear modulus. Additionally, a fitting procedure in algorithm also contributes to the accuracy of both storage shear modulus G' and loss shear modulus G''. The error threshold is set as 1% and the optimal solution set is chosen based on the minimum error function value.

Parylene-C films of different thicknesses were prepared on TSM surface by thermal deposition. In the beginning, G' and G'' increase with Parylene-C's thickness rising from 0.34 μm to 2.04 μm because of inadequate sensitivity of viscoelastic effect, and then inclined to be constant relatively; however, as the thickness ascending further, the dispersion of G' and G'' is increasing gradually due to the excessive electrical-response attenuation. As a result, the ideal thickness range for Parylene-C on TSM is from 2.04 μm to 3.55 μm, and the average G' and G'' are 0.155±0.011 GPa and 4.78±0.44 GPa, respectively. With total fitting error keeping stable below 0.100%, the high reliability and resolution of the whole extraction process is confirmed.

***Abstract*—Viscosity is one of the characteristic parameters of liquid. The measurement of liquid viscosity is required in many applications. Compared with other acoustic wave device, the shear-horizontal acoustic plate mode wave (SH-APM) device is suitable for liquid sensing. In this paper, the theoretical model of SH-APM device loaded with viscous liquid is built using the propagation characteristics of acoustic wave in laminated mediums, the liquid viscosity is introduced by adding the imaginary part in liquid elastic tensor, and the condition of exciting SH-APM in the piezoelectric plate by inter-digital transducers is researched. Choosing PZT-5H piezoelectric ceramic as substrate material, the numerical calculation is implemented and the SH-APM device is fabricated accordingly. Using different ratios of pure water and glycerol as liquid samples, the validity of liquid viscosity sensing by SH-APM is proved by the experimental results.**

Keywords—shear horizontal acoustic plate mode wave; liquid viscosity; PZT-5H; propagation velocity; propagation attenuation

I. INTRODUCTION

As to the acoustic wave device, generally the excitation and detection of the acoustic wave are realized by the inter-digital transducers (IDT) deposited on the surface of the piezoelectric substrate. The changes of the acoustic wave propagation characteristics with external pressure, temperature, gas, and liquid, etc. could be used as sensing functions [1]. Compared with surface acoustic wave (SAW) device, the acoustic plate mode wave (APM) device has two interfaces. When one interface is deposited with IDTs as acoustic excitation, the other interface can be loaded with liquid sample. Furthermore, when the APM has only SH (shear-horizontal) particle displacement normal to the propagation direction and parallel to the plate surface, the attenuation because of the liquid sample is very small. So the SH-APM device is suitable for liquid sensing [2].

The characteristic parameters of liquid include density, viscosity, volume elastic modulus, permittivity, and conductivity, etc. Among these liquid parameters mentioned above, the former three belong to mechanical parameters, and the latter two are electrical parameters. Because of the variety of liquid's characteristic parameters and the complexity of APM's propagation characteristics, until now the researches in APM liquid sensing mainly focus on non-viscous liquid [3]. That is, the viscosity of the liquid is neglected; only the detection of the non-viscous liquid by APM is analyzed, which limits the development of the APM liquid sensors. In fact, the measurement of liquid viscosity is required and important in many applications.

In this paper, the liquid viscosity is introduced by adding the imaginary part in liquid elastic tensor, the condition of exciting SH-APM in the piezoelectric plate by inter-digital transducer is concluded, and the theoretical model of SH-APM device loaded with viscous liquid is built using the propagation characteristics of acoustic wave in laminated mediums. The piezoelectric ceramic PZT-5H is used as substrate material, by numerical calculation and experimental analyses, the validity of liquid viscosity sensing by SH-APM is proved, which provides guidance for the further research on APM liquid viscosity sensors.

II. THEORETICAL ANALYSIS

Strictly speaking, all the elastic mediums including piezoelectric materials could show viscosity to a certain extent [4]. Considering the viscosity of the medium, the extended Hooke's law is as follows [5].

$$T_{ij} = (c_{ijkl} + j\omega\eta_{ijkl})S_{kl}, \tag{1}$$

where T_{ij} and S_{ij} are the stress and strain tensor, respectively; c_{ijkl} and η_{ijkl} are the medium's elastic and viscous tensor, respectively, which have the same symmetry characters; the indices i, j, k and l are assumed to be 1, 2, 3; $\omega=2\pi f$ is the circular frequency, With the compressed matrix notation, the constants $\boldsymbol{c}_{ijkl}$ and η_{ijkl} can be represented by matrices $\boldsymbol{c}_{pq}$ and η_{pq} with the conventions p and q varying from 1 to 6.

Therefore the viscosity of the medium is shown by introducing the imaginary part in liquid elastic tensor. Generally, the viscosity of the piezoelectric material could be neglected. When the liquid's viscosity is above 0.0015Pa.s, the viscosity of the liquid must be considered. The liquid viscosity is marked as η_L, which denotes the shear viscous constant η_{44}.

The liquid's viscous constants are [6]:

$$\eta_{44} = \eta_L,\ \eta_{11} = \frac{4}{3}\eta_L,\ \eta_{12} = \eta_{11} - 2\eta_{44} = -\frac{2}{3}\eta_L. \tag{2}$$

After considering the liquid's viscosity, the elastic constants of the viscous liquid are:

$$c_{44} = j\omega\eta_L,\ c_{11} = c_L + \frac{4}{3}j\omega\eta_L,\ c_{12} = c_{11} - 2c_{44} = c_L - \frac{2}{3}j\omega\eta_L, \tag{3}$$

where c_L is the liquid's volume elastic modulus.

The APM device coordinates loaded with liquid is shown in Fig. 1. The APM is excited by the IDTs on the surface of the substrate. The liquid is in contact with the other interface of the substrate, and the region $x_3 < -d$ is the liquid medium.

When the APM device is loaded with viscous liquid, generally the energy leakage would happen, and the APM becomes the leaky plate wave. This leads to the attenuation

along the propagation direction x_1, and the acoustic field quantities have the following form:

$$\begin{cases} u_i = A_i \exp[-jk(\xi x_1 + \beta x_3 - vt)] \\ \phi = A_4 \exp[-jk(\xi x_1 + \beta x_3 - vt)] \end{cases}, \quad (4)$$

where u_i (i =1, 2, 3) is mechanical displacement; ϕ is electrical potential; v and A_i are the propagation velocity and wave amplitude, respectively; k is the wave vector along the propagation direction; ξ and β represent the attenuation factors along the propagation direction x_1 and the depth direction x_3, respectively.

$$\xi = 1 - j\gamma, \quad (5)$$

where γ is the propagation attenuation of the APM. When the APM hasn't energy leakage, γ =0.

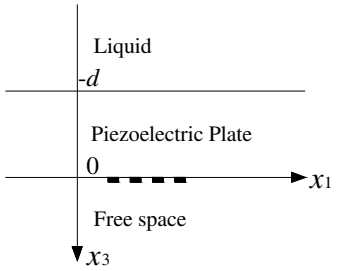

Fig. 1 The APM device coordinates loaded with liquid

The Christoffel equations in the piezoelectric medium have the following matrix form:

$$\begin{bmatrix} \Gamma_{11} & \Gamma_{12} & \Gamma_{13} & \Gamma_{14} \\ \Gamma_{21} & \Gamma_{22} & \Gamma_{23} & \Gamma_{24} \\ \Gamma_{31} & \Gamma_{32} & \Gamma_{33} & \Gamma_{34} \\ \Gamma_{41} & \Gamma_{42} & \Gamma_{43} & \Gamma_{44} \end{bmatrix} \begin{bmatrix} A_1 \\ A_2 \\ A_3 \\ A_4 \end{bmatrix} = 0. \quad (6)$$

Because of the material symmetry character, in some particular substrate cut orientation and acoustic wave propagation direction or the polarization direction, the Christoffel equations would become

$$\begin{bmatrix} \Gamma_{11} & 0 & \Gamma_{13} & 0 \\ 0 & \Gamma_{22} & 0 & \Gamma_{24} \\ \Gamma_{31} & 0 & \Gamma_{33} & 0 \\ 0 & \Gamma_{42} & 0 & \Gamma_{44} \end{bmatrix} \begin{bmatrix} A_1 \\ A_2 \\ A_3 \\ A_4 \end{bmatrix} = 0. \quad (7)$$

On the above conditions, (u_1, u_3) and (u_2, ϕ) decouple. The Christoffel equations turn to two independent sub-equations. One is the pure mechanical Rayleigh wave with u_1 and u_3 coupling without u_2 and ϕ.

$$\begin{bmatrix} \Gamma_{11} & \Gamma_{13} \\ \Gamma_{31} & \Gamma_{33} \end{bmatrix} \begin{bmatrix} A_1 \\ A_3 \end{bmatrix} = 0. \quad (8)$$

The other is the acoustic wave with u_2 and ϕ coupling without u_1 and u_3.

$$\begin{bmatrix} \Gamma_{22} & \Gamma_{24} \\ \Gamma_{42} & \Gamma_{44} \end{bmatrix} \begin{bmatrix} A_2 \\ A_4 \end{bmatrix} = 0. \quad (9)$$

As to the acoustic wave excited by IDTs on the piezoelectric substrate, the vibration displacement and electrical potential must couple. So the acoustic wave corresponding to the latter sub-equations has only the vibration displacement along x_2 direction, which is called the shear-horizontal (SH) APM.

Corresponding to the APM device coordinates as shown in Fig. 1, when the substrate's elastic constants and piezoelectric constants satisfy the following conditions, the SH-APM would be excited by IDTs.

$$\begin{cases} c_{14} = c_{16} = c_{34} = c_{36} = c_{45} = c_{56} = 0 \\ e_{11} = e_{13} = e_{15} = e_{31} = e_{33} = e_{35} = 0 \end{cases}. \quad (10)$$

When the propagation characteristics of the acoustic wave in laminated mediums are researched, the following principles should be followed [7]:

(1). At the interface between two mediums, the wave vectors along the propagation direction should be equal.

(2). When both the two mediums are solids, the stress and displacement at the interface between the two mediums should be continuous.

(3). When one medium or both the two mediums are liquids, the stress at the interface should be continuous. As to the continuity of the displacement, it differs depending on the viscous character of the liquid. When the liquid is non-viscous, the interface is allowed to generate surface glide, only the normal component of the displacement satisfies the continuity condition; when the liquid is viscous, the displacement components in the three directions must be continuous.

According to the above principles, the boundary conditions of the SH-APM loaded with viscous liquid could be expressed in the following matrix form:

$$[N][H] = 0, \quad (11)$$

where [H] is a vector, [N] is a 6×6 matrix.

The equation group (11) includes six boundary conditions: the continuity of the normal component of the stress T_{32} at x_3= 0 and x_3= -d; the electrical boundary conditions at x_3= 0 and x_3= -d; the continuity of the displacement u_2 at x_3= -d; the continuity of the electrical potential ϕ at x_3= -d.

The SH-APM's displacement u_3=0, and there is not the continuity of the stress T_{33} in (11), so the volume elastic modulus c_L of the liquid is not included in the boundary conditions. Furthermore, similar to the APM loaded with non-viscous liquid, the elimination of the influences of the liquid permittivity and conductivity to the SH-APM's propagation characteristics could be realized by sputtering a thin metal film at x_3= -d. When the electrical boundary condition is free at x_3= 0 and metalized at x_3= -d, only the liquid's density and viscosity influence SH-APM's propagation characteristics.

Based on the above boundary conditions, utilizing the partial wave theory and the surface effective permittivity method [8], the changes of SH-APM's propagation velocity and attenuation with liquid's density and viscosity could be numerically simulated and analyzed.

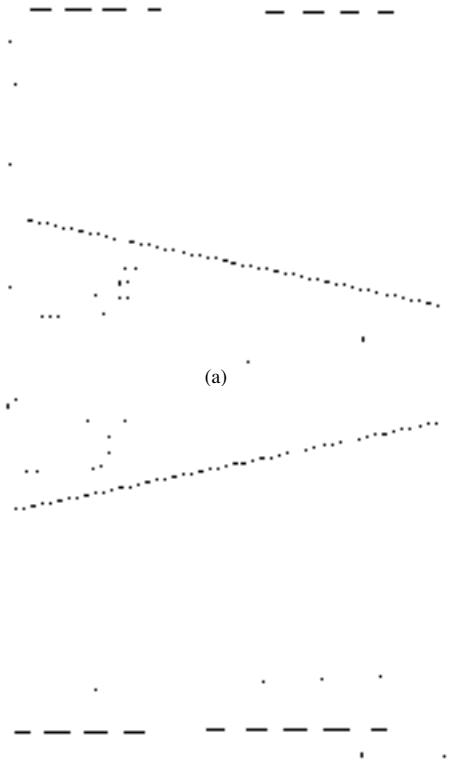
III. NUMERICAL SIMULATION

According to the theoretical analysis, when the electrical boundary condition is free at the interface deposited with IDTs and metalized at the interface loaded with liquid, the liquid sensing model of SH-APM can be formulated as follows:

$$\Delta v = \left(\frac{\partial v}{\partial \rho_L}\right)\rho_L + \left(\frac{\partial v}{\partial \eta_L}\right)\eta_L, \quad (12)$$

$$\Delta \gamma = \left(\frac{\partial \gamma}{\partial \rho_L}\right)\rho_L + \left(\frac{\partial \gamma}{\partial \eta_L}\right)\eta_L. \quad (13)$$

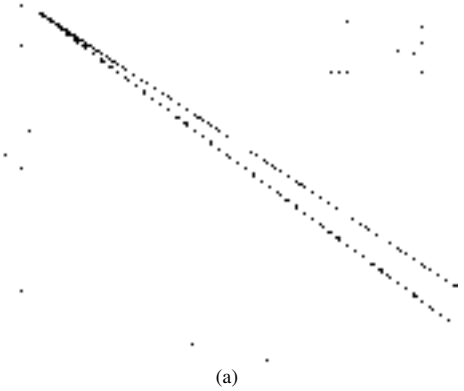
The piezoelectric ceramic belongs to polycrystalline material, which has the merits of large electro-mechanical coupling coefficient, isotropic in transverse orientation, unlimited in geometrical dimensions, high performance-to-price ratio, etc. The material constants of the piezoelectric ceramic PZT-5H satisfy the conditions of exciting SH-APM, at the same time the excitation efficiency is comparatively high. Therefore PZT-5H becomes the preferable material for the research of SH-APM. As to the PZT-5H piezoelectric substrate with the ratio of plate thickness to acoustic wavelength d/λ=0.15, the period of IDT P =1mm, when the electrical boundary condition is free at x_3= 0 and metalized at x_3= -d, the changes of SH-APM propagation velocity and attenuation with liquid density and viscosity are depicted in Figs. 2 and 3, respectively.



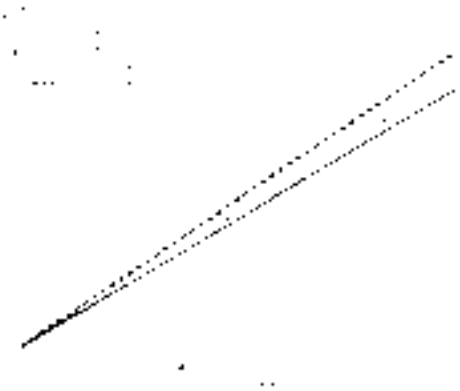
(a)

(b)

Fig. 2 The changes of SH-APM propagation characteristics of PZT-5H with liquid density: (a) propagation velocity; (b) propagation attenuation



(a)



(b)

Fig. 3 The changes of SH-APM propagation characteristics of PZT-5H with liquid viscosity: (a) propagation velocity; (b) propagation attenuation

As can be seen, the propagation velocity v and propagation attenuation γ of SH-APM have linear relation with the square root of liquid density ρ_L and viscosity η_L. The velocity v decreases with the increases of ρ_L and η_L. On the contrary, the attenuation γ increases with the increases of ρ_L and η_L. By comparing Figs. 2 and 3, we find out that the changes of v and γ because of η_L are much larger than those because of ρ_L. It could be approximated that the changes of v and γ result only from liquid viscosity η_L, and the liquid sensing model of SH-APM can be further simplified as:

$$\Delta v = (\frac{\partial v}{\partial \eta_L})\eta_L, \tag{14}$$

$$\Delta \gamma = (\frac{\partial \gamma}{\partial \eta_L})\eta_L . \tag{15}$$

IV. Experimental Analysis

The SH-APM device is fabricated for the purpose of researching its liquid viscosity sensing characteristics. The piezoelectric material is PZT-5H whose polarization direction is normal to the sagittal plane. The geometrical dimensions of the device are listed in Table. 1. The encapsulation and photo of the SH-APM device are shown in Figs. 4 and 5, respectively.

Table.1 Geometrical dimensions of the SH-APM device

Substrate	length LL (mm)	25
	width W (mm)	10
	thickness d (mm)	0.15
IDT	pairs N	6
	period P (mm)	1
	width a (mm)	0.25
	distance b (mm)	0.25
	aperture w (mm)	5
	center distance l (mm)	12

The network analyzer is utilized as the measurement instrumentation. The resonant frequency f and insertion loss IL could be obtained by the amplitude-frequency characteristic curve.

The relation between resonant frequency f and propagation velocity v is:

$$f = v/\lambda = v/P . \tag{16}$$

The relation between loss L and propagation attenuation γ is:

$$L = -\frac{20}{\ln 10} k\gamma \cdot l = -54.575 \frac{l}{P} \cdot \gamma \cdot \quad (17)$$

In the experiment, the loss L is obtained by the insertion loss IL loaded with liquid subtracted from the insertion loss IL' in the free space. Therefore, after f and IL are measured by the network analyzer, the realistic v and γ of the fabricated SH-APM device could be calculated by equations (16) and (17).

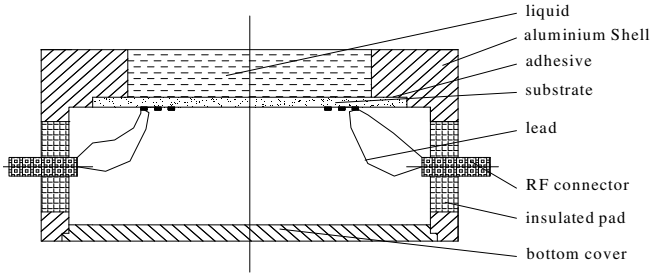


Fig. 4 The encapsulation of the SH-APM device

Fig. 5 The photo of the SH-APM device

Fig. 6 shows the amplitude-frequency curves of the SH-APM device in the free space, loaded with pure water and glycerol. As can be seen, because the pure water is non-viscous, there is almost no difference between the curve in the free space and that loaded with pure water. Because the glycerol is viscous, the SH-APM becomes the leaky plate wave, resulting in the increase of the propagation attenuation.

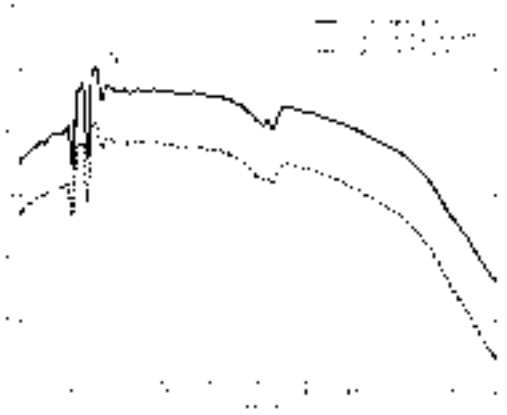

Fig. 6 The amplitude-frequency curves of the SH-APM device in the free space, loaded with pure water and glycerol

Using different ratios of pure water and glycerol as the liquid samples, the amplitude-frequency curves of the SH-APM device are shown in Fig. 7. The higher the glycerol's concentration is, the bigger the liquid's viscosity is. As can be seen, the insertion loss IL increases with the increase of liquid viscosity. At the same time, the increase of liquid viscosity leads to the corresponding decrease of resonant frequency f.

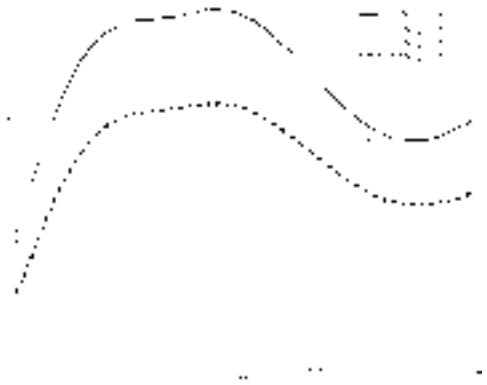

Fig. 7 The amplitude-frequency curves of the SH-APM device loaded with different ratios of pure water and glycerol

V. CONCLUSION

This paper describes the theoretical analysis, numerical simulation, and experimental analysis of the SH-APM device as liquid viscosity sensing. Choosing PZT-5H piezoelectric ceramic as substrate material, the SH-APM device is fabricated. Using different ratios of pure water and glycerol as the liquid samples, the experimental results are in agreement with the theoretical analyses.

***Abstract*—The sensitivity achieved by large laser gyroscopes opens the perspective of observing in a ground laboratories very thin relativistic effect related to the Earth rotating mass (gravitomagnetic effect or Lense-Thirring effect). The required accuracy asks for a strict control of the ring cavity geometry. Here we present a control procedure that can be applied in order to solve this task.**

Keywords- Laser gyroscopes; Geodetic; Optical resonators; Gravitomagnetism; General relativity; Multiagent control, Derivative free minimization

I. INTRODUCTION

Ring lasers have achieved very high sensitivity for precise monitoring of the Earth rotation. The 16 m^2 square G gyrolaser, located in laser ranging station of Wettzell, Bavaria, has a resolution better than 10^{-12} rad/s, attained in approximately one hour of data taking (~$4 \cdot 10^3$ s) [1]. It is, actually, the most accurate ring-laser in the world. Thanks to its monolithic structure, where the mirrors are kept in position by optical contact on precisely tooled monolithic block of Zerodur, a glass with a "null" linear thermic expansion coefficient, G demonstrates a very high long-term stability that made possible the observation of very tiny geodetic effect, like polar motion and Chandler wobble [2]. A further increase in the angular resolution and a tri-axial gyro-system would, then, allow to reach 10^{-14} rad/s; the sensitivity requested for measuring the Lense-Thirring General Relativity effect (also known as frame dragging) [3]. Such a task requires a precise control of the gyros geometry as well as a full understanding of its dynamics. In the present communication we analyze the problem of the geometry control, while the problem of the control of the laser dynamics has been presented elsewhere [4].

.

II. GEOMETRY CONTROL

The rotational resolution necessary for an accurate measurement of the Lense-Thirring effect is about one order of magnitude better than the actual G performance. Gyro's sensitivity depends on its scale factor, *i.e.* A/λp the ratio between the area enclosed by the optical path and its length times the optical wavelength. So that the first action is to increase the dimension of the optical ring cavity. As a matter of fact, the longer is the optical cavity the larger is its quality factor for equal round-trip losses (this is a reasonable assumption, considering that the losses are essentially given by the mirrors). Then we should expect that the ultimate resolution of a ring laser gyroscope will increase proportionally at least to the second power of its linear dimension. Larger ring laser gyroscopes, named UG-1 and UG-2, with heterolithic structure enclosing an area respectively of 367.5 m^2 and 834.34 m^2, were built in Christchurch (New Zealand) [5], but, in spite of the increasing of the dimensions, they demonstrated a much lower performance with respect G; this is due to the lack of long term stability of their heterolithic structure (G in Wettzell has a monolithic structure in Zerodur). However, Zerodur blocks

The research is sponsored by INFN

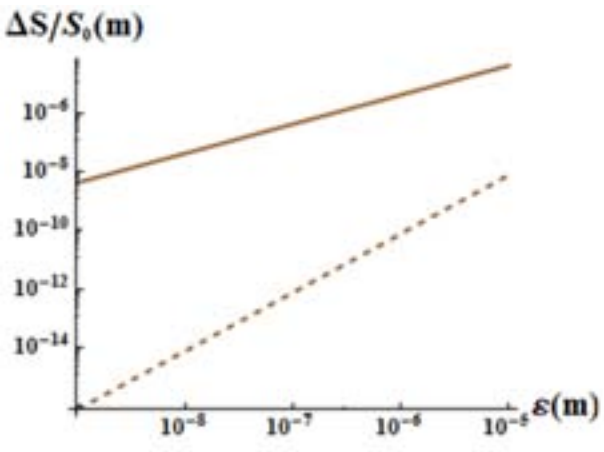

Figure 1. Relative variation of the scale factor of a gyroscope of 1 m in side, when the mirrors are moved from the "perfect square" geometry by a quantity ε for each degree of freedom. Continous line: movements in all the 6 degrees of freedom are considered. Dashed line: the diagonal lengths are locked to a fixed value.

larger than G are not available, and in any case it would be prohibitely costly.

So, to increase the long-term stability by suitable active controls on the ring geometry is a necessary step toward the realization of ring laser for General Relativity test.

Let us consider a ring optical cavity, defined by four identical spherical mirrors, very close to a "perfect" square. In principle, such a system has 12 degrees of freedom so that tri-axial linear actuators acting on the 4 mirrors would give a complete control of the optical cavity. However, the system rigid body movements reduce the actual degrees of freedom to 6. The stability problem can be further simplified by considering the symmetry of a perfect square. We, in addition, ask that the passive linear Fabry-Pérot cavities that are naturally installed along the square diagonal are optically accessible so that an external laser can be used for monitoring their configurations. The interferometric measure of the length of these diagonal cavity can be used for monitoring the geometry of the whole ring. Moreover, we note that, the stability of the ring cavity implies that also these Fabry-Pérot cavities are stable. The optical perimeter of the ring, as well as the linear FP lengths, can be accessed with high accuracy by comparing the laser emission wavelength with an optical reference standard (say, a I_2 stabilized He:Ne or a frequency comb locked to an atomic frequency standard).

It is easy to demonstrate that, by locking the two linear cavities to an equal constant value d, for small deviations ε_i of the mirrors coordinates from the perfect square, the deviation of the perimeter length from the exact value of $2d\sqrt{2}$ can be expressed as the sum of quadratic terms in ε_i. As we show in Fig. 1, we can achieve 10^{-10} accuracy on the scale factor with a 10^{-5} accuracy on the mirrors positions, provided that d is stabilized better that one part on 10^{10}.

Exploiting these geometrical properties, it will be possible to design a multivariable control algorithm that performs the initial calibration, starting from a generic geometry in order to reach a "near perfect" square shape. It will be as well possible to stabilize the desired geometry against drifts driven by changes in the environmental conditions. The procedure will be implemented by means of standard control techniques, by acting on a suitable linear combination of the residual degrees of freedom that diagonalizes the error matrix, using extremality conditions on the ring perimeter.

III. Experimental work

In the INFN laboratory in Pisa a laser gyroscope of relative small dimension (1.35 m of side) has been developed [6,7]. This apparatus is presently located in the Gran Sasso underground laboratories of INFN, in order to test whether the site is suitable to locate the GINGER (Gyroscopes IN General Relativity) experiment. At the same time, a new ring laser gyroscope, with optical access to linear cavities along the diagonals, has been designed aiming at testing the ring response to known geometrical distortion, and as well validating the control model. The gyroscope, named GP-2 is a square ring cavity, with 1.6 m side. The mirror holder is placed on a flat granite slab with a design accuracy of the order of a few hundreds of μm. A coarse horizontal adjustment of the mirrors position is available through manual micrometer stage, while 6 PZT linear stages allow finer control.

As explained above, of the original 12 degrees of freedom related to the mirrors' center of curvature, 6 can be traced out by considering rigid body translations and rotations of the whole apparatus. Then, acting on 6 linearly independent degrees of freedom by PZT is sufficient for realizing the full geometrical control. To this aim, one of the mirror holder will be equipped with a tri-axial PZT (x and y parallel to the granite table along the diagonal and orthogonally to it respectively, z perpendicular to the granite), while the other three mirrors are equipped with a 1-dimension stage in the direction of the respective diagonal. The granite will be mounted with the axis parallel to the Earth rotation axis (that is in the meridian plane with an inclination, at our latitude, with respect to the vertical of about 47°), in order to maximize the Sagnac signal thus minimizing the orientation errors on the scale factor. The requested control of the diagonal cavities length will be implemented by standard Pound-Drever-Hall (PDH) technique. Each cavity will be referenced to a stabilized laser source in order to retrieve its absolute length. The goal is to reach equal lengths in order to ensure that the corresponding ring cavity draws a prefect square. As a matter of fact, the cavity length L is related to the resonance frequency by :

$$\nu_n = \frac{c}{2L}(n+\varepsilon),$$

where $\varepsilon = \frac{1}{\pi}\arccos(1-L/R)$ and R is the mirrors radius of curvature. To remove the ambiguity on the mode number n, we measure the Fabry-Pérot free spectral range (FSR) by applying to the interrogating laser a second modulation at a frequency that is a multiple of the FSR itself.

To study, onto a test bench, the locking process we have built a linear cavity of 1.320 m of length. By scanning the laser

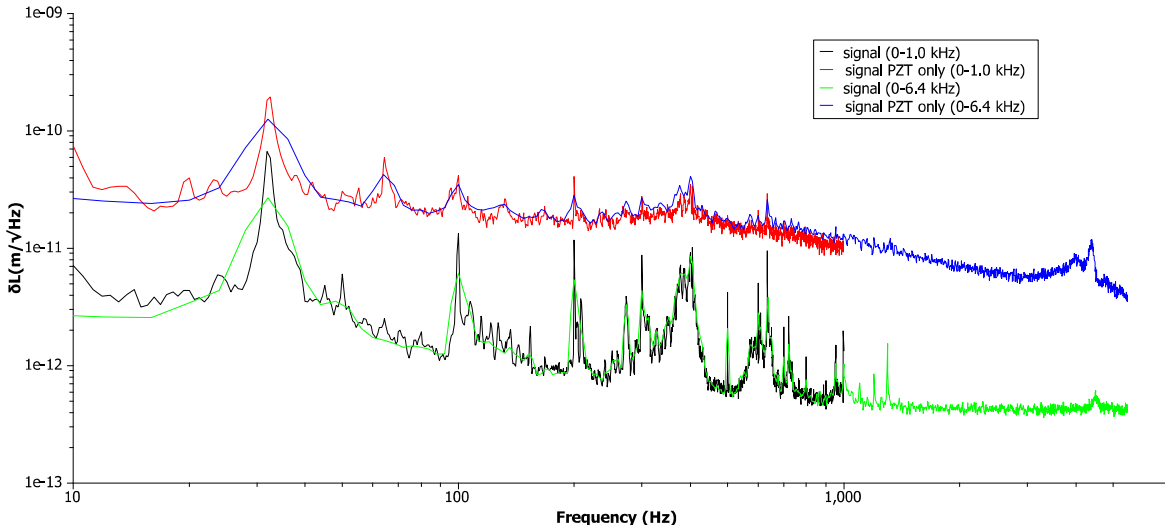

Figure 2 – Spectral density of the cavity length with the laser locked to the laser by slow (PZT only, upper trace) and by broad-band correction (lower trace)

frequency, we measured a finesse near to 470, consistent with the actual mirror reflectivity of 99.7%. In Fig. 2 we report preliminary PDH locking of the interrogating laser to such cavity, using a modulation frequency of 37 MHz.

ACKNOWLEDGMENT

We would like to acknowledge Filippo Bosi for its support on the mechanical design of GP2; we acknowledge also Gabriele Balestri, Giulio Petragnani. Antonino Ragonesi, and Francesco Francesconi for the technical support.

***Abstract*—We present the characteristics and the performances of a heterodyne detection scheme allowing a robust frequency lock of the G-Pisa ring laser [1,2] to a He-Ne Doppler shift stabilized reference laser. The system demonstrated a continuous unattended control of the laser frequency for several days of operation of the gyroscope with a single mode output power of about 500 pW.**

I. INTRODUCTION

Ring laser gyroscopes are presently one of the most important instrument in the field of precise rotation measurement [3]. They have high resolution, excellent stability and a wide dynamic range. The principle of operation of that sensor is based on the Sagnac effect, which states that two optical beams counter propagating inside the same ring complete the turn with a time difference proportional to the angular velocity of the local reference frame measured with respect to an inertial reference frame. Inside an optical cavity this difference becomes proportional to the frequency.

He-Ne ring lasers with cavity dimensions larger than 1 m can operate as ultra stable rotation rate sensors. For such systems, the two opposite beams generated inside the cavity are frequency split because of the Sagnac effect. The information about the rotation rate of the cavity is encoded in the optical beat between the counter propagating beams. If A is the laser area, P the perimeter, λ the wavelength, Ω the Earth rotation rate, and $\mathbf{n}$ the normal to the laser plane, this beat frequency is written as:

$$\Delta f_{Sagnac} = \frac{4A}{P\lambda}(\vec{\Omega} \cdot \vec{n})$$

In order to reduce the mutual coupling between the two opposite beams, a high Q-factor of the optical resonator is required and no intracavity elements can be used to select single mode operation. This implies, in general, a very low output power down to the level of some hundreds pW. Such a low power and the large acoustic phase jitter make the extraction of a clean measurement of the optical frequency of the gyroscope a not trivial operation.

II. FREQUENCY STABILIZATION

The experimental apparatus showing all the conditioning electronics is sketched in Fig.1.

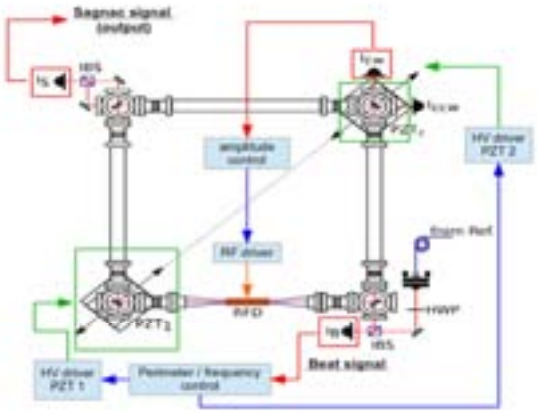

Fig. 1. G-Pisa experimental apparatus. ICW, ICCW: gyrolaser monobeams; IS: Sagnac signal (main system output); IBS: beam splitter; PZT1, PZT2: piezoelectric actuators; RFD: Radio Frequency Discharge; Amplitude Control: controller for the output power stabilization; RF Driver: power amplifier driving the discharge.

The beat note between the He-Ne reference laser [5] and the Gyro-laser (about 200 MHz) is detected by means of an Avalanche Photo-Diode (APD). After amplification, the

voltage signal is mixed with that coming from a local oscillator (Voltage Controlled Oscillator: VCO) operating at a carrier frequency of 130 MHZ. The mixed output is filtered around 70 MHZ with a bandwidth of 2 MHz, and an envelope detector determines the amplitude to frequency discrimination around the filter frequency pass band. Scanning the controlling voltage of the VCO and adding a sine wave modulation, it is possible to extract an error signal by using a lock-in amplifier. The lock-in filtered output signal is finally sent to the Gyro-laser piezo controls, to stabilize its length (i.e. frequency).

The beat note detection and the frequency stabilization schemes are shown in Fig.2 and Fig. 3 respectively.

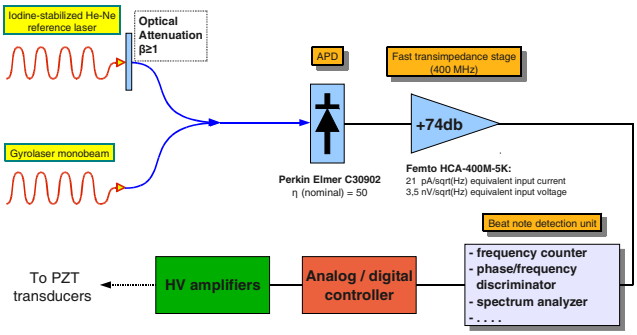

Fig. 2. Beat note detection scheme

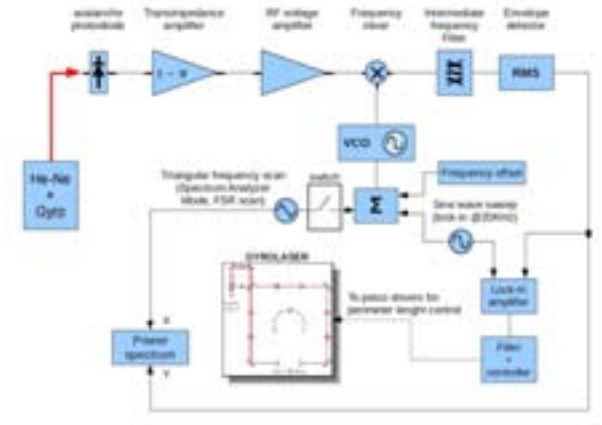

Fig. 3. Frequency stabilization scheme

The lock-in output (error signal) is shown in Fig. 4.

III. Results

The fractional frequency Allan deviation of the beatnote between the moonbeam gyrolaser output and the reference laser has been determined during a 10 days run, and the result is reported in Fig. 5 (black curve, left axis). The red curve represents the open loop fractional frequency instability of the system, and was obtained monitoring the signal sent to the piezoelectric actuators in order to close the loop.

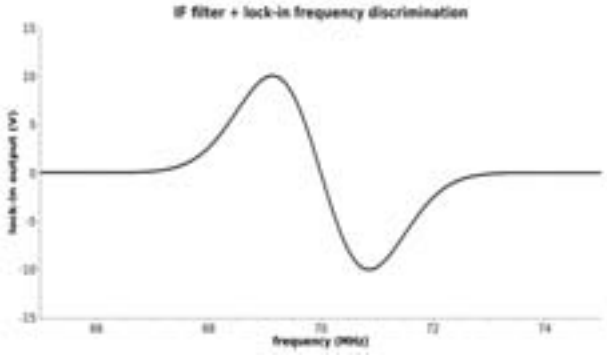

Fig. 4. The lock-in output (error signal)

On the right axis we provided a scale representing the equivalent length instability referred to the gyrolaser perimeter, that is 5.4 meters.

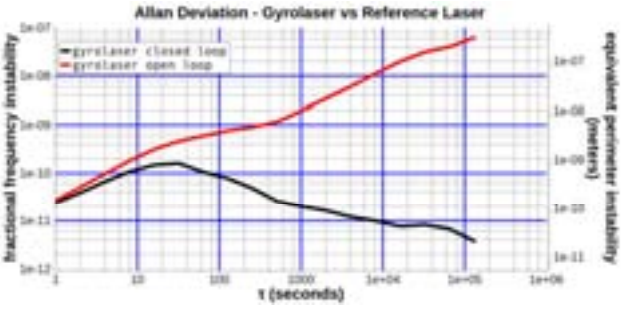

Fig. 5. Open loop and closed loop Allan deviation

IV. Conclusions

Such a scheme could be utilized to stabilize a gyrolaser frequency, and could also be employed to allow a phase lock in conjunction with a traditional PLL.

We can enumerate some peculiarities of a frequency stabilization system like that: it is cost effective, robust, and simple to implement. Moreover, it could be employed to allow the PLL phase lock of the system. Further improvements are possible employing a Iodine stabilized reference laser, increasing the bandwidth of the control.

***Abstract*—The composite clock architecture we explored is composed of a VCO controlled by both a hydrogen maser and a cesium standard. We realized two composite clock prototypes: an industrial one (passive maser + commercial cesium) and another one suitable for metrological laboratories (active maser + high stability cesium).**

This paper describes the performances of both systems, from 0.01 s to 10 days.

I. Dual frequency locked loop principle

How to lock a VCO on a H-Maser for mid term stability and on a Cesium for long term stability (see fig. 1)?

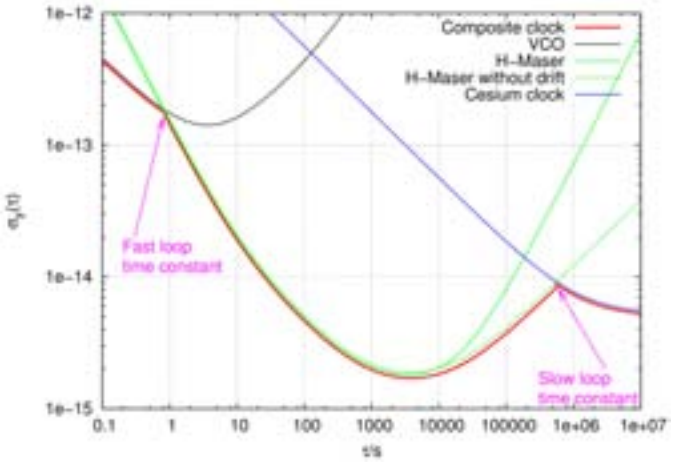

Fig. 1. Time stability of reference clocks.

By using both a fast ($\tau \sim 1$ s) and a slow loop ($\tau \sim 10$ d) as described in fig. 2.

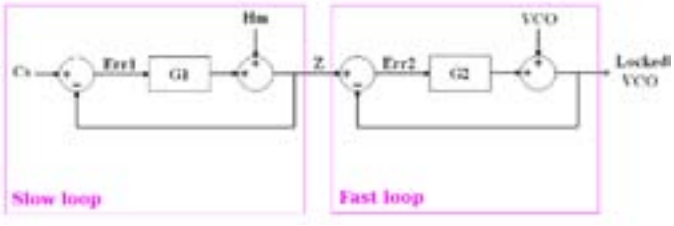

Fig. 2. Dual frequency locked loop principle.

II. Reference clocks and prototypes

A. Two prototypes

We decided to realize two composite clock protypes in order to compare them together.

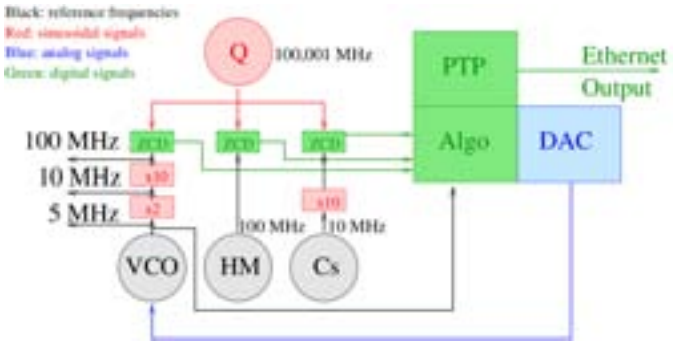

Fig. 3. Block diagram of the composite clock.

Composite clock	Short term reference	Mid term reference	Long term reference
CC 1	5 MHz BVA VCO	OSA 3705 passive H-Maser	OSA 3210 Cs clock
CC 2	10 MHz BVA VCO	Datum MHM 2010 act. H-Maser	5071A opt. 001 Cs clock

Each prototype (see fig. 4) is composed of [1], [2]:

- a DMTD block, where are connected the 100 MHz input from the reference clocks; the ZCD mixes the input frequencies with a 100.001 Mhz coming from a shifted VCO and provides beat frequencies of $\sim$ 1 kHz
- a ZCD block which converts the sine beat frequencies into square signals
- an FPGA where the algorithm [3] is implemented
- a Digital to Analog Converter for the VCO control.

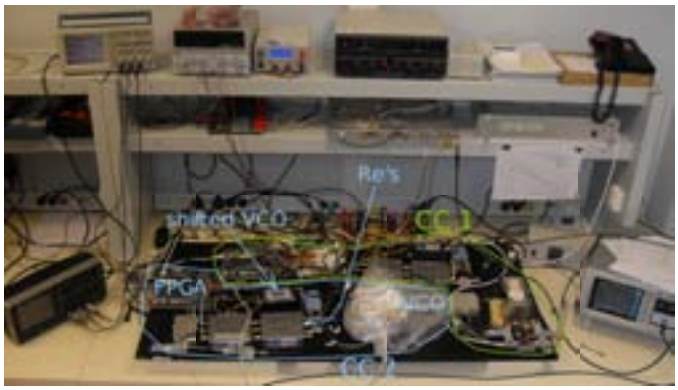

Fig. 4. The two Composite Clock prototypes.

B. Expected stability performances:

CC 1: $\sigma_y(1\text{ s}) < 3 \cdot 10^{-13}$, $\sigma_y(\tau) < 10^{-13}$ for 10 s $< \tau <$ 1000 s, $\sigma_y(1000\text{ s}) = 10^{-14}$, $\sigma_y(\tau) < 10^{-13}$ for $\tau >$ 1000 s

CC 2: $\sigma_y(1\text{ s}) = 10^{-13}$, $\sigma_y(\tau) < 10^{-13}$ for 1 s $< \tau <$ 100 s, $\sigma_y(\tau) < 10^{-14}$ for 100 s $< \tau <$ 1 day, $\sigma_y(\tau) = 10^{-14}$ for $\tau >$ 1 d.

III. Adjustment of the Control Parameters

The performances of the composite clocks are directly connected to the choice of the time constants (see fig. 5).

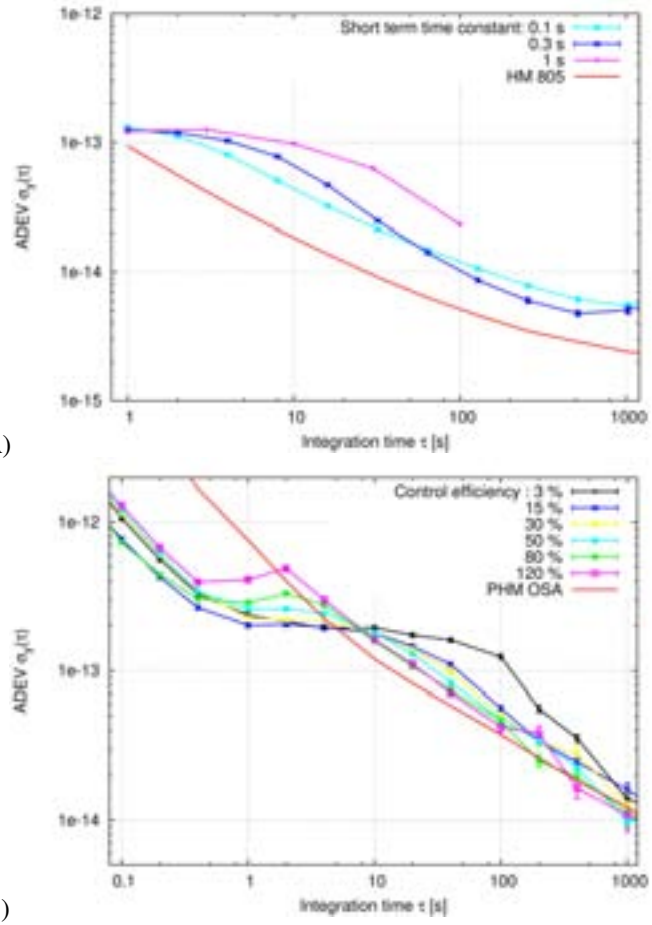

Fig. 5. Influence of the short term time constant (A) and long term time constant (B).

Beside the short and long term time constants, the control efficiency must also be chosen carefully (see fig. 6). It can be defined as the ratio of the command value sent to the VCO over the setpoint, i.e. the command value which should be used in order to totally cancel the error signal.

We selected the following parameters:

Composite clock	CC 1	CC 2
Control efficiency	30 %	30 %
Short term time constant	0.50 s	0.33 s
Long term time constant	10 d	3 d

IV. Initialization Phase and Steady State

During initialization phase ($\equiv$ short term time constant), CC is solely controlled by the Maser. Fig. 7 shows how the

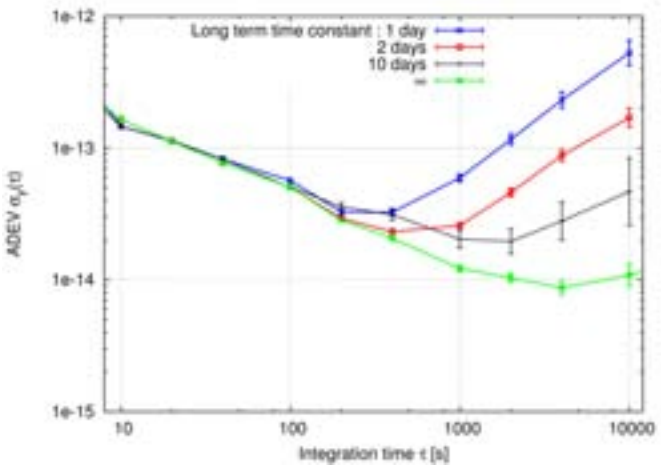

Fig. 6. Influence of the control efficiency for a given short term time constant (1 s).

composite clock frequency of the composite clock switches from the one of the Maser to the one of the Cesium clock.

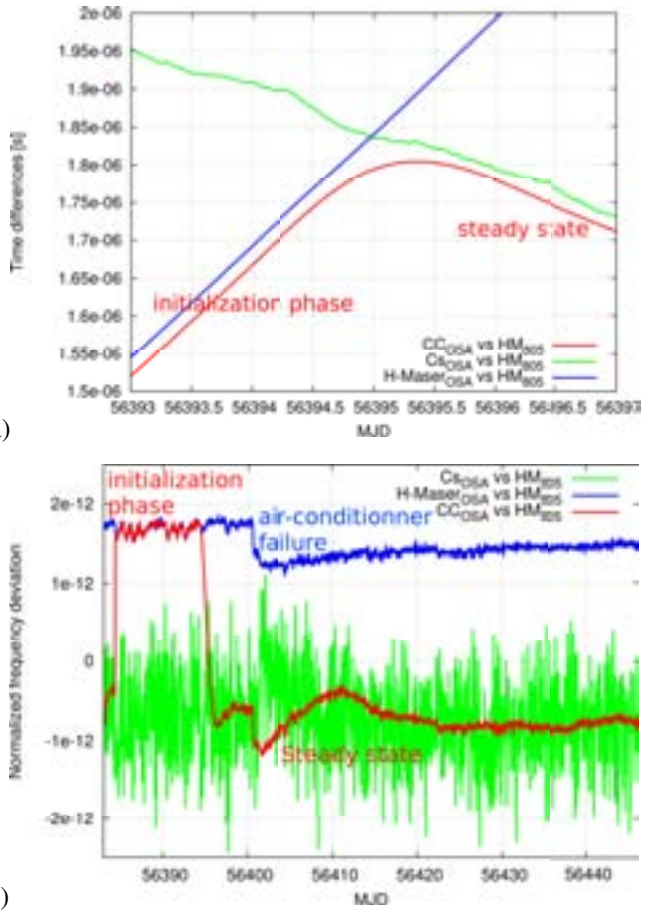

Fig. 7. Transition between the initialisation phase and the steady state of the composite clock seen from the time error data (A) and frequency deviation samples (B).

Fig. 7 shows also the effects of an air-cooler failure in the clock room (MJD 56402).

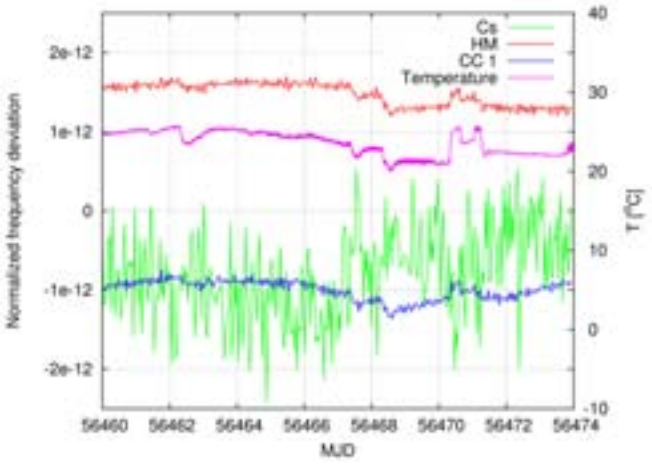

Fig. 8. Correlation between the clock room temperature and the frequencies of the clocks.

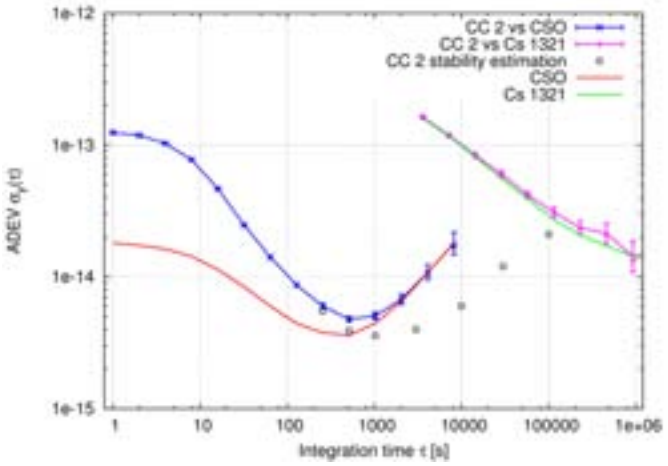

Fig. 10. Measurement of the short and long term stability of CC 2 and estimation of its mid term stability.

V. Temperature sensitivity

Fig. 8 exhibits clearly that the temperature sensitivity of the composite clocks is due to the temperature sensitivity of the reference clocks.

VI. Stability of CC 1

CC 1 stability was measured against the HM 2010 and a Cs 5071A which are more stable than the references of this composite clock. Fig. 9 shows that CC 1 meets partially the specifications.

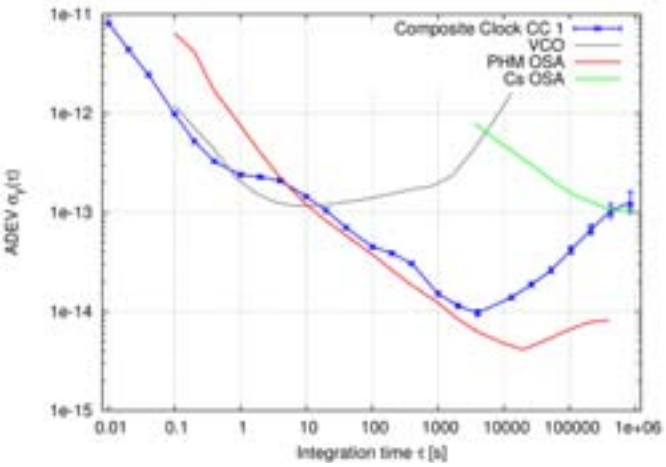

Fig. 9. Stability of CC 1.

VII. Stability assessment of CC 2

The stability of CC 2 was more difficult to measure because we only have one active H-Maser.

Its short term stability was measured thanks to a measurement campaign with the mobile Cryogenic Sapphire Oscillator "Uliss" of Femto-ST (April 2013). The long term stability was measured against another 5071A. However, the mid term stability of CC 2 may only be estimated (see fig. 10).

Fig. 11 shows that CC 1 meets partially the specifications.

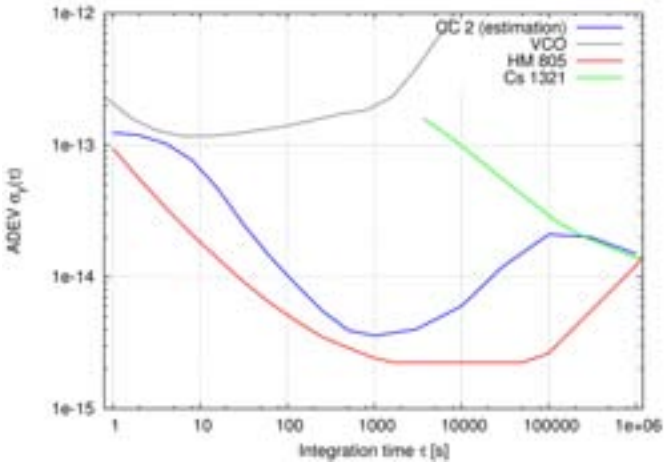

Fig. 11. Estimated stability of CC 2.

VIII. Expected improvements

We could obtain a better fit of the reference clocks by:

- optimizing the long term time constant
- reducing the control sensitivity to electromagnetic disturbances
- increasing the control acuteness.

IX. Acknowledgements

This work was partially funded by an Interreg contract. The authors whish to thank Oscilloquartz for their support and Femto-ST for the measurement campaign with Uliss.

***Abstract*—The group of Polish Time Laboratories has been cooperating closely from at least 15 years. From very beginning also Lithuania was participating in this group. The first common initiative was organizing independent Polish Atomic Timescale TA(PL) [8]. In 2004 has started a project to develop Database for Polish Atomic Timescale TA(PL) [5] to automate the process of time-standards comparison and calculate implemented group timescale ensembles algorithms (weighted average algorithm for a group of time-standards).**

Ensemble algorithms are supposed to be more stable than any of the standard within the group. This very useful feature makes an ensemble a very good stable reference to control and supervise behavior of every standard. In the future it could be also used to steer Polish official realization of international Universal Coordinated Time (UTC) the UTC(PL) maintained by Central Office of Measurement (GUM). The set of ensemble algorithms was primary implemented in Database: original algorithm of TA(PL) based on ALGOS [6], [7] (algorithm developed by International Bureau of Measurements –BIPM), one day-shifted ALGOS version and AT1 [2] (algorithm developed by National Institute of Standard and Technology -NIST).

During last years the Time-team of Institute of Telecommunications has implemented in Database a realization of AT2 algorithm developed on the basis of theorem published by NIST. Preliminary results shows that AT2 is more stable than others.

The last part of article shows analysis of results of new implemented algorithms and comparison to former implementations.

Keywords—time, timescalescale ensemble, database, Polish Atomic Timescale

I. DATABASE FOR POLISH ATOMIC TIMESCALE (TA(PL))

The National Institute of Telecommunications (NIT) cooperates within Group of polish Time Laboratories which are developing Polish Independent Atomic Timescale TA(PL). From the beginning Lithuanian Center for Physical Sciences and Technology (CPST) also has participated in calculations. Number of time standards which form our timescale have changed from 7 to about 20 during the time. All Laboratories are equipped with atomic standards which are held in special rooms equipped with precise air-condition, secure electricity supply and with appropriate time transfer systems satellite or optical fiber.

Complete list of Laboratories is shown below:

- Central Office of Measurements (GUM): 4 timestandards

  Astro-geodynamical Laboratory (AOS) of Polish Research Space Center: 4 timestandards
- National Institute of Telecommunications: 2 timestandards
- Military Metrology Laboratories: 3 locations (CWOM-B, CWOM-Z, SWOM), 4 timestandards
- Polish Telecommunication – Orange: former national telecommunication operator, 3 locations (CBR, ZGO, TP_Anin) – 3 timestandards (3 waiting for connection)
- Lithuania – Center for Physical Sciences and Technology (CPST) – 2 timestandards

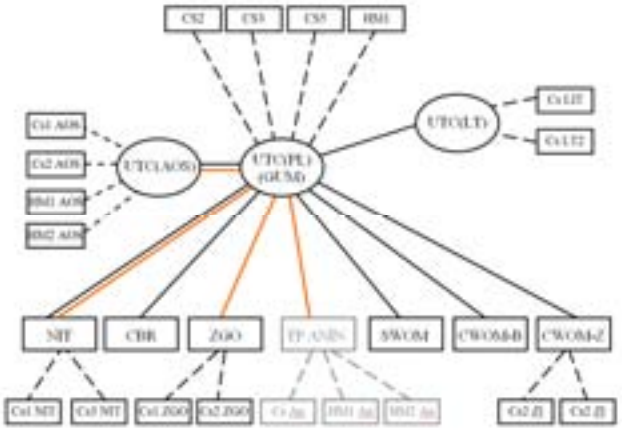

Fig. 1. Independent Polish Atomic Timescale (TA(PL)) timestandards comparision scheme

Presented results were obtained during realization of the project „Research and development of time and frequency ensembles on Database for TA(PL)" financed by polish National Science Centre.

The figure above (Fig.1.) shows actual TA(PL) comparisons scheme. Dashed lines represents internal comparisons of clocks within every laboratory. Black lines represents GPS CV satellite links and orange lines shows fiber-optics connections/comparisons [1].

The task for Time and Frequency Metrology Laboratory (of NIT) is to create timescale ensemble algorithms and implement it on Database for TA(PL) [3], [5]. The result was the automated system that allows almost real time control over compared time standards. The main participant of these works is polish Central Office of Measures (GUM) which is assigned by law as a distributor of official Polish Time UTC(PL) and other laboratories from the Group.

Main role of the Database was to reduce time of waiting for results of comparisons of clocks from BIPM which was necessary to control time and frequency. In the beginning the delay was about 1.5 month. Now the UTC Rapid test-service is available once a week. Database allows to get the needed corrections every day or even few times a day with appropriate ensemble timescale algorithm.

Database is organized in three major subsystems:

- Data acquisition unit – managing of data files
- Calculation unit – calculation of clocks comparisons and timescales algorithms
- Results presentation unit – presenting demanded results

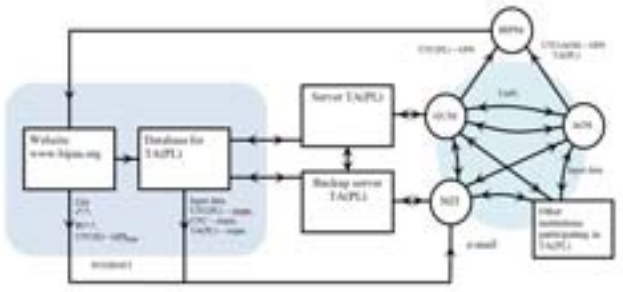

Fig. 2. Database workflow scheme

Database can handle wide range of comparison file types:

- Standard GPS/GLONASS data files – compatible with CGGTTS format
- Direct clock-clock data files (also via fiber-optic links)
- Correction files – with information about known phase and frequency steps

Database provides many useful functions such as comparisons clocks one to one, UTC and any of implemented algorithm, comparisons of any algorithm to UTC/TAI and also for advanced users it also allows to modify initial parameters of test timescales and proceed calculation (this function is very useful to tune up algorithms). It is possible to calculate standard analysis such as ADEV and TDEV or estimation of drift by using Discrete Model function.

Database presents also different useful information about localization of clocks and their types, information board to announce important declarations by users of Database, upload function of many types of files to share with other users and download function of original clocks comparison data files.

Fig. 3. Analytical functions of Database for TA(PL)

II. Database Timescale Ensemble Foundations

The main function of the Database is to automatically calculate implemented timescale ensemble algorithms and Polish Atomic Timescale algorithm among others. It makes possible to steer physical realization of Official Polish Time UTC(PL) by GUM, as close as possible to UTC.

Timescale ensemble algorithm [7], [10] is a special construction of weighted mean average of comparisons' results of atomic timestandards. Weights for individual timestandards are calculated from the results history.

The final result of calculation is a table of corrections for every clock within the group compared to timescale ensemble. The equation below presents a base definition of timescale ensemble $A(t)$:

$$A(t) = \frac{\sum_{k=1}^{N} w_k(t)\left[H_k(t) - \hat{H}_k(t)\right]}{\sum_{k=1}^{N} w_k} \quad (1)$$

where:

$w_k(t)$ – weight of the timestandard k
$H_k(t)$ – result of the timestandard k in moment t
$\hat{H}_k(t)$ – prognosis of the timestandard k in moment t from timescale A
t – time of calculation of the ensemble
N – number of timestandards.

III. ALGORITHMS IMPLEMENTED IN DATABASE FOR TA(PL)

At the beginning the number of standards in our Group was close to 10 rather than 20. So small number was very hard to overcome due to target we wanted to achieve. The purpose of implement new timescale algorithms was:

- Realization of timescale ensemble with good med-term stability and shortest access time possible
- Better control of timestandards beetween BIPM and GUM reports publication
- Possibilty of steering the physical time signals (eg. National realization of UTC)

In the course of the number of timestandards has increase making this tasks easier to complete.

At the beginning there were implemented three ensemble timescale algorithms original ALGOS based, day-shifted ALGOS and AT1. In the next part of this section, the main features of implemented algorithms will be listed.

ALGOS algorithm (the both versions) can be characterized as follows:

- Algorithm is calculating weights by analyzing frequency changes in set period of time
- Frequency deviations are calculated for period of a month
- The average value of frequency deviations is calculated for last 12 previous months and then compared with the last result

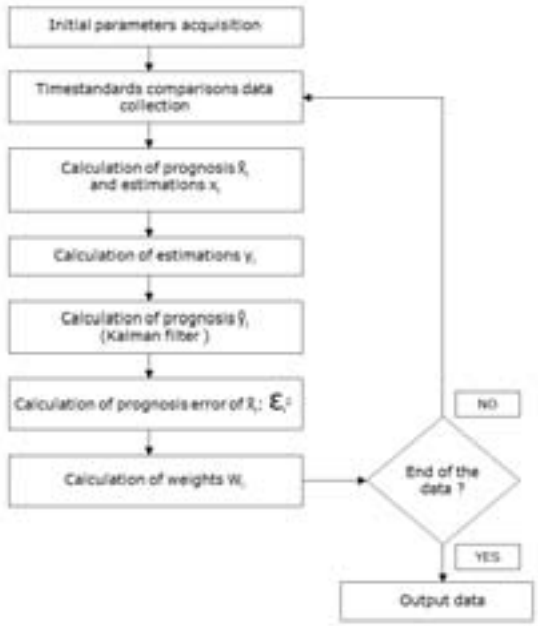

Fig. 4. AT2 algorithm scheme

The last activity was implementation a new timescale algorithm better suited for our Group AT2 developed and presented by NIST [2]. Fig. 3. shows the workflow scheme of this algorithm.

AT1 and AT2 algorithms are very similar. Basic differences:

- Noise model
- Prognosis calculation method for drift and frequency deviation

In the case of an AT1 algorithm, frequency prognosis is calculated as the mean average of results obtained in previous steps of algorithm. Weights are decreasing in geometric progression in time and drift is constant.

An AT2 algorithm is modification of AT1. It calculates frequency deviations and drift from Kalman filter.

Next figures show some results of research. Fig.5. presents the result of research on initial parameters of AT2 algorithm. All initial parameters was exactly thy same except matrix element in Kalman model responsible for the drift and frequency deviation estimation. Despite the fact tahat agorithm is higly adaptive, if goal woud be to reduce frequency deviation with reference to TAI [6], [7], [10], precise analysis shoud be done before starting the algorithm. Stability of compared results was very similar.

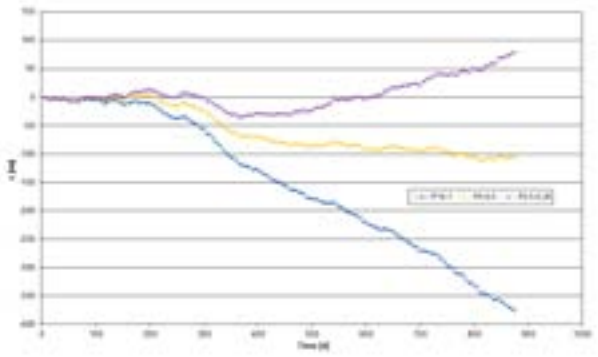

Fig. 5. Research on initial parameters dependencies of AT2 algorithm

Next two figures shows stability comparison between implemented in Database three ensemble algorithms.

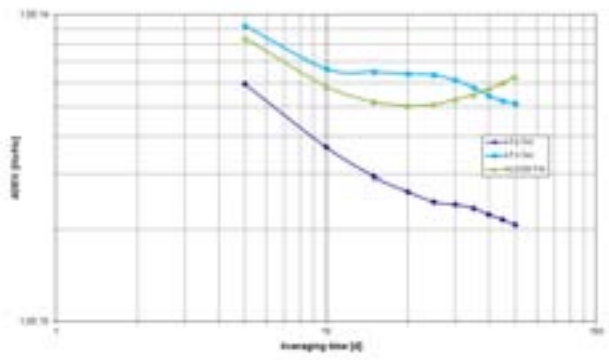

Fig. 6. ADEV comparison of implemented algorithms

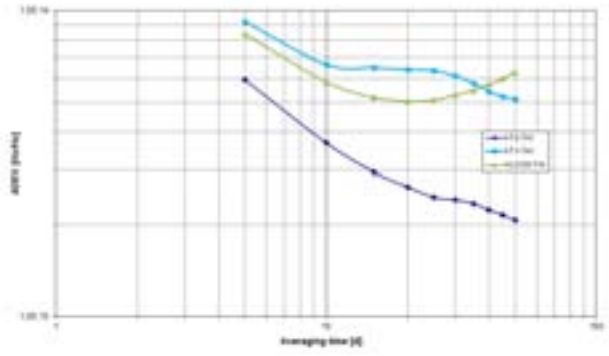

Fig. 7. TDEV comparison of implemented algorithms

Fig. 6. and Fig. 7. shows that AT2 algorithm implemented in Database seems to be more stable than others, at least in case of rather not so big number of clocks in our Group.

IV. FUTURE PLANS

Presented results shows, that implemented AT2 algorithm have a great potential to be very useful reference for steering UTC(PL), but research must be continued and new set of functions added to Database for TA(PL).

Our work concerns now on implementation new functions for fault detection problems (accidental phase or frequency shifts), advanced filtering of input data (Vondrak filtering), and functions for automatic steering of physical time signal (eg. UTC(PL)). Further development of Database should allow also real-time automatic comparison of different time transfer methods.

We are planning also implementations of new analytical functions and prepare daily automatic report sent by email to Database users.

***Abstract*—The signal path delay difference due to satellite motion relative to the ground stations adds non-reciprocity to Two-way Satellite Time and Frequency Transfer (TWSTFT). For the availability of broadcast ephemeris for the geostationary satellite for TWSTFT in BeiDou navigation system, an iterative method for signal path delay difference estimation due to the satellite motion is proposed, which is compared with the ranging method. The one day TWSTFT experiment data with BeiDou GEO satellite at 140°E experiment between Beijing and Sanya has been analyzed, which show that the signal path delay difference is less than 0.14ns and the difference of the results using these two methods is less than 0.11ps. This implies that there is no need to conduct ranging when the broadcast ephemeris is available for the estimation signal path delay difference.**

Keywords—TWSTFT; iterative method; ranging; signal path delay difference; broadcast emphmeris

I. INTRODUCTION

Two-way Satellite Time and Frequency Transfer (TWSTFT) based on signal exchange via Geostationary Earth Orbit (GEO) Satellite has been conducted worldwide [1]. The non-reciprocity correction is important for TWSTFT, which includes Sagnac correction, ionospheric correction, tropospheric correction, earth station delay difference and signal path delay difference geometrically due to satellite motion relative to the earth [1]. In previous studies, the ranging data between the ground station and GEO satellite is used to estimate signal path delay difference [2-4]. In BeiDou Navigation System, TWSTFT via navigation GEO satellite is implemented [5]. The broadcast ephemeris is available as orbit data for the GEO satellite in BeiDou Navigation System, which gives a chance for a new method called iterative method to estimate signal path delay difference.

II. SYSTEM AND EXPERIMENT DESIGN

Since the distances of the satellite from the two sites are usually different, the signals transmitted by the two sites at the same time will reach the satellite at different time [6]. Due to the relative motion of GEO satellite to the ground stations, the signals will reach the satellite at different positions as demonstrated in Fig.1.

In TWSTFT, each ground station transmits a radio frequency signal modulated by pseudorandom noise (PRN) codes referring to its own clock to GEO satellite as the real lines upwards in Fig. 1. The GEO satellite retransmits the signals to the earth. Each ground station receives the transmitted signals from the other station demonstrated as the real lines downwards in Fig. 1 and its own (called round-trip ranging) demonstrated as dashed lines in Fig. 1.

If we define $\tau_{\mathrm{Ui|Sat}}$ as signal path delay geometrically from ground station i upward to GEO satellite, and $\tau_{\mathrm{Di|Sat}}$ as signal path delay geometrically from GEO satellite downward to ground station i, the non-reciprocity for TWSTFT due to signal path delay difference geometrically is as below:

$$\tau_{UD,Sat} = 0.5((\tau_{U1}|_{Sat} - \tau_{D1}|_{Sat}) - (\tau_{U2}|_{Sat} - \tau_{D2}|_{Sat})) \quad (1)$$

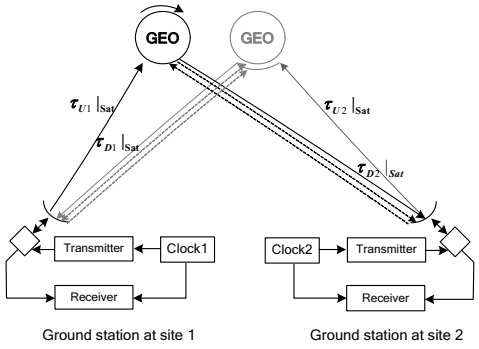

Fig. 1. Two-way Satellite Time and Frequency Transfer with satellite motion

III. ITERATIVE METHOD

As demonstrated in Fig.1, the positions of GEO satellite when it transmits signals for two-way links are important for signal path difference estimation. The iterative method is a way to estimate these GEO satellite positions when the receiving epoch is known and the broadcast ephemeris is available.

The proposed iterative method works as follows.

- Step 1: to estimate an initial signal transfer delay from GEO satellite to the ground station.
- Step 2: to estimate the epoch when GEO satellite transmits signal with the receiving epoch subtracted by the initial signal path delay.
- Step 3: to estimate the GEO satellite position at the transmitting epoch with the broadcast ephemeris.
- Step 4: to estimate the signal transfer delay between the estimated GEO satellite position and the position of ground station receiving signal with Sagnac correction by coordinate rotation [7], ionospheric correction [1], and tropospheric correction [8].
- Step 5: to repeat from Step 1 to Step 4 using the updated estimated signal transfer delay as the initial signal transfer delay in Step 1, until the error between the adjacent estimated signal path delays is below the defined threshold.

Then, the GEO satellite position at the transmitting epoch for two-way links can be estimated. Finally, signal path delay difference between two ground stations via GEO satellite can be obtained by the difference of geometry distances of two-way links after Sagnac correction.

IV. Experiment and Conclusions

The TWSTFT experiment data for one day with BeiDou GEO satellite at 140°E experiment between Beijing and Sanya has been analyzed. The signal path delay difference is estimated with ranging method described in [2] and the iterative method respectively.

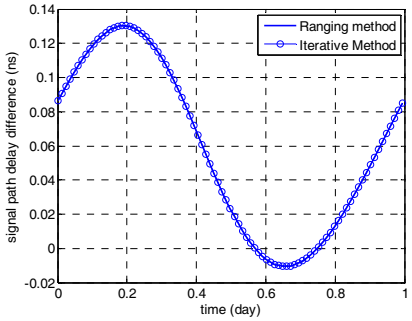

Fig. 2. Signal path delay difference estimated by ranging method and iteration method.

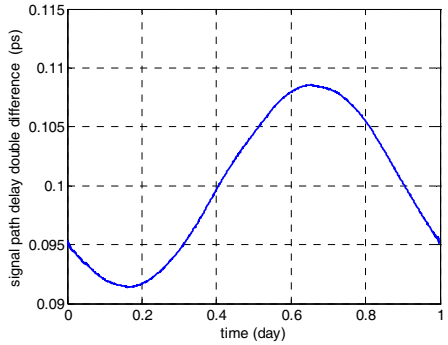

Fig. 3. Signal path delay double difference: the difference of the signal path delay estimated by ranging method and iterative method.

The experiment results show that the signal path delay difference is less than 0.14ns and the difference of the results using these two methods is less than 0.11ps.

This implies that there is no need to conduct ranging when the broadcast ephemeris is available for the estimation signal path delay difference.

Study and Application of Real-Time Frequency Deviation Adjustment Algorithm in Establishing a Time Scale

Yiwei Wu, Lei Chen, Xiangwei Zhu, Gang Ou
School of Electronic Science and Engineering, National University of Defense Technology
Changsha, China
Email: Yiwei_Wu_sh@126.com

***Abstract*—The time scale algorithm is the key of the establishment of a time scale. This paper proposes a real-time frequency deviation adjustment algorithm. This paper describes the idea and implementation of this algorithm. The algorithm utilize a Kalman filter to estimate the state between the master clock and the other clock, and then adjust the frequency deviation and predict the next time deviation between these two clocks and thus reconstruct the time deviation. The simulated experiments utilize two commercial cesium clocks (Symmetricom -5071A). The principle, idea and performance of the Kalman filter is studied and analyzed. The simulated results indicate that the frequency stability of this reconstructed time deviation is improved effectively when utilizing this algorithm. Since the reconstructed time deviation is the adjusted clock difference between the master clock and the other clock, the conclusion can be got that the frequency stability of the master clock's time scale is also improved effectively. The algorithm is real-time, and its implementation is with low cost and easy to realize and control, so the algorithm is of high engineering and application values.**

Keywords—Time scale algorithm; Frequency stability; Kalman filter; Real-time frequency deviation adjustment;

I. INTRODUCTION

Satellite navigation system is essentially a time synchronization system. It is necessary to establish a stable time scale of satellite navigation system. The time scale algorithm[1] is the key of the establishment of a time scale. Since satellite navigation system needs real-time forecasting the state of onboard atomic clocks, the time scale should be real-time and predictive. For high-precision positioning and timing, the requirement for the short-term stability of the time scale is relatively high.

This paper proposes a real-time frequency deviation adjustment algorithm. The principle, the essential idea and the implementation of the algorithm are described in this paper. Since this paper utilizes a Kalman filter to estimate the state of the atomic clocks, the principle, idea and performance of the Kalman filter are also studied in depth in this paper. In this paper, the observations are measured clock difference of PTB (Germany). The simulated results of the established time scale are analyzed. The appropriate conclusions are drawn in the end. The research will have impact on the establishment of a time scale.

II. BASIC PRINCIPLES AND ANALYSIS OF THE ALGORITHM

A. Basic principles and implement of the real-time frequency deviation adjustment algorithm

The main aim of a time scale algorithm is to improve the frequency stability of a time scale. This paper proposes a real-time frequency deviation adjustment algorithm which is different from the frequency steering algorithm and the weighted-average algorithms.

To illustrate the main idea more clearly, only two atomic clocks are used at first. The main steps of this algorithm are follows. Firstly, use a Kalman filter to estimate the state between the master clock and another clock. Secondly, adjust the frequency deviation and predict the next time deviation between these two clocks and thus reconstruct the time deviation.

$$x'(t+\tau) = x(t) + \hat{y}(t) \times \tau \qquad (1)$$

$\hat{y}(t)$ is the estimated frequency deviation. τ is the time interval. $x(t)$ is the first time deviation. $x'(t+\tau)$ is the reconstructed time deviation.

These two steps make up a whole cycle. In the next cycle, the time deviation at the next time can be predicted by the estimated frequency deviation and the reconstructed time deviation, and the next reconstructed time deviation can be obtained.

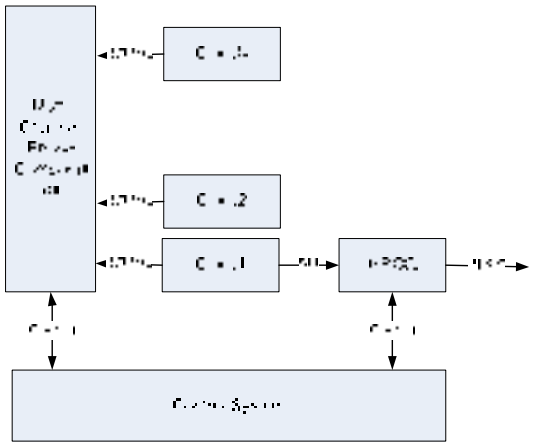
$$x'(t+2\tau) = x'(t+\tau) + \hat{y}(t+\tau) \times \tau \qquad (2)$$

Then continue the cycle. At last, a whole reconstructed time deviation can be obtained. The whole reconstructed time deviation is the adjusted clock difference between the master clock and the other clock. The observations of this algorithm are the first time deviation and each estimated frequency deviations.

If there exist N clocks, N-1 estimated frequency deviations between the master clock and other clocks can be obtained when running this algorithm. After that, a weighted-average algorithm will be designed to further improve the stability,

which is not the emphasis in this paper. This paper utilizes two clocks to illustrate the performance of the algorithm.

The common implementation is given below.



Figuer 1 Implementations of the algorithm

In the picture, HROG represents a high resolution phase and frequency offset generator. Clock represents an atomic clock, which can be a cesium clock or a hydrogen maser. Control System can be a PC.

The multi-channel phase comparator measures the clock differences between each clock. The PC obtains the clock differences in real time, and utilizes the Kalman filter to estimate the state between the master clock and the other clock. At the same time the PC sends command to the HROG to adjust the frequency deviation of the master clock according to equation (1) and (2). The output of the HROG is the time scale, which can be used as UTC(k). Thus, a time scale is established[1][2].

To conclude, the algorithm is real-time, and its implementation is with low cost and easy to realize and control, so the algorithm is of high engineering and application values.

In the following of this paper, since Kalman filter[2][3][4][6] plays important role in this algorithm, the idea, principle of the Kalman filter are described in detail.

B. Idea, principle of the Kalman filter

The stochastic differential equation of an atomic clock[2][6][7][8] can be described as follow.

$$\begin{cases} x(t) = x_1(t) + n_1(t) \\ \cdot \\ x_1(t) = x_2(t) + n_2(t) \\ \cdot \\ x_2(t) = x_3(t) + n_3(t) \\ \cdot \\ x_3(t) = 0 \end{cases} \quad (3)$$

$x_1(t)$, $x_2(t)$ and $x_3(t)$ represent the time deviation, a part of the clock frequency deviation and part of the so-called frequency drift of this clock respectively. $n_1(t)$、$n_2(t)$ and $n_3(t)$ are Gaussian processes, which represent the white phase noise, the white frequency noise and the walk random frequency noise whose variances are σ_1^2, σ_2^2 and σ_3^2 respectively.

The atomic clock state equation and observation equation[6][8][9][10] can be written as equation (4) and (5) respectively.

$$X[k+1] = \Phi X[k] + \eta[k] \quad (4)$$

$$Z(k) = H \bullet X(k) + V \quad (5)$$

X[k] represents the state of the atomic clocks. Φ represents the state transition matrix. $\eta[k]$ represents the innovation. *Z(k)* represents the observation which is usually the clock difference. *H=[1 0 0]* is the design matrix. *V* represents the measurement noise whose covariance matrix is *R*. *Q* is the covariance matrix of η [k] which can be written as follow.

$$Q = \begin{bmatrix} \tau\sigma_2^2 + \frac{1}{3}\tau^3\sigma_3^2 & \frac{1}{2}\tau^2\sigma_3^2 & 0 \\ \frac{1}{2}\tau^2\sigma_3^2 & \tau\sigma_3^2 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (6)$$

Equations (3), (4) and (5) imply that the noise component of *Z(k)* are the linear sum of the phase white noise $n_1(t)$ and the measurement noise *V*[8].

The estimated atomic clock state can be obtained according to the following Kalman filter equations.

$$\begin{cases} \hat{\overline{X}}_{k,k-1} = \Phi_{k,k-1}\hat{\overline{X}}_{k-1,k-1} \\ P_{k,k-1} = \Phi_{k,k-1}P_{k-1,k-1}\Phi_{k,k-1}^T + Q_{k-1} \\ K_k = P_{k,k-1}H_k^T(H_kP_{k,k-1}H_k^T + R_k)^{-1} \\ P_{k,k} = (I - K_kH_k)P_{k,k-1} \\ \hat{\overline{X}}_{k,k} = \hat{\overline{X}}_{k,k-1} + K_k\left(\overline{Z}_k - H_k\hat{\overline{X}}_{k,k-1}\right) \end{cases} \quad (7)$$

The conclusion can be got that the essential idea of the Kalman algorithm is to estimate $x_1(t)$, $x_2(t)$ and $x_3(t)$ of an atomic clock respectively. At the same time, the phase white noise $n_1(t)$ and the measurement noise *V* in $x_1(t)$ are smoothed out compared to the original clock difference. Besides those noise components, the white frequency noise in $x_2(t)$ is also smoothed out compared to the original frequency deviation. Besides those noise components, the walk random frequency noise in $x_3(t)$ is further smoothed out compared to the original frequency drift. To conclude, the Kalman algorithm is a status estimation algorithm as well as a noise removing algorithm.

The above analysis implies the reference is an ideal time scale which contains no noise. But in fact the observation is the clock difference. The noise components of the time difference are the linear sum of those of the two clocks.

The Allan variances of these two atomic clocks can be written as follows.

$$\sigma_{y1}^2(\tau)=h_{-2}^1\frac{(2\pi)^2}{6}\tau+h_{-1}^1 2\ln 2+h_0^1\frac{1}{2\tau}+ h_1^1\frac{1}{(2\pi\tau)^2}\{3[2+\ln(2\pi f_h\tau)]-\ln 2\}+h_2^1\frac{3f_h}{(2\pi\tau)^2} \quad (8)$$

$$\sigma_{y2}^2(\tau)=h_{-2}^2\frac{(2\pi)^2}{6}\tau+h_{-1}^2 2\ln 2+h_0^2\frac{1}{2\tau}+ h_1^2\frac{1}{(2\pi\tau)^2}\{3[2+\ln(2\pi f_h\tau)]-\ln 2\}+h_2^2\frac{3f_h}{(2\pi\tau)^2} \quad (9)$$

$\sigma_{y1}^2(\tau)$ and $\sigma_{y2}^2(\tau)$ are the Allan variances of these two clocks. h_{-2} , h_{-1}, h_0, h_1 and h_2 represent noise coefficients. The superscript 1 and 2 of the noise coefficients represent the first and second atomic clocks respectively. f_h is the high cut-off frequency.

The Allan variance of the clock difference is follows.

$$\sigma_y^2(\tau)=(h_{-2}^1+h_{-2}^2)\frac{(2\pi)^2}{6}\tau+(h_{-1}^1+h_{-1}^2)2\ln 2+(h_0^1+h_0^2)\frac{1}{2\tau} +(h_1^1+h_1^2)\frac{1}{(2\pi\tau)^2}\{3[2+\ln(2\pi f_h\tau)]-\ln 2\}+(h_2^1+h_2^2)\frac{3f_h}{(2\pi\tau)^2} \quad (10)$$

The noise variances can be obtained as follows.

$$\begin{cases}\sigma_1^2=\sigma_{pw}^2=\dfrac{f_h}{(2\pi)^2}(h_2^1+h_2^2)=\sigma_{pw1}^2+\sigma_{pw2}^2\\ \sigma_2^2=\sigma_{fw}^2=\dfrac{1}{2}(h_0^1+h_0^2)=\sigma_{fw1}^2+\sigma_{fw2}^2\\ \sigma_3^2=\sigma_{rw}^2=\pi^2(h_{-2}^1+h^2{}_{-2})=\sigma_{rw1}^2+\sigma_{rw2}^2\end{cases} \quad (11)$$

So the each kind of noise variance of the clock difference is the linear sum of that of the two clocks.

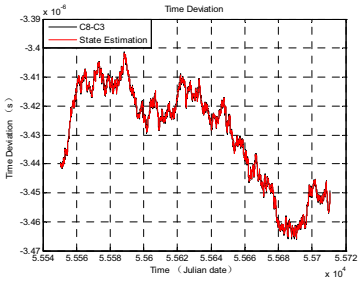
Given the clock difference, the noise coefficients can be obtained by the inversion of the Allan variance, and then the noise variances and Q can be obtained.

Although Q contains noises of two clocks, the Kalman filter cannot distinguish them. We can suppose that the noises come from one clock and the other clock is an ideal time scale. Thus we can use the same method to remove the noise components of the clock difference as that to remove the noise components of an atomic clock.

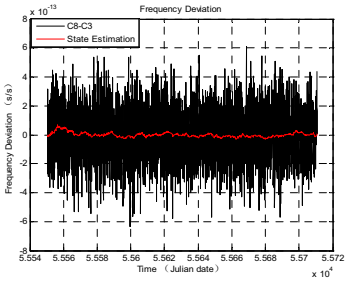
III. Performance of the Algorithm

A. Performance of the Kalman filter

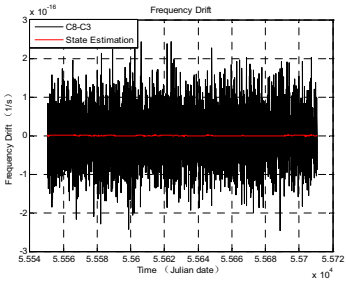
Using clock difference between two commercial cesium clocks (Symmetricom-5071A) C8-C3 as the observation, running the Kalman algorithm, the estimated state can be obtained.



(a) The original time deviation and $x_1(t)$



(b) The original frequency deviation and $x_2(t)$



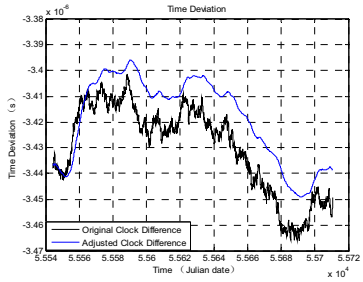
(c) the original frequency drift and x3(t)

Figuer 2 the original state and the estimated state

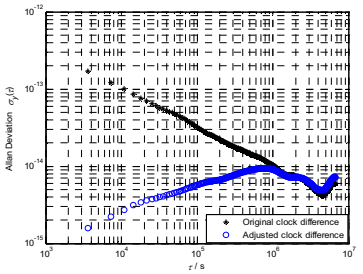
The simulation results indicate that the Kalman algorithm can estimate $x_1(t)$, $x_2(t)$ and $x_3(t)$ and smoothes out the noise components in $x_1(t)$, $x_2(t)$ and $x_3(t)$ from the original time deviation, frequency deviation, frequency drift respectively.

B. Performance of the Real-Time Frequency Deviation Adjustment Algorithm

Using clock difference C8-C3 as the observation, running the real-time frequency deviation adjustment algorithm to reconstruct the time deviation, the adjusted clock difference is obtained.



（a） The original clock difference and the adjusted clock difference.



（b） The Allan Deviations of the original clock difference and the adjusted clock difference.

Figuer 3 Time Deviations and Allan Deviations of the Time Scale and the original clock difference

In the picture, the black curves represent the original C8-C3 clock difference and its Allan deviation, and the blue curves represent the adjusted clock difference and its Allan deviation. The stabilities of the original clock difference and the adjusted clock difference are shown in the following table.

Table 1 Frequency Stabilities of each Time Scales

Frequeny Stability (ADEV)	Original Clock Difference	Adjusted Clock Difference (Reconstructed Time Deviation)
1h	1.78×10^{-13}	8.38×10^{-16}
1d	3.53×10^{-14}	4.60×10^{-15}
5d	1.56×10^{-14}	8.50×10^{-15}
30d	6.63×10^{-15}	6.69×10^{-15}
60d	4.60×10^{-15}	5.58×10^{-15}

Conclusions can be got as follows. Since the Kalman filter smoothes out the noises from the frequency deviation effectively, the white frequency noise component of the adjusted clock difference is decreased. The stability at the average time less than 5 days is significantly improved. When $\tau = 3600s$, the stability of the adjusted clock difference is 8.37 $\times$ 10^{-16}, which is significantly better than that of an active hydrogen maser VCH-1003M. Since the adjusted clock difference contains noises of the master clock and the other clock, the conclusion can be got that the stability of the master clock's time scale is also improved effectively. The simulation results indicate that this real time frequency deviation adjustment algorithm is effective.

IV. CONCLUSION

This paper proposes a real-time frequency deviation adjustment algorithm, and gives its implementation. The idea and main steps of this algorithm are described in this paper. This paper proves that the Kalman filter can effectively estimate the state and smooth out noises. To illustrate the main idea more clearly, only two commercial cesium clocks (Symmetricom-5071A) are used in the simulation. The simulate results indicate that the amount of the white frequency noise of this time deviation is decreased and the stability of this time deviation at the average time less than 5 days is improved effectively. The stability at the average time of 1 hour of this time deviation is 8.37 × 10^{-16}, which is significantly better than the stability of an active hydrogen maser VCH-1003M. Since the time deviation is the adjusted clock difference between the master clock and the other clock, the conclusion can be got that the stability of the master clock's time scale is also improved effectively. The algorithm is real-time, and its implementation is with low cost and easy to realize and control, so the algorithm is of high engineering and application values.

ACKNOWLEDGMENT

To express my sincere appreciation to PTB who provides the experimental data.

***Abstract*- In this work the clock parameters determination of several timing receivers TTS-4 (AOS, PL), ASHTECH-Z-XII3T (PTB, USNO) and SEPTENTRIO POLARX4TR (ORB,) by use of the Precise Point Positioning (PPP) technique were presented. The clock parameters were determined for several time links based on the data delivered by time and frequency laboratories mentioned above. The computations cover the period from June 1 2012 to May 31, 2013 and were performed in two modes with 7-day and one-month solution for all links. All RINEX data files which include phase and code GPS data were recorded in 30-second intervals. All calculations were performed by means of Natural Resource Canada's GPS Precise Point Positioning (GPS-PPP) software based on high-quality precise satellite coordinates and satellite clock delivered by IGS as the final products. The received results were compared with the results obtained by GPS CV and TWSTFT.**

The used independent PPP technique is a very powerful and simple method which allows for better control of antenna positions in AOS and a verification of other time transfer techniques like GPS CV, GLONASS CV and TWSTFT. The precision of the PPP technique is only comparable to the glass fiber link PL-AOS realized at present by PL and AOS time labs. Currently PPP technique is one of the main time transfer methods used at AOS considerably improving and strengthening the quality of the Polish time scales UTC(AOS), UTC(PL), and TA(PL).

I. INTRODUCTION

In this paper, the results of analysis of the GPS 30-seconds phase and code RINEX data by use of the Precise Point Positioning technique are presented. The PPP method is described in [1, 2]. All analyzed data were gathered by different timing receivers: two TTS-4 [3] receivers located at Astrogeodynamic Observatory Borowiec (AOS) and Central Office of Measures (GUM, PL), two ASHTECH Z-XII3T's working at Physikalisch-Technische Bundesanstalt (PTB) and U.S. Naval Observatory (USNO) and one SEPTENTRIO POLARX4TR situated at Observatoire Royal de Belgique (ORB). All laboratories are equipped with H-masers, excepting PL where the reference clock is a caesium standard. For the first time we presenting a one year comparison of UTC(AOS), UTC(PL), UTC(PTB), UTC(ORB) and UTC(USNO) atomic timescales supported by PPP technique. This work is a continuation and extension of the studies presented during 43th PTTI [4].

All PPP calculations were made in two modes: 7-day and 35-day solutions for the period from June 1, 2012 to May 31, 2013. In these modes the computations were done for four time links: AOS-PL and AOS-PTB (short baselines), AOS-ORB (medium baseline) and AOS-USNO (very long baseline). All computations were performed by means of the Natural Resource of Canada GPS Precise Point Positioning (GPS-PPP) software [5], release 052011; IGS's *sp3* precise orbits and *clk* final products were used.

Additionally the comparison of UTC(AOS)-UTC(PTB) and UTC(AOS)-UTC(USNO) using three time transfer techniques (GPS CV, TWSTFT and PPP) were accomplished in order to show what is the difference in precision for various time transfer techniques realized nowadays by most time labs in the world.

The obtained PPP results presented in this paper characterize a high precision of PPP method w.r.t. other time transfer techniques, which is essential for advanced future works with other GNSS systems of the new generation like Galileo, Beidou and IRNSS.

It is remarkable that today PPP method is only comparable to the glass-fiber link experiments [6].

II. PPP STRATEGY

The all RINEX data were downloaded directly from the receiver (AOS), from BIPM server (PL) and from CDDIS server (PTB, ORB and USNO). The 7-day solution means that seven 24-hour files of data were combined into one file. The same method was applied for 35-day mode. All RINEX data files contained phase and code GPS measurements. For PPP computations the NRCan PPP software were used. In Fig. 1 the basic options nad parameters of the software are shown. The software takes into account both code and phase observations. All processing was carried out for L3 in static mode, in reference to the ITRF2008 frame and was based on GPS 15-minute *sp3* and 30-second *clk* final files delivered by IGS, downloaded from the CDDIS data base.

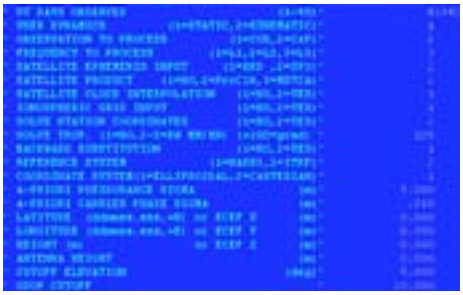

Fig. 1. Basic options and parameters of the NRCan PPP software (release 05211).

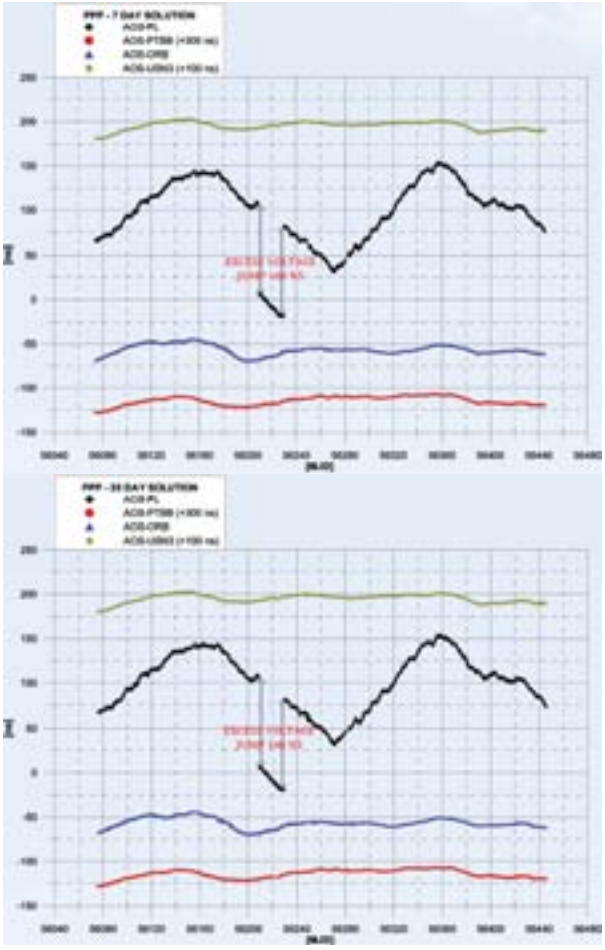

Fig. 2. PPP 7-day (top) and 35-day (bottom) solutions for AOS-PL (black), AOS-PTB (red), and AOS-ORB (blue) and AOS-USNO (brown).

In Fig. 2, the results of PPP computations of all discussed time links are presented. The results cover the period from June 1, 2012 (56079 MJD) to May 31, 2013 (56443 MJD). For better clarity of Fig. 2, the results are rescaled by +300 ns for AOS-PTB and +100 ns for AOS-USNO. In the case of AOS-PL time link a big jump about 100 ns is visible. This disturbance was appeared because of an excess voltage in GUM on October 8, 2012 (56208 MJD) and was eliminated 21 days later on October 29, 2012 (56229 MJD).

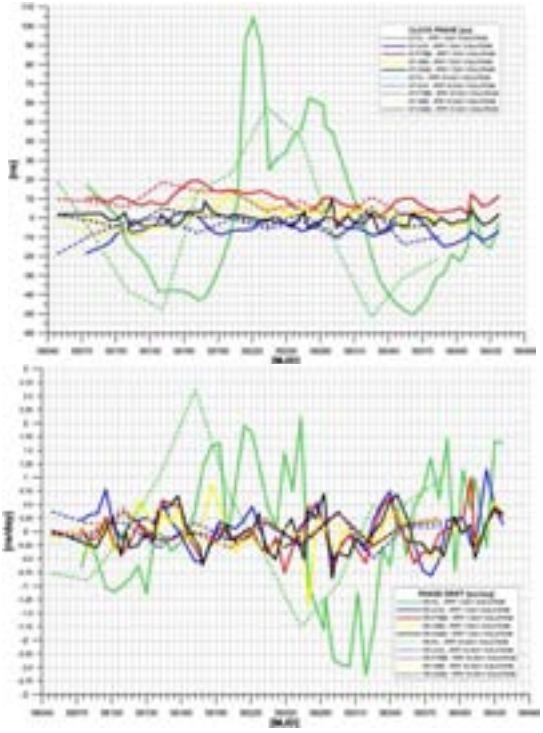

Fig. 3. Clock phase (top) in ns and phase drift (bottom) in ns/day for GUM (green), AOS (blue), PTB (red), ORB (yellow) and USNO (black) for 7-day (solid line) and 35-day (dashed line) PPP solutions.

In Fig. 3 the PPP results of clock phase (CP) and phase drift (PD) are displayed. The CP means receiver clock offset and the PD means receiver clock offset in the function of time. CP is expressed in ns and PD in ns/day. In Fig. 3 the results of CP and PD were presented for each time lab (receiver) separately. The 7-day mode gaved 53 points and 35-day mode gaved 12 points. All points were combined by means of solid and dashed lines, respectively.

Fig. 3 confirms that regulated UTClabs scales synchronized by 1 pps and frequency signal from H-maser reference standard characterized high stability of the realized time scale. In the case of PL (GUM) the big jump of CP and PD in the middle of Fig. 3 is clearly visible. It is connected to the excess voltage occured on October 2012 in GUM (see Fig. 2).

Other form of the results presentation is time deviation demonstration. In Fig. 4-7 the time deviation of all analyzed time links in 7-day and 35-day PPP modes are shown.

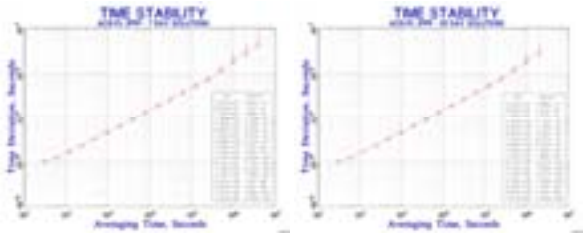

Fig. 4. Time deviation for AOS-PL time link in 7-day (left) and 35-day (right) solution.

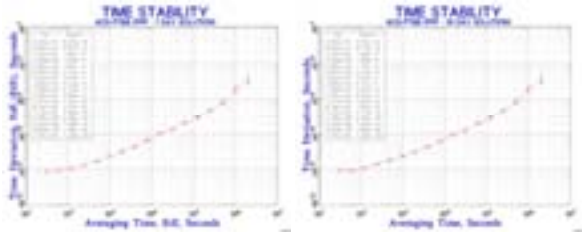

Fig. 5. Time deviation for AOS-PTB time link in 7-day (left) and 35-day (right) solution.

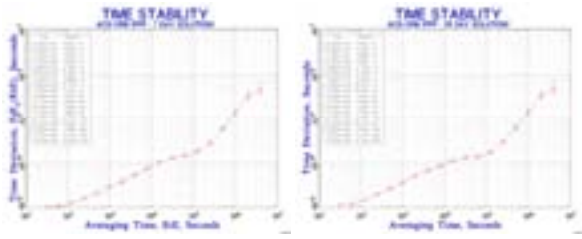

Fig. 6. Time deviation for AOS-ORB time link in 7-day (left) and 35-day (right) solution.

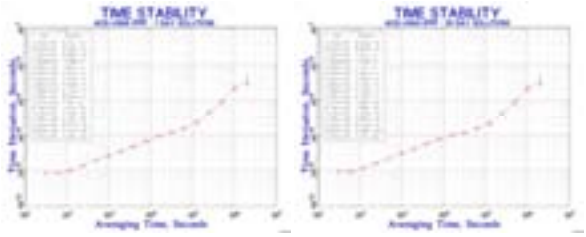

Fig. 7. Time deviation for AOS-USNO time link in 7-day (left) and 35-day (right) solution.

Table 1 shows the time deviation obtained for all PPP time links both for 7-day (7D) as well as 35-day (35D) modes. The best short-term time stability (σ) is for the AOS-PTB and AOS-USNO baselines. If τ is increasing into 24-hour direction then the best time stability are presented by AOS-ORB baseline.

The quality of the results of time transfer techniques, presented in this work is described by RMS as calculated from averaged 24-hour solutions by least squares estimation according to the following formula:

$$\mathrm{RMS} = \sqrt[2]{\frac{\sum_{i=1}^{n} r_i^2}{n}}. \qquad (1)$$

TABLE I
TIME DEVIATION FOR ALL ANALYZED PPP TIME LINKS

time link	AOS-PL		AOS-PTB	
tau [s]	7Dσ [s]	35Dσ [s]	7Dσ [s]	35Dσ [s]
3.00e+01	9.82e-11	9.88e-11	8.35e-12	9.16e-12
6.14e+04	3.75e-9	3.80e-9	2.01e-10	1.93e-10
1.23e+05	5.42e-9	5.47e-9	2.86e-10	2.75e-10
time link	AOS-ORB		AOS-USNO	
tau [s]	7Dσ [s]	35Dσ [s]	7Dσ [s]	35Dσ [s]
3.00e+01	1.02e-11	1.19e-11	8.11e-12	8.92e-12
6.14e+04	1.46e-10	1.35e-10	1.47e-10	1.48e-10
1.23e+05	1.80e-10	1.73e-10	2.19e-10	2.04e-10

Residuum *r* is defined as the difference between the actual value (time lab1 clock – time lab2 clock) and the value predicted by linear regression. The *n* is the number of residua. For 7-day PPP mode the RMS are from 0.08 to 0.98 ns for AOS-PL, from 0.01 to 0.26 ns for AOS-PTB, from 0.01 to 0.31 ns for AOS-ORB and from 0.01 to 0.53 ns for AOS-USNO. For 35-day PPP solution the RMS are from 0.05 to 0.87 ns for AOS-PL, from 0.01 to 0.26 ns for AOS-PTB, from 0.01 to 0.51 ns for AOS-ORB and from 0.01 to 0.53 ns for AOS-USNO. The results showed above mean that PPP results both for 7-day as well as 35-day solutions are comparable.

III. PPP vs. GPS CV and TWSTFT

The last step in these studies were to compare the PPP results with the results obtained from GPS CV (L3P) and TWSTFT techniques. The computations were performed for two time links, AOS-PTB and AOS-USNO and cover the period from September 20, 2012 (56190 MJD) to May 31, 2013 (56443 MJD). This period is shorter to period used for PPP strategy (see section 2) because of an accessibility of CGGTTS and TWSTFT data for PTB and USNO. The data were downloaded from BIPM where are available as of September 20, 2012. In Fig. 8 the PPP, GPS CV (L3P) and TWSTFT results were shown. For better view of Fig. 8 the PPP results for an appropriate time links were rescaled.

The comparison results were presented with time deviation expressed by σ in seconds.

Table 2 shows the time deviation obtained for all PPP time links both for 7-day (7D) as well as 35-day (35D) modes and for GPS CV (L3P) and TWSTFT computations.

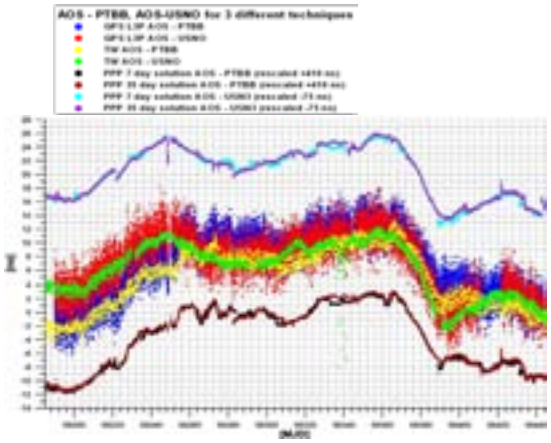

Fig. 8. The comparison of PPP, GPS CV(L3P) and TWSTFT results for AOS-PTB and AOS-USNO time links in the period from September 20, 2012 to May 31, 2013.

TABLE II
TIME DEVIATION FOR AOS-PTB AND AOS-USNO TIME LINKS OBTAINED FOR PPP, GPS CV (L3P) AND TWSTFT COMPUTATIONS IN THE PERIOD 56190-56443 MJD.

time link	AOS-PTB		AOS-USNO	
	PPP			
tau [s]	7Dσ	35Dσ	7Dσ	35Dσ
3.00e+01	6.51e-12	7.37e-12	6.19e-12	7.24e-12
6.14e+04	1.33e-10	1.23e-10	1.18e-10	1.17e-10
1.23e+05	2.08e-10	2.01e-10	1.53e-10	1.59e-10
tau [s]	GPS CV L3P			
9.60e+02	1.37e-09		1.69e-09	
6.14e+04	3.42e-10		5.98e-10	
1.23e+05	4.34e-10		5.94e-10	
tau [s]	TWSTFT			
7.20e+03	4.68e-10		2.75e-10	
5.76e+04	3.42e-10		1.86e-10	
1.15e+05	2.47e-10		1.64e-10	

The averaged RMS received for GPS CV calculations are from 1.15 to 1.85 ns for AOS-PTB and from 1.27 to 2.40 ns for AOS-USNO. The RMS for TWSTFT are from 0.05 to 1.05 ns for AOS-PTB and from 0.04 to 1.23 ns for AOS-USNO. The RMS obtained from PPP both 7-day as well as 35-day PPP solutions are the same and were estimated to be between 0.01 to 0.26 ns and 0.01 to 0.53 ns for AOS-PTB and AOS-USNO, respectively. The best precision is for PPP technique.

The foregoing results are comprehensible because code and phase GPS measurements used by PPP are recorded every 30 seconds. For GPS CV this interval is 16 minutes and for TWSTFT only 2 hours.

IV. SUMMARY AND CONCLUSIONS

This work covers the analysis of one year of data for several (short and long) time links AOS-PL, AOS-PTB, AOS-ORB and AOS-USNO. All calculations and analyses are based on the results obtained with Precise Point Positioning technique. All PPP results confirm the high quality of this technique in comparison to the other time transfer techniques presented in this study. It is noticeable that the all PPP results both for 7-day as well as 35-day solutions are comparable. The quality of the results of time transfer techniques, presented in this work is described by RMS calculated from averaged 24-hour solutions by least squares estimation. The RMS obtained for AOS-PTB, AOS-ORB and AOS-USNO time links vary from 0.04 to 0.05 ns. The PPP results obtained for AOS-PL time link are more or less 1 order of magnitude worse because of cesium atomic clock used by GUM. In this case the RMS is 0.27 ns both for 7-day as well as 35-day solutions. The short-term time stability (30 sec. interval) PPP results differ from 8.11e-12 s (USNO) to 9.82e-11 s (PL) for 7-day solution and from 8.92e-12 s (USNO) to 9.88e-11s (PL) for 35-day solution. More results for time deviation analysis are presented in the paper.

The PPP results obtained in two modes (7 and 35-days) were compared with the results obtained from GPS CV (L3P) and TWSTFT techniques. The computations were carried out for two time links, AOS-PTB and AOS-USNO. The RMS for GPS CV L3P results are 1.44 ns (AOS-PTB) and 1.77 ns (AOS-USNO). For TWSTFT the RMS results are 0.53 ns and 0.25 ns for AOS-PTB and AOS-USNO, respectively. As an independent method, the PPP allows the verification of other time transfer techniques like GPS CV and TWSTFT realized by AOS.

The PPP technique is currently the only time transfer technique comparable to the glass fiber link PL-AOS. The application of the PPP method improves and strengthens the quality of the Polish time scales UTC(AOS), UTC(PL), and TA(PL).

This work continues with calculations including GLONASS ephemeris products and GLONASS RINEX data.

Abstract—**GPS Time Transfer is a perfect combination of the advantages of GPS atomic clock group and the receiver crystal oscillator. But is now mostly just used code pseudorange observation equation solving user clock offset in GPS timing receiver, while ignoring the impact of the receiver clock drift. In order to improve the GPS receiver Timing precision, the single satellite timing method is discussed, and the extended Kalman filter algorithm is used to estimate and predict the clock offset and clock drift. The receiver clock model is constructed by the clock offset and clock drift. The clock offset and clock drift have integral relationship, and often used as Kalman filter state variables. The white noise spectral amplitudes of clock offset noise and clock drift noise can be related to the classical Allan variance parameters Based on relationship between Allan Variances and Power spectral density Parameters. The pseudorange-rate equation is derived according to pseudorange observation equation. The error source is analyzed and quantified with respect to the pseudorange and the pseudorange-rate. The EKF method is tested and verified based on IGS data, and the timing precision of the GPS single satellite can be improved through this method.**

Keywords-Kalman filter; The single satellite timing; Clock offse; Clock drift

I. GPS TIME TRANSFER PRINCIPLE

The Global Positioning system (GPS) is global satellite navigation system that provides three major functions of positioning, velocity measurement, and time transfer. The key of the precise time transfer is three types of time synchronization which are the time synchronization between Universal Time Coordinated (UTC), GPS Time (GPST), satellite clock and user clock. Synchronization of a satellite clock with UTC at nanosecond level is made possible by use of atomic frequency standards aboard the satellites and in the monitor stations of the Control Segment [1].

The receiver clock bias at epoch t(GPS time) can be modeled as

$$\delta t_u(t)=\frac{1}{c}(\rho^{(k)}(t)+c\delta t^{(k)}(t-\tau)-c\delta t_{rec}-r^{(k)}(t,t-\tau)-I^{(k)}(t)-T^{(k)}(t)-\varepsilon_\rho^{(k)}(t)) \quad (1)$$

Where $\rho^{(k)}(t)$ is the pseudorange measurement from the k-th satellite at epoch t; $r^{(k)}(t,t-\tau)$ is the actual distance between the receiver antenna at signal reception time t and the satellite antenna at signal transmission time(t- τ), and it is known if we can get the antenna position; $r^{(k)}(t,t-\tau)$ is the satellite clock offset relative to GPST which can be computed by formula (1); $I^{(k)}(t)$ and $T^{(k)}(t)$ are the ionospheric and tropospheric propagation delays, respectively; δt_{rec} includes signal delays due to the antenna, preamplifier, cable, and receiver hardware; $\varepsilon_\rho^{(k)}(t)$ accounts for modeling errors and unmodeled effects. It can be modeled by Gaussian noise which has zero mean and σ_ρ^2 variance .

II. GPS TIME TRANSFER METHOD BASED ON EKF

Substituting the antenna position (x_{R1}, y_{R1}, z_{R1}) at epoch t and satellite position $(x_{sat}, y_{sat}, z_{sat})$ at epoch $t-\tau$ into equation (1), the result is

$$\rho^{(k)}(t)=r^{(k)}(t,t-\tau)+I^{(k)}(t)+T^{(k)}(t)-c\delta t^{(k)}(t-\tau)+c\delta t_{rec}+c\delta t_u(t)+\varepsilon_\rho^{(k)}(t) \quad (2)$$

Where $r^{(k)}(t,t-\tau)=\sqrt{(x_{rec}-x_{sat})^2+(y_{rec}-y_{sat})^2+(z_{rec}-z_{sat})^2}$.

One obtains the receiver clock bias by equation (2). In order to get the receiver clock bias relatively accurately, the receiver clock drift should be considered. The clock offset and clock drift have integral relationship, and often used as Kalman filter state variables.

The receiver clock drift can be found by taking the derivative of $\rho^{(k)}(t)$ with respect to t. The result is:

$$\dot{\rho}^{(k)}(t)=\dot{r}^{(k)}(t,t-\tau)+\dot{I}^{(k)}(t)+\dot{T}^{(k)}(t)+c\delta f_u(t)-c\delta f^{(k)}(t-\tau)+c\delta \dot{t}_{rec}+\dot{\varepsilon}_\rho^{(k)}(t) \quad (3)$$

Where $\dot{I}^{(k)}(t)$ is the ionospheric propagation delay rate; $\dot{T}^{(k)}(t)$ is the tropospheric propagation delays rate; $\delta \dot{t}_{rec}$ is signal delay rate due to the antenna, preamplifier, cable, and receiver hardware ; These values can be ignored because of tiny variable in short time. The satellite clock drift can be obtained by

This paper is supported by West Light Foundation of The Chinese Academy of Sciences(No:2012YD04).

$$\delta f^{(k)}(t-\tau) = a_{f1} + 2a_{f2}(t_{GPS} - t_{oc}) + \Delta\dot{t}_r \quad ,$$
$$\Delta\dot{t}_r = Fe_s\sqrt{a_s}\dot{E}_k \cos E_k .$$

Actually, $\dot{r}^{(k)}(t, t-\tau)$ is the range rate between user and satellite, and can be written as a projection of the relative velocity vector on the satellite line-of-sight vector. The result is

$$\dot{r}^{(k)}(t, t-\tau) = (v^k - v)\cdot l^k \qquad (4)$$

Where, v^k is satellite velocity vector, known from the navigation message broadcast by the satellite; v is the user velocity, to be estimated; The user-to-satellite line-of-sight unit vector l^k can be given by

$$l^k = \frac{1}{\sqrt{(x_{sat}-x_{R1})^2 + (y_{sat}-y_{R1})^2 + (z_{sat}-z_{R1})^2}} \begin{bmatrix} x_{sat}-x_{R1} \\ y_{sat}-y_{R1} \\ z_{sat}-z_{R1} \end{bmatrix}.$$

If user is stationary, the user velocity v is zero. Since $\dot{I}^{(k)}(t)$, $\dot{T}^{(k)}(t)$ and $\delta\dot{t}_{rec}$ are very small, they can be approximated as zeros. Substituting $\dot{I}^{(k)}(t), \dot{T}^{(k)}(t)$, $\delta\dot{t}_{rec}$ and v into equation (4), the result is

$$\dot{\rho}^{(k)}(t) = v^k \cdot l^k + c\delta f_u(t) - c\delta f^{(k)}(t-\tau) + \varepsilon_{\dot{\rho}}^{(k)}(t) \qquad (5)$$

Since the carrier phase difference of the adjacent sampling time is more smoother than the pseudorange difference, the pseudorange-rate is represented by the carrier phase difference. $\varepsilon_{\dot{\rho}}^{(k)}(t)$ can be modeled by Gaussian noise which has zero mean and $\sigma_{\dot{\rho}}^2$ variance , and be independent of $\varepsilon_{\rho}^{(k)}(t)$.

As can be seen from above, the unknown timing errors δt_u and $\delta f_u(t)$ arising from user receiver clock and the GPS system time play a role in GPS time transfer. Two state components are used to model this offset, namely clock bias δt_u and clock drift $\delta f_u(t)$, which represent the phase and frequency errors of receiver clock respectively. Within the navigation algorithm, the two state models are employed commonly as Fig.2 shown.

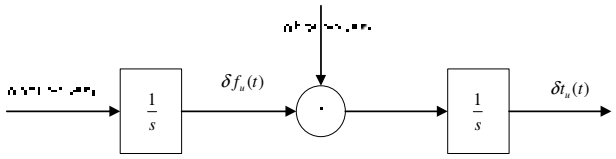

Figure 1. Receiver clock model

The equivalent discrete model can be modeled as

$$\begin{bmatrix} \delta t_{u,k} \\ \delta f_{u,k} \end{bmatrix} = \begin{bmatrix} 0 & T_s \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \delta t_{u,k-1} \\ \delta f_{u,k-1} \end{bmatrix} + \begin{bmatrix} e_{t,k-1} \\ e_{f,k-1} \end{bmatrix} \qquad (6)$$

Where e_t is the clock bias white noise with mean value is zero; e_f is the clock drift white noise with mean value is zero. They are independent mutually and their power spectra are S_t and S_f respectively.

The process noise covariance matrix in discrete time is given by

$$Q_{k-1} = \begin{bmatrix} S_t T_s + S_f \frac{T_s^3}{3} & S_f \frac{T_s^2}{2} \\ S_f \frac{T_s^2}{2} & S_f T_s \end{bmatrix} \qquad (7)$$

III. Recursive Extended Kalman filtering algorithm

The Kalman filter estimates a process by using a form of feedback control: the filter estimates the process state at some time and then obtains feedback in the form of measurements. As such, the equations for the Kalman filter fall into two groups: time update equations and measurement update equations.

Assuming that the initial state-space is $\begin{bmatrix} \delta t_{u,0} \\ \delta f_{u,0} \end{bmatrix}$, and the initial posteriori estimate error covariance matrix is P_0, the recursive process is shown as following:

1) **Predict:** The time update equations are responsible for projecting forward the current state and error covariance estimates to obtain the a priori estimates for the next time step. The time update equations can also be thought of as predictor equations.

$$\begin{bmatrix} \delta\hat{t}_{u,k}^- \\ \delta\hat{f}_{u,k}^- \end{bmatrix} = A \begin{bmatrix} \delta\hat{t}_{u,k-1} \\ \delta\hat{f}_{u,k-1} \end{bmatrix} \qquad (8)$$

The state transition matrix is then

$$A = \begin{bmatrix} 1 & T_s \\ 0 & 1 \end{bmatrix}.$$

The a priori estimate error covariance is then

$$P_k^- = AP_{k-1}A^T + Q \qquad (9)$$

P_{k-1} is the a posteriori estimate error covariance, while Q is from equation (7).

The time update projects the current state estimate ahead in time.

2) **Correct:** The measurement update equations are responsible for the feedback—i.e. for incorporating a new measurement into the a priori estimate to obtain an improved a posteriori estimate. The measurement update equations can be thought of as corrector equations.

The first task during the measurement update is to compute the Kalman gain. The Kalman gain is given by

$$K_k = P_k^- C^T (CP_k^- C^T + R)^{-1} \qquad (10)$$

Where , R is the measurement noise covariance, $C = 3\times10^8 \times \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$.

The next step is to actually measure the process to obtain y_k, and then to generate an a posteriori state estimate by incorporating the measurement as in equation (11).

$$\begin{bmatrix} \delta\hat{t}_{u,k} \\ \delta\hat{f}_{u,k} \end{bmatrix} = \begin{bmatrix} \delta\hat{t}^-_{u,k} \\ \delta f^-_{u,k} \end{bmatrix} + K_k\left(y_k - C\begin{bmatrix} \delta\hat{t}^-_{u,k} \\ \delta f^-_{u,k} \end{bmatrix}\right) \qquad (11)$$

Where,

$$y_k = \begin{bmatrix} \rho^{(1)}(t) - \sqrt{(x_{sv} - x_u)^2 + (y_{sv} - y_u)^2 + (z_{sv} - z_u)^2} - I^{(1)}(t) - T^{(1)}(t) + c\delta t^{(1)}(t) - t) - c\delta t_{sv} \\ \dot{\rho}^{(1)}(t) - v^T \cdot I^1 + c\delta f^{(1)}(t - t) \end{bmatrix}$$

The final step is to obtain an a posteriori error covariance estimate. The a posteriori estimate error covariance is given by

$$P_k = (I - K_k C)P_k^- \qquad (12)$$

Where, I is the identity matrix.

The measurement update adjusts the projected estimate by an actual measurement at that time.

3) Repeat the procedure from 1) to 2).

After each time and measurement update pair, the process is repeated with the previous a posteriori estimates used to project or predict the new a priori estimates. This recursive nature is one of the very appealing features of the Kalman filter—it makes practical implementations much more feasible.

IV. THE DETERMINATION OF FILTER PARAMETERS

In the actual implementation of the filter, the measurement noise covariance R is usually measured prior to operation of the filter. The determination of the process noise covariance Q is generally more difficult, because we typically do not have the ability to directly observe the process [9].

The long-term stability of GPS timing receiver depends on GPS atomic clock group mostly. The short-term stability of GPS timing receiver is determined by the receiver crystal oscillator. The typical calculating cycle is 1s, namely T_s=1s, and the short-term stability is determined by the crystal oscillator's performance during the 1s. Most receivers use Quartz Crystal Oscillator which are relative cheap and have good stability in 0-10s. The white noise spectral amplitude S_t and S_f can be related to the classical Allan variance parameters [3].The approximate relation is $S_t = 2h_0$ and $S_f = 8\pi^2 h_{-2}$. Typical Allan Variances for various timing standards are shown in Table 1 [4,5]:

TABLE 1. TYPICAL ALLAN VARIANCES FOR VARIOUS TIMING STANDARDS

Clock Standard	h_0	h_{-1}	h_{-2}
TXCO, Temperature compensating crystal oscillator	2×10^{-19}	7×10^{-21}	2×10^{-20}
Temperature-controlled Crystal Oscillator	8×10^{-20}	2×10^{-21}	4×10^{-23}
Rubidium Clock	2×10^{-20}	7×10^{-24}	4×10^{-29}

Substituting T_s=1s, S_t and S_f into formula (7), the result is

$$Q = \begin{bmatrix} 2h_0 + \frac{8}{3}\pi^2 h_{-2} & 4\pi^2 h_{-2} \\ 4\pi^2 h_{-2} & 8\pi^2 h_{-2} \end{bmatrix} \qquad (13)$$

The measurement noise covariance R which is equal to $R = \begin{bmatrix} \sigma_\rho^2 & 0 \\ 0 & \sigma_{\dot\rho}^2 \end{bmatrix}$ is derived through formula (2) and (3). The equivalent measurement noise for the pseudorange and the pseudorange-rate is analyzed as following:

Through formula (1), such parameters as user position, satellite position, satellite clock offset, the receiver hardware delay, the ionospheric delay and the tropospheric delay are needed to calculate receiver clock bias. Parameters mentioned above are obtained from navigation messages, but have some errors. Errors are absorbed into the equivalent measurement noise, and are listed in table 2. They are assumed to be independent of each other, so the equivalent measurement noise of pseudorange is given $\sigma_\rho^2 = (16.3e-9\times3e8)^2 \approx 24m$.

TABLE 2. TYPICAL MEASUREMENT ERRORS OF PSEUDORANGE

Error source	Standard error(ns)
Satellite clock	6.7
Group delay	1
Broadcast ephemeris	6.7
the ionospheric delay	13
the tropospheric delay	1.67
Receiver noise and Resolution	0.03
Multipath	0.67
Receiver position	0.33
Receiver hardware delay	1
Total	16.3

Through formula (5), such parameters as user position, satellite position, satellite velocity, and satellite clock drift are needed to calculate the clock drift $\delta f_u(t)$. Such parameters are listed in table 3. Satellite clock drift is in the order of magnitude 1e-11, which is converted to about 0.01ns. They are assumed to be independent of each other, so the equivalent measurement noise of pseudo-range rate is given $\sigma_{\dot\rho}^2 = (6.71e-9\times3e8)^2 \approx 4m$.

TABLE 3. TYPICAL MEASUREMENT ERRORS OF PSEUDORANGE RATE

Error source	Standard error(ns)
Satellite clock drift	0.01
Broadcast ephemeris	6.7
Receiver noise and Resolution	0.03
Receiver position	0.33
Total	6.71

P_0 is the initial posteriori estimate error covariance matrix. A smaller initial value of P_0 means a greater weight factor given to the priori state estimate. If the output of filter mainly depends on the priori state estimate information, it can easily lead to filter diffusion[8]. In the actual implementation of the filter, considering the model error and the current measurement information, P_0 can be tune largely.

V. SIMULATION AND VERIFICATION

We can get the observation file and the GPS satellite ephemerides file of IGS tracking stations. We use the above

model and the traditional model to calculate the receiver clock offset using MATLAB.

At first, the smoothness of the pseudorange difference(the single difference and the double difference) and the carrier phase difference(the single difference and the double difference) is compared. The observation data is the GPS 20th satellite from IGS tracking stations. The simulation result is shown in Fig.2.

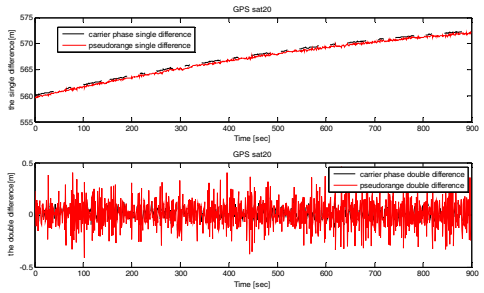

Figure 2. Smoothness comparison of Pseudorange-rate and carrier phase rate

The standard deviation of the pseudorange double difference is 0.14m, but the standard deviation of the carrier phase double difference is only 0.05m. Since the carrier phase difference of the adjacent sampling time is more smoother than the pseudorange difference, the pseudorange-rate is represented by the carrier phase difference.

Usually in the practical application, considering the model error and the current observation information, P_0 can be tune largely. In the article, $P_0 = \begin{bmatrix} 10 & 0 \\ 0 & 10 \end{bmatrix}$, $\begin{bmatrix} \delta t_{u,0} \\ \delta f_{u,0} \end{bmatrix} = \begin{bmatrix} 0.1 \\ 0.001 \end{bmatrix}$ simulation result is shown in Fig.3 .

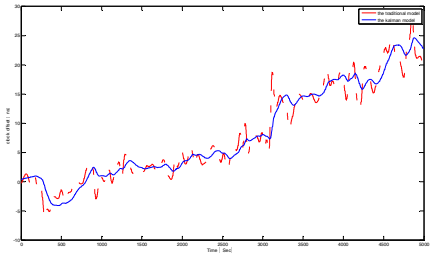

Figure 3. Simulation result

Fig.3 illustrates the clock offset of the Kalman model has the same tendency with the traditional model, but jumping range decreases greatly.

The standard deviation of the clock offset single difference based on kalman filter is 0.02ns, but the standard deviation of the clock offset single difference based on traditional model is 0.07ns. This can be seen in figure 4.

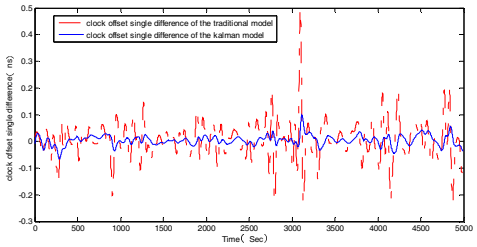

Figure 4. the clock offset single difference

This simulation proves that the kalman filter is effective and the accuracy of time transfer can be improved by the kalman model.

VI. CONCLUSION

This paper study the application of extended kalman filter in GPS time transfer. Two state models is used to estimate and predict the clock offset and clock drift. Based on relationship between Allan Variances and Power spectral density Parameters, process-noise covariance matrix is deduced. The error source is analyzed and quantified with respect to the pseudorange and the pseudorange-rate, and the measurement noise covariance matrix is presented. The EKF method is tested and verified based on IGS data, and the timing precision of the GPS single satellite can be improved through this method.

ACKNOWLEDGMENT

My deepest gratitude goes first and foremost to Professor Hu Yonghui, for his constant encouragement and guidance.

***Abstract*—A method of transferring high precise time based on the satellite digital TV broadcasting system (DVB-S) is presented in this paper. PCR (Program Clock Reference) in the signal of TV is considered as the Time Synchronization Flag, precise timestamp captured by PCR is real-time recorded in both transmitting segment and user segment, so time in both sides will be synchronized roughly. Then the period of signal from transmitting segment to user segment is calculated by Precise Satellite Ephemeris, and the time will be synchronized precisely. The experimental result showed the method is feasible, and the RMS< 100ns.**

Keywords—DVB-S, satellite digital TV, PCR, time service, signal transmission delay

I. INTRODUCTION

The TV system is one of the modern radio broadcasting systems. It has the advantage of low prices and operating easily to the method of transmission and adjustment of time and frequency by TV signals. High precision can be achieved by this method in a short time. Furthermore, TV signal is strong and can be obtained easily. So this is a remote transmitting and adjusting time and frequency method which will be popularized easily.

The research of transmitting and adjusting time and frequency by TV system is? started in the 1960s of the last century, and some achievements have been achieved by analog TV standard. With the development of TV industry, the Analog TV will be replaced by the Digital TV gradually. Nowadays digitization is generally completed by the TV broadcast station all around China. So it is necessary to work out a new method of transmitting and adjusting time and frequency under new TV system standard.

All TV broadcast stations in China broadcast program by DVB-S. The main content of this paper is the method of transferring high precise time based on the satellite digital TV broadcasting system.

The work was supported by "Western Light Talents training program of CAS"(Y305YZ1301) and "Scientific Research Equipment Development Project of CAS"(YZ201218(Y307YR1301))

II. METHODS

The main idea of the method is broadcasting signals with standard time information to area which can be covered by the scope of satellite by using Satellite Digital TV broadcasting system. The users can compare the received signal from TV broadcasting system with standard time for high-precision time synchronization?. System block diagram is shown in Fig. 1.

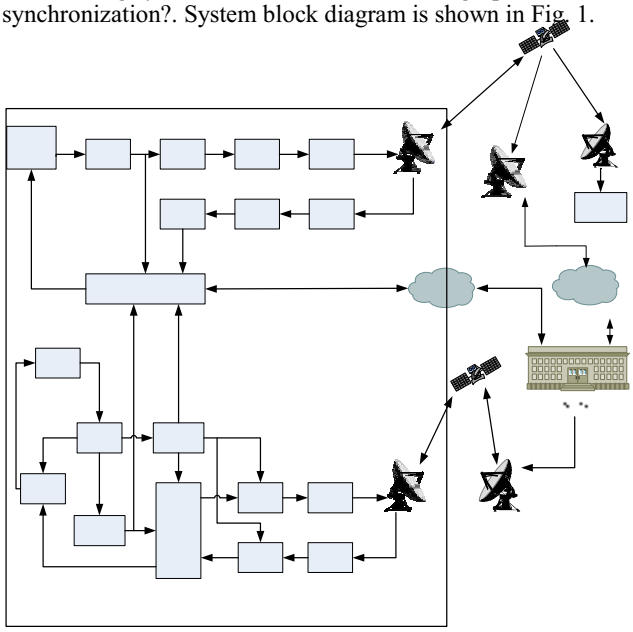

Figure 1. System block diagram of Satellite Digital TV Time Service System

The method is constituted of three parts described as follows:

A. Standard Time Source

There are many methods to obtain standard time in the Satellite Digital TV broadcasting stations, such as obtain UTC

time by using GNSS High-precision Time Service Receiver, trace local time to UTC reference laboratories by using cable and so on. In this test, UTC (NTSC) is used as the standard time reference, and TV broadcasting station is in Nanjing, China. It is about 1000 kilometers between them. That's why we use Two-way Satellite Time and Frequency Transfer (TWSTFT) for tracing time in TV broadcasting station to UTC (NTSC), and the precision of synchronization which will be maintained by atomic clock is 1ns.

B. Remote time synchronization based on the Satellite Digital TV Time Service System

Signals in Satellite Digital TV System are the platform of this method. PCR in TV system is regarded as the Synchronization Flag. The PCR is detected in the end of Multiplexer under broadcasting station on the floor, and timestamp will be captured by PCR. Meanwhile, the timestamp is broadcasted by private channel. After terminal users receiving the TV signals, timestamp can be captured by PCR. At the same time, the moment of broadcasting PCR can be obtain by receiving data in private channel. Finally, the time of broadcasting and receiving each PCR can be recorded by users, so the time synchronization can be achieved by the time interval between broadcasting and receiving one PCR.

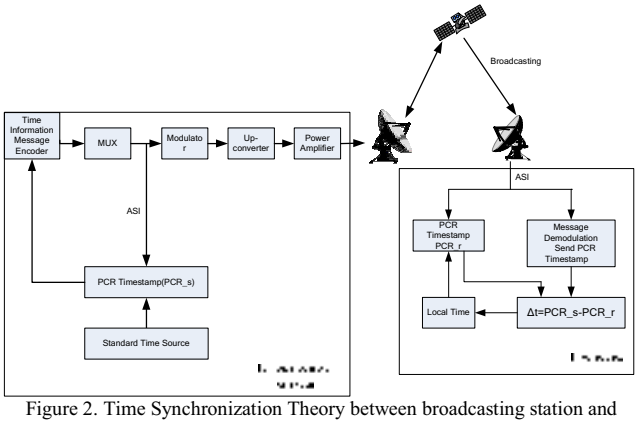

Figure 2. Time Synchronization Theory between broadcasting station and users

In the TV broadcasting station, PCR in TV signals is detected in the output of Multiplexer, and the moment PCR is transmitted will be recorded with reference to standard time source. Then the PCR data and the transmitting time information will be packed to timestamp which is PCR_s, and the timestamp will be broadcasting by private channel.

Under the user terminal, TV signals are received and PCR is detected. The receiving time of PCR in the signals is recorded with reference to of local time by receiver. Then the PCR data and the receiving time information will be packed to timestamp which is PCR_r. At the same time, the transmitting time information of this PCR can be obtained by demodulating data from private channel. Finally, Time Correction between the standard time in broadcasting station and the time in user receivers can be calculated by the transmitting and receiving time information of one same PCR.

$$\Delta t = PCR\_r - PCR\_s \tag{1}$$

C. Precise measurement of delay time in the channel

Rough time synchronization in user receiver to broadcasting station can be achieved by the method descried above. Precise time synchronization needs to measure the delay time in the channel from stations to users, and the receiving time also needs to be corrected.

The path of broadcasting is shown in Fig. 3.

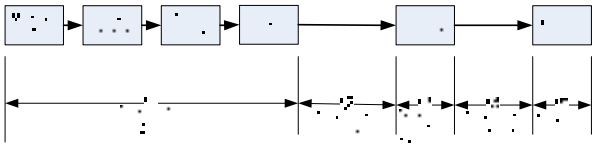

Figure 3. Path of broadcasting time service

As is shown in the Fig. 3, the whole delay time in the path includes: delay time of ground equipment, delay time in the up path, delay time of satellite transponder, delay time in the down path, and delay time of receiver, etc. The whole delay time is about 200ns~300ns in the entire path with experience. So the time in user receiver must be corrected by measuring delay time described above precisely in order to achieve high-precision time synchronization.

The TV system is a one-sided communication system. The positions in space of main nodes need to be known for precise measurement. The positions of antennas in the broadcasting station and user receiver can be measured precisely on the floor, and the satellite orbits can be measured and forecasted by the Ground Tracking and Orbit Determination Net of National Time Service Center (NTSC). So the whole path is divided into two parts: *t1+t2+t3* is the up path *dt1*, *t4+t5* is the down path *dt2*.

For *dt1*, signal loop delay time can be measured by receivers placed in the broadcasting station. The positions of satellites can be calculated by ephemeris, and the one-sided delay time can be calculated by the positions of broadcasting antennas. Then *dt1* is obtained by the loop delay time deducted one-sided delay time. It is shown in Fig. 4.

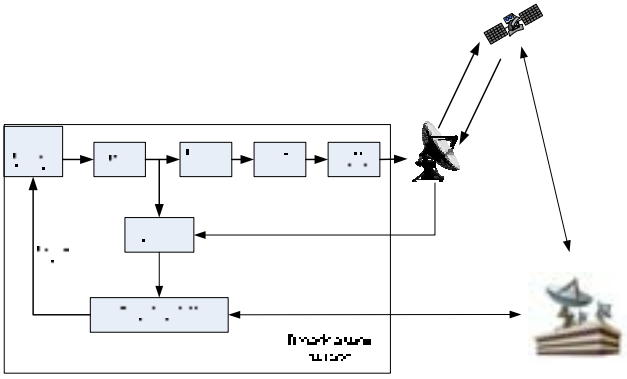

Figure 4. Difference method for measuring up path delay time

Down path delay time is mainly included of the space down path delay time dt_{down} and the receiver delay time *t5*. Space down path delay time dt_{down} can be calculated by using equation 2 below.

$$dt_{down} = \frac{\sqrt{(s_x - du_x)^2 + (s_y - du_y)^2 + (s_z - du_z)^2}}{c} \quad (2)$$

In this equation:

s_x, s_y, s_z is the three-dimensional coordinate of satellites;

du_x, du_y, du_z is the three-dimensional coordinate of ground broadcasting antennas;

c is the speed of light;

The real-time coordinate is calculated by satellite ephemeris in the navigation message. The positions of broadcasting antennas and the speed of light are known.

In the down path delay time, receiver delay time *t5* is as same as receiver down path delay time, so it will be offset after processing and be ignored afterwards. The up path delay time *dt1* is express by equation 3

$$dt1 = dt_{circle} - dt_{down} - t5 = dt_{circle} - \frac{\sqrt{(s_x - du_x)^2 + (s_y - du_y)^2 + (s_z - du_z)^2}}{c} - t5 \quad (3)$$

In this equation, dt_{circle} is obtained by difference receivers, and dt_{down} is obtained by equation 2.

For *dt2*, it is mainly include of space down path delay time dt_{down} and user receiver delay time *t5*. It can be obtained by equation 4.

$$dt2 = dt_{down} + t5 = \frac{\sqrt{(s_x - u_x)^2 + (s_y - u_y)^2 + (s_z - u_z)^2}}{c} + t5 \quad (4)$$

In this equation,

s_x, s_y, s_z is the three-dimensional coordinate of satellites;

u_x,u_y,u_z is the three-dimensional coordinate of user receiving antennas;

c is the speed of light;

The whole delay time *dt* in all path can be obtained:

$$dt = dt1 + dt2 = dt_{circle} - \frac{\sqrt{(s_x - u_x)^2 + (s_y - u_y)^2 + (s_z - u_z)^2} - \sqrt{(s_x - du_x)^2 + (s_y - du_y)^2 + (s_z - du_z)^2}}{c} \quad (5)$$

III. RESULT

The Satellite Digital TV Time Service Broadcasting System is established in Satellite Earth Station of Jiangsu Broadcasting Corparation in China based on the method described above. Function and performance of system is tested in five cities of China (Urumchi, Changchu, Xi'an, Nanjing, Haikou). The results demonstrate that the method is feasible, and the precision of synchronization < 100ns.

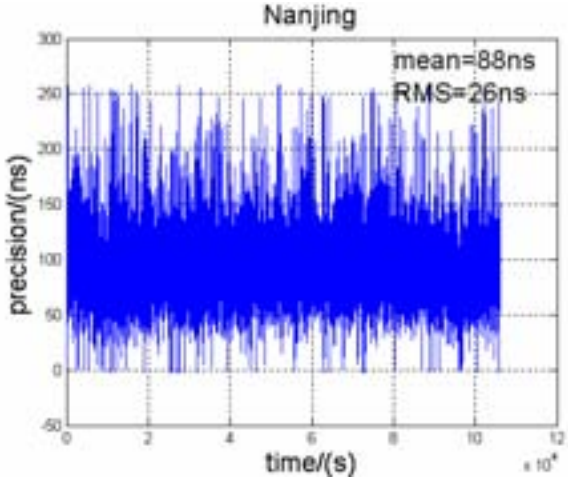

Figure 5. Test result in Nanjing

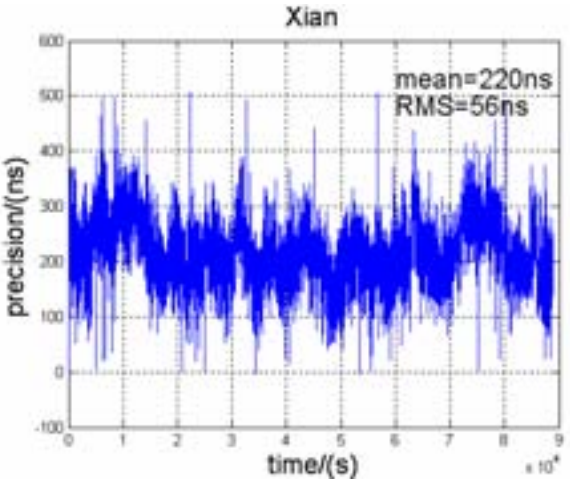

Figure 6. Test result in Xi'an

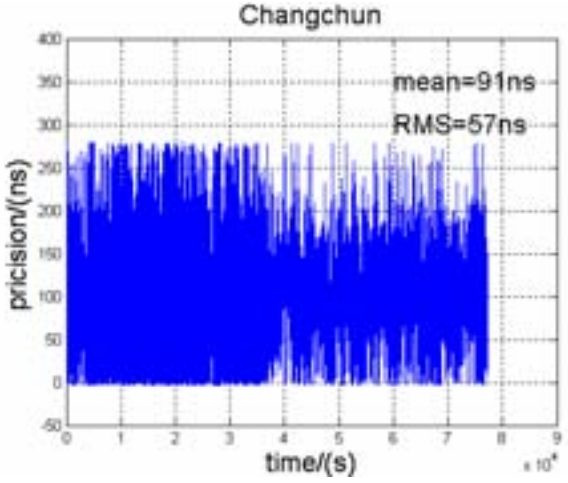

Figure 9. Test result in Changchun

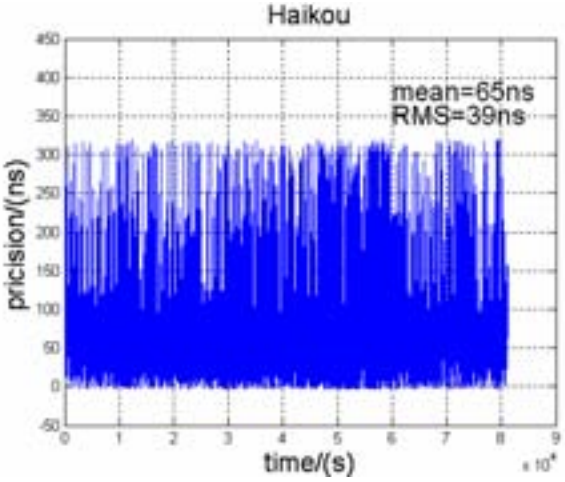

Figure 10. Test result in Haikou

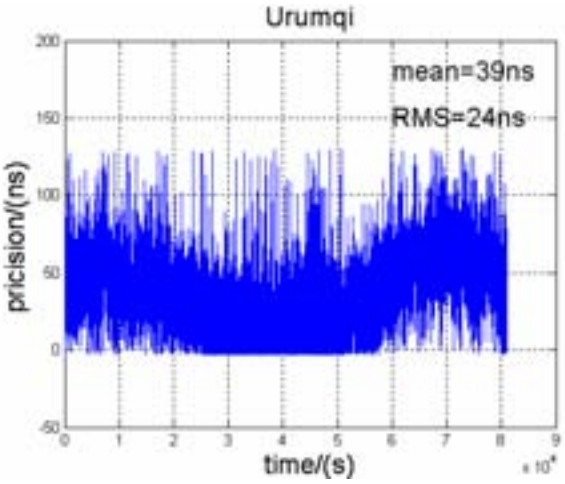

Figure 11. Test result in Urumchi

This system is only designed for checking correctness. The GPS time source is used as the time reference standard. So the time reference errors in broadcasting station and the errors in the test places is also included in the test result. In addition, device delay time, atmosphere errors, Sagnac effection, etc is not to taken into account in the test system. So there are many spaces to improve.

IV. CONCLUSION

The tested results demonstrate that it is feasible to precise synchronize time by Satellite Digital TV system. It is high-precision and strong anti-jamming of this method. Based on this test, delay time analysis and correction is need for improving time synchronization precision in subsequent work.

A Simple Computation Technique for Improving the Short Term Stability and the Robustness of GPS TAIP3 Common-Views

***Abstract*— We propose a new simple technique to improve the short term stability and the robustness of Common-Views (CV) of Global Positioning System (GPS) satellites. We use the ionosphere free linear combination of P-code data broadcast on both GPS carriers, called TAIP3, the data files being built according to the Common GNSS Time Transfer Standard (CGTTS) format. Instead of averaging the outliers out by using a given filter around a mean value computed for each CGTTS sampling epoch, we average the outliers out from a linear fit on daily CV files. We analyze the results over more than 200 d of data. Over a short baseline between remote stations, we see that the average number of satellites left by the daily filtering for the CV computation is almost twice as large as the number obtained from the epoch filtering, increasing that way the robustness of the time transfer. On the short term stability of the time transfer, the white phase noise modulation is improved by a factor larger than the square root of 2, above what was expected. Over a long baseline, the improved short term stability is about twice smaller between 10 000 s and 1 d, together with an average increase of more than 20 per cent on the number of satellites left after filtering for the CV computation. We study the singular event which causes the discrepancy between these two criteria, and conclude that the daily approach is providing the best results in all cases. This automated filtering technique might be useful for any GNSS time transfer based on code data.**

Keywords: GPS, Common-Views, time transfer.

I. INTRODUCTION

The LNE-SYRTE in Observatoire de Paris (OP), Paris, France, is the institute designated by the French National Metrology Institute (NMI) Laboratoire National de Métrologie et d'Essais (LNE) in the field of Time and Frequency metrology. In this frame, the laboratory has a long history in developing remote clock comparisons by using the well-known Common-View (CV) technique on signals broadcast by the Global Positioning System (GPS). In particular, OP has been using for more than ten years data files in the Common GNSS Time Transfer Standard (CGTTS) format [1] based on the ionosphere free linear combination of GPS P-Code pseudo-ranges collected on both carriers by geodetic receivers, namely the TAIP3 technique [2]. To improve the time transfer short term stability, OP had also developed a technique based on the filtering of CV around a mean value computed for each CGTTS epoch, which are sampled on 16 min periods, in order to average the outliers out [3]. Through the years, other teams had also proposed some averaging techniques like for instance in [4].

In this paper, we propose a new simple approach, aiming at improving the short term stability together with the robustness of GPS CV from TAIP3 data files. The technique is described in Section II. We analyze the results obtained over two different kinds of baselines: one short baseline between OP and the Physikalisch Technische Bundesanstalt (PTB), Braunschweig, Germany, in Section III; and one long baseline between OP and the United States Naval Observatory (USNO), Washington DC, USA, in Section IV. The conclusion is in Section V.

II. THE NEW AVERAGING TECHNIQUE

LNE-SYRTE is operating continuously two geodetic GPS receivers in a common-clock and common-antenna set-up. The receivers are called OPMT and OPM2, and this ensemble is for more than ten years the basis of the International GNSS Service (IGS) station located in OP called OPMT. When looking at the TAIP3 CV between both receivers, we noticed that there were epochs where some given satellite data were outside the global mainstream. Figure 1 shows a typical plot of raw TAIP3 CV data between OPMT and OPM2 over one month, for all GPS satellite vehicles (SV) tracked, with a different symbol for each satellite. For such outliers, the epoch filtering might sometimes lead to biased mean values, increasing that way the short term noise of the time transfer.

From there we decided to try to improve the computation of the CV mean values by averaging out the kind of satellite outliers we see in Figure 1 in a different way. We start from the CGTTS GPS TAIP3 files collected by two different receivers, and we compute CV daily files. We then compute a linear fit over one day of CV data, and we average out all 3 sigma outliers in an iterative process. We tested different cycles, but we finally concluded that the best results were obtained with an iterative process without any limitation. This allows to suppress

either “bad” CV due to some problems in the reception of a given satellite signal, or CV exhibiting abnormal high noise, or any unusual outliers from a biased satellite. Back to the CGTTS TAIP3 CV data files, we compute a mean value between the remaining CV for each common CGTTS epoch, leading to the time transfer results for the reference time scales. Figure 2 shows the processing results on the TAIP3 CV between OPMT and OPM2 over the same period of time as in Figure 1. The dispersion of the data after daily filtering appears limited to a little more than 3 ns peak to peak. Note that the quantified distribution of the filtered CV displayed here is only due to the limited resolution of 0.1 ns in the CGTTS data format.

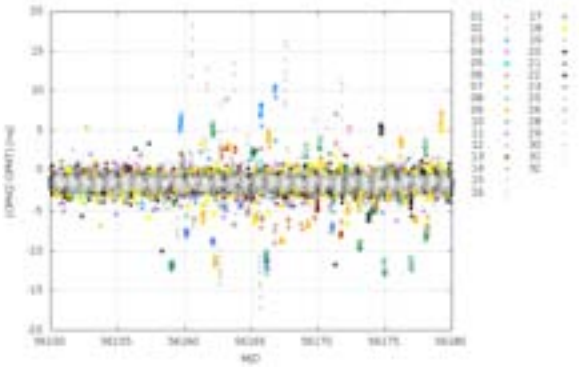

Fig. 1. Raw TAIP3 CV data between OPMT and OPM2 implemented in OP in a common-clock and common-antenna set-up. The corresponding GPS SV number symbols are given on the right of the figure.

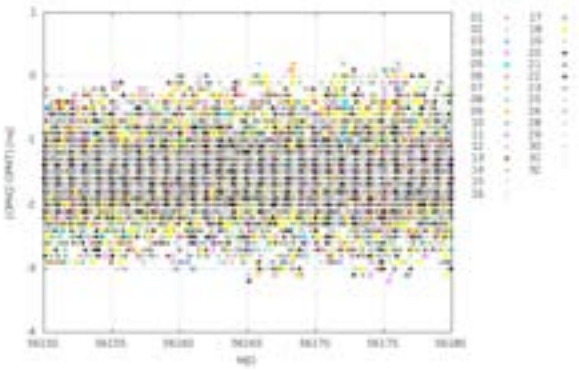

Fig. 2. TAIP3 CV between OPMT and OPM2, after application of the new filtering approach. The corresponding GPS SV number symbols are on the right of the figure.

The analysis of this new technique is based on two different criteria. First, we compare the average number of remaining satellites between the former OP epoch filtering and the new daily approach on time transfer data. In the case the new technique would average out less satellite CV compared to the former one, it would show an increase of robustness in the time transfer link. And second, we compute the Allan Time Deviation (TDEV) of the CV, obtained either from the former OP epoch filtering or with the new daily approach for the same period of time between two stations. We expect there should be some consistency between both criteria if the short term noise is white, as an average increase in the remaining CV by a factor n should lead to a decrease in the TDEV by a factor $\sqrt{n}$.

We have applied this technique on the TAIP3 CV between OPMT and OPM2. The remaining number of satellites left after filtering is about 82 % larger for the daily new approach compared to the former epoch filtering, increasing that way the robustness of the resulting CV. Figure 3 shows the TDEV of the OPM2 – OPMT CV for three different data sets over 200 d. In blue, the TDEV of raw data is plotted. A very small number of data have already been filtered out here, either because the figures were obviously not related to any measurement with GPS satellites, or because of some technical problems in OP for that given epoch. What appears as a large periodic effect in this TDEV is related to some regular and irregular outliers, which are precisely the outliers we wish to suppress. In red, the TDEV of the former epoch filtering developed by OP [3]. The outliers having been averaged out, the TDEV exhibits a white phase noise modulation (slope – ½) up to an averaging period of about 2 d, where the flicker floor of the common receivers’ noise is limiting the stability to between 20 and 30 ps [5]. And in green, the TDEV of the new daily approach shows from the sampling period on an improvement by a factor 1.37, which is in complete agreement with the increased number of CV after filtering, as we get $\sqrt{1.82} = 1.35$. It confirms the white phase noise modulation which dominates until the flicker floor of both receivers’ noise.

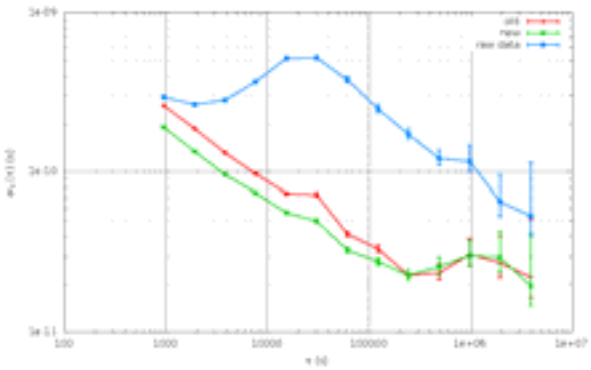

Fig. 3. Allan Time Deviation (TDEV) of the TAIP3 CV between OPMT and OPM2 in a common-clock and common antenna set-up. In blue, the original raw data. In red the former epoch filtering OP process. And in green the new daily approach.

To analyze what happens between remote UTC(k) time scales, we have applied this new daily filtering approach on two different links. In Section III, we show the results obtained over a short baseline of around 1000 km between OP and PTB. In Section IV, we show the results over a long baseline of more than 6000 km between OP and USNO.

III. THE OP – PTB LINK

This GPS link is of particular importance for LNE-SYRTE, because it may be used by the Bureau International des Poids et Mesures (BIPM) for its computation of the Temps Atomique

International (TAI), leading to the Key Comparison UTC – UTC(OP) [6]. We have used TAIP3 data collected in remote stations for more than 200 d. The average number of remaining satellite CV after filtering of the outliers through the new daily approach appears to be 80 % larger than the CV number obtained from the former OP epoch filtering technique.

Figure 4 shows the TDEV obtained from filtered CV between OP and PTB, either when using the former averaging software (in red) or with the new daily approach (in green). As expected over such a short baseline, because of numerous satellites available to compute the CV, the short term noise is very close to a white phase noise modulation, as can be seen in the – ½ slope, until the noise of the UTC(k) difference becomes higher. Therefore, the short term stability should be improved by a factor close to $\sqrt{1.80} = 1.34$. But we see here a gain of 1.49 on the TDEV from the sampling period on, which is slightly larger than expected. This does not question the consistency of both results: it only indicates that the filter quality was also improved, and this is discussed in more detail in the next Section. A noise below 0.2 ns can be reached just above an averaging period of 10 000 s, where the asymptotic behavior of the plot is limited by the remote time scale noise.

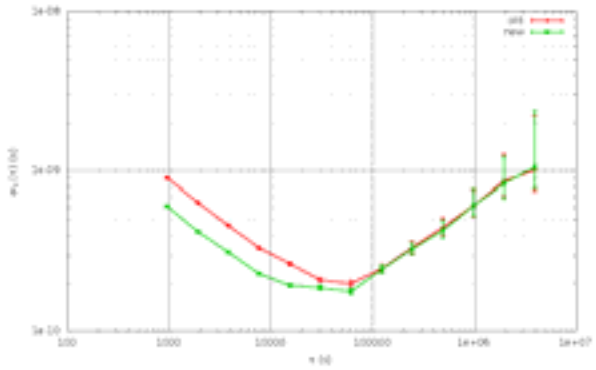

Fig. 4. Time Allan Deviation (TDEV) of the TAIP3 CV between OP and PTB: the former OP epoch filtering results are in red, the new daily approach results are in green.

These results are showing a clear improvement over short baselines when using the new daily filtering approach compared to the former OP epoch filtering. Next Section discusses the example of a long baseline.

IV. THE OP – USNO LINK

Here too, we have used TAIP3 data collected in remote stations for more than 200 d. The average number of remaining satellite CV after filtering of the outliers through the new approach appears to be 22 % larger compared to the CV number obtained from the former OP technique. But it has to be remembered that over such a large baseline, the total number of available CV is always lower compared to a continental link.

Figure 5 shows the TDEV obtained from filtered CV between OP and USNO, either when using the former epoch averaging OP software (in red) or with the new daily filtering approach (in green). In the case the phase noise modulation would be white, the improvement on the TDEV first points from sampling period on should be about 11 %. We see here a gain of a factor 1.38 on the first TDEV point at the sampling period, and 1.29 on the second TDEV point, both being much larger than expected. But before reaching an averaging period of 10 000 s, the noise of the data filtered by the former OP epoch processing seems affected by an unexpected modulation, leading to a difference close to a factor 2 between that TDEV and the new daily filtering approach up to an averaging period above 1 d. The noise of the UTC(k) difference becomes higher than the time transfer noise for an averaging period above 5 d.

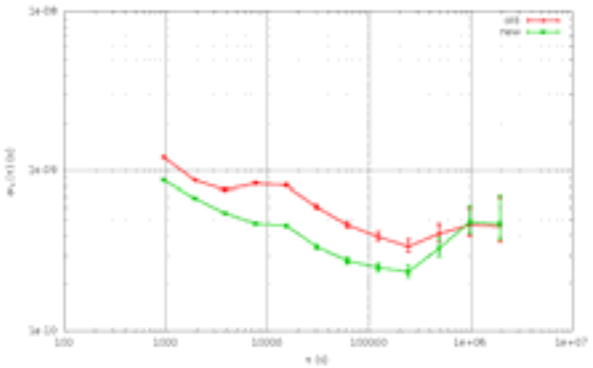

Fig. 5. Time Allan Deviation (TDEV) of the TAIP3 CV between OP and USNO: the former OP epoch filtering results are in red, the new daily approach results are in green.

After analysis, it appears that the large unexpected TDEV improvement between 10 000 s and 1 d is related to a singularity in the TAIP3 CV data. For some unknown reason, during a few consecutive CGTTS epochs, the TAIP3 CV raw data were biased on some satellite measurements which were not in line with the time transfer results obtained before and after that singularity. Figure 6 shows the event on the filtered results of CGTTS epoch sampled CV mean values.

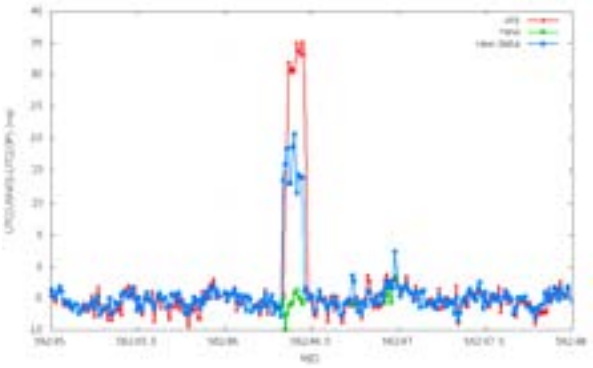

Fig. 6. Biased singularity in the OP-USNO CV. In blue, the mean value of the raw CV data including outliers to be averaged out. In red the results obtained from former OP epoch filtering. In green the results obtained after application of the new daily filtering approach.

In Figure 6, the mean values issued from an epoch averaging of the raw data are in blue. During the singularity event having appeared, the mean values are located between the mainstream data before and after the event and some large outliers which CV are far above 40 ns away. But because there were numerous satellites involved, the former OP epoch averaging technique provides as mean values the inconsistent results in red. The former OP epoch filtering gives too much credit to the outliers, rejecting the good data and computing a mean value based on unfiltered outliers: the CV averages are not in line anymore with the other CV mainstream results. In the contrary, the new daily approach in green consistently averages out the outliers, and provides the expected results in line with the CV mainstream results. We assume that this happens even for small outliers, and this explains why the improvements on the TDEV are larger than expected in the short term when comparing to the increase of CV numbers. Clearly, the new approach provides more stable and more robust results than the former OP processing.

V. CONCLUSION

In this paper, we propose a new simple averaging technique for TAIP3 GPS CV which improves both the stability and the robustness of time transfer between remote stations. Instead of averaging the outliers out by using a given filter around a mean value computed for each CGTTS sampling epoch, we average the outliers out from a linear fit on daily CV files. Between two GPS receivers in common-clock and common antenna set-up, the number of available CV left after filtering is 82 % larger than with the former epoch filtering developed by OP. The white phase noise improvement on a TDEV plot is consistently in line with that result, from the sampling period on until the averaging period where the flicker floor of the receivers' noise is the limit.

Over a short baseline of less than 1000 km between remote stations, we obtain a similar increase in the CV number after filtering, but the TDEV improvement is slightly larger than expected. Over a long baseline of more than 6000 km, the TDEV improvement is also much larger than expected. But this can be explained by the way the former OP epoch processing was giving too much credit to some outliers for the computation of the CV mean values compared to the global mainstream. The new daily approach gives more consistent results, improving that way both the short term stability and the robustness of time transfer in all cases.

This new processing approach has been implemented in OP in a completely automated way. As being a very simple filtering technique, we expect it might be useful in the future for any GNSS time transfer based on code data.

***Abstract*—With the development of science technique in aeronautic and astronautic testing navigation, communication, as well as electric power, etc, time synchronization has been needed in more and more engineers and sciences fields. Dual one-way ranging can get more veracity of measure precision than one-way due to eliminating the common measure error between two points. This article describes the use of dual one-way pseudo-code and carrier phase precise measurement for realizing time synchronization technique. The results of the experiment showed that DRTS system reached 0.15cm and 5ps in 1s time interval, the precision of this system reached 3.46ns and 9.43ps by using different and the same frequency reference of the order of e-10/d respectively. Dual one-way ranging and time synchronization can be applied in aeronautic and astronautic measurement and control system, and in achieving high precision time platform in message transfer field. It also can provide time service between satellite and satellite, satellite and ground station, aircrafts, stations and other patterns.**

Keywords—Precise Ranging; Time Synchronization; Dual One-way Ranging Measurement.

I. INTRODUCTION

With the rapid development of aerospace test, navigation, communications, electricity and other scientific technology, more and more engineering and scientific fields require precision time synchronization. Such as: the world time laboratory needs the precision time synchronization which is based on the order of a nanosecond or sub-nanosecond; Satellite launching, monitoring and control, test range atomic clocks need the Calibration; During communications between the navigation satellites, satellite and ground station, and ground stations, precision time synchronization is required; In addition, the Autonomous Formation flight AFF, networking aircraft, also need the precision baseline measurements and time synchronization. However, in our country, there is no mature commercial product of time synchronization terminal which is based on two-way precision ranging. Therefore, the users still have to import this kind of product from other countries.

II. THE PRINCIPLE OF DUAL ONE-WAY RANGING [1, 2]

In Dual one-way pseudo-range measurement, at least one transmitter and one receiver need to be installed in each of the two terminals. By means of dual one-way ranging, both of them can obtain a relative pseudo-range through pseudo-code and carrier phase measurements, which can eliminate the clock error and realize precision time synchronization between the two terminals. The Timing principle of DOWR is shown in figure 1.

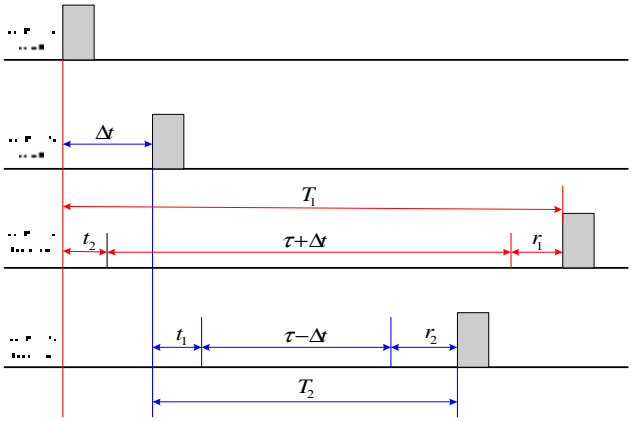

Fig. 1. Timing principle of DOWR.

Figure 1 shows that:

$$T_1 = t_2 + \tau + r_1 + \Delta t \quad (1)$$

$$T_2 = t_1 + \tau + r_2 - \Delta t \quad (2)$$

Δt is The clock difference between the two terminals A and B; T_1 and T_2 are the local pseudo-range respectively measured by terminal A and B; the transmitting device delay and the receiving device delay of terminal A are t_1 and r_1; similarly, the transmitting device delay and the receiving device of terminal B are t_2 and r_2; and the electromagnetic wave propagation delay between the antennas of the two terminals is τ. Through the Equations 1 and 2, the clock error and the real distance between terminal A and B can be obtained.

$$\Delta t = \frac{1}{2} \cdot [\,(T_1 - T_2) - (t_2 - t_1) - (r_1 - r_2)\,] \quad (3)$$

$$D = \frac{1}{2} \cdot [\,(T_1 + T_2) - (t_1 + t_2) - (r_1 + r_2)\,] \cdot c \quad (4)$$

Here, assume $t_{12} = t_1 + r_2$, $t_{21} = t_2 + r_1$:

Supported by West Light Foundation of The Chinese Academy of Sciences (Y211YR2601).

$$\Delta t = \frac{1}{2} \cdot [(T_1 - T_2) + (t_{12} - t_{21})] \quad (5)$$

$$D = \frac{1}{2} \cdot [(T_1 + T_2) - (t_{12} + t_{21})] \cdot c \quad (6)$$

In the process of measurement, T_1 and T_2 can be respectively extracted from the code tracking loop of terminal A and B, and then be embed into the data region of a transmission frame, which can be sent to each other through the data exchange link. Since the one-way propagation delay t_{12} and t_{21} can be obtained through the Calibration, therefore, by means of DOWR, the measurement value of time comparison and the precise distance can be obtained.

III. THE CONSTRUCTION FRAMEWORK OF DRTS

The DRTS system consists of six parts, which are receive channel, transmit path, frequency reference, IF signal processor, display and control computer and power distribution, as shown in figure 2. This system mainly consist of such device as rubidium, Doppler analog unit, the reference amplifier and splitter, frequency synthesizer, noise source, A/D sampling, baseband processing unit, BPSK modulator, equipment monitor unit and computer.

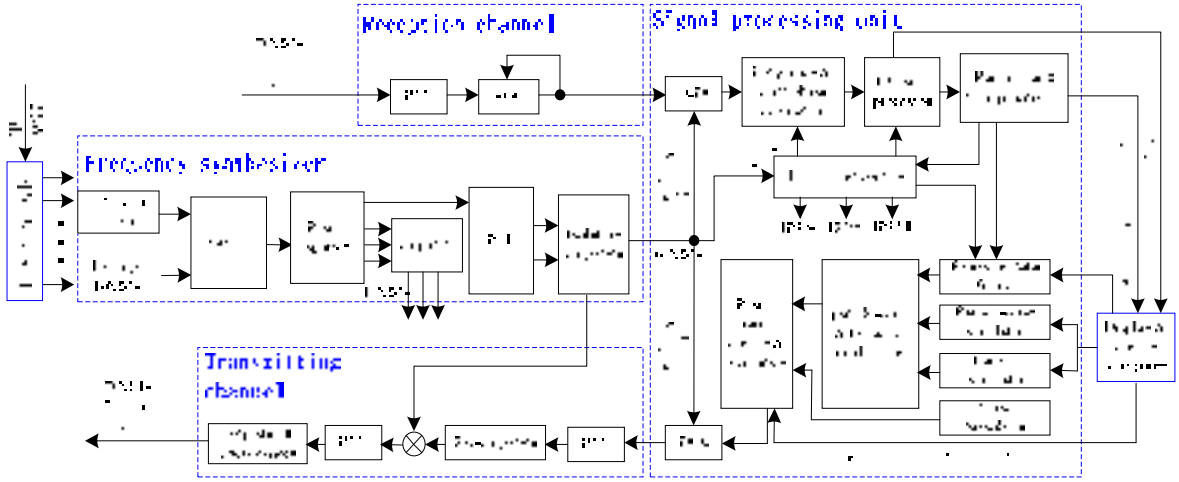

Fig. 2. Block diagram of the overall function of the device

IV. THE TECHNOLOGY USED IN DRTS SYSTEM

The principle of One-way pseudo-range measurement in DRTS system and pseudo-range measurement in GNSS are substantially the same. When the code tracking loop of Terminal A is locked, parameters like synchronous frame count, data bits count, spread code phase count and spread chip phase count will be output, so that the terminal A will get the time delay measurement between the synchronization timing of a local transmitting frame and the synchronization timing of a received frame transmitted by terminal B after a series of calculation. The distance we get is the distance between A and B at the time that the head of a frame is transmitted. For each received frame head sent by terminal B, the distance value will be updated correspondingly. Therefore, the output cycle of distance and the cycle of transmission frame are equal in value.

The main technologies of the system includes: the design, generation and transmission of ranging signal; the rapid capture of the ranging signal; Tracking and demodulation of the ranging signal; and the high-precision signal processing method. The accuracy of Time synchronization depends directly on the accuracy of the pseudo-range measurement, which can be greatly improved by the method of carrier phase smoothed pseudo-range. The detailed content could be found in reference [3]. Meanwhile, in order to adapt to the highly dynamic environment, an algorithm of second-order FLL assisted third-order PLL will be used in the tracking loop. Some of the indicators for the simulation environment of figure 2, 3 and 4 are: the velocity is 8000m/s, the acceleration is 20g and the accelerated acceleration (jerk) is 2g/s. As can be seen from the figures, about two seconds after the signal capture, the estimated carrier phase residual, carrier frequency residuals and pseudo-code phase residuals tend to be zero, which means the tracking loop of this system has the ability to adapt to the high dynamic environment.

V. SIMULATION AND EXPERIMENTAL RESULTS

A. *The prototype of DRTS system*

The prototype of DRTS Experimental system is shown in figure 6.

Fig. 6. The prototype of the experimental system

B. *The discrimination of signal tracking quality*

The oscilloscope display of the transmitting pseudo-code and the traced pseudo-code are shown in Figure 7, from which we can easily find that there is an obvious fixed delay between them.

The error output of DLL phase discriminator represents the tracing accuracy of the code loop; similarly, the error output of carrier phase loop discriminator represents the tracing accuracy of carrier loop. Inside the FPGA, the output of the code tracing loop filter is a 0.2ms-long data, and the per second acquisition of the tracking error of a data code phase std=0.00487chip, as shown in figure 8. The tracing error of carrier phase std=0.398 ° , as shown in figure 9.

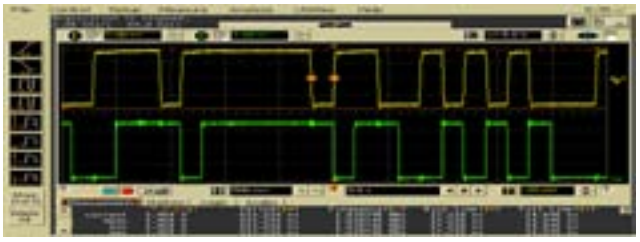

Fig. 7. The oscilloscope display of the transmitting pseudo-code and the traced pseudo-code

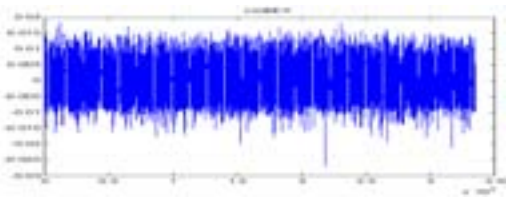

Fig. 8. Code phase tracking error

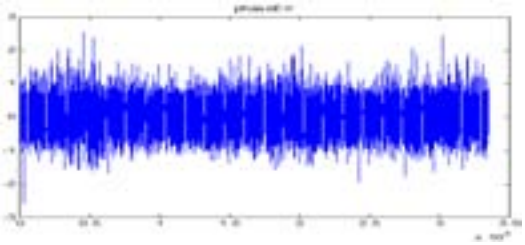

Fig. 9. Carrier phase tracking error

C. *Result figure of system test*

Use a 60-meter-long symmetrical cable to simulate the space link in the test. Assume that the delay of two-way symmetrical coaxial cable is T, which also means that T is equal to the product of the propagation velocity v (ns/m) of the signal in the cable and the length of the cable, plus the transmission delay t1 and the reception delay t2 of the system, which can be expressed by the equation 60*v+t1+t2=T. After several tests and calculations, we can get these results that the propagation velocity v of the obtained signals in the coaxial cable is about 5ns / m, and the sum of transmission and reception delay of the device at the time of boot is about 40.2ns.

Then, use the same source and different sources rubidium clock to do some tests, which can get the local pseudo-distance, pseudo-range of the opposite side, clock error and the true distance. The test results are shown in Figure 10 and Figure 11. After the indicators of the entire terminal system has been tested, the results show that the daily stability of different sources rubidium atomic frequency standard is e-10 and the daily accuracy is e-9, and the accuracy of ranging and time synchronization of the terminal ≤1.038m/3.46ns (STD), which has met the original design requirements and can be used in the

precision baseline measurement and time synchronization of the inter-satellite network, such as the Autonomous Formation aircraft.

If use the same source rubidium in the same order of magnitude, then the testing accuracy is 0.279cm/9.3ps (STD), which characterizes the measurement optimum in this certain environment. And the ranging and time synchronization resolution is up to 0.15cm and 5ps (@1s), one time higher than the similar foreign products [4]. Detailed comparison is shown in Table 1. Due to the lower stability and accuracy of the reference frequency resource used by foreign similar product, the ranging and time synchronization accuracy are not directly comparable. However, according to the data analysis, we know that if the frequency of the reference sources are in the same order of magnitude, this system will have a better performance than foreign similar products.

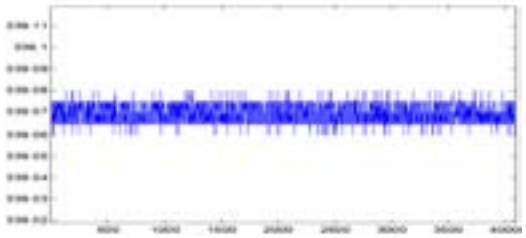

Fig. 10. 60m with the same resource

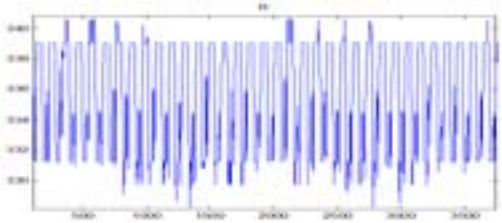

Fig. 11. 60m with different resource

TABLE I. COMPARISON OF DRTS AND SATRE

comparison	Dual Ranging Time Synchronization (DRTS)	Satellite Time and Ranging Equipment (SATRE)
Code rate	5M	0.5,1,2.5,5,10,20M
Center frequency	15MHz	70MHz
Resolution of Ranging and Time Synchronization	0.15cm、5ps(@1s)	0.3cm、10ps(@1s)
Accuracy of ranging and time synchronization	Different resource 3.46ns(reference frequency <e-10/d); The same resource 9.3ps(reference frequency <e-10/d)	<200ps(reference frequency-14/d)

D. Computer supporting software package

Computer supporting software function modules include:

- Parameter control of serial communication port, baud rate, data bits, stop bits, parity, etc.
- Numerical display and graphical interface display: including the respective pseudo-range measurement value, the clock difference and the true distance between the two stations.
- Data analysis and processing modules: data acquisition, display and storage of the results.

The new technology and method used in this software includes:

- Automatically adjust the size and location of character and control button on the software interface according to the resolution.
- This program can read the number of the existed logical serial port from the system registry form, and make it available to the users to choose, which avoid the occurrence of such problems as the blind display of the software and the blind serial selection of the users.
- Create a dedicated thread to ensure the timeliness and stability of communication.

VI. CONCLUSION

Due to the symmetry of the measurement path of DOWR principle, the common error between these two points is eliminated and higher measurement accuracy is obtained compared to one-way ranging. In this paper, on the basis of pseudo-code phase and carrier phase of the dual one-way precision ranging, a preliminary exploration of time synchronization between two points is conducted. Systematic errors are mainly caused by these two aspects, that is, the zero drift caused by the RF front-end and combination of zero drift caused by baseband circuit, and the RF phase delay caused by the temperature change [5]. In addition, when it comes to the versatility of device and its ability of the seamless connection with similar foreign product, the system needs to be further optimized. In brief, the Two-way ranging and time synchronization system can be applied to future earth integrated aerospace monitoring and control, high-precision time measurement and control platform of information transmission, and also can provide time service to the communication between the satellites, satellite and ground station, aircraft, ground stations, etc.

Abstract— **In Global Navigation Satellite Systems (GNSS) the role of atomic clocks is essential for the determination of the user position. Nowadays, several satellite navigation systems are operating and different clock technologies have been employed on board satellites, taking benefit of the improvements reached during the last tens of years. The analysis of GNSS clock performance is thus crucial for ensuring the GNSS positioning and timing capabilities.**

We performed an analysis on the clock estimates generated by the Information-Analytical Centre [1] (IAC) of the Russian Federal Space Agency, which provides a service similar to the one of the International GNSS Service (IGS). Therefore, we collected and processed the RINEX for clock files containing satellite clock estimates for GPS and GLONASS constellations, from 2008 to 2013: with our statistical tools [2] we performed an analysis of the performances of the different space clock technologies employed on board different GNSSs. In particular, we focused the attention on the frequency behaviour and the frequency stability, evaluating also the stationarity of these characteristics, with the aim of classifying and analysing the clock anomalies.

In this paper, the attention is mostly focused on the change in clock noise variance.

Keywords—GNSS timing; atomic clocks; clock anomalies; change in noise variance

I. INTRODUCTION

Atomic clocks and time scales are fundamental in Global Navigation Satellite Systems (GNSSs). Each satellite of the constellation carries more than atomic clocks, as a reference for all the timing operations.

It is known that in GNSSs the position is determined from the time of flight of signals transmitted from satellites: hence, any error in the time measures generates an error in the positioning. This is the main reason why very stable and accurate atomic clocks are of extreme importance to guarantee small positioning errors.

In GNSS, different clock types are employed on board satellites: Rubidium Atomic Frequency Standards (RAFS) are used in GPS and Galileo, Caesium clocks are used in GPS and GLONASS, while Passive Hydrogen Masers (PHM), the best clocks ever realized for space applications, are flown on Galileo satellites.

Clocks can experience anomalies for several physical reasons [3,4]. Clock anomalies impact directly on the positioning error: in fact clock stability and predictability are dramatically corrupted in case of anomalous clock behaviour and the user ranging error is increased. It is therefore crucial to understand clock anomalies.

We are carrying out a thorough study of clock anomalies on GPS and GLONASS clocks. Our interest arises from the fact that we have been characterizing clock anomalies for Galileo and we aim to have a clear general picture on space atomic clock behaviour .

We start by classifying the main anomalies in GNSS clocks.

Main families of anomalies that we are observing on satellite clocks are:

- apparent deterministic oscillations
- frequency jumps
- change in the noise variance

Our final goal is to build a detailed statistics of all the anomalies affecting GNSS space clocks.

In this work we will focus on the changes in the clock noise variance.

II. EXPERIMENTAL ACTIVITY

A. Sources of Data

As input for our analysis, we collected the GPS and GLONASS RINEX for clock files from June 2008 to April 2013, from the Information-Analytical Centre (IAC) [1] of the Russian Federal Space Agency.

The IAC is an organization which provides accurate estimates of clocks and orbits of GPS and GLONASS satellites, in addition to information on the GNSS status.
The IAC estimates of satellite clocks and orbits are comparable with those evaluated by the International GNSS Service (IGS) [5], the leading processing centre in the world.
We collected also the first Galileo clock data from the Multi-GNSS Experiment (MGEX) of the IGS [6].
We processed the satellite clock data with the tools regularly employed at INRiM for clock characterization [7], to assess the performances of the different clock families.
We concentrated on the main anomalies present in the satellite clocks, namely apparent deterministic oscillations, frequency jumps, and changes in the noise variance.
Changes in the noise variance are addressed in this paper.

B. Changes in the noise variance

When a clock experiences a change in the variance the performances are degraded.
The change can be local, as in the example illustrated in Fig 1, where the noise variance, as estimated by the Allan deviation, is increased then returns to the original level.
We study the changes in the noise variance with the Dynamic Allan Deviation (DADEV) [8,9], which allows to observe also some phenomena which would not be visible with the classical Allan Deviation.
Fig 2 shows the dynamic Allan deviation of the data presented in Fig 1: the first two peaks are due to the two jumps in the clock phase offset illustrated in Fig 3, while the change in the noise variance is clearly visible in the increase of DADEV level between days 260 and 265.
Changes in the noise variance may indicate major problems in the clock behaviour.
As seen in Fig 4, showing the evolution of caesium clock on board GPS satellite G30, the noise variance started increasing progressively: on day 133 the clock was then declared not usable until further notice, before being definitely decommissioned on day 201 [10].
After this malfunctioning, satellite SVN 30 (labelled with PRN G30) was then substituted by the spare satellite SVN 35 on day 228, with a Rubidium clock. [11].

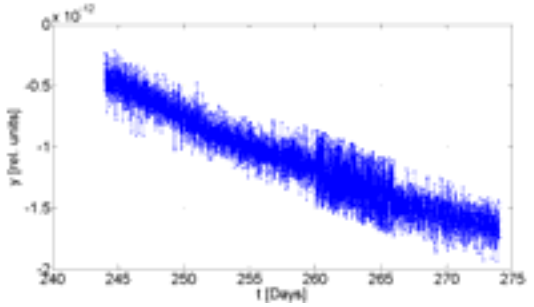

Fig 1: GPS G25 RAFS clock vs GPS Time Normalized Frequency Offset, September 2010

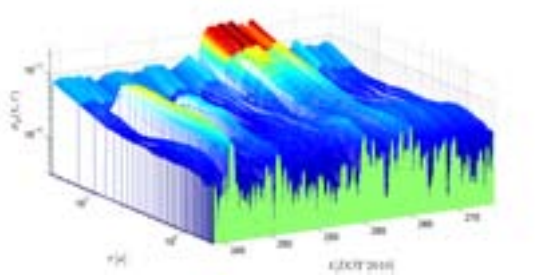

Fig 2: GPS G25 RAFS clock vs GPS Time Dynamic Allan Deviation, September 2010

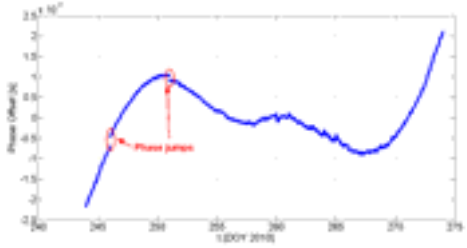

Fig 3: GPS G25 RAFS clock vs GPS Phase Offset, 2nd order drift removed, September 2010

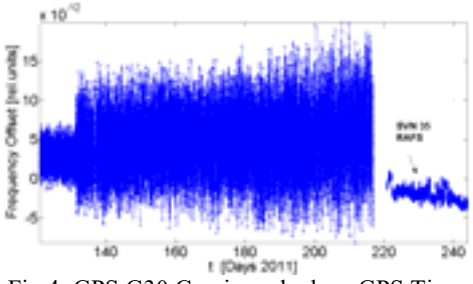

Fig 4: GPS G30 Caesium clock vs GPS Time Normalized Frequency Offset, May-June 2011

This is a clear example in which the change in noise variance indicates the status of clock health, which can be monitored by means of the Dynamic Allan Deviation.
Fig 5 reports the Dynamic Allan Deviation of satellite G30, including the period before and after the breakage: the higher level of the DADEV until day 220 represents the increase in the noise variance. The single peak before day 140 is generated by a jump in the clock phase offset.
After the satellite change, it can be observed that the level of DADEV is noticeably decreased.
In both the examples reported in this paper, the change in the noise variance is associated to an increase of the level of Dynamic Allan Deviation: a detection surface can be set [12]

in order to rise alarms for potential anomalies when the threshold is exceeded.

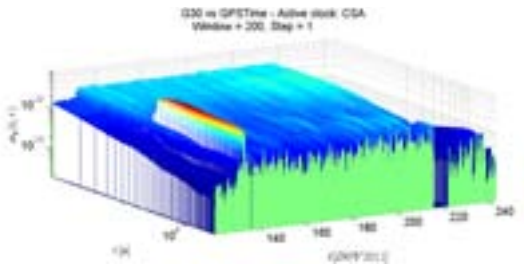

Fig 5: GPS G30 vs GPS Dynamic Allan Deviation, May-June 2011

III. CONCLUSIONS

The exam of the GNSS space clock behavior reveals some anomalies that can be significantly impacting the navigation performance. We have carried out an analysis over 4 years of GPS and GLONASSS space clock data and we have identified a few type of clock anomalies. Among them the increase of the clock noise variance can be a sign of the end of life f a clock and can therefore be a warning at system level. We have investigated the capacity of the Dynamic Allan variance to detect and interpret such situations, showing the potentiality of the tool and its valid application to GNSS clock management.

***Abstract*—With the progress of Global Navigation Satellite Systems(GNSSs),which mainly includes GPS, GLONASS, GALILEO as well as BeiDou, multi-system joint working mode has become research focus and application trend. But, Each satellite navigation system has its own independent system time, such as GPST, GLONASST, GST and BDT. The System time offset between the two satellite navigation systems is one of the most important aspects of their interoperability. It will cause combined navigation position solution bias and time solution. Therefore, it is necessary and significant to monitor and research system time offset.**

A method of GNSS System Time Offset monitoring which is called Signal- in-Space Reception method is put forward and its principle is described. In this method, UTC(NTSC) time scale is regarded as reference time scale on account of its status of standard time and frequency resources. Then, The time offset between each satellite navigation system time and UTC(NTSC) which include UTC(NTSC)-GPST, UTC(NTSC)-GLONASST, UTC(NTSC)-BDT,UTC(NTSC)-GST can be acquired. Thus, system time offset among satellite navigation systems, such as GPST-GLONASST, can be acquired with about 5ns (1 σ) precision.

On the basis of above described method, GNSS System time offset monitoring system has been set up since 2011 and it is gradually improved and perfected. A great deal of monitoring data has been collected. Addition to common error sources, some special error sources related to GNSS timing receiver such as receiver delay, inter-system hard delay bias, inter-frequency biases and so on are analyzed, as they can effectively affect monitoring results and precision. The monitoring data and IGS precision orbit as well as corresponding data published by BIPM Circular T Bulletin are combined together to determine above error values. The results of the error items and GNSS system time offset monitoring results are to be showed.

Keywords—GNSS; System time offset; Monitoring; Signal-in-Space Reception; Error sources

I. INTRODUCTION

At present, GNSSs (Global Navigation Satellite Systems) has got into a new era of vigorous development, which mainly includes GPS, GLONASS, Galileo and BDS[1,2,3,4,5].Each GNSS systems are based on time difference measurement that is why accurate and stable system time is one of the security conditions for the satellite navigation system working. Therefore, every GNSS system has its own time reference system, the system time of GPS is GPST, which is traceable to UTC (USNO); GLONASS system time is GLONASST, traceable to UTC (SU); Galileo system is GST (Galileo System Time), was controled to the TAI or UTC by the Time Service Provider (TSP). BDs system time is referred as BDT, BDT using a continuous time scale which is no leap second insertion, and it traces to international TAI or UTC through UTC (NTSC) [6, 7]. In the multi-mode navigation applications, the use of satellite clock correction broadcast by satellite navigation message, GPS pseudorange correction to GPST, GLONASS pseudoranges correction to GLONASST and BDs pseudorange correction to the BDT. Thus, the system time offset between different systems will cause the deviation of positioning[8], so that users encounter the bias of position information when they are calculating. For the above reasons, it is necessary to using a unified system time in user terminal for positioning. There are many ways to measure and determine the system time offset [4], this article focuses on the method of GNSS system time offset monitoring which is called Signal-in-Space Reception method.

II. METHOD OF GNSS SYSTEM TIME OFFSET MONITORING

A. *Review of monitoring methods*

GPS and Galileo have already reached agreements between the two systems, and the advance of GGTO monitoring is in processing. Due to the permission of where USA and Europe are located, GGTO monitoring technologies include two-way satellite time transfer and common view methods [9]. China's Beidou satellite navigation system, Galileo satellite navigation system and the Russian GLONASS systems also can use these two methods for monitoring the system time offset. However, these methods require both sides to negotiate firstly, and also including political factors as well as expensive fees, another important problem is the geographical constraints, because it needs to be observed with the same satellite whether it is two-way satellite time transfer method or common view method. Based on the above considerations, the best monitoring method of GNSS system time offset can turn to receive the Siganl-in-Space. The reasons are as follows: 1.every GNSS system is a high-precision timing system, each GNSS system not only has their own time system and traceable links, but also has ability for transferring the system time to users through the GNSS satellites.2. Currently, the performance of high-end commercial receiver is more and more remarkable for timing and positioning, moreover combined GPS / GLONASS /

Spported by"Western Light Talents training program of CAS" roject (Y109YR2701),2010

GALILEO / BDS, its precision can be further improved by accessing a high-precision external frequency reference .3. System time offset monitoring by Signal-in-Space Reception without geographical limitations and much cheaper. Nevertheless, using this method to monitoring system time offset needs to consider many error factors, these will be described in later chapters.

National Time Service Center(NTSC) of CAS is the specialized research institute for Chinese national standard time production, maintain and dissemination. Since 2005, the deviation between the Coordinated Universal Time (UTC (NTSC)) establishes and maintains in National Time Service Center and the international standards Coordinated Universal Time (UTC) is in remains within 20ns. Signal-in-space Receiption method for system time offset monitoring is based on the UTC (NTSC) standard time and frequency.

B. Signal-in-Space Reception method for GNSS system time offset monitoring

The system time offset monitoring principle by receiving space signals is as follows: we take the standard frequency signal of the National Time Service Center as a frequency reference, the standard time signal as the reference time scale, the differences between UTC (NTSC) and GNSST are measured (including UTC (NTSC)-GPST, UTC (NTSC)-GLONASST, UTC (NTSC)-BDT, UTC (NTSC)-GST, etc.), Figure 1 shows the measuring principle, take the GPS and GLONASS systems as an example, UTC (NTSC)-GPST and UTC (NTSC)-GLONASST can be measured at the NTSC ,then we can obtain the GPST-GLONASST directly.

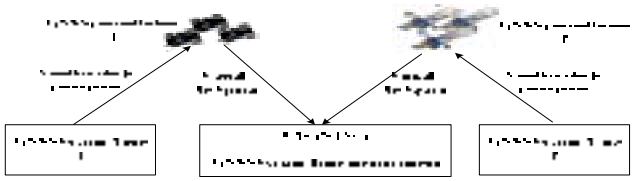

Figure1. Schematic diagram of system time offset monitoring by signal-in-space reception

Figure 2 describes the core equipment of this monitoring method is GNSS timing receiver and the time interval counter. In the precise known of GNSS receiver antenna phase center, each navigation system spatial navigation signals received by timing receiver, the receiver pseudo-range and high-precision time interval counter measurement value are used so as to calculate the difference between UTC (NTSC) and each GNSS system time.

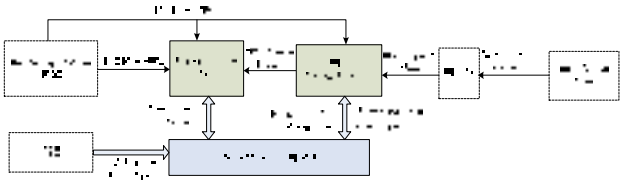

Figure2 Block diagram of receiving space signal to achieve the system time offset monitoring

Figure2 shows that the difference between UTC (NTSC) and GNSST (GPST, GLONASST,BDT, GST, etc.) can be calculated in Equation (1) below:

$$UTC(NTSC)-GNSST=\left(\rho-\mathrm{r}+dt-\mathrm{pd}-\mathrm{d}\left(\mathrm{ion}\right)-\mathrm{d}\left(\mathrm{trop}\right)-\mathrm{Ep}\right)/\mathrm{c}-TICValue-\Delta ChDelay+\Delta ISDB \quad (1)$$

Where GNSST is the GNSS system time, ρ indicates the pseudorange from receiver to the satellite, r represents the real geometric distance between satellite and ground, dt is the satellite clock bias, pd is the orbit error, d (ion) is the ionospheric delay, d (trop)is the tropospheric delay, Ep indicate other errors, c is the speed of light, TICValue is the measurement value of precision time interval counter, ΔChDelay indicates that the receiver relative channel delay bias, ΔISDB represents the inter-system hardware delay bias.

Since more than 5 satellites of every GNSS constellation can be received at a fixed position, at the NTSC, the average number of received GPS satellites and GLONASS satellites both over 8. In addition, the system time offset monitoring is done at one second interval, so we can use the following ways to further improve the monitoring precision: (1)Averaging the system time offset monitoring results for all visible satellite.(2)Smoothing monitoring data per minute.(3)Using IGS or other precise orbit to correct monitoring data, further eliminating the ephemeris error.

III. THE ERROR SOURCES OF SYSTEM TIME OFFSET MONITORING AND MEASUREMENT OF THE IMPORTANT PARAMETERS

A. Error budget for system time offset monitoring

The monitoring precision error budget of system time offset determination by Signal-in-Space reception is as follows[10,11]:

(1). Satellite orbit error is about 4.5ns;

(2). Satellite clock error is about 4.5ns;

(3).Transmission link error is about 3ns, including the ionosphere and troposphere, ionosphere using dual-frequency correction;

(4). Receiver error is about 3ns, including receiver noise error, the receiver delay error, inter-frequency bias, multipath errors, etc;

(5). The error of time interval counter measurement is about 0.5ns;

(6). The reference clock error of about 2ns;

(7). The inter-system hardware delay bias is about 2ns.

NO.1-NO.6 errors are caused by monitoring a single satellite, error No. 7 result from difference between the signal frequencies of multi-GNSS systems in receiver [12], the total error estimate as follows:

$$\sqrt{4.5^2+4.5^2+3^2+3^2+0.5^2+2^2+2^2}\approx 8.0ns \quad (2)$$

It has been described in 2.2, using multi-satellite system time offset monitoring value for the mean, and the average

values were further smoothed in a period of time, this will eliminate monitoring errors witch have characteristic of noise, such as receiver measurement noise. And part of the satellite clock error and signal propagation delay will be eliminated as well. Therefore, the monitoring result can be acquired with the 5ns (1σ) estimation precision.

B. Receiver delay measurement

In order to implement the function to monitor the GNSS system time offset, we use a simpler method for determining the receiver delay, which is that measurement of receiver time delay based on UTC (NTSC). As National Time Service Centre maintaining the standard time scale UTC (NTSC) is set by the internal atomic clock comparison, as well as international internal laboratory comparisons (TWSTFT and GPS) to maintain its precision, we can take advantages of its resources to the measurement of receiver relative delay. Reference[13] can explain the specific principle for receiver delay measurement.

The following table shows the 6 groups of receiver delay values which are calculated by the application of 27 days of monitoring data and the corresponding BIPM data(including $\Delta\tau_2$ = UTC-UTC(NTSC) and $\Delta\tau_3 = UTC - GPST$). Where $\Delta\tau_1$ represents monitoring value of UTC(NTSC)-GPST which contains τ_{rec} and τ_{rec} is the receiver delay to be measured, which contains an antenna and the cable delay. The results can be seen from the table that the receiver delays are about 186.86±0.85ns and fluctuation range is small. This receiver delay value is measured from the antenna phase center to 1PPS output of the timing receiver, which includes an antenna delay, antenna cable delay, the receiver internal delay and a cable delay τ_{cable} for connecting 1PPS of the timing receiver.

TABLE 1 RECEIVER RELATIVE DELAY MEASUREMENT RESULTS

Date	$\Delta\tau_1$	$\Delta\tau_2$	$\Delta\tau_3$	τ_{cable}	τ_{rec} **(ns)**
2013.2.21	185.0	0.5	-0.1	21.2	**185.7**
2013.2.26	173.4	10.6	-2.7	21.2	**186.8**
2013.3.3	174.9	8.9	-3.9	21.2	**187.8**
2013.3.8	173.5	12.2	0.0	21.2	**185.9**
2013.3.13	176.2	7.0	-3.9	21.2	**187.2**
2013.3.18	175.0	5.7	-7.0	21.2	**187.8**
Average	**176.3**	**7.5**	**-2.9**	**21.2**	**186.9**

C. Inter-frequency biases measurement

The receiver channel delay biases depend on the frequency of the satellite signal. For the GPS system, as the use of code division multiple access (CDMA) signal system, all the satellites using the same carrier frequencies (the inter-frequency bias which is caused by the same satellites transmitting signals at different carrier frequencies is outside the scope of this paper), the delay biases between each channel is very small, about sub-millimeter and can be neglected. However, the GLONASS system uses frequency division multiple access (FDMA) signal system, satellite signals of different frequencies generated the receiver channel delay different from each other, and there is a certain deviation, called the inter-frequency bias. In a single navigation system data processing, the delay of each channel does not be calibrated in general, because the biases will be absorbed by clock error parameters. But Observed in the case of multi-mode, in order to improve the monitoring precision of GNSS system time offset, it is necessary in advance to the GLONASS channel delay biases for precision measurements.

The use of GNSS simulator to test the GLONASS L1 carrier signal inter-frequency biases of Septentrio PolaRx4 receiver, take the receiver channel which receives the frequency number 0 GLONASS satellites as reference channel, the inter-frequency biases of other channels can be calculated relative to the reference channel, thus the results were compared to analyzed.

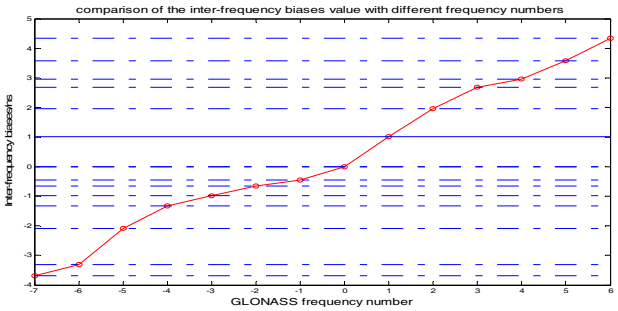

Figure3 Comparison of the inter-frequency biases value with different frequency number of GLONASS

Figure 3 shows the measurement results of GLONASS infer-frequency biases on different frequency number. It can be seen from figure above that for the Septentrio PolaRx4 receiver, the inter-frequency of GLONASS seems to vary with the frequency number. Although the magnitude of change is uncertain, the value exhibits linear increasing trend along with frequency number is increasing in general, and it is vary with respect to the frequency number 0 of GLONASS satellites in-4ns to +5 ns. Fortunately, for receiver of the same brand, the variation did not change with temperature change, it is the result of the carrier phase measurement in receiver DSP chain [14]. The GLONASS channel delay bias is found to have a wide range, hence it must be eliminated based on the received GLONASS frequency value in the system time offset monitoring.

IV. DATA ANALYSIS OF SYSTEM TIME OFFSET MONITORING

A. Monitoring data analysis

On the basis of the method of system time offset monitoring and the measurement results of some important parameters above described, UTC (NTSC)-GPST and UTC (NTSC)-GLONASST data between February 20 to March 29 in 2013 are analyzed in detail, the results are shown in Figure 4 and Figure 5.In order to analyze the monitoring precision, three kinds of time offset results were compared, one is monitoring result, another is calculated value with BIPM, the third one is data from GLONASS broadcast ephemeris. The

UTC (NTSC)-GPST data with BIPM shown in Figure 4 is calculated from UTC-UTC (NTSC) and UTC-GPST data as well as the GPST-GLONASST data with BIPM is calculated from UTC-GPST and UTC-GLONASST data shown in figure 5.However, the monitoring result, GPST-GLONASST is calculated by UTC (NTSC)-GPST and UTC (NTSC)-GLONASST. It is noteworthy that there is a inter-system hardware delay for 210ns between calculated GPST-GLONASST value by circular T and our monitoring data GPST-GLONASST, and the value was deducted during the drawing.

From figure 4 and figure 5 can be seen, the changing trends of both the UTC (NTSC)-GPST or GPST-GLONASST monitoring data are consistent with data from the broadcast ephemeris and value with BIPM.

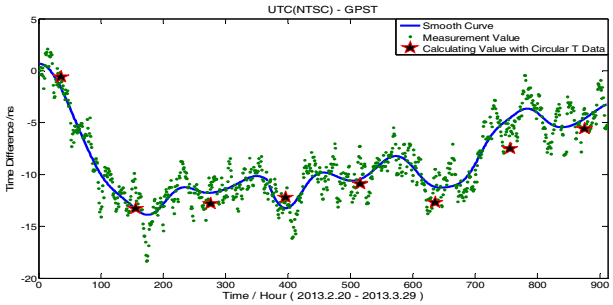

Figure 4 Comparison of measurement value and calculating value with circular T data for UTC (NTSC)-GPST

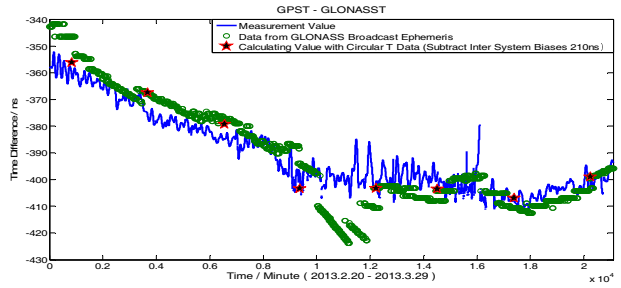

Figure 5 Comparison of three kinds of Results for GPST-GLONASST

B. Afterwards correction for monitoring results using IGS data

When monitoring the system time offset by receiving space signals, as the ephemeris error is one of the most important factors. Therefore,we have adopted the IGS rapid precise ephemeris data (delayed 17 hours) from March 1, 2013 to March 28, 2013,the corresponding monitoring data UTC (NTSC)-GPST were subsequently corrected. Modified result as shown in Figure 6:

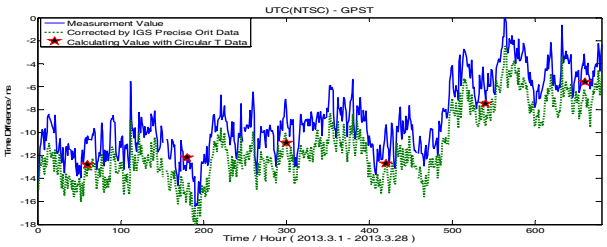

Figure6 Comparison of three kinds of Results for UTC (NTSC)-GPST

As can be seen from figure 6, there is a little difference between the monitoring result UTC (NTSC)-GPST after correction and calculated value with circular T, effect is not very obvious yet .in fact, we do not currently have an absolute standard reference to assess the monitoring value for the before and after correction. Nevertheless, it is certain that the IGS precise orbit products provide precise data [15].

V. CONCLUSIONS AND OUTLOOK

This paper mainly focus on the discussion of monitoring system time offset by means of Signal-in-Space Reception. GNSS system time offset monitoring system by Signal-in-Space Reception has begun trial operation at NTSC. We have been able to monitor UTC (NTSC)-GPST and UTC (NTSC)-GLONASST so far and expect to gradually improve the monitoring system in the future. We are planning to add UTC(NTSC)-BDT monitoring .

***Abstract*—In the paper the realization of the method enabling real-time computation of ADEV, TDEV, and HDEV performed in the real time for multi-channel time error measurement is described.**

Keywords-timing signal; time error; Allan deviation; time deviation; Hadamard deviation; real-time computation

I. INTRODUCTION

Allan deviaton ADEV, time deviation TDEV, and Hadamard deviation HDEV are the parameters used for describing the quality of timing signals generated by the clocks. Time deviation is commonly used for evaluation of the synchronization signals in the telecommunication network. The limit values of TDEV for the network interfaces are defined by the telecommunication standards [1, 2, 3]. These parameters allow the variations of time interval provided by the synchronization signal to be assessed and the type of phase noise affecting the signal to be recognized. Hadamard deviation is insensitive for the presence of the frequency drift and can be used for recognition of higher types of the phase noise. The estimates of the parameters are computed for a series of observation intervals using the sequence of time error samples previously measured at some network interface. The evaluation of the timing signal is commonly a two-stage process: calculation of a parameter follows the time error measurement. However, the real-time parameters' computation performed during the time error measurement process is also possible. The application of the real-time computation allows to simplify the analysis of the timing signals.

There are many situations, that more than one timing signal has to be analyzed in the same time. In the node of the telecommunication network, we have access to timing signals generated by several clocks installed in the node equipment (e.g. SSU, SEC, or central office's clock), as well as to the timing signals obtained from the data streams arriving from several directions. Such situation can be also considered when we want to perform the three cornered hat procedure in order to compare some clocks without the knowledge, which one is better. A multi-channel time error meter with computation algorithms applied could be suitable for this analysis.

The computation methods enabling assessment of the parameters in the real time were previously proposed and tested [6, 8]. The experimental tests have proved the ability of the computation of these parameters in the real time for a single data series as well as for multi-channel time error measurement [7].

In the paper the results of the implementation of the algorithms enabling joint real-time ADEV, TDEV, and HDEV assessment performed during multi-channel time error measurement are presented. To test these methods in a real measurement process, a special measuring system enabling multi-channel time error measurement was used.

II. ADEV, TDEV, AND HDEV ESTIMATORS

Allan deviation and time deviation are computed based on the averaging of second differences of the phase process $x(t)$ of the analyzed timing signal. We can assume for the telecommunication applications, in the case of negligible influence of frequency drift, that ADEV and TDEV are estimated based on the time error function measured between the analyzed timing signal and the reference one [4]. In the case of Hadamard deviation the third difference of the phase process $x(t)$ is averaged.

When computing in the real time, we do not have access to the time error samples indexed by $i+n$ or $i+2n$ (as in the common parameters' estimators) for the current time instant described by the index i, because these samples have not been measured yet. We have access to the sample currently measured (for the current sampling instant i) and the samples measured earlier (with indexes smaller than i) and stored in the equipment's memory. Therefore, the indexes in formulae for common ADEV, TDEV, and HDEV estimators should be changed in the case of real-time calculation.

The rearrangement of indexes for the parameters' estimators was performed in [5, 7]. As result of the conversion the estimators were obtained in the forms suitable for the real-time computation. The value of the parameter currently computed (for current sampling instant i) depends on the currently measured sample, small number of previously measured samples, and values of sums accumulated in the previous sampling instant. ADEV estimator's formula for a current instant i and selected measurement channel m is given in the form:

This work was supported by the National Science Centre in the frame of the project N N517 470540.

$$ {}_m\hat{ADEV}_i(n\tau_0)=\sqrt{\frac{1}{2n^2\tau_0^2(i-2n)}\left({}_mA_{i-1}(n)+\left({}_mx_i-2{}_mx_{i-n}+{}_mx_{i-2n}\right)^2\right)} \quad (1) $$

were ${}_mA_i(n)$ is the sum of squares of second differences of time error samples

$$ {}_mA_i(n)=\sum_{j=2n+1}^{i}\left({}_mx_j-2{}_mx_{j-n}+{}_mx_{j-2n}\right)^2, \quad i>2n $$

and ${}_mx_i$ denotes the time error sample measured at the sampling instant i in the m-th channel. The value of time deviation for the current sampling instant i is estimated using the formula:

$$ {}_m\hat{TDEV}_i(n\tau_0)=\sqrt{\frac{1}{6n^2(i-3n+1)}\left[{}_mS_{ov,i-1}(n)+\left({}_mS_{i-1}(n)+{}_m\Delta_i(n)\right)^2\right]} \quad (2) $$

where ${}_mS_{ov,i}(n)$ and ${}_mS_i(n)$ are the sums updated for each sample i, given in the form:

$$ {}_mS_{ov,i}(n)={}_mS_{ov,i-1}(n)+{}_mS_i^2(n) $$

$$ {}_mS_i(n)={}_mS_{i-1}(n)+{}_m\Delta_i(n), \quad i>3n $$

$$ {}_mS_{3n}(n)=\sum_{j=2n+1}^{3n}\left({}_mx_j-2{}_mx_{j-n}+{}_mx_{j-2n}\right), \quad j>2n $$

and ${}_m\Delta_i(n)$ is a third difference of the time error samples measured in the m-th channel:

$$ {}_m\Delta_i(n)=-{}_mx_{i-3n}+3{}_mx_{i-2n}-3{}_mx_{i-n}+{}_mx_i $$

The sum ${}_mS_{3n}(n)$ is the first element of the overall sum ${}_mS_{ov,i}(n)$. The conversion of the Hadamard deviation estimator brought the formula in the form dependent on the sum of squares of third differences computed for the preceding sampling instant $i-1$ and the current difference ${}_m\Delta_i(n)$

$$ {}_m\hat{HDEV}_i(n\tau_0)=\sqrt{\frac{1}{6n^2\tau_0^2(i-3n)}\left({}_mB_{i-1}(n)+\left({}_m\Delta_i(n)\right)^2\right)} \quad (3) $$

where ${}_mB_i(n)$ is the sum of squares of third differences of time error samples

$$ {}_mB_i(n)=\sum_{j=3n+1}^{i}\left({}_mx_j-3{}_mx_{j-n}+3{}_mx_{j-2n}-{}_mx_{j-3n}\right)^2, \quad i>3n $$

As a result of the conversion of the parameters' formulae, in order to compute ADEV, TDEV, and HDEV for a selected data sequence m (m-th measurement channel), current sampling instant i and given observation interval $\tau=n\tau_0$, we need the values of appropriate sums ${}_mA_{i-1}(n)$, ${}_mS_{ov,i-1}(n)$, ${}_mS_{i-1}(n)$, and ${}_mB_{i-1}(n)$, currently measured sample ${}_mx_i$, and previously measured samples ${}_mx_{i-n}$, ${}_mx_{i-2n}$, and ${}_mx_{i-3n}$ stored in the memory.

III. Multi-channel Computation of the Parameters

The idea of real-time computation for multi-channel time error measurement is presented in Fig. 1. The measurement of the time error is performed using a multi-channel measuring system consisting of M time error meters. We assume that the measurement is performed with the same sampling interval for each time error meters. The time error samples are collected from the time error meters, aggregated in one data stream, sent jointly to the computer and then stored in one data structure on the hard drive of the computer. Recently measured time error samples can be temporarily stored in the buffer placed in the memory. The organization of data structures can play important role in the real-time computation [6].

The real-time computation process of the parameters was designed as single-threaded process, i.e. all necessary operations are performed within one sampling interval, between the successive sampling instants. Therefore the algorithm must be time effective, in order to not exceed the sampling interval by the computation time.

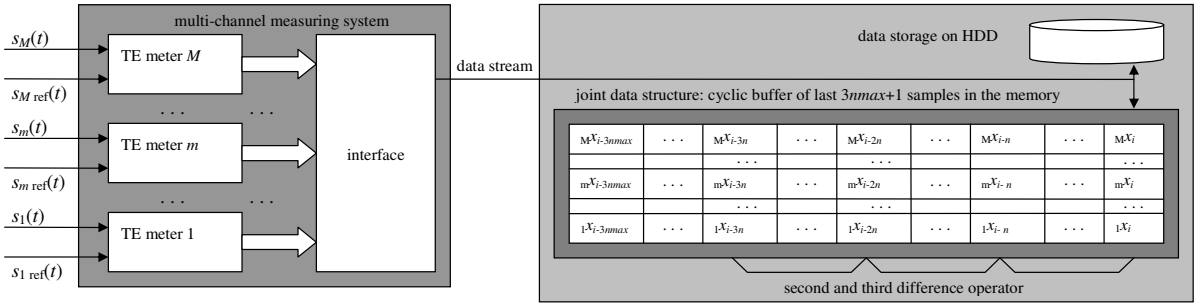

Figure 1. Idea of multi-channel TE measurement and data structures for real-time computation

The results of the experimental tests of the computation methods described in [7] proved the possibility of joint computation of the parameters in the real time. The computational experiments have shown better performance of joint data structure applied in the real-time multi-channel computation [6]. In order to minimize the time of data access, the cyclic buffer in the memory is created. The time error samples received from the time error meters are simultaneously stored on the hard drive and in the cyclic buffer in the computer memory. All computational operations according to (1), (2), and (3) will be performed on the samples stored in this buffer, which will reduce the time of data access. The buffer should have the length of $3n_{max}+1$ items (where $\tau_{max}=n_{max}\tau_0$ is the maximum observation interval considered), in order to store all samples necessary for the computation.

Detailed procedure of the operations performed within one sampling interval during multi-channel real-time computation for the data structure described above will be as follows:

1. Read TE samples from the TE meters and store them in the data file and in the buffer.
2. For a given observation interval $\tau = n\tau_0$ (given n) read TE samples measured n, $2n$, and $3n$ sampling intervals earlier for each channel from the buffer.
3. Compute the sums according to (1-3) successively for each channel.
4. Compute current averages and their square roots according to (1-3) successively for each channel.
5. Execute Steps 2-4 for successive greater observation intervals (greater n) from the range considered.
6. Go to the Step 1 (measure a new vector of TE samples).

The object of the computation performed using this procedure operating on joint data structure is M-dimensional vector. Therefore the computation performed for a given n requires only one execution of the data reading procedure within a single loop. As result the time of data access is reduced.

IV. Realization of Multi-Channel Computation

The algorithm described above was implemented using a modified version of the measuring system SP-4000 designed in the laboratories of Poznan University of Technology [8]. This system consists of two separate units: a measuring unit and an external computer controlling the measurement and computation process. The measuring unit contains four time error meters, build-in rubidium oscillator as a source of reference signal, and additional devices enabling synchronization to the GPS signals and communication with the external computer. This system enables independent time error measurement in four channels, recording of measured values, and *off-line* analysis using its usually software. The new algorithm proposed brings a new functionality to the timing signal evaluation process. The features of this software are following:

- 4-channel TE measurement in the same time with the same sampling interval;
- sampling interval range from 1/32 s till 1 s;
- real-time joint computation of ADEV, TDEV, and HDEV for all channels;
- graphic user interface enabling the presentation of measured TE values and computed parameters' values in the real time;
- range of observation intervals from 0.1 s till 1000 s;
- number of observation intervals considered within one decade:1, 2, 5, 10, or 20.

The time error meters are set for the measurement of timing signals used in the telecommunication network having the frequency of 2048 kHz, but the signals with different frequencies can be also measured.

The example screenshots showing the measurement and computation process are presented in Fig. 2 and 3. Time error is measured in four channels (timing signals generated by unsynchronized OCXO and rubidium oscillators were compared) with the sampling interval τ_0=1/32 s (Fig. 2) and τ_0=0.5 s (Fig. 3). The values of ADEV, TDEV, and HDEV are computed for 5 observation intervals per decade in the range from $3\tau_0$ (0.1 s and 1.5 s) till 1000 s. Successive points on the parameters' plots representing the values computed for successive observation intervals are added when the sufficient number of samples have been measured.

V. Conclusions

In the paper the realization of multi-channel real-time computation of ADEV, TDEV, and HDEV have been presented. The solutions that make possible the cooperation between multi-channel time error measuring unit and the real-time assessment of the parameters have been described. These methods can be applied in a measuring system controlled by usual personal computer, as well as in a system with build-in especially designed microprocessor system. The solution enabling multi-channel real-time analysis of timing signals can be very useful in the service and maintenance of the telecommunication networks as well as in the analysis of high quality oscillators.

***Abstract*—This paper deals with the problem of real-time computation of Maximum Time Interval Error for multi-channel time error measurement. The results of tests of the computation methods are presented and discussed.**

Keywords-timing signal, time error, maximum time interval error, real-time computation

I. INTRODUCTION

The effective diagnostics of the telecommunication network often requires an investigation into the quality of a timing signal at several interfaces of the network at the same time. This investigation involves in measurements of adequate time errors and computations of some standard parameters – point estimates of Maximum Time Interval Error (MTIE) among others [1, 2, 3]. Since MTIE should be watched at different network interfaces simultaneously and in real time, a multi-channel time error meter equipped with programs implementing appropriate algorithms could be applicable for such investigation.

Authors of this paper have proposed and described [10] two methods enabling MTIE assessment performed in the real time for multi-channel time error measurement. First solution is based on the time effective MTIE computation method with binary decomposition [4]. Second solution exploits the time effective extreme fix (EF) method [5] successfully applied earlier for single-channel real-time MTIE assessment [6, 8, 9]. In the paper the results of experimental tests of these methods are presented. The calculations were performed for several data sequences representing different behavior of time error taken with sampling interval τ_0=1/30 s, which is often used in the telecommunication applications. The results of calculation for various conditions using both methods are discussed.

II. MTIE POINT ESTIMATE

According to the international standards, the point estimate of the Maximum Time Interval Error is defined as the maximum peak-to-peak time error variation of a given timing signal, with respect to an ideal timing signal within a particular time period [1, 2, 3]. MTIE can be estimated from the formula

$$\hat{MTIE}(n\tau_0) = \max_{1\le k\le N-n}\left(\max_{k\le i\le k+n} x_i - \min_{k\le i\le k+n} x_i\right) \qquad (1)$$

where $\{x_i\}$ is a sequence of N samples of time error function $x(t)$ taken with sampling interval τ_0, $\tau=n\tau_0$ is an observation interval, and n can change from 1 till N–1 depending on the considered values of observation intervals.

III. MULTI-CHANNEL MTIE COMPUTATION

Real-time computation of the timing signal parameters for multi-channel time error measurement enables continuous observation of the quality of a series of timing signals simultaneously at the same time. The idea of the real-time multi-channel computation is presented in Fig. 1 [10]. The multi-channel measuring system consists of M time error meters. The time error samples are measured with the same sampling interval, collected from the time error meters, aggregated in one data stream, sent jointly to the computer and then stored in one data structure on the hard drive of the computer. Recently measured samples can be temporarily stored in the buffers placed in the memory. The organization of data structures can play important role in the real-time computation. It depends on the computation method applied.

IV. REAL-TIME COMPUTATION PARADIGM AND METHODS

The following computation paradigm is assumed: in order to compute the MTIE estimate simultaneously for several observation intervals and several data series (obtained from the measurement channels) in the real time, all necessary operations have to be done in the time interval between two successive time error samples, i.e. during the sampling interval τ_0; if some operation cannot be completed during prescribed time it is suspended until the end of measurement and then finished. The ability of real-time assessment depends on the several conditions: number and length of the observation intervals considered, number of measurement channels, data structures and organization, computation ability of the equipment, and time error data behavior.

This work was supported by the National Science Centre in the frame of the project N N517 470540.

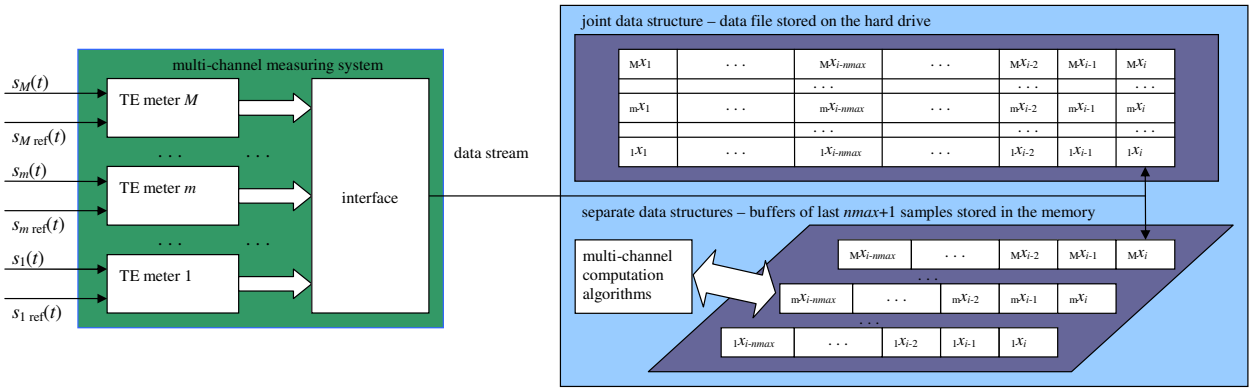

Figure 1. The idea of multi-channel time error measuring system with real-time MTIE computation

Two methods – extreme fix (EF) method [6] and binary decomposition method [4, 7] are used in presented test. Effectiveness of EF method depends on nature of data, in opposite to the effectiveness of binary decomposition method which is data independent.

The calculation process by means of the EF method runs independently for all observation intervals in all channels. The computations for current sampling instant are performed for particular observation intervals in order from shortest to longest interval. First, the observation intervals having the same length for each channel are analyzed. Next the longer observation intervals are considered. The idea of the real-time computation using the EF method for multi-channel measurement is presented in Fig. 2. Suspension of the analysis for particular observation interval can be performed in order to protect the measurement and computation process against exceeding the limit of the computation time (length of the sampling interval). Recently measured $n_{max}+1$ time error samples ($\tau_{max}=n_{max}\tau_0$ is the longest observation interval considered) for each channel can be stored in the buffers in the memory in order to reduce the data access time, which is the crucial issue in the real-time computation [6, 8]. Therefore all search operations will be performed using the data stored in the tables in the operational memory of the computer, which will reduce the computation time substantially.

The calculation process by means of the binary decomposition method runs independently for each channel. Application of joint data structure for the reduced samples – placed in the operational memory (if possible) or on the hard drive – is suggested in order to simplify the data access. Because of regularly running data reduction process, the samples with the same indexes are used for comparison for each channel. Single data reading procedure involving vector of samples will be more time effective than several independent procedures, especially for the data structures placed on the computer hard drive. The computations for current sampling instant are performed for particular observation intervals in order from shortest to longest interval. The idea of real-time computation using the binary decomposition method for multi-channel measurement is presented in Fig. 3.

V. Computation Experiment

The real-time multi-channel MTIE computation methods presented above were tested in the computational experiment. The calculations were performed *off-line* but the *on-line* real-time work was imitated. Three sets combining four time error sequences were used in the experiment. The first set (set A) consists of four sequences representing the realizations of one of typical noises of the timing signals – white phase modulation (WPM). The second set (set B) contains the results of comparison of unsynchronized oscillators: two sequences are obtained from the comparison of OCXO with rubidium oscillator, the other two from the comparison of two rubidium oscillators. These sequences show the effect of frequency difference, which is critical for the efficiency of the EF computation method. The last set of TE sequences (set C) represents various performance of timing signal. This set contains two WPM sequences, one OCXO versus rubidium sequence, and one rubidium versus rubidium sequence. The time error samples were taken with the sampling interval $\tau_0=1/30$ s.

Two different personal computers were used in the experimental tests: first computer with Core 2 Quad 2.83 GHz, and second one with I7 3.5 GHz microprocessor. The observed quantity was the maximum time spent for the calculation performed within one sampling interval. We have assumed that this time cannot exceed the length of sampling interval $\tau_0=1/30$ s = 33.3… ms.

In order to compare the time efficiency of both methods, the MTIE computations were performed for the same set of observation intervals. Because we cannot compute the MTIE using binary decomposition for arbitrary chosen observation intervals, the calculations were performed for observation intervals having the power of 2 samples. The starting (shortest) observation interval had 2 samples for binary decomposition and 4 samples for EF method (the computation for 2-samples interval is not necessary in this case). The maximal observation interval had 32 768 samples. Therefore MTIE was computed for 15 observation intervals by means of binary decomposition and for 14 observation intervals by means of the EF method. The results of the computations are presented in Table I.

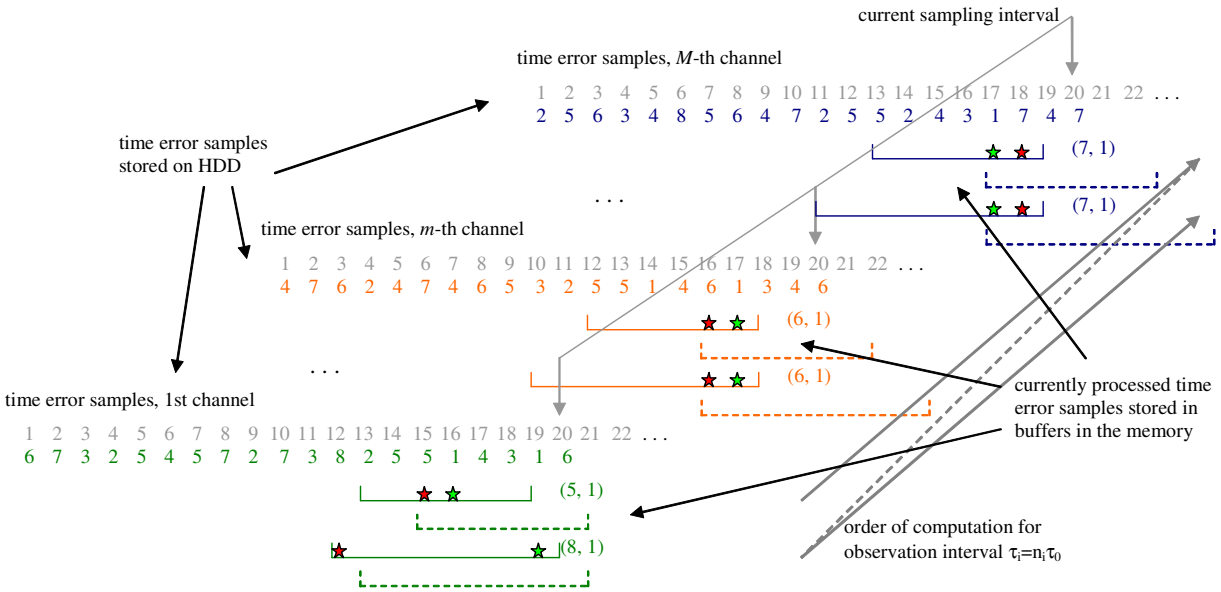

Figure 2. Real-time multi-channel MTIE computation using the EF method

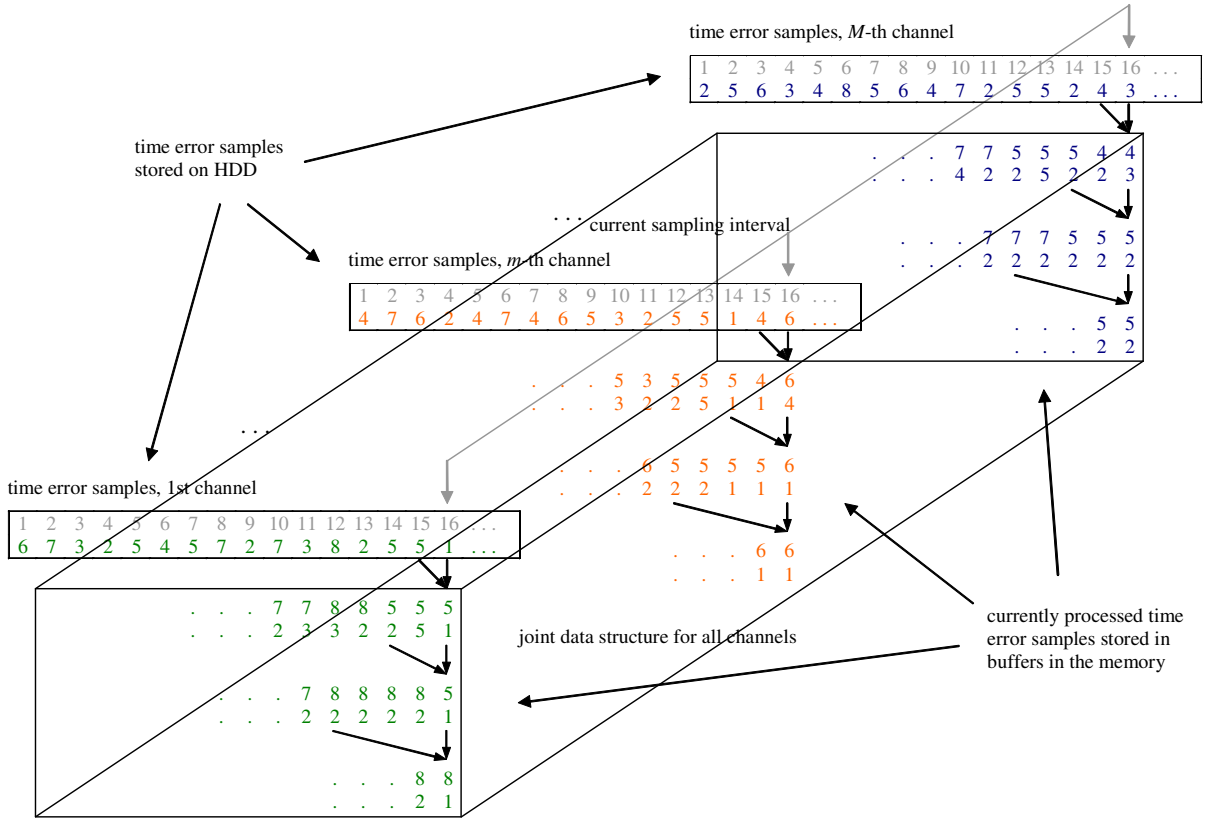

Figure 3. Real-time multi-channel MTIE computation using binary decomposition method

TABLE I. MAXIMUM TIME OF MTIE COMPUTATION USING EF AND BIN METHODS

computer	method	set of TE sequences		
		A	*B*	*C*
		t-max [ms]		
Core2Quad 2.83 GHz	EF	0.578	1.906	1.609
	BIN	0.017	0.017	0.017
I7 3.5 GHz	EF	0.250	0.920	0.702
	BIN	0.014	0.014	0.014

In order to examine the performance of the EF method for various configurations of observation intervals, another series of MTIE computations was performed. The computations were made for two set of 21 observation intervals from the range from 0.1 s till 1000 s. The first set consist the intervals having linear distribution of their values within one decade (i.e. 0.2 s, 0.4 s, 0.6 s, 0.8 s, and 1 s within the first decade, 2 s, 4 s, 6 s, 8 s, and 10 s in the second decade etc), the second set contains the values with logarithmic distribution. The results of computation are presented in Table II.

TABLE II. MAXIMUM TIME OF MTIE COMPUTATION USING EF METHOD

computer	set of intervals	set of TE sequences		
		A	*B*	*C*
		t-max [ms]		
Core2Quad 2.83 GHz	LOG	0.344	3.141	2.875
	LIN	0.297	3.219	2.859
I7 3.5 GHz	LOG	0.243	1.076	0.733
	LIN	0.218	1.232	0.764

The results presented in Table I show the supremacy of the binary decomposition methods applied for the real-time MTIE computation. The regular process of data reduction resulting in the operations performed on the pairs of samples caused very short time of computation observed within one sampling interval. The maximal time of computation observed for EF method was much longer, but still shorter than the length of sampling interval considered. The longest computation time (almost 2 ms for the computer with Core 2 Quad microprocessor) was obtained for the set of time error sequences showing the effect of the frequency difference. The same set have caused the longest computation time observed (more than 3 ms) for the calculations performed for other configurations of observation intervals (Table II). However, increasing of the number of intervals considered simultaneously (from 14 to 21) and changing their values has not changed the observed time dramatically. The suspension of computation is not necessary for the conditions considered.

The results of the tests show the possibility of extending the operations performed within one sampling interval. Short computation time observed allows to consider increasing the number of analyzed intervals within the same range or extending the range of observation intervals. A greater number of time error sequences analyzed (more measurement channels) could also be considered. At least, a shorter sampling interval or a slower computer could be applied.

VI. CONCLUSIONS

The methods presented allow to perform the MTIE computation in the real time for multi-channel time error measurement. The experimental tests proved the ability of real-time MTIE computation by means of both methods proposed for time error measurement performed in four or more channels with sampling interval 1/30 s. The methods can be applied in a measuring system controlled by usual personal computer, as well as in a system with build-in especially designed microprocessor system. The regular data reduction of binary decomposition method results in very short time of computation observed within one sampling interval. The EF method is more flexible in terms of length and range of the observation intervals considered than the binary decomposition method.

***Abstract*—The key problem of telephone time service by PSTN is how to synchronize user time with standard time, in other words, measuring time delay of transmission is the important problem. Now, there are two methods of measuring time delay, the first way is by transmitting character signal; the second way is through phase-detecting. The precision of measuring time delay will have a directly influence on system synchronization time precision, also, The traditional analog modulation/demodulation will highly effect the precision, but the phase error is inevitably because of the effect caused by the noise and channel characteristic when using phase-detecting. A new method, using correlation of PN code will be presented in this paper. Testing shows it can obviously improve the precision of telephone timing service.**

Keywords—PSTN, NTSC, Telephone Time Servict

I. INTRODUCTION

The telephone time service is one of the method that transfer time information with the public switched telephone network (PSTN), whose accuracy is mainly affected by the precision of measurement of propagation time-delay. At the present time, the system is commonly shown in Figure 1, which is composed of the user device and the time server which synchronize with the standard time. An external standard time signal is received as a time reference to establish a standard digital clock in the telephone time service system, and then to build up the transmission time code format with it. Between the server and the user machines, it's through a modem connected to the PSTN for data exchange, that means the server transfers the standard time information to the users or the user machine inquires the server for the standard time information.

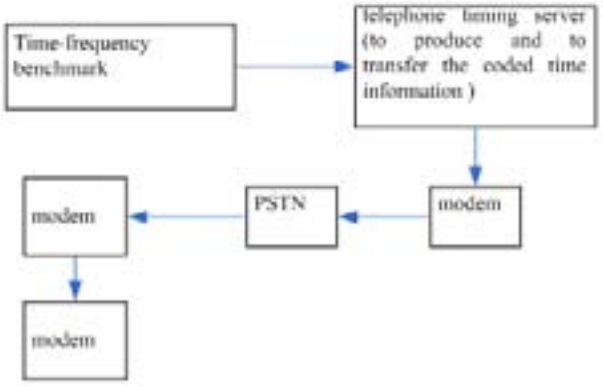

Fig 1 Telephone time service system

The primary problem of telephone time service which transfers the time information with PSTN is accurate measurement of the propagation time delay and encoding the time information. But the accurate measurement of the propagation time delay is more important, which directly affects the synchronization accuracy of the phone timing, therefore, the following introduces two existing methods, the character method and the single-carrier phase method, to measure the propagation time delay.

A. Character method

Due to the modulation and demodulation for the character signals in telephone timing system needing some time to setup which is accumulated and unsure, so that each transmitted character generates different time delay, with which a large error will be leaded. In other way, the volatility of the establish time needed in the process of MODEM modulating or demodulating signals is much greater than the channel

propagation time delay, which severely restricts the accuracy of telephone timing.

B. Single-Carrier Phase method

This method often appears larger deviations, after repeatedly measuring, which reveal channel time delay fluctuation small. The result of time synchronization between the client and the server is poor. It is because the UTP (unshielded twisted pair) from the user's machine to the telephone switching end office is easily induces the electromagnetic noise, industrial noise, day electrical interference, etc around. These kinds of noise impact easily on the phase signals, as well as its own characteristics of telephone channel and some unclear reasons, which will cause serious distortion of the phase signal. For the characteristics of telephone UTP easily induces the electromagnetic noise interference, it needs to further improve the delay detection signal's robustness. Further, the method based on zero-crossing detection has some errors, in the detection of phase point often causes false judgments, resulting in the precision of time detection is lower.

It shows the character and single-carrier phase methods both has some deficiencies from the above analysis, in order to improve the measurement accuracy, a new method which use pseudo-random code for PSTN channel propagation time delay measurement is especially presents.

II. A NOVEL TIME-DELAY MEASURING TECHNOLOGY BASED ON PN CODE

At present, the telephone time service systems have disadvantage in time-delay measuring in channel, for example the serious error occurred by environment, the weak anti-jamming time-delay detecting signal, the low time-delay detecting precision. Because the time-delay detecting precision affects the synchronization precision of the telephone time service system, we suggest a novel time-delay measuring method that the pseudo random code is used to measure propagation time-delay to improve the telephone time service system grant time precision.

Now, the pseudo random code is widely used in the communication area and the wireless range finding area and so on. This technology based on the research of the traditional single carrier wave, the transmitting character and the theory of the PSTN and the mode of the PSTN, uses the relativity of the pseudo random code to measure the time-delay. It has the character of anti-jamming and high time-delay detecting precision and secrecy of the pseudo random code. The pseudo random code cans also achieve a low Signal-to-Noise reception, CDMA communication and so on.

A. Designing of PN code in telephone channel

In the telephone time service system, the frequency of the pseudo random code is 1.023KHz, the list length is 1023-bit (cardinal code number). The cycle of the pseudo random list is 1023/1.023*1023 or 1s. The structure of the PN code generator is illustrated in Figure 2. G1 and g2 are two 10-bit shift registers which generate the pseudo random code with 1023-bit length. The register's state is united with XOR circuit and fed back to the front level. The character multinomial of g1 and g2 is:

$$\begin{cases} g_1(x) = 1 + x^3 + x^{10} \\ g_2(x) = 1 + x^2 + x^3 + x^6 + x^8 + x^9 + x^{10} \end{cases} \quad (1)$$

The band width value of the telephone channel ranges from 0.3KHZ to 3.4KHZ. To reduce the lost frequency of the transmitting signal in the phone channel, we use a frequency shift technology which is a modulation method to generate the PN code with 1.023Khz frequency value and 1023-bit length. The generated PN code is modulated with 2Khz sine wave and its frequency band width value ranged from 0.977Khz to 3.023Khz, whose frequency is suitable for the phone channel in theory.

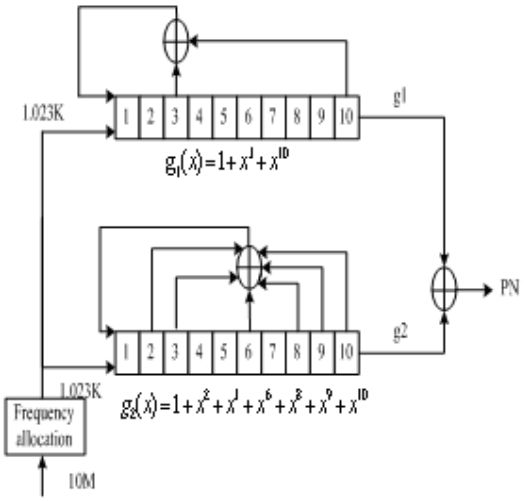

Fig 2 The frame of the PN code generator

In the telephone time service system the measurement technology of propagation time-delay which uses PN code is adopted. It takes a longer circuit specific pseudo random list which has better self-relativity to measure the propagation time-delay. The pseudo random code list has the character of self-relativity and mutual-relativity to ensure the system can capture the received pseudo random list reliably under the proper condition of Signal-to-Noise value. Because the frequency of the pseudo random code list has been expanded, the system has better anti-jamming character and is less disturbed to reduce the probability of miscarriage of justice. Once the connection is set up in the PSTN channel, the propagation time interval serial number is affirmed, that is to say the time-delay is invariable in one communication. The dissymmetrical channel is changed into the symmetrical channel to resolve the time-delay measure problem consisted in the dissymmetrical channel.

B. The self-relativity simulating of PN code in the phone channel

8KHZ sampling frequency is used to sample the pseudo random code signal modulated in the transmitting with 100s length and that transmitted to the receive end, and then sampled data is separately operated with the local pseudo random code signal in relativity by Matlab to get the relative peak value. The pseudo random code signal with the length 100s is generated by FPGA and modulated to transmit.

To analyze if the self-relativity character of the received pseudo random code signal passed through the phone channel is affected by the PSTN or not, we separately operate them in relativity in frequency field and get their relative peak value.

The relative peak value of the signal before transmitted through PSTN and the local pseudo random code showed as figure 3. The relative peak value of the signal transmitted through the PSTN and the local pseudo random code showed as figure 4. IT is shows that the relativity character changed in a small way in fig3 and fig4. The relativity character of the pseudo random code passed through the channel does not deteriorate evidently.

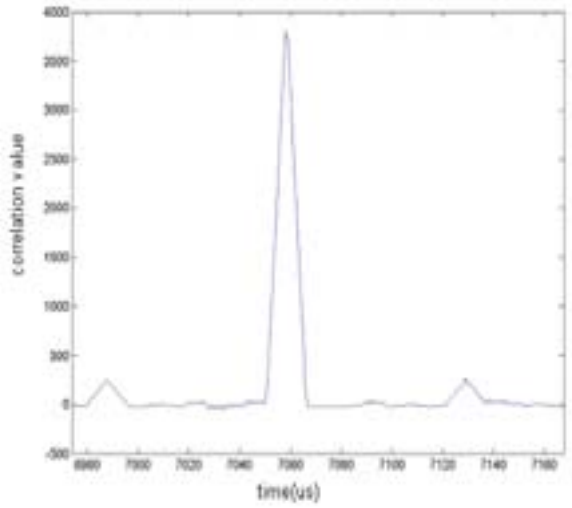

Fig 3 the relative peak value of the signal before transmitted through PSTN and the local pseudo random code in time field.

III. RESULT OF TESTING

In processing of testing, it is designed two steps to measure the propagation time-delay in PSTN channel. First, data on the end of receive is sampled, and then the method of software is used to analyse the tracking PN code. By this way, the fluctuation of propagation delay of PSTN channel is estimated, which is used to design the parameter of loop. After designing the parameter of loop, the counter is used to test the propagation delay. The following testing is realized between the telephone exchange end, the status of telephone link is better.

The fluctuation of propagation delay is estimated. In order to do this, the software of data sampling is used to sample the pseudo code signal which propagated in the PSTN channel. The sample rate is 200KHz and time is 20 seconds. The data sampled is operated to correlate with the pseudo code signal generated locally. It is because of the period of PN code which is 1 second, so, the peak value of correlation is obtained each second. The propagation delay is obtained from the position of sampling which is the peak value.

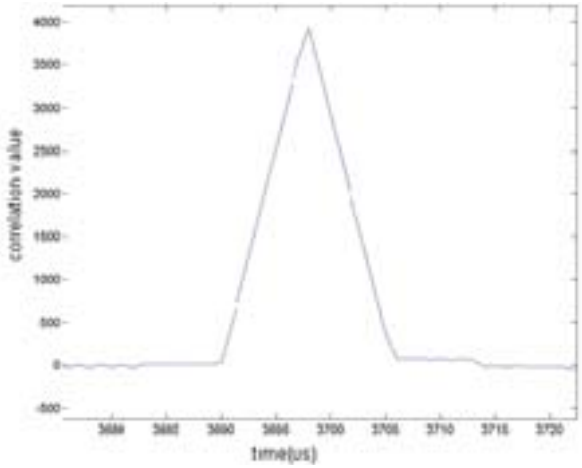

Fig 4 the relative peak value of the signal transmitted through the PSTN and the local pseudo random code in time field

Because of the 200KHz sampling rate, there is 200000 data. The position of each data denotes the 5 us time interval. The position of peak value of 20 seconds is in the same position. It shows the propagation delay measured by this way is under 5 us. So, the result that the measuring precision with the novel timing-delay measuring method based on the PN code in PSTN is better than 5 us is obtained.

IV. CONCLUSION

In this paper, the novel timing-delay measuring method based on the PN code in PSTN is presented, which can be used to improve the propagation delay measuring precision better than 5us. It can greatly improve the quality of the telephone time-service and it has a very better foreground in application in the future.

***Abstract*—The most demanding goal of the Global Geodetic Observing System initiative is the definition of station positions to an accuracy of 1 mm and the corresponding velocities to 0.1 mm/year. The main remaining sources of error are caused by systematics, leading to intra- and inter- technique biases. In this work, we have focused on Very Long Base Interferometry (VLBI) and phase calibration generator currently in operation. This unit is injecting calibration tones into the detection chain through an input coupler located near the input of the antenna. The tones propagate further through entire detection chain and are recorded with the observed signal. Then they are extracted in post processing. These tones are generated out of an atomic frequency standard. The supplied frequency is significantly influenced by temperature and mechanical changes since usually a long cable is employed to bring the frequency to the calibration unit. To monitor the electrical length of the cable, calibration with a picosecond precision is essential. We have redesigned a phase calibration unit so that it enables the implementation of the Two Way Time Transfer (TWTT) method on single coaxial cable using two event timers to monitor the electrical length of the critical cable. Such a system has been installed in parallel to the unit currently in operation. The comparison of the TWTT method with previous measurement method is presented.**

I. Introduction

The aim of this project is to check the system currently in use which measures the cable delay carrying 5 MHz from VLBI building to the receiver of the VLBI antenna at Geodetic Observatory Wettzell. A new phase calibration system based on Two Way Time Transfer (TWTT) is used for this purpose; and the results of both methods are compared. The VLBI technique is very critical to phase stability measurement with respect to the reference frequency, which is in many cases hydrogen maser. To fulfill extreme phase stability measurement of the astronomical radio sources in the receiving chain (local oscillators, filter, cables, etc.) there is an test signal injected near the VLBI input receiver. Use of such a signal allows monitoring of phase variations of the open loop detection system over the observation time by comparing received signals to a stable calibration tones locally generated in the detection bandwidth. For such a system the one of the most important thing is to monitor the cable delay carrying the reference frequency into the antenna.

The currently implemented pCal system is using cable delay measurement system, which is based on mixing the reference signal from H Maser with divided signal from the same source. Such signal is then sent up to the phase calibration unit, where the signal is reflected back. After the reflection, the signal carries the phase modulation which is proportional to the cable length. In the VLBI room, there is a high resolution phase comparator comparing phase of the reflected signal with H Maser reference. Thanks to time expansion in the phase comparator (2.5 ps of cable length is equal to 1 us phase difference) the phase can be measured using common counter, with high resolution [1].

The approach described in this paper is based on TWTT using two Event Timing (ET) devices [2].

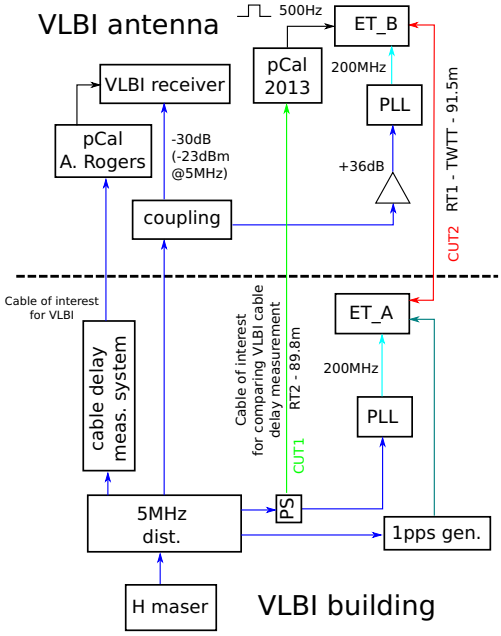

Fig. 1. Block diagram of the experiment setup. Delays of two RG-214 cables (indicated as CUT1 and CUT2) between VLBI antenna and VLBI building were monitored in addition to RG-214 cable used by original system. Event timing device NPET B along with a frequency multiplier and pCal were situated inside the antenna horn whereas identical event timer NPET A along with its frequency multiplier were situated at VLBI building.

II. Experiment

The experiment lasted several weeks and consists of cable delay measurements during several VLBI observing sessions

as well as during out of service periods.

A. Experiment topology

A new phase calibration system was installed in parallel to the system currently in use allowing delay measurements another cable of the same type (RG-214) and similar length during the experiment. Moreover, by employing the TWTT method, delay of third RG-214 cable is obtained as byproduct. All the three cables lie along each other on the same way from VLBI antenna horn to the VLBI building, thus all cables are affected by almost the same influences. Temperature variations and cable bending (during the azimuth and elevation transitions of the antenna) are the most significant influences affecting the cable delay.

The block diagram of the experiment is depicted in Fig. 1. Delays of two RG-214 cables were measured using two event timers with subpicosecond precision. A new pCal, the block diagram of which is in Fig. 2, was employed to generate calibration pulses synchronous with the frequency transmitting through the cable under test (CUT1). As opposed to current way of the cable delay measurements, the phase variations are measured directly by ET.

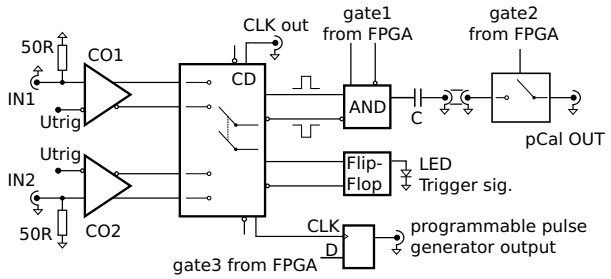

Fig. 2. Block diagram the new pCal.

Each cable delay measurement is performed as follows. At first, the difference of the two time scales are measured by means of TWTT. NPET A generates a pulse and measures the time of its generation (t_{A1}). After the pulse propagates through the measured cable, NPET B detect it and store the time of arrival (t_{B1}). Then the procedure is performed in reverse order: NPET B generates a pulse and measure its time of arrival (t_{B2}) as well as NPET A after the pulse propagation through cable under test (t_{A2}). The time scale difference may be computed as

$$\tau_s = \frac{(t_{B1} - t_{A1}) + (t_{B2} - t_{A2})}{2}.$$

Additionally, having these four values, the cable delay (of CUT2) is obtained as

$$\tau_c = \frac{(t_{B1} - t_{A1}) - (t_{B2} - t_{A2})}{2}.$$

Note that this byproduct can be used as a reference cable delay measurement.

Meanwhile the new pCal generates pulses synchronous with the reference frequency. After the difference of both ET time scales is obtained, the ET in the VLBI antenna switches to the second input and measures the times of arrival of these pulses. In this manner, the phase variations of the reference frequency (on CUT1) can be monitored, e.g., with the electrical elongation of the cable, the cable delay increases and, consequently, the pCal pulses are retarded. Opposite process is observed with shortening of the cable.

B. Results

The experiment lasted several weeks during which the delay of the two cables under test were monitored. Moreover, data from current method of cable delay measurement were gathered as well. The monitoring ran under different conditions, namely during standard VLBI observing session, during out of service periods, and also during deliberate out-of-session antenna movements. The first case is shown in Fig. 3.

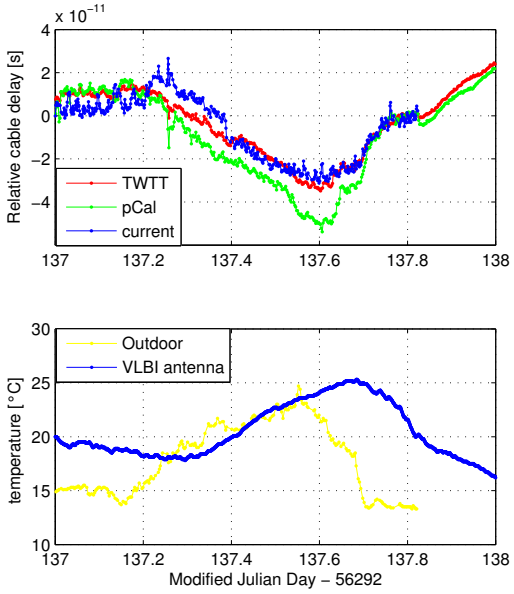

Fig. 3. Cable delay measurement during VLBI observing session. Blue, red, and green curves show cable delay variations measured by current method, TWTT method (CUT2), and by means of new pCal (CUT1) respectively. A clear dependency on outdoor temperature and temperature inside VLBI antenna (measured near pCal) is shown.

Dependency on outdoor (and consequently inside VLBI antenna) temperature is apparent. The cable leading to the pCal seems to be more dependent on outdoor temperature. The slightly different temperature dependency among the cables is probably due to different lengths of the cables. Subtracting the lengths of CUT1 and CUT2, cable length difference of 1.7 m is obtained. It is hard to determine the temperature distribution along the way of the cables; however, it may be roughly estimated from outdoor temperature and temperature inside the VLBI antenna. Considering temperature dependency of RG-214 of -0.5 $\mathrm{ps\,K^{-1}m^{-1}}$ (measured in temperature chamber), cable length difference of 1.7 m, and 10 K temperature

step, the cable delay difference will be of 8.5 ps. Along with temperature dependency of the new pCal (below 1 ps/K), this can explain different slopes of the cable delay changes seen on Fig. 3.

It is also worth to focus on the cable delay variations after the end of the VLBI session (day of year >137.82). These are significantly smoother due to absence of the VLBI antenna transitions among various attitudes (azimuth and elevation), thus constant strain imposed on cable.

Influence of azimuth and elevation changes on cable delay is illustrated in Fig. 4. During the test, the azimuth and subsequently elevation of the VLBI antenna was gradually increased. Dependence of cable delay on the antenna position is quite apparent. Note that unlike the temperature dependency which had the same sign for all the cables, the sign of antenna attitude dependency of one cable is opposite to the other two.

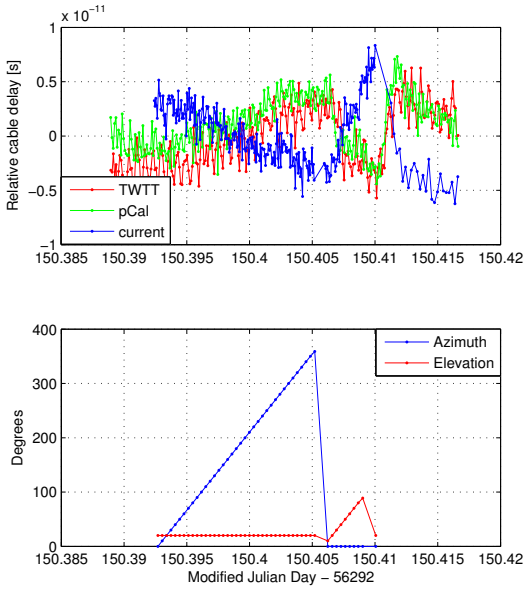

Fig. 4. Cable delay dependency on azimuth and elevation of the VLBI antenna. Position of the antenna was gradually changed and delays of all the three cables were measured. The test was performed in a quite short time in order to prevent the temperature influences from affecting the measurement results. Note the opposite dependency for one of the cables.

Each cable delay measurement with the new pCal is calculated from times of arrival of 500 pulses each two seconds. The precision of the pulse measurements is securely below 20 ps RMS, thus the precision of cable delay measurement is below 0.9 ps ($20/\sqrt{500}$ ps). Unlike the new concurrently installed system which measures the cable delay continuously notwithstanding VLBI measurements, the original system measures the cable delay once before each VLBI measurement (approximately once per one to three minutes) during the observing session. In order to estimate the precision of such a cable delay measurement, an out-of-session measurement with 1 second repetition rate (practical limit of the method) was performed. The precision calculated over 100 measurements is of 1 ps RMS.

III. Conclusion

The function and performance of the VLBI phase calibration system at Geodetic Observatory Wettzell was veryfied by newly designed pCal system with picosecond precision. Additionally, the results were confirmed by measurements of third cable delay obtained as a byproduct of the TWTT method. Both temperature and strain influences affecting the cable delay were identified. Results of all the three cables match each other to the level of few picoseconds. The differences of the results were explained by slightly different lenghts of the cables leading from VLBI building to the VLBI antenna resulting in slightly different sensitivity to external influences.

***Abstract*—In order to steer master clock in timekeeping laboratory, it is necessary to identify a suitable algorithm for steering UTC(K) to UTC for a period of 45 days with 5-day latency. An algorithm is proposed to modify a traditional quadratic polynomial prediction model whose random error term is represented by a linear combination of periodic term. In the case of steering, the performance of the underlying algorithm is examined in depth, together with a comparison against simulated results of QP .**

Keywords- UTC-UTC(K) time offset; classic spectral Analysis; Quadratic Polynomial Model

I. INTRODUCTION

Coordinated Universal Time (UTC) is regarded as reference timescale for the time coordination around the world. UTC is equivalent to TAI, but with the addition of leap seconds, so that offset between UT and UTC is constrained within 0.9 s. It is computed and made available every middle month by BIPM through its Circular T which is represented by the values of the offsets UTC- UTC (K) in the last month with 5-day latency. In order to steer master clock in timekeeping laboratory, it is necessary to identify a suitable algorithm for steering UTC(K) to UTC for a period of 45 days with 5-day latency. In another word, the algorithm is developed to predict the time offset between UTC and UTC(K) for up to 45 days with 5-day latency.

One of the traditional prediction models for UTC-UCT(K) time offset is the quadratic polynomial model [1] which is represented as QP in this paper. Fig. 1 shows the random error of UTC-UCT(NTSC) time offset based on the QP with different historical data length, and the curves display a certain periodic. By describing as a linear combination of periodic term[2][3], the random error term in QP is able to be predicted in terms of spectral analysis as well as lease square. Therefore, an algorithm combining with quadratic polynomial model and random error is established. In the case of prediction, a brief introduction of the underlying algorithm is illustrated at the beginning. The performance of the algorithm is examined in depth, together with a comparison against the simulated results of .

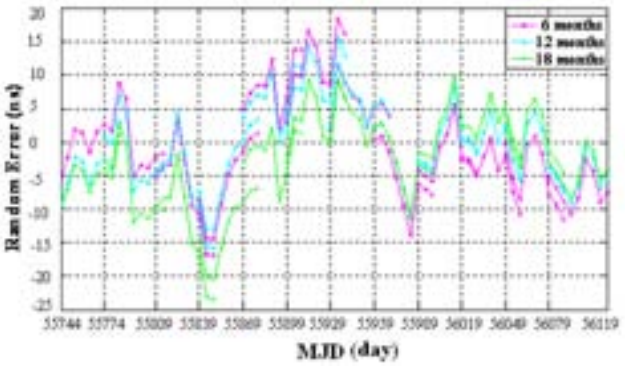

Figure 1 Random error of quadratic polynomial model for UTC-UTC(NTSC) with different fitting data length (July 2011-June,2012) (ns)

II. OVERVIEW OF THE ALGORITHM

A. The quadratic polynomial model with periodic item

As for the quadratic polynomial model, its random error can be divided into two parts, system error and residual. The system error is considered as linear combination of periodic term, while the residual term is regarded as white noise.The algorithm to predict the UTC-UCT(K) time offset is given by [4]:

$$x_i = a_0 + a_1\Delta t_i + a_2\Delta t_i^2 + \left[\sum_{j=1}^{m} A_j\cos(\omega_j\Delta t_i) + B_j\sin(\omega_j\Delta t_i)\right] + v_i \qquad (1)$$

Where $x_i = UTC_i - UTC(K)_i$, $i = 1,2,\mathrm{L}\ ,n$, n is data length, $\Delta t_i = t_i - t_0$, t_0 is initial time, ω_j is frequency, $j = 1,2,\mathrm{L}\ ,m$, m is order of the periodic term， v_i is residual term，and a_0, a_1, a_2, A, B are parameters. Before getting these

This paper is supported by Key Program of The National Nature Science Fundating of China (Grant No. 11033004).

parameters by least square, it is necessary to identify ω and m by means of wavelet and classical spectral analysis .

Represented by the periodic term, the random error term in equation (1) should get rid off noise first by the Daubechies wavelet with one order, which is able to convert the time series data into discrete data that is match Fourier transformation, and ,then,the low frequency parts remain.

The system error with low frequency part is the sum of periodic term under different frequencies which correspond to a certain power spectral density $P_x(\omega)$ respectively. The bigger the power spectral density , the more contribution of a signal corresponding to a certain frequency to the original data. Therefore, the classic spectral analysis is introduced to identify the frequency ω and the order m . The classic spectral analysis, is based on Fourier reformation and it mainly contains two methods, periodogram and correlogram.

The periodogram obtains the power spectral density $P_x(\omega)$ by processing data on time field by Fourier Transformation directly and multiplying frequency spectral by its conjugate , which is shown as (2) and (3):

$$X_N(\omega)=\sum_{n=0}^{N-1}x(n)e^{-jn\omega} \quad (2)$$

$$P_x(\omega)=\frac{1}{N}\left|X_N(\omega)\right|^2 \quad (3)$$

The correlogram, on the other hand, processes the time field data based on correlation function $\hat{R}_x(k)$ and, according to the Wiener-Khintchine theory, it obtain the power spectral $P_x(\omega)$ by Fourier Transformation from $\hat{R}_x(k)$. The procession is described as equation (4) and (5):

$$\hat{R}_x(k)=\frac{1}{N}\sum_{n=0}^{N-1}x(n+k)x^*(n),k=0,1,L\ ,M \quad (4)$$

$$P_x(\omega)=\sum_{K=-M}^{M}\hat{R}_x(k)e^{-jk\omega} \quad (5)$$

The result of either method provides the series of power spectral against their corresponding frequency and ω and m are identified by a reference value of the power spectral density. The frequency ω is selected by its corresponding power spectral density which is bigger than the reference value , while the order m is number of the power spectral density which is bigger than the reference value. In this paper, we implement periodogram and correlogram seperately and denote the algorithm based on periodogram as “ QP+MP ” and correlogram as “QP+MC”.

III. SIMULATION AND ANALYSIS

Based on the QP+MP and QP+MC, a simulation is implemented to predict UTC-UTC(NTSC) time offset for up to 45 days with 5-day latency. The steering is processed for 12 months since July 2011((MJD55744- MJD56119). In this case, UTC-UTC(NTSC) time offset data from Circular T of BIPM[7] is used and it is divided into two parts in which one is treated as historical data to fit the model and another is used to evaluate it. The evaluation is primarily justified by predicted residual Root Mean Square (RMS) which is the predicted residuals root mean square of the difference between simulated value and observed value of Circular T, which is given by equation (6).The smaller RMS, the better simulation performance.

$$RMS=\sqrt{\frac{\sum_{i=1}^{n}(\mu_i-x_i)^2}{n}} \quad (6)$$

Since the long time span of the historical data which data back to 1998, it is necessary to select a proper historical data length before the simulation. Besides, in order to evaluation convenience, RMS is the mean of the simulated results for 12 months.

A. *Identifying Historical Data Length*

The simulation of UTC-UTC(NTSC) time offset is processed based on QP+MP and QP+MC separately with up to three years of historical data , along with the corresponding results from quadratic polynomial model.

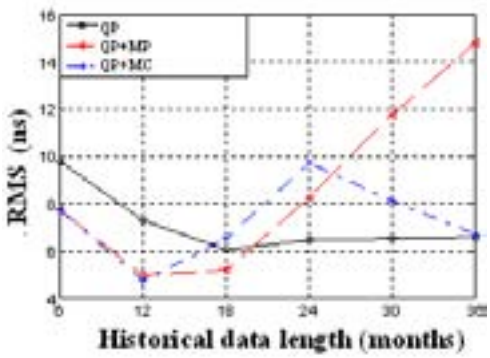

Figure 2 the mean of RMS (ns)of QP, QP+MP and QP+MC with difference historical data length（July,2011——June,2012）(ns)

As Fig. 2 shows, with 12 months length of historical data, both QP+MP and QP+MC shows competitive results against quadratic polynomial model. However, with the historical data increase up to three years, the simulation results of three models show different trend respectively, but neither of them show better prediction. Therefore, 12 months historical data length is proper to predict UTC-UTC(NTSC) time offset based on either QP+MP or QP+MC .

B. *Performance Evaluation*

Table 1 displays the statistical results of the simulated residual, such as mean and standard deviation as well as combined uncertainty ($\mathbf{U_c}$).Combined uncertainty comprises type a uncertainty（ $\mathbf{U_a}$ ） and type b uncertainty($\mathbf{U_b}$) and it is given by:

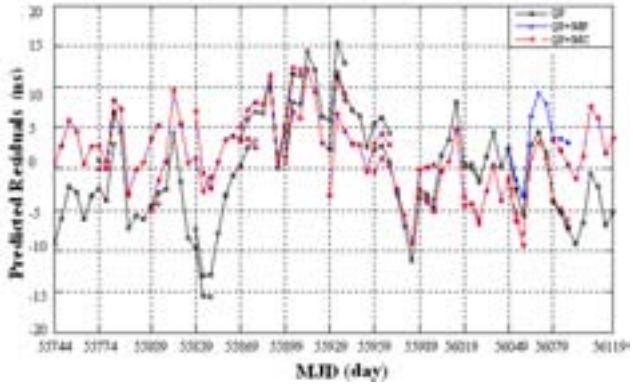
$$U_c=\sqrt{U_a^2+U_b^2}\ . \quad (7)$$

In this paper, $\mathbf{U}_a$ is random uncertainty and is represented by Allan variance in time filed, while $\mathbf{U}_b$ is system uncertainty and it is difference between mean of simulated data and mean of observed data. Fig 3 and Table 1 show that the simulated results of QP+MP or QP+MC are very close and both are better than the quadratic polynomial model.

TABLE I PERFORMANCE EVALUATIONS OF PREDICTION MODEL（NS）

Criterion / Model	SD	Mean	U_c
PQ	4.4	5.2	4.3
PQ+MP	3.5	4.2	3.2
PQ+MC	3.4	4.1	3.2

Besides, with the 12 months historical data length, the predicted residuals of UTC-UTC(NTSC) time offset based on QP+MP or QP+MC separately between July 2011 and June 2012, together with the observed UTC-UTC(NTSC) time offset from T-Circular in the same period, are shown in Fig. 3.



Figre 3 Predicted Residuals throughout 12 months based on three models （July,2011——June,2012）(ns)

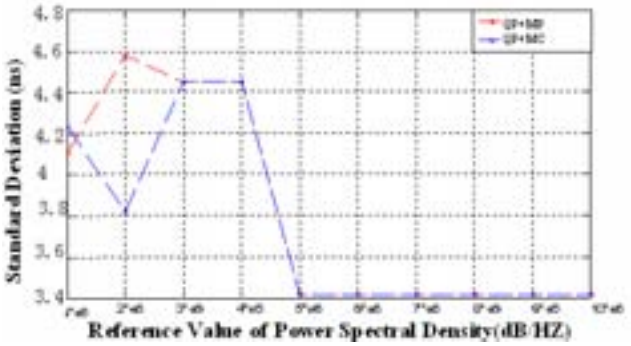


Figure 4 the SD of QP+MP or QP+MC with different reference value of power spectral（July,2011——June,2012）(ns)

It is worth to notice that Fig. 3 shows a very similar simulated results between QP+MP or QP+MC. Few difference become obvious since MJD56019. There are some possible reasons may contribute to this situation. On one hand, based on the theory of classic spectral analysis, the correlatgram differ from the poredicogram by an additional parameter —— maximum delay. The smaller maximum delay, the smoother of power spectral density. The simulation shows that the SD of QP+MC do not change until the maximum delay increase to 20。This paper defines maximum delay for QP+MP as 1. In particular, when the maximum delay m=N-1， QP+MP is equivalent to QP+MC [5]. On the other hand, the reference value of power spectral density is one of the key factors for the algorithm in that it identify the ω and m. However, in this paper, it is an experience value. Therefore, the definition of maximum delay and the reference value may contributes to the difference between QP+MP or QP+MC. Furthermore, Fig.4 displays the effect of selection of reference power spectral density against standard deviation(SD) and it displays that the same competitive performance of both methods turn up when the reference value increase. As it is the general feature including simulated results12 months, it can not avoid some special case which is shown in end of the curve in Fig. 3. Therefore, the selected reference value leads to the similar results of both methods. But it may differ at same special period. At last, the little difference of prediction between QP+MP or QP+MC may be caused by the selection of reference value of power spectral density.

IV. CONCLUSION

Steering UTC(K) to UTC is important to realize the evaluation between local master clock and other system timescale. In this paper, an algorithm with additional linear combination of periodic term is introduced so that the performance of quadratic polynomial model is improved. According to the discussion and analysis of the simulated results, the underlying algorithm based on 12 months historical data shows a plausible feature against the quadratic polynomial model. However, one of the shortcomings of this algorithm is that the prediction precision fails to improve with historical data increase. Besides, as for the spectral analysis for this algorithm, both reference value of power spectral density as well as maximum delay are considered as two factors that limit the performance of the algorithm.

Abstract—**The dominant part of the total uncertainty budget in the [UTC-UTC(*k*)] is from the type B uncertainty (u_B) in time link calibration. In fact, 60% of the type A uncertainty (u_A) in UTC time links are < 1 ns while the 93% of $u_B \geq 5$ns. In 2011, the BIPM launched a pilot experiment to reduce the u_B from 5 ns at present to ≤ 2 ns and has developed a standard calibration scheme, namely METODE, associated with an integrated portable GNSS calibrator together with the reference receivers stationary at BIPM. Similar setups are made in TL. Using these systems, we performed a series experiments at BIPM, OP and TL to study the attainable uncertainty of METODE. The results are compared to that of the traditional differential receiver calibrations.**

Keywords : UTC, Time transfer, Calibration

I. THE UTC TIME LINK CALIBRATION

60% of the type A uncertainty (u_A) in the UTC time links are < 1 ns meanwhile 93% of type B uncertainty (u_B) are ≥ 5ns. The u_B in the time transfer calibration is the dominant part in the combined uncertainty budget (u) in the [UTC-UTC(*k*)] [12]. u_B < 2 ns suggests u < 2 ns. This is the target of the time link calibration experiment [7,8].

Time *link* calibration has a long history in the BIPM Circular T computations. The most often case is to transfer a more accurate time link calibration to a lower accurate or no calibrated one [6,14] between the TWSTFT (TW), GPS and GLONASS time links, termly the *alignment*. The relative *equipment* calibrations for UTC generation are in principle: the TW *link* calibration with a mobile TW station [19] and the GNSS *receiver* calibration with a traveling GPS receiver [15,16,20]. In Circular T, the u_B of the first case is about 1.0 ns that makes about 7% of the total UTC links and 5-10 ns for the second that make about 65%. The rest of 28% of UTC links have the u_B=20 ns, i.e., never calibrated [2]. Absolute calibrations are not considered in this paper.

Since 2007, the BIPM began to consider to unify the TW and GNSS calibrations and proposed a new calibration method, namely **METODE** (MEasurement of TOtal DElay) [1,6-9]. Unlike the *alignment*, the *equipment link* calibration requires a traveling calibrator which might be a mobile TW ground station [19] or a traveling GPS receiver [3,4]. Associated with METODE, BIPM developed a standard calibration scheme in which an integrated and pre-cabled portable calibrator (Std_B) is used. It is composed of a 10 MHz distributor, a PPS distributor and two GNSS geodetic setups each include a set of independent receiver, antenna and cables, as illustrated in Figure 1. The calibrator and the fixed reference receivers are like '*black*' boxes for which we do know and do not need to know their internal delays. All we require is their short-term stabilities during the calibration tours, typically 3 months. In this paper, we discuss the reachable uncertainty of the METODE through carefully designed experiments [7,9].

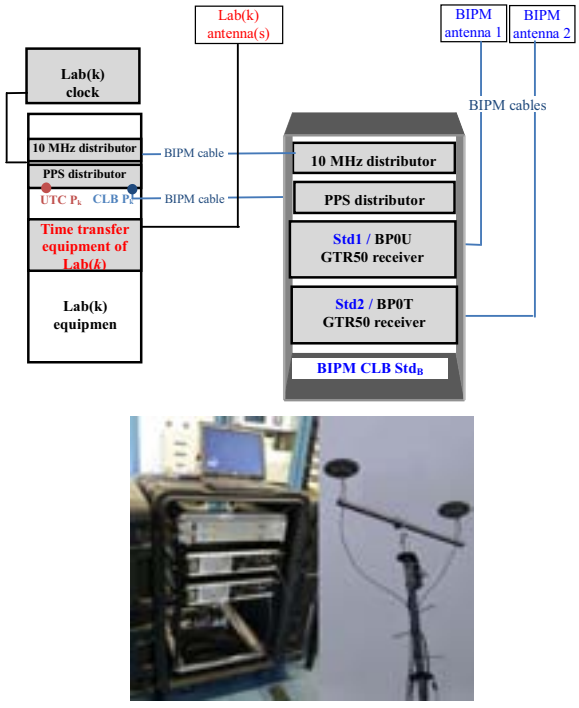

Figure 1. The 2013 setup of the BIPM travelling calibrator Std_B with two GTR50 GPS receiver-antenna systems

II. TOTAL DELAY AND TOTAL UNCERTAINTY IN THE UTC TIME LINK CALIBRATIONS

The *total delay of a GNSS receiver* (Dly_R) at Lab(*k*) is the total electronic delay between the phase center of the antenna and the UTC point $UTCP_k$, Figure 1. It is the sum of all the

sub-delays of all the pieces of equipments including the receiver, the splitter(s), the frequency and pps distributor(s), the amplifier(s), the phase micro stepper(s) etc. plus the cables/connectors between the antenna and the receiver as well as the cables between all the laboratory equipments. In short, Dly_R is the delay on the path of the satellite signal from the antenna to the $UTCP_k$.

However the Dly_R is not measurable and not need to be known in the BIPM link calibration scheme. The Dly_R serves only to define the Dly_L, the total delay of a time *link* between Lab(*i*) and Lab(*j*). The Dly_L is defined as $Dly_L(i\text{-}j)=Dly_R(i)-Dly_R(j)$. Correspondingly, the total uncertainty in Dly_L is that in the total delay of a link U_M. Taking Lab(*j*)=PTB, the pivot of the UTC time links, the difference: $D(i)=Dly_L(Std_B\text{-PTB})-Dly_L(i\text{-PTB})$ is the calibration correction for Lab(*i*).

III. Design of the Experiments to Evaluate the Total Uncertainty

We use different methods with respect to other studies, e.g. [3,4]. The basic idea is to measure a delay using completely different and independent methods and to compare the results. The RMS (the root of mean squares of the differences between the different and independent methods) will provide an estimate of the total uncertainty (u_M). This plus the instabilities of the reference and the travel receivers (by comparing the reference receivers and the closures) make the total uncertainty of the METODE link calibration: U_M (u_B).

Four independent methods are being used:

A) The METODE using the GPS P3 or PPP data;
B) A SR620 time interval counter (TIC), for which the measurement uncertainty is given by the manufacturer to be about 0.5 ns [13], actually smaller from our experience;
C) A portable Cs standard;
D) The comparison with the earlier calibration experiments between BIPM and OP [25,28]

The estimation takes the RMS as the U_M. The crucial issue is the instabilities of the stationary and traveling receiver-systems involved in the METODE, as seen the variations in the reference receiver-system. Figures 2 and 3 demonstrate the relative variations in CCD (common clock differences) of P3 and PPP between the two Z12T BIPM reference receivers (BP0C and BP0M) over two 10-day periods. Both are maintained in the air-conditioned time laboratory. The variations are up to 1 ns. This explains the necessity of the closure measurements and the use of the double receiver-cable-antenna systems for both the fix and travel equipments. In the discussion below, the mean value of the double system is used.

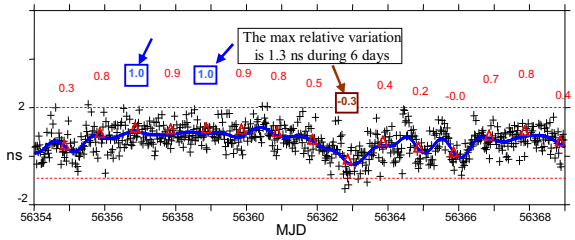

Figure 2. P3 CCD of BP0M-BP0C between 56354-56369

The GTR50 [5] is chosen in the calibrator Std_B thanks to its facility in application and the easier traveling condition. It requires only the PPS signal inputs and no additional latching determination with a TIC is needed at Lab(*k*). One assumption is that the trigger error of each reboot is near constant so as to be partially cancelled in the METODE differential setups. This is proven in our tests.

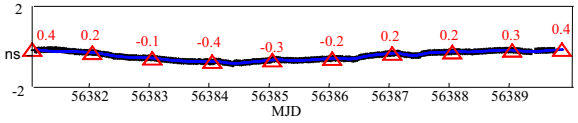

Figure 3. PPP CCD of BP0M between MJD 56381-56390

IV. Main Results

A. METODE vs. TIC SR620 over cables of different lengths

By adding and removing the cables of different lengths before the 1PPS input of the Std_B, we can artificially produce delays/offsets, as described in Figure 4. We then compare the delays measured by two methods: a TIC directly measuring the cable delays and the METODE. In the later, we compute the differences between the GPS data collected by the Std_B which are impacted by the added/removed cables and that of the non-impacted reference receivers. See Figure 4 for the 15.1 ns and 52.5 ns artificial offsets in the CCD.

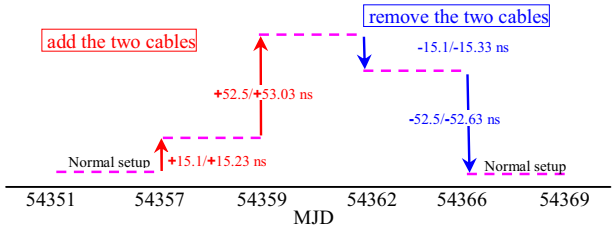

Figure 4. The 4 offsets in the total delays designed on different MJD measured by the TIC SR620 and the METODE calibrator StdB (P3)

Table I lists the results. The mean values of the differences between the METODE and the TIC SR620 are -0.032 ns for the cable of delay 15.1 ns and -0.291 ns for the cable of delay 52.5 ns. Take the bigger one 0.3 ns which can be considered as the u_M of the METODE and is smaller than the u_A of the P3 code (0.7 ns) and that of the total uncertainty of the TIC SR620 of about 0.5 ns [13]. GPS PPP and GLONASS data gives similar result. Note here that the u_M covers all the uncertainty sources due to the GPS's, the TIC's and all the cable delays.

TABLE I. Result of the Measured Delay/Offset Values by TIC and METODE by P3

MJD	Add(+) and Remove(-) Cables	TIC SR620 /ns	METODE GPSP3 GTR-Z12T/ns	Mean Dif. of TIC-METODE /ns
1	*2*	*3*	*4*	*5*
56357.4	+C158	15.1±0.5	15.228±0.053	0.228
56359.6	+C58+C83	52.5±0.5	53.029±0.096	-0.478
56362.6	-C158	15.1±0.5	15.325±0.045	-0.291
56366.5	-C58-C83	52.5±0.5	52.627±0.066	-0.107
		15.1±0.5	15.276±0.049	-0.031

	52.5±0.5	52.828±0.082	-0.292
Mean Dif. of TIC-METODE	15.1±0.5	-0.176	-0.032
	52.5±0.5	-0.328	-0.291

B. METODE vs. TIC SR620 or other method over short baselines

A 10 m CCD test was performed at TL in April 2013. The two clocks are compared with METODE calibrator (P3) and a TIC. The setup is shown in the Figure 5. The RMS of the differences of METODE and TIC is 0.7 ns.

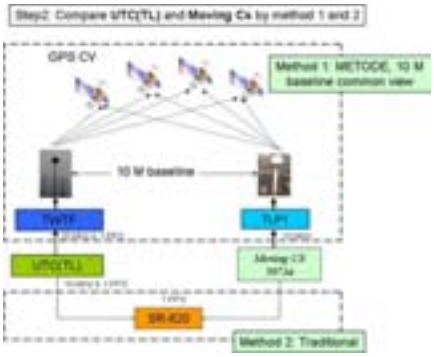

Figure 5. The 10 meter baseline between the UTC(TL) and the mobile Cs. The CCD are measured continuously by both METODE and a TIC SR 620

Two CCD setups were made during 56394-56404 at OP as depicted in Figure 6. The reference receiver at OP is the Z12T OPMT. The last BIPM calibration was carried out in May and June in 2008 between OPMT and BP0C. Repeated calibrations show that OPMT is very stable. This experience is hence also providing a comparison with the calibration of 2008.

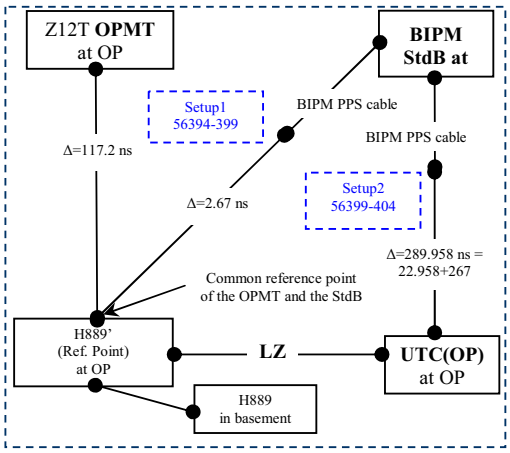

Figure 6. The CCD setups of the Std_B at OP driven by two references: the maser H889 and UTC(OP)

Hourly differences between HM 1400889 and UTC(OP) are given in the LZ file supplied by OP. On the other side, it can also be independently measured by METODE calibrator. The RMS of the differences between the LZ and the METODE PPP is 0.117 ns and that of the P3 is 0.495 ns. This is the maximum static uncertainty of the METODE in a laboratory condition because it contains also the uncertainties in the LZ data (0.2 ns) together with all cable delay measurements.

The reference clock of Setup1 is the HM 1400889 and the reference clock of Setup2 is UTC(OP). Figure 7 shows the difference of the averaging values of the two setups is 0.486 ns, which covers the uncertainties of the METODE calibrator and the LZ as well as the uncertainty in the cable delays between. Again, it covers also all the GPS measurement uncertainties.

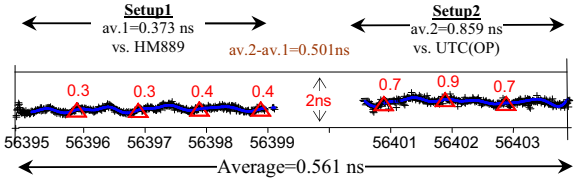

Figure 7. PPP CCD OPMT-Std_B at OP: Setup1 and Setup2

C. METODE vs. mobile Cs clock over a 25 km baseline

A 25km CCD baseline experience was carried out at TL. A mobile Cs clock was transported together with the METODE calibrator developed by TL.

In the 25km baseline test, we replace the absolute reference from the direct SR620 measurement to a linear fitting to the SR620 result. Table II gives the daily average of the differences between the results of the METODE and the mobile Cs clock. It should be pointed out that these differences include, among others, the instability of the mobile Cs clock which may be up to 1 ns depending on various conditions of temperatures, transports and power etc. By the table, the daily RMS are within 1 ns except for 56391 when occurred an earthquake of 6 degree. The RMS of them is 0.92 ns.

TABLE II. DAILY AVERAGES OF THE DIFFERENCES BETWEEN THE RESULTS OF THE METODE AND THE MOBILE CS CLOCK

MJD	RMS/ns
56384	0.454
56391	1.447
56392	0.609
56393	0.849

D. The closures

After 11 days' between 56394 and 56404 staying at OP, the BIPM Std_B was returned. A closure of 0.3 ns on average was found. This should be taken into account in the estimate of METODE uncertainty.

E. METODE calibration vs. classical receiver calibration

BP0C was absolutely calibrated in 2001 [15,16,20]. The related calibration uncertainty u_B is about 2.3 ns. Table III gives the differences of the results by METODE calibration and by the 2008 classical receiver calibrations of OPMT vs. BP0C. By PPP, the difference of the calibration is 0.9 ns between OPMT and BP0C. In the table, u_A is the measurement uncertainty. This is to study the discrepancy between the classic and the METODE calibrations and will not be taken into account in the estimate the reachable uncertainty of METODE.

TABLE III. DIFFERENCES OF THE CALIBRATION RESULTS OF METODE AND THE 2008 CLASSICAL RECEIVER CALIBRATIONS

Receivers	PPP±u_A/ns	P3±u_A/ns
OPMT vs. BP0C	0.929±0.060	0.971±0.068

In summary, above the Sections A, B, C and D give separately the uncertainty estimates about: 0.3 ns, 0.7 ns, 0.5 ns and 1.0 ns. The RMS is 0.7 ns.

V. CONCLUSION

For the *total delay*, we estimate accordingly the U_M, the *total uncertainty* in the METODE link calibration which is composed of:

- Measurement uncertainty (u_A): about 0.1 ns~0.3 ns (u_A of PPP link [2,18]);
- Calibration uncertainty of the calibrator Std_B: 0.3~1.0 ns;
- Instability of the reference and travel receivers: 0.5~1.0 ns;
- Others 1.0 ns (unexpected)

The total uncertainty of METODE U_M is hence 1.1~1.8 ns.

The experiments were carefully designed to investigate the total uncertainty of the METODE link calibration. In conclusion, the reachable uncertainty is ≤ 1.8 ns in the worst case without considering the long-term variations. From [10,21], the later might be up to a few ns.

The BIPM calibrator Std_B appears suitable for such a task. Two DICOM GTR50 GPS time transfer receivers are thoroughly studied for the use of the METODE. It proves the stability, simplicity and precision for UTC time link calibration purpose.

Compared with the 2008 classic calibration result with the BIPM BP0C as the reference, we obtained a total delay calibration correction of 0.9 ns to the OP OPMT.

The UTC/TAI Tsoft software is improved to perform the METODE application. A standard algorithm is under development. A priori, the PPP data will be used for the UTC time link calibration.

A set of Ashtedch Z12-T and Septentrio PolaRx GPS/GLONASS receivers from BIPM and OP participated in the whole campaign between both laboratories. The collected data are currently under analysis. The BIPM Std_B equipment is planned to travel to PTB, AOS, PL and TL to further study the attainable uncertainty in the UTC time links.

***Abstract*—Traditional phase comparison must be carried out between the two frequency sources with the same values. However, recent researches have found that phase comparison also can be implemented between frequency sources with different values and obtain higher resolution.**

The paper analyzes the phase difference regularity of arbitrary period signals' comparison. Discuss in detail that fine quantized phase step phenomenon and how the step value to reflect the higher resolution. When two signals with different frequencies are compared, their phase differences are in special order according to the frequency ratio, and, because of small frequency deviation existing, corresponding phase differences in every least common multiple period are different. As for the equivalent phase-discrimination frequency, ABf_{maxc}*, has very high resolution, under the condition of proper reference frequency, the technology in the paper can reach higher measuring resolution. As for the development of present base standard sources and the research on fine quantified phase step phenomenon between period signals, the signal comparison in RF band could reach ps resolution and even fs. Because the hardware used in detecting coincidence information will bring some trigger error and compared signals' own noise will bring some phase uncertainty, the software in connection with algorithm can be used in the technology. On account of instruments' own drift, pulse average method and pulse filling method can be used, and moreover, self-calibration.

***: When the frequency values of compared signals are respectively f_1 and f_2 and their greatest common factor frequency is f_{maxc}, $f_1=Af_{maxc}$, $f_2=Bf_{maxc}$.**

Keywords—phase comparison; phase difference; measuring resolution

I. INTRODUCTION

The phase comparison between periodic signals is the important method to the high resolution measurement technology. The variety of the phase difference between periodic signals reflects a regularity phenomenon of the phase quantization step by step between the frequency signals. The research has a favorable application and development in the field of the time-frequency measurement and control. The periodic signals have the periodic characteristic. Several frequency signals bring about the quantization on time by fine variation of the phase differences for a long time. The phase quantization can provide a theoretical evidence for the technology on the phase comparison, particularly high-precision comparison between random signals. The phase difference between periodic signals varies periodically with the period of their least common multiple[1], while the arbitrary periodical phenomenon can be presented by the phase difference group. On the research of the group theorem, the regularity of the phase difference will be shown properly to get the corresponding characteristics.

This work was supported by the National Science Foundation of China under Grant No. 61201288 and 10978017, and the Fundamental Research Funds for the Central Universities, China (Grant No. K5051304019).

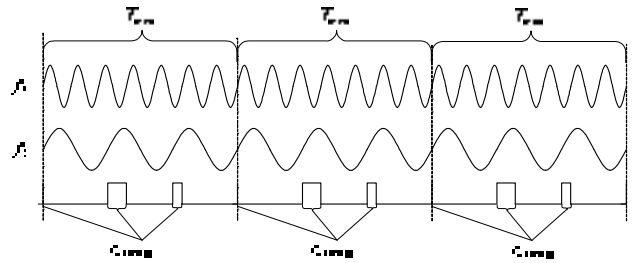
II. CHARACTERISTIC OF PHASE DIFFERENCE BETWEEN DIFFERENT FREQUENCY SIGNAL

The traditional phase comparison is often carried out between the two frequency sources with the same values. The results is a series of phase difference arranged in the order of monotone increasing or monotone decreasing, and the phase variation between two nearby phase differences is constant, which is related to the tiny frequency difference of the two frequency sources. The smaller the additional frequency difference is, the higher comparison it shows and the more difficult the measurement is.

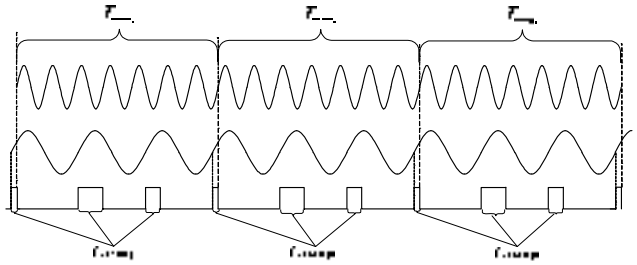
The concept of the phase difference usually aims at the frequency signals with the same value, whose application can show the relationship between the signals more particularly. On the basis the measurement, control, transformation, synthesization and so on can obtain higher precision compared with other methods. But both the phase comparison and the processing usually require the same frequency or the rigorous relationship between the frequencies, which limits its application. In some cases, it is necessary to introduce the complicated frequency transformation for the comparison in the wide frequency range or between the given different frequency signals. It is necessary to discuss whether the phase comparison and processing method can be applied to the different condition.

For the different frequency signals, it is usually difficult to find the variation regularity between the phase differences in a continuous period. At this time, if the period is of the least common multiple T_{minc} between the signals, the several phase difference collections consisting of the two compared signals in a period T_{minc} are called a group. It will not appear the state of the completely same phase difference and the permutation and combination in the different order of the toleration based on the quantitative phase shift resolution $\triangle T$ (just right the equivalent phase cycle). [2]When the relationship on the two frequency signals is constant and no relative variation is present, the value

and arrangement of the corresponding phase difference in each period T_{minc} is completely the same .



(a) Comparison of the ideal stable signals when the origin phase is zero



(b) Comparison of the ideal stable signals when there is an origin phase

Fig.1 the phase relationship based on $T_{\min c}$ (without relative frequency variation)

For example, the phase difference collection in two T_{minc} front and back is a group each, and all the phase difference values have the strict relationship based on corresponding group and the distance of T_{minc}. As Fig.1 shown, the results of comparison are expressed in Fig.(a) when the origin phase difference of the comparison signals is zero, and the results of comparison are expressed in Fig.(b) when the origin phase difference of the comparison signals is not zero. It is clear to see the fact that whether there is an origin phase, the group consisting of each phase difference in the period of the least common multiple is the same in the corresponding T_{minc} for the ideal stable signals.

This kind of the phase relationship is more common in practical comparison. The indirect continuous characteristics will appear in the corresponding phase difference for each phase difference group in T_{minc}, when the frequency of the comparison signals is different and there is tiny frequency difference present. The range of each phase difference variation is limited, namely that it monotonically increases to the periodic quantity of less periodic signals (the maximum of the phase difference) and then return to the state of the phase coincidence (the minimum of the phase difference). Each phase coincidence is the critical state of the phase difference from the maximum to the minimum. Otherwise, each of the phase difference monotonically decreases to the state of the phase doublication (the minimum of the phase difference) and then return to less periodic signals (the maximum of the phase difference), as Fig.2 shows.

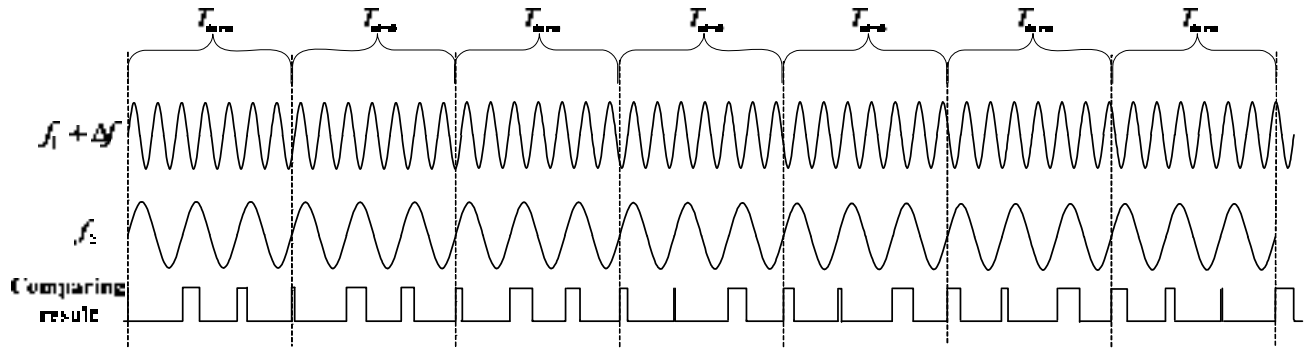


Fig.2 Comparison of the signals with additional frequency difference

Therefore, the consecutiveness of the phase difference variation between the random frequency signals does not appear in each T_{minc}, and it appears in the phase difference group by the interval T_{minc}. With the time going by, the phase difference group that is seemed chaotic can represent the variation of the added relative frequency difference and the phase difference between signals based on the given consecutiveness. In Fig.2, the magnitude and arrangement of the phase difference in the group are both different, but the variation tendency of the corresponding phase difference in each group is of the same discipline. To any phase difference in the group, it only increases the phase variation quantity caused by $\triangle f$ in the next group increasingly or decreasingly in turn.

III. USING OF THE EQUIVALENT COMPARISON FREQUENCY

On the process of the signal comparison, the technology can obtain extremely high resolution on the condition to choose proper referenced frequency, because that the equivalent frequency of phase ABf_{maxc} has the extremely high resolution.

Traditional phase comparison is carried out between the two frequency sources with the same values. The quantitative resolution of the phase difference depends on the relative frequency difference and the named period. If the two compared signals are f_1 and f_2, where $f_1=f_2+\triangle f$, , the n phase differences between the two signals are respectively $\Delta T=nq$, where n=0, 1, 2, 3, ……T1/q. Simultaneously,

$$q = \frac{f_{maxc}}{f_1 f_r}$$

It is of the quantitative phase shift resolution.whose reciprocal is called the equivalent frequency of phase ABf_{maxc}, and f_{maxc} is the greatest common divisor of *f1* and *f2*. T_1 is the period of the signal f_1. The variation of the phase difference is always the integral multiple of q, which can vary from zero to T_0/q. In the other word, the phase difference makes the quantization by the quantitative phase shift resolution and varies monotonously. Therefore, taking advantage of it, the higher measurement resolution will be obtained by choosing the comparison signal properly.

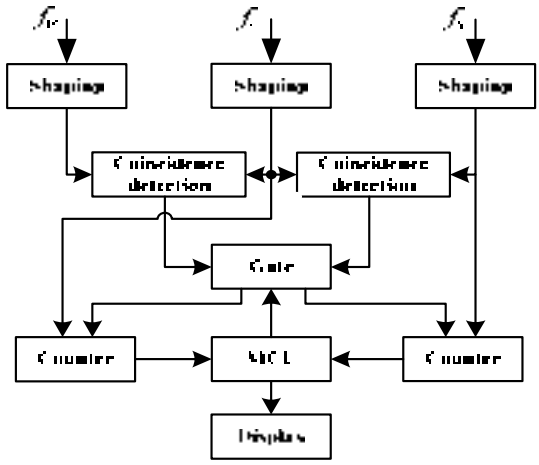

Fig.3 Schematic diagram of phase difference measurement

f_x and f_0 are the two compared signals of the same value or the multiple relationship of the public reference source, and there is the frequency difference or relative frequency difference between the public reference source f_c and the measured frequency signals. The high stable public reference signal f_c makes a detection of phase group superposition with f_x and f_0 respectively, which the frequency of f_c can be changed. Taking the advantage of the comparison between the frequency signals in multiples of each other, it can properly increase the quantitative phase shift resolution between the signals relatively to reduce the measurement requirement of wires.

There are some comparison measurements on the standard of different frequency resource in the experiment. To control the quantitative phase shift resolution between compared signals within 1ns, the public resource should be set with the offset ±1Hz , ±10Hz and ±100Hz after the frequency multiplication, which will make the foundation for the practical measurement of the high resolution. Table 1 shows the corresponding quantitative phase shift resolution after the different frequency multiplication on the mediation source, where f_{equ} is the equivalent frequency of phase between compared signals and is the reciprocal of the quantitative phase shift resolution each other. When the phase difference variation between is within 0º~360º, the corresponding time interval is a period of the low-frequency signal, such as the measured signal of 10M, whose phase difference variation is in 0~100000ps.

Tab.1 the quantitative phase shift resolution

f_x	f_0	f_c	$\Delta T=1/f_{equ}$ (s)
10MHz	10MHz	10MHz±1Hz	1.0×10^{-14}
10MHz	10MHz	50MHz±10Hz	2.0×10^{-14}
10MHz	10MHz	20MHz±100Hz	5.0×10^{-13}
10.23MHz	10.23MHz	10.23MHz±10Hz	9.5×10^{-14}
10.23MHz	10.23MHz	20.46MHz±10Hz	4.7×10^{-14}

Each time, the speed of the frequency shape moving is different causing by the relative acceleration of the real-time phase difference, because of the different small frequency difference Δf between the two compared signals input, namely that the time interval and the slope of the shape are different between the two 0º~360º nearby. The measurement result of the phase comparison of the public oscillator source 2 times the frequency relative to the standard frequency f0 shows in Fig 4 with choosing OSA5585B-CS of 10M as the measured signal, SR625 Rb of 10MHz as the reference signal and 20MHz+100Hz composed by Hp8662A as the public oscillator source.

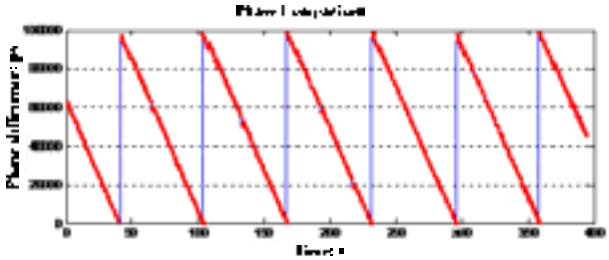

Fig. 4 Phase comparison of the signal of 10MHz （f_c=10MHz+100Hz）

Because of the error of $-T_{minxc}$~ T_{min0c} present between the referential gate and the practical gate, the error between the two practical gates nearby is $-2T_{minxc}$~ $2T_{min0c}$, which lead to the fluctuation between a constant value for the frequency pulse count of f_x and f_c. The practical gate is not constant, and the frequency pulse count of f_x and f_c will increase or reduce at the same time in the practical gate, but it will not influenced on the final calculative result.

The curve described by the frequency pulse count is mainly influenced by the phase difference of f_x and f_c, f_0 and f_c, and the practical gate. The slope of each part depends on the phase difference, and the practical gate leads to the fluctuation of the count value. The hardware detecting signals inside will lead to some triggered errors, which will influence the measurement result; the noise of the compared signal itself can also make it uncertain for the phase difference at the same time. For the influence on the drifting of the device itself, making the calibration itself with the same resource can eliminate the influence on the drifting with the operation simultaneously taking the advantage of the method of pulse on average and pulse filling.

IV. ANALYSIS AND CONCLUSION

This is the conclusion of the quantum mechanics that all the physical quantity is quantized in the most basic sense. For the clearness in math, the quantization property can be ignored

in the macroscopic measurement, and therefore the signals can be expressed in the continuous form. The quantization acts as a technology making the continuous signals dissociated, whose extent leads to the precision. The phase difference variation between periodic signals does be the quantization each other of the phase relationship in nature. The degree of the quantized precision also represents the degree of the mutual compared resolution between the signals, and represents the highest precision measured between the signals. The intrinsic frequency characteristics of the phase of quantum between the frequency signals, namely the quantitative phase shift resolution, can show the high resolution of the comparison, synchronous realization of the phase group , the control and the utilization, which is of important significant. The fundamental theorem on high precision measurement in the phase difference is based on the periodic characteristics between the different frequency signals and the concepts of the phase group synchronization to realize the mutual phase comparison. On the basic of the concepts and theorems of the equivalent frequency of phase, the least common multiple period, the equivalent comparison and so on in the chapter, the public oscillation source is introduced to make the high precision phase comparison and research on the two signals of the same frequency value. The phase difference measurement with high precision can be realized by taking advantage of the phase difference group synchronization, whose resolution of the measurement can be within 10ps.

***Abstract*— The Time Transfer by Laser Link (T2L2)[1] experiment aim to synchronise remote ultra stable clocks over large-scaled distances using two laser ranging stations. T2L2 ultimate time transfer capability can only be demonstrate with a picosecond range ground mastering. We focus this year in knowledge and equipment improvement to perform a T2L2 time transfer with accuracy and stability of a few picoseconds.**

A deep analysis of signals stability has been carried out this year in the time and frequency laboratory in *Plateau de Calern*. The aim was to better understand the limits and hardware configuration and to enhance time and frequency distribution for T2L2 experiment. We showed phase noise and stability problem on our H-maser distribution. Final measures were conducted in October in collaboration with SYRTE. Then a complete equipment reorganisation was done.

This paper focus on the time and frequency laboratory characterization before and after the reorganisation. We introduce our new equipments and present our new H-maser time scale and discuss the performances obtained.

Keywords—Atomic time, time and frequency distribution, T2L2

I. INTRODUCTION

T2L2 is a time transfer technique based on an international collaboration between laser stations and a dedicated space segment implemented on-board the altimeter satellite Jason 2. The project is operational since 2008 [1], [2], [3]. T2L2 relies on the propagation of laser pulses that permit to enhance the performance of time transfer by one or two order of magnitudes as compared to existing microwave techniques such as GPS and Two-Way Satellite Time and Frequency Transfer (TWSTFT).

It provides the capability to compare today's most stable frequency standards with unprecedented stability and accuracy [4]. Ultimate expected T2L2 performances are in the 100 ps range for accuracy, with a time stability of about 1 ps over 1,000 s and 10 ps over one day [5]. These performances can be reach only with a picoseconds ground mastering. This paper presents the new time and frequency laboratory organisation and the new dedicated equipment. It shows the new signal distribution to both laser stations MéO and FTLRS and concludes on the performances reach for T2L2 campaigns.

II. TIME AND FREQUENCY CALERN LABORATORY

In order to reach T2L2 expected performances, we have improved the time and frequency Calern laboratory signals distributions. During 2012, we focused in two points: time scale stability and signal distribution mastering.

Former configuration was relying on two clocks, a cesium clock to generate TA(OCA) and an H-Maser for high performance metrology. This architecture has two drawbacks. First the presence inside the same systems of two different clock signals could generate some cross modulations and thus degrade the performances. Second, such a configuration implied to do some post processing in order to take into account and correct the drift of the H-Maser (To stay synchronised with TA(OCA)).

In this way, we constructed a unique time scale based on our hydrogen maser T4S. It is distributed to both Calern laser stations with new distribution equipment STS and STD. The figure 1 gives a simplified view of the new time and frequency distribution in Calern. The figure 2 shows the overlapping Allan deviation of TA(OCA) before the reorganisation and after. We made the measurement with the Symmetricom 5120A phase noise analysis system. We can conclude from this measurements that we reach the T4S raw performances even after the HROG-10 micro-phase stepper without phase correction ($6{,}13\ 10^{-16}$@4.10^3 seconds). We had also drastically reduced the noise density.

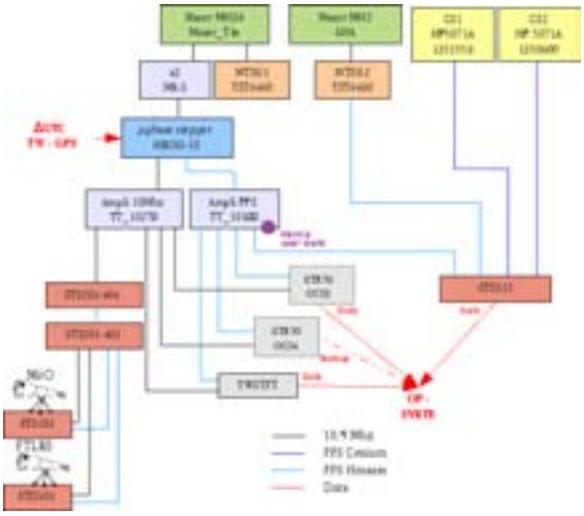

Fig. 1. Simplify diagram of time and frequency distribution from Calern laboratory to both laser stations.

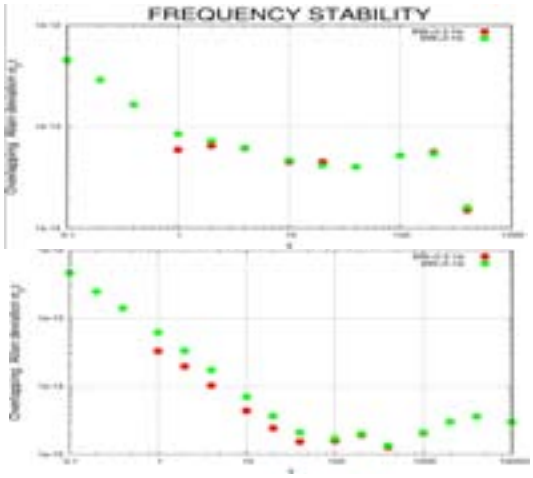

Fig. 2. Overlapping Allan deviation of TA(OCA) before laboratory reorganisation (top) and after in October 2012 (bottom).

The key points of this laboratory optimisation are:

- A single local atomic time scale based on the hydrogen maser T4S MH36.
- Acquisition of a set of ultra stable PPS signal generator: STS and distributor STD.
- Daily and automated maser frequency correction compared to UTC (OP) via GPS and TWSTFT.

Since May 2013 TA(OCA) is steered by applying daily frequency corrections in automated way (Fig. 3). The time difference between TA(OCA) and UTC(OP) is monitored in quasi real time by TWSTFT and by 2 geodetic GPS receiver. After a first period of debug TA(OCA) is expected at less than 20 ns from UTC with a frequency instability of few 10^{-15}. This must be reached by the end of this year.

Fig. 3. Simplify link between OCA time scale and UTC(OP)

III. New Subps Time and signal distribution: STS and STD

If one considers a typical distance between the stations of 100 m, a thermal sensitivity of the cable used to propagate the time reference of 100 fs/m °C and a long term thermal variation in the range 20°, the total delay variation can reach 200 ps which is far away to picosecond objective. To solve this difficulty we designed an ultra stable time signal generator STS201 including an event timer able to monitor the absolute time delay variation in the propagation of the signals between laser station and time and frequency laboratory (Fig. 4). The instrument was developed in the framework of the T2L2 experiment through a collaboration between several partners [6]. This monitoring is made through a double propagation of the signal emitted by the distributor and repeated by the user (laser station). This redistribution can be made through a passive connection if the distance is smaller than a few 10 meters or an active repeater for larger distances. We also designed such a repeater (STD101) well suited for distances of a few 100 meters. It includes an ultra-fast differential comparator connected to a distribution unit.

Fig. 4. Ultra stable time signal generator including a sub-picosecond event timer able to measure the time propagation of the signals.

The repeatability error of the instrument is better than 1 ps rms for the PPS distribution and better than 800 fs rms for the time delay measurement made by the event timer. Figure 5 illustrates the time stability measurement of a PPS signal generated by the instrument and measured by its internal event timer.

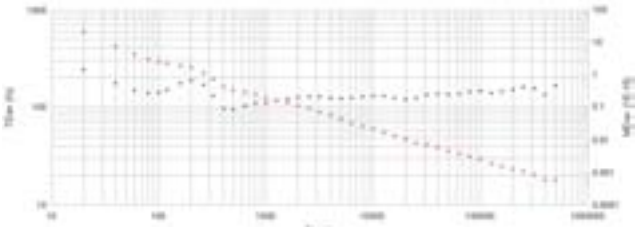

Fig. 5. Time stability of a PPS signal generated by the instrument and measured by its event timer. TDev in black and Mdev in red. The global drift of the measurements is smaller than 1 ps over 10 days. The peak value at 200s is due to the laboratory temperature control.

The STS201 instrument can be slaved with a 1, 5, 10, 100 or 200 MHz external reference. It can generate, through 2 independent channels, a signal between PPS and 100 MHz with an integer division of an internal 400 MHz local oscillator. This functionality permits to generate both PPS signal for time scale synchronization together with a 10 or 100 MHz signal for the time base of any other event timer.

IV. TIME DISTRIBUTION TO LASER STATIONS

Figure 6 is a schematic description of the laser ranging stations of OCA. There are 2 laser stations and a time a frequency lab in the same monument. The laser station on the left (MéO) is based on a 1.54 meter telescope. It was primary designed for laser ranging on the moon and is now the reference station for T2L2. The station on the left (FTLRS) is based on a very small 13 centimeter telescope. It is a mobile station that can be deployed in only 2 days all over the world. The time and frequency laboratory is located between the stations. It is 80 m from MéO Station and 50 m from FTLRS. Each station receives both a PPS signal and a 10 MHz frequency reference. The PPS signal is used to discriminate a zero crossing of a given 10 MHz period for time scale synchronization purpose. The 10 MHz signal is the time reference used by the event timer of the stations. A second STS generator is used at MéO to regenerate another 10 MHz signal coming from the time and frequency laboratory. A STD distributor is used at FTLRS to repeat the 10 MHz signal.

To get a time transfer at the picosecond level it is crucial to have an ultra stable time distribution between the reference clock and the laser stations.

Figure 7 is a typical phase measurement of the double 10 MHz link between laser station and time and frequency lab over 1 week. Phase variations are induced by the thermal variation of the coaxial cables.

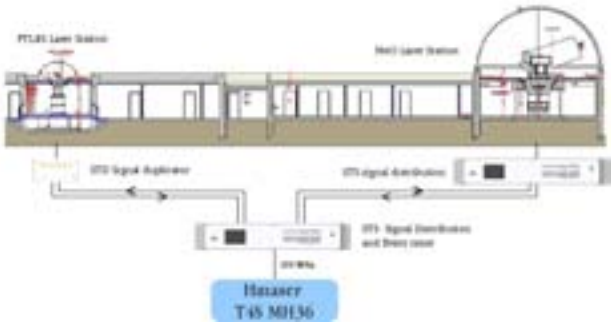

Fig. 6. T2L2 long term stability with MéO and FTLRS in co-location in Calern: simplified experimental setup

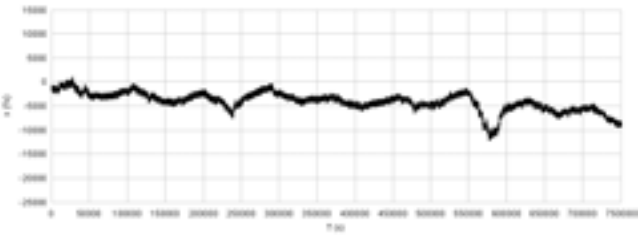

Fig. 7. Typical Phase measurement of the double 10 MHz link between FTLRS station and Time and frequency lab over1 week

Figure 8 shows modified Allan (Mdev in red) and time (Tdev in black) deviations in black of the link between MéO laser station and the Calern time and frequency laboratory. We can see the stability performance of this link is impressive: less than 0,2 ps at 1000 seconds and less than 2ps at one day.

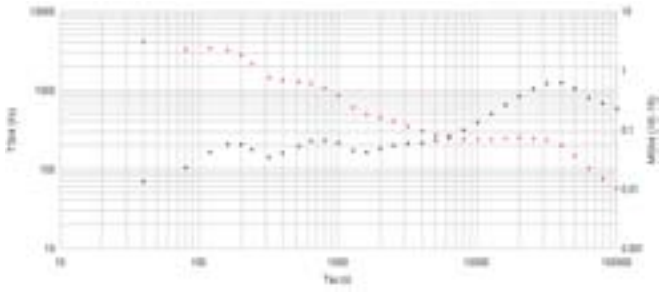

Fig. 8. TDev (black) and MDev (red) of the link between Laser station and Time and frequency lab (50 m)

Data coming from the STS201 event timer are recorded in real time and archived on a server. During the T2L2 data reduction process, start time of the laser events have to be time shifted to take into account the cable time variation measured by STS201. This process will be integrated in the very next future inside the automatic computation of the T2L2 scientific mission center.

V. IMPROVEMENT FOR T2L2 CAMPAIGNS

Today, Calern Time and Frequency laboratory is fully operational. A single local atomic time scale based on the hydrogen maser and corrected compared to UTC(OP) with TWSTFT and GPS is distributed to both laser stations. The signal distribution is monitored to the picoseconds with STS/STD time signal distributors. This is fully compliant for T2L2 experiments and can be transposed to other laser stations.

All the time transfer techniques are calibrated. The laser stations are calibrated with dedicated system (STX301 event time, optical fibre …) [1] with 50ps of global uncertainty. Thanks to the new equipment and time signal distribution, drift and time variation are monitored in real time with 1 ps of uncertainty. The TWSFTF system have been calibrated with SYRTE GPS receivers in March 2013 with a global uncertainty about 3 ns. We will do a new calibration in September-October 2013 with TimeTech mobile station. And our two GTR50 receivers have been calibrated with SYRTE GPS receivers in March 2013 with a global uncertainty about 3 ns. A new calibration will be done in November 2013.

With this new time and frequency architecture, we are organising two main T2L2 campaigns. The first one aims to demonstrate T2L2 stability performance in co-location. We have done it in Calern with both laser stations MéO and FTLRS from December 2012 to June 2013. The results will be published soon. The other one will begin in September 2013 to November 2013. The FTLRS laser station will be in Paris (OP) and this campaign will involve other European Laser Station. The aim will to statue ground to ground T2L2 stability and accuracy ultimate performance.

Synchronization of Ultrafast Lasers

Huan Zhao, Shengkang Zhang, Jun Ge, Nuanrang Wang
National Key Laboratory of Metrology and Calibration Technology, Beijing Institute of Radio Metrology & Measurement, Beijing, 100039, China

Abstract—**We demonstrate the high precise active synchronization between two independent ultrafast lasers with a RMS timing jitter less than 30fs. With the technique of cavity length monitoring by two PZTs, three PLLs, a motorized translation stage and a computer, this high-precise synchronization remains several hours.**

Keywords- ultrafast laser; active synchronization; phase locked loop; timing jitter

I. INTRODUCTION

Ultrafast laser has important applications in physics, chemistry, biology and advanced manufacture for it could "photograph" the instantaneous actions of atom and molecule. In a typical ultrafast pump-probe experiment, the laser is divided into two beams working as pump and probe light separately. Despite the two beams are synchronized and probably with different power, the key parameters such as central wavelength and pulse width are identical, thus the experiment results are limited. Synchronization of different ultrafast lasers are developed in the last decades and it plays indispensable roles in many researching, e.g. time-resolved measurement, entangled photon pair generation for quantum key distribution, phase-coherent synthesis of multicolor pulses, and far-IR-THz wave generation by means of difference frequency generation(DFG).

This Letter reports our research on highly precise active-synchronization between two independent femtosecond Ti:sapphire lasers. The lasers are firstly synchronized by two phase locked loops(PLL) at relative large timing-jitter, then the sum frequency generation(DFG) signal of the two lasers is fed back to the above PLLs, which acts as the third PLL and improves the precision of the synchronization significantly. Furthermore, by controlling the motion of motorized translation stage inside the ultrafast laser, the synchronization could maintain for several hours.

II. EXPERIMENT TECHNIQUES

A. synchronization based on Two PLLs with DBM

In the experiment, we made two prism-dispersion-controlled KLM (kerr-lens mode-locked) lasers named as TWIN1 and TWIN2[1], which both have about 800nm central wavelength, 100fs pulse width and 80MHz repetition rate. One of the cavity mirrors is attached on A side of the piezoelectric actuator(PZT) which B side is attached on the mirror mount, in order to lighten the load of PZT, this mirror has only a diameter of 6mm and thickness of 1mm.. The PZT inside TWIN1, named as TL PZT, is AE0505D08 made by Thorlabs Inc, its maximal displacement is 6μm@100V voltage, and the resonant frequency is above 10kHz. While the PZT inside TWIN2, named as PI PZT, is PL055.21 made by PI Ltd, its maximal displacement is 2μm@100V voltage, and the resonant frequency is above 100kHz. These two PZTs will be driven by different PLLs and play respective roles in the synchronization.

Essentially, synchronization is achieved by locking the repetition rate of two ultrafast lasers to make them at a fixed value or shift simultaneously. The technique of synchronization includes passive-synchronization[2] and active one[3], the former bases on the cross-phase modulation effect and the latter bases on PLL. In this letter, we focus on the discussion of active synchronization. The PLL for active synchronization is different from electrical one, although the latter could achieve synchronization with timing jitter of picosecond magnitude. There is no real voltage controlled oscillator(VCO), here we call E-VCO, in active synchronization, which is instead by the combination of photodetector, PZT and laser cavity, here we call L-VCO. E-VCO and L-VCO have very different properties. Firstly, the L-VCO has much smaller gain constant less than 1 part in 10^4 of its center frequency, while the E-VCO has the same order to its center frequency. Secondly, the length of laser cavity is susceptible to environment effects, thus there are much more frequency noises in L-VCO, and the amplitude-to-phase conversion is very strong that is hard to be taken off completely. Furthermore, the relationship between frequency and voltage of E-VCO is almost linear, while it is relative more complex in L-VCO, dues to the nonlinear relation between the repetition rate and the laser cavity length.

In general, the feedback error signal for active synchronization is produced by double-balanced mixer (DBM). The photodetectors extract the repetition rate signals of the two ultrafast lasers and import them to the DBM, then the filtered, integral and amplified error signal is loaded on the PZT to adjust the cavity length of the lasers. Since the repetition rate depends on the cavity length of the laser, the PZT can compensate the relative variation of the cavity length and then synchronize the lasers precisely. The DBM could also deal with harmonics of the repetition rate signals, and the higher harmonic, the lower AM-PM phase noise, thus the error signal is more sensitive to the timing jitter of the ultrafast lasers and the synchronization is with higher precision.

Fig.1 shows the schematic diagram of the PLL driving PI PZT inside TWIN2, PIN is a high-speed photodetector D400FC produced by Thorlabs Inc with 100ps rising edge and 1GHz bandwidth, BPF is a 80MHz band-pass filter with 800MHz central frequency and 80MHz bandwidth, OPA is a DC~1GHz wide-band amplifier, DBM is a double-balanced

mixer, LF is a loop filter, OPA227 is a amplifier with high precision and low noise, PA45 is a power amplifier with high voltage and large current.

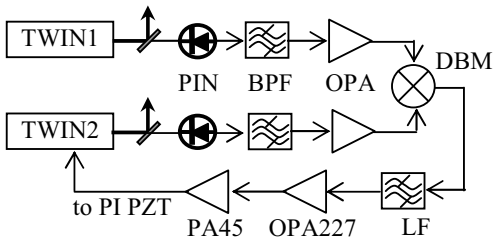

Fig.1 Schematic of PLL1

The BPF extracts the tenth harmonic components of the mode-locked signal of TWIN1[4], i.e. 800MHz, and the DBM works as frequency and phase discriminator. The error signal from the PLL load on PI PZT and drives it to modulate the cavity length rapidly. The loop bandwidth of the PLL is >20kHz, and the operated resonant frequency of PI PZT is >50kHz, so it is defined as a high speed, broadband PLL named as PLL1. It could compensate the relative variations of the cavity length between TWIN1 and TWIN2 and synchronize them with high precision, fast speed response and servo.

Despite of the high speed response, the maximum displacement of PI PZT is less than 0.7μm(the operated voltage load on it is <30V), while the relative cavity length difference of the two lasers maybe much larger than it, so the synchronization could not maintain very long time(more than 10 seconds) just by the PLL1, so we need another PZT with longer displacement to maintain a long-term synchronization.

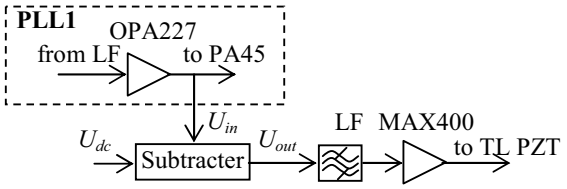

Fig.2 Schematic of PLL2

Fig.2 shows a schematic diagram of another PLL, namely PLL2, which drives TL PZT inside TWIN1. The TL PZT expands a maximum value of 2μm, and it can compensate the relative variation of the cavity length for longer time(>30 minutes generally). In fig.2, U_{in} is from the OPA227 in PLL1, it subtracts a constant voltage U_{dc}(U_{out}= U_{in}- U_{dc}, U_{dc} is a constant), then the difference signal is fed into LF, and the output signal acts on TL PZT after amplified by MAX400(a precise amplifier). The loop bandwidth of LF is about 30Hz, so we define PLL2 as low-speed PLL. The function of PLL2 is to keep U_{out} as zero, that is to keep U_{in} with the same as U_{dc}.

The PLL2 can work together with PLL1 by controlling the loop bandwidth and gain. Once these two PLLs activate normally, TWIN1 and TWIN2 could output synchronized laser pulses trains stably. However, the timing jitter is about hundreds of femtoseconds, which is obviously too large compared to the 100fs laser pulse width, thus we should improve the precision of synchronization further for the practical application.

B. Optical PLL

The template is used to format your paper and style the text. All margins, column widths, line spaces, and text fonts are prescribed; please do not alter them. You may note peculiarities. For example, the head margin in this template measures proportionately more than is customary. This measurement and others are deliberate, using specifications that anticipate your paper as one part of the entire proceedings, and not as an independent document. Please do not revise any of the current designations.

When TWIN1 and TWIN2 are synchronized by the two PLLs mentioned above, we focus two laser beams into a nonlinear crystal to generate sum frequency laser. A photodetector is used to detect the sum frequency laser and convert it into electrical signal. As you know, the signal intensity is very sensitive to the temporal position of the laser pulses, much more sensitive than the output of DBM in PLL1. If feeding this SFG signal back to the above PLLs, it could improve the precision of active synchronization significantly.

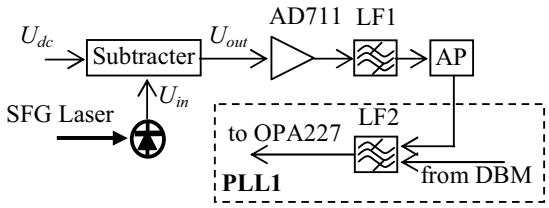

Fig.3 Schematic of PLL3

As indicated in Fig.3, the electrical signal converted from the sum frequency laser pulses firstly subtracts a constant voltage U_{dc}(U_{out}=U_{in}-U_{dc}), then fed into a loop filter(LF1) after amplified by AD711(a fine operational amplifier), the output voltage signal passes through an adjustable potentiometer(AP) and then it is input LF2 together with the error signal from DBM in PLL1, after that LF2 generates the new controlling signal to drive PI PZT. All of these could be regarded as PLL3, an optical phase locked loop.

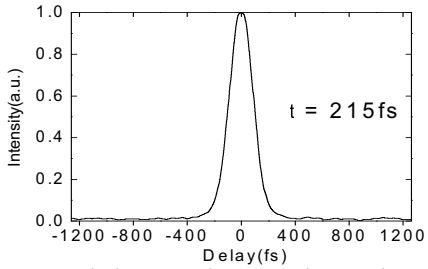

Fig.4 Cross-correlation trace between the synchronized lasers

Once PLL3 activates normally together with PLL1 and PLL2, the timing jitter of TWIN1 and TWIN2 could reduce to tens of femtosecond. We have measured the precision of synchronization with correlation method[5], fig.4 shows the trace of cross-correlation signal with 215fs FWHM, fig.5

shows the time record of the intensity fluctuation of the SFG laser at a fixed time delay when the cross-correlation signal is half of the maximum. Thus the calculated rms timing jitter is about 30fs, which proves that it is very effective using the sum frequency laser pulses as feedback signal to improve the precision of synchronization.

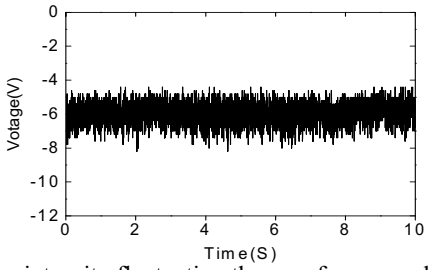

Fig.5 Power intensity fluctuation the sum frequency laser

The PZT control will enable the cavity length to be adjusted finely and quickly for accurate synchronization. The mirror mount, which the PZT is attached on, is fixed on a motorized linear translation stage which controlled by a computer, so the cavity length of the ultrafast laser can also be controlled by the computer in a relatively larger scale, and the controlling speed is much lower compared to PZT. In the experiment， the computer is utilized to monitor the real-time variation of the cavity length difference between these two synchronized lasers. By controlling the motion of the translation stage inside the ultrafast laser, it may compensate the variation of the relative cavity length caused by the surrounding environmental influence. Therefore, once two ultrafast lasers have been successfully locked, they will always keep synchronization with low timing jitter.

III. RESULTS AND DISCUSSIONS

In conclusion, we have demonstrated the active synchronization between two independent femtosecond Ti:sapphire lasers with high precision. There are totally three PLLs playing different roles in the experiment, two PLLs using DBM as phase detector work for preliminary synchronization with relative large timing-jitter, then an optical PLL using the sum frequency laser pulses as feedback signal activates to achieve much higher precision of synchronization, which reduces the timing jitter of the two ultrafast pulse trains from hundreds of femtoseconds to below 30fs measured in 10 seconds.

Abstract— **In this paper we are presenting the concept of the multipoint dissemination of RF frequency signal via a fiber optic network with actively stabilized propagation delays. The idea allows to add tapping nodes and side branches to the main point-to-point frequency transfer link, constituting a tree-like dissemination network. We are demonstrating the experimental results with the 100 km-long side branch starting at the 110th km of the 170 km-long main link. At the end of the side branch we obtained the Allan deviation of a 10-MHz frequency signal of about 4×10^{-17}, and the time deviation not greater than 1.2 ps for 10^5 s averaging.**

Keywords-Frequency dissemination; atomic clock; optical fibers; fiber network.

I. INTRODUCTION

Recently a significant development of fiber-optic based time and frequency (T&F) transfer systems may be observed. A lot of ideas of the frequency (and sometimes also the time) transfer were presented, based on transmission of either a highly coherent optical carrier, or an intensity-modulated light [1]–[5]. The main problem, which should be overcome using any approach is a fluctuation of the propagation delay of the fiber, caused mainly by varying temperature, and on much smaller scale by some mechanical stresses and random fiber birefringence (know also as polarization-mode dispersion).

Our group at the AGH University of Science and Technology is developing the T&F dissemination method based on active electronic stabilization of the propagation delay of the link [4], [5]. Recently we described an idea of point-to-multipoint frequency dissemination, with simultaneous stabilization of all the delays from the common input to all outputs of the system [6]. We demonstrated the experimental results for access nodes located along the main link. In this work we are presenting the new experiments with the side branch configuration, allowing to deliver the frequency reference signal to locations far away from the main link.

II. ACTIVELY STABILIZED SIDE BRANCH

The general concept of our system is depicted in Fig. 1. It comprises the Local and Remote Modules, responsible for stabilization of the propagation delay between the input and the remote output of the trunk link. The Access Module, located at some point along the trunk fiber, taps small portions of the optical signals propagating in both the forward and backward directions and is responsible for stabilizing the propagation delay from the input of the system to the side branch output. The simplest way of tapping the signals propagating along the trunk fiber is to insert the passive directional coupler into the main (trunk) optical path. (When needed the tapping may be combined with optical amplification by means of a bidirectional optical amplifier.)

Ignoring for a moment the Access Module we will recall the core idea of stabilizing the propagation delay of the main (trunk) link. In the Local Module the incoming frequency signal goes through the electronic variable delay line, and then reaches the electro/optic (E/O) converter (the intensity-modulated laser). Next the signal passes the optical circulator and propagates in the forward direction down the trunk optical fiber to the remote location. There it is back-converted to the electrical form and feed to the output, but also turned back to the trunk fiber in the backward direction. The signal coming back to the Local Module is converted to the electrical form, enters the second variable delay line, and reaches the phase detector, which second input is connected to the input port of the module. The phase detector senses the phase difference between the input and feedback signals, and cancels it by varying the delays of both the forward and backward delay lines by the same amount. Thus the round-trip delay in the system is kept constant, unaffected by the fluctuations of the fiber delay. Making the reasonable assumption that the variations of the fiber propagation delay are the same in forward and backward directions, it may be shown that also the input-to-output delay is kept constant. (For more detailed discussion see [4].)

The signal propagating to the side branch output starts at the coupler port marked by letter **A**. After conversion to the electrical form, passing through the variable delay line and being converted again to the optical domain, it reaches the Branch Output Module. There it is redirected back-ward, similarly as in the trunk link, and enters the second variable delay line. The phase detector in the Access Module cancels

This work was supported by Polish National Science Centre under the decision DEC-2011/03/B/ST7/01833.

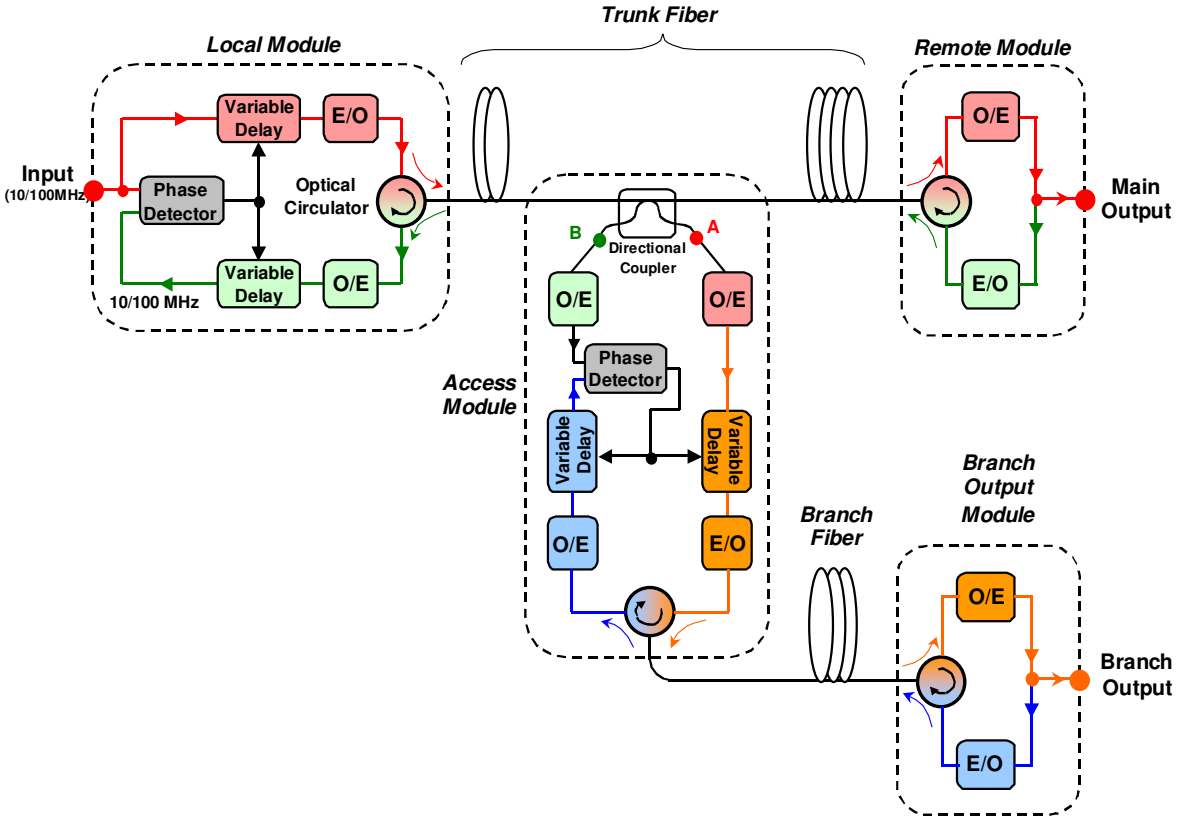

Figure 1. Block diagram of the point-to-multipoint dissemination system.

the phase difference between the signal coming back from the side branch and that coming back from the Remote Module of trunk link (point **B** of the coupler). As we shown in [6], the phase fluctuations observed at both outputs of the coupler (**A** and **B**) are of the same magnitude but opposite sign. Thus the side branch output, being "in the middle" between **A** and **B** points, is not affected by phase fluctuations occurring in the trunk fiber. Also the phase (delay) fluctuations occurring in the branch fiber are canceled similarly as in the basic trunk link [6].

III. EXPERIMENT

The experimental setup is depicted in Fig. 2. The 10-MHz frequency signal was disseminated from the Local Module to two outputs: the Remote Module, terminating the trunk line (173 km of fiber), and Branch Output Module, terminating the 98 km-long side branch. To compensate the attenuation of the optical paths there were three single path bidirectional amplifiers (SPBAs) involved in the setup. Evaluation of the disseminated signals stability was performed using a high-speed, real-time digital oscilloscope (Agilent DSO81004A) and dedicated software built in Matlab. The spooled fibers, SPBAs and Access Module were located in two different, not air-conditioned laboratories, and underwent temperature variations of about 5°C. The two spans of field-deployed fibers were located in Krakow metropolitan area. The rest of the equipment was located in restricted-access laboratory with temperature stability of about 0.5°C.

The results of our measurements are shown in Figs. 3-5, in the form of time-domain plots of the phase fluctuations, as well as the time deviation (TDEV) and the overlapping Allan deviation (ADEV). One set of data was obtained during

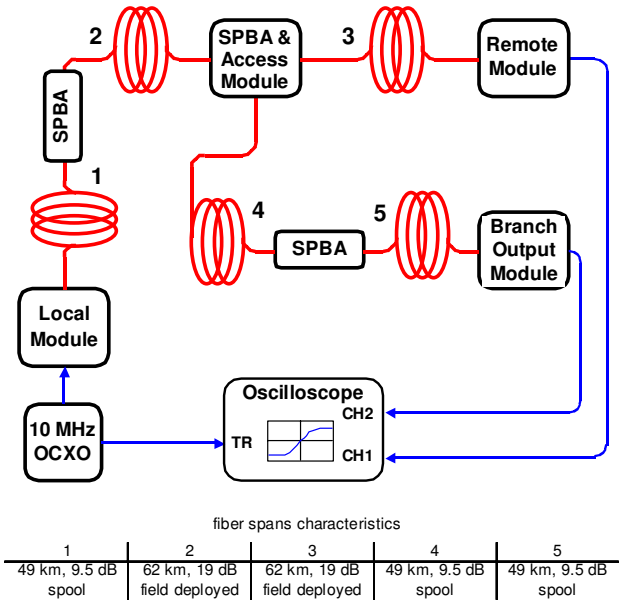

Figure 2. The experimental setup.

12-days long measurement with delay stabilization deactivated (open loop), and during next 12 days in normal (closed loop) configuration.

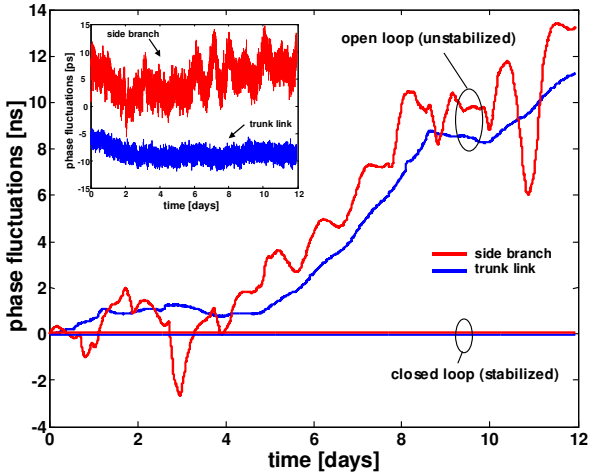

Figure 3. Time-domain phase fluctuations for closed loop and open loop configurations. In the inset the closed-loop fluctuations revealed by picosecond-range vertical scale.

In all figures the expected stabilization feature at both the trunk link and the side branch is clearly visible. The stability obtained in the trunk link is very similar to obtained previously in our other experiments with the basic point-to-point configuration [4], [5], and for the side branch the stability is somehow degraded; ADEV and TDEV is about two times to three times larger. It may be explained noticing that the side branch stability is affected by impairments of all electronic and optoelectronic components present in all modules visible in Fig. 1, whereas the trunk link is not affect by adding of the side branch system (except some optical power tapping). However, the stability obtain at the side branch output is still very good, and significantly outperforms stability of nowadays commercial atomic clocks, especially for longer averaging time.

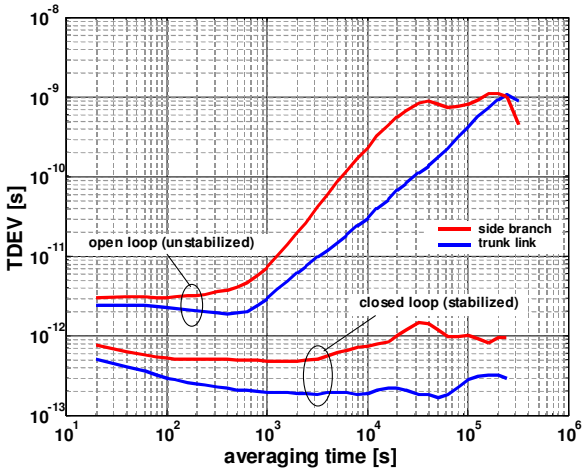

Figure 4. Time deviation for closed loop and open loop configurations.

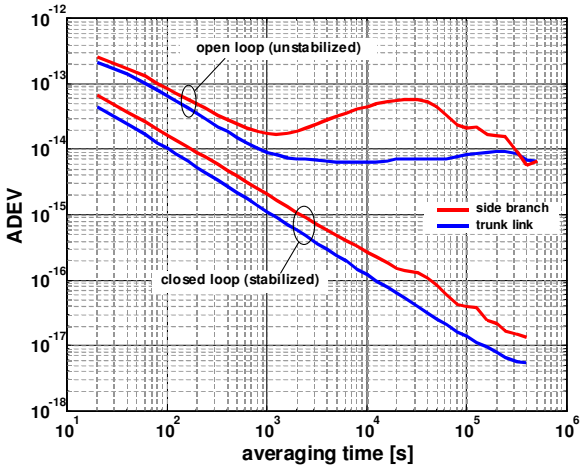

Figure 5. Overlapping Allan deviation for closed loop and open loop

IV. CONCLUSIONS

We experimentally verified the new concept of actively stabilized frequency dissemination system with the side branch connected in some point of the trunk link. Adding of the branch did not affect the trunk link stability, whereas the side branch stability occurred to be two to three time worse comparing to the main (trunk) link, because of much more complicated hardware setup involved in the branch system. Basing of this idea also a more complex, tree-like point-to-multipoint frequency dissemination network may be built.

The natural continuation of this research will be incorporating the time transfer to the point-to-multipoint system, on basis similar to used in our point-to-point system.

***Abstract*— We describe experiments with the AGH-designed fiber optic system for time and frequency dissemination, based on an active stabilization of the fiber delay. The measurements were performed at the Physikalisch-Technische Bundesanstalt, Braunschweig, over a field-deployed optical fiber loop going from PTB to the Magnesium clock laboratory in the Leibniz Universität Hannover and back (149 km, 45 dB attenuation).**

Keywords-time, frequency, dissemination, optical fiber, atomic clock

I. INTRODUCTION

The system for dissemination of time and frequency signals exploiting an electronic stabilization of the propagation delay of the optic fiber link was recently designed and developed at the AGH University of Science and Technology in Krakow, Poland [1]. It allows remote access to 5/10/100 MHz and 1 or 100 pulses per second (PPS) signals generated by atomic sources (e.g. cesium clocks and fountains or hydrogen masers) with the stability and accuracy being at the level of the source producing the signals. Tests performed at AGH showed the Allan deviation (ADEV) around a few times 10^{-17} at one day averaging and the time deviation (TDEV) below 1 ps for 10 MHz and 1 PPS signals, respectively. The system also showed a picosecond-level capability of the calibration of the time transfer. We performed the tests using the fibers spooled in the lab as well as the field-deployed link running from our lab to Skawina near Krakow and back (~120 km) [1], [2].

The purpose of our current work was to perform additional, independent tests of the system stability and calibration accuracy, using various measurement approaches and different fiber optic link, exploiting high-speed real time digital oscilloscope, K+K Phase Recorder [3], dual mixer time difference (DMTD) technique [4] with harmonic trackers and time interval counters (TIC).

II. FIBER OPTIC LINK

To perform the evaluation the time and frequency dissemination system with the stabilization of the propagation delay was installed over a field-deployed fiber optic link running from the Physikalisch-Technische Bundesanstalt (PTB) in Braunschweig to the Magnesium frequency standard laboratory in the Leibniz Universität Hannover (LUH) and back [5]. This link uses standard SMF-28 type fiber with the total length about 149 km, showing the attenuation around 45 dB (estimated from the OTDR measurements). To compensate the attenuation of the fiber we planned to place remotely-controlled single path bidirectional Er-doped amplifier (SPBA) [2], [6] in the middle of the span, in the Magnesium frequency standard laboratory at LUH. The diagram showing the details of the link is presented in Fig. 1a.

After installing all the equipment it appeared that the system could not lock and operate properly. Detailed analysis of the optical paths revealed that although most of the optical connectors used were of APC type, a few ordinary PC

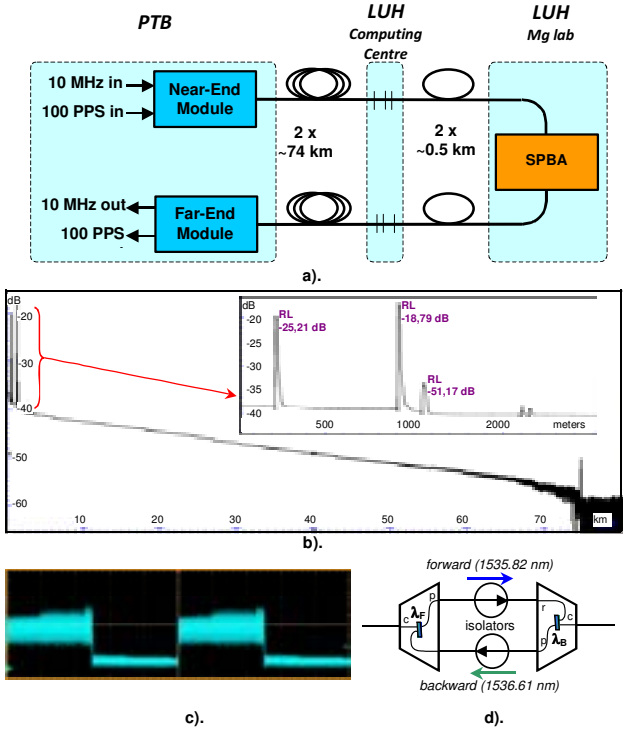

Figure 1. PTB-LUH-PTB fiber optic link: overview (a), PTB-LUH OTDR plot (b), signal observed at the input of the Far-end module and structure of the wavelength-selective isolator (d).

This work was supported by the European Metrological Research Programme EMRP under SIB-02 NEAT-FT. The EMRP is jointly funded by the EMRP participating countries within EURAMET and the European Union. Support by the Centre of Quantum Engineering and Space-Time Research (QUEST) is gratefully acknowledged.

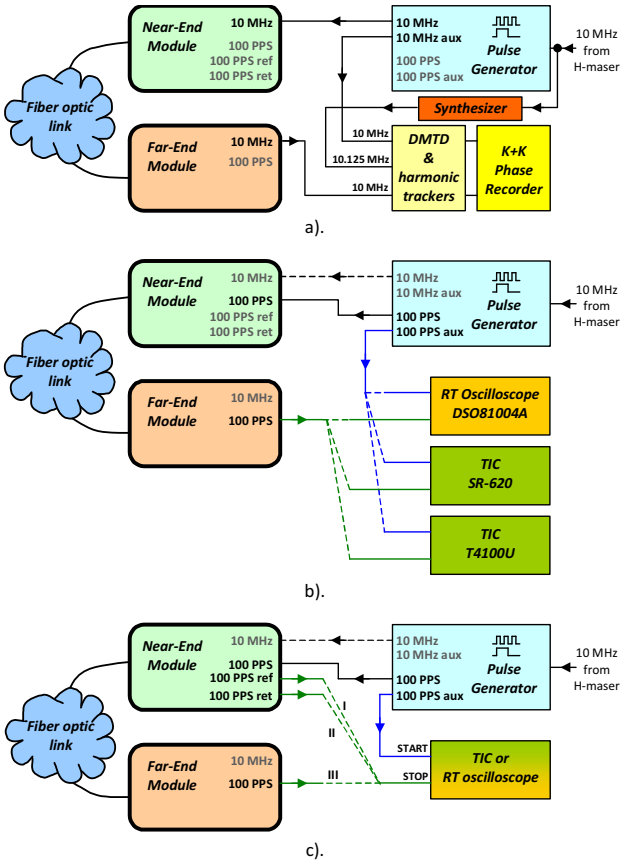

Figure 2. Diagram of test setups used for evaluating time and frequency dissemination system: stability of frequency dissemination (a), stability of time dissemination (b) and time calibration (c).

connectors were also used. They were located close to the SPBA at the LUH Computing Center and showed exceptionally high reflections (between –26 dB and –13 dB accordingly to OTDR measurements – see example OTDR trace in Fig. 1b). As a result the optical signal reaching the receiver of the Far-End Module suffers from both the multiple reflections and noise (generated inside the SPBA from its amplified spontaneous emission - ASE) – see Fig. 1c. This was the reason of malfunction of our dissemination system.

Replacing of suspicious connectors with the APC ones was impossible and cleaning them did not help much so we decided to add a wavelength-selective isolator (see Fig. 1d) at LUH at one side of the SPBA. This module appeared to be very effective in breaking the optical feedback loop around SPBA. After its installation the quality of the signal received by the Far-End module improved to the level allowing for normal operation of our system.

III. Measurement Setup and Evaluation Methods

To evaluate the time and frequency dissemination system we arranged a number of measurements using the setups sketched in Fig. 2. In all these setups we used a pulse generator, having main as well as auxiliary 10 MHz and 100 PPS signals, synchronized to a 10 MHZ signal derived from a hydrogen maser.

For the frequency stability measurement we applied the DMTD technique to increase the resolution of K+K Phase Recorder, using a dedicated hardware developed at PTB, including mixers and PLL-based harmonic trackers, (see Fig. 2a). In this setup 10 MHz frequency signal from the main output of the pulse generator was applied to the input of Near-End Module. The DMTD module received 10 MHz signals from the auxiliary output of the pulse generator and from the Far-End Module, using 10.125 MHz signal, synchronized to the H-maser, as a common reference. Resulting multiplication factor was thus equal to 80.

To measure the time dissemination stability we used the setup shown in Fig. 2b, where the time difference between 100 PPS pulses from the auxiliary output of the pulse generator and output of the Far-End Module was registered by either the oscilloscope or the TIC. For the oscilloscope measurements we exploit the feature of our pulse generator allowing inserting the programmable delay between its main and auxiliary outputs. This allows compensating a long delay of the fiber link (~730 µs), leaving only the residual (below 10 µs) to measure by the oscilloscope, limiting this way the influence of its timebase instability on the measurement results. We decided to use the 100 PPS time signal instead of a standard 1 PPS to reduce the impact of the short-term noise of both the measurement setup and the measured system itself.

The setup we used to measure the accuracy of time dissemination is presented in Fig. 2c. The unique feature of our system is the possibility to accurately determine (calibrate) the propagation delay it introduces between its time reference point (i.e. the 100 PPS_ref point marking the exact moment of transmitting the actual 100 PPS pulse) and 100 PPS output, using only the signals available at the Near-End Module [1], [6]. It is given by the equation:

$$\tau^{C}_{REF\to OUT} = \frac{1}{2}\left[\tau_{REF\to RET} + \Delta\tau_{F\_FB} + \tau_{C}\right], \qquad (1)$$

where $\tau_{REF\to RET}$ is measured round-trip delay, $\Delta\tau_{F\_FB}$ is the difference between the propagation delay in the forward and backward directions of the fiber link and τ_C is the calibration constant determined before installation of the system with a short patchcord in place of the fiber link (this way $\Delta\tau_{F\_FB} \approx 0$). Further $\Delta\tau_{F\_FB}$ may be estimated from the equation:

$$\Delta\tau_{F\_FB} = \Delta\lambda_{FB} D\,, \qquad (2)$$

where D is the total chromatic dispersion and $\Delta\lambda_{FB}$ is the difference of the wavelengths used to transmit the signals in the forward and backward directions. (The correction factor for the Sagnac effect has already been omitted in equation (2) because of loop configuration used in described experiment.)

Performing a measurement of the accuracy of the time dissemination requires a few steps. First, having the START and STOP inputs of the TIC (or two channels of the oscilloscope) connected between the auxiliary output of the

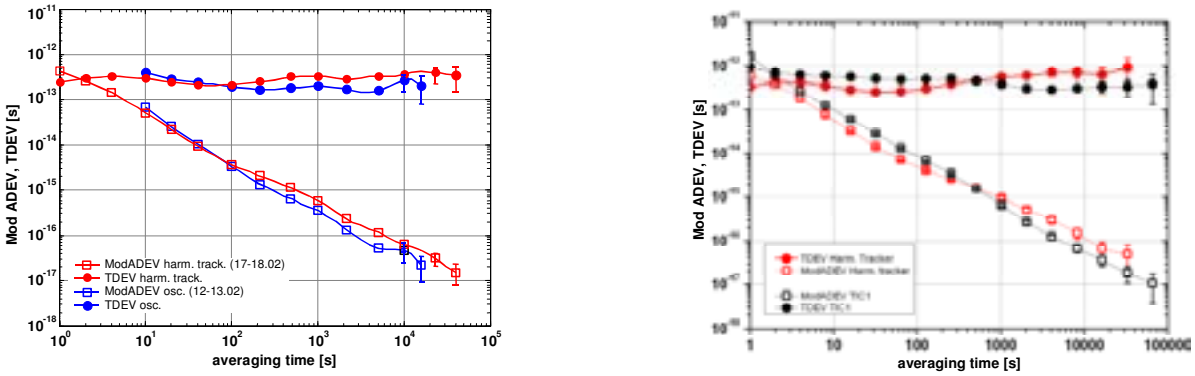

Figure 3. Time and frequency stability comparison: a) - DMTD with harmonic trackers (10 MHz) and oscilloscope (100 PPS), b) - DMTD with harmonic trackers (10 MHz) and SR620 (100 PPS).

pulse generator and the 100 PPS_ref output of the Near-End Module (marked "I" in Fig. 2c) we measure the reference time interval τ_I that takes into account all constant delays (i.e. the propagation delays of the cables, the delay between the main and auxiliary outputs of the pulse generator and the delay between the 100 PPS input and 100 PPS_ref point). In the second step (marked "II" in Fig. 2c) we measure the time interval τ_{II} changing the signal at the STOP input to 100 PPS_ret. Subtracting τ_I from τ_{II} we get the round-trip delay $\tau_{REF\to RET}$ that enters equation (1). The true, directly measured propagation delay $\tau^M_{REF\to OUT}$ may be determined by calculating $\tau_{III}-\tau_I$ according to configuration "III" in Fig. 2c. It may further be compared with the value calculated from equation (1). It is essential to use the same cable connecting the STOP input of the TIC to the source of the signal in all these three steps. For the procedure to be complete we still need the total chromatic dispersion D that may either be known from the fiber link operator or, better, measured using e.g. the procedure described in [6], using a tunable laser transmitter and a TIC.

IV. Results of Evaluation

Using the fiber optic link and the test setups described in two previous sections we arranged a number of measurements to evaluate the stability of time and frequency dissemination as well as time dissemination accuracy. The most important results are summarized below.

A. Time and Frequency Stability

Some representative ModADEV/TDEV curves showing the time and frequency stability are presented in Fig. 3a and b. These are shown jointly because in our dissemination system the 100 PPS signal is recovered from 10 MHz frequency signal so both are phase coherent. Even the structure of output buffers is exactly the same, so both signals should display similar stability. In Fig. 3a comparison of curves registered in two measurement sessions between 12-13.02.2013 and 17-18.02.2013 are shown; the measurement period for Fig. 3b was 22-25.02.2013. The frequency stability was measured using DMTD technique, whereas time stability was measured using DSO81004A oscilloscope (Fig. 3a) and SR620 TIC (Fig. 3b).

Analyzing the results one may observe, as expected, quite close agreement between the stability of time and frequency signals. The slope of the curves, close to τ^{-1}, suggests that the flicker phase noise dominates. For long averaging times the ModADEV approaches values close to 10^{-17} that agrees well with other measurements performed in our lab on the link with comparable length and attenuation. The TDEV is below 1 ps, also being in agreement with our other results.

There are, however, some noticeable differences. In Tab. I the values of ModADEV for a few averaging periods are summarized for different measurement methods. One may notice that DMTD technique gives best results for short averaging times, generally below 100 s. For longer times the DMTD results start to worsen, being even worse than TIC results. An analysis of the data from K+K Phase Recorder revealed some spikes, that are probably related to the temperature variations in the lab caused by human activity (see Fig. 4 as an example). No such effects were noticed in records from the oscilloscope and SR620 TIC. We expect that a better thermal shielding and careful selection of all DMTD components will reduce the sensitivity to environmental temperature fluctuations significantly.

Quite interesting and surprising is a good long-term performance of SR620 TIC, showing ModADEV and TDEV comparable as measured using the oscilloscope. This may be explained noting that when counting of the 100 PPS pulses with the TIC we gained on hundred-fold averaging reducing its

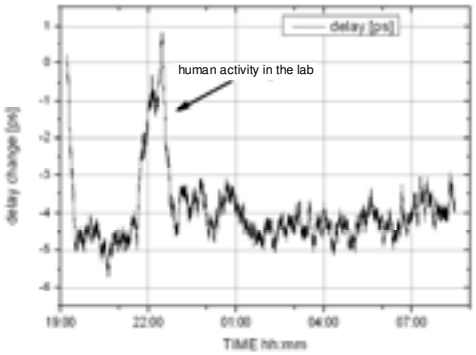

Figure 4. Fragment of the record registered using DMTD technique with harmonic trackers.

TABLE I. MODADEV FOR DIFFERENT MEASUREMENT METHODS

	Averaging time [s]		
	1s	***10^2s***	***10^4s***
DMTD	$4\text{-}6\cdot10^{-13}$	$3\text{-}5\cdot10^{-15}$	$6\text{-}11\cdot10^{-17}$
DSO81004A	-	$3\cdot10^{-15}$	$4.3\cdot10^{-17}$
SR620	$2\cdot10^{-12}$	$8\cdot10^{-15}$	$5.5\cdot10^{-17}$

noise substantially.

B. Time Transfer Calibration

The calibration of time transfer was performed twice – for the first time at 14.02.2013, and further verified at 25.04.2013. During these two months the system was powered off and disconnected from the fibers for some period. After powering on again and reconnecting the fibers no any additional procedures (like tuning or recalibration) were performed. The oscilloscope used for the measurements was transported from Braunschweig to Krakow and back between the two sessions, and all the cabling was rearranged for the second session. The results of these calibrations are summarized in Tab. II.

The value of τ_C includes not only internal differences of the forward and backward propagation delays of the Near- and Far-End Modules but the difference embedded in the wavelength selective isolator as well. It was determined at PTB using the DSO81004A oscilloscope. The value of $\Delta\tau_{F\_FB}$ was measured using the tunable-laser technique [6].

At first calibration performed in February using the oscilloscope the difference between the measured and calculated propagation delays was equal to 18 ps. This is close to expanded uncertainty (i.e. two sigma value giving 95% level of confidence) of both directly measured delay of the link (σ=7 ps) and theoretically calculated delay of 149 km long link using SMF-28 fiber (σ=9 ps) [6]. The calibration was checked again in April, after termination of the link operation mentioned above. This time besides using the oscilloscope we also used a picosecond-accurate T4100U TIC developed at the Warsaw Military University of Technology [7]. The differences between the measured and calculated delays were 19 ps (DSO81004A) and 22 ps (T4100U), being in a very good agreement with the initial calibration performed in February.

TABLE II. RESULTS OF TIME TRANSFER CALIBRATION

Date	February 2013	April 2013
Temperature TX/RX	29,7°C / 23,2°C	28,8°C / 23,7°C
τ_C	52263(±7.2) ps	52270(±7.2) ps
$\Delta\tau_{F\_FB}$	1687(±14) ps	1688(±14) ps
$\tau_{REF\rightarrow RET}$	1457903829(±7) ps (Osc)	1457903828(± 7) ps (Osc) 1457903831(±15) ps (TIC)
$\tau^M_{REF\rightarrow OUT}$ (measured)	728978908(±7) ps (Osc)	728978912(±7) ps (Osc) 728978917(±15) ps (TIC)
$\tau^C_{REF\rightarrow OUT}$ (calculated)	728978890(±9) ps	728978893(±9) ps (Osc) 728978895(±12) ps (TIC)
$\tau^M_{REF\rightarrow OUT} - \tau^C_{REF\rightarrow OUT}$	**Δ = 18(±12) ps (Osc)**	**Δ = 19(±12) ps (Osc)** **Δ = 22(±18) ps (TIC)**

The results confirm that this time transfer technique is reproducible to better than about 5 ps.

V. CONCLUSION

Evaluation of the AGH developed time and frequency transfer system performed at PTB using 149 km long fiber optic link in loop configuration showed ModADEV at the level of $4\text{-}6\cdot10^{-17}$ at 10^4 s and TDEV well below 1 ps. Stability is similar for both 100 PPS and 10 MHz signals. Results obtained with all applied measurement methods are consistent, however for short averaging times the DMTD technique with harmonic trackers prevails, whereas for longer times DSO81004A oscilloscope and SR620 TIC performs better. Good long-term TIC results are mainly because of hundred-fold averaging because of measuring 100 PPS signal instead of usual 1 PPS.

Time transfer calibration of the link was performed twice – the difference between the measured and calculated propagation delay does not exceed 22 ps, even after one month of powering off of the system. Thanks to inserting the wavelength selective isolator it was possible to operate the system even in the presence of unusually strong reflections of optical connectors.

The results obtained confirm that the developed solution for fiber optic time and frequency transfer of microwave signals is reliable and suitable for dissemination of the signals from nowadays atomic sources, like Cs-clocks, H-masers and Cs-fountains.

***Abstract*—Bi-directional optical frequency links for phase-stabilized frequency transfer require bi-directional amplifiers. Here we present some results from the development and test of two types of bidirectional amplifiers, Er^{+}-doped fiber amplifiers (EDFA) and fibre Brillouin amplifiers (FBA). to be deployed along a fiber link connecting SYRTE/France and PTB/Germany.**

Keywords—frequency metrology, fiber, amplifier

I. Introduction

When transferring an optical signal propagated over hundreds of kilometres in the C-band, the attenuation of the signal is one of the major concerns, as it ranges from .2 to .3 dB/km. This means that amplifiers are needed every hundred of km. For phase stabilised frequency transfer [1-3], the key idea is to partially reflect back the incoming light at the remote end of the link, and to measure and compensate the perturbation of the optical phase after one round-trip. It relies on the strong hypothesis that the noises are identical on the both directions of propagation. As a matter of fact phase-stabilised fibre links need fully bi-directional amplifiers.

II. Development of bi-directional Erbium Doped Fiber Amplifier

A straight forward approach, that complies with Telecom regulations, is to use Er^{+}-doped amplifiers (EDFA). In contrast to standard EDFA, we develop in partnership with IDIL bi-directional EDFA where the optical isolators are removed. It is advantageous that they are well known and reliable equipments, and that they are available now on the market. Largely autonomous in operation, they are almost insensitive in polarisation, what matters, as fibre links don't maintain the input state of polarisation. The maximum gain is +25 dB, for input signal ranging from -45 to -20 dBm. The Noise Figure is below 5 dB. The main drawback comes from the non-immunity to stray reflections as the optical isolators were removed for bi-directional operation. To prevent the amplifier from self-oscillating, the gain is limited to well below +25 dB. On the French link architecture for instance, the average gain over 6 amplifiers is as low as +16 dB/amplifier. They work continuously for more than 2 years without interruptions nor trouble shooting. Remote communications abilities were set up recently, and are now commercially available on the market[4]

The alternative approach that was developed on dark fibre architecture is to take advantage of Brillouin scattering to achieve high gain and wavelength-selective amplifiers.

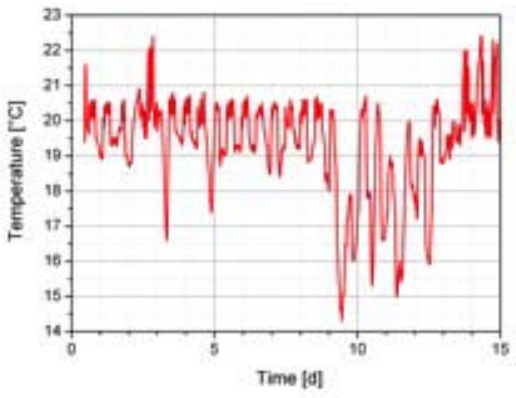

Figure 1 Temperature in a telecommunication hut in rural Germany (spring).

III. Development of Fibre Brillouin Amplifier (FBA) Modules

Fibre Brillouin Amplifiers (FBA) for frequency transfer via phase-coherent bi-directional links have been demonstrated and used in a laboratory environment [3,5]. Main features are a high small-signal gain of more than 40 dB and a narrow gain spectrum [6].

These features make Brillouin amplification a promising technique adapted to bi-directional links.

High amplifier gain allows for a larger distance between amplifier locations, reducing the complexity of the overall setup. Taking advantage of a gain of 40 dB, a transparent link can be set up with distances of around 200 km between the amplifier stations. However, currently Rayleigh backscattering as well as back-reflections prohibit the use of gains in excess of around 20 dB when using broad band bi-directional amplifiers, as uncontrolled lasing may occur.

Brillouin amplification in silica fiber on the other hand has a narrow gain profile with typical widths of around 10 MHz. Hence the amplification of light traveling towards the remote end and of the returning light require different pump frequencies, as the returning light in phase stabilized links typically is marked by a frequency shift of several tens of

Megahertz. In addition selection rule (momentum-conservation) implies that only counter-propagating light with respect to the pump wave-vector is amplified. This allows to discriminate the respective signal light from backscatter light. The main drawback is that the needed pump power is above the standard telecommunication regulation, and hence cannot be implemented so far on shared public network.

In contrast to applications in the laboratory, field-able Brillouin amplifiers require largely autonomous operation under less well-controlled conditions. One challenge are varying temperatures, as experienced in a telecommunication hut during a field test, where a test setup was placed at a distance of about 160 km. While a gain of around 40 dB was observed here and automated locking of the pump frequency to the signal could be achieved, considerable temperature excursions triggered further development of mitigation techniques to keep the pump frequency within the range of operation of the amplifier.

As Brillouin amplification relies on the interaction between signal light and pump laser light, depending on the available power the relative polarization of signal and pump is expected to affect the amplification [6].

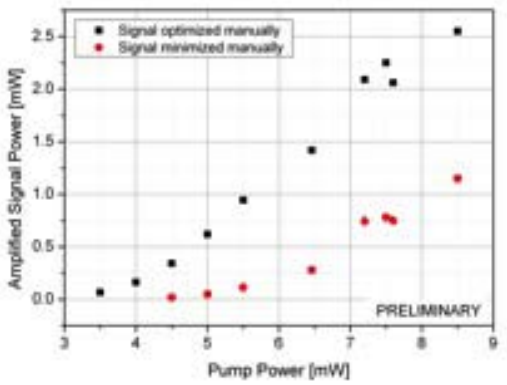

Figure 2 Dependence of the amplified signal power on the relative polarization, set manually, of pump and signal light (31 km fiber spool, signal input power around 80 nW).

We performed a laboratory test employing about 30 km of spooled standard silica fiber, a signal power of around 80 nW and a pump power of around 6,5 mW and automated polarization steps covering the Poincaré sphere.

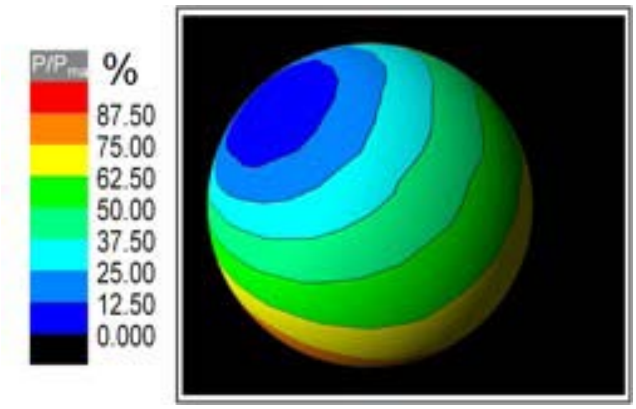

Figure 3 Poincaré sphere of the relative polarization between signal and pump (with an arbitrary offset of the polarization angles; automated steps in polarization) with the colour coded intensity of the signal power relative to the maximum observed power.

Here we found a likelihood of around 10% for losing about 75% of the possible amplified signal power, assuming that all states of relative polarization may occur with equal probability.

To mitigate slow polarization changes, we have developed an automated algorithm for remote polarization optimization upon request or when triggered e.g. by a drop in signal power.

Current and future work includes active mitigation of temperature swings, the development and implementation of remote communication as well as investigating and implementing FBA chains

***Abstract*—We report on the design and the realization of a digital architecture based on a tracking direct digital synthesizer (DDS) driven by a Field Programmable Gate Array (FPGA) for the implementation of a coherent optical link for time and frequency dissemination. The realized digital system has been implemented and characterized on a real fiber link on a 47 km metropolitan optical telecommunication network using a Dense Wavelength Division Multiplexing, that is shared with the internet data traffic. We describe the technique, the hardware and the characterization of the link, and we compare the new digital system with the analogic one, that uses common fiber links electronics.**

Keywords—Fiber link, Time and Frequency transfer, Digital Electronics, DDS, FPGA

I. INTRODUCTION

Nowadays, optical fiber links are a key technology for science and metrology. They allow the remote comparison of very accurate clocks, as Cs fountains or optical clocks [1-3]. Their resolution exceeds the state-of-the-art satellite techniques by several orders of magnitude, paving the way for a number of scientific experiments in the fields of high resolution spectroscopy, radio-astronomy, fundamental physics. Using a coherent optical link it is possible to exploit the optical clocks accuracy after few hundreds seconds of measurement over hauls up 1000 km, an unprecedented result. This is a fundamental achievement, as they are the most promising candidates for a forthcoming redefinition of the second. It is possible to achieve frequency dissemination (and comparisons) at the 10^{-16} level of stability [2,3] and time dissemination at the 100 ps level [4] over hauls of 1000 km. This resolution needs the compensation of the phase noise introduced by the fiber due to mechanical stresses and temperature variations, using a bidirectional Doppler cancellation technique [5].

The development of this optical fiber networks is of major interest also for high–tech industries, making available high quality T&F signals in real time, without the need of routine calibration. This research field is growing worldwide, and it is well represented in the European metrology scenario within the EU metrological program EMRP (NEAT-FT project). Among the present challenges for optical links, there is the investigation on new techniques for phase-coherent comparison of remotely located optical clocks, separated by distances of up to 2000 km using optical fiber links. Within this challenge is the development of the equipment necessary for reliable operation of fiber links and all technological steps towards a full and reliable optical link infrastructure. Moreover, these infrastructures should be easily adaptable to perform widespread dissemination of high performance metrological signals towards a larger variety of users, so the development of scalable, modular equipment is needed.

The National Institute of Metrology (INRIM) realizes in Italy accurate T&F signals and disseminates them to a variety of scientific laboratories and industries. Presently, INRIM maintains two Cs fountain primary frequency standards, with an accuracy at the 10^{-16} level [6], and is developing an optical clock based on Yb atoms [7]. To improve the quality of T&F dissemination, INRIM realized together with other major National Institutions, the LIFT project (the Italian Link for Frequency and Time) an optical link along a 642 km fiber that connects Torino to Milano, Bologna, and Firenze, under operation since May 2013 [8]. This optical link is based on a dark fiber architecture, i. e. the fiber is completely dedicated to the experiment. Besides the Torino-Firenze optical link, INRIM has installed a local coherent fiber link in Torino, using a 47 km haul normally used for internet data traffic [9] on a dark channel architecture.

The electronics involved in both links is well established [10] and is based on a frequency mixer used as phase comparator, joined with a frequency divider to extend its phase input and a tracking oscillator or a quartz filter to clean up the beat note of the local laser with the round trip radiation. In addition, a couple of frequency-meters are needed to evaluate the correction to apply to the laser for the link compensation and to monitor the system.

In this work, we propose an alternative digital solution that integrates the whole electronics for detection, compensation and monitoring in a single board based on three DDS driven by an FPGA. The system is compact, flexible and cost effective, providing a complete characterization of the link and the modularity for more complex architectures, such as the multi-point delivering of the ultrastable laser along the haul for real coherent optical fiber networking [11]

II. COHERENT OPTICAL LINK

The optical link allows to transfer an ultrastable laser signal over long distance without appreciable degradation of its phase/frequency by compensating the fiber noise. Fig. 1 shows a particular arrangement suitable for comparing two remote ultrastable lasers. The link is bidirectional and allows to detect potential link anomalies by comparing the measures of the two laboratories. The figure also groups the optical components and the electronics. Here we focus on the electronics involved whose tasks are: 1) detection of the fiber noise φ_e; 2) calculation and applying the correction φ_c; 3) monitoring the link by detecting φ_m. In addition, some phase/frequency meters are necessary to register the main signals, i. e. the correction to the fiber and, primarily, the monitor that, in the figure, is the result of the ultrastable lasers comparison.

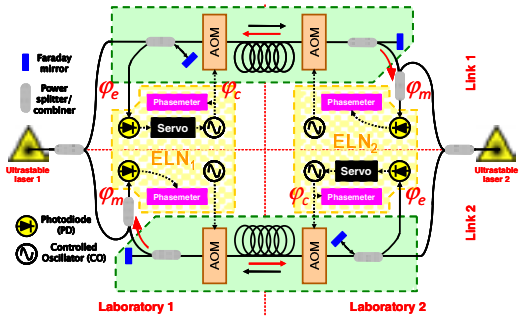

Fig. 1. Bidirectional coherent optical link

In Fig. 2 we also show the experimental set-up.

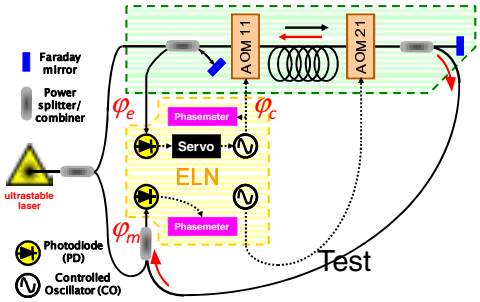

Fig. 2. Experimental setup

A. Traditional analog implementation

The analog implementation (Fig. 3) is well established and proved to allow coherent frequency dissemination over hundreds of kilometers with a residual uncertainty in the 10^{-19} range [1, 2].

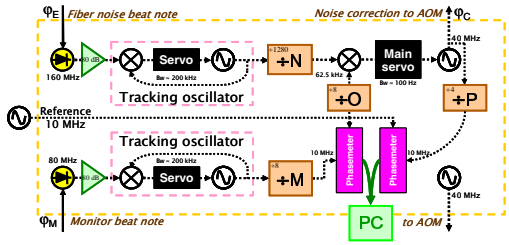

Fig. 3. Analog implementation of the fiber link electronics

In principle, the electronics is very simple: one mixer to detect the beat note that contains the fiber noise, an operational amplifier to generate the correction and a Voltage Controlled Oscillator (VCO) to drive the AOM. In practice, some additional circuitry is necessary: some frequency dividers to extend the mixers input range and a couple of tracking oscillators to clean-up the beat notes in order to properly drive the frequency dividers. The most expensive part is represented by the instruments used to record the signals: phase-meters are the natural choice, being the phase proportional to the optical length, but we often encounter frequency-meters. They are cheaper, but introduce some complications in data analysis due to dead time and to phase noise type.

B. Implementation with Tracking DDS

The proposed implementation can be conceptually obtained by the analog one by simply substituting the VCOs with Direct Digital Synthesizers (DDS) [12, 13] and, consequently the analog servos with digital ones implemented on FPGA (see Fig. 4).

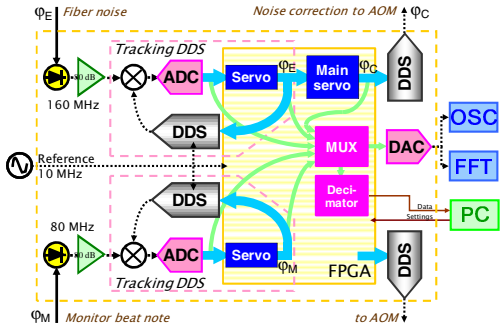

Fig. 4. Fiber link electronics based on Tracking DDS.

The DDS is used in a different manner with respect to the VCO, because the servo drives its phase instead of its frequency. In this manner, by considering the phase imposed to the DDS to track the beat note, we have direct access to the information required φ_e (φ_m). The fiber noise data is then processed by the main servo to calculate the correction that is applied to the AOM by directly driving the phase φ_c (and not the frequency) of the DDS.

The information of interest (φ_e, φ_m and φ_c) is digitally represented and available without the need of any additional

instrumentation. It can be sent to a PC by means of a module implemented in the FPGA that integrates a decimator to reduce data rate and to set the measurement bandwidth that, consequently, is well defined.

In addition, the internal data can be sent to a DAC to have their analog representation that can be observed with the traditional instruments: FFT spectrum analyzer and oscilloscope.

C. Cycle slips

The noise and consequently the required tracking bandwidth is proportional to the length of the link. The actual bandwidth (about 15 kHz) is limited by the time required to write data in the DDS via a serial bus. It is suitable for medium link, up to 50 km. The presence of non-stationary extra noise causes cycle slips. They will be avoided by using in the next design a DDS with parallel data bus that will allow to reach a tracking bandwidth of about 500 kHz. For the moment, we have to remove them for properly analyzing the data.

We tried two algorithms: the first (algorithm A) simply removes discontinuities larger than a suitable threshold; the second (algorithm B) removes discontinuities multiple of half a cycle. The latter can be applied only if the peak-to-peak noise is lower than half a cycle and this can be reached (even for long link) by closing the measurement bandwidth to a few hertz, in order to filter out the big bump from 10 Hz to 1 kHz in the spectrum of the monitor. The second algorithm works much better as shown by the figure below.

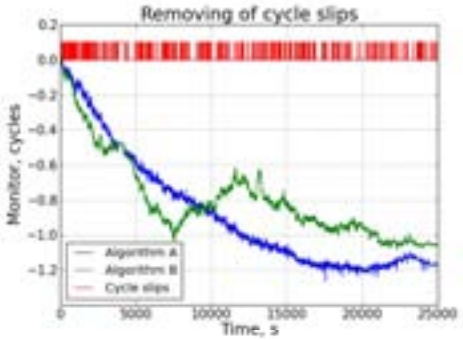

Fig. 5. Comparison of two techniques for cycle slips removing.

III. Results

The electronics based on the Tracking DDS has been tested on a 47 km long loop in Torino. Taking advantage of the loop configuration, it is possible to compare the output of the fiber with the ultrastable laser at the input of the link and get a characterization of the complete system. In addition, it is possible to get the two beat notes and drive the two AOMs with one electronic system.

To demonstrate that the electronics presented is able to fully characterize the link, we report the spectrum up to 100 kHz of the monitor (φ_c) and of the closed loop fiber noise (φ_e). They are obtained by using the DAC output and an FFT spectrum analyzer (Fig. 6 And Fig. 7). We can deduce many informations, such as the bandwidth of the two tracking DDSs, the main loop bandwidth, the one-way and round-trip delays. In particular Fig. 7 shows the easy and fast tuning of the main loop by digitally changing its gain.

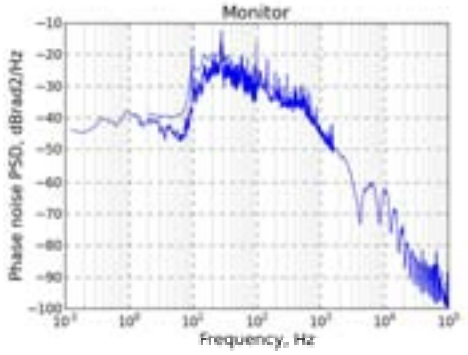

Fig. 6. Monitor PSD from DAC output.

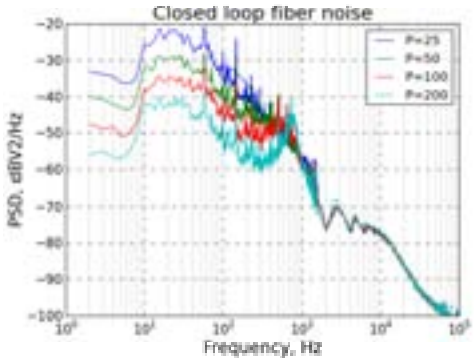

Fig. 7. Closed loop fiber noise (from DAC) with different loop gains

On the other hand, it is possible to directly analyze the downloaded data in the auxiliary PC. The available bandwidth is 4 kHz, and is wide enough to characterize the link. The measurement bandwidth is well defined and can be adjusted by setting the integrated decimator.

The monitor is in the femtosecond range in front of correction to the fiber of hundreds picoseconds (Fig. 8 and 9).

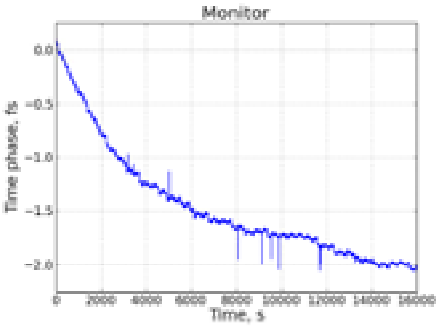

Fig. 8. Monitor signal (φ_m) in time domain.

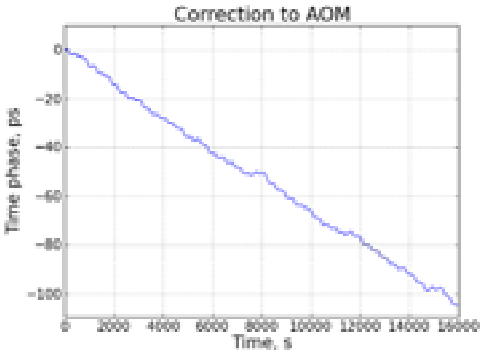

Fig. 9. Correction to the fiber (φ_c).

This allows to disseminate an ultrastable laser with a residual fractional frequency noise of about 10^{-17} at 1 s reaching $4x10^{-20}$ at 1000 s (Fig. 11).

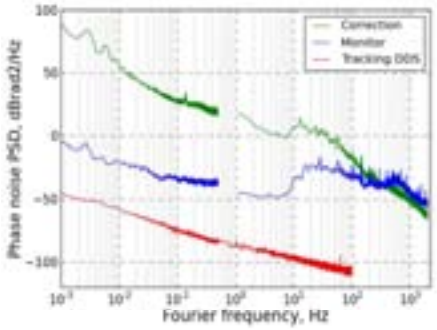

Fig. 10. Phase noise PSD of φ_n, φ_n, and Tracking DDS.

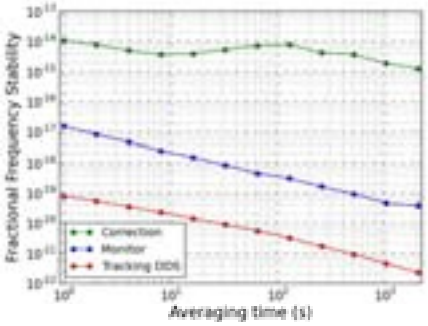

Fig. 11. Allan deviation of φ_n, φ_n, and Tracking DDS. Measurement bandwidth: 0.5 Hz.

IV. CONCLUSIONS

We implemented and characterized the digital electronics for coherent optical link. The digital architecture is based on a tracking DDS driven by an FPGA. The system is very flexible allowing fast and easy tuning as well as monitoring the data of interest, without any external instrumentation. Its digital nature makes it suitable for remote operation, opening new possibilities of application, such as intermediate laser regeneration in very long optical links.

It has been tested on a real urban link exhibiting a frequency stability of 10^{-17} at 1 s and reaching the 10^{-20} region at 1000 s.

We are developing a new version with extended tracking bandwidth that will allow to use this technology in very long optical links.

Abstract—**This paper proposes a one point to multi-point distributed time transfer scheme using optical fiber links. The corresponding control protocol and adapters for the proposed scheme are designed and implemented. A 1 to 8 experimental system over 20km single-mode fiber with stabilities less than 50ps is demonstrated.**

Keywords-time transfer; optical fiber; distibuted time transfer; one point to multi-point time transfer;

I. INTRODUCTION

Time transfer over optical fiber links [1-9] has attracted extensively interests due to its advantages of broad bandwidth, low loss and so on. Up to now, research on optic-fiber time transfer is mainly focused on the point-to-point transmission [1-9]. However, high precise distributed time transfer is also demanded by many applications like distribution system, locating faults, and scientific experiments [11]. The distributed time transfer can be conducted through coaxial cable or satellite channel [12-13] with electrical distributor. But these schemes have several disadvantages, such as susceptible to transmission interference, high loss, low stability, and so on. J. Laufl et al. has proposed a distributed time transfer over optical fiber link with electrical distributor [10]. Although optical fiber link has better performance than coaxial cable or satellite channel, electrical distributor will lead to extra electrical noise and is complexity since it is an active device and needs O/E/O conversion.

In this paper, we propose a distributed time transfer scheme over a one point to multi-point passive fiber optical network. The distributed control protocol and adapters for the proposed scheme are designed and implemented. A 1 to 8 experimental system over 20km single-mode fiber is demonstrated. The stabilities in different conditions are measured. The results show that stabilities less than 50ps can be reached.

II. DISTRIBUTED TIME TRANSFER SCHEME

Fig.1 illustrates the system architecture of the proposed distributed time transfer over fiber link, where a master node is connected to several slave nodes through an optical distribution network (ODN) made up of passive optical splitters and optical fibers. Different topologies such as star and tree can be adopted on the basis of certain application requirements. Bidirectional optical amplifier can also be used on each sub-link to increase the transmission distance. Slave nodes are accessed to the master node using a time division multiple access (TDMA) mechanism. The clock at each slave node is compared to the high precise reference clock at the master node by two-way time transfer method [5-9] during each assigned sub-period, and is free running on the other time.

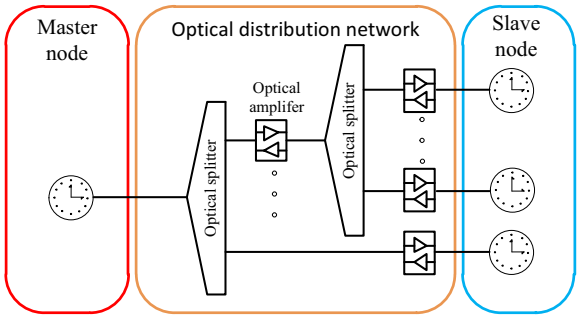

Fig. 1 The architecture of the proposed distributed time transfer over optical fiber

The TDMA control mechanism for the proposed scheme is illustrated in fig. 2 schematically. The whole procedure works periodically under the control of the master node. Each period is divided into a series of sub-period corresponding to slave nodes one by one. The control processing step in each period is as follows.

1) Get current slave node according to certain sequence, and enter the corresponding sub-period.

2) There are three processing phases in each sub-period.

Phase 1: The master node broadcasts a connection request that contains the address of the current slave node to all slave nodes by the optical distribution network. The current slave node, whose address is the same as the destination address in the connection request, replies a connection confirmation to the master node. When the master node receives the connection confirmation, the connection between the master node and current slave node is established.

Phase 2: Two-way time transfer between the master node and the slave node are carried out on the built connection in the phase 1.

Phase 3: When the maximum times of two-way time transfer is reached, the master node sends a disconnection request to the slave node, and the slave node replies a disconnection confirmation to release the connection between them.

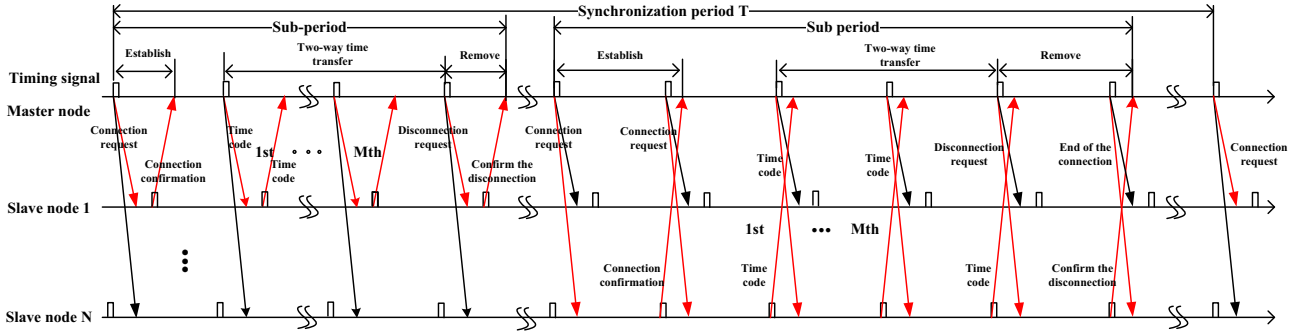

Fig. 2 The TDMA control mechanism for the distributed time transfer scheme

3) If the current slave node is the last one, start a new period. Otherwise, take the next slave node as the current slave node, step into the next sub-period.

III. Experimental System

The experimental setup of the proposed scheme is shown in Fig.3. The system consists of a master node, an ODN made up of a 1 to 8 optical splitter and fibers, and 8 slave nodes. The length of the optical fiber between the master node and each slave node is about 20 km.

Each node contains a Rb clock and an adapter. The Rb clock provides 1PPS and 10MHz to the adapter. Each adapter is used to transmit local time scale to the optical fiber and recover the time scale of remote nodes from received signal. During each sub-period, the difference between the local time signal T_{Si} and the received remote time signal T_{Ri} is measured by a Time Interval Counter (TIC) i at each node. Time difference between the master node and a slave node can be expressed as follows according to the principle of two-way time transfer [5-9].

$$\Delta T_{0i} = \left(TIC_0 - TIC_i\right)/2$$

The i denotes the slave node i $\left(i = 1,2,\cdots 8\right)$.

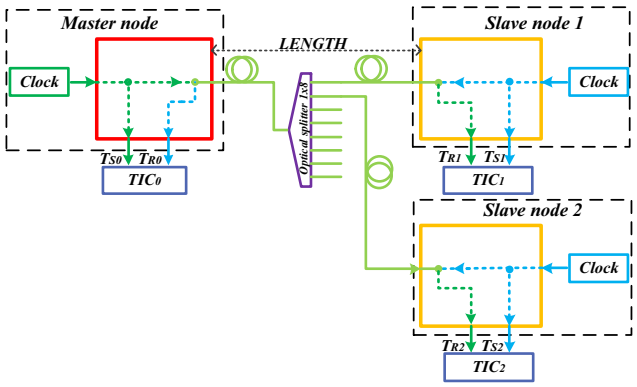

Fig.3 The setup of the proposed distributed time transfer

The picture and the structure of adapter at each node are shown in Fig. 4. It consists of two main components: a FPGA chip and a SFP (Small Form-factor Pluggable) transceiver. In the FPGA, there are four main modules: microprocessor, encoder, decoder, and physical transmit logic unit. The microprocessor is mainly used to carry out the TDMA control protocol proposed in section II. The encoder and decoder are used to complete the encoding and decoding of time code and control protocol frame (Ethernet frame in our experiment), respectively. The physical transmit logic unit is used to implement logic transmission and receive codes. The SFP transmitter is used to implement O/E and E/O conversion.

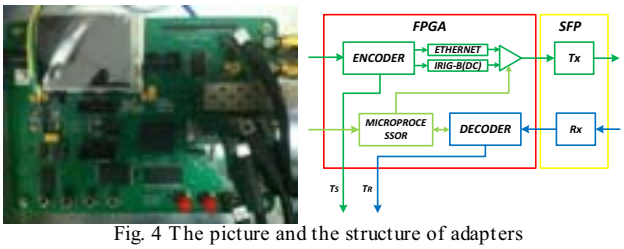

Fig. 4 The picture and the structure of adapters

IV. Results

We performed a set of experiment in order to verify the distributed time transfer via optical fiber links, test developed adapters, and evaluate stability of time transfer in laboratory environment.

Fig. 5 shows the measured results when the sub-period is 1 hour. Blue and Green curves are the measured time difference between the master node and two slave nodes (node1 and node 2), respectively as a function of time. The time division based distributed two-way time transfer with a sub-period of 1 hour can been observed, which is coincident with the TDMA control mechanism in section II. The RMS in every sub-period is also calculated and given as purple and red lines for slave node 1 and slave node 2, respectively. We can see that stability with a standard deviation less than 50ps in each sub-period can be achieved.

Fig. 6 illustrates experiment results when sub-period is 2 hours. We can see that the sub-period of two-way time transfer become 2 hours and the time transfer stability is close to the results in fig. 5.

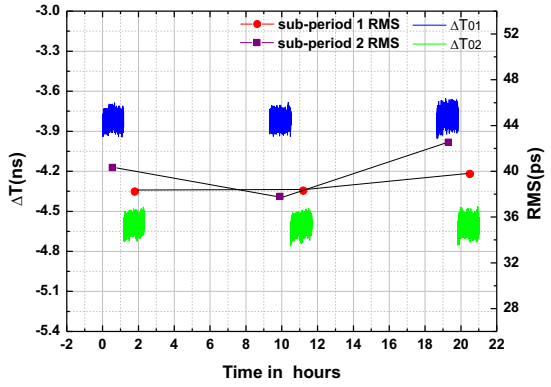

Fig. 5 The measured results when each sub-period is 1 hour. Blue and green are the time difference between the master node and two slave nodes, respectively, and purple and red lines are their RMS in each sub-period

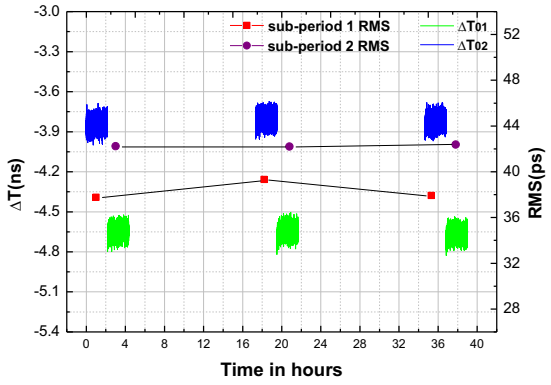

Fig. 6 The measured results when each sub-period is 2 hours. Blue and green are the time difference between the master node and two slave nodes, respectively, and purple and red lines are their RMS in each sub-period

V. CONCLUSIONS

In this paper, a distributed time transfer scheme over a one point to multi-point passive fiber optical network is proposed. A control protocol based on TDMA and adapters for the distributed time transfer scheme are designed and implemented. A 1 to 8 time transfer experimental system over 20km single-mode fiber is demonstrated. The stabilities less than 50ps are reached.

Compass Receiver Positioning Algorithm Under Bad Conditions Based on Unequal Interval Clock Prediction

Jianwei Zhan, Hang Gong, Bo Xu, Guozhu Zhang, Gang Ou
College of Electronic Science and Engineering, National University of Defense Technology, Changsha, 410073, China
sophy_zjw@nudt.edu.cn

***Abstract*—In the typical urban environment where the satellite visibility is limited or the satellite signal is weak due to the blockage or signal jamming, the availability of the navigation satellite system would be degraded, resulting in conventional four-satellite positioning method is very hard to satisfy the requirement of continuous positioning. To solve this problem, a combined prediction model based on the improved polynomial model and the improved grey model is proposed, which adopts a time interval coefficient and a dynamic weighting factor to predict the receiver clock bias (RCB), and then a predicted clock value from the proposed model is introduced to aid positioning. The experimental results based on BeiDou Navigation Satellite System (COMPASS/BDS) observation data demonstrate that the model is more suitable for predicting RCB both under unequal and equal conditions. Moreover, for 50 s RCB predictions duration of the short satellite signal shading outages, the three-dimensional (3-D) position error using the clock-aided position algorithm is slightly larger than about 2.76% than four-satellite 3-D position error, and thus, the availability of positions can be improved efficiently.**

Keywords—satellite navigation; receiver clock bias; clock-aided; combined model; unequal interval

I. INTRODUCTION

It is widely known that at least four code pseudorange measurements are required to determine user three-dimensional (3-D) position and receiver clock bias (RCB). However, in certain applications, such as in the underground traffic routes, the tunnels, and park garages, typically less than four satellites are available due to the blockage to receiver-to-satellite line of sights. In the paper, 3D incomplete condition is defined as the situation where only three satellites are available; and 4D complete condition is defined as the situation where at least four satellites are available [1]. In the typical urban environment, the probability of 3D incomplete condition occurrence is more than 10%, and the average duration of the short satellite signal shading outages statistically is about 50 s [2], which would result in statistically longer time to first fix and time to reacquisition. In this case, a position estimate of the movable object can't be determined by the conventional method using at least 4 satellites signals, such as COMPASS-based PVT method. Thus, the availability would be degraded. To solve this problem, a method using additional measurement information from an external sensor can be adopted to provide 3-D position determination, such as a barometer altimeter, RFID, pseudolites, an electronic map, and so on [3-6]. However, the range of the above method with sensor aiding is limited due to the high-cost devices. In contrast, it is a simple, flexible, and cost-effective way to provide clock-aided PVT services with the RCB prediction model.

Recently, several research in RCB prediction model and corresponding positioning algorithm has been presented. The detailed characteristics and limitations are summarized here [7-10]: (1) previous studies focused on chip-scale atomic clocks or oven controlled crystal operator (OCXO), but the receiver clock is not limited to those. For example, a temperature controlled crystal operator (TCXO) is equipped widely in chip receivers as a clock, the frequency of which is stable or changes in a predictable manner over at least 50 s, (2) conventional RCB prediction model is based on the equal interval RCB series. However, because the intermittent characteristics of the satellite signal shading outages, RCB series obtained under the typical urban environment is unequal interval, and (3) a single RCB prediction model has its own characteristics and scope of applications, and the robustness can not be assured in each instance. So further studies are still necessary.

In order to solve the problem under 3D incomplete condition, taking into account the nonlinear characteristic of the RCB series, an improved polynomial model based on the generalized extended interpolation method and an improved grey model are established. Furthermore, a combined prediction model and the corresponding clock-aided positioning algorithm (CA-PVT) are proposed.

II. RCB PREDICTION MODELS

A. Improved RCB Polynomial Model

Assuming that $x(t_1)$, $x(t_2)$, $\cdots$, $x(t_m)$ is the RCB series obtained from COMPASS pseudorange measurements and the difference between t_i and t_{i-1} is not const. Generally, according to the characteristics, the RCB is modeled using a popular prediction polynomial function [11].

$$x(t_i) = \alpha_0 + \alpha_1(t_i - t_0) + \alpha_2(t_i - t_0)^2 + \cdots + \alpha_n(t_i - t_0)^n + w(t_i),\ i > m \tag{1}$$

where $\alpha_0, \alpha_1, \alpha_2, \cdots, \alpha_n$ are parameters estimated from the available measurements; n is the order of the model determined

by means of the residuals; t_0 is the reference time, generally, normalized to 0; $w(t_i)$ is composed of various noise sources, such as phase noise and measurement noise.

Because the RCB data near the time t_n has the greatest impact on the prediction, $\boldsymbol{\alpha}$ can be estimated by means of the least square method. The estimate is defined as:

$$\begin{cases} \hat{\boldsymbol{\alpha}} = \min\limits_{\boldsymbol{\alpha}} \left\| \boldsymbol{x} - \mathbf{H}\boldsymbol{\alpha} \right\| \\ \boldsymbol{x}(t_n) = \boldsymbol{H}_{\mathbf{n},:}\boldsymbol{\alpha} \end{cases} \tag{2}$$

where $\boldsymbol{H}_{n,:}$ is the n-th row of the matrix **.** Eq. (2) can be solved by Lagrange multiplier [12]. And $\boldsymbol{\alpha}$, $\boldsymbol{x}$, $\boldsymbol{H}$ are defined as follows:

$$\boldsymbol{\alpha} = [\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2, \cdots \boldsymbol{\alpha}_n]^{\mathrm{T}} \tag{3}$$

$$\boldsymbol{x} = [x(t_1), x(t_2), \cdots x(t_m)]^{\mathrm{T}} \tag{4}$$

$$\boldsymbol{H} = \begin{bmatrix} 1 & t_1 & \dots & t_1^n \\ 1 & t_2 & \dots & t_2^n \\ \dots & \dots & \dots & \dots \\ 1 & t_m & \dots & t_m^n \end{bmatrix} \tag{5}$$

B. Improved RCB Grey Model

Grey system works on the unascertained systems with partially known and partially unknown information, which reduces the effects of noise and obtain the data regularity by bringing accumulated generating operation and inverse accumulated generating operation [13]. Here the most important section in grey model is that it can achieve a high precision with only a few data. Based on these advantages, we attempt to take the RCB series as a grey system.

Conventional GM(1,1) is established based on the equal interval data and thus can not be directly applied to unequal interval RCB series prediction. Fortunately, several method have been explored in other applications, for example, an amendatory metabolism unequal interval grey model (AMUGM (1, 1)) has been proposed [14], which can be used both in linear and unequal interval series through background value optimized. Compared with other methods, it has wider applications. Therefore, it is a very effective way to utilizing it for unequal interval RCB series prediction. In the paper, only the final expression of the predicted RCB estimate is given as

$$\hat{x}(t_{m+p}) = \frac{1}{\Delta t_{m+p}}(1 - e^{\hat{a}(\Delta t_{m+p})}) \left[x(t_1) - \frac{\hat{b}}{\hat{a}} \right] e^{-\hat{a}(t_{m+p} - t_1)} \tag{6}$$

where $\hat{a}$ is the development parameter; $\hat{b}$ is the coordination parameter. And the unequal interval $\triangle t_{m+p}$ is defined as.

$$\Delta t_{m+p} = t_{m+p} - t_{m+p-1}, p \geq 1 \tag{7}$$

C. Dynamic weighted combined model

As discussed in the previous sections, any single prediction model has its own characteristics and applicability. For example, the physical characteristics of the polynomial model is specific, with good short-term prediction performance, while grey model has long-term prediction performance advantage in the case of only a few observation data available. Therefore, it is an effective method by combining of the improved polynomial model and the improved Grey model via the linear weighted equation.

Let $\hat{x}_p(t_i)$ and $\hat{x}_{GM}(t_i)$ are the smoothed estimates of RCB at the instant time t_i, obtained by the improved polynomial model and the improved AMUGM(1, 1) model, respectively, and $\varepsilon_p(t_i)$ and $\varepsilon_{GM}(t_i)$ are the corresponding errors. Then, the new $\hat{x}(t_i)$ and $\varepsilon(t_i)$ can be obtained using the weighted linear combined model, as follows:

$$\begin{cases} \hat{x}(t_i) = w_{\mathrm{p}}\hat{x}_{\mathrm{p}}(t_i) + w_{\mathrm{GM}}\hat{x}_{\mathrm{GM}}(t_i),\ i = 1, 2, \ldots, m \\ w_{\mathrm{p}} + w_{\mathrm{GM}} = 1 \end{cases} \tag{8}$$

$$\begin{cases} \varepsilon(t_i) = w_{\mathrm{p}}\varepsilon_{\mathrm{p}}(t_i) + w_{\mathrm{GM}}\varepsilon_{\mathrm{GM}}(t_i) \\ w_{\mathrm{p}} + w_{\mathrm{GM}} = 1 \end{cases} \tag{9}$$

where the weighting factors w_{p} and w_{GM} could be estimated by means of the least square method and are constrained to

$$\min_{w} I = \boldsymbol{\varepsilon}^{\mathrm{T}}\boldsymbol{\varepsilon} \tag{10}$$

The solution to (10) can readily be found by first differentiating $\boldsymbol{\varepsilon}^{\mathrm{T}}\boldsymbol{\varepsilon}$ with respect to w_{p}.

$$w_{\mathrm{p}} = \frac{2(\boldsymbol{\varepsilon}_{\mathrm{GM}}^{\mathrm{T}}\boldsymbol{\varepsilon}_{\mathrm{GM}} - \boldsymbol{\varepsilon}_{\mathrm{p}}^{\mathrm{T}}\boldsymbol{\varepsilon}_{\mathrm{GM}})}{\boldsymbol{\varepsilon}_{\mathrm{p}}^{\mathrm{T}}\boldsymbol{\varepsilon}_{\mathrm{p}} - 2\boldsymbol{\varepsilon}_{\mathrm{p}}^{\mathrm{T}}\boldsymbol{\varepsilon}_{\mathrm{GM}} + \boldsymbol{\varepsilon}_{\mathrm{GM}}^{\mathrm{T}}\boldsymbol{\varepsilon}_{\mathrm{GM}}} \tag{11}$$

The dynamic weighted combined model established can be used to make short-term RCB prediction with high precision, but the performance will degrade gradually with time due to the fixed parameters. To solve this issue, a sliding window is proposed to lock the latest RCB, and thus the length of RCB data utilized for modeling is fixed, which reduces the storage capacity and computational load.

III. CLOCK-AIDED POSITIONING ALGORITHM

A. Clock-aided Principle

After generating predicted RCB estimate at some time by utilizing the dynamic weighted combined model, we can augment the basic equation with an additional clock-aided equation to be defined below.

$$\omega_x \hat{x}(t_i) = [0 \quad 0 \quad 0 \quad \omega_x][\Delta x \quad \Delta y \quad \Delta z \quad \Delta t]^{\mathrm{T}} + \omega_x \varepsilon(t_i) \quad (12)$$

where ω_x is the standard deviation of pseudorange measurement error σ_s normalized to the standard deviation of predicted RCB error σ_b. It is a weighting factor to scale the Eq. (12) when σ_s is not equal to σ_b.

B. Receiver Clock-aided Positioning Accuracy

In the case of the CA-PVT algorithm, the positioning accuracy is affected by the prediction performance of the RCB. This impact can be expressed as

$$\boldsymbol{P} = \sigma_s^2 (\boldsymbol{H}_3^{\mathrm{T}} \boldsymbol{H}_3)^{-1} + \sigma_b^2 (\boldsymbol{H}_3^{\mathrm{T}} \boldsymbol{H}_3)^{-1} \boldsymbol{H}_3^{\mathrm{T}} \boldsymbol{C}\boldsymbol{C}^{\mathrm{T}} \boldsymbol{H}_3 (\boldsymbol{H}_3^{\mathrm{T}} \boldsymbol{H}_3)^{-1} \quad (13)$$

where $\boldsymbol{H}_3$ is the 3×3 geometry matrix, $\boldsymbol{C}$ is 3 × 1 vector of ones. As observed in Eq. (13), if the error covariance σ_b of the clock bias is greater than the product of the time dilution of precision (TDOP) and the user-range error (URE) σ_s, the positioning accuracy through the clock-aided method performs worse than the one of the unaided method. Therefore, high-precision clock error prediction model will improve positioning accuracy.

$$\begin{aligned} \sigma_b^2 \sigma_s^{-2} &> (\boldsymbol{C}^{\mathrm{T}}\boldsymbol{C} - \boldsymbol{C}^{\mathrm{T}} \boldsymbol{H}_3 (\boldsymbol{H}_3^{\mathrm{T}} \boldsymbol{H}_3)^{-1} \boldsymbol{H}_3^{\mathrm{T}} \boldsymbol{C})^{-1} \\ &= \mathrm{TDOP}^2 \end{aligned} \quad (14)$$

IV. EXPERIMENT RESULTS AND ANALYSIS

A. RCB Prediction Performance Evaluation

To assess the performance of the proposed CA-PVT algorithm, an experiment is carried out in a typical urban environment in the city of Changsha, China, on March 20, 2013. Observation data is collected by using a fixed COMPASS receiver with a sampling rate of 1 Hz, which includes each visible satellite position, pseudorange, dilution of precision (DOP) and RCB. In addition, SOW of the first epoch is 265151 s, and the standard deviations of pseudorange measurement are σ_{GEO} = 6.5 m, σ_{IGSO} = 4.5 m, $\sigma_s = \sigma_{GEO}$, respectively. To model the scenario under 3D incomplete condition, the elevation cutoff angle is set to 30° during some time, thus, the number of visible satellite would less than four. As a simple illustration of clock prediction, the experimental scenario is shown in Fig. 1.

The *x*-axis and *y*-axis represent the relative time and the RCB using satellite signals, and the three segments suffers from the incomplete condition denoted as A, B and C, respectively. Here, we define $\triangle t_A$, $\triangle t_B$, $\triangle t_C$ as the corresponding duration, for Fig. 3, $\triangle t_A$ = 54 s, $\triangle t_B$ = 14 s, $\triangle t_C$ = 14 s.

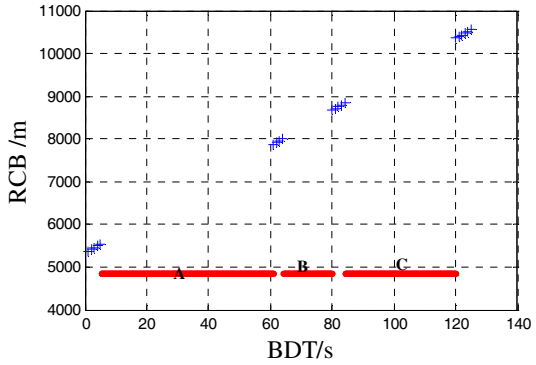

Fig. 1. Experimental scenario in the typical urban environment

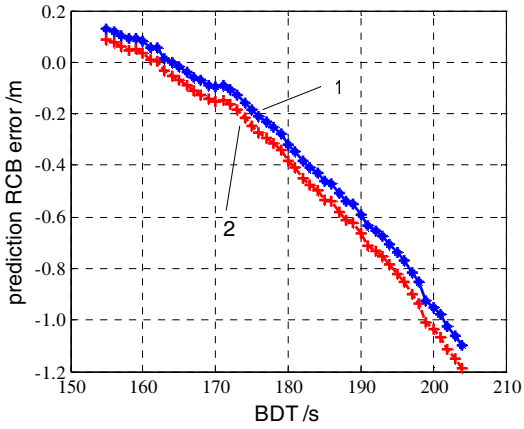
B. Comparison of Combined Model to Polynomial Model

To assess the precision of the RCB short-term prediction, a comparison of urban canyon performance for the combined dynamic weighted combined model to the RCB polynomial model is made based on the above experimental scenario. Since the average duration of 3D incomplete condition is 50 s, a prediction time span 155 to 205 epochs is set, and the results are shown in Fig.2.



1—the combined dynamic weighted model, s= 13.206 m^2,△= 0. 003%
2—the second-order polynomial model, s=16.3175 m^2,△= 0.003%

Fig. 2. Comparison of the predicted RCB estimates using the combined dynamic weighted model and the second-order polynomial model in typical urban environment

From the comparison results, it shows that both the prediction errors grow with the prediction interval. More specifically, at the 175 epoch, the precision error of the combined model is -0.279 m, and the conventional polynomial model is -0.343 m; at the 200 epoch, the errors of the models reach -1.096 m and -1.187 m, respectively. Moreover, the combined model achieves 1.764 m improvement in RMS error. Therefore, the combined model performs well, and is better than any of the single one by dynamic linear weighting.

C. *Clock–aided Positioning Performance Evaluation*

To evaluate the performance of the proposed CA-PVT algorithm, a comparison of the position accuracy between CA-PVT algorithm and COMPASS-based PVT algorithm o is carried out with 20 epoch observation data. The PRN number of satellites utilized in CA-PVT algorithm is C01, C04, and C07, respectively; while in COMPASS-based PVT algorithm, C01, C04, C07, and C08, respectively; and the sampling rate is 1 Hz. Fig. 3 shows the comparison result, which is our main result.

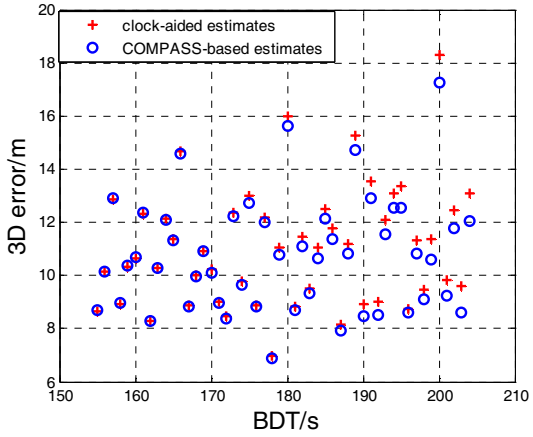


Fig. 3. The positioning result using CA-PVT algorithm and COMPASS-based PVT algorithm

Fig. 3 demonstrates that both the position errors obtained from the two algorithms increase with the prediction time. Note that, because of affected by RCB prediction error, the RMS error with CA-PVT algorithm is 11.263 m, which is slightly larger than the one 10.960 m with COMPASS-based PVT algorithm. However, the level of accuracy with clock-aided remains acceptable for our Standard Positioning Service, and the service is available.

From the comparison in this section, we can come to the conclusion that the PVT performance of CA-PVT algorithm is close to the one provided by COMPASS-based PVT algorithm with four pseudorangement measurement. Therefore, the proposed CA-PVT benefits the continuity and the availability improvement.

V. CONCLUSION

This paper considered the navigation continuity problem of COMPASS receiver equipped with TCXO during short satellite signal shading outages. A combined prediction model and the CA-PVT algorithm have been proposed based on the assumption that the frequency drift rate of TCXO change smoothly and predictably over tens of minutes. The experimental results based on COMPASS observation data show that for 50 s RCB prediction in the urban environment, the 3-D position error using the proposed CA-PVT algorithm is slightly larger than about 2.76% than the one provided by COMPASS-based PVT algorithm with four satellites, and the robustness, the availability and the continuity would be improved efficiently at a low cost.

***Abstract*—We present a proposal of determination of the density shift of the $^1S_0 - ^3P_0$ clock transition in neutral cold strontium atoms. Since the direct use of the double forbidden, intercombination clock transition (698 nm) may be difficult we propose to use a three photon photoassociation. The measurement will be performed with the magneto-optical trap set-up designed for the experiments with both ^{88}Sr and ^{87}Sr isotopes.**

I. Introduction

Recent progress in optical atomic clocks with neutral strontium atoms in an optical lattice allows reduction of the clock uncertainty to 10^{-16} level [1]. The most important contribution to the accuracy budget in strontium atomic clock comes from the black body radiation (BBR).

Another important contribution to the accuracy budget comes from cold atoms collisions in the lattice. Cold collisions of neutral atoms lead to the density shift of the measured clock transition. This effect can be reduced by lowering atomic densities but to reach the accuracy below 10^{-16}, cold collisions have to be investigated more precisely.

In this work we report apparatus for determination of the scattering properties of atoms in the $^1S_0$ and $^3P_0$ states. We plan to perform direct measurements with the clock transition (698 nm) or to use a three photons photoassociation with the 689, 688 and 679 nm lasers. The measurement will be performed with the magneto-optical trap which allows one to cool down strontium atoms to few μK. Along with the photoassociative measurements, we are building in our laboratory the second set-up, exclusively designed as the optical lattice atomic clock with strontium atoms. This second set-up will be used as a frequency reference.

II. Photoassociation

Density shift in a cold atomic sample depends on the scattering length a, which is determined by a difference between the energy of collision and the closest bound molecular state (Δ in Fig. 1). Δ can be measured by observation of photoassociation and creation of molecules. For efficient photoassociation, a high density of atoms (high collision rate) is required and can be ensured in a magneto-optical trap operating on the $^1S_0 - ^3P_1$ transition.

Direct measurement with one photon (near the clock transition) may be difficult, since the $^1S_0 - ^3P_0$ transition is very weak. Nevertheless, it may be enhanced by broadening of the transition by the magnetic-field induced mixing of the $^3P_0$ and $^3P_1$ states [2].

Another way to reach a bound state involves three photons. The intercombination $^1S_0 - ^3P_1$ transition at 689 nm (natural width around 10 kHz) can be used together with the $^3P_1 - ^3S_1$ and $^3S_1 - ^3P_0$ transitions at 688 an 679 nm respectively (both with natural width in MHz range).

III. Apparatus

The photoassociation measurement will be done with the existing set-up, consisting of a Zeeman slower [3], blue and red magneto-optical traps [4]. The apparatus allows cooling atoms down to μK temperate.

Atoms are first cooled in the blue MOT. 679 and 707 nm repumping lasers are used in this stage. High magnetic field

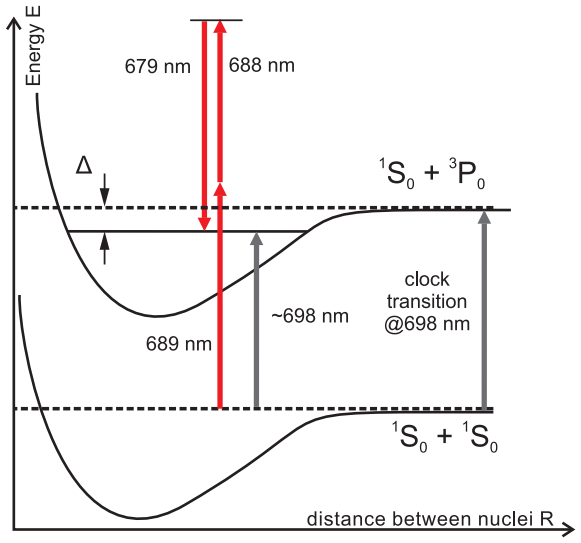

Fig. 1. Two possible ways to photoassosiate atoms close to the clock transition.

gradient (up to 100 G/cm) allows trapping atoms in the triplet state in a magnetic trap [5] which can be used to trap simultaneously several isotopes. In the red MOT we can trap up to 10^7 atoms.

The second cold strontium apparatus is under construction. The set-up is designed exclusively as an optical atomic clock with ^{87}Sr. At the moment the blue MOT is already working. Further cooling in this set-up will be done in an optical lattice by the 689 nm laser. At the moment, the optical lattice at the "magic wavelength" [6] is being installed.

For the photoassociative measurement we will use the 689 nm laser with spectral width below 8 Hz. The laser frequency can be tuned up to 20 GHz. The laser is offset locked to a master laser which is stabilised to the ultra-stable cavity [7]. The 688 nm laser is under construction together with the clock laser for the 698 nm strontium line.

The optical lattice clock together with an optical frequency comb would serve as a frequency reference. The comb is stabilized to a rubidium standard. Long term drift is removed by a lock to the GPS signal.

IV. Plans and conclusion

Presently, we are performing photoassociative spectroscopy with the 689 nm laser. In near future, with the clock and the 688 and 679 nm lasers we want to determine the density shift of the clock transition in strontium. At the same time we are building the second cold strontium set-up which will serve as a frequency reference.

***Abstract*—High voltage radio frequency (RF) supply is a critical part in the ion trap system. To predict the resonant frequency of the RF supply for the ion trap, we model the helical resonator and the ion trap as a lumped element circuit. Based on the model we present the construction process of a helical resonator. We measured resonant frequency for different loads. The experimental results are in good agreement with our model.**

Keywords- ion trap; helical resonantor; resonant frequency

I. INTRODUCTION

Radio frequency (RF) ion trap has found a wealth application in many fields of fundamental as well as applied physics in recent years. Microwave atomic clocks [1, 2] and optical atomic clock [3, 4] have been built based on several different ions. Ion trap is also an important tool in quantum simulation [5] and quantum information processing [6] since the external degrees of freedom of the ions can be cooled down to the vibrational ground state and the ions feature long coherence time. Ion trap can also be employed in mass spectroscopy[7].

RF drive for ion traps should feature both high voltage and high frequency. High voltage RF for the trap means large trapping depths and longer trapping lifetimes. Commercial RF amplifiers can generate several watts of RF power, however, the amplifiers and their loads should be impedance matched, and otherwise most of the power will be reflected. In order to transmit as much power as possible into the trap, a high Q-factor resonator is used to match the impedance of a RF amplifier and an ion trap. Applying RF voltages via a high Q-factor resonator reduces the power in unwanted frequencies being applied, reduces their contribution to motional heating of ions [8] and also provides higher voltages per input power. It is generally preferable that a predictable driving frequency of ion trap can be given so that high secular frequency can be obtained [9]. Higher secular frequency means higher efficiency in laser sideband cooling.

The high-Q resonator can be realized through a helical resonator. The unloaded resonant frequency and Q-factor of a helical resonator have been studied before [10]. Generally the unloaded helical resonator can achieve rather large resonant frequency and Q-factor. However, when the resonator is connected to a capacitive load, i. e. an ion trap, the resonant frequency and Q-factor will decreased substantially [11]. Less effort has been made on how to predict the loaded resonant frequency.

In this paper we will model the resonator with a lumped element electrical equivalent model and predict the resonant frequency under the realistic condition when the helical resonator is connected to an ion trap. Based on our model, we constructed a helical resonator and experimentally measured the resonant frequency under different loads to confirm our prediction. We also used the resonator to drive a linear Paul trap to test its practical performance.

II. MODEL

A helical resonator consists of a copper can, one main coil and one antenna coil inside. The main relevant parameters of a helical resonator include the shield diameter D, shield height h, coil diameter d, coil height b, winding pitch τ and coil wire diameter d_0. To realize an optimal resonance these parameters can be chosen according to the empirical study of Macalpine and Schildknecht [10]. They also gave an empirical formula to predict the resonant frequency when the resonator is under unloaded operation.

$$f_0 = \frac{\omega_0}{2\pi} = \frac{48300}{ND}\,\mathrm{MHz} \tag{1}$$

N is the total number of windings of the main helical coil and D is the shield diameter in mm. When a load is connected to the resonator, the resonant frequency will decrease. To analysis the resonant frequency of the combined system, Fig. 1 shows a lumped element circuit to model the helical resonator and its load.

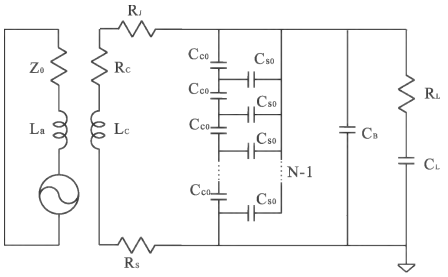

Figure 1. Diagram showing the equivalent circuit.

The resonant frequency of the whole system can be calculated by:

$$f_l = \sqrt{\frac{C}{(C+C_l)}} f_0 \tag{2}$$

Here f_0 is the unloaded resonant frequency of the helical resonator which can be calculated from the above empirical formula (1). Therefore we can use the following equation to calculate the resonant frequency of the loaded system:

$$\omega_l = \sqrt{\frac{C}{(C+C_l)}} \frac{2\pi \times 48300}{ND} \tag{3}$$

Here C_l is the capacitance of the equivalent total load, C is the equivalent capacitance of the resonator without load. The equivalent total load includes the effects of the BNC connector of the output of the helical resonator, the wire between the BNC connector and the ultimate load.

The equivalent capacitance of the resonator without load should include the contribution of two parts: *Cs* and *Cc*. *Cs* is capacitance between the helical coil wire and the surrounding shield. *Cc* is the self-capacitance of the helical coil. The two values can be calculated from the empirical formula.

Here Cc is given by [11]:

$$C_C \approx (0.1126\frac{b}{d}+0.08+\frac{0.27}{\sqrt{\frac{b}{d}}})d\times 10^{-10} \quad (4)$$

Cs is given by [11]:

$$C_S \approx 39.37b\frac{0.75}{\log\left(\frac{D}{d}\right)}\times 10^{-12} \quad (5)$$

When *Cc* and *Cs* are combined to form *C*, it is not a simple relationship of parallel connection or series connection. Figure 1 shows how the equivalent capacitance *C* is composed from *Cs* and *Cc*. Here C_{C0} = (N-1)*Cc* and C_{S0} = *Cs*/(N-1). From Fig. 1 the equivalent *C* can be calculated.

III. CONSTRUCTION

We constructed a helical resonator to confirm our analysis. First we choose the f_0 to be 50 MHz. Then *N* should be about 9.5 according formula (1). Since the coil diameter *d* should be in the range such that 0.45< *d/D* <0.6. We choose it to be 55mm. additionally the axial length of the coil *b* should be restricted in such a way that *b/d* > 1. We choose it to be *b*=83 mm. Furthermore, lengths for the shield should be *h*=*b* + *D*/2=133 mm. The winding pitch is given by τ=*b*/*N*=8.7 mm. The ratio *b/d* here determines the valid range of the wire diameter d_0 to the pitch should be $0.4<d_0/\tau<0.6$. We choose d_0 to be 5 mm. This wire size is expected to be so rigid that it is not susceptible to mechanical vibrations. Diameter of the antenna coil is half of the coil and antenna coil is generally wound into 2-3 turns.

The antenna coil is constructed out of 2 mm wire. For the main helix coil which has a diameter of 5 mm, since it is very important to maintain the winding pitch and the diameter to be constant, we use a specialist machine and a tube to wind the coil. Since it is hard to solder the coil to the shield, the main coil is attached to the shield by soldering it onto a BNC connector. Then a BNC short head is connected to it, which is on the outside of the shield. In order to minimize the coil to shied capacitance the coil is placed centrally inside the shield.

In order to obtain good couple between the antenna coil and main coil, the distance between them is designed to be adjustable. The top hat and the shield are designed with matching thread. Turning the top hat changes the distance between the two coils. Thus the couple of the antenna coil and the main coil can be adjusted. This adjustment can allow an optimal coupling. Figure 2 shows the picture of the helical resonator.

Figure 2. Picture of the helical resonator.

IV. TEST AND RESULTS

We use different loads and measure the resonant frequency as well as the Q-factor when these loads are connected to the resonator. Several different length coaxial lines are used as the capacitive loads of the resonator. The resonant frequency of the helical resonator is analyzed with Agilent E5061B analyzer.

Figure 3 shows a plot of the resonance frequencies as a function of the capacitances of the loads. We are interested in capacitance range from 5 pF to 50 pF since this is the typical range over which the generally used ion trap capacitance can vary. It can be seen from Fig. 3 that the resonance frequencies decrease as the capacitances increase, and the result fit with our model nicely.

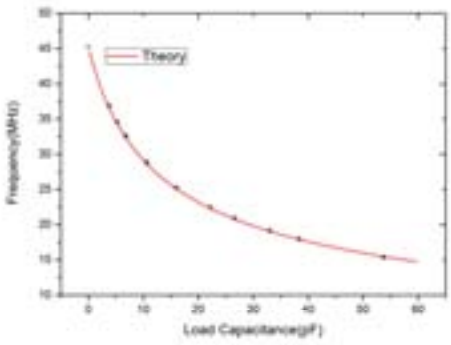

Figure 3. Resonant frequency as a function of the load capacitance.

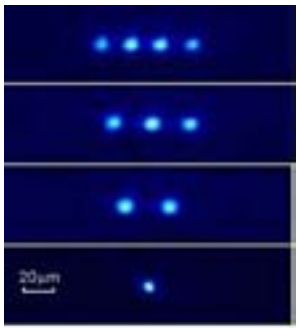

Figure 4. Picture of the trapped ions.

To test the practical performance of the resonator, we used it to drive a linear Paul trap. The Q-factor of the resonator was still about 300 after the trap is connected. A 24.77 MHz RF drive was applied to the blade electrodes through helical resonator. A 280 nm FHG laser from Toptica is used to cool and detect the ions. Pictures of $^{24}Mg^{+}$ are recorded by an EMCCD camera (DU-897D-CS0-UVB, Andor). The result is shown in Fig. 4.

V. CONCLUSION

In conclusion, we have shown a model about the helical resonator and load, predicted the resonant frequency and Q-factor. We constructed a helical resonator and measured its resonant frequency and Q-factor under different loads. The experimental results are in good agreement with our model. Good performance of the RF driver will make it useful for applications of ion trap systems.

Determination of Mode Number Using Two Laser Combs with Large Difference in Repetition Rate

Jin-Long Peng, Tze-An Liu, and Ren-Huei Shu
Center for Measurement Standards
Industrial Technology Research Institute
Hsinchu, Taiwan
jlpeng@itri.org.tw

***Abstract*—Two Er-fiber laser combs with repetition frequency of 500 MHz and 400 MHz are used to measure the frequency of a free-running external cavity diode laser. The mode number is determined by operating the 500 MHz comb at two different repetition rates while keeping the repetition rate of the 400 MHz comb unchanged. A monochromator measures the wavelength of the ECDL to offers an approximate mode number to help determining the mode number shift between the two repetition rates of the 500 MHz comb. The mode number of the beating comb line can be determined with short average time of 1 s.**

Keywords-optical frequency measurement; optical frequency comb; mode-locked laser; mode number; dual-comb

I. INTRODUCTION

Mode-locked (ML) femtosecond laser functioning as an optical frequency comb has revolutionized optical frequency metrology over a decade [1]. To measure the frequency of a laser under measurement (LUM) using a mode-locked laser comb, the mode number of the beating comb line must be determined. Besides using a wavelength meter to offer a precise *a priori* knowledge of the frequency of the LUM, mode number can be determined by measuring the beat frequencies at various repetition rates [2, 3]. Using single comb operated at different repetition rate is limited to measure stable optical frequency with fluctuations of some tens of kHz [3]. Peng et al. developed methods based on two combs with repetition rate difference of kHz to measure the mode number, which can be independent of the frequency fluctuations of the LUM [4-6]. However, the two combs need to have almost the same length of laser cavity or their cavity length be tunable to close to each other. Inaba et al. demonstrated the comb mode determination using two combs with large difference in repetition rate [7]. But, they need long measurement time of 1000 s to average down the uncertainty of the beat frequency. Newbury et al. demonstrated dual-comb spectrometer capable of rapid absolute measurement of a dynamic continuous-wave laser within sub-millisecond [8]. However, they need highly coherent dual-comb system phase-locked to optical frequency reference.

In this paper, we demonstrate method that can determine the mode number in short average time of 1 s using two fiber laser combs with large difference in repetition rate and phase-locked to a microwave frequency reference.

II. THEORY

This method relies on measuring the beat frequencies at two different repetition rates of comb1 while keeping the repetition rate of comb2 unchanged. Furthermore, a monochromator is used to measure the wavelength of the LUM to offer an approximate frequency to help determining the mode number shift of comb1 when its repetition reate is changed. First, the LUM is mixed with comb1 at f_{r11} and comb2 at f_{r2} and two beat frequencies f_{b11} and f_{b21} are generated and measured simultaneously. Then, the repetition frequency of comb1 is changed to f_{r12}, while the repetition rate of comb2 remains to be f_{r2}, and two another beat fequencies f_{b12} and f_{b22} are generated and measured simultaneously. For simplicity, assume that the carrier-envelope-offset (CEO) frequencies of the two combs are zero and the signs of the beat frequencies are determined to be positive. Therefore, the frequency of the LUM can be expressed as:

$$f_L = n \cdot f_{r11} + f_{b11} = k \cdot f_{r2} + f_{b21}, \quad (1)$$

$$f_L = (n+m) \cdot f_{r12} + f_{b12} = k \cdot f_{r2} + f_{b22}, \quad (2)$$

where n and k are the mode number of the beating comb lines for comb1 and comb2, respectively; m is the mode number shift of comb1 when the repetition rate is changed from f_{r11} to f_{r12}. From (1) and (2), the mode number n can be derived as

$$n = \frac{m \cdot f_{r12} + (f_{b21} - f_{b11}) - (f_{b22} - f_{b12})}{f_{r11} - f_{r12}}. \quad (3)$$

Also, m can be expressed as

$$m = \frac{n \cdot (f_{r11} - f_{r12}) - (f_{b21} - f_{b11}) + (f_{b22} - f_{b12})}{f_{r12}}. \quad (4)$$

Since all the beat frequencies in the parentheses of (3) and (4) are simultaneously measured, the frequency fluctuation of the LUM can be subtracted; therefore, the beat frequency difference is equal to the frequency difference of the beating comb lines and is independent of the frequency fluctuation of the LUM. To determine the integer n using (3), the uncertainty of the numerator, which is dominated by the

relative frequency fluctuation between the beating comb lines since the two combs are usually phase-locked to a common microwave frequency standard, must be much less than the value of the denominator. For a usual tracking instability of the repetition frequency of 10^{-13}, the relative frequency fluctuation of the beating comb lines in the visible and near infrared range is less than 100 Hz. Similar to [6], f_{r11}-f_{r12} in the order of kHz is large enough to determine n. For a laser comb with repetition rate of 500 MHz, the comb mode near 1560 nm will change only by 1 if the repetition frequency is changed by 1 kHz. Since m is a small integer and all the other terms in (4) except n can be precisely measured, we can use monochromator to measure the wavelength of the LUM to get an approximate mode number n_{approx} and substituted into (4) to replace n and obtain m first. After m is determined, n can be calculated using (3).

III. Experimental Setup and Results

The experiment is demonstrated using two Er-fiber laser combs with repetition rates of 500 MHz and 400 MHz to measure the frequency of a free-running external cavity diode laser (ECDL) at wavelength of 1560 nm (NewFocus velocity 6328H).

The two Er-fiber laser combs have similar σ-type ring oscillator mode-locked by semiconductor saturable absorber mirror and deliver pulses centered at 1560 nm with bandwidth larger than 10 nm. The other part of the fiber laser comb construction is similar to that one published in [9]. Each comb has three output ports. One port is used to detect the repetition frequency and monitor the fiber laser oscillator. The other two ports are two branches of supercontinua. One branch is used for the CEO frequency detection and the other is used for optical frequency measurement. Each fiber comb is located inside an aluminum box of A3 paper size with 6.5 cm thick. To the best of our knowledge, this is the most compact fiber laser comb with an f-2f interferometer inside.

The power of the ECDL is split into two parts by a 3-dB coupler and then combined with the monitor ports of the two combs with two 3-dB combiners. The outputs from the two combiners pass through two monochromators to filter the beating comb lines. To measure the wavelength of the ECDL, the two combiners are first disconnected from the two combs. The wavelength of the ECDL is determined when maximum power passed through the monochromator is measured. The measured wavelength is 1560±10 nm, which corresponds to an approximate mode number of 384365±0.7%. Then, the two combiners are connected to the two combs again. The beat frequencies are detected by two InGaAs photodiodes. Two polarization controllers are used before the 3-dB combiners to control the polarization of the comb lines and optimize the beat signals. The beat signals are filtered by low pass filter and counted by two universal frequency counters (Agilent Technologies 53132A). The counters are triggered by an external signal generated from a pulse generator and have a gate time of 1s.

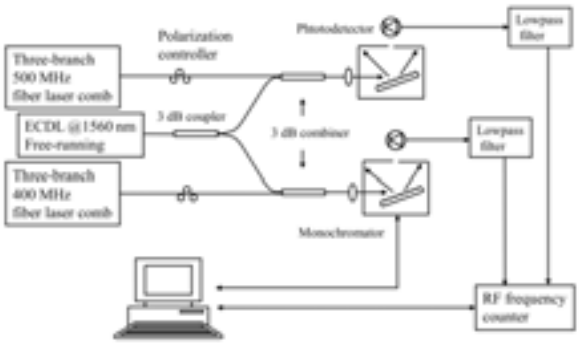

Figure 1. Experimental setup for the optical frequency measurement.

The repetition frequency of comb1 is first controlled to be 500 MHz and that of comb2 is about 400 MHz. The CEO frequencies of the two combs are controlled to be the same value of 140 MHz. The two beat frequencies of comb1 and comb2 mixed with the ECDL are simultaneously counted by the triggered counter and collected by a personal computer through Labview program. The measured beat frequencies are shown in Fig. 2 (a). They are correlated with the frequency drift of the free-running ECDL. The difference of the two beat frequencies is shown in Fig. 2 (b) and not dependent on the drift of the ECDL. Then, the repetition frequency of comb1 is changed to 499.99866 MHz and that of comb2 is not changed. Another two beat frequencies are measured as shown in Fig. 2 (c) and their differences is shown in Fig. 2 (d). The sign of the beat (CEO) frequency is determined by observing the variation of the beat frequency while changing the repetition

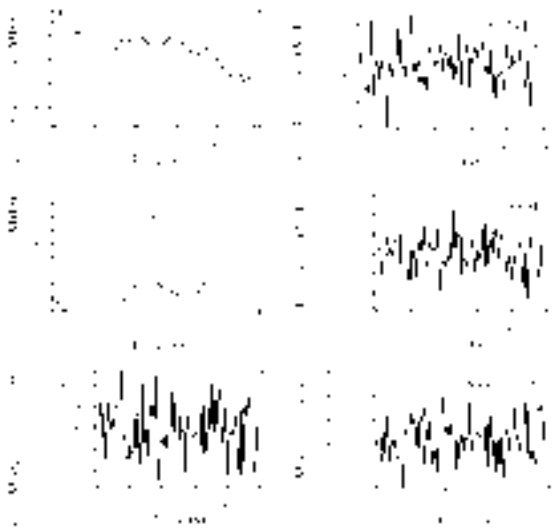

Figure 2. Simultaneously measured beat frequencies f_{b11} and f_{b21} at f_{r11} =500 MHz (a); f_{b12} and f_{b22} at f_{r12}=499.99866 MHz (c); comb2 is fixed at about 400 MHz; dashed line fir of comb1, solid line for comb2. Parts (b) and (d) are the frequency difference of (a) and (c), respectively. Parts (e) and (f) are the calculated m using n_{approx}=384365 and n values, respectively.

(CEO) frequency. All beat frequencies have positive sign. The CEO frequency of comb1 is determined to be negative. The calculated m using n_{approx}=384365 is shown in Fig. 2 (e). The uncertainty of n_{approx} introduces only extra 0.7% uncertainty to the values shown in Fig. 2 (e). It is obviously m=1. The calculated n is shown in Fig. 2 (f). The uncertainty is only 0.09. Clearly, n=384417. The frequency of the ECDL can then be determined to be 384417×500 MHz-140 MHz+f_{b11}.

For average time of 1 s, the maximum fluctuation of the calculated n is only about 0.2; therefore, this method can determine n in short average time of 1 s and is suitable for measuring the frequency of the free-running laser as demonstrated.

IV. Conclusions

We have demonstrated using two fiber laser combs with repetition frequency of 500 MHz and 400 MHz to measure the frequency of a free-running external cavity diode laser. The required average time for the determination of the mode number of the beating comb line is as short as 1s. This method is suitable for measuring the frequency of a free running laser as long as its frequency drift does not interfere the beat frequency measurement.

Abstract—**Many locking approaches have been exploited to stabilize the mode-locked laser (MLL), helping to generate high-stable microwave sources. We present a novel miniaturized stabilization scheme for MLL, based on a rubidium coherent population trapping (CPT) atomic resonator. By directly frequency-locking the repetition rate of the MLL to a ^{85}Rb CPT resonance, we demonstrate a very small stabilization system (length of 5 cm, width of 5 cm and height of 2.2 cm) for MLL with a long-term instability of ~3×10^{-12}.**

Keywords-ultrafast laser, coherent population trapping; frequency stabilization.

I. INTRODUCTION

Ultrafast lasers, based on the phenomenon of mode-locking, have obtained a considerable attention in many fields [1, 2] these years. There is a considerable interest in achieving both so high and stable repetition rate of a mode-locked laser (MLL) as to synthesize a high-stable and low-noise microwave source [3]. To generate the high-stable microwave from a MLL, the MLL should be stabilized to a frequency standard [4]. Many stabilization approaches have been proposed to achieve this [5-12]. In these approaches, the MLLs were phase-locked to very high-stable external frequency references, including atomic microwave, optical clocks, and narrow optical-linewidth continuous wave (CW) lasers. Many experiments have shown that these approaches can improve the stability and phase noise of the MLL significantly. However, the large physical size and system complexity of these approaches is a problem in practical application. A small stabilization system with long-term stability, therefore, should be proposed to meet the portable requirement of some practical applications. In this paper, we demonstrate a miniaturized MLL stabilization scheme to directly frequency-lock the repetition rate of MLL to an atomic CPT resonance [13, 14], generating a stable microwave with a decent long-term stability. The key point of this approach is that this stabilization system is not simply used as conventional locking technique to synchronize the MLL and a frequency reference, but also acts a self-locking loop in an atomic clock to directly stabilize the repetition rate of a MLL to an atomic resonance, where the MLL is similar in spirit to the electronic oscillators. A Rb CPT resonance is chosen as the atomic resonance here because it is easy to miniaturize the physical parts in CPT atomic clock [15, 16]. We built a small ^{85}Rb physics package with the length of 33 mm, width of 13 mm and height of 18 mm, as the frequency resonator, and integrated a frequency-locking servo-loop circuit to stabilize the repetition rate of a MLL to a ^{85}Rb CPT resonance at a hyperfine frequency. With this technique, we achieve a very small ultrafast laser stabilization system with length of 5 cm, width of 5 cm and height of 2.2 cm, leading to a long-term frequency instability of ~3×10^{-12}.

II. SCHEME OF FREQUENCY STABILITION USING CPT RESONATOR

The miniaturized atomic frequency standard based on CPT has been studied for many years [13]. In this paper, we utilize a ^{85}Rb CPT resonator to achieve a miniaturized stabilization system, for directly frequency-locking the repetition rate of the MLL to a ^{85}Rb CPT resonance. In ^{85}Rb CPT, as the decay rate of the ground state coherence is small, the resonance with a small linewidth forms a high-precision frequency reference.

The setup of this MLL stabilization system based on CPT in ^{85}Rb is illustrated in Fig. 1. It contains a ^{85}Rb CPT resonator, a passive Er-doped MLL with fundamental repetition rate of 144.5 MHz, and a servo-loop circuit. The objective of the stabilization system is to directly frequency-lock the repetition rate (the 21st harmonic) of the MLL to the ^{85}Rb CPT resonance at a hyperfine frequency of 3.035 GHz. The frequency of the vertical cavity surface emitting laser (VCSEL) driven by a high-precise laser current source is tuned to the ^{85}Rb D1 absorption line. A bias-T is used to couple the VCSEL injection current, and a RF signal of 3.035 GHz extracted from the MLL is used to modulate the VCSEL. The laser beam illuminates the vapor cell containing a natural mixture of both Rb isotopes (^{85}Rb and ^{87}Rb) and buffer gas (Ne and Ar) to excite the atomic transition and CPT resonance. The good noise properties of the VCSEL improve the performance of the resonator, allowing accurate detection of narrow CPT resonance. A photodetector (PD) converts the variation of the transmitted laser power to an electronic signal. The electronic signal is delivered into two different lock-in amplifiers. One lock-in amplifier is used to control the laser current and stabilize the VCSEL operating at the wavelength of the ^{85}Rb $5^2S_{1/2}$– $5^2P_{1/2}$ transition (D1 line). The other one generates the frequency-error signal to finely tune the pump source of the MLL [17], and then locks the 21st harmonic repetition rate of

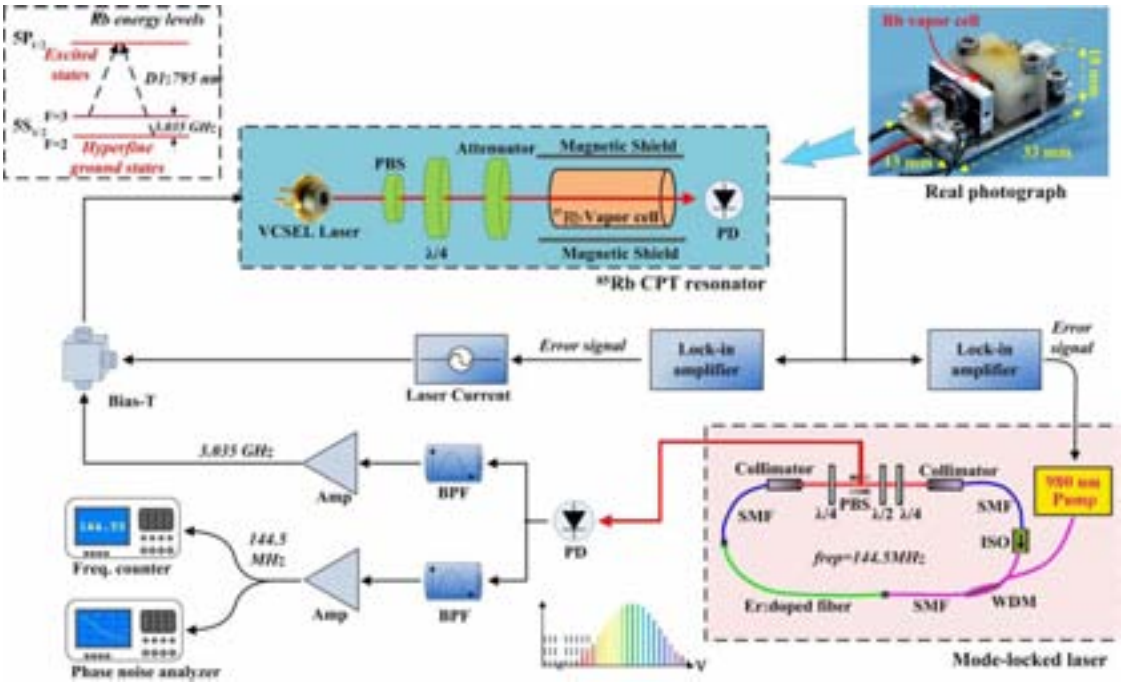

Figure 1. Direct frequency stabilization scheme of MLL with a ^{85}Rb CPT atomic resonator.

the MLL to the Rb CPT resonance. Essentially, these two lock-in amplifiers form two stabilization servo loops. With the help of the servo loops, the VCSEL optical frequency and repetition rate of the MLL are stabilized to the absorption spectrum of ^{85}Rb D1 line and a ^{85}Rb hyperfine frequency of 3.035 GHz respectively. We extracted the fundamental repetition rate of the MLL into a frequency counter and a phase noise analyzer, for measuring the frequency instability and the phase noise.

The key component in our stabilization is the small ^{85}Rb CPT resonator with the length of 33 mm, width of 13 mm and height of 18 mm, and this resonator dominantly determines the physical size of our stabilization. It consists of a VCSEL equipped with integrated microlenses, a small ^{85}Rb vapor cell and a low-noise PD [18, 19]. The schematic of the CPT resonator is also shown in Fig. 1. With the VCSEL laser, phase-coherent first-order sidebands can be generated directly with high efficiency by modulating the laser frequency via injection current. The ^{85}Rb Λ system is used in our resonator because the VCSEL laser operating at the wavelength of the ^{85}Rb $5^2S_{1/2}$– $5^2P_{1/2}$ transition (D1 line) is easily accessible and the modulation bandwidth of VCSEL lasers covers the ground-state hyperfine splitting. In practice, the VCSEL laser emits light close to the 795 nm D1 line in Rb. To tune the wavelength to this line, we adjust the temperature of the VCSEL with a resistive element placed around the laser. The laser beam passes a polarizing beam splitter (PBS), quarter-wave plate and an attenuator lens, where it is circular polarized and attenuated, respectively. Finally, the beam enters a glass blown ^{85}Rb vapor cell, where a PD placed after the cell monitors the transmitted light. The cell is placed at the center of a solenoid which generates a magnetic field to lift the Zeeman degeneracy of the hyperfine states. All physical parts of the resonator are integrated on a magnetic shielded board, and its real photograph is illustrated in Fig. 1.

III. EXPRIMENTAL RESULT

To investigate the performance of proposed stabilization scheme, we conducted a long-term stabilization experiment. The MLL was exposed to the environment with temperature stabilization and air flow control. The 21st repetition rate of the MLL was directly frequency-locked to a Rb CPT resonance at the hyperfine frequency of 3.035 GHz for hours. In addition, to examine the stabilization performance, we compared our direct-stabilized MLL system with a conventional CPT clock (SA.45s, Symmetricom). This clock is a commercial CPT clock, and has a same configuration and physical size of our CPT stabilization loop, where the only difference is that its frequency oscillator is not the MLL but a high-stable electronic crystal oscillator and a microwave synthesizer.

The linewidth of the CPT resonance is a key parameter to determine the short-term instability and the phase noise of the CPT stabilization system [14]. Therefore, we first measured the CPT linewidthes excited by the MLL and an electronic oscillator respectively. Fig. 2 clearly shows that, compared to an electronic oscillator generated from a microwave synthesizer (Agilent N9310), the MLL oscillator excites a narrower linewidth. The linewidth is closely related to the laser light mixed with the microwave at 3.035 GHz, and the purer light will excite the narrower linewidth. Therefore, the

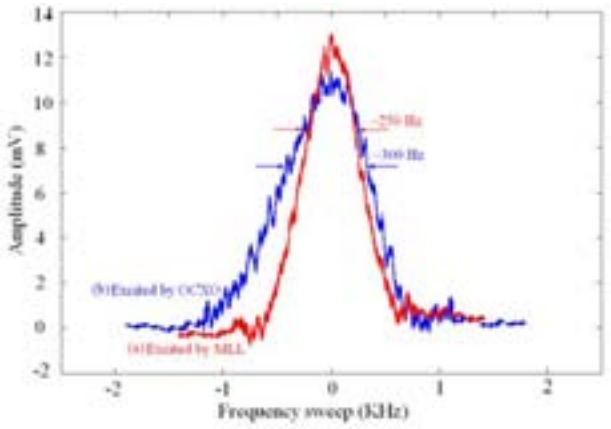

Figure 2. CPT resonance linewidthes are excited by a MLL oscillator and a high-stable electronic oscillator at 3.035 GHz respectively. (a) was excited by the MLL (with the phase noise of ~-110 dBc/Hz at 10 KHz offset). (b) was excited by the high-stable electronic microwave synthesizer (Agilent N9310, with the phase noise of ~-90 dBc/Hz at 10 KHz offset).

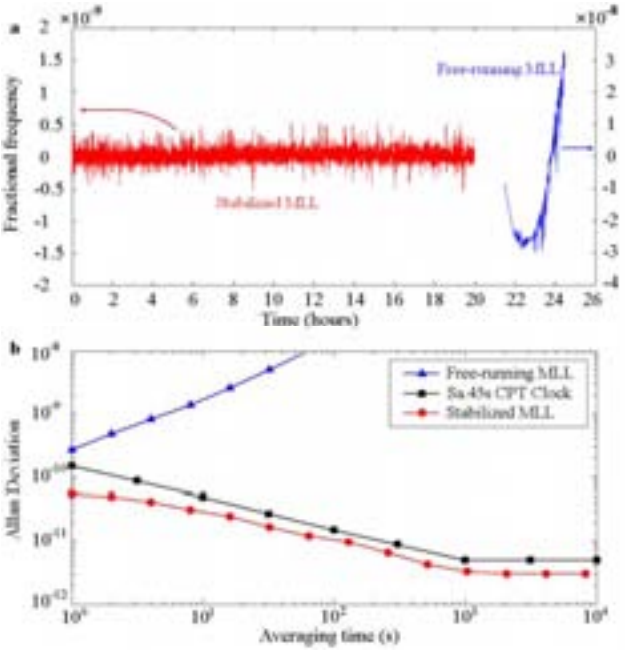

Figure 3. (a) Time records of measured fundamental repetition frequency at 144.5 MHz for stabilized MLL and free-running MLL. The measurements for stabilized MLL and free-running MLL lasted ~20 hours and ~2 hours respectively. (b) Fractional frequency instabilities for stabilized MLL, free-running MLL and a commercial Rb CPT clock.

difference of the linewidthes is primarily due to the qualities of the different microwaves. In fact, with electronic microwave oscillator, it is difficult to obtain a more ultrastable pure microwave than the MLL, because the electronic oscillator and the frequency synthesizer will introduce extra electronic noises and hence deteriorate the quality of the microwave.

We measured the frequency instabilities and phase noises of stabilization system. Fig. 3a shows the frequency drifts of microwaves (fundamental repetition rate of 144.5 MHz) extracted from the free-running MLL and the stabilized MLL. In the figure, we can see that the system using a Rb CPT resonator performs a good stabilization of frequency-locking. The frequency drift of the stabilized MLL shows a flat curve over the measure time (20 hours), for the CPT resonance limits the frequency drifts severely. The frequency instabilities of the microwaves extracted respectively from the free-running and the stabilized MLL are shown in Fig. 3b, and that of a commercial CPT clock (SA.45s, Symmetricom) with the same size as our stabilization system is also illustrated for comparison. The instability of the free-running MLL is 3×10^{-10} for a 1-s gate time and much higher than 10^{-8} for a 100-s gate time (filled triangle in Fig. 3b). The stabilization loop with Rb CPT resonator improves the instability to 5×10^{-11} for a 1-s gate time and about 3×10^{-12} at 1000-s (filled circle in Fig. 3b). The short-term and long-term frequency instability for the stabilized MLL is both a little lower than that of the commercial Rb CPT clock (filled square in Fig. 3b). This shows that the Rb CPT resonator improves the MLL's instability within the whole frequency range, compared to conventional CPT clock with the same physical size.

Fig. 4 shows the phase noises of the microwave extracted from the free-running MLL and the stabilized MLL. A phase noise curve of a microwave signal synthesized from the commercial Rb CPT clock (Sa.45s, Symmetricom) is also illustrated in the same figure. The figure shows that the phase noise of the free-running MLL is ~-45 dBc/Hz at 1 Hz offset and ~-130 dBc/Hz at 1 MHz offset. Compared with the free-running MLL, the stabilization loop with Rb CPT resonance improved the phase noise to ~-67 dBc/Hz at 1 Hz offset. We found the phase noise at 1 MHz offset cannot be improved, because the phase noise at high-frequency off is determined by the MLL in itself. We can see that the stabilized MLL has a lower phase noise than the electronic microwave oscillator at full frequency offset. This implies that the phase noise of the

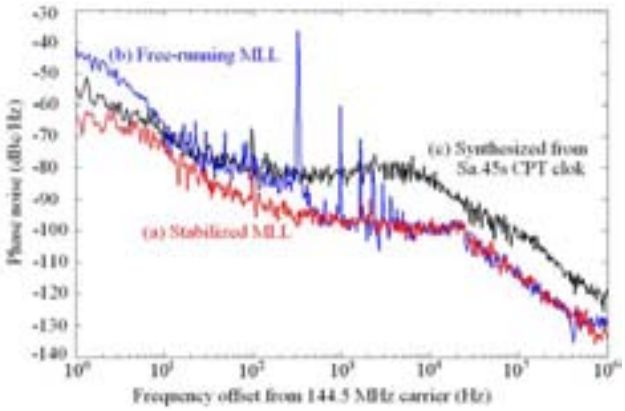

Figure 4. Phase noise spectrum of the generated microwaves for stabilized MLL (a), free-running MLL (b), and microwave signal synthesized from the Sa.45s CPT clock (c).

stabilized MLL using Rb resonance is just limited by the Rb CPT resonance and the optical parts. These experimental results demonstrate that the stabilization scheme using the Rb CPT resonance, with a very small physical size, has a good long-term stabilization performance for the MLL.

IV. CONCLUSION

In summary, the proposed stabilization scheme where the MLL is directly frequency-locked to the Rb CPT resonance is different from the conventional PLL technique. For repetition rate stabilization of MLLs, the most commonly used PLL stabilization schemes [5-7] usually synchronize the MLL to an external frequency standard. Besides, many experiments reported that, with a PID regular, the PLL stabilization technique can perform a good performance of long-term stabilization [5-7]. However, in most case, we find that the frequency instability of a MLL stabilized by the PLL technique is higher than the frequency reference [7]. This implies that the electronic circuits in the PLL will bring the extra stability loss in the stability transfer from the frequency reference to the MLL. In addition, the connection between the external frequency reference and the PLL stabilization system will introduce extra noise in phase and amplitude which reduces the stabilization performance. To avoid the stability loss and the extra noise, an approach which directly stabilizes the MLL to the ^{85}Rb CPT resonance is proposed in this paper. By directly transferring the frequency stability of the atomic hyperfine frequency to the MLL, this approach can improve the frequency stability of the MLL significantly. Besides the improvement in frequency stability, the approach can also simplify the system complexity and dramatically reduce the physical size because of the removal of the PLL servo circuit. Although some PLL stabilization schemes using high-stable Rb or Cs atomic clocks with big physical size have a better instability performance, the miniaturized stabilization scheme with a decent long-term stability is just the advantage of our approach. We believe that the proposed approach have a superior stability to other stabilization techniques with the same small physical size.

***Abstract*—A new collaborative European project "International timescales with optical clocks" (ITOC) aims to tackle the key challenges that must be addressed prior to a redefinition of the SI second. A coordinated programme of comparisons will be carried out between European optical clocks developed in five different laboratories, enabling their performance levels to be validated at an unprecedented level of accuracy. Supporting work will be carried out to evaluate relativistic effects that influence the comparisons, including the gravitational redshift of the clock transition frequencies. A proof-of-principle experiment will also be performed to demonstrate that optical clocks could be used to make direct measurements of the Earth's gravity potential with high temporal resolution.**

Keywords-optical clock; redefinition of the second; international timescales; time and frequency transfer; geodesy

I. INTRODUCTION

The SI second is currently defined in terms of the frequency between the two ground state hyperfine levels of the ^{133}Cs atom. However the most advanced optical atomic clocks have now reached levels of stability and accuracy that significantly surpass the performance of the best caesium primary frequency standards. For example, the Al^+ optical clock at NIST has an estimated systematic uncertainty below 1 part in 10^{17} [1], and several others have reached uncertainties below 1 part in 10^{16} [2–4]. In contrast, the accuracies of the best caesium fountain primary standards are in the range 2 – 5 parts in 10^{16} [5–9]. As a result, an optical redefinition of the SI second is being considered by the international community [10].

The key prerequisite for a redefinition of the second is the integration of optical atomic clocks into the international timescales TAI (International Atomic Time) and UTC (Coordinated Universal Time). This requires a coordinated programme of clock frequency comparisons to be carried out, to validate the uncertainty budgets of the optical clocks, to anchor their frequencies to the present definition of the second, and to establish the leading contenders for a new definition.

Such a comparison programme is planned within a new collaborative European project "International Timescales with Optical Clocks" (ITOC). Since the current satellite link infrastructure used to compare microwave clocks in spatially separated laboratories is inadequate to match the increased stability of optical clocks, several alternatives will be explored, with the emphasis on techniques that could be applied on an intercontinental scale. To support the comparison programme a complete evaluation will also be made of all relativistic effects influencing time and frequency comparisons at the 10^{-18} level of accuracy, including the gravitational redshifts of the clock transition frequencies.

II. CLOCK COMPARISON PROGRAMME

To date, very few direct comparisons of optical clocks have been carried out to verify their estimated performance levels. Frequency comparisons between two Al^+ optical clocks at NIST demonstrate agreement at the 1.8 parts in 10^{17} level, consistent with the estimated uncertainty of the older of the two clocks [1], whilst a recent comparison of two strontium optical

lattice clocks at LNE-SYRTE showed that they agreed to within their uncertainty budget, with a total uncertainty of 1.5 parts in 10^{16} [11]. Both comparisons involved two optical clocks developed in the same laboratory. Almost all information about the reproducibility of optical clocks developed in different laboratories comes from independent absolute frequency measurements made relative to local caesium fountain primary frequency standards. For example, four independent absolute frequency measurements of the optical clock transition in ^{87}Sr agree at the part in 10^{15} level [11–14], whilst similar agreement is observed between two measurements of the electric octupole clock transition frequency in $^{171}Yb^{+}$ [3,15]. However such comparisons are inherently limited by the uncertainties of the primary standards. The ITOC project aims to address this deficiency by carrying out a tightly integrated programme of frequency comparisons between European optical clocks at a level limited only by the accuracies of the clocks themselves.

The proposed clock comparison programme is illustrated in Fig. 1; it involves four different types of measurement and optical clocks in five different laboratories.

Firstly, frequency comparisons will be carried out locally between optical clocks developed in individual laboratories, either by direct beat frequency comparison (for clocks of the same type) or by using femtosecond optical frequency combs to measure optical frequency ratios (for different types of clock). Since it has previously been shown that femtosecond combs do not fundamentally limit optical frequency comparisons at the 10^{-18} level or even lower [16], these types of comparison will lead to the highest levels of stability and accuracy, with the accuracies achieved depending on the limiting systematic shifts for each type of clock.

To compare optical clocks developed in different laboratories, two different techniques will be used. Two comparisons will be performed using transportable optical clocks developed at PTB and MIKES (a strontium optical lattice clock and a strontium ion optical clock). The focus will be on the development and characterization of transportable optical clocks with the best possible levels of accuracy and stability. This is in contrast to other efforts to develop optical clocks for space applications, where these pure metrological goals may be compromised by the restrictions imposed on the mass, size and power consumption of the clocks. Secondly, an improved two-way satellite time and frequency transfer (TWSTFT) technique based on an increased chip rate will be investigated. The goal is a gain in stability by one order of magnitude compared to state-of-the-art frequency comparison techniques via satellite (including various GPS methods) [17], to a stability of 1×10^{-16} after one day of averaging.

Finally, a set of absolute frequency measurements of the optical clocks will be made with uncertainty limited by the caesium primary frequency standards used as the reference. These measurements are essential to allow the frequencies of the optical clocks to be determined relative to the current definition of the second with the lowest possible uncertainty. This will maximize their potential contribution to TAI prior to a redefinition, and also ensure that no discontinuity is introduced at the point of redefinition.

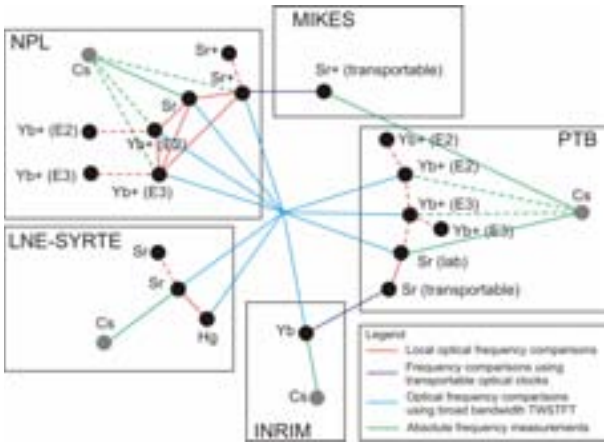

Figure 1. ITOC clock comparison programme. The aspiration for the broad bandwidth two-way satellite time and frequency transfer (TWSTFT) measurement campaign is to compare as many optical clocks as possible in the four participating laboratories. Dotted lines indicated measurements that will be carried out within other projects, but included within the self-consistency analysis performed within the ITOC project.

Within the comparison programme, there will be a sufficient number of cross-checks to allow internal self-consistency checks to be performed. A frequency matrix formalism will be set up and a least-squares analysis procedure developed to perform self-consistency checks on a large body of data for the first time.

When the project was formulated, optical fibre links had already been demonstrated to be suitable for optical frequency comparison at the 10^{-18} level for clocks separated by hundreds of kilometres [18–20], but no links between the laboratories of interest were firmly established. However this situation is soon expected to change and optical clock comparisons performed using such links in other projects will be included in the self-consistency analysis along with other values available in the scientific literature.

The statistical and systematic uncertainties of the optical clocks are not the only important factors when considering their use to derive steering corrections to TAI [21]. Although unattended operation of caesium fountain primary frequency standards with low dead time is now routinely achieved in several laboratories, optical clocks have not yet reached this level of reliability. A local flywheel frequency reference must thus be used to obtain TAI steering data, which results in a significant additional uncertainty contribution. A further uncertainty contribution arises from the performance of available frequency transfer techniques. Whilst currently operational methods offer stabilities which are satisfactory for TAI steering by caesium fountain standards, their performance would significantly degrade the inherent uncertainties achievable with optical clocks. The relevance of these two factors for TAI steering will be quantified, based on the typical performance characteristics of optical clocks, state-of-the-art flywheel oscillators and the expected improvements in frequency transfer techniques.

III. Relativistic Timescales and Geodesy

The levels of stability and accuracy reached by optical clocks are now such that, to derive the maximum benefits from incorporating them into international timescales, relativistic effects influencing the comparison must be evaluated at an improved level of accuracy. These include the Sagnac effect, the velocity of the clocks with respect to an inertial reference frame, and the gravitational redshifts of the clock transition frequencies.

To support the comparison programme outlined in section II, an evaluation will be made of the relativistic effects important in the broadband TWSTFT technique and how these can be corrected or effectively eliminated. The relativistic effects relevant for time and frequency transfer using optical fibre links will also be studied, for which it will be necessary to develop methods to account for signal propagation in a medium with a refractive index larger than unity. Finally, the potential use of continuously operating transportable optical clocks for time transfer will be investigated.

To determine the gravitational redshift corrections for the optical clocks involved in the comparison programme, it is necessary to determine the gravity potential at each clock site. Although only gravity potential differences need to be determined for the frequency comparisons, absolute potential values relative to a defined reference surface are required for future integration of the optical clocks into international timescales. For optical clocks with a projected fractional accuracy of 10^{-18}, an accuracy of about 0.1 m^2s^{-2} in the gravity potential is required, corresponding to about 1 cm in height. This level of accuracy represents a significant improvement on the current state-of-the-art and also requires the evaluation of time-varying effects such as solid Earth and ocean tides due to the effects of the moon and the sun. Setups will be designed to determine the static gravity potential at the clock locations and gravity surveys will be performed around each clock site. These gravity observations will then be included in a re-evaluation of the existing gravity database and used to compute a refined European geoid model. To account for the time-varying effects, tidal potential time series will also be computed for each clock site.

IV. Proof-of-Principle Clock-Based Geodesy Experiment

Although the main focus of the ITOC project is on the future realization of international timescales, we also aim to demonstrate the impact that optical clocks could have on the field of geodesy, by showing that they can be used to measure gravity potential differences over medium–long baselines with sensitivity at the decimetre level.

In contrast to other instruments used for gravity measurements, optical clocks are directly sensitive to the gravity potential, which determines their gravitational redshift. Within the ITOC project we will carry out a proof-of-principle experiment to show that the gravitational redshift of optical clocks can be used to measure the gravity potential difference between two well-defined locations.

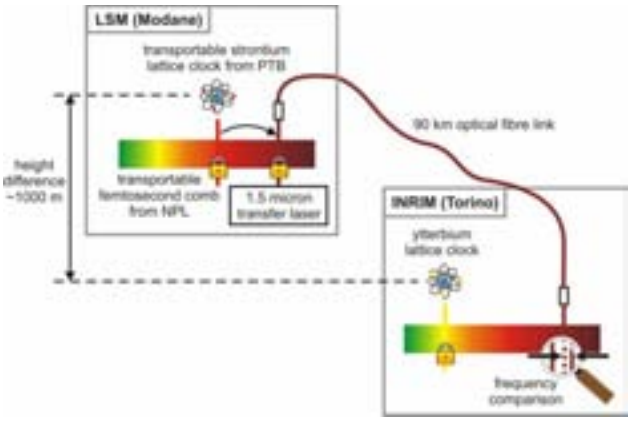

Figure 2. Schematic diagram of one possible configuration for the proposed proof-of-principle clock-based geodesy experiment.

The proposed experiment is illustrated in Fig. 2. One of the optical clocks will be the ytterbium optical lattice clock at INRIM in Turin, Italy. The other will be the transportable strontium optical lattice clock from PTB, which will be taken to the Laboratoire Souterrain de Modane (LSM) in the Fréjus tunnel, just over the France-Italy border. The frequency comparison between the two clocks will be performed using an optical fibre link between the two laboratories. Two optical frequency combs are also required for the frequency ratio measurement between the two optical clocks, because the transmission window of the optical fibre link is at 1.5 μm. Since no frequency comb is available at LSM, a transportable comb from NPL will be used to link the frequency of the transportable lattice clock to that of a 1.5 μm transfer laser.

The INRIM-LSM test-bed offers a large gravity potential difference, with a height difference of approximately 1000 m between the two sites. The expected gravitational redshift is therefore about 10^{-13}, while the target accuracies of the clocks are 5×10^{-17}. Since instability targets are $1\times10^{-15}\,\tau^{-1/2}$ for the clocks and $1\times10^{-14}\,\tau^{-1}$ for the optical link, these accuracies are expected to be reached after a few hours measurement time. Knowing the proper frequency ratio between the two clocks, which will be determined by transferring the PTB transportable lattice clock to INRIM, it should thus be possible to measure the 1000 m elevation difference between two points separated by about 90 km at the decimetre level within a few hours. The value obtained by using the clocks in this way will be compared with the result obtained using standard geodetic methods.

V. Conclusions

The most direct impact of the ITOC project will be on the top-level realization of the SI unit of time, in providing results and procedures to prepare for a future redefinition of the second. This will be achieved by input to the Consultative Committee for Time and Frequency (CCTF) and its associated working groups. In particular, the results will lead to improved frequency values for secondary representations of the second, and independent verification of the performance of optical clocks developed in different laboratories.

The international scientific community will also benefit from validated clock comparisons as a basis for tests of fundamental physical theories. One example is the search for temporal variation of the fine structure constant by comparing transition frequencies in different optical atomic clocks. The demonstrated performance of the ground-based optical clocks will also benefit fundamental science space missions such as ACES (Atomic Clock Ensemble in Space) and STE-QUEST (Space-Time Explorer and Quantum Equivalence Principle Space Test).

The proof-of-principle clock-based geodesy experiment carried out within the project will demonstrate that optical clocks can be used to make direct measurements of the Earth's gravity potential. High-resolution measurements made at selected well-defined locations using transportable optical clocks could bring significant benefits to the geodesy community in terms of achieving a consistent alignment of national height systems within Europe, as well as checks of global and regional geoid models, established by alternative means. Such measurements would also complement the data obtained from satellite missions such as GOCE or GRACE, which provide global coverage but give values that are spatially averaged over length scales of about 100 km.

More generally, accurate time and frequency references underpin numerous technologies that we have come to take for granted in everyday life, particularly in the areas of communication and navigation. Building on the developments realized within the ITOC project, it will be possible to disseminate time and frequency with unprecedented stability to end users of international timescales. In this way, the stability and accuracy of optical clocks, confined today to a few laboratories, will be made available to industry, and can be expected to lead to widespread impact on innovation, science and daily life.

ACKNOWLEDGMENT

The ITOC project is part of the European Metrology Research Programme (EMRP). The EMRP is jointly funded by the EMRP participating countries within EURAMET and the European Union.

***Abstract*—We propose a small satellite mission that aims for testing the foundations of special relativity by performing a Kennedy-Thorndike (KT) experiment. A potential boost dependence of the velocity of light is measured by comparing a length reference (i.e. a highly stable optical resonator) with a molecular frequency reference. By employing clocks with 10^{-16} frequency stability at half orbit time (45 min) and by integration over 5000 orbits (2 years mission lifetime with 50% duty cycle) a 1600-fold improvement in measuring the Kennedy-Thorndike coefficient is targeted, compared to the current best terrestrial test.**

I. Introduction

Many candidates of a quantum theory of gravity, e.g. string theory and loop quantum gravity, predict a violation of the Lorenz symmetry at some scale. In order to test the fundamental assumptions of special relativity, a broader framework – a test theory – has to be considered, in which special relativity is embedded. This framework usually includes a set of parameters. For a specific choice of these parameters special relativity is recovered. The Robertson-Mansouri-Sexl (RMS) theory [9], [11] is such a test theory[1], which allows for a speed of light $c(\vec{v},\theta)$ that depends on the velocity of the frame with respect to some preferred frame[2], $\vec{v}$, and the orientation of the frame, θ:

$$\frac{c(\theta,\vec{v})}{c_0} = 1 + (\alpha - \beta + 1)\,\frac{\vec{v}^2}{c^2} + \left(\beta - \delta - \frac{1}{2}\right)\frac{v^2}{c^2}\sin^2\theta \tag{1}$$

The last term describes the anisotropy of light propagation and is limited by Michelson-Morley experiments to $\beta - \delta - \frac{1}{2} \leq (4 \pm 8)\cdot 10^{-12}$, cf. [6]. The Ives-Stilwell experiment measures the relativistic Doppler effect. The current most precise experiment yields $\left|\alpha + \frac{1}{2}\right| \leq 8.4 \cdot 10^{-8}$, cf [10]. The first term in Eq. (1) describes the velocity dependence of the velocity of light. The current best Kennedy-Thorndike experiments to measure this term were carried out by Tobar et al., see [4], and give for the KT coefficient $\alpha - \beta + 1 = -(4.8 \pm 3.7)\cdot 10^{-8}$. In the framework of the RMS theory, the Kennedy-Thorndike experiment, the Michelson-Morley experiment and the Ives-Stilwell experiment are sufficient to validate special relativity ($\alpha = -\frac{1}{2},\ \beta = \frac{1}{2},\ \delta = 0$).

[1]Other even more general test theories like the Standard Model Extension (SME) can be used as well, see e.g. [2], [7] and in particular [8] for the relation of the SME with the RMS.

[2]The frame in which the Cosmic Microwave Background is isotropic is a natural choice.

Here we propose a space mission that would improve the measurement of the KT coefficient by a factor of 1600. An improvement by a factor 100 is expected solely by going to space. This is due to an orbital velocity $v_{sat} \approx 7.4\frac{\mathrm{km}}{\mathrm{s}}$ of the satellite with 650 km altitude, which is about 25 times higher than that of a ground based laboratory. This would increase the amplitude of the variation of the speed of light in Eq. 1 by that factor. Furthermore, the shorter integration period of 90 min in a low earth orbit compared to 1440 min in a ground based laboratory gives an additional improvement by a factor 4. The rest of the improvement is due to employing better clocks.

Additionally, performing the KT experiment in space offers many advantages. For example, several noise sources like tidal effects and atmospheric pressure effects, which have the same period as the intended measured variation of c due to Lorentz violation are not present in space, and also mechanical distortions due to gravity are eliminated. The latter is especially relevant for the optical cavity described in the next section.

II. Payload configuration

A modern KT experiment is performed by comparing two frequency standards in a beat measurement, where one frequency reference depends on the explicit value of the speed of light - typically an optical cavity - and the second reference is independent of c - typically an atomic or molecular clock. Thus, if c depends on the velocity of the frame as discussed in Sec. I, then a modulation of the laboratory velocity would lead to a modulation of the recorded beat signal. In a satellite, this would yield to a beat signal varying with the orbital motion.

The principle setup is depicted in Fig. 1. In the experiment proposed here, we compare a laser at 1064 nm stabilized to an optical cavity and one laser at 532 nm stabilized to a hyperfine transition in molecular Iodine. In fact, one laser is sufficient if a frequency doubler and an AOM for frequency shifting is used. This would also suppress some common noise effects. However, for redundancy we included two lasers here. The frequency comparison is realized by recording their beat signal in the DMU. A space qualified version of a 1064 nm solid-state laser is available by Tesat Spacecom GmbH.

Laser frequency stabilization using optical cavities is realized in many laboratories worldwide. They utilize cavities made of thermally ultra stable materials such as Ultra Low

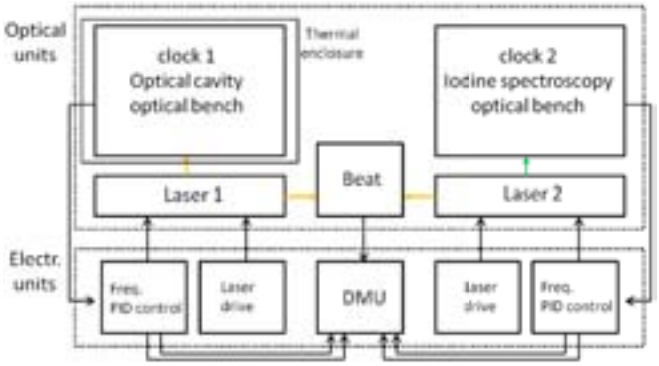

Fig. 1. Schematic representation of a Kennedy-Thorndike experiment. The beat frequency between a cavity stabilized laser and a molecular frequency reference based on Doppler-free Iodine spectroscopy is measured.

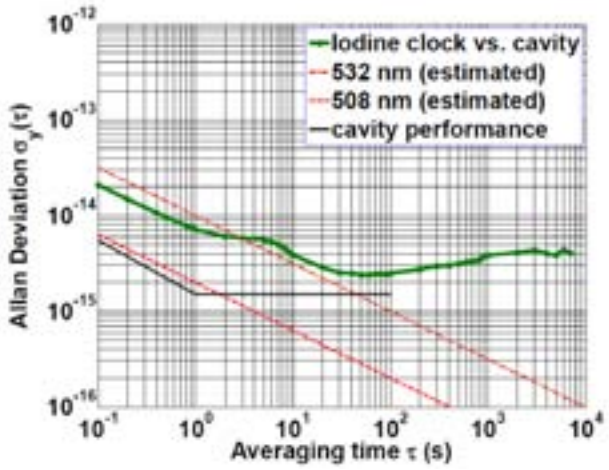

Fig. 2. Frequency stability of the Iodine based frequency reference developed in a collaboration of the University of Applied Sciences Konstanz and the Humboldt University of Berlin. The frequency stability was obtained by a beat measurement with a cavity setup.

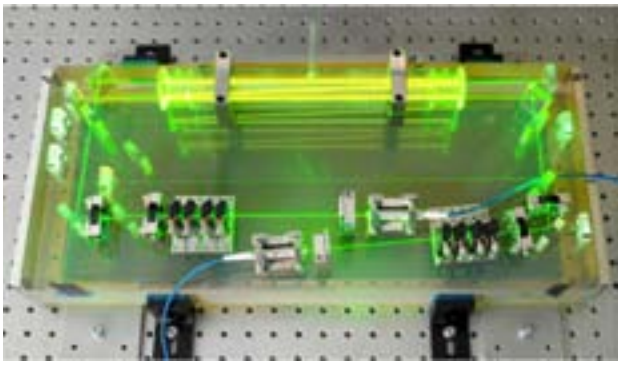

Fig. 3. Photograph of the Iodine based frequency reference realized on elegant breadboard (EBB) level. The baseplate made of OHARA Clearceram has dimensions of 25 cm x 55 cm x 5 cm [12].

Expansion (ULE) glass or Zerodur glass ceramics. State-of-the-art laboratory setups, as e. g. realized at the Humboldt University of Berlin show a frequency stability in the low 10^{-15} range at integration times of 100 s. Currently, several activities are ongoing, in order to develop a space-compatible high-finesse cavity stabilization setup [1], [5].

Also, Iodine based frequency reference is a well known technology, realized in a variety of laboratories. A setup on Elegant Breadboard (EBB) level was developed in a cooperation of the University of Applied Sciences Konstanz and the Humboldt University of Berlin, demonstrating $4 \cdot 10^{-15}$ frequency stability at integration times between 1 s and 10^4 s, cf. the measurement shown in Fig. 2 [3], [12]. The setup is realized using modulation transfer spectroscopy (MTS) and operates at a wavelength of 532 nm. It uses an OHARA Clearceram baseplate where the optical components are integrated using adhesive bonding technology, see 3. The dimensions of the spectroscopy unit are 25 cm x 55 cm x 10 cm. In a current DLR funded activity, a setup on EM (engineering model) level is developed based on the experiences gained with the EBB setup. The EM setup is further improved with respect to compactness and thermal and mechanical stability. After integration it will undergo environmental testing such as thermal cycling and vibration tests.

By switching to a nearby line at 508 nm wavelength an improvement in frequency stability by a factor of almost 10 is expected. However, this makes a development of a space qualified laser operating at that wavelength necessary.

III. Mission overview

The proposed mission housing a KT experiment has been designed to operate in a low earth orbit (LEO). The orbit will be circular and sun-synchronous in order to minimize temperature variations at the optical cavity as well as reducing the needs for radiation and thermal shielding. Meeting the science goals requires the temperature variations of the bus spacecraft interfaces to be < 1K at the orbit period.

The instrument is sensitive to mechanical vibrations in that a perturbation of the spacecraft bus will cause a change in the cavity length increasing the science signal noise. To minimize the spacecraft bus induced vibration, simple spin stabilization is used for attitude control and solar panels used to minimize the impact of thermal snap when transitioning through the eclipse.

The spacecraft will fly at 650 km orbital altitude with a 90 minutes orbital period. The designed mission will have 2 years lifetime with a 50% duty cycle. Therefore, by employing clocks with a 10^{-16} frequency stability at orbit time and by integration over 5000 orbits, a 1600-fold improvement in measuring the KT-coefficient is targeted.

The proposed mission corresponds to a small satellite technology, in which the space vehicle mass (including spacecraft bus and instruments) is estimated to 150 kg consuming 100 W of average power.

IV. Conclusion

The proposed mission with a modern Kennedy-Thorndike experiment is designed to test the symmetry of spacetime by measuring violations to the velocity independency of the speed of light, one of the fundamental postulates of special relativity. The orbital velocity and period will enhance any asymmetry signal 100 times respect to ground, therefore, it is planned to improve the KT coefficient 1600 times compared to previous experiments performed in laboratories.

ACKNOWLEDGMENT

The development of the Iodine frequency references on EBB and EM level is supported by the German Space Agency Deutsches Zentrum für Luft- und Raumfahrt (DLR) with funds provided by the Federal Ministry of Economics and Technology (BMWi) under grant numbers 50QT1102 and 50QT1201.

CMOS-MEMS Resonators and Their Applications

Sheng-Shian Li
Institute of NanoEngineering and MicroSystems, National Tsing Hua University, Hsinchu, Taiwan
Email: ssli@mx.nthu.edu.tw

Abstract—**This paper reports on the recent progress of the high-*Q* integrated micromechanical resonator, oscillator, and filter using the "CMOS-MEMS technology" to enable monolithic integration of MEMS and IC. The paper scope covers three major parts, including (i) the fabrication technologies of the CMOS-MEMS resonators and their associated circuitry; (ii) the performance enhancement of the resonators on motional impedance, quality factor, power handling, thermal stability, frequency tuning, and parasitic feedthrough; (iii) the implementation of the CMOS-MEMS resonators for frequency generation (i.e., oscillators) and frequency selection (i.e., filters) functionalities. In the first part, various fabrication technologies in the 0.35μm and 0.18μm CMOS technology nodes are presented, showing their own features and advantages. In the second part, several strategies in design aspects and material point of views were proposed to enhance the performance of the CMOS-MEMS resonators. In the last part, designs and experimental results of the CMOS-MEMS oscillator and filter are presented. We take full advantage of the IC and semiconductor strength in Taiwan to develop several CMOS-MEMS resonator platforms towards single-chip implementation for timing reference, oscillator, filter, and sensor applications.**

Keywords-CMOS-MEMS; Resonator; Integration; High Q; Power Handling; Motional Impedance; Thermal Stability; Frequency Tuning; Feedthrough Cancellation; Oscillator; Filter

I. Introduction

Mechanical resonators are the key element for frequency control where the high-*Q* tanks implemented by the resonators form crucial building blocks, including frequency generation, frequency selection, and even sensing. Off-chip vibrating components, such as quartz and SAW (surface acoustic wave) devices, have dominated this market for more than fifty years. However, their bulky size and CMOS incompatibility hinders the miniaturization of electronic systems and impedes the cost-down and integration for portable applications. In order to reduce size, power consumption, and increase quality factor, vibrating micromechanical circuits fabricated using IC-compatible MEMS technologies have been developed in the past decade towards the integration with on-chip RF transistor circuits [1]. However, prior approaches for the CMOS-MEMS integration leads to complexity and compromise of fabrication processes, impeding the fast cycling time of product development and causing huge barriers for MEMS design houses. As a solution, the foundry-oriented CMOS-MEMS platform provides ease of use, fast prototyping, and circuit integrated features for vibrating RF-MEMS applications.

As depicted in Fig. 1, this paper reviews several generalized platforms utilizing the foundry CMOS technologies [2], showing several unique features, such as ease of use, low cost, fast turnaround time, and innate MEMS-circuit integration.

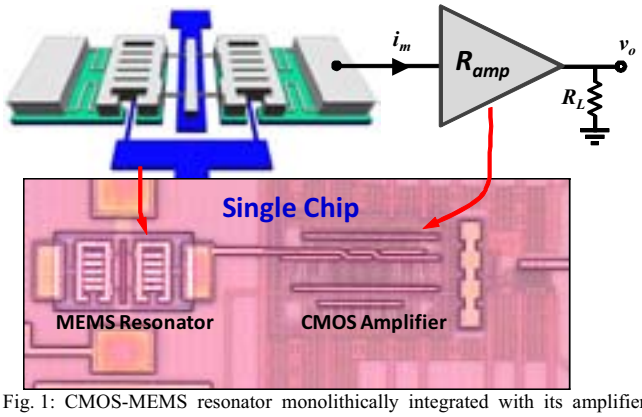

Fig. 1: CMOS-MEMS resonator monolithically integrated with its amplifier circuitry.

With such a resonator platform, various configurations of CMOS-MEMS resonators monolithically integrated with circuits have been demonstrated as shown in Fig. 1.

II. Fabrication Technologies

We have developed several CMOS-MEMS resonator platforms [3][4][5][6] co-fabricating mechanical resonators and their amplifier circuits for MEMS/IC integration. The platforms can be mainly categorized into two different release methods - oxide removal and metal removal maskless post-CMOS processes, implemented in both 0.35μm 2-Poly-4-Metal (2P4M) and 0.18μm 1-Poly-6-Metal (1P6M) CMOS technologies. In the following contents, their pros and cons will be discussed.

A. Oxide Removal Release Process in a 0.35μm CMOS [3]

Fig. 2 presents the cross-section of the 0.35μm CMOS process, clearly showing its two polysilicon layers and four metal interconnect layers, respectively, and the fabricated

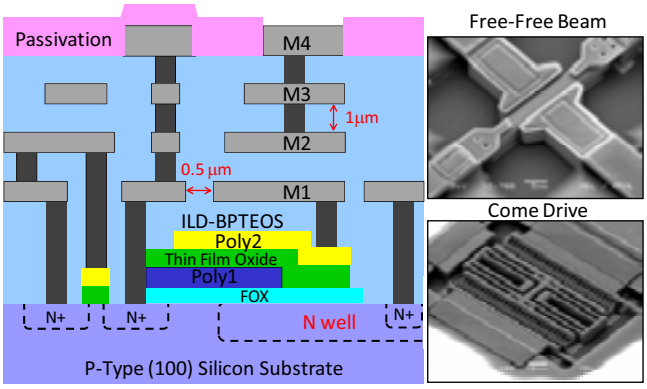

Fig. 2: Chip cross-sectional view and SEM photos of the fabricated resonators using the oxide removal release process in a 0.35μm CMOS technology.

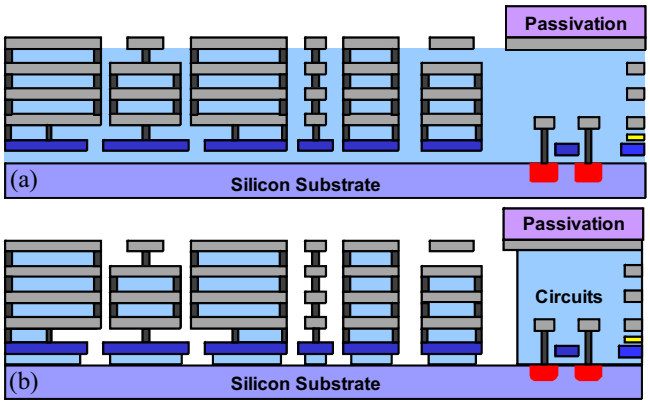

Fig. 3: Fabrication process flow for a CMOS-MEMS resonator in a 0.35µm 2P4M technology under the oxide removal post process. (a) Chip prepared by the CMOS foundry. (b) Device is released by a buffer HF solution.

resonators, such as beam and come-drive resonators, can be seen in the right. The fabrication flow is quite simple as shown in Fig. 3 where the device can be released in a commercially available buffer HF solution, Silox Vapox III. Fig. 3(b) indicates that (i) various resonators, such as in-plane and out-of-plane versions, and (ii) different combinations of the structural materials, such as mere metal and metal/oxide composite, can be realized in this platform to offer more flexible design options. Note that the minimal electrode-to-resonator gap spacing is limited by the feature size of the 0.35µm CMOS technology node such that the motional impedance of the fabricated resonators is in several MΩ due to their low electromechanical coupling coefficient.

B. Oxide Removal Release Porcess in a 0.18µm CMOS [4]

To address the issue of high motional impedance in section II.A, we transfer this oxide removal process into a 0.18µm CMOS where the cross-sectional schematic and physical views are shown in Fig. 4. The electrode-to-resonator gap spacing is reduced via the minimal feature size of the 0.18µm CMOS (1.8X smaller than the 0.35µm CMOS) while the transducer area can be increased by the 6-metal stacking (4-metal stacking in the 0.35µm CMOS). The combined merit of the gap and area contributes to much lower motional impedance as compared to the 0.35µm CMOS-MEMS resonators. Fig. 5 presents the performance comparison between the 0.35µm 2P4M and 0.18µm 1P6M platforms, showing the advanced technology nodes would lower the motional impedance, reduce the dc-bias voltage, and attain

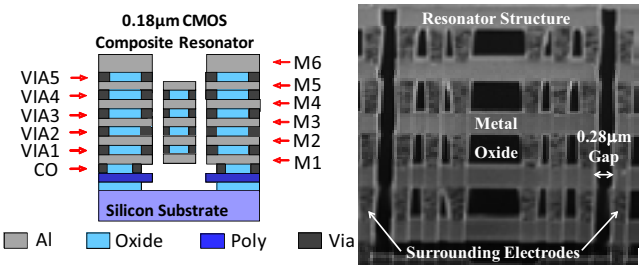

Fig. 4: CMOS-MEMS resonator in a 0.18µm 1P6M CMOS-MEMS platform.

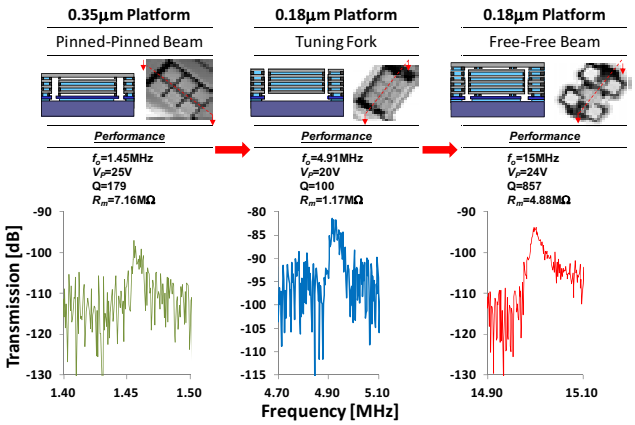

Fig. 5: Performance comparison of the CMOS-MEMS resonators in 0.35µm 2P4M and 0.18µm 1P6M CMOS-MEMS platforms.

higher resonance frequencies.

C. Metal Removal Release Process in a 0.35µm CMOS [5]

Although the oxide removal process only requires one maskless wet etching step, the metal-rich feature of the aforementioned resonators places a bottleneck on quality factor Q since the structural aluminum is often treated as a high-loss acoustic material. As can be seen in Fig. 5, Q is lower than 1,000, which is not sufficient for the later oscillator and filter implementation. To address low-Q issue in the oxide removal process, we proposed a metal removal post process to form low-loss oxide-rich resonator structures to enable high Q.

As indicated in Fig. 6, the device was first prepared by the CMOS foundry using a standard 0.35µm 2P4M CMOS process. Then the etching solution containing H_2SO_4 and H_2O_2 was utilized to remove metal layers. This maskless etching technique provides excellent selectivity between the metal and dielectric layers; therefore, the issues from time-based etching in part II.A and II.B can be greatly alleviated. Finally, Reactive Ion Etching (RIE) was used to remove the passivation layer for the following wire bonding. Fig. 7 presents a resonator SEM view, an integrated CMOS-MEMS

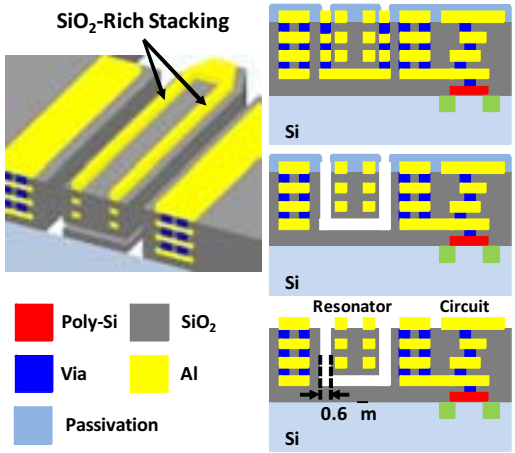

Fig. 6: CMOS-MEMS resonator using the metal removal post process in a 0.35µm 2P4M CMOS-MEMS platform.

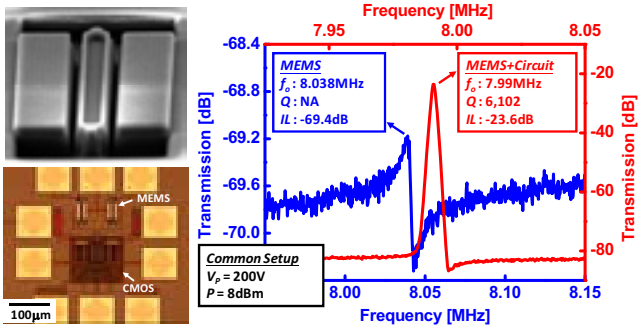

Fig. 7: Performance of a 0.35μm CMOS-MEMS resonator using the metal removal post process.

system, and their frequency characteristics including the standalone resonator and MEMS/IC integrated version. Q of the oxide-rich resonator is greater than 6,000, which is 6X higher than the metal-rich counterparts in Fig. 5.

D. Metal Removal Release Process in a 0.18μm CMOS [6]

The release approach in part II.C has also been transferred into a 0.18μm CMOS node as shown in Fig. 8 to gain the smaller feature size of the advanced CMOS for low motional impedance. To fabricate the CMOS-MEMS double-ended-tuning-fork (DETF) oxide-rich resonator in Fig. 8, chips were manufactured using a standard TSMC 0.18μm 1P6M CMOS process. Then a metal wet etchant was utilized to remove the sacrificial metals, hence providing air gap spacing of around 0.53μm. Finally, the RIE was utilized to open bond pads. Fig. 8 also presents a cross-sectional image of the DETF structure and its measured frequency characteristic, showing Q greater than 4,800 due to its oxide-rich feature. The achievable resonance frequency is higher than that of the device in part II.C (Fig. 5) owing to its smaller gap spacing via the 0.18μm CMOS.

III. Motional Impedance

The major bottleneck of the capacitive resonators comes

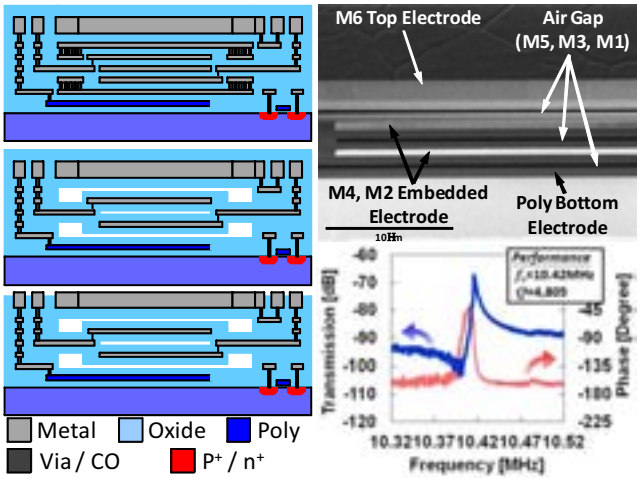

Fig. 8: Fabrication process flow, SEM, and frequency response for a CMOS-MEMS resonator in a 0.18μm 1P6M technology under the metal removal post process.

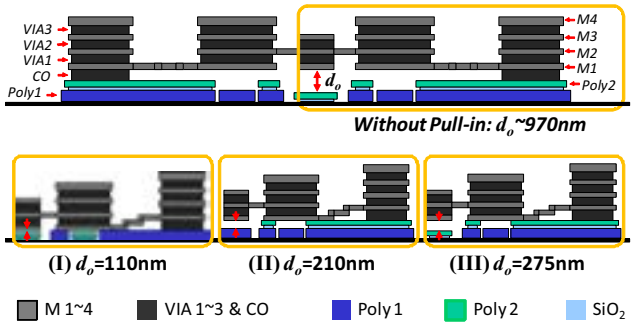

Fig. 9: Pull-in gap reduction mechanism implemented in a 0.35μm CMOS-MEMS resonator for motional impedance reduction.

from the relatively higher motional impedance (often much larger than 50Ω) due to their low electromechanical coupling capability which is several orders of magnitude lower than that of the piezoelectric counterparts. The CMOS-MEMS resonators inherit such a deficiency where the motional impedance is typically several MΩ as indicated in Fig. 5 [3][4]. The limit of the electromechanical coupling stems from the minimum feature size of the CMOS technologies as described in section II, even if advanced technology nodes are utilized. Here, we proposed several approaches in design aspects to greatly reduce the motional impedance of the CMOS-MEMS resonators without pursuing costly, nm-regime CMOS processes.

A. Pull-in Gap Reduction Design

Based on the pull-in mechanism of capacitive transducers, we proposed an effective gap reduction approach [7] in a standard CMOS-MEMS technology to reduce the electrode-to-resonator gap spacing without the need of advanced CMOS nodes, hence providing a cost-effective solution to alleviate performance degradation using conventional CMOS-MEMS platforms. With the well-known electrostatic pull-in effect, various gap-reduction configurations utilizing the existing layers of the 0.35 μm 2P4M CMOS technology have been demonstrated to achieve deep-submicron gaps, significantly lower the motional impedance of the resonators to 100kΩ range suitable for oscillator implementation. Using the gap reduction mechanism depicted in Fig. 9, beam resonators with gaps of 110nm, 210nm, and 275nm, respectively, have been successfully demonstrated that achieves comparable electro-

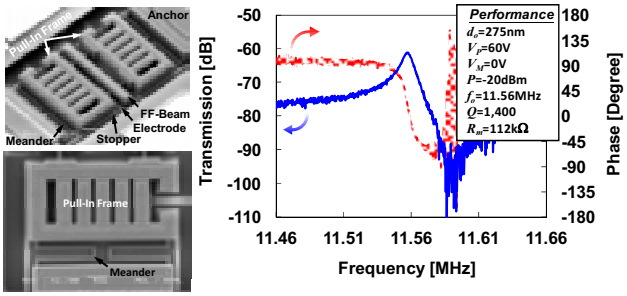

Fig. 10: SEMs and measured frequency characteristic of a 0.35μm CMOS-MEMS resonator under a pull-in gap reduction design to achieve low motional impedance.

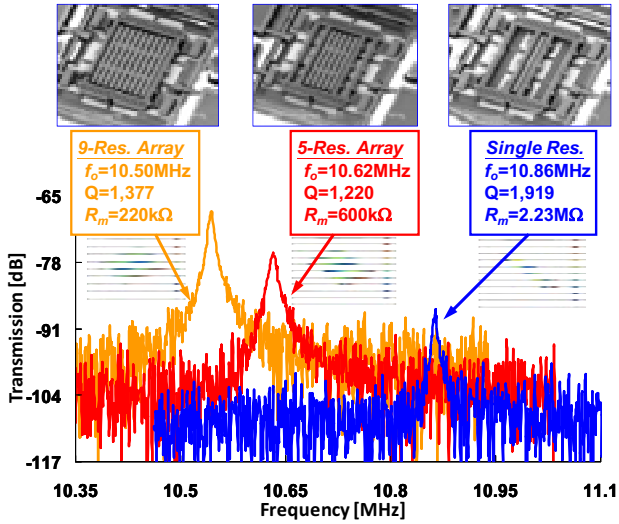

Fig. 11: Comparison of single resonator and 9-resonator array under the same motional impedance and input power.

mechanical coupling [2], as shown in Fig. 10, with their non-CMOS-MEMS counterparts [1].

B. *Mechanically-Coupled Array Design*

Under the same 0.35μm CMOS-MEMS resonator platform, a mechanically-coupled array design [8] offers an efficient approach to reduce the motional impedance which is inversely proportional to the number of the constituent resonators in an array device. More resonators mechanically coupled as an array, the smaller motional impedance. Since the coupled array becomes a multi-degree-of-freedom mechanical system, a high-velocity coupling scheme was used to accentuate the desired mode shape and reject the spurious modes. As shown in Fig. 11, the proposed 9-resonator and 5-resonator arrays [8] have been experimentally characterized to have 10.1X and 3.7X smaller motional impedances, respectively, as compared to a single resonator. In addition, the resonator array is benefitted from the large transduction area to effectively reduce the required dc-bias voltage while maintaining reasonable motional impedance.

IV. Quality Factor

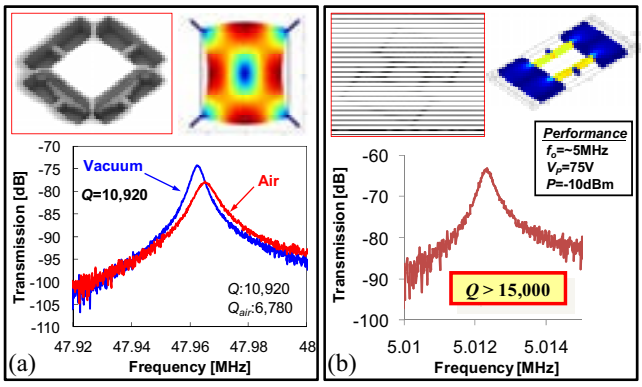

Fig. 12: (a) Lame-mode and (b) longitudinal-mode CMOS-MEMS resonators feature Q > 10,000, verifying high Q of bulk-mode designs.

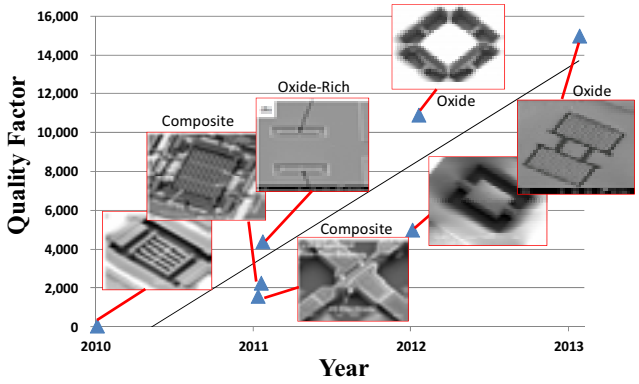

Fig. 13: Progress on quality factor of the CMOS-MEMS resonators developed in our group.

As compared to the single-crystal or polysilicon based MEMS resonators, Q of the CMOS-MEMS resonators becomes a main issue to be used in timing reference and wireless applications. Due to the lossy nature of the metal materials in the CMOS back-end-of-line (BEOF) configuration, CMOS-MEMS metal-rich composite resonators often suffer Q limited to 1,000 as indicated in Fig. 5. We have proposed several approaches to resolve this bottleneck.

A. *Nodal Support Design*

Q in MEMS resonators is often dominated by the support loss once they are operated in vacuum and the thermal elastic damping is avoided by the designed frequencies. We have adopted a nodal support design [8][9] to effectively isolate the vibrating energy of the resonant structure from its anchors, thus verifying Q of the nodal support design is two orders of magnitude higher than that of the conventional designs [7].

B. *Oxide-Rich Design*

In addition to the nodal support design, material loss also plays a significant role on resonator Q. A simple way to overcome this structural loss is to increase the constituent ratio of the SiO_2 (i.e., low-loss material) inside the resonator, thus enabling high Q. We took advantage of the metal removal post process described in section II.C and II.D to form oxide-rich resonators since SiO_2 is treated as high-Q structural material. The oxide-rich CMOS-MEMS resonators [5][6] in Fig. 7 and Fig. 8 feature 3-4X higher Q than that of the metal-rich versions in Fig. 5. Please note the flexural-mode vibration now becomes the limiting factor once the oxide constituent ratio is maximized.

C. *Bulk-Mode Design*

To further boost Q of the CMOS-MEMS resonators, the flexural-mode design can be switched into a bulk-mode vibration. Fig. 12 presents the measured frequency characteristics of Lame-mode [10] and dog-bone like [11] CMOS-MEMS resonators with Q greater than 10,000, indicating the high-Q nature of the bulk-mode resonators. With proper structural materials and resonator designs, we

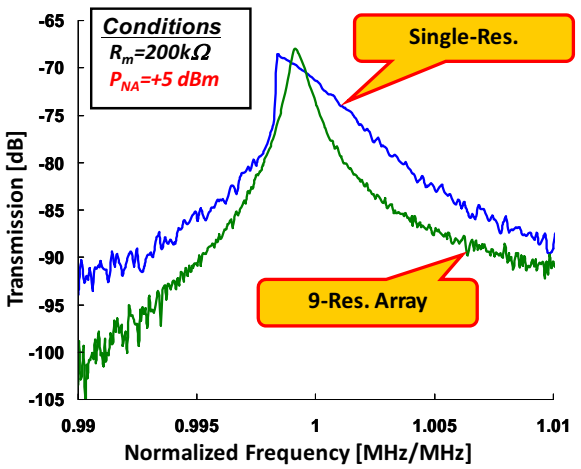

Fig. 14: Comparison of the single resonator and 9-resonator array under the same motional impedance and input power.

have proved Q of the CMOS-MEMS resonators is comparable to the silicon-based resonators.

Fig. 13 finally presents the progress on quality factor of our proposed CMOS-MEMS resonators in the past four years. As can be seen, Q greater 10,000 has been realized by the combination of the nodal support design, oxide-rich structural material, and bulk-mode operation, thus greatly benefiting the future oscillator and filter applications.

V. Power Handling and Linearity

Upon high input power levels, capacitive resonators often suffer the Duffing nonlinearity resulted from both capacitive and mechanical nonlinearities, hence degrading output power and phase noise performance of oscillators implemented using those resonators. The mechanically-coupled array design [8] described in section III.B not only reduces their motional impedance but greatly enhances the power handling capability since the effective stiffness of the N-resonator array ideally is N times higher than that of a single resonator, thus contributing N times larger power handling ability. Fig. 14 presents the frequency characteristics of single resonator and 9-resonator array designs under the same input power, where the former falls into the nonlinear regime while the later still preserves the linear vibration with a symmetrical frequency response and high Q.

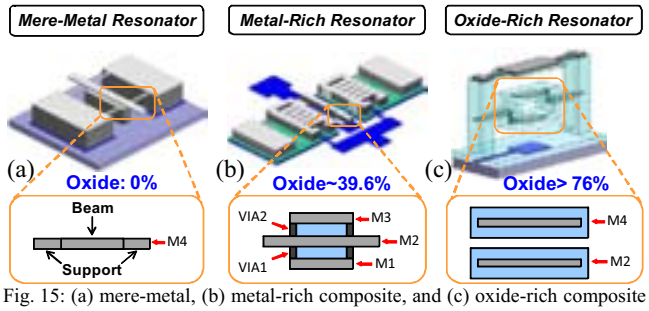

Fig. 15: (a) mere-metal, (b) metal-rich composite, and (c) oxide-rich composite structures of CMOS-MEMS resonators to modulate TC_f.

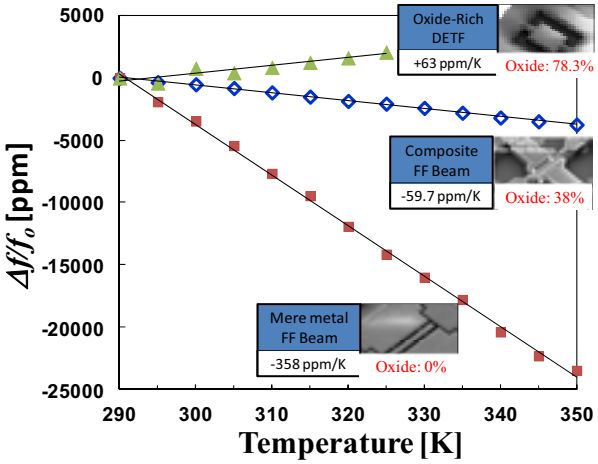

Fig. 16: Temperature coefficient of frequency in CMOS-MEMS resonators can be adjusted by the constituent ratio of SiO_2.

VI. Thermal Stability

A. Passive Temperature Compensation

The CMOS-MEMS resonators mostly composed of metals are sensitive to temperature variation due to the very negative temperature coefficients of Young's modulus (TC_E's) of their constituent metal materials. To improve the thermal stability of those CMOS-MEMS resonators, the silicon-dioxide (SiO_2) in the CMOS back-end-of-lone (BEOL) process with positive TC_E offers a simple "passive" temperature compensation scheme where metal-oxide composite structures can be utilized to build resonators capable of improving their thermal stability [3]. For example, the oxide constituent ratio of the CMOS-MEMS resonators can be adjusted as indicated in Fig. 15 where the mere-metal, metal-rich, and oxide-rich structures would lead to very negative, slightly negative, and very positive temperature coefficients of frequency (TC_f's). Fig. 16 presents the comparison of fractional frequency change versus temperature measurements for mere-metal, metal-rich composite, and oxide-rich composite beam resonators, verifying our design concept in Fig. 15 and indicating the near-zero TC_f is plausible once the ratio between SiO_2 and metal is optimized. Thus, the use of SiO_2 as part of the composite structures in CMOS-MEMS resonators brings an easy and effective temperature compensation scheme [2].

B. Active Temperature Compensation

To further enhance the thermal stability of the CMOS-MEMS resonators down to ppm level, a constant-resistance control [12] was implemented as a low-cost active compensation scheme with which TC_f of the CMOS-MEMS resonators was dramatically improved with a record-low value, -12.5 ppm/K [11], to date among any CMOS-MEMS resonators. Note that the polysilicon layers from the CMOS BEOL process are embedded inside the proposed resonator structures, serving as the key element for the constant-resistant control.

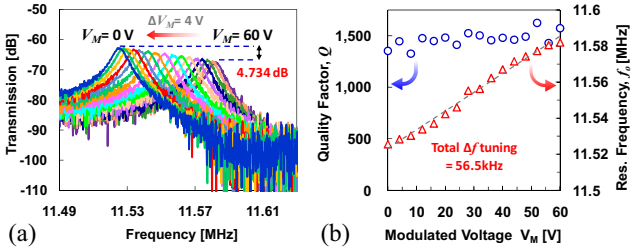

Fig. 17: (a) Frequency tuning capability and (b) steady Q under different modulated voltages.

VII. Frequency Tuning

With enhanced TC_f through the use of both the passive and active temperature compensation approaches mentioned in section VI, the CMOS-MEMS resonators simply demand a linear frequency tuning mechanism with low cost and low power consumption for final temperature compensation. In the high-end applications, frequency tuning capability is necessitated. On the other hand, initial frequency trimming of batch-fabricated resonators is also of great importance for commercialization. The resonance frequency of capacitive-type MEMS resonators can be tuned via their dc-bias voltages through the electrical stiffness; however, the change of motional impedance as well as the parabolic relationship between the bias voltage and frequency makes such a post-fabrication trimming technique not suitable for real implementation. To solve this issue, we proposed a quasi-linear frequency tuning via the adjustment of an independent bias voltage [2] without consuming any dc power, showing 5,000 ppm tuning range and sensitivity of 83.3 ppm/V, as shown in Fig. 17(a). In addition, such resonators under frequency tuning operation still preserve steady quality factor Q with very limited influence on motional impedance as shown in Fig. 17(b), hence ensuring stable resonant performance suited for future oscillator and time-keeping applications.

VIII. Feedthrough

The differential pair of CMOS amplifiers is often used to remove the common-mode noise and to preserve correct transmission and phase even with the presence of the parasitic capacitances. The weak electromechanical coupling makes the capacitive resonators very sensitive to parasitic feedthroughs

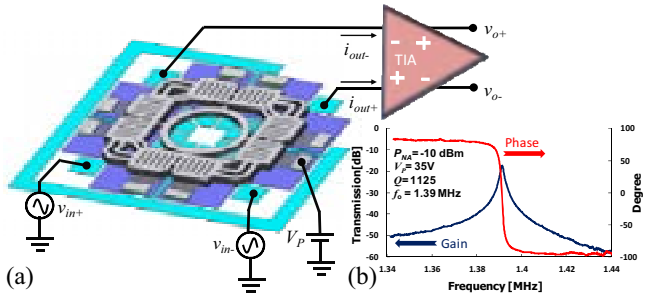

Fig. 18: (a) Fully-differential CMOS-MEMS circuit and (b) its measured frequency characteristic.

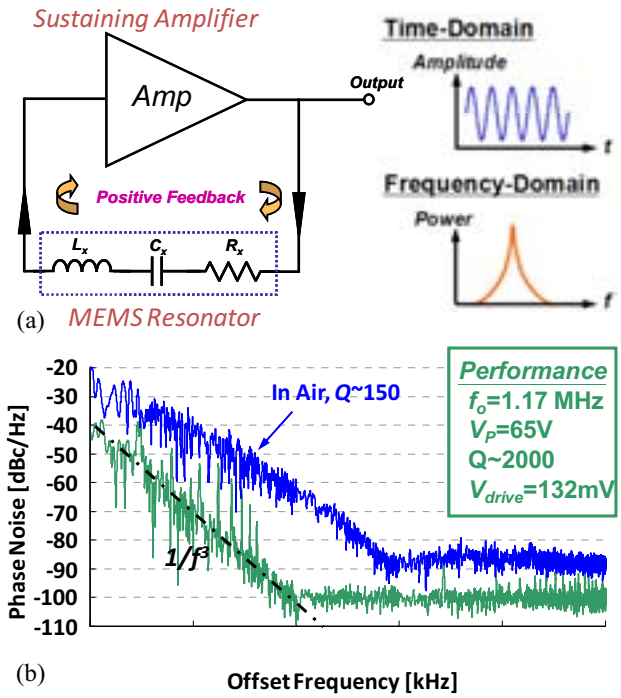

Fig. 19: (a) Closed-loop oscillation and (b) phase noise performance of a CMOS-MEMS oscillator.

since the resonance behavior (i.e., the motional current) is often masked by the feedthrough signals. Therefore, similar concept has been implemented in capacitive resonators to cancel the feedthroughs. A CMOS-MEMS ring resonator featuring differential-mode of mechanical operation was integrated with a fully-differential transimpedance amplifier as shown in Fig. 18, demonstrating a clear resonance behavior where the transmission amplitude is quite symmetric without anti-resonance while its phase is cross 0° at resonance [13]. With the fully-differential configuration applied both on MEMS and IC, Barkhausen criteria can be easily fulfilled for oscillator implementation.

IX. Oscillator Implementation

After addressing the bottlenecks and proposing solutions to enhance performance of the CMOS-MEMS resonators, the oscillator implementation is of great importance for timing and frequency synthesizing applications. As depicted in Fig. 19(a), the micromechanical resonator and its sustaining amplifier can form a closed loop to ensue oscillation once Barkhausen criteria (loop gain >1 and loop phase = 0°) are satisfied. In our group, a single-chip CMOS-MEMS oscillator has been successfully demonstrated in vacuum, exhibiting the phase noise performance, as shown in Fig. 19(b), is comparable to the silicon-based oscillators. Even in air (i.e., large squeeze film damping), the oscillator was still functional, indicating the great potential to be used in gas, chemical, and mass sensing application based on frequency-shift mechanism. The abovementioned approaches to improve quality factor and

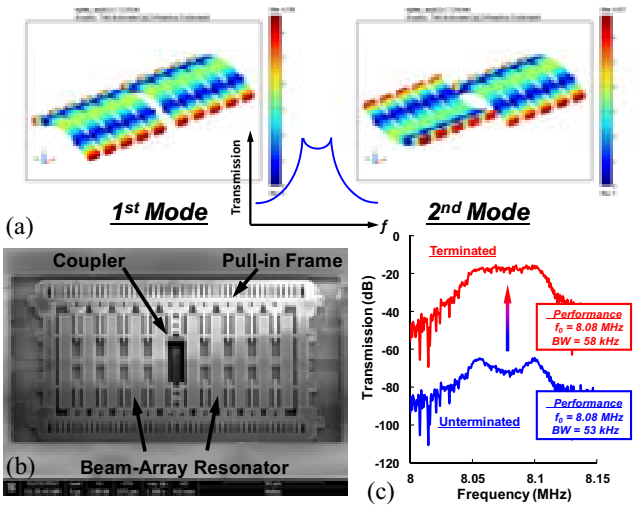

Fig. 20: (a) Simulated filter modes, (b) SEM view, and (c) un-terminated and terminated frequency response of a mechanically coupled CMOS-MEMS filter.

power handling of the CMOS-MEMS resonators would benefit the close-to-carrier and far-from-carrier phase noise performance, respectively, of the implemented oscillators. In addition, the reduction of the motional impedance described in section III would lead to the overall phase noise reduction for the CMOS-MEMS integrated oscillators.

X. Filter Implementation

Another significant building block for frequency control and wireless communication is the frequency selection element. The developed CMOS-MEMS resonators can serve as the fundamental elements for bandpass filters. Since the resonance frequency of the CMOS-MEMS resonators is limited, it is best to be used in sensors front-end with much lower operation frequencies. Fig. 20 presents a CMOS-MEMS filter composed of two CMOS-MEMS resonator arrays mechanically coupled through a quarter-wavelength mechanical link to enable a narrow-bandwidth bandpass filter for channel selection [14]. The in-phase and out-of-phase filter modes shown in Fig. 20(a) form the passband of a filter. The fabrication is the same as the CMOS-MEMS resonators in section II.A and the SEM view of the fabricated filter is shown in Fig. 20(b). After filter termination, a flat passband and real insertion loss can be obtained as shown in Fig. 20(c).

XI. Conclusions

In the past few years, the CMOS-MEMS technology has been thoroughly explored and implemented in vibrating MEMS applications. The CMOS-MEMS resonator fabrication platforms bring low cost, batch production, fast turnaround time, and MEMS/IC integration to the resonator applications. Most of the bottlenecks in CMOS-MEMS resonators, including motional impedance, quality factor, power handling/linearity, thermal stability, frequency tuning, and feedthrough issues, have been addressed using various design and material strategies. In addition, the oscillator and filter implementation is also covered in this paper. This technology is expected to pave a way to realize fully-integrated high-performance CMOS-MEMS oscillators and filters which would benefit future single-chip transceivers for wireless communications.

2DEG Electrodes for Piezoelectric Transduction of AlGaN/GaN MEMS Resonators

Laura C. Popa and Dana Weinstein
Massachusetts Institute of Technology
Cambridge, MA, USA

***Abstract*—A 2D electron gas (2DEG) interdigitated transducer (IDT) in Gallium Nitride (GaN) resonators is introduced and demonstrated. This metal-free transduction does not suffer from the loss mechanisms associated with more commonly used metal electrodes. As a result, this transducer can be used for both the direct interrogation of GaN electromechanical properties and the realization of high *Q* resonators. A 1.2 GHz bulk acoustic resonator with mechanical *Q* of 1885 is demonstrated, with frequency quality factor product (*f*·*Q*) of 2.3×10^{12}, the highest measured in GaN to date.**

Keywords-MEMS Resonator, IDT, Gallium Nitride, 2DEG, Compund Semiconductor, Piezoelectricity

I. INTRODUCTION

Monolithic integration of micro-electromechanical (MEM) resonators can provide basic RF and mm-wave building blocks with high *Q* and small footprint for use in wireless communication, microprocessor clocking, navigation and sensing applications. Direct integration of MEMS with standard integrated circuits (ICs) is motivated primarily by improved size, weight and power (SWaP), and relaxed constraints on IOs and on impedance matching [1]. Moreover, for high frequency applications (UHF band and above), this integration side-by-side with control circuits is critical for the elimination of parasitics associated with bond pads and off-chip routing.

The majority of IC integration efforts for resonators have focused on Si-based and metal-based MEMS in CMOS [2,3,4,5] where transduction mechanisms are limited to electrostatic, thermal, and piezoresistive transduction. However, many opportunities exist for MEMS in piezoelectric III-V materials used for mm-wave ICs (MMICs). Wide band-gap compound semiconductors such as GaN are used increasingly for high power (>10W/mm), high frequency (>100 GHz) applications due to high electron velocity, charge density (1×10^{13} cm^{-2} in AlGaN/GaN), and critical electric field >3 MV/cm. In its Wurtzite crystal structure, GaN also exhibits high piezoelectric coefficients (k_T^2 up to 2%) necessary for low insertion loss, large bandwidth MEMS filters.

The AlGaN/GaN heterostructure used to form High Electron Mobility Transistors (HEMTs) for MMICs is typically grown on SiC, diamond, or sapphire substrates to ensure high quality material [6]. However, the cost of such substrates has prompted the development of GaN on (111) Si. As this is a relatively new technology, material growth optimization is an active field of study. While ample information is available on the electrical properties of GaN on Si, electromechanical characterization is lacking. In this work we demonstrate AlGaN/GaN resonators that can be used to intimately interrogate the electromechanical properties of GaN. These resonators are driven piezoelectrically using 2DEG interdigitated transducers (IDTs). This metal-free transduction allows for the elimination of losses associated with metal electrodes typically used in piezoelectric resonators.

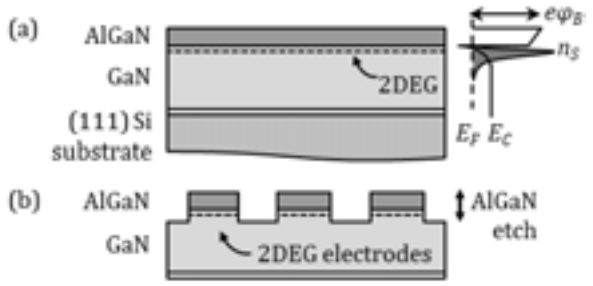

Figure 1. AlGaN/GaN heterostructure on (111) Si. (a) A 2DEG is confined in the conduction band potential well at the interface between AlGaN and GaN. (b) 2DEG electrodes are patterned via a shallow AlGaN etch.

II. DISSIPATION MECHANISMS IN MEMS RESONATORS

In order to isolate the intrinsic mechanical properties of GaN, it is necessary to minimize other loss mechanisms that limit the *Q* of a MEMS resonator. These losses can be classified into extrinsic dissipation mechanisms, which are design-dependent, and intrinsic ones, which depend on the properties and quality of the material [7]. Dominant extrinsic loss mechanisms include anchor loss and air damping. The energy dissipated into the substrate can be minimized through an appropriate anchor design. Meanwhile, air damping is less significant for high frequency bulk modes, and can be eliminated by operation at low pressure. Intrinsic mechanisms include thermoelastic damping (TED), phonon-electron scattering and phonon-phonon scattering. While TED becomes less significant in the case of high frequency bulk modes and phonon-electron interactions are not a limiting mechanism in semiconductors, phonon-phonon scattering defines the fundamental limit of resonator *Q* [8].

A study of this fundamental limit is required to interrogate the acoustic performance of various GaN growth processes. However, most piezoelectric transducers are realized using metal electrodes. Metal electrodes result in added acoustic losses, and contribute to mode distortion through mass loading. In AlN, efforts to minimize losses associated with metal in piezoelectric resonators have included physically separating the

electrodes from the piezoelectric film [9] and segmentation of IDT metal electrodes [10]. In GaN, the standard MMIC platform provides a metal free conductive sheet inherent to the heterostructure, which can be used to define electrodes, eliminating the metal completely from the resonant structure.

III. 2DEG ELECTRODES

The piezoelectric resonator presented here uses 2DEG IDTs to drive acoustic waves in an AlGaN/GaN heterostructure. 2DEG electrodes have previously been demonstrated as IDTs in a SAW AlGaN/GaN filter [11] as well as for piezoelectric actuation of AlGaN/GaN heterostructures [12,13]. However this is the first use of 2DEG IDTs in MEMS resonators. The authors have recently demonstrated a switchable piezoelectric transducer using the 2DEG as a bottom electrode and Schottky metal as a top electrode [14].

The starting AlGaN/GaN heterostructure used in the current work is illustrated in Fig. 1(a). Large spontaneous and piezoelectric polarizations form a sharp potential well confining electrons in a 2D plane just below the interface of AlGaN and GaN [15]. This 2DEG is conductive enough to form electrodes for piezoelectric transduction. The 2DEG can be patterned with a shallow AlGaN etch as shown in Fig. 1(b). To drive acoustic waves in the structure, an AC electric field is applied through the GaN, between the interdigitated 2DEG electrodes.

At resonance, strain fields defined by the mode shape induce a polarization field through the direct piezoelectric effect. For Wurtzite crystal materials such as GaN, the induced polarization field can be written as:

$$\boldsymbol{P_{PE}} = (e_{51}\epsilon_{zx})\hat{\boldsymbol{x}} + (e_{51}\epsilon_{yz})\hat{\boldsymbol{y}} + \left(e_{31}\epsilon_x + e_{31}\epsilon_y + e_{33}\epsilon_z\right)\hat{\boldsymbol{z}} \quad (1)$$

Taking z along the Wurtzite c-axis, ϵ_x, ϵ_y, and ϵ_z are the strains along the x, y and z-axis, respectively, and ϵ_{yz} and ϵ_{zx} are shear strains. Here, e_{31}, e_{33} and e_{51} are the piezoelectric coefficients found in the Wurtzite crystal structure. There are two contributions to the bound charges associated with this polarization field. First, an interface charge σ is generated by a discontinuity in the polarization at the AlGaN/GaN interface:

$$\sigma = (\boldsymbol{P_{PE,AlGaN}} - \boldsymbol{P_{PE,GaN}}) \cdot \hat{\boldsymbol{z}} \quad (2)$$

Second, the polarization generates volume charge ρ throughout the heterostructure:

$$\rho = -\nabla \cdot \boldsymbol{P_{PE}} \quad (3)$$

The overall mechanically induced charge is found by integrating σ along the AlGaN/GaN interface in the region defined by the IDT and integrating ρ over the GaN volume under the IDT. The summed contribution of the interface and bulk charges is compensated by free charge flowing into the 2DEG, which translates into an AC current.

IV. FABRICATION

The ability to form metal-free electrodes is dependent on the presence of a 2DEG, which is an inherent feature of existing GaN MMIC technology. This platform can be leveraged to fabricate 2DEG IDT piezoelectric resonators with only two additional masks as shown in Fig. 2. The starting material is an AlGaN(25nm)/GaN(1.7μm) stack grown by Molecular Beam Epitaxy on a (111) Silicon substrate, using a thin AlN nucleation layer [16]. The growth of the material in this work was performed at Raytheon with subsequent fabrication at MIT. A shallow BCl_3/Cl_2 plasma etch of the AlGaN is used for both electrical isolation between devices and patterning the 2DEG IDTs. The 2DEG is removed from the regions where the AlGaN is etched away, by eliminating the potential well generated by the AlGaN/GaN interface.

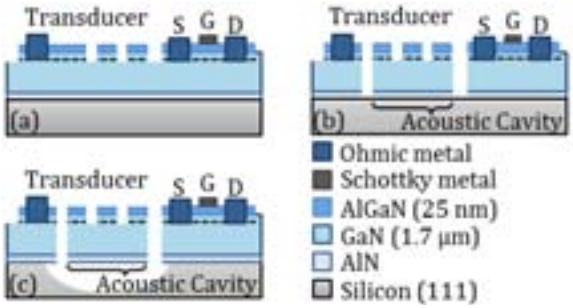

Figure 2. Fabrication involves two additional steps to (a) existing GaN MMIC technology, including (b) a deep GaN etch, and (c) a release step.

A Ti/Al/Ni/Au metal stack is deposited and patterned, followed by a rapid thermal anneal (RTA at 870˚C, 30 sec) to form Ohmic contacts to the 2DEG. While in a typical HEMT process flow these Ohmics are used to access the source and drain of the transistors, in this work they also serve as a means of electrically contacting the 2DEG electrodes. This takes place outside of the resonant cavity to avoid metal loading. From the Ohmic metal contact, the 2DEG forms a conductive path through the suspension beams onto the resonator. At this point, the piezoelectric transducer is completely defined. To extend the process for the inclusion of HEMTs, a Ni/Au/Ni gate metal stack can be deposited and patterned to form Schottky contacts for the gate (Fig. 2(a)). An additional Cl_2 inductively coupled plasma etch of the GaN layer defines the acoustic cavity (Fig. 2(b)). Finally, a XeF_2 isotropic Si etch releases the resonators from the substrate (Fig. 2(c)).

V. RESULTS

A GaN piezoelectric resonator using a 2DEG IDT is shown in Fig. 3(a), with the simulated resonant mode shape shown in Fig. 3(b). This structure corresponds to "Design A", with dimensions 50 by 65 μm and using quarter wavelength suspension beams to minimize anchor losses. For comparison, an identical resonator using Ohmic metal IDTs is also fabricated.

Devices were tested under vacuum to reduce air damping. A 50Ω terminated 2-port measurement was performed. The parasitics of the RF pads were deembedded using an open structure. Since the goal of this work is to isolate the mechanical performance of the AlGaN/GaN resonators, further deembedding needs to be

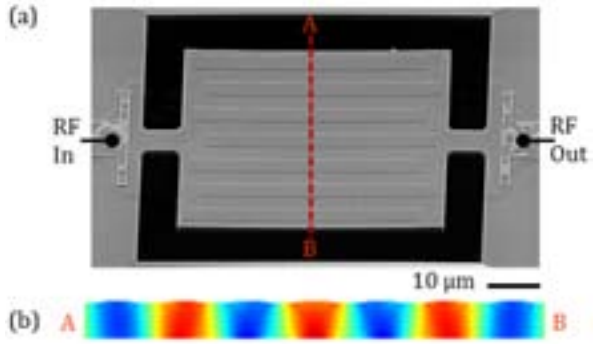

Figure 3. (a) SEM of GaN resonator with 2DEG IDT. The 2DEG electrodes are patterned with a 70 nm deep AlGaN etch. Ohmic contacts are used to access the 2DEG outside of the resonant structure. (b) Strain fields of the bulk contour mode excited using the 2DEG IDT.

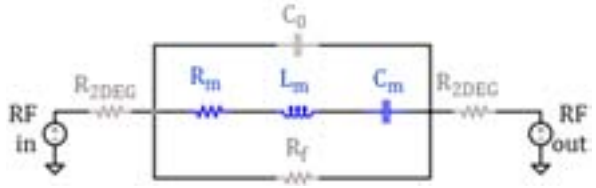

Figure 4. Equivalent circuit model of 2DEG IDT. Elements in blue represent the mechanical resonance while elements in grey are electrical parasitics of the structure and are deembedded from the measurement.

performed to eliminate electrical parasitics, especially the loss associated with feed-through capacitance and the series resistance of the 2DEG. The equivalent circuit describing this device is captured by Fig. 4. After parameter fitting was performed to extract C_0, R_f, and R_{2DEG}, these contributions were deembedded from the admittance of the device, leaving only the mechanical response shown in Fig. 5(a). The measured deembedded frequency response of the resonator with Ohmic metal IDT is shown in Fig. 5(b). The mechanical quality factor of the device with metal electrodes is 3× lower than that of the 2DEG IDT, which can be attributed to the additional damping mechanisms associated with metal electrodes, as discussed in §II.

Table 1 summarizes the extracted mechanical Q and $f{\cdot}Q$ products for two resonator designs, each measured using 2DEG IDTs and metal IDTs. As mentioned above, "Design A" resonators use quarter wavelength suspension beams. In the case of "Design B", a phononic crystal is used to mechanically isolate the resonant mode. In both cases, the Q of the 2DEG IDT device is significantly higher than that of the metal IDT.

TABLE I. COMPARISON OF 2DEG AND METAL IDT RESONATORS

		Extracted Parameters			
		f (MHz)	Q_m	$f{\cdot}Q_m$ (s^{-1})	k_T^2 (%)
Design A	2DEG	523.7	1587	8.3×10^{11}	0.091

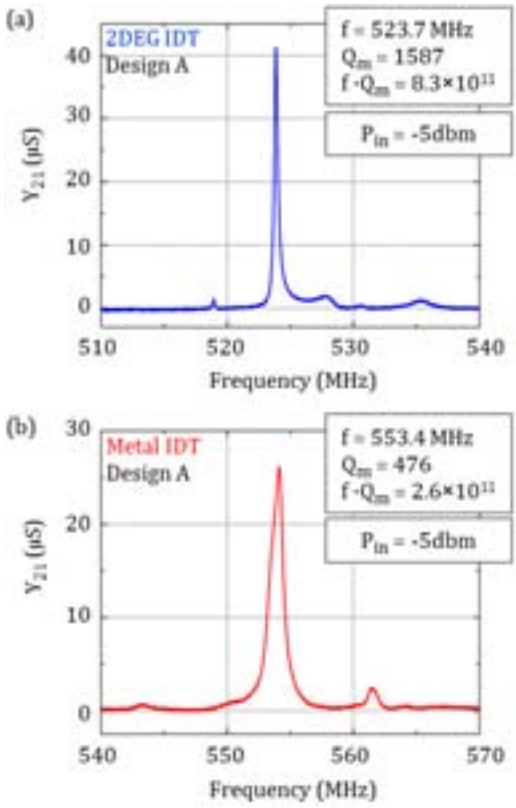

Figure 5. (a) Frequency response of "Design A" resonator using 2DEG IDT after deembedding the electrical parasistics. (b) The deembedded measured response of a metal IDT resonator with equivalent design.

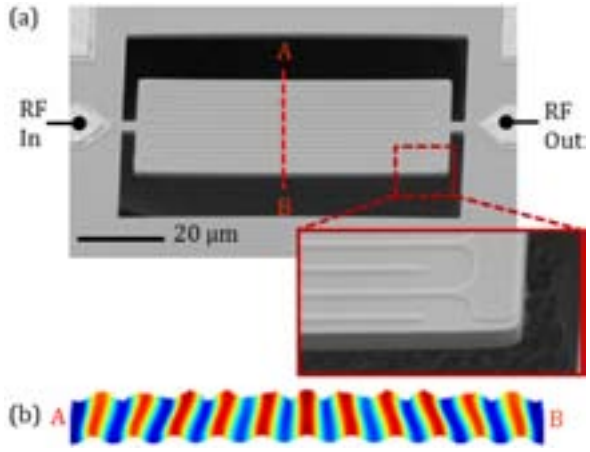

Figure 6. (a) SEM of 1.2 GHz 2DEG IDT resonator. The 2DEG electrodes are patterned with a 90 nm deep AlGaN etch. (b) Mode shape showing the strain fields induced at resonance.

A 2DEG IDT designed to operate at 1.2 GHz is shown in Fig. 6(a), with the simulated mode shape illustrated in Fig. 6(b). This device was tested under vacuum, and the same deembedding technique described above was used to extract the mechanical frequency response. A bulk mode resonance was detected at 1.22 GHz with a Q of 1885, which is the highest measured $f{\cdot}Q$ product in GaN to date.

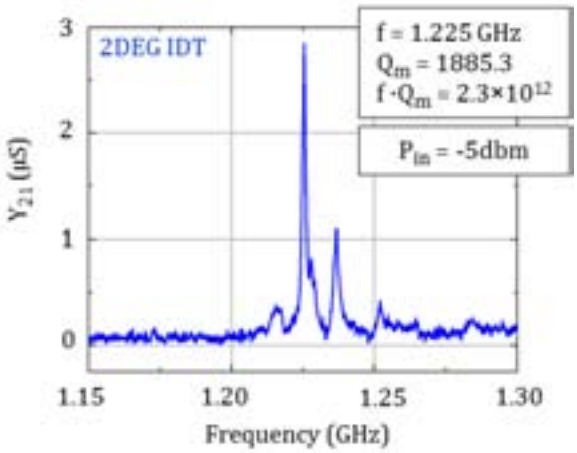

Figure 7. Deembedded frequency response of 1.22 GHz 2DEG IDT resonator. The extracted mechanical resonance has the highest $f \cdot Q$ product measured in GaN to date (2.3×10^{12} at 1.225 GHz).

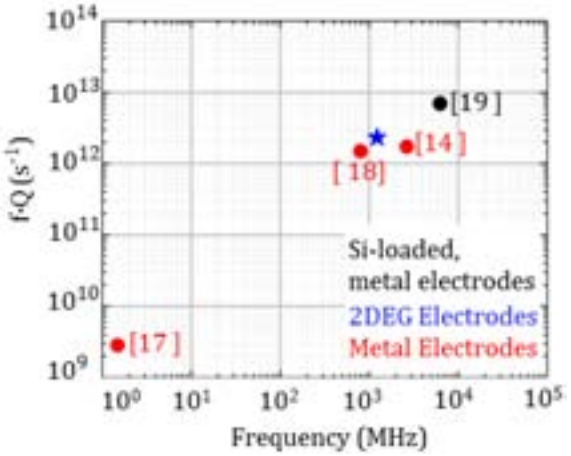

Figure 8. The 2DEG IDT resonator demonstrated here achieved the highest $f \cdot Q$ product in GaN resonators. Ref. 19 shows $f \cdot Q$ of 6.9×10^{12} in a Si-loaded resonator, which does not represent intrinsic GaN properties.

VI. CONCLUSION

We have introduced and demonstrated a GaN piezoelectric resonator that uses 2DEG electrodes to drive and sense acoustic waves. This resonator is metal-free, enabling the highest mechanical $f \cdot Q$ product in GaN to date at 2.3×10^{12}. A benchmarking of this work against state-of-the-art GaN resonators is shown in Fig. 8. Ref. [19] demonstrates an $f \cdot Q$ of 6.9×10^{12} at 6.3 GHz, represented by the black data point. It should be noted that this device uses silicon loading to boost Q, so it is not representative of the fundamental limits of GaN.

This demonstration of metal-free resonators allows for the intimate interrogation of GaN material properties, in the absence of losses and distortions associated with metal electrodes. This work was realized in a standard MMIC heterostructure, with only two modifications to the HEMT process flow. This highlights the potential of 2DEG electrodes for benchmarking the electro-mechanical properties of GaN for material optimization.

ACKNOWLEDGMENT

The authors thank William Hoke and Thomas Kazior (Raytheon) for GaN growth, and process and model discussions. Fabrication took place at MIT's Microsystems Technology Laboratories.

***Abstract*—This paper presents a new technique to increase the quality factor, *Q*, of AlN Contour Mode Resonators (CMRs). The technique uses etched slots in the body of AlN CMRs to reduce energy dissipation through the anchors. The reduction of the energy lost through the supporting anchors improves the device *Q* without altering its electromechanical coupling, k_t^2. An almost 50% improvement in the Figure of Merit, *FoM*, defined as the product between *Q* and k_t^2, has been measured in 220 MHz AlN CMRs.**

I. Introduction

MEMS resonators have been widely researched because they offer the possibility to implement stable frequency references and filtering functions through a CMOS compatible process. The improvement of their quality factor, *Q*, is highly desirable, as it would improve phase noise in oscillators and lower losses in filters.

AlN Contour Mode resonators have shown low motional resistance and moderate *Q* in the radio frequency bands. It has been observed [3,5] that the equivalent damping in AlN CMRs is mostly due to anchor loss and interfacial dissipation. The former is due to acoustic energy lost through the supporting anchors. The latter is due to stress jumps at the interface between different materials in the resonator's body. It has also been shown [3,5] that anchor loss represents the main source of energy dissipation in Very High Frequency (VHF) and low Ultra High Frequency (UHF) bands (up to 500 MHz). In contrast, interfacial dissipation [2,4] represent the main source of energy dissipation above 500 MHz.

This paper presents a new technique to reduce anchor losses in AlN CMRs. The technique has been applied to 220 MHz AlN CMRs and has brought an improvement of *Q* of almost 50%, without any deterioration of the electromechanical coupling coefficient. This approach uses etched slots in the body of the resonator, and close to the anchors, to limit the energy leaking to the substrate through the anchors. The slots behave as acoustic reflectors placed at the edge of the resonator's active region. These reflectors reduce the energy transmitted to the substrate, increasing the acoustic energy trapped in the cavity.

To validate the new design approach, and to verify an analytical model that describes this phenomenon, four different configurations of 220 MHz AlN CMRs with different slot's dimensions have been fabricated and tested. An *ad-hoc* developed finite element code was used to model the effect of the slots in each configuration and predict the resonator *Q*.

The authors would like to thank the DEFYS DARPA contract # FA86501217624 for funding.

II. AlN Contour-Mode Resonators

The principle of operation of AlN CMRs has been already analyzed in previous papers [1]. The devices described in this paper are Lateral Field Excitation (LFE) resonators [1], which are constituted by a piezoelectric layer of AlN sandwiched between two metal plates (Fig.1). The patterned top metal plate has the shape of an interdigitated structure, in which each adjacent finger is biased with opposite polarity to excite the resonator into lateral vibrations. A floating bottom metal is used to confine the electric field in the AlN, ensuring that a high k_t^2 is attained.

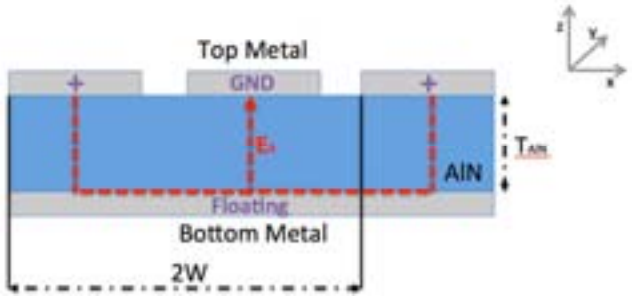

Figure 1: Cross-Section of a 3 fingers LFE AlN CMR.*W* is the finger's width and T_{AlN} is the thickness of the AlN film. The electric field lines, in red, are confined to be mostly in the vertical direction by the floating bottom metal plate. The polarity of the voltage applied to each metal strip is indicated in purple.

The voltage applied to the interdigitated top metal electrode establishes an electric field, E_0, in the AlN film. Considering the limited thickness of the AlN film, the curvature of the electric field lines is negligible. Therefore, to a first order of approximation, E_0 can be considered as oriented exclusively in the z-direction (Fig.1). In CMRs the electric field generates strain through the equivalent piezoelectric coefficient, d_{31}. The generated strain is maximum when the device is excited close to the resonance frequency. The resonance frequency of an AlN CMR is set by the period, $2W$ (Fig.1), of the voltage polarity distribution in the interdigitated top metal electrode and by the acoustic velocity

of the resonator stack. The expression for the resonance frequency of the AlN CMR is given by:

$$f_0 = \frac{1}{2W} \cdot \sqrt{\frac{E_p}{\rho_p}} \qquad \text{[Eq.1]}$$

where E_p and ρ_p are equivalent Young's modulus and mass density, which are a function of the corresponding physical properties of each of the materials that form the resonator stack.

III. Anchor Losses

As shown in [3,5], anchor loss represents the main source of acoustic energy loss for AlN CMRs with resonance frequency in the VHF range. The width-extensional vibrations excited in the AlN film also generate a longitudinal wave that propagates in a direction orthogonal to the main vibration (Fig.2). This longitudinal wave is responsible for the loss of energy through the anchors. As Fig. 2 clearly shows, the anchors and theirs semi-infinite extensions in the substrate represent a path for the longitudinal wave to propagate and dissipate some of the energy generated in the resonator's active region. Although a 2-D analysis should be used to quantify the anchors' dissipations, a simplified 1-D analytical model is adopted here. To a first approximation, the maximum displacement related to the longitudinal wave is proportional to the maximum displacement of the width-extensional mode of vibration and to the AlN Poisson ratio, ν. Therefore, considering a generic point, $P_0(x_0,y_0)$,on the resonator's body (Fig.2), the displacement vector $\vec{\mu}$at P_0 can be seen as the sum of two orthogonal components. In this simplified model, one component represents the desired width-extensional contour-mode, and the other represents the orthogonal mode (Fig.2) that is generated by the main vibration through ν:

$$\vec{\mu}(x_0, y_0) = \mu_x \cdot \hat{x} + \mu_y \cdot \hat{y} = \mu_x \cdot (\hat{x} + \nu \cdot \hat{y}) \qquad \text{[Eq.2]}$$

Hence, for this simple model the displacement function in the y-direction can be attained as a function of the displacement in the x-direction (Fig.2).

The lateral displacement, μ_x, in an AlN CMR is also assumed to be given simply by:

$$\mu_x = A_0 \cdot \cos[kx] \qquad \text{[Eq.3]}$$

where A_0 is the peak-to-peak amplitude of the vibration, k is the wave number associated with the width-extensional acoustic mode, and x is the direction of vibration.

The vicinity of the anchors to the resonator's active region allows assuming the propagation of the longitudinal wave through the anchors to be almost cylindrical. Therefore, in the general case of W_a<W the energy lost through the anchors can be calculated considering the expression of μ_y in -W/2<x<W/2. An expression for the energy lost per unit length of the resonator will be then formulated:

$$W_{lost} \propto \nu^2 \cdot \int_{-W/2}^{W/2} \frac{1}{2}[E_p \cdot T_{AlN}] \cdot (\frac{d\mu_x}{dx})^2 dx \qquad \text{[Eq.4]}$$

where T_{AlN} is the thickness of AlN.

The quality factor, Q, of a resonator is defined as the ratio between the energy stored and the energy lost:

$$Q = \frac{W_{stored}}{W_{lost}} \qquad \text{[Eq.5]}$$

Considering the case of devices with resonance frequency lower than 500 MHz, it is possible to neglect any other source of dissipation in the resonator, except for anchor loss. Q can then be considered to be inversely proportional to W_{lost}. This is clearly an approximation, but it works well with the 220 MHz devices reported here.

The reduction of the energy that escapes from the anchors would results in an increase of the device Q. The increase in Q is electrically modeled as a decrease of the resonator motional resistance R_m[1], and would lead to lower energy dissipation in filters and oscillators.

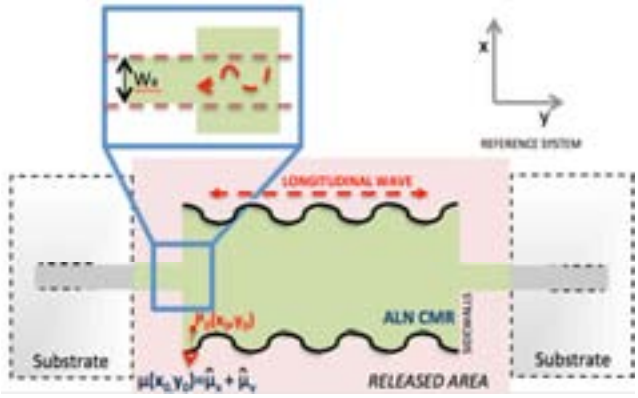

Figure 2:Schematic representation of an AlN CMR used to highlight the existence of a longitudinal mode orthogonal to the main lateral,width-extensional mode of vibration. The device is connected to the substrate through two supporting anchors through which the longitudinal wave escapes the resonator body.

IV. Etched Slots To Reduce Anchor Losses

A new design approach is presented here to reduce anchor losses and, consequently, to increase Q in AlN CMRs. This technique is based on the introduction of etched slots in the AlN film, in close proximity of the anchors (Fig.3). Each slot is effectively an air gap that is created during the etching of the AlN film. The slot's surface represents a free-stress boundary that totally reflects the longitudinal incident wave coming from the resonator's active region. The main design dimensions of the slots are the width, w, and the length, l (Fig.3). w is chosen to have a value close to the minimum feature size that can be defined by the available lithographic equipment (~ 1 μm) . This is done so as to minimize the impact of the slot on the mode of vibration of the resonator. The slot's length, l, directly impacts the amount of acoustic energy that is reflected back after hitting the walls of the slot. This energy, W_{inc}, can be calculated as:

$$W_{inc} \propto v^2 \cdot \int_{-l/2}^{l/2} \frac{1}{2}[E_p \cdot T_{AlN}] \cdot (\frac{d\mu_x}{dx})^2 dx \qquad \text{[Eq.6]}$$

To evaluate Q a new reflection coefficient, Γ is defined. Γ is the ratio between the energy that hits the slot's wall and is reflected back to the cavity, W_{inc}, and the energy that would be lost through the anchor if the slots were to be removed, W_{lost}.

$$\Gamma = \frac{W_{inc}}{W_{lost}} \qquad \text{[Eq.7]}$$

Using (Eq.4) and (Eq.6) it is possible to write the reflection coefficient as:

$$\Gamma = \frac{[\frac{-2\lambda}{2\pi} \cdot \sin(\frac{2\pi}{\lambda} \cdot \frac{l}{2}) \cdot \cos(\frac{2\pi}{\lambda} \cdot \frac{l}{2}) + l]}{[\frac{-2\lambda}{2\pi} \cdot \sin(\frac{2\pi}{\lambda} \cdot \frac{W}{2}) \cdot \cos(\frac{2\pi}{\lambda} \cdot \frac{W}{2}) + W]} \qquad \text{[Eq.8]}$$

where λ is the acoustic wavelength ($\lambda=2W$) (Fig.1). This reflection coefficient permits to readily estimate the Q improvement if we assume that all the losses in the resonator are represented by W_{lost}:

$$\frac{Q_{slot}}{Q_{conventional}} = \frac{1}{(1-\Gamma(l))} \qquad \text{[Eq.9]}$$

where Q_{slot} is the quality factor of the resonator with slots and $Q_{conventional}$ is the quality factor of an identical resonator without slots. The predicted Q as a function of l is plotted in Fig.4. A $Q_{conventional}$ equal to 2000 was assumed for a 220 MHz AlN CMR.

V. Fabrication

The microfabrication process used for making the devices analyzed in this paper is a 3-mask process. 10 nm of Ti and 100 nm of Pt were deposited and patterned on a high resistivity silicon wafer. Subsequently, 1 µm of AlN was sputtered followed by the deposition and patterning of 100 nm of Al. The etching of AlN, followed by the structural release in XeF_2, completed the fabrication process.

VI. Experimental Results

To validate the technique presented in this paper, four different configurations of 220 MHz AlN CMRs have been built (Fig.3). Configuration A represents a device without slots; configurations B, C and D are obtained from A by inserting two slots at a distance of 3.5µm from the edge of the resonator (Fig.3). Configuration B has a slot length (Fig.4) equal to 3.5 µm; configuration C has a slot length equal to 7 µm; configuration D has a slot length equal to 14 µm. The slot width w is about 1µm for all configurations. The anchor's width is 8.6 µm and the anchor's length is 7 µm.

The experimental results are averages of 8 devices for A, 7 devices for B, 6 devices for C and 6 devices for D. The devices were extracted from 8 different dices coming from the same wafer. The reason why not all 8 devices were considered for calculating the averages for B, C and D is that some of these devices were not functional. The reason of the reduced yield is not to be attributed to the introduction of the slot, but issues with wafer processing.

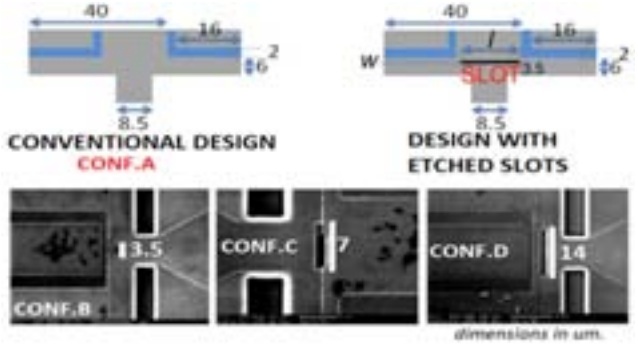

Figure 3: Geometries of configurations A, B, C and D.The slot's length is highlighted in the SEM for configurations B,C and D.

The average measured Q for each configuration is shown in Fig.4. This trend shows that increasing the slot's length with respect to the acoustic wavelength ($\lambda \approx 40\mu m$) results in an improvement of Q. Indeed, configuration D presented the highest quality factor. The measured trend is in line with the analytical prediction (Fig.4 – in green). This validates the design approach and confirms that the use of slots can improve the Q of resonators operating at 220 MHz. As shown in Fig.5, the improvement in Q comes with a proportional decrease of R_m with respect to the conventional configuration. Since this design approach does not deteriorate k_t^2, an almost 50% improvement in the *FoM* of the resonator has been obtained. The measured admittance of the best devices for each configuration is shown in Fig.5.

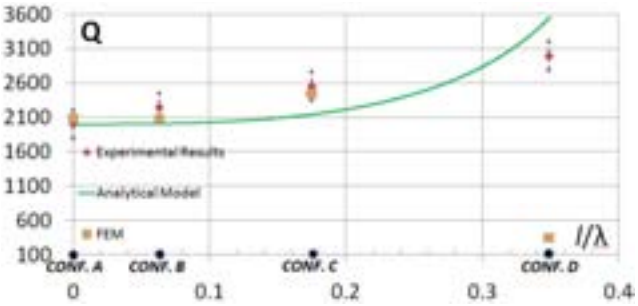

Figure 4:Red diamonds:Experimentally obtained average Q for configurations A,B,C and D. Yellow squares:Q simulated by FEM. Green line: analytical prediction of Q as a function of the slot's length l, according toEqs.7-8.

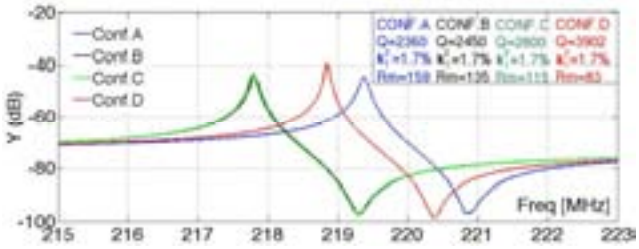

Figure 5: Admittance of the best device measured for each configuration. R_m decreases as we move from configuration A to configuration D. No variation in k_t^2 is measured.

VII. FEM SIMULATIONS

A dedicated 3D finite element (FE) tool has been employed to analyze the impact of the etched slots on the resonator *Q*. The dissipation of elastic waves radiating from the anchor of the resonator into the elastic subspace is simulated via the Perfectly Matched Layer (PML) technique.

Extensive validation of this FE tool for the prediction of Q for MEMS resonators has been previously reported [5,6].

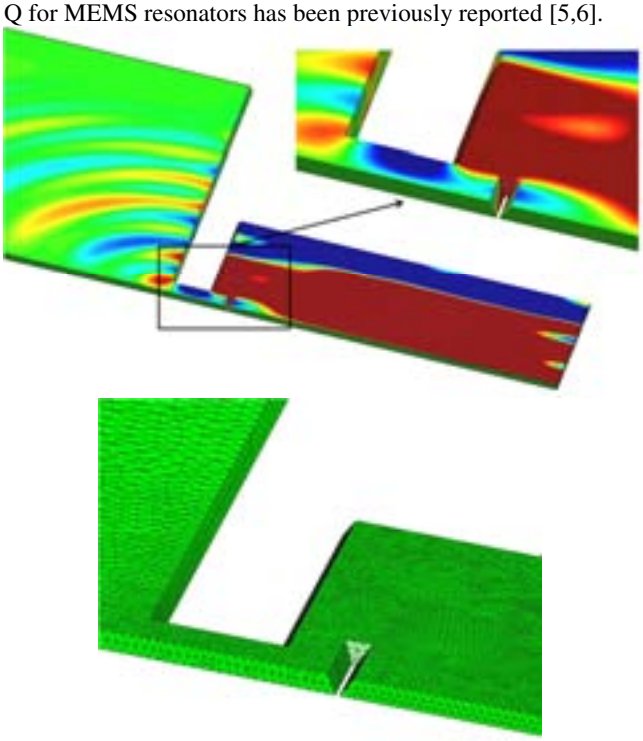

Figure 6: Rapresentation of the waves dissipating into the substrate and mesh used in the FEM simulations.

Figure 6 depicts the geometry of the device used in the numerical simulations. Given the symmetry of the problem, only 1/4 of the resonator has been discretized. To ensure accurate solution, approximately 180000 10-node tetrahedra have been used for the space discretization.

The results of the numerical analyses are reported with the experimental data In Figure 4. The FE data show good agreement with experiments for the first three slot lengths On the contrary, for conf. D the mismatch between numerical predictions and experiments is significant. A careful investigation of the possible cause of this discrepancy is still ongoing. Especially, we have noticed that the FE data continue to follow the analytical values for slot lengths greater than $l/\lambda > 0.35$. Hence, the discrepancy appears to be isolated to this specific data point. The analyses performed to date have shown that the resonator *Q* is greatly affected by a number of geometrical parameters of the resonator. In particular it has been observed that *Q* strongly depends on the sidewall angle and on the shape of the regions where the anchor connects to the substrate and to the resonator. As an example, if the sidewall angle for configuration D is taken as 55° instead of 60°, the quality factor raises from 363 to 1100. Furthermore, since conf. D presents the longest slot (see Figure 3) it is reasonable to assume that it will be mostly affected by the anchor shape (which shows rounded edges) near the resonator. We expect that a more accurate description of the resonator geometry would eliminate the existing discrepancy.

VIII. CONCLUSIONS

In this paper, a new design technique for improving the *Q* of VHF and low UHF designs of AlN CMRs has been presented. The technique uses etched slots in the body of the AlN film close to the anchors. This method reduces anchor losses, and improves *Q*. A 1-D analytical model, and a finite element code have been developed to respectively describe the physical role of the slot and predict the resonator *Q* for different slot's dimensions. Using this approach an average 50% increase in *Q* and in the *FoM* was recorded for 220 MHz AlN CMRs.

hui.y@husky.neu.edu; qian.z@husky.neu.edu; rinaldi@ece.neu.edu

***Abstract*—This paper presents the first demonstration of a high frequency (2.8 GHz), lateral field excited (simple two masks fabrication process), combined lateral-thickness extensional mode of vibration aluminum nitride (AlN) micro-electro-mechanical systems (MEMS) resonator with unprecedentedly high figure of merit ($k_t^2 \cdot Q > 45$). For the first time, a single interdigital electrode was employed to excite a high frequency mode of vibration in an AlN plate (1.5 µm thick) by making use of both the d_{33} and d_{31} AlN piezoelectric coefficients. The resulting MEMS resonator showed high quality factor, Q~2000, (thanks to the high quality AlN film directly deposit on top of the Silicon substrate) and the highest electromechanical coupling coefficient ever reported for AlN MEMS resonators employing a single electrode, k_t^2~2.5% (thanks to the coherent combination of d_{33} and d_{31} coefficients to transduce one single mechanical mode of vibration).**

Keywords—Aluminum Nitride; MEMS Resonators; Combined Mode; Electromechancial Coupling Coefficient; Figure of Merit

I. INTRODUCTION

The high frequency Aluminum Nitride (AlN) Micro-Electro-Mechanical Systems (MEMS) contour mode resonator (CMR) technology [1] has shown great potential for the implementation of single-chip, multi-frequency RF filters and frequency sources. The CMR technology has the same advantages of thin film bulk acoustic resonators (FBARs) over SAW devices in terms of miniaturization and IC integration capabilities. Nevertheless, the CMR technology employs the d_{31} piezoelectric coefficient of AlN to transduce a lateral-extensional mode of vibration in the micromechanical structure, in contrast to FBARs, which use the d_{33} piezoelectric coefficient of AlN to transduce a thickness-extensional mode. Therefore, the operating frequency of CMRs is lithographically set by the lateral dimensions of the device (rather than by the thickness of the AlN layer as in the FBAR case) enabling the fabrication of multiple frequencies of operation on the same silicon chip. This is a crucial feature for advanced wireless communication systems, for which single-chip, multi-band RF solutions are becoming the dominant trend.

Nevertheless, the performance of an electromechanical resonator is in general evaluated in terms of figure of merit (*FOM*) defined as the product of quality factor (Q) and electromechanical coupling coefficient (k_t^2) of the resonator. High Q>2000 is typically achieved in high frequency AlN CMRs while only limited values of k_t^2<2.5% have been demonstrated for this class of devices due to the relatively small value of the d_{31} piezoelectric coefficient of AlN employed to excite the contour-extensional mode of vibration [2] (in contrast to FBAR devices which show higher values of k_t^2 ~6% [3] being the d_{33} piezoelectric coefficient more than two times larger than the d_{31}). Furthermore, such piezoelectric coefficient-limited values of k_t^2 can only be achieved by maximizing the confinement of the excitation electric field across the thickness of the AlN layer, which requires the use of a thickness field excitation scheme (TFE, shown in Fig. 1(a)) involving a top and bottom electrode (4-mask fabrication process). Lateral field excitation (LFE, Fig. 1 (b)) schemes involving the use of a single interdigital electrode on top of the AlN plate have been proposed [4]. Such LFE configuration greatly simplifies the fabrication of the device (2-mask fabrication process required). Furthermore, operation in the super-high frequency band (up to *9.9 GHz*) [5] and values of Q as high as *2200* [6] have been demonstrated using LFE. Nevertheless, it has been theoretically demonstrated [7] that only relatively low values of k_t^2< 1.5% can be achieved using the LFE configuration due to the reduced confinement of the excitation electric field across the thickness of the AlN layer.

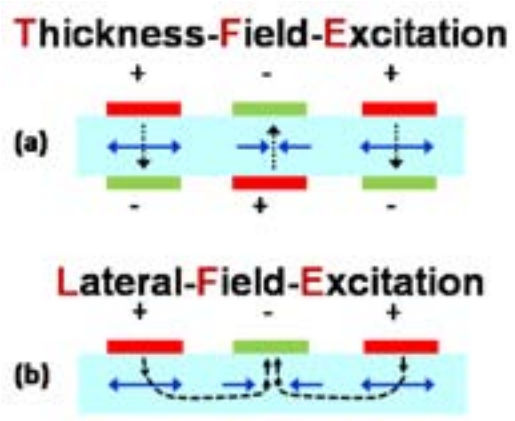

Fig. 1. Schematic illustration of the TFE and LFE schemes of AlN CMRs: the black dash arrows represent the electric field and blue solid arrows represent the in-plane displacement of the AlN plate.

In this work, for the first time high operating frequency (*2.8 GHz*), quality factor (Q~*1855*) and electromechanical coupling coefficient (k_t^2~*2.48%*) were simultaneously

This work was supported by DARPA Young Faculty Award contract No. N66001-12-1-4221.

demonstrated in a LFE AlN MEMS resonator whose thickness and lateral dimension were properly designed to transduce a single mechanical mode of vibration based on the coherent combination of the d_{31} and the d_{33} piezoelectric coefficients of AlN. Such combination of piezoelectric coefficients enhanced the k_t^2 of the device resulting in a *2.8 GHz* LFE AlN MEMS resonator with unprecedentedly high *FOM~46* despite the use of a single interdigital top-electrode (simple 2-mask fabrication process).

II. DESIGN AND FABRICATION

A conventional LFE CMR is composed of a simple two-layer structure in which an interdigital metal electrode is deposited on top of an AlN plate. When an AC signal is applied to the top interdigital electrode a contour-extensional mode of vibration is excited through the equivalent d_{31} piezoelectric coefficient of AlN. Given the equivalent mass density, ρ_{eq}, and Young's modulus, E_{eq}, of the material stack that forms the resonator, the center frequency, f_0, of this laterally vibrating mechanical structure, is set by the pitch, W, of the top interdigital electrode [1]. For the combined mode resonator proposed in this work, the pitch, W, of the interdigital electrode and the thickness, T, of the AlN layer were optimized through FEM simulation in order to excite a single mechanical mode of vibration based on the coherent combination of d_{31} and d_{33} piezoelectric coefficients which maximizes the electromechanical coupling coefficient of the device.

A 2D finite element method (FEM) simulation was performed using CMOSOL Multiphysics to investigate the k_t^2 dependence on the thickness, T, of the AlN resonator for a given value of the interdgital electrode pitch, W, hence wavelength, $\lambda=2W$. The simulation result, reported in Fig. 2, indicates that high values of $k_t^2 > 2.5\%$ (~ two times higher than the best values achievable with conventional LFE AlN CMRs [8]) can be achieved for T/λ values ranging between *0.35* and *0.55* for which the d_{31} and the d_{33} piezoelectric coefficients of AlN are coherently exploited to excite a single combined mode of vibration with enhanced k_t^2.

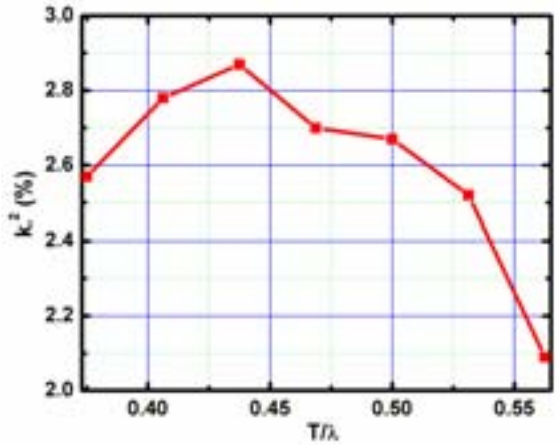

Fig. 2. FEM simulated k_t^2 dependence on T/λ for an AlN LFE resonator employing a single top interdigital electrode ($\lambda=2W$) .

The simulated admittance curve and the corresponding 2D mode shape of vibration for $T/\lambda=0.47$ are shown in Fig. 3. The simulation result clearly shows that, at the resonance frequency, the lateral-extensional and thickness-extensional modes are combined into a single mechanical mode of vibration with enhanced electromechanical coupling coefficient, $k_t^2 \sim 2.78\%$.

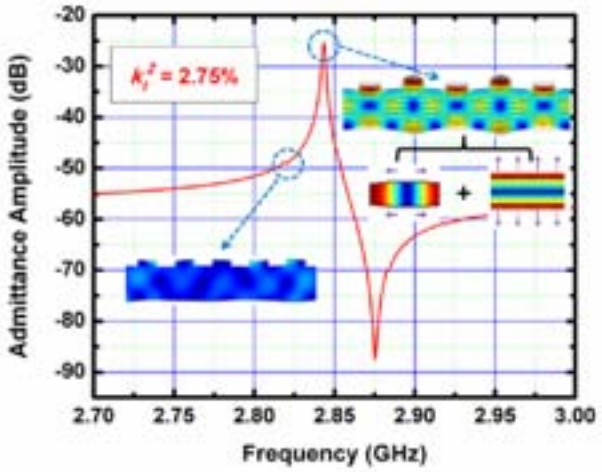

Fig. 3. FEM simulated admittance curve and 2D mode shape of vibration of the LFE combined mode AlN resonator. A single combined mode of vibration is predicted. A spurious mode at a frequency slightly lower than the resonance is also predicted and observed in the experimental data in Fig. 6.

Based on the aforementioned analysis, a device prototype with $T/\lambda=0.47$ was designed and fabricated. The pitch, W, of the interdigital electrode was set to *1.6 μm* and the thickness, T, of the AlN was accordingly chosen to be *1.5 μm.* The proposed AlN resonator was fabricated using a simple two-mask microfabrication process (Fig. 4): 1.5 μm thick AlN film was sputter-deposited on top of a high resistivity Silicon wafer. Then, 200/50 nm thick Al/TiN film was deposited on top of AlN film and patterned by lift-off process to define the top interdigital electrode. Next, the AlN film was etched by ICP in Cl_2 based chemistry to define the shape of the resonator. Finally, the Silicon substrate underneath the AlN resonator was released by XeF_2 isotropic etching. The SEM image of the fabricated device is shown in Fig. 5.

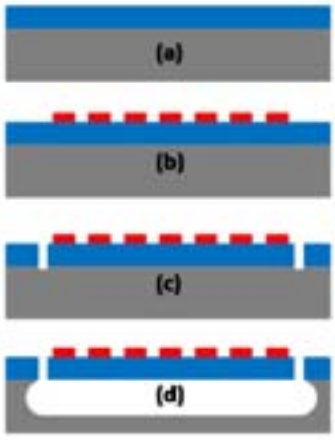

Fig. 4. 2-mask microfabrication process of the AlN combined mode MEMS resonator: (a) AlN thin film was sputter-deposited on top of Si substrate; (b) Al/TiN film was deposited on top of AlN film and patterned by lift-off process; (c) AlN film was etched by ICP in Cl_2 based chemistry; (d) Si substrate was released by XeF_2 isotropic etching.

III. EXPERIMENTAL RESULTS

The electrical performance of the fabricated AlN LFE combined mode MEMS resonator was measured by an Agilent E5071C network analyzer after performing an open-short-load calibration. The measured admittance response versus frequency and the Butterworth-van Dyke (BVD) fitting are shown in Fig. 6. A single resonance peak was measured at *2.82 GHz* in agreement to the FEM simulation. As expected, high quality factor, *Q of 1855* (thanks to the direct deposition of AlN film on a polished Silicon substrate) and high electromechanical coupling coefficient, k_t^2*~2.48%* (thanks to the combined d_{31} and d_{33} piezoelectric coefficients) were achieved. The measured k_t^2 of *2.48%* and the corresponding *FOM~46* are the highest ever reported among LFE AlN MEMS resonators employing a single top interdigital electrode (2-mask fabrication process).

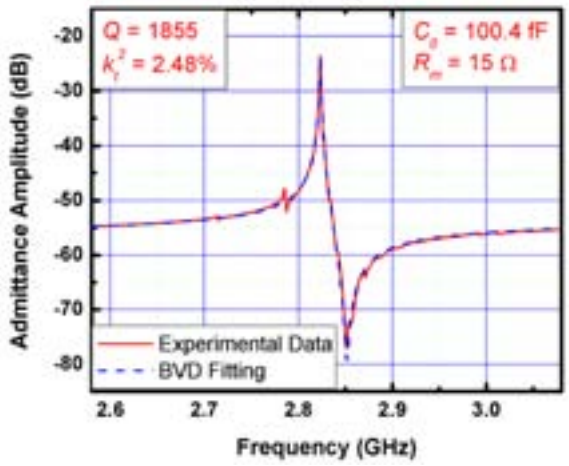

Fig. 6. Measured admittance curve and BVD fitting of the fabricated LFE combined mode AlN MEMS resonator.

IV. CONCLUSION

In this paper, a novel design concept for the implementation of high electromechanical coupling AlN MEMS resonators was experimentally verified. A single interdigital electrode was employed to excite a high frequency mode of vibration in an AlN plate (1.5 µm thick) by making use of both the d_{33} and d_{31} AlN piezoelectric coefficients and a high frequency (*2.8 GHz*), lateral field excited (simple 2-mask fabrication process), combined mode of vibration AlN MEMS resonator with unprecedentedly high figure of merit ($k_t^2 \cdot Q$ ~ *46*) was experimentally demonstrated. The measured figure of merit is the highest ever reported among LFE AlN MEMS resonators employing single top interdigital electrode (2-mask fabrication process).

***Abstract*— Surface Acoustic Wave (SAW) and Bulk Acoustic Wave (BAW) devices are largely used in telecommunication for radio Frequency (RF) signal processing. Nevertheless, these devices are limited by various factors such as short-circuit between electrodes for SAW and precise thickness control for BAW. This paper shows the interest of a new kind of transducer using Periodically Poled Lithium Niobate (PPLN) developed to overcome SAW and BAW technological limits. A former PPLN-based wave-guide was presented some years ago exploiting planar technologies. The novelty of the present work lies in the 3D structuring of the transducer allowing for very high aspect ratio structures exhibiting a theoretical electromechanical coupling about 20% and a phase velocity up to 20 km.s^{-1}.**

Keywords- Periodically poled transducer; Lithium Niobate; high aspect ratio ridge

I. INTRODUCTION

Surface acoustic wave (SAW) devices using inter-digitated transducer (IDT) are commonly used for passive radio-frequency components such as resonators and filters. This mature technology is particularly addressing RF filter demands, yielding a yearly production of billions of pieces. Although effective and massively produced, SAW devices based on IDTs are limited by various factors when addressing the demand for frequency operation in excess of 2.5 GHz. Among these limitations, the nature of the mode and single crystal acoustic properties do not allow for the excitation of surface waves with phase velocity much higher than 6 km.s^{-1} (leaky-longitudinal SAW on Lithium Niobate – $LiNbO_3$ [1]). Also, currently implemented industrial technologies for SAW devices provide electrode width in the vicinity of 0.3 µm. Such lithography resolution requires high quality control of IDT finger definition to avoid any risk of short-circuit between electrodes (preventing the correct operation of the resulting SAW device).

Many efforts are presently developed to address these issues, along various principles and structures (RF Micro-Electro-Mechanical Systems – RF MEMS – such like Film Bulk Acoustic Resonators, Solidly Mounted Resonators, and a population of locally vibrating parts excited using electrostatic forces [2]). An approach has been identified as an attractive combination of bulk and surface wave transducer characteristics, using ferroelectric polarization to generate an interference grating for acoustic waves. The so-called periodically poled transducer (PPT) is actually taking advantage of a planar definition of the acoustic period (similarly to SAW) and a bulk propagation, allowing for various kinds of mode and acoustic propagation to be exploited. It consists of a periodic polarization of ferroelectric materials such as single crystal $LiNbO_3$, combined with plane electrodes exciting and detecting waves propagating in the bulk of the material [3], providing an alternative to IDT's exhibiting remarkable properties. As shown in [3], assuming a given grating period, the frequency of a PPT is twice higher than the one of IDT, as PPTs do naturally operate on a second harmonic regime, as explained in fig. 1. This kind of PPT was successfully manufactured as shown in [3] and [4], but the best experimental electromechanical coupling remained smaller than 1%. More specifically in [4], a Periodically Poled Lithium Niobate (PPLN) wafer was stacked between two silicon wafers to guide acoustic waves and to reduce the temperature coefficient of frequency [4], allowing for transducer working from 65MHz to 1.3GHz with a TCF of -50 ppm.K^{-1}, i.e. twice smaller than the TCF of PPT on pure $LiNbO_3$ plates.

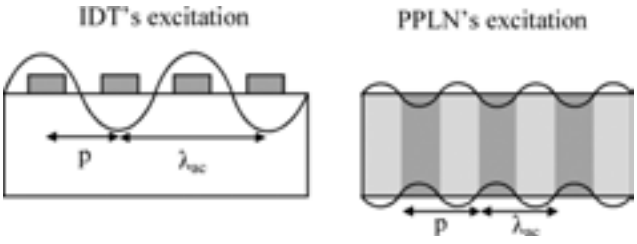

Figure 1. Excitation principle for (left) inter-digitated transducer and (right) periodically poled lithium niobate

As this new device only allows for the excitation/detection of acoustic modes with limited electromechanical coupling (1% in the best case for $LiNbO_3$ and Lithium Tantalate – $LiTaO_3$), they revealed poorly appropriate to modern RF filter challenges, requiring electromechanical coupling up to 10% or even more. However, these two materials are known to allow for much more coupled mode excitation, particularly concerning bulk waves. Even if advanced transducer combinations provide advantageous conditions for wave trapping [4], PPTs based on this basic architecture are not

capable to overcome such coupling values (PZT – Lead zirconate titanate – was found theoretically capable of larger mode coupling, but it poorly suits RF requirements due to excessive intrinsic acoustic losses [5]). To overcome this limitation, various electrode configurations and excitation conditions have been investigated, resulting in a new device architecture based on a high aspect ratio structure (ridge) which allows for coupling higher than 20%. This kind of structure is used for optical waveguides ([6], [7], [8]) allowing to develop new devices requiring highly guided light.

Using a homemade simulation tool [9], different device designs have been studied to determine the best configurations. Ridges are achieved by dicing trenches into $LiNbO_3$ periodically poled wafers [10]. The sides of the ridges are polished during the saw dicing, yielding wave confinement. Electrodes then are deposited on the ridge sides using gold or aluminum sputtering. The characterization of such transducers then is achieved by using a network analyzer. The agreement between theory and experiment has been checked to confirm theoretical predictions, assessing the efficiency of the developed concept and the associated analysis.

Device manufacturing is detailed in the following sections of the paper. The obtained devices are characterized to emphasize the advantages of these ridge-based PPTs.

II. TRANSDUCER MANUFACTURING

The fabrication of the new device based on PPLN ridge is described in this section. Two dicing methods are described to illustrate saw-dicing capabilities for manufacturing high aspect ratio structures.

A. Description of the process flow-chart

For this process, a 500µm thick Z-cut Lithium Niobate wafer was used. First, a photo-lithography process is achieved to pattern the shape of future inverted domains (Fig. 2 a) and 2 b). Lithium Niobate then is wedged between two seals to introduce an electrolyte without leaks. A mechanical system allows for keeping the wafer and seals together (Fig. 2 c). An electric field higher than the coercive field of Lithium Niobate (21kV/cm) is applied between the two sides of the wafer. A photo-resist layer is used as an electric insulator. Consequently, areas covered by the photo-resist are not inverted (Fig. 2 d). For more details about poling steps, the reader should refer to ref. [3]. After the poling step, the wafer is coated with a photo-resist overlay and diced to fabricate ridge shaped transducers. Saw-dicing is performed along X axis over depths ranging from 100µm to 500µm (Fig. 2 e). Aluminum electrodes are then sputtered on the device walls and patterned by lift-off. Electrode deposition method is depending on the saw-dicing depth. In that purpose, the device can be tilted by few degrees to reach ridge bottoms (Fig. 2 f).

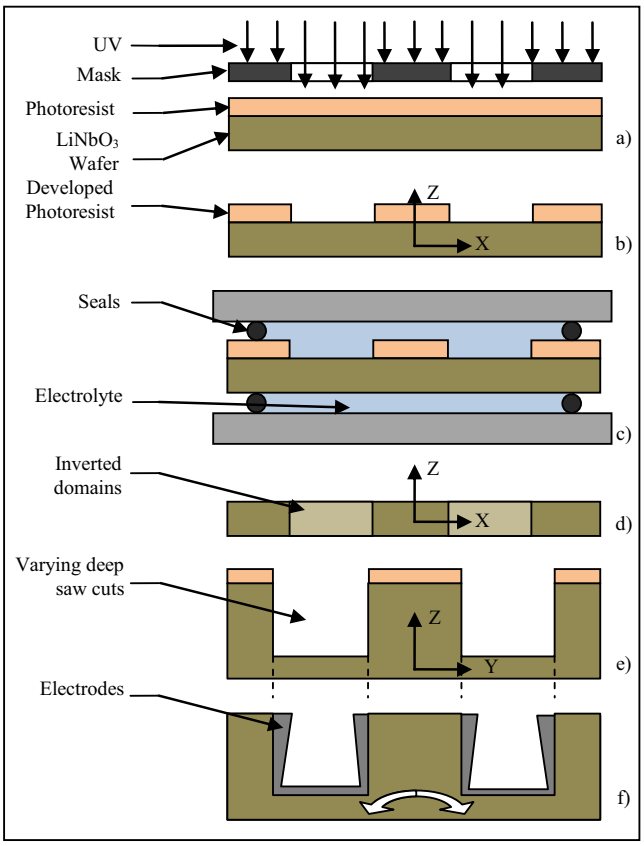

Figure 2. Process steps for Lithium Niobate PPT-ridge fabrication

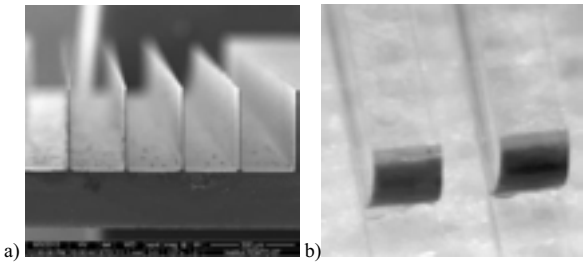
B. Dicing

Saw-dicing is the main technological process for this kind of PPT-ridges. It also provides the final structure of the device and therefore it conditions the transducer performances which largely depend on dicing quality and precision. This process is achieved using a DISCO saw apparatus, with diamond blade of 400µm width and 5.2cm diameter. Two ridge-width-spaced cuts are achieved to obtain one ridge. Parameters such as feed rate and operating speed have been optimized to get the best side wall quality. A photo-lithography process is first performed on the poled wafer to allow for electrode patterning. Two dicing methods have been investigated to determine the most effective one.

- The first one consists of dicing a ridge to a depth smaller than the wafer thickness (500µm), allowing ridge narrower than 10µm and higher than 100µm. This method allows for very narrow ridges, yielding then high working frequencies (above one GHz) and width over poling period (w/p) ratios of 0.2 and 0.4 – identified as the best working points to reach the highest electromechanical coupling. An example of these ridges is shown on fig. 3. a).
- The second method consists in dicing the whole thickness of the wafer. This method allows for devices

very close to theoretical configurations. However, device width can't be smaller than about 100µm due to technological limits, therefore w/p ratios of 0.2 and 0.4 can be reached only for period larger than 500µm. Figure 3.(b) shows ridges diced through the whole depth of the wafer.

For both methods, the process is developed to achieve polished ridge sides (5 < Ra < 50nm with Ra the average roughness), the better the side quality, the better the wave confinement.



a) b)

Figure 3. Ridges achieved with the dicing first method a) and with the second dicing method b)

For the first method, electrodes are sputtered on ridge sides by tilting device by few degrees (fig. 2 f). A lift-off process then is achieved to pattern the electrodes. The second method allows for a direct sputtering on ridge sides as the device can be tilted by 90° within the sputtering machine.

C. Transducer Characterization

Only the second type of device is characterized here because of simulation model and experimental setup completion. Before achieving the device characterization, electrodes are deposited on its (YX) sides. One electrode is deposited all along the device to ensure the contact between the PCB plate and the device. Another electrode is deposited only on the poled area (see fig. 4), allowing for the excitation of this area only (avoiding any parasite bulk response).

Figure 4 shows one of the experimental devices (λ=600µm, w=120µm), stuck on a PCB with a conductive silver paste. Another device (λ=600µm, w=200µm) has been characterized to check result coherence.

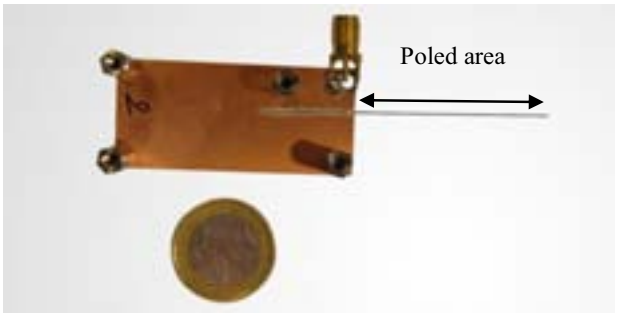


Figure 4. As-prepared ridge-PPT device for characterization.

The SMA port shown in fig. 4 is connected to the network analyzer on one side and to the device by a thin gold wire on the other side allowing for the characterization of the transducer. Device response is recorded for frequencies ranging from 1MHz to 30MHz. Due to their design and dimensions, these devices were particularly suited to check the position of resonance frequencies and confirm the existence of coupling close to 20%. Theoretical investigations show that there are two interesting resonant modes: a longitudinal mode around 10.3MHz (k^2 = 9%) and a shear mode around 16.8MHz (k^2 = 22%). Figure 5 compares the frequency analysis of the device (measured conductance) with simulation results (harmonic conductance).

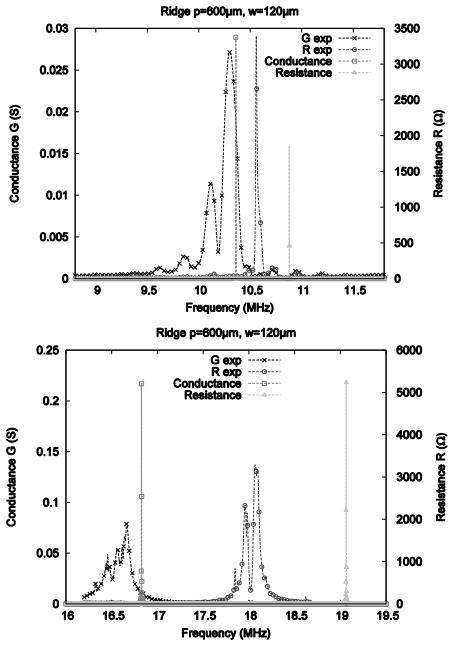

Figure 5. Comparison between experimental (actual conductance) and theoretical (harmonic conductance) device response.

The deviation between theoretical and experimental frequencies of the two investigated modes at 10.3MHz and 16.8MHz respectively is smaller than 1% (fig. 5). This matching is not only explained by the adequacy between the finite element model and the actual device design but also by the accuracy of $LiNbO_3$ physical coefficients used in the computation ([10]). The device was indeed not poled nor excited on its stuck extremity, yielding it very close to a "free-free model". Experimental coupling coefficient of these devices is not as high as predicted but it is found 20 times larger than former $LiNbO_3$ PPTs [4]. Moreover, the experimental electromechanical coupling evolution follows the theoretical prediction, as shown in Table 1. The difference between theoretical and experimental couplings can be explained by the quality of the ridge sides. Due to the indented profile of the ridge, its width is not constant along its length,

leading to resonant mode spreading and electromechanical coupling decreasing.

TABLE I. TRANSDUCERS CHARACTERIZATION RESULTS AT λ =600µm

Length (cm)	Depth (µm)	Width/period ratio (µm)	Resonance frequency (kHz)		Electromechanical coupling (%)	
			Exp.	Theo.	Exp.	Theo.
5	500	0.20	16665	16821	14.95	22.08
			10299	10364	4.88	9.09
		0.33	11468	11553	10.94	18.33
			10316	10093	8.42	10.76

These results confirm nevertheless the existence of the two predicted acoustic resonant modes close to the expected frequencies, and as a side result, the accuracy of our simulation tool. They also confirm that coupling coefficients can reach values larger than 10%, depending of the device configuration.

CONCLUSION

A new type of structures has been successfully manufactured to allow for experimental investigation of waves excited and propagating in ridge-PPTs. The obtained results are encouraging, emphasizing a very good agreement between simulation and experiment. Electromechanical coupling coefficients of about 15% have been experimentally demonstrated, according to theoretical predictions, which is a key-point for the future exploitation of these devices as wide-band filter for telecommunication. Wave velocities in excess of $9km.s^{-1}$ have been also observed, in line with theoretical predictions. This result indicates that waves propagating in the proposed ridge-PPT are capable to largely overcome SAW velocities and may advantageously compete with Lamb waves characteristics. The proposed approach is therefore a serious alternative for high frequency acoustic devices needed for the telecommunication standard of the future.

***Abstract*—Bulk Acoustic Wave devices with effective phonon trapping demonstrate extremely low losses superior to any other mechanical systems currently under investigations. It is demonstrated that quality factors of such systems approach the level of 10^{10} at relatively high frequencies approaching one GHz. The record high $Q \times f$ product of 1.6×10^{18} opens a wide range of applications for such devices including testing of fundamental physics, quantum hybrid systems and high precision frequency generation.**

I. Introduction

This work gives a general overview of the recent achievements and future perspectives of the cryogenic quartz Bulk Acoustic Wave (BAW) devices. The work discusses the major issues related to such devices including loss mechanisms and nonlinearities. Identification of loss mechanisms in extremely high quality factor system is an important step in their further development. Characteristics of the state-of-the-art acoustic cavities given in this work open a door for various applications of such systems ranging from frequency standards to tests of fundamental physics.

Section II discusses principles of operation of BAW resonators from the point of view of phononics. The following section discusses various loss mechanisms in detail giving some estimations. Section IV discusses two sources of nonlinearities experimentally observed in cryogenic acoustic cavities. Section V gives characteristics of the most advanced BAW cavities investigated at cryogenic temperatures. Section VI section summarises the progress and problems of possible applications of cryogenic BAW devices in the area of frequency standards. And, finally, Section VII proposes applications of acoustical cavities for various physical experiments.

II. Overview of the Quartz BAW Cavities

In record low loss regimes at low temperatures [1]–[4], Bulk Acoustic Wave quartz resonators could be regarded as an acoustic analogue of well-known optical Fabry-Pérot cavities. Indeed, the former are typically composed of two partially transmitting mirrors aligned to confine the light beam in confined space. Incident photons of the cavity exhibits multiple reflection allowing it to interfere with itself many times. If the wave length of the light is such that interference does occur within the cavity, the resonance conditions are met and the energy is effectively stored in the system. The same operation principles are utilised in BAW plate resonators where the role of photons (real particles defined in the space) is played by phonons (quasi-particles defined in a crystal lattice), quanta of lattice vibration. These quasi-particles exhibit multiple reflection from the vacuum-crystal interfaces playing the role of mirrors. In the same way as in optics, the resonance conditions are met when the phonon wavelength leads to multiple interference of sound with itself.

The number of phonon self-interference events is limited by the cavity quality factor. The quality factors of the acoustic cavities are approaching 10^{10} for the wavelengths approaching 400 μm giving cavity linewidths of orders of tens of miliHz. This parameter is limited by a number of factors that can be classified into two classes: phonon leakage to the environment [5] or material-related loss mechanism. The former class represent phonon losses due to clamping mechanisms which hardly depend on temperature. The latter type groups mechanisms related to the material of the cavity, which includes phonon-phonon dissipation due to the crystal anharmonisity, thermoelastic losses, two-level system absorption, phonon scattering, etc. These mechanisms are discussed in the next section.

For almost all applications of acoustic cavities it is vital to keep the system losses as low as possible. For this purpose, the phonon leakage losses must be engineered to a minimum. For the plate cavity geometry this is achieved by an effective phonon-trapping technique. The solution is to trap acoustic energy in the centre of the disk plate while the disk is clamped from the sides. The trapping is done by introducing curvature into one of the plate surfaces by manufacturing a plano-convex shape [3], [6]. This variable plate thickness increases the local phonon frequency along the plate disk radius closer to the edges. The corresponding energy difference along the radial direction due to this curvature can be considered as an

978-1-4799-0342-9/13/$31.00 ©2013 IEEE

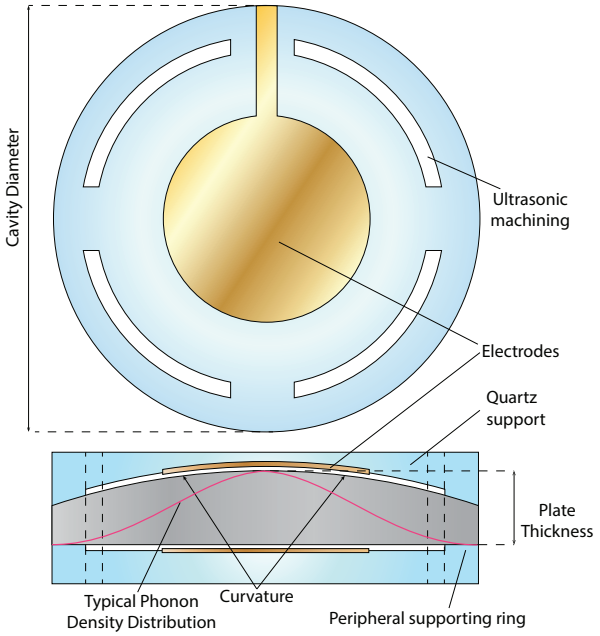

Fig. 1. Acoustic cavity design. The effective phonon trapping reduces phonon density near the disc border preventing losses due to phonon tunnelling to the environment. Phonon density distribution is typically Gaussian for a main overtone mode.

effective potential well. So, phonons are trapped if their total transverse energy (corresponding to in-plane wave numbers) do not exceed the energy difference between the edge and the centre. This situation significantly decreases the probability to find a resonant phonon near the clamping points. Theoretical treatment of the energy trapping problem from the point of view of linear elastodynamics is given in [6]. The calculations predict the mode shape in the form of polynomial-normal distribution. This result has been confirmed by means of X-ray spectroscopy [7], [8]. The cavity design is sown in Fig. 1 demonstrating the typical phonon density for the investigated modes.

An acoustic cavity can exhibit resonance conditions for different phonon polarisations corresponding to different sound velocities. The two quasi-transverse polarizations are known as B (fast-shear) and C (slow-shear) modes. It is demonstrated [1], [2] that the quasi-longitudinally polarised phonons corresponding to the A-mode exhibit the minimum material losses at cryogenic ($\sim$ 4 K) and deep-cryogenic ($\sim$ 20 mK) temperatures. Thus, from this point on, only longitudinally polarised modes are discussed.

The operation of optical cavities require lasers as sources of coherent optical radiation. For acoustical analogues, the cavity may be pumped by an external signal source through effective electromechanical coupling due to the piezoelectric effects of crystals. For this purpose, two conducting electrodes impose a potential difference between two surfaces of the plate that creates a gradient of the electric potential along the plate thickness. The spatial Fourier harmonics of this gradient are coupled to mechanical vibrations through the piezoelectric effect. Frequencies of these vibrations are set by plate dimensions, material properties and the order of the harmonic. This type of vibration is referred as a thickness vibration that has to be distinguish from parasitic flexure vibration modes. Detection of the plate vibration is performed by measuring the displacement current between the surfaces of the plate. To minimise the acoustic losses due to the electrodes, they are separated from the crystal plate by a tiny vacuum gap. This solution is known as the BVA-technology [9]. Electrodes are deposited on two quartz supports placed on each side of the resonator, and in such a way that the gap between electrodes and resonator surfaces is typically between 5 and 10μm [2], [3].

III. Acoustic Losses

Total intrinsic losses of an acoustic cavity apart from phonon tunnelling to the environment are a sum of losses due to different mechanisms:

$$\frac{1}{Q} = \frac{1}{Q_{phonon-phonon}} + \frac{1}{Q_{TLS}} + \\ + \frac{1}{Q_{scattering}} + \frac{1}{Q_{thermoelastic}} + \text{etc}, \quad (1)$$

where the Q-values represent different mechanisms discussed in this section. Temperature and frequency dependancies of these losses are given in [4].

The first phonon loss mechanism in acoustic cavities at low temperatures and relatively high frequencies is loss mechanism due to phonon-phonon scattering over crystal lattice anharmonicity ($Q_{phonon-phonon}$ in equation (1)). This mechanism was first analytically considered by Landau for the case of shear-polarized phonons [10], [11]. The original work discards such losses for longitudinal phonons in the case of two phonon collision, due to significantly higher sound velocity. Later revisions of the theory considered the case of three colliding phonons [12] predicting the following law: $Q^{-1}_{phonon-phonon} \sim T^{-6.5}$. This law is experimentally observed for acoustic cavities between between 6K and 13K [4]. The acoustic wave attenuation α is proportional to the resonance angular frequency ω as long as $\omega\tau_{TH} \gg 1$ where τ_{TH} is the average lifetime of thermal phonons, $\hbar$ the Planck constant, and k_B the Boltzmann constant. So, the $Q_{phonon-phonon}$-factor of an acoustic wave propagating with velocity V

$$Q = \frac{\pi\omega}{V\alpha} \quad (2)$$

would no longer depend on frequency ω. Since these conditions are met in the case of considered systems, the Q-factor tends to be independent of f ($Q = const$ law) and thus independent of the cavity overtone number [4].

It is known the even Top High Quality synthetic crystals are hosts of different kind of impurity ions. In the case of the synthetic alpha quartz material, these ions are Al^{3+}, Na^{+} and Li^{+}, Si^{4+}, H^{+}, etc [13]–[16] studied by various methods. Although the utilised material is premium pure, concentration of these ions could reach $1-3$ ppb. These randomly spread

ions exhibit quantised energy level behaviour and typically appear as two-level systems (TLS) absorbing acoustic phonons. Temperature dependence of associated losses (Q_{TLS} in equation (1)) is predicted to obey the $T^{-0.3}$ [17] scaling law which is also observed in acoustic cavities [3], [4]. Such dependence have been also observed in a various of electromechanical systems [18]–[22].

Despite predictions of the Landau-Rumer theory on frequency-independent losses, the increase of cavity losses at higher frequencies (typically $100 - 220$ MHz) occurs for the most of the experimentally studied devices [1]–[4]. This phenomenon can be explained by phonon scattering on the cavity surfaces ($Q_{scattering}$ in equation (1)). This type of scattering originates from the surface roughness as well as from the presence of a dead layer. The reflection coefficient on a rough surface with a roughness variance σ^2, assuming a gaussian probability density, and can be expressed as $R = e^{-2k^2\sigma^2}$ [23] , for the phonon wave number k.Thus, the reflection is equivalent to a modified path causing an attenuation equal to $\alpha^{'} = \alpha + \ln(R/h)$, where h is the cavity thickness. So, for an overtone number $n = kh/\pi$, the Q-factor is given as:

$$Q_{scattering} = \frac{h^2}{2n\sigma^2} \tag{3}$$

Since the resonant frequency $\omega = 2\pi f$ is almost proportional to the overtone number n, this mechanism results in $Q \times f = const$ scaling law. The highest measured Q-values are close to estimated values of $Q_{scattering}$, demonstrating that the cavity roughness could be a limiting factor for higher frequencies. The surface scattering mechanism explains better performance of the cavities with a better surface polishing grading [4]. The largest observed values of Q-factors correspond to $\sigma = 1$ nm, which is consistent with specification of the fabrication process. For other cavities, the standard deviation varies from 4 or 7 nm, which is also in agreement with used polishing processes.

A cause of the quality dependence on the frequency for even higher resonance frequencies (> 200 MHz) is bulk phonon scattering. At such frequencies, the expected $Q = const$ law is overcame by $Q \times f^3 = const$ dependence. This type of frequency scaling law corresponds to elastic Rayleigh scattering of waves over microscopic particles whose dimensions are smaller than a wavelength. This type of wave scattering is known to be the main mechanism of loss in optical fibres [24]. Rayleigh scattering attenuation is inversely proportional to the forth power of the wavelength, or equivalently directly proportional to the fourth power of frequency: $\alpha \sim f^4$. So, using relation (2), this gives the experimentally observed $Q \sim f^{-3}$ law. Acoustic wave scattering over this quenched randomness is analogous to a light beam scattering in optical fibres. When a phonon hits an impurity or other imperfection of the crystal structure, it can maintain the same direction of propagation without attenuation, or alternatively change the direction of propagation and escape the cavity [5] giving rise to energy loss. Rayleigh scattering of acoustic waves has been theoretically predicted and observed for various polycrystalline and glass materials [25]–[27].

Another loss mechanism that can potentially be observed for quasi-longitudinally polarised phonons is the thermoelastic losses mechanism. So, the $Q_{thermoelastic}$ for longitudinal vibration can be estimated based on the description the coupled equations of motion of the medium and the equation of thermal conduction [28]. Simplified estimations of such losses can be made assuming an isotropic medium and propagation along the Z-axis which is the most experimentally studied case. This analysis implies calculation of a turning-point frequency f^* that shows if a mechanical system works in adiabatic or isothermal regimes:

$$f^* = \frac{V_3^2}{2\pi\chi_3} \tag{4}$$

where χ_3 is the material diffusivity, and V_3 is the wave velocity for a propagation along the Z-axis. The former is calculated based on data on thermal conductivity and heat capacity at cryogenic temperatures [29], [30] giving $1 \leq f^* \leq 5.5$ MHz for $3 \leq T \leq 10$K. Over this temperature range, all the resonant frequencies are always greater than f^*, and acoustic wave propagates in the quasi-isothermal regime. For this regime, the maximum attenuation is:

$$\alpha_\infty = \frac{\epsilon_3 \pi f^*}{V_3} \tag{5}$$

with ϵ_3, where λ_{33} are calculated from the thermal expansion tensor and the tensor of isothermal elastic constants of crystalline quartz. Whereas the thermal expansion coefficients have been measured at low temperatures [29], the elastic constants on the other hand can just be roughly approximated by their values at room temperature. Nevertheless, the corresponding thermoelastic losses estimated from equation (2) remain always at least two orders of magnitude lower than those measured below 10K. Since α_∞ is almost independent of frequency for a given material, these type of losses result in $Q/\omega = const$ law.

IV. Sources of Nonlinearities

The most common source of nonlinearities of acoustic cavities at cryogenic cavities is due to crystal anharmonisity [31] which comes as higher order terms in a crystal Hamiltonian describing atom vibrations. These terms are responsible for mode couplings leading to the Landau-Rumer losses, in particular. As explained above, these losses come when the acoustic phonons of a driven mode are scattered by thermal phonons of the material modes on the crystal anharmonicity. Although the crystal anharmonicty is involved in the loss mechanism, the mode behaviour remains linear until the point where self interaction between acoustic phonons becomes pronounced. So, despite the fact that all Taylor series terms of the Hamiltonian representing the lattice anharmonicity could potentially take part in the loss mechanisms, only the linear losses resulting from the lowest (three-phonon mixing) Hamiltonian terms [12] have been experimentally observed in extremely high-Q acoustic cavities. It is the mixing between acoustic phonons

that leads to the nonlinear effects in BAW devices known as the isochronism defect [32], [33]. This nonlinear phenomenon appears as resonance frequency dependance on incident power and the bistability effect at higher powers. Such effects could be observed with extremely low loss modes for incident powers as low as -45 dBm. This phenomenon at room and cryogenic [34] temperatures is well-described by a Duffing oscillator model both where the nonlinearity is introduced into an equation of motion as a cubic dependance of a resonance frequency on the amplitude of the vibration.

The related effect is due to frequency-temperature relations when due to dissipation injected phonons increase the temperature that causes the resonance frequency shift. This effect typically observed in cryogenic BAW devices at high enough powers (typically above $-30..-25$ dBm) even though frequency-temperature sensitivity of the acoustic modes decreases with temperature.

Another source of nonlinear behaviour in cryogenic acoustic cavities is attributed to various sorts of defects resulting in a high degree of disorder resulting. In the case of high quality factor cavities and large number of defects, the probability of phonon interaction with such impurities is high enough to be detected macroscopically. Such situation arises when an effective phonon-trapping cavity is build of unswept quartz crystal. The main feature of such crystals is comparatively high concentration (up to 10 ppm) of alkali impurities Na^+, Li^+, K^+ trapped in potential-wells near substitutional Al^{3+} [35]. If such potential well is not harmonic, than phonon-impurity interaction leads to a nonlinear loss term in the equations of motion for a macroscopic acoustical mode. This results in anomalously strong nonlinearity that is observed for a cavity incident powers as low as -95 dBm. Such nonlinearity can be modelled by a stable van der Pol oscillator where the nonlinearity is introduced through the power dependent loss term in the equations of motion. Experimentally, the phenomenon is observed by various effects including: 1) frequency sweep discontinuity and related oscillatory instability regions, which manifested as a abrupt response moving away from the resonance with increasing incident power; 2) frequency-power dependence, seen as frequency shift with increasing power; 3) power sweep discontinuity, observed as an abrupt change of the modulus of the reflection coefficient for a given frequency with only a small increase of incident power; 4) self-induced transparency, which was seen as an avoided crossing with incident power causing the doubling of the frequency response extrema at given values of incident power. These nonlinear phenomena in devices at cryogenic temperatures are still a matter of current investigations.

V. Characteristics of State-of-the-Art Acoustic Cavities

Various types of acoustic cavities have been tested at both liquid helium and mili-Kelvin temperatures. Among those types, acoustic cavity design described in Section II demonstrated superior Q-factors and $Q \times f$ products. For such design, the main geometric parameters are the plate disc diameter, plate thickness and curvature radius. Other important parameters are material quality (all cavities are manufactured with Top High Quality alpha synthetic quartz) and surface roughness. The summary of these parameters and corresponding experimental measurements is given in Table. I.

The measured characteristics of these cavities demonstrate that the cavity losses are minimised by improved surface polishing and increased disk radius. The former results in minimisation of surface scattering losses that are believed to be the limiting mechanism in the $100-200$ MHz frequency range. The latter improves decreases phonon-tunnelling to the environment.

VI. Applications to Frequency Standards

Extremely low loss systems of any sort are very attractive for building secondary frequency standards. In the case of cryogenic BAW devices, the goal of building such system is twofold. On one hand, it can result in building a hyper-stable frequency source whose frequency (of the order of tens of Megahertz) is close to the reference frequency of met of laboratory equipment ($5-10$ MHz). Unlike microwave and optical clocks that will not require significant frequency devision that unavoidably leads to losses in frequency stability. On the other hand, it helps to understand whether or not the BAW technology has reached its limits. It is important to predict the frequency stability limits of this quartz oscillators in comparison with other technologies [36].

To improve stability of frequency sources, ultra-narrow linewidths of cryogenic acoustic devices can be utilised by either active [37] or passive methods [34]. The first approach implies building a cryogenic analog of a well-known quartz oscillator with a cryogenic BAW as a frequency selective element. The second solution utilises the resonator as a part of a discriminator in a negative feedback that improves long term stability of a given frequency source. The active solution is more challenging. First, there is a limited choice of electronic components, which exhibit unnatural behaviour and high characteristic dispersion (for devices from the same series) [38]. Moreover, the gap between simulation and experiment remains considerable. This leads to unpredictable results, such as, the inability to excite optimal modes. In addition, long cool down-warm up cycles of cryocoolers make oscillator adjustments almost impossible. Although this approach is potentially, more fruitful since one can benefit not only from high qualities of cryogenic BAW drives but also from low (temperature) noise of electronic components.

The early attempts to build secondary frequency sources based on BAW devices [31], [34], [37], [39] reveal that the main advantage of the cryogenic quartz devices – very high quality factors – is annulled by the absence of a frequency-temperature turnover point, and strong nonlinear effects. Although multiple turn-over points in frequency-temperature characteristics of chosen OTs was observed at temperatures below 1K [3], their utilisation is impractical due to limitations of widely used cryocoolers. Although at the stage of the first realisation, oscillators based on cryogenic BAW quartz

TABLE I

technology may result in moderate improvement of the long term frequency stability over their room-temperature counterparts [31], [34], they still cannot compete with the state-of-the-art cryogenic microwave sapphire oscillators. The next generation of quartz frequency sources should be based on specially designed resonators with a frequency-temperature turnover point at 4K, have passive and active vibration compensation system, employ more reliable active devices.

VII. APPLICATIONS IN FUNDAMENTAL AND APPLIED PHYSICS

Low loss mechanical systems play a very important role as instruments in the investigation of a wide variety of fundamental physics problems including quantum measurement and computation [40], spin detection, ultra-sensitive force detection, gravitational wave detection and more. Thus, the demonstrated extremely low losses in BAW cavities have potential applications in a variety of areas of physics including fundamental aspects and applications. Whether the former can emily extremely long coherence times of such devices, the latter can benefit from better understanding of process in crystal solids.

The equilibrium ground state of hybrid mechanical systems has become a topic of interest of many research groups [41]. To achieve the operation of hybrid mechanical systems in their quantum ground state, it is vital to develop resonators with very low losses at temperatures approaching absolute zero. The frequencies accessible using mechanical systems are low, and thus a lower temperature is required (governed by $\hbar\omega > k_B T$) to reach the equilibrium ground state. The average number of thermal phonons is governed by the Bose-Einstein distribution

$$n_{\mathrm{TH}} \sim \frac{1}{e^{\frac{\hbar\omega}{k_B T}} - 1}, \tag{6}$$

which dictates, for example, that a frequency of greater than 144 MHz is required to have $n_{\mathrm{TH}} < 1$ at a temperature of 10 mK. Recent years have seen mechanical resonators developed with frequencies as high as 11 GHz [42], corresponding to $T = 0.53$ K for an average phonon occupation number below unity. But such high frequencies of mechanical systems come at the cost of high losses. For instance, O'Connell et al. [43] demonstrated single phonon control of an FBAR resonator at 6.07 GHz, but exhibiting a quality factor of only 260 making full Wigner state tomography impossible. This low value of Q significantly limits the coherence time of hybrid systems based on these devices. Aside from conventional thermodynamic cooling, the ground state or Standard Quantum Limit could potentially be reached by exploiting an low loss resonance, where the mode can be cold damped through feedback or a parametric processes. In the ideal case, the ratio Q/T remains constant, where the acoustic Q-factor is reduced as the mode amplitude is then damped and electromagnetically cooled to a lower temperature. So, once again, the ground state is achieved by means of degrading loss characteristics. So, BAW cavities have a considerable advantage over these traditional mechanical resonators like micro-toroids and membranes which require additional cooling techniques (parametric, sideband cooling) by having high enough resonance frequencies (now approaching 1 GHz) and over film devices by having much higher quality factors (up to several thousands of millions above 240 MHz at 15 mK). Recently, acoustic modes in the ground state have been observed for a BAW device with a loaded quality factor above half a billion. Comparison of BAW cavities with other mechanical systems near the quantum ground state is shown in Table II. The comparison assumes that the ratio of Q/T remains constant for resonator cooled either parametrically or with a negative feedback. By coupling acoustic cavities to nonlinear elements like Josephson Junctions, quantum bits with extremely high coherence times could be designed. In addition, piezoelectric nature of a cavity can be exploited to create strong photon-phonon coupling regimes of a hybrid systems.

Moreover, unlike nano-scale mechanical resonators used in the majority of quantum mechanics-related experiments, acoustic cavities are macroscopic objects of considerable effective mass varying in the range of $0.1 - 10$ milligrams for modes between 100 and 10 MHz. This fact means that experiments with BAW cavities in the ground state can be a promising approach to unifying quantum mechanics and general relativity in a single experiment [51] by measuring gravitational deviation from the canonical commutation relationship. This implies possibilities to utilise such systems in testing fundamental physics.

Besides applications to quantum hybrid systems, extremely high sensitivity should allow future applications of acoustical cavities to be broadened and be used as an alternative (to optical cavities) experimental base for broad range of physical experiments, including material characterisation [52], quantum cavity electromechanics [53], [54], quantum metrology [51], [55] etc. Indeed, potentially phonon cavities can be considered

TABLE II

COMPARISON OF SOME MECHANICAL RESONATORS, WHICH HAVE BEEN COOLED EITHER TO OR NEAR THE GROUND STATE, OR HAVE ACHIEVED HIGH Q-FACTORS. THE TABLE SHOWS THE FREQUENCY, Q-FACTOR, ENVIRONMENTAL TEMPERATURE, NUMBER OF THERMAL PHONONS (n_{TH}) AND Q-FACTOR IF THE SYSTEM COULD BE COOLED IDEALLY TO $n_{\mathrm{TH}} = 1$ PHONON (ASSUMING $Q/T = \mathrm{CONST}$).

Experiment	**Frequency (Hz)**	Q**-factor**	**Temperature (K)**	$n_{\mathbf{TH}}$	$Q(n_{\mathbf{TH}} = 1)$
Silicon [44]	1.96×10^{4}	2×10^{9}	4	4.3×10^{6}	677
Sapphire [45]	5.33×10^{4}	6×10^{8}	4	1.6×10	554

Nb-Al-SiN beam [50]	6.3×10^{6}	10^{6}	0.10	330	4.4×10^{3}
Quartz BAW -21st OT [3]	6.54×10^{7}	1.2×10^{9}	0.021	6.2	2.6×10^{8}
Advanced Quartz BAW			0.015	< 1	0.7×10^{9}

as an alternative to photon cavities in many low-frequency, low-power experiments. The advantages of acoustic devices is the ease of operation and integration into higher-order electronic systems, compact size, natural way of combination of mechanical motion and electromagnetic environment, as well as artificial lattice impurities.

***Abstract*—A novel evanescent-mode Möbius-coupled resonator oscillator is developed for the applications of synthesized X-band signal sources in RADAR and modern communication systems.**

Keywords-Evanescent-Mode, Mobius Resonator, Oscillator

I. INTRODUCTION

It is important to achieve low phase noise in various applications. The phase noise increases a bit error rate in telecommunication links, degrades stability of beam in particle accelerators and decreases sensitivity of radars. DROs represent an interesting solution to improve the stability by reducing the bit error rate because high quality factor of a Dielectric Resonator (DR) allows for achieving an excellent phase noise performance at microwave and millimeter wave frequencies. Dielectric resonators are ceramic materials which have high dielectric permittivity, high quality factor, and high temperature stability. They have much smaller size compared to cavity resonators; therefore, they are frequently employed in the design of frequency stable RF circuits, especially in oscillators [1]-[5].

When high data-rates have to be transferred, as with M-QAM modulation in LTE, LMDS, and fixed frequency point-to-point digital radio and satellite-links, these systems need low phase noise signal sources either free running or phase-locked. RADAR systems and Research Laboratories also require ultra-low noise sources to generate ultra-low noise carrier signals.

A wide range of military, industrial, medical, test and measurement markets demand these very stable frequency sources with enhanced phase noise performance and low thermal drift. A popular solution in the range of 3 to 30 GHz frequency spectrum is the dielectric resonator oscillator (DRO), recognized for its superiority in ultimate noise floor and spectrum purity when compared to other competing solutions such as multiplied lower frequency fundamental sources [6]-[9].

A novel Mobius-coupled printed resonator oscillator is reported in this paper for the application of synthesized signal sources in RADAR and modern microwave communication systems. The concept of the Mobius strips is based on the fact that a signal coupled to a strip shall not encounter any obstruction when travelling around the loop; enabling compact high Q-factor resonators [10]-[14].

A necessary and sufficient condition for a Mobius surface to be developable is that its Gaussian curvature should everywhere vanish. Given a curve with non-vanishing curvature there exists a unique flat ruled surface (the so-called rectifying developable) on which this curve is a geodesic curve (as shown in Figure 1) is described by [1]

$$\vec{x}(s,t) = \vec{r}(s) + t[\vec{b}(s) + \eta(s)\vec{t}(s)] \quad (1)$$

$$\tau(s) = \eta(s)k(s), \quad s = [0, L], t = [-w, w] \quad (2)$$

Where $\vec{r}$ is a parameterization of a strip with r as centerline and of length L and width 2w, where $\vec{t}$ is the unit tangent vector, $\vec{b}$ the unit binormal, k the curvature and τ the torsion of the centerline, the parameterized lines s = const. are the generators, which make an angle β = arc[tan(1/η)] with the positive tangent direction. Due to the unique properties of Mobius strips, the shape minimizes the deformation energy, which is entirely due to bending, can be described by [1]

$$V = \frac{1}{2} D \int_0^L \int_{-w}^{w} k_1^2 (s,t) dt ds \quad (3)$$

where $D = 2h^3E/[3(1-\nu^2)]$, with $2h$ the thickness of the strip, and E and ν Young's modulus and Poisson's ratio of the material. In this paper, a planar Mobius-coupled resonator oscillator is described, and the method for miniaturization can be applied to tunable filters, antenna and matching networks.

The eigenfunctions of the Mobius resonator form an orthogonal basis set; presents an interesting possibility for the design of metamaterial for the application in tunable oscillators, antenna, and filter circuits [6]. The oscillator's loaded Q factor Q_L is [11]

$$Q_L = \frac{\omega_0}{2} \left| \frac{d\varphi(\omega)}{d\omega} \right|_{\omega=\omega_0} = \frac{\omega_0}{2} \tau_d; \quad \tau_d = \left| \frac{d\varphi(\omega)}{d\omega} \right|_{\omega=\omega_0} \quad (4)$$

$$\tau_d = \left| \frac{d\varphi(\omega)}{d\omega} \right|_{\omega=\omega_0} = \frac{\varphi(\omega_0 + \Delta\omega) - \varphi(\omega_0 - \Delta\omega)}{2\Delta\omega} \quad (5)$$

where $\varphi(\omega)$ is the phase of the oscillator's open loop transfer function at a steady state and τ_d is the group delay of the resonator. From (4)-(5), Q_L is proportional to the group delay; therefore, for low oscillator phase noise application, the design goal is to maximize the group delay of Mobius strip resonator by incorporating phase-injection techniques. The unique characteristic of Mobius strip is self-phase-injection properties along the mutually coupled surface of the strips, which enables higher quality factor for a given size of the printed transmission line resonator [12].

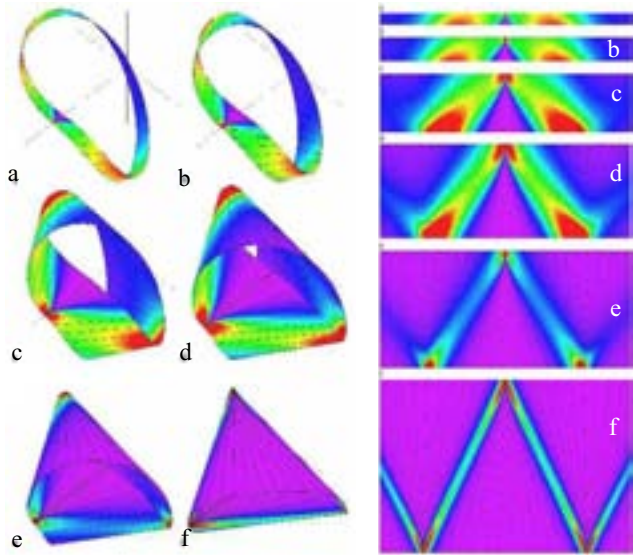

Figure 1: Computed Mobius strips (coloring changes according to the local bending energy density, from violet for regions of low bending to red for regions of high bending). The left panel shows their 3D shapes for w = 0.1 (a), 0.2 (b), 0.5 (c), 0.8 (d), 1.0 (e) and 1.5 (f), and the right panel the corresponding developments on the plane [1]

II. MOBIUS-COUPLED EVANESCENT MODE RESONATOR

The printed coupled resonator based oscillator can overcome problem associated with DRO, except the poor phase noise performance due to inherent low Q-factor associated with printed transmission line resonator. The Q (quality) factor of the coupled planar resonator network can be enhanced by introducing slow wave propagation dynamics, however large physical size and mode-jumping restricts the application especially at lower frequencies [13]. The loaded quality factor Q_L of the coupled resonator network is given in terms of unloaded quality factor Q_o as [14]:

$$[Q_L(\omega_0)]_{electrical-coupling} \cong 2\left[\frac{Q_0}{(1+\beta_e)}\right]_{\beta_e<<1} \cong 2Q_0 \quad (6)$$

$$[Q_L(\omega_0)]_{magnetical-coupling} \cong 2[Q_0(1+\beta_m)]_{\beta\to 1} \cong 2Q_0 \quad (7)$$

$$[Q_L(\omega_0)]_{hybrid-coupling} \cong 2\left[Q_0\frac{(1+\beta_{mh})}{(1+\beta_{eh})}\right]_{\beta_e<<1,\ \beta_{mh}\to 1} \cong 4Q_0 \quad (8)$$

Where coupling factor β (β_e for electric field, β_m for magnetic field, and β_h for hybrid field)

From (8) hybrid coupling (β_h) acts as a Q-multiplier effect, but this phenomena holds good for fixed frequency operation only and very difficult to realize broadband Q-multiplier dynamics which is necessary for wideband oscillators [14]. In addition to this, mode-jumping caused by undesirable higher order mode generation in hybrid coupling makes this structure not suitable for tunable wideband VCO (voltage controlled oscillator) applications. The alternative approach is to tune the coupling factor β_j over the desired operating frequency band in conjunction with higher order mode-suppressing network. But broadband mode-suppression is not an easy task in multi-mode resonator structure. A simplified approach is to use injection-locking and phase-synchronization techniques for broadband applications.

A. Möbius-Coupled Evanescent-Mode resonator Oscillator

A novel mode-coupled self-injection locked oscillator is developed in response to replacing expensive DRO (Dielectric Resonator Oscillator) for reference signal sources for modern communication systems. Figures (2), (3), and (4) show the typical block diagram, layout, and measured phase noise plot of the 10.2 GHz oscillator using a SiGe Hetrojunction-bipolar-transistor (HBT) active device were fabricated on Rogers substrate material with a dielectric constant of 2.2 and thickness of 20mils (microstripline/stripline) for the validation of the approach.

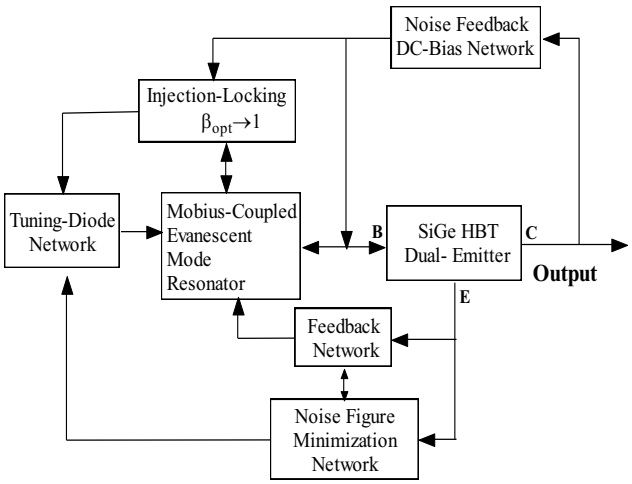

Figure 2: A typical block diagram of X-band MCEMR (Mobius-Coupled Evanescent Mode Resonator) oscillator

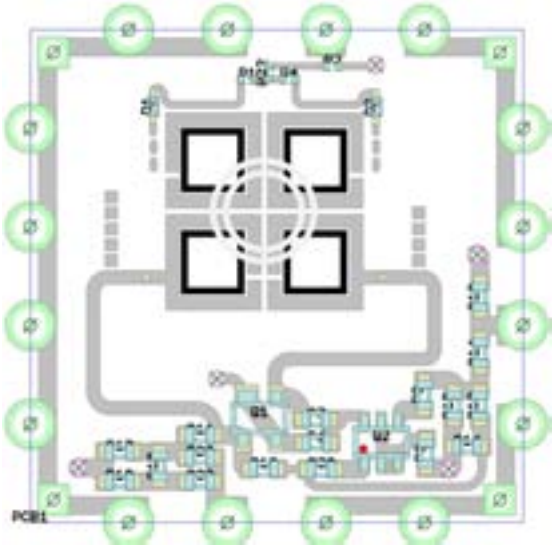

Figure 3: Layout of 10.2 GHz MCEMR VCO (0.9x0.9x0.2 inches)

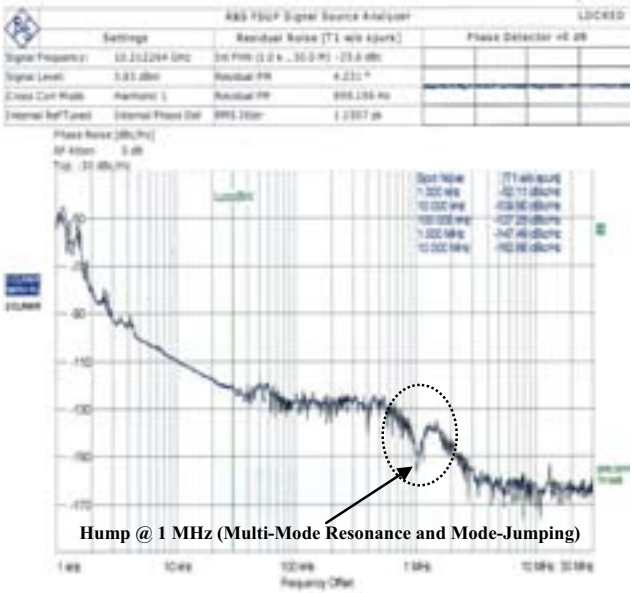

Figure 4: Measured Phase Noise Plot of 10.2 GHz MCEMR VCO

The oscillator works at DC bias of 10 Volt and 30 mA, measured output power exceeds +5 dBm. As shown in Figure 4, there is hump and dip between 100 kHz and 10 MHz offset from the carrier, possibly due to the resonator mode-jumping phenomena. By incorporating multi-mode-injection-locking, mode-jumping can be suppressed and stable oscillation can be guaranteed.

B. Examples: Compact Size MCEMR VCO

The tiny MCEM VCO is designed with rugged construction to minimize vibration noise and microphonic effects to prevent unwanted modulation.. Figure 5 shows the typical printed resonator layout for the realization of MCEMR VCO in 0.5"x 0.5" x 0.08" inches square package. Figure 6 shows the CAD simulated phase noise plots of oscillator circuits using different configurations of planar resonator topologies depicted in Figure 5. This exercise is done for the basic understanding of the SMD (surface mounted device) packages low cost high performance signal source applications. As shown in Figure 5, different possible configurations of MCEMR VCO are built on Rogers substrate material with a dielectric constant of 2.2 and thickness of 20mils (microstripline/stripline). The drawback of these resonator structures (Figure 5) is narrow tuning range and inferior phase noise performance. Figure 6 shows the measured plot of unloaded Q-factor of the printed resonator structures (electrical coupled, magnetic coupled, hybrid or mixed coupled, and Möbius coupled) for giving brief insight about the improvement in quality factor in planar domain.

As shown in Figure 6, the Möbius coupled printed resonator (MCPR) structure act like a Q-multiplier, peaking at 8.6 GHz due to the convergence of evanescent- modes. It can be seen in Figure 6 that Möbius resonator exhibits the undesired multi-mode resonant characteristics, and care must be taken to suppress these spurious modes for low jitter in RADAR applications. The drawback of this approach is multi-mode frequencies and mode-jumping (encircling the resonator characteristics), restricts the broadband operations.

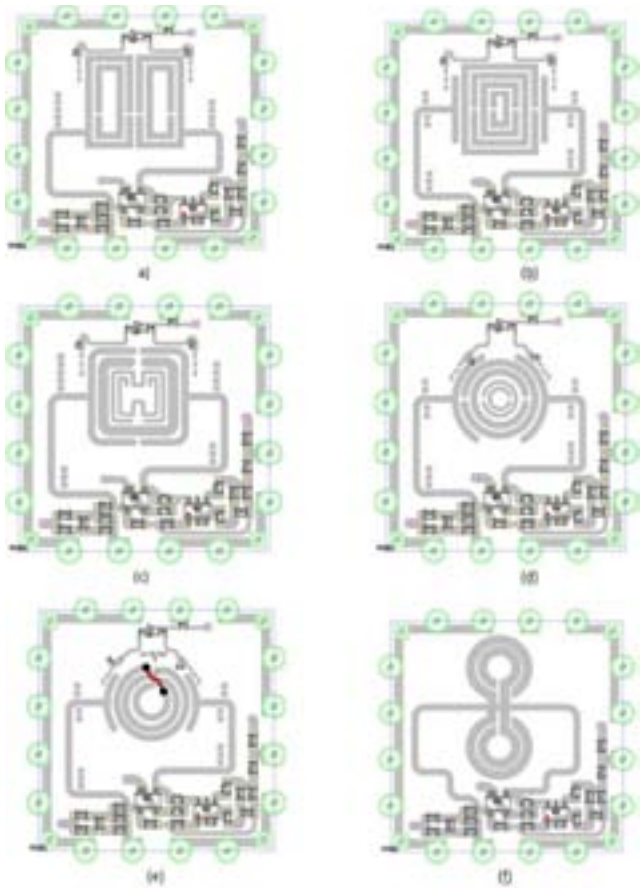

Figure 5: shows the layout of the SMD (surface mounted device) version of 0.5"x 0.5" x 0.08" inches square package are developed for low cost signal source applications: (a) 3.2 GHz Oscillator, (b) 4.7 GHz Oscillator, (c) 8.2 GHz Oscillator, (d) 12.2 GHz Oscillator, (e) 14.2 GHz Oscillator, and (f) 18 GHz Oscillator (20mils substrate height, 2.22 dielectric constant)

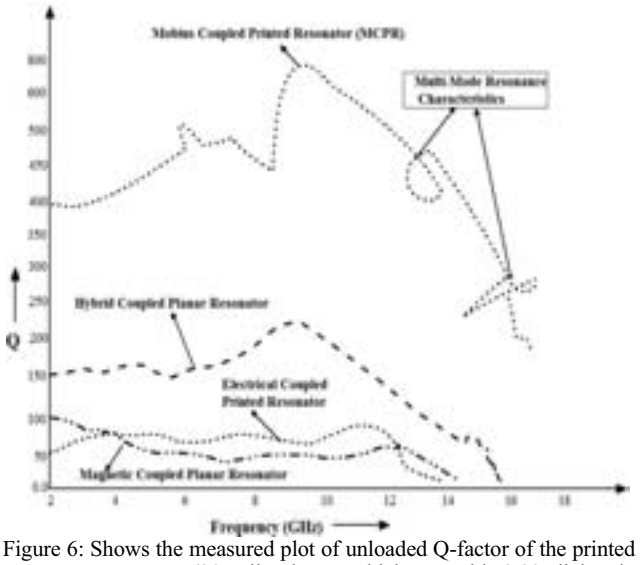

Figure 6: Shows the measured plot of unloaded Q-factor of the printed resonator structures (20 mil substrate thickness with 2.22 dielectric constant, 0.35x0.35x0.18 inches).

To overcome this problem, mode stabilization (injection of higher order modes into the resonant cavity with proper phase shift that improves the stability factor) control circuit is incorporated [15]-[16]. This degrades the Q factor by 10-20% resulting in degradation in phase noise performances by 3-6 dB but overcomes the problem of mode jumping, therefore, stable operation. The mode-injection locked MCEMR VCO using a SiGe Hetro-junction-Bipolar-transistor (HBT) active device, built on 20 mils substrate material with a dielectric constant of 2.2 illustrated in Figure 7 overcomes the limitation of oscillators circuits depicted in Figures 3 and 5.

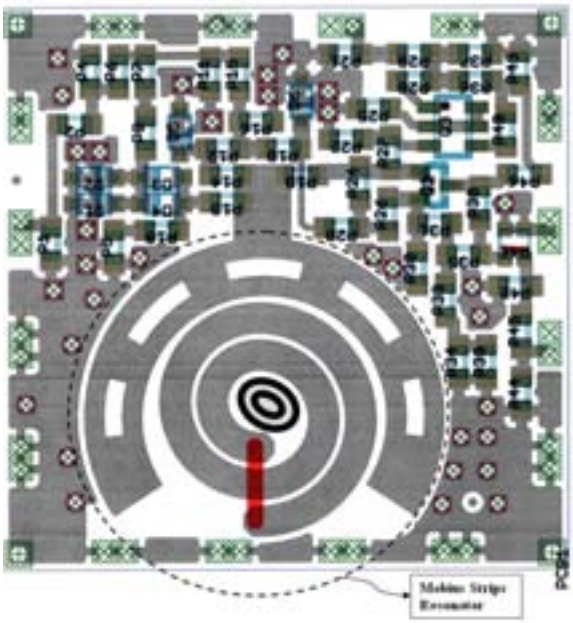

Figure 7: Shows the layout of mode-injection-locked 10.24 GHz oscillator (depicts the Möbius strips resonator used for high Q-factor resonator (PCB layout is done with 20 mil substrate thickness with 2.22 dielectric constant, 0.5x0.5x0.18 inches)

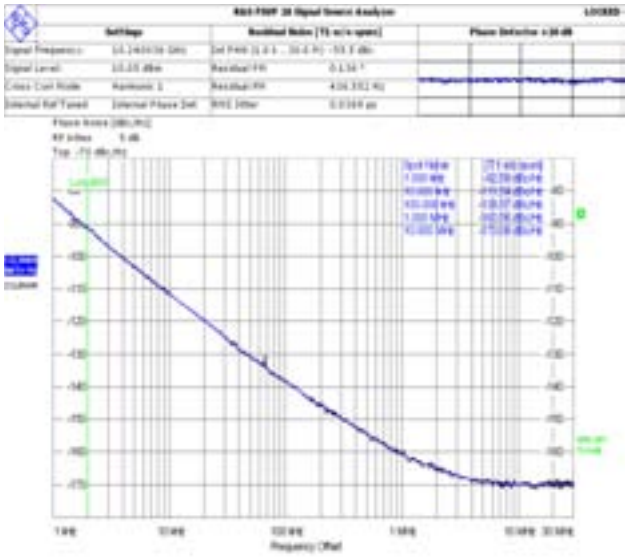

Figure 8: Measured Phase Noise Plot of mode-locked MCEMR VCO

The frequency is set at the fundamental resonance of MCEMR (Mobius-Coupled Evanescent Mode Resonator) and can be electrically tuned by using varactor tuned network (Tuning voltages of 1 to 24 VDC enable variations in the center frequency by ±400 MHz to compensate for frequency drift in phase-locked systems).

Figure 8 shows the measured phase noise plot of 10.24 MCEMR VCO, the measured phase noise @ 10 kHz offset is better than -110dBc/Hz, validates the tuning capability without degrading the phase noise performance in SMD packaged version.

III. CONCLUSION

Mobius-Coupled Evanescent-Mode (MCEM) resonators are attractive due to several reasons: the Mobius effect makes them very compact and can support evanescent mode coupling for obtaining Q-multiplier effect at resonant condition, thus low phase noise signal source solutions. Mobius-Coupled Evanescent-Mode (MCEM) resonator approach described in this paper offers cost-effective and integrable alternative for DRO circuits.

***Abstract*—Nanowire (NW) resonant nanoelectromechanical systems (NEMS) with integrated electronic signal transduction are attractive for realizing ultra-low-power nanomechanical radio-frequency (RF) signal processing. A major challenge lies in the high motional impedances of electrostatically-transduced high-frequency NW NEMS resonators. In this digest paper, we describe a technique for realizing oscillators that can achieve stable and low phase noise oscillations with such characteristic high motional impedances in NW NEMS. The technique is based on the basic theory of designing CMOS Pierce oscillators with low phase noise and low power consumption. We further design an oscillator with 1.5V power supply, which features a phase noise level of -104dBc/Hz at 10kHz offset from a 1GHz carrier, and consumes only 2.5µW power. Cadence circuit simulations on oscillator performance demonstrate the theoretical insights from this study may be important for designing oscillators based on challenging nanoresonators with high motional impedances.**

Keywords—Pierce oscillator; nanoelectromechanical systems (NEMS); nanowire resonator; motional impedance; phase noise; low power; feedback; oscillator circuit

I. INTRODUCTION

Modern communications demand integrated circuits and systems with ever improving spectral purity, efficiency, and power consumption. Wide interests and extensive efforts have been focused on developing alternatives to crystal resonators, *e.g.*, microelectromechanical systems (MEMS), toward chip-scale oscillators [1-3]. Meanwhile, solutions to the present and potential shortcomings of MEMS oscillators, *e.g.*, temperature instability, are being actively investigated [4,5]. While many challenges remain for developing and establishing optimal MEMS-CMOS cointegration processes for various specific applications, system-in-package (SiP) MEMS oscillators with off-chip MEMS have been widely adopted and are prevailing.

Silicon nanowire (SiNW) NEMS resonators are of interest for oscillators due to a number of merits, including ultrasmall dimensions, very high frequencies, ultralow operating power levels, and high quality (Q) factors [6]. These merits and features are expected to translate into promises for interesting oscillator performance. The motional impedance (resistance) R_m, however, is often large at high frequencies, particularly for NW NEMS. Here, instead of discarding and finding ways of avoiding nanodevices with large R_m values, we explore the possibility of embracing the high R_m's in NW NEMS.

This presentation was made possible, in part, through financial support from Case School of Engineering, student travel support from the School of Graduate Studies at Case Western Reserve University, and from the 2013 Joint IEEE UFFC, EFTF, and PFM Symposium.

II. LOW PHASE NOISE PIERCE OSCILLATOR DESIGN

Figure 1a illustrates the scheme of a Pierce oscillator and the equivalent electronic circuit of a NEMS/MEMS resonator with electrostatic transduction. This consists of a series *LCR* circuit (*motional* branch) in parallel with a static capacitor C_g. The oscillator circuit includes three non-resonator-based capacitors C_1, C_2 and C_3', (the latter in parallel with C_g whose parallel combination is called C_3). We shall derive signal-to-noise ratio (SNR) and phase noise equations to gain insights into the design of low phase noise NW NEMS oscillators.

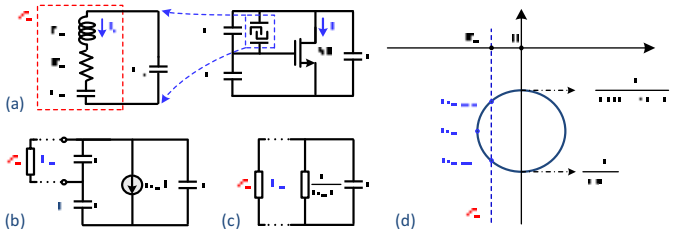

Fig. 1. Illustration of NEMS Pierce oscillator and design principles. (a) Schematic of a Pierce oscillator with equivalent circuit of the NEMS resonator. (b) Small-signal model of the oscillator. (c) Approximate schematic at $C_3 << C_1, C_2$. (d) Negative impedance trajectory of the motional branch ($-Z_m$ line) in Laplace domain with change of frequency-pulling, and the impedance trajectory of the rest of the oscillator with change in G_m (circle).

To find the oscillation frequency f_{osc} of a Pierce oscillator referenced to a nanoelectromechanical resonator, we analyze the small-signal schematic (Fig. 1c), an approximate to that in Fig. 1b if $C_3 << C_1, C_2$ (the latter assumption explained in Section III). Though change of G_m affects f_{osc} (Fig. 1d), in low power designs (small G_m), we have

$$\omega_{osc} \equiv 2\pi f_{osc} \cong 1/\sqrt{L_m C_m}\,, \tag{1}$$

i.e., pulling frequency is not large, since $C_m << C_2$. Thus, with such relative set of oscillator capacitors, f_{osc} will not be much different from the unloaded resonance frequency of the NEMS/MEMS resonator.

To find noise due to loss from the motional resistance, we note that energy stored in the motional impedance (a series tank) can be expressed as $E_m = (1/2) L_m I_m^2$, which helps to write the signal current (squared) in the series tank as

$$I_m^2 = 2E_m / L_m \cong 2E_m \omega_{osc}^2 C_m . \quad (2)$$

Equipartition theorem of thermodynamics [7] states that for a system in equilibrium at temperature T, each independent degree of freedom of the system has a mean energy of $(1/2)k_B T = (1/2)L_m \langle i_{N,m}^2 \rangle$, where $\langle i_{N,m}^2 \rangle = S_{i_{N,m}} \Delta f$, Δf and $S_{i_{N,m}}$ are mean square, bandwidth and power spectral density (PSD) of the current noise due to motional dissipation. Therefore, we have the noise current mean square due to loss in the motional branch (series tank) equals

$$\langle i_{N,m}^2 \rangle = k_B T / L_m \cong k_B T \omega_{osc}^2 C_m , \quad (3)$$

where k_B is Boltzmann constant. From (2) and (3), the ratio of motional noise PSD to power of the signal is

$$\frac{S_{i_{N,m}^2}}{I_m^2} \propto E_m^{-1} \propto \frac{1}{L_m I_m^2} \cong \frac{1}{L_m (C_3/C_1)^2 I_{bias}^2}, \quad (4)$$

where I_{bias} is the oscillator bias current. The above relation does not consider noise due to the active circuit though. Thus, a parameter γ to account for the effect of MOS channel noise (dominant noise of the active circuit) referred to the motional branch [8] is introduced, yielding a total current noise

$$S_{i_{N,tot}^2} = (1+\gamma) S_{i_{N,m}^2} = \left(1 + \frac{S_{i_{N,ch}^2}}{4k_B T R_m (\omega_{osc} C_2)^2}\right) S_{i_{N,m}^2}, \quad (5)$$

where $S_{i_{N,ch}^2}$ and $S_{i_{N,tot}^2}$ are, respectively, the current spectral densities of the MOS channel noise and the total oscillator noise referred to the motional branch. Using linear time-invariant noise theory, the total phase noise spectral density is

$$S_{\varphi_{N,tot}^2} = \frac{1}{2} \frac{(1+\gamma) S_{i_{N,m}^2}}{(|I_m|/\sqrt{2})^2} \propto \frac{\left(1 + \frac{S_{i_{N,m}^2}}{4k_B T R_m (\omega_{osc} C_2)^2}\right)}{L_m (C_3/C_1)^2 I_{bias}^2}. \quad (6)$$

Equation (6) clearly gives very good design intuition to us. In low power designs where I_{bias} is very small, in order to decrease total phase noise, L_m, C_3/C_1 and C_2 should increase. The first two parameters decrease phase noise due to both mechanical and active noise while C_2 only decreases effect of active circuit noise. However, as we will see in the next section, in a contradicting condition with low phase noise requirement, $C_3 << C_1, C_2$ should be met so that the oscillator starts self-sustained oscillation. This makes it inevitable to use large L_m to achieve low phase noise. We will also see trade-offs of using large C_2 on power consumption in Section IV.

There are different methods to increase L_m in mechanical resonators with electrostatic transduction. Reference [9] gives the formulation by which L_m and R_m scale inversely while C_m directly proportional to square of parameter $\eta = V_p \partial C/\partial x$, where V_p is the polarization (DC) voltage and $\partial C/\partial x$ is the change in capacitance between the mechanical resonator and the electrode per unit displacement (x) across the resonator-electrode gap. The parameter η shows how L_m can be increased by decreasing bias voltage across resonator-electrode or some NEMS dimensions and/or increasing initial (static) gap distance where in all cases R_m also increases. This clearly shows the necessity of dealing with high-R_m resonators in design of low phase noise Pierce oscillators.

III. Oscillation Start-Up and Reducing Power

A. Oscillation Start-Up

Impedance of the motional branch can be restated as [8,10]

$$Z_m = R_m + j \cdot 2p/\omega C_m , \quad (7)$$

where p is the frequency pulling defined as $p = (\omega - \omega_m)/\omega_m$, with ω and ω_m denoting the operating frequency and motional-branch resonance frequency. Negative impedance ($-Z_m$) of the motional branch for different frequencies makes up a line trajectory with constant real part ($-R_m$) and variable imaginary part in Laplace plane (Fig. 1d). The input impedance of the rest of Pierce oscillator circuit (see Fig. 1a right panel, between gate and drain nodes), when combined with the parallel static capacitor of the NEMS resonator C_g, can be modeled by Z_c. This impedance changes by change of the transconductance G_m of the driver MOS and makes up a circular trajectory (in case of linear circuit operation) in the Laplace plane (Fig. 1d). Figure 1d depicts that oscillation happens at intersection of the line (impedance $-Z_m$) and the circle (impedance Z_c) assuming both resonator and circuit have linear behavior. In fact, this is a pictorial expression of the Barkhausen criterion [11]. Oscillation occurs for G_m between $G_{m,min}$ and $G_{m,max}$.

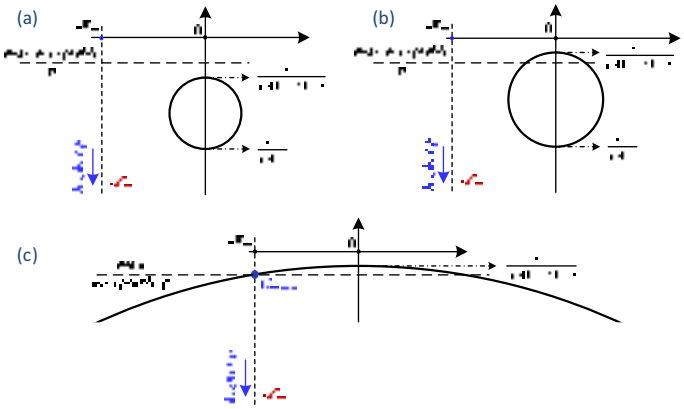

Fig. 2. Trajectories of negative motional impedance ($-Z_m$, vertical lines) and the impedance of the rest of Pierce oscillator (circles). (a) When R_m is high and there is no intersection between the two trajectories for any G_m. (b) When C_{12} is increased to make it potentially possible for the two trajectories to intersect at acceptable pulling frequencies. (c) When C_3 is decreased enough to make the intersection (oscillation start-up) happen.

An important challenge which can be explained through Fig. 2a is with oscillators that are referenced to high R_m and high f_{res} resonators. As (7) shows, for resonators with high ω_m, the absolute value of imaginary part of $-Z_m$ decreases. In other words, for the whole oscillator to oscillate at frequencies near ω_m, the circle should intersect with the line at points very close to the real (horizontal) axis. This necessitates using large $C_{12} = C_1 C_2 / (C_1 + C_2)$. For resonators with high R_m, we need to lower C_3 below what can be currently achieved by off-

chip (or integrated) components. In fact, even the CMOS parasitic capacitances can be larger than the desired C_3.

Therefore, to enable a Pierce oscillator based on high-R_m and high-ω_m resonator to realize stable and self-sustained oscillation, we take two steps, collectively. First, the circle should shift up to cross the line of maximum acceptable p by increasing both C_1 and C_2 (Fig. 2b). Second, the circle diameter should increase by decreasing effective C_3 (Fig. 2c). This way, the circle and the line would intersect.

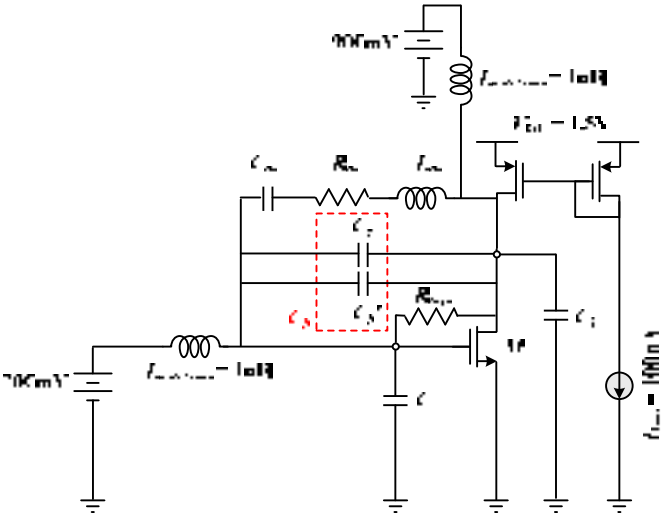

Fig. 3. Circuit schematic of the designed Pierce oscillator referenced to a series L_m- C_m-R_m NW NEMS resonator. Two bonding wire inductors (instead of a single one parallel to the resonator) are employed, between gate or drain at one end and the ac ground at the other end, respectively. DC voltage sources of 700mV and 900mV, and a very large R_{bias} are used to bias the circuit at the correct operting point. The bias current of I_{bias}=100nA is chosen to attain the very low power consumption levels.

To decrease C_3, we need a method as simple as possible so that it does not create unwanted side effects which are quite probable at high operation frequencies. A good solution would be adding a bonding wire inductor parallel to C_3. The value of the inductor should be chosen in such a way that at oscillation frequencies, the inductor cancels out a good portion of C_3, yielding a very small effective C_3.

B. Reduction in Power Consumption

As an alternative to the method suggested, we can use two inductors from gate and drain nodes, respectively, to the ac ground. To compare the two approaches, we note that increasing C_2 as suggested earlier to decrease effect of active circuit noise and also to enable the oscillator to attain stable oscillation at high resonator f_{res} with small p, might lead to a low-impedance path to ground which increases power consumption. Thus, the second approach can cancel out a good portion of C_2 to keep the circuit power consumption low. However, this does come along with the expense of a higher pulling frequency p.

We should also note that decreasing C_3 by any technique decreases the power consumption. From ref. [8], we can determine that that for linear oscillator circuit operation, the real part of Z_c is

$$Z_c = \frac{-G_m C_1 C_2}{\omega^2 (C_1 C_2 + C_2 C_3 + C_3 C_1)^2 + (G_m C_3)^2}. \qquad (8)$$

From (8) we can conclude that for constant G_m and lower C_3, the circuit provides more negative resistance. In other words, instead of increasing G_m to make the circle intersect with the line, we can just decrease C_3.

There is another phenomenon [8] that is worth mentioning. In practice, the oscillator circuit may behave nonlinearly with bias currents even as small as several 10nA if the amplitude of the AC signal I_m is large. In those cases, increase in G_m (by increase in bias current) causes Z_c to be not only a function of bias current, but also a function of the AC signal I_m. The higher amplitude of I_m, the more positive the real part of Z_c will be. This is why increasing R_m has also a good effect that decreases the nonlinear behavior of the oscillator circuit, which in turn makes the resistance of Z_c more negative.

IV. Design Example and Simualtion Results

In this Section, a Pierce oscillator (Fig. 3) is designed and simulated to verify our design intuitions derived earlier in this paper. The mechanical resonator assumed for this simulation is a doubly-clamped SiNW resonator with length (L), width (w), thickness (t) and quality (Q) factor of, respectively, L=419nm, w=20nm, t=80nm and Q=2000. The MOS technology used for this circuit is CMOS 0.35µm process and all simulations are done with Cadence Spectre simulator.

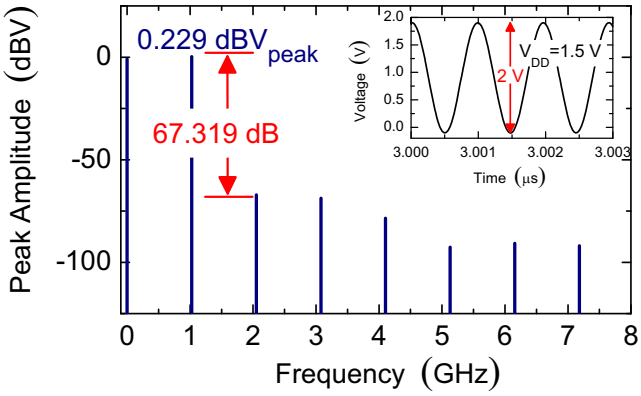

Fig. 4. Cadence simulated steady-state output voltage waveform (between drain and ground) of the fundamental and higher harmonics versus frequency. The large relative difference between the fundamental and the second harmnic demonstrates the linearity of the circuit. *Inset*: The steady-state voltage signal versus time with peak-to-peak amplitude of ~2V when the oscillator is not loaded at the output node.

The bias voltages of 0.7V and 0.9V and a large R_{bias} are used to bias the circuit in the desired operating condition. The bias current of I_{bias}=100nA is also provided using a simple current mirror to make the circuit operate at low power consumption conditions. Such low bias currents are usually used in analog instrumentation front ends (*e.g.*, ref. [12]). Our two-inductors approach is implemented with two 1nH bonding wire inductors (the 2 L_{wirebond}'s in Fig. 3). Figure 4 shows the computed steady-state voltage amplitude of the fundamental and higher harmonic resonances versus frequency at the output (drain of M in Fig. 3).

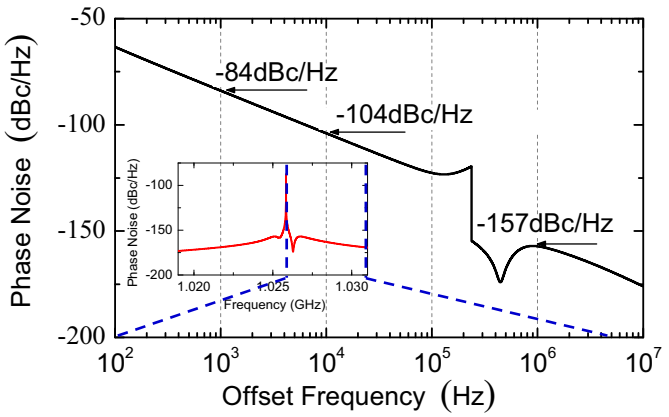

Fig. 5. Phase noise simulation results from Cadence PSS simulator at the oscillator output at different offset frequencies around f_{osc}. Inset shows the phase noise in a wider range versus absolute frequencies. At very small offset frequencies, the phase noise of the wider-range diagram (inset) seems to be smaller which is due to limited frequency resolution in wide-range simulation.

The large relative difference of ~67.32dB between the fundamental and the second harmonic clearly demonstrates the excellent linearity of the circuit. The inset in Fig. 4 shows the voltage *versus* time waveform when the circuit is in steady-state operation. For V_{DD}=1.5V, the output between drain and ground has a peak-to-peak amplitude of ~2V when there is no external circuit loading output of the oscillator.

Figure 5 demonstrates the computed steady-state oscillator phase noise versus offset frequency. The inset to Fig. 5 shows the phase noise performance versus absolute frequency in a wider range. This simulation using the Cadence PSS simulator clearly shows the effectiveness of our design methodology for achieving low phase noise in the designed NEMS oscillator. In order to have an intuition on the performance of our oscillator, phase noise at different offset frequencies as well as power consumption are compared to other prominent recent related works (measurement results) in Table I.

V. Conclusions

In this work, we have first mathematically analyzed the challenges and opportunities of designing low phase noise and low power Pierce oscillators with frequency references based on nanowire electromechanical resonators with high motional impedances. Our analyses on the high-frequency, high-R_m resonators and oscillator requirements provides a set of design insights and implementable guidelines, especially on satisfying oscillation conditions, attaining low phase noise and low power consumption. The design guidelines have been verified by designing a prototype 1GHz nanowire NEMS oscillator, and by computing its performance using Cadence simulator.

TABLE I. Summary of Nanowire NEMS Oscillator Design in This Work, in Comparison with Other Related Works

	R_m	f_{osc}	P_{con}	Phase Noise [dBc/Hz]

***Abstract*-The paper mainly focuses on the effect on the oscillator phase noise by the loaded quality factor Q_L in Classical Leeson Model, derives that the equivalent circuit parameters of resonator and the oscillation circuit parameters have conclusive concern with the loaded quality factor Q_L. And the experimental verification is made on the basis of two kinds of oscillator circuits (Pierce oscillator circuit and Butler common-base oscillator circuit) and three kinds of acoustic resonators (120MHz SC-cut crystal resonator, 315 MHz one- port SAW resonator and 10.7 MHz $LiTaO_3$ BAW resonator). The further experiment shows the changes of the crystal oscillator phase noise with different drive levels and presents that besides some parameters such as Q_L, the crystal resonator amplitude-frequency (AF) characteristics can also affect the oscillator phase noise apparently. And then, the acoustic oscillator phase noise model can be established on the basis of the physics, which contains the resonator equivalent parameters, the oscillator circuit parameters and the affection of the resonator AF characteristics.**

I. INTRODUCTION

With the continuing development of modern communication technology, the need for the high stability crystal oscillators has increased. Phase noise is one of the most important characteristics of crystal oscillators. It is a key factor which limits the performance of electronic system. Therefore, the study of crystal oscillator output spectrum and methods to reduce the phase noise are the primary problems in the process of designing crystal oscillators.

II. CLASSICAL LEESON MODEL ANALYSIS

Leeson formula is as follows:

$$S_{\Delta\phi}(f_m)=[1+\frac{1}{f_m^2}(\frac{f_0}{2Q_L})^2]S_{\Delta\theta}(f_m) \quad (1)$$

Where f_m is offset frequency, f_0 is center frequency, Q_L is loaded quality factor, $S_{\Delta\phi}(f_m)$ is the power spectral density of the output phase noise, $S_{\Delta\theta}(f_m)$ is the power spectral density of the oscillator input phase noise. And

$$S_{\Delta\theta}(f_m)=\frac{FkT}{P_{si}}\left(1+\frac{f_c}{f_m}\right) \quad (2)$$

Where f_c is corner frequency , f_m is offset frequency， F is noise figure, k is Boltzmann constant, T is absolute temperature, and P_{si} is input signal power.

When the oscillator is stable and the signal output from the amplifier, we can get the expression of the single sideband power spectral density of the output phase noise $S_{\Delta\phi}(f_m)$ from the Leeson model:

$$S_{\Delta\phi}(f_m)=\frac{1}{2}\frac{FkT}{P_{si}}(1+\frac{f_c}{f_m})\left[1+\frac{1}{f_m^2}(\frac{f_0}{2Q_L})^2\right] \quad (3)$$

When applying this model to design a feedback oscillator, one should know what key points should be paid more attention to and what drawbacks of this model also should be noted.

As we can see in (3), the distribution of the oscillator phase noise spectrum corresponds with the power-law. According to the relationship between the flicker noise corner frequency f_c and the half-bandwidth $f_0/2Q_L$, we can do a further analysis of the structure of the oscillator phase noise spectrum.

When $f_0/2Q_L > f_c$ (i.e. low Q resonator), the expression (3) of the power spectral density of the output phase noise can be approximated as:

$$S_{\Delta\phi}(f_m)=\begin{cases}\left(1+\frac{f_c}{f_m}\right)\frac{FkT}{P_{si}}\times\frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2, & f_m<f_c\\ \frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2\frac{FkT}{P_{si}}, & f_c<f_m<\frac{f_0}{2Q_L}\\ \frac{FkT}{P_{si}}, & f_m>\frac{f_0}{2Q_L}\end{cases} \quad (4)$$

When $f_0/2Q_L < f_c$ (i.e. high Q resonator), the expression (3) of the power spectral density of the output phase noise can be approximated as:

$$S_{\Delta\phi}(f_m)=\begin{cases}\left(1+\frac{f_c}{f_m}\right)\frac{FkT}{P_{si}}\times\frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2, & f_m<\frac{f_0}{2Q_L}\\ \left(1+\frac{f_c}{f_m}\right)\frac{FkT}{P_{si}}, & \frac{f_0}{2Q_L}<f_m<f_c\\ \frac{FkT}{P_{si}}, & f_m>f_c\end{cases} \quad (5)$$

According to (3) - (5), the quality factor Q_L can not only affect the intensity of the output phase noise, but also affect the structure of the output phase noise power-law spectral density. In order to improve the oscillator phase noise, besides the requirements of a high Q_L, a low noise figure F of the circuit, a low corner frequency f_c of the transistor device and a high input signal power P_{si} are also required.

III. DESIGN EXAMPLES AND ANALYSIS

In the past few papers, determinants between loaded quality

factor Q_L and equivalent parameters of a resonator and that of a oscillation circuit have already tried to be revealed.

Fig. 1 shows the relationship between the Q_L (calculated from the Pierce crystal oscillator circuit) and the circuit parameter C_1 (collector to ground capacitance) [8].

The 120MHz SC-cut 5th overtone resonator is utilized in the calculation in Fig. 1 and the unloaded quality factor Q_0 is about 1.05×10^5, Lq is about 8.8mH.

TABLE I shows the measured phase noise data of the Pierce Oscillator using the above crystal resonator when C_1 is 51pF and 18pF, respectively. (The measured phase noise curves are shown in Fig.2 and Fig.3)

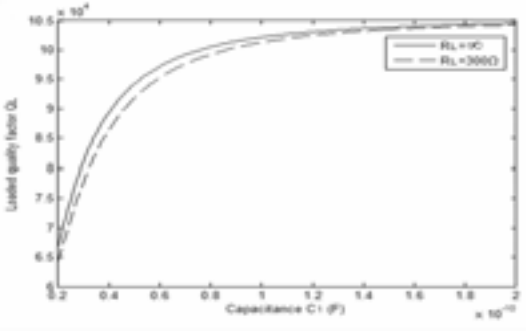

Fig.1.The result of Q_L calculated by MATLAB.

TABLE I. The measured phase noise data

C_1	Offset 10Hz	Offset 100Hz	Offset 10KHz	Offset 100KHz
51 pF	-104.3 dBc	-134.3 dBc	-170 dBc	-175 dBc
18 pF	-100.2 dBc	-132.6 dBc	-171 dBc	-176.5 dBc

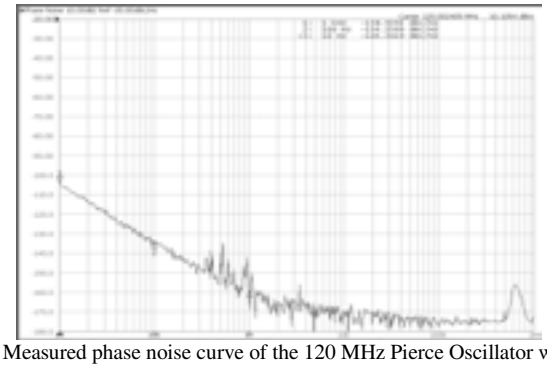

Fig.2. Measured phase noise curve of the 120 MHz Pierce Oscillator when C_1 is 51pF.

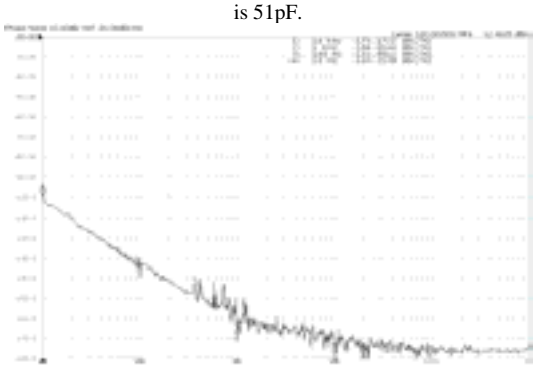

Fig.3. Measured phase noise curve of the 120MHz Pierce Oscillator when C_1 is 18pF.

Fig.4 shows the relationship between the Q_L (calculated from the Butler common-base SAW oscillator circuit) and the circuit parameter C_2 (to ground capacitance) [9].

The 315MHz one-port SAW resonator is utilized in the calculation in Fig.4 and the unloaded quality factor Q_0 is about 1.06×10^4, Lq is about 75μH.

TABLE II shows the measured phase noise data of the Butler common-base Oscillator using the above SAW resonator when C_2 is 30pF and 20pF, respectively. (The measured phase noise curves are shown in Fig.5 and Fig.6)

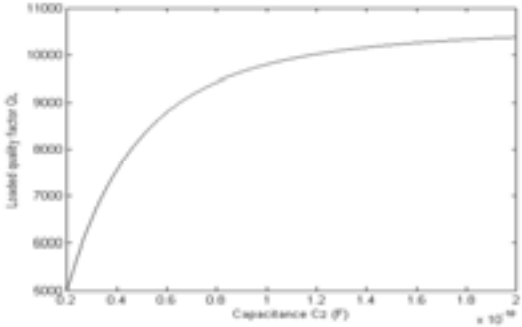

Fig.4.The result of Q_L calculated by MATLAB.

TABLE II.The measured phase noise data

C_2	Output	Offset 100Hz	Offset 1KHz	Offset 10KHz	Offset 1MHz
30 pF	9.9 dBm	-90.0 dBc	-125.5 dBc	-157.0 dBc	-170 dBc
20 pF	10.5 dBm	-88.0 dBc	-123.3 dBc	-155.4 dBc	-170 dBc

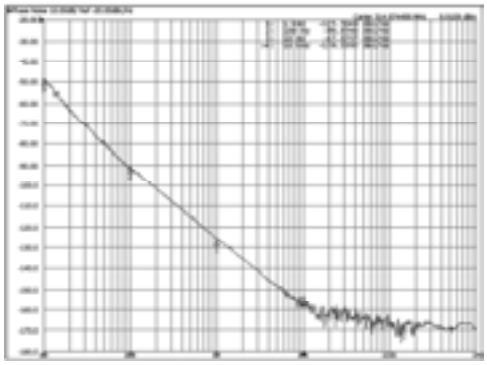

Fig.5.Measured phase noise curve of the 315 MHz Butler common-base Oscillator when C_2 is 30pF.

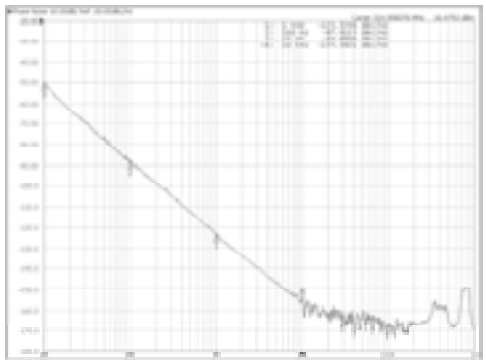

Fig.6 Measured phase noise curve of the 315 MHz Butler common-base Oscillator when C_2 is 20pF

Fig.7 shows the relationship between the Q_L (calculated from the Butler common-base $LiTaO_3$ BAW oscillator circuit) and the circuit parameter C_2 (to ground capacitance) [10].

The 10.7 MHz $LiTaO_3$ BAW resonator is utilized in the calculation in Fig.7 and the unloaded quality factor Q_0 is about

1.24K, Lq is about 3.8×10^{-4} H.

TABLE III shows the measured phase noise data of the Butler common-base Oscillator using the above $LiTaO_3$ BAW resonator when C_2 is 330pF and 160pF, respectively. (The measured phase noise curves are shown in Fig.8 and Fig.9)

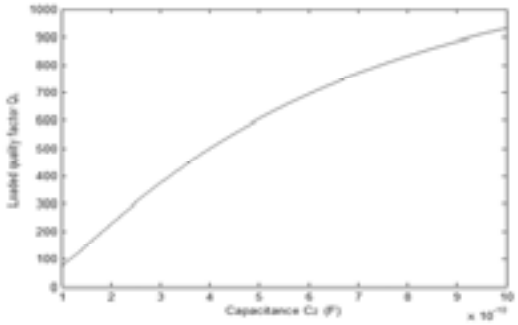

Fig.7.The result of Q_L calculated by MATLAB.

TABLE III.The measured phase noise data

C_2	Output	Offset 10Hz	Offset 100Hz	Offset 1KHz	Offset 100KHz
330 pF	10.3 dBm	-85.2 dBc	-116.7 dBc	-145.5 dBc	-180 dBc
160 pF	11.9 dBm	-81.0 dBc	-113.7 dBc	-143.8 dBc	-180 dBc

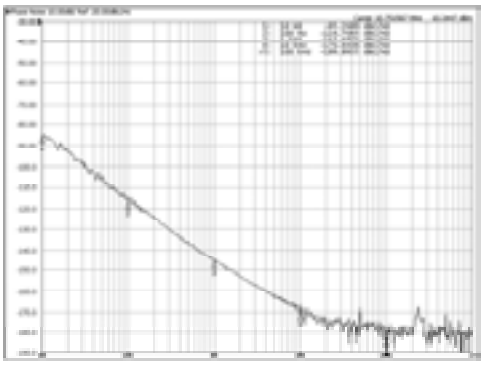

Fig.8. Measured phase noise curve of $LiTaO_3$ oscillator when C_2 is 330 pF.

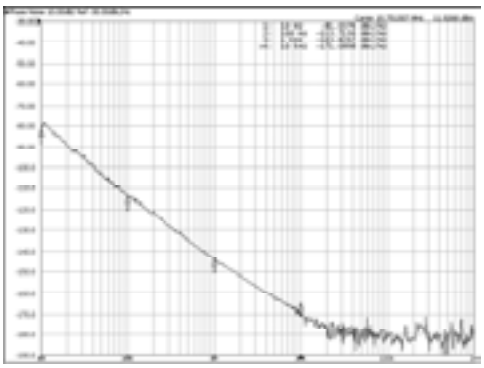

Fig.9. Measured phase noise curve of $LiTaO_3$ oscillator when C_2 is 160 pF.

The initial experimental results show that this method that low phase noise oscillators are designed based on improving Q_L can ameliorate the near carrier frequency phase noise level, and this design is feasible. But, if the value of C becomes larger, the output amplitude will become lower. This is unfavorable for reducing the phase noise. In addition, the derivation of Q_L is just takes into account the passive network, without taking into account the active device and the nonlinear effect produced by active and passive devices. And matching problem exists in the actual circuit. In summary, this design can only be qualitative.

IV. The Effects Of Resonator Amplitude Frequency Characteristics

Further experiments find that one crystal oscillator with different drive levels and output power performs different phase noise level.

TABLE IV and V show the measured phase noise result under the different outputs amplitude. The Pierce oscillator using 100MHz AT-cut 3th overtone crystal resonator is utilized in TABLE IV and C_1 is about 1.2fF, Q is about 130K. In contrast, Pierce oscillator using 10MHz SC-cut 3th overtone crystal resonator is utilized in TABLE V and C_1 is about 0.2fF, Q is about 1160K.

TABLE IV.The phase noise data of 100MHz crystal oscillator with different drive levels

Output amplitude	Output frequency	Offset 10Hz	Offset 100Hz	Offset 1000Hz
-17.9 dBm	100010343 Hz	-97 dBc	-132 dBc	-148 dBc
-15.2 dBm	100010372 Hz	-96 dBc	-130 dBc	-150 dBc
-12.2 dBm	100010432 Hz	-92 dBc	-125 dBc	-152 dBc
-9.0 dBm	100010557 Hz	-83 dBc	-119 dBc	-153 dBc

TABLE V.The phase noise data of 10MHz crystal oscillator with different drive levels

Output amplitude	Output frequency	Offset 10Hz	Offset 100Hz
1.8 dBm	9999628 Hz	-123 dBc	-155 dBc
-0.6 dBm	9999589 Hz	-130 dBc	-154 dBc
-6.4 dBm	9999568 Hz	-134 dBc	-153 dBc

The relationship between the near carrier frequency phase noise and oscillator drive levels is presented clearly in TABLE IV and V. Since this is the same oscillator, it is hard to explain from the point of view of Q_L. However, as the data in both TABLE IV and TABLE V are mainly about the close-in deterioration, it also can't explain from the point of view of the circuit noise factor F in (3) of the Classical Leeson Model. That is because F can make both the close-in noise and the noise floor of the phase noise curve change synchronously, i.e., if the circuit drive are considered raised, since the nonlinear effect of the circuit can result in the increase of F, both the close-in noise and the noise floor of the phase noise curve should deteriorate synchronously with the drive levels.

We can only get the reasonable explanation for this phenomenon from the point of view of the crystal resonator AF (amplitude-frequency) effect [1]-[5]. According to this, the equation (3) of the Classical Leeson Model might add an additional term, which presents the influence of the crystal

resonator AF (amplitude-frequency) effect on the oscillator phase noise.

V. CONCLUSION

Based on the above calculations, experimental results and analysis, the following conclusions are presented:

- What mainly affects the oscillator phase noise in the acoustic resonator is the loaded Q (i.e. Q_L) but the unloaded Q (i.e. Q_0). The Q_L in (3) of the Classical Leeson Model is not only associated with the equivalent parameters of the acoustic resonator, but also related to the circuit parameters of the oscillator.
- On terms of the near carrier frequency phase noise, although the raise of the Q_L is beneficial to the phase noise levels, the oscillator designers shouldn't always raise the Q_L value only, for it can lead to lower output amplitude, and is unfavorable to reduce the oscillator phase noise. In order to achieve a better phase noise level, it's essential to find a reasonable compromise between seeking high Q_L and maintaining output power.
- The equation (3) of the Classical Leeson Model might add an additional term, which presents the influence of the crystal resonator AF (amplitude frequency) effect on the oscillator phase noise, especially the near carrier frequency phase noise.

In a word, according to the conclusion of the initial study, the equation (3) of the Classical Leeson Model should be rewrite as:

$$S_{\Delta\phi}(f_m) = \frac{1}{2}\frac{FkT}{P_{si}}\left(1+\frac{f_c}{f_m}\right)\left[1+\frac{1}{f_m^2}\left(\frac{f_0}{2Q_L}\right)^2\right]+\frac{\tilde{K}}{f^n} \qquad (6)$$

Where $\tilde{K}$ is a dynamic parameter associated with the AF characteristic of the resonator and its value is different with the drive levels. Meanwhile, from experience, the value of n is about 3<n<4.

Design, Simulation and Test of an Oscillator Suitable for Wafer Level Evaluation of SAW Resonator Phase Noise

Dan Porga, Twinkle Shah, Mike Driscoll (Consultant)
Phonon Corporation
Simsbury, CT, USA
danp@phonon.com

***Abstract*— In a well-designed BAW or SAW oscillator, the primary contributor to near-carrier, flicker-of-frequency noise should be the resonator itself and not the sustaining stage amplifier [1-4]. Determination of resonator short-term frequency stability (self-noise) at the wafer level is highly desirable from both the perspective of resonator selection prior to packaging and evaluation of processing conditions resulting in low noise resonators. The objective of this work was to develop a methodology where the flicker-of-PM noise contributions of the sustaining stage amplifier and the resonator could be reliably and independently determined. In addition, the methodology needed to be compatible with and tolerant of coaxial probe connections to on-wafer resonator arrays. The current status is that the results obtained for evaluation of packaged and on-wafer devices are quite comparable.**

Keywords- SAW Resonator, oscillator, modular amplifier, phase noise, wafer probe

I. INTRODUCTION

To achieve the objective, a 50 ohm loop test oscillator was constructed. Candidate amplifier residual phase noise was determined via operation in an oscillator using an intentionally low delay (low Q) "noiseless" frequency control element in order to very easily identify those amplifiers whose contribution towards oscillator near-carrier noise was about 10dB below the best anticipated SAW resonator noise performance. Next, the test oscillator (using a previously characterized amplifier) was installed in a wafer probe set-up to evaluate SAW resonator self-noise. Extraordinary measures were needed to reduce the effects of acoustic noise, electrical interference and vibration. Finally, the test oscillator was used to evaluate packaged SAW resonators and the results were compared with the wafer probe results.

II. METHODOLOGY

A. Test Oscillator Block Diagram

A 50 ohm oscillator loop consists of an amplifier, power splitter, attenuator, phase shifter and resonator. Fig. 1 shows the basic configuration of the test oscillator. In this figure, a band-pass filter is substituted for the resonator.

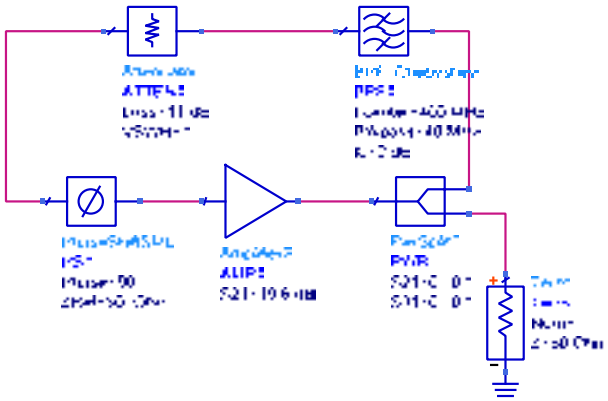

Figure 1. Test Oscillator Block Diagram

B. Leeson's Equation

Single-sideband phase noise (hereon abbreviated phase noise), L(f), is commonly used to characterize oscillators. L(f), is related to the power spectral density of phase fluctuations, $S_\Phi(f)$, as follows.

$$L(f) = 10\log\left[\frac{1}{2}S_\phi(f)\right] \tag{1}$$

Leeson's equation (2) relates oscillator closed loop performance to open loop component characteristics (first bracket) and the effect of closing the loop (second bracket) [6,7].

$$\frac{1}{2}S_\phi(f)_{osc} = \left\{\frac{1}{2}S_\phi(f)_{amp} + \frac{1}{2}S_\phi(f)_{res}\right\}\left\{1+\left(\frac{f_q}{f}\right)^2\right\} \tag{2}$$

$$f_q = \left(\frac{1}{2\pi\tau}\right) \tag{3}$$

$$\frac{1}{2}S_\phi(f)_{amp} = \frac{10^{\left[\frac{Lamp(1Hz)}{10}\right]}}{f} + 10^{\left[\frac{-177-Pin+NF+FF}{10}\right]} \tag{4}$$

$$\frac{1}{2}S_\phi(f)_{res} = \frac{10^{\left[\frac{Lres(1Hz)}{10}\right]}}{f\sqrt{\left(1+\left(f/f_q\right)^2\right)}} \tag{5}$$

Where f=frequency offset from carrier (Hz), f_q=resonator half bandwidth (Hz), τ=loop delay (s) at the carrier frequency, Pin=amplifier input power (dBm), NF=amplifier noise figure (dB) and FF=amplifier noise figure degradation from operating in compression (dB). Also, $L_{amp}(1Hz)$ and $L_{res}(1Hz)$ are the open loop 1 Hz flicker intercepts (dBc/Hz). These are the quantities we wish to measure. 1 Hz intercepts, as opposed to flicker corner frequencies, are chosen because they are independent of the noise floor.

From (2), the effect of closing the loop is a degradation in phase noise performance for $f<f_q$. This is unfortunate for products, but useful for measurements. Since the closed loop noise close to the carrier is much stronger than the open loop noise, it is much easier to measure.

C. Data Fitting

The measured oscillator data was fit to the following model.

$$\frac{1}{2}S_{\phi}(f)_{fit} = \sum_{i=0}^{4} \frac{10^{\left\lceil \frac{Li(1Hz)}{10} \right\rceil}}{f^i} + \frac{L_{5052}(1Hz)}{1+(f/Fc_{5052})^2} \quad (6)$$

Where $L_i(1Hz)$ are closed loop 1Hz intercept points (dBc/Hz) determined by the fitting process. $L_3(1Hz)$, for example, will be referred to as the 3rd order intercept. The measurements presented in this paper were made using an Agilent 5052B Signal Source Analyzer. The measurements exhibit a degradation vs. actual phase noise performance over the approximate frequency range of 2kHz to 500kHz. This is thought to be due to the in-band noise associated with the phase lock loops in the instrument. The last term in the model fits that degradation. $L_{5052}(1Hz)$ is the closed loop 1Hz intercept (dBc/Hz) and Fc_{5052} is a cutoff frequency (Hz). It is included for completeness, but is not important for flicker characterization.

Many fitting strategies were evaluated to minimize the effect of environmental noise on the probe data. These included asymmetric error weighting, windowing to reduce the impact of large errors and frequency masking. The best correlation between wafer and component data was obtained using straight least mean square fitting with a frequency mask for the probe data only.

From Leeson's equation, oscillator performance should be dominated by the 0th and 3rd order intercepts with potential contribution from the 2nd order intercept. 1st and 4th order contributions are not expected. In practice, 1st and 2nd order contributions were not observed in the data and 4th order was used to identify poor quality data. For the resonators evaluated in this paper, probe measurements with 4th order intercepts greater than -30dBc/Hz were considered invalid due to external noise impacts. While poor 4th order intercept indicates poor data, good 4th order intercept does not necessarily indicate good data. Environmental noise can degrade the 3rd order intercept as well. The RMS error between the fit and the data was used as another indication of data quality. In our probe measurements, we observed particular sensitivity in the offset range 100Hz-300Hz. This region was masked during fitting but included when calculating RMS error. Thus, it gave an indication of the severity of the environmental noise impact.

D. Calculate Open Loop Intercepts From Fit Results

From (2), (4) and (5) we see the amplifier and resonator open loop flicker result in 3rd order closed loop phase noise characteristic. Equating the 3rd order terms in (2), (4) and (5) with the model (6) and evaluating at f=1Hz, we get (7).

$$10\log\left\{10^{\left\lceil \frac{Lamp(1Hz)}{10} \right\rceil} + 10^{\left\lceil \frac{Lres(1Hz)}{10} \right\rceil}\right\} = L_3(1Hz) - 20\log(f_q) \quad (7)$$

With (7) we can determine the open loop intercepts $L_{amp}(1Hz)$ and $L_{res}(1Hz)$. Note the 3rd order fit of the measured data, $L_3(1Hz)$, is determined by the strong closed loop phase noise close to the carrier. It is not affected by the oscillator noise floor, the measurement system noise floor nor the 5052B degradation mentioned earlier. Since the noise is strong, it can be measured without cross-correlation. This speeds up the measurement and is helpful in reducing environmental noise impact during wafer probing. The f_q term is easily obtained by measuring the loop delay on a network analyzer.

III. AMPLIFIER CHARACTERIZATION

Equation (7) suggests desired conditions for measuring $L_{amp}(1Hz)$. The contribution of SAWR self noise can be removed from the oscillator signal via resonator removal and replacement by an L-C resonator or band-pass filter. Enhancement of the resulting oscillator closed loop phase noise allows simple and accurate measurement. This is accomplished by making f_q in (3) large or, equivalently, the oscillator loop group delay small. Both of these were achieved by substituting a rather wide band-pass LC filter (low Q) for the resonator in the loop. Fig. 2 illustrates the setup used. Here the amplifier was soldered to a connectorized PCB. For production testing, a fixture for the amplifier would be used to enable rapidly testing multiple devices.

In this work we characterized the amplifiers at 400MHz. The loop components consist of an amplifier (MMIC, 19.6 dB), a power splitter (-3.5 dB), a band pass filter (-2.5 dB, 40MHz bandwidth, 17.3nsec group delay) and a variable phase shifter. After subtracting the loop loss, we will have 13.5 dB excess gain in the loop. For oscillation to occur, the loop gain must be 0dB and the loop phase 0 degrees at the frequency of oscillation. We establish these conditions by measuring the open loop S21 on a network analyzer and make adjustments as necessary. Using a low level stimulus to avoid compressing the amplifier, the loop gain is set to about 2dB. For the above loop, we used an 11dB RF attenuator in the path to achieve 2.5dB excess gain. The network analyzer stimulus level is increased until the amplifier compresses to the point of 0dB loop gain. Finally, the phase shifter is adjusted to 0 degrees loop phase at the desired frequency of oscillation. The data presented below was obtained at 400MHz.

Figure 2. Low Q Phase Noise Measurement Set Up

Several amplifiers were evaluated, including inexpensive, tape-and-reel type MMIC amplifiers containing darlington pair configurations with resistive feedback as well as SMP modular amplifiers [5]. A reasonably large spread in 1/f PM noise was observed for different model tape-and-reel MMIC amplifiers purchased from the same vendor. The same method was used in a discrete component sustaining stage, and in that case, resonator loading was both measured and successfully simulated via determination of the $1/(2\pi\tau)$ corner frequency in the amplifier phase noise plots.

Fig. 3 shows phase noise measurements of a MMIC amplifier, an SMP modular amplifier and a discrete NPN amplifier using the low Q oscillator technique described above. The data was fit to the model (6) and (7) was used to determine the open loop 1Hz intercept: $L_{amp}(1Hz)$. The results are presented in Table I. The discrete NPN amplifier exhibits the best flicker performance of the three presented and is significantly better than the expected SAW resonator flicker performance at this frequency.

IV. RESONATOR CHARACTERIZATION

Since we are now interested in characterizing resonators, the amplifier contribution should be minimized. Good practice would be to select an amplifier whose 1Hz flicker intercept is at least 10dB better than the resonator under test. Once a suitable amplifier is selected and characterized, it is used for all resonators under test; Thus $L_{amp}(1Hz)$ in (7) is known. The test oscillator can be used to characterize packaged or on-wafer resonators. The setup to test packaged resonators is similar to Fig. 2, except the band-pass filter is replaced with a resonator in a test fixture.

At wafer probe, the oscillator's short term frequency stability can be significantly affected by ambient acoustic noise and vibration. Measures have been taken in this experiment to reduce the ambient noise as well as reduce the measurement sensitivity to noise. This is challenging since the noise we are trying to suppress is low frequency (10Hz-1kHz). The measures discussed below have improved data quality significantly, but more work remains to be done. To reduce ambient vibration, the prober (Electroglass 1034) was located on an outside wall of the facility. Currently, it is located on the second floor; moving to the ground floor should provide additional benefit. Additionally, the prober is mounted on a two stage vibration isolation table. To reduce ambient acoustic noise, the prober is located in a quiet room as removed from people and equipment as possible. Measurements were performed at night when activity in and around the building is minimal and unused equipment, particularly roof-top air handlers, could be powered off. The prober was also shielded by an acoustic enclosure; however, it did not provide much benefit below 500Hz. Measures were required to reduce acoustic noise generated by the prober itself. Fans were either located remotely (power supply relocated) or computer controlled to turn off during measurements. The prober employs a linear motor that rides on an air bearing which was a significant source of ambient noise. The compressed air was shut off via computer control during measurements. Similarly, any vacuum leaks holding the wafer to the chuck degraded the data. It was observed that the probe tip to wafer interface was particularly sensitive. Robust micro-positioners and probe tips helped as did securing all cabling. Fortunately, the probe electronics did not seem to impact the data; however, the AC power to the microscope light did. Turning the light off after setup alleviated the problem.

SAW resonators at 320MHz were selected to evaluate the methodology. Fig. 4 illustrates example on-wafer and packaged data with the resulting fits. Wafer data was collected with no cross-correlations and three averages. This wafer run exhibited the least degradation due to environmental noise obtained so far, yet degradation is still observed between 100Hz and 400Hz. A frequency mask from 100Hz to 300Hz

was applied to the wafer data during the fitting process. The packaged resonator was much less susceptible to environmental noise as can be seen in the figure. This data was collected with 10 cross-correlations and no averages.

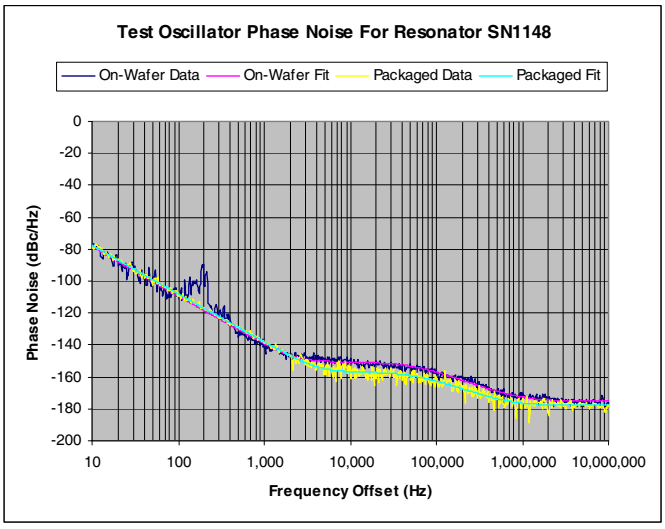

Figure 4. Example Resonator On-Wafer Data and Fit

Linear regression was performed on the wafer and packaged resonator data. The regression was statistically significant with an adjusted R^2 value of 95%. The resulting equation, $L_{res}(1Hz)_{pkg}=0.9996L_{res}(1Hz)_{wafer}$, was the desired result. Fig. 5 illustrates the data and the resulting fit. The relation does not perfectly predict packaged data performance from probe data, but it is useful for ranking resonator die for assembly. Table II presents summary statistics on the difference $L_{res}(1Hz)_{pkg}$- $L_{res}(1Hz)_{wafer}$. The average difference is close to 0dB. This allows accurate comparison of wafers, with different process conditions for example, by comparing the average performance of many die on each. Large data sets are needed to reduce the impact in the variability in the data. This was previously not practical without automated data collection and processing.

V. SUMMARY AND CONCLUSIONS

The goal of this project, the successful development and demonstration of a technique to accurately determine SAW resonator on-wafer phase noise performance, has been accomplished.

The in-oscillator technique uses a sustaining stage amplifier whose phase noise contribution is 10dB below that of best-measured resonators and allows determination of the noise contribution of devices with further improved noise level through design and processing optimization.

Determination of probe oscillator sustaining stage amplifier 1/f PM noise, was greatly facilitated via use of a low group delay filter substituted for the SAW resonator.

The most challenging aspect of this effort involved the minimization of vibration and acoustic induced oscillator phase noise degradation.

ACKNOWLEDGMENT

The authors would like to thank Dr. Tom Martin for many helpful technical discussions.

Abstract*— It is a common belief that a noise-free frequency divider by *D* scales down the input phase by a factor of 1/*D*, thus the phase-noise power spectral density (PSD) by $1/D^2$. We prove that the behavior described *does not apply to digital dividers.

Instead, the digital divider scales the white phase-noise PSD down by 1/*D*. Phase downsampling and aliasing, inherent in digital frequency division, is the reason. However the $1/D^2$ law holds asymptotically for flicker, where the aliases can be neglected.

We propose a new de-aliased divider, which scales the input phase-noise PSD by approximately $1/D^2$. The scheme is surprisingly simple and suitable to CPLD and FPGA implementation.

Keywords*— *aliasing; digital frequency divider; phase noise; white noise; flicker

I. Introduction

The noise-free frequency divider can be assimilated to an ideal gearbox that divides the input frequency by *D*, transferring the total jitter $x(t)$ – better referred to as `phase time' or `phase-time fluctuation' – from the input to the output. Accordingly, the output phase noise is $\varphi_{out}(t) = \varphi_{in}(t)/D$, and its power spectral density (PSD) $[S_\varphi(f)]_{out} = [S_\varphi(f)]_{in}/D^2$. So, a modulo-10 divider reduces the input phase noise by 20 dB.

Unfortunately, the output *white* noise of the classical digital divider (Π divider) is ruled by $[S_\varphi(f)]_{out} = [S_\varphi(f)]_{in}/D$. Since the denominator is *D* instead of D^2, a modulo-10 divider reduces the input noise by 10 dB instead of 20 dB. This is due to aliasing, thus it is inherent in the square-wave frequency division (Π divider), and independent of technology.

This article stands on [1], clarifies some issues, and introduces the Λ-type divider. This divider fixes the aliasing by adding shifted square waves with resistors, which results in a triangular-wave output (Fig. 2). Therefore, the noise of the Λ divider is ruled by $[S_\varphi(f)]_{out} = [S_\varphi(f)]_{in}/D^2$, which outperforms the phase noise of the Π-type divider by a factor of 1/*D*.

The $1/D^2$ and 1/*D* laws result from simple mathematical properties of white noise. Of course thermal noise, shot noise, and flicker noise add up, and the noise due to the technology as well.

II. Sampling and Aliasing

It is well known that the spectrum around all multiples of the sampling frequency is down-converted to baseband, and overlaps to the main part of the spectrum. This is the essence of aliasing, fully explained by the sampling theorem. The same fact can be interpreted as a consequence of energy conservation, as the sampling process preserves the total noise power. The power is by virtue of the Parseval theorem equal to the noise PSD integrated over the full bandwidth. Therefore, band compression results into white-noise enhancement by the same factor.

Real-world white noise has constant PSD spanning from 0 to the bandwidth *B* of the system. In the presence of white noise, aliasing deteriorates the SNR by a factor of B/f_N, where f_N is the Nyquist frequency (half the sampling frequency).

By contrast, flicker results in little and generally negligible degradation of the SNR. This happens because the PSD is proportional to $1/f$, so the aliases are small as compared to the base band.

A. Input stage

In digital circuits, the input stage converts the sinusoidal clock input into a square wave. As a relevant consequence, phase noise shows up only at the rising and falling edges, while the signal is saturated in between. This means that phase noise is *sampled* at the frequency 2ν, hence the Nyquist frequency is $f_N = \nu$. Denoting the bandwidth of the input stage with *B*, aliasing increases $S_\varphi(f)$ by a factor of B/ν. For instance, a 100 MHz sinusoid processed by a 300 MHz logic circuit results into a degradation of the input noise by approximately 4 dB.

B. Π-type divider

The classical digital divider is called Π-type divider from the graphical similarity of the output pulses with the Greek letter Π.

In a modulo-*D* divider, one edge every *D* edges propagates from input to output (Fig. 1). This is a hard decimation process, with no low pass (anti-aliasing) filter. In this condition, aliasing increases the white noise by a factor of *D*. Since the pure gearbox scales $S_\varphi(f)$ down by $1/D^2$ and alias enhances it by a factor of *D*, overall the input white noise is governed by the $[S_\varphi(f)]_{out} = [S_\varphi(f)]_{in}/D$ law.

Oppositely, flicker ($1/f$) noise is well approximated by the $[S_\varphi(f)]_{out} = [S_\varphi(f)]_{in}/D^2$ law because the aliases are comparatively small.

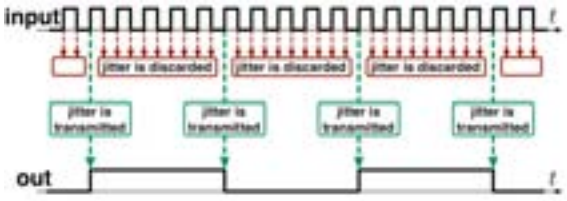

Fig. 1. Output sampling mechanism in Π divider.

C. Λ-type divider

The Λ divider generates a triangular wave signal by combining D square-wave signals shifted by half cycle of the input clock. Figure 2 shows an example of implementation for $D = 10$. Alternate topologies are also possible.

In Fig. 2, two ÷10 Π dividers are used, one driven by the rising edge of the input clock, and one driven by the falling edge. The outputs are delayed by 5-bit shift register, so that 10 phases of the intermediate square wave at $\nu/10$ are available, spanning over 180º. The sum of these intermediate signals is a triangular-wave like staircase (Fig. 3). Of course, the Greek letter Λ in the name derives from the graphical analogy with the triangular waveform.

The relevant feature of the Λ divider is that the output is sampled at the frequency 2ν, i.e., twice the input frequency, instead of $2\nu/D$, which fixes the alias of the Π divider. An alternate interpretation is that the white random signals at the intermediate outputs are statistically independent. Adding D of them results in facror-of-$1/D$ lower phase noise. As a consequence, the Λ divider is governed by the $1/D^2$ law, which is the theoretical limit for the noise-free divider.

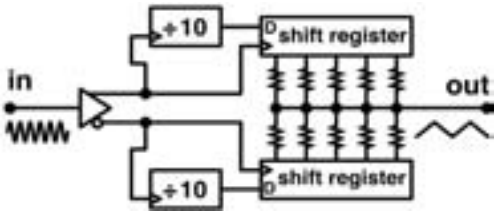

Fig. 2. Λ divider block diagram.

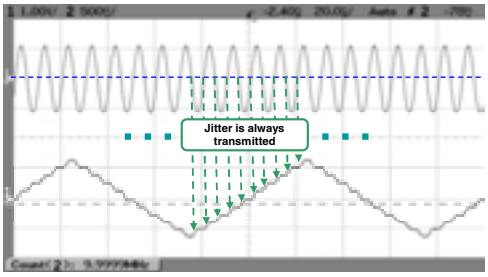

Fig. 3. Waveform at the input and at the output of a Λ divider.

III. Experiments and Results

The Divider Under Test (DUT) is implemented in a CPLD Altera EPM3064A [2], a simple 64-cell device with 10 ns speed grade, kind of the `ancestor' of the FPGA, which for our purposes can be programmed in three ways:

- The simple Π-type divider,
- A multi-buffer Π-type, which is the scheme of Fig. 2 with the `shift registers' re-configured as buffers, i.e., with no shift at all,
- The Λ divider, as it is in Fig. 2.

The resistor network is a SMD array mounted close to the CPLD.

The phase-noise test instrument [3] implements the cross-spectrum technique described in [4].

A. Aliasing

The first experiment is the demonstration of the aliasing phenomenon in the Π and Λ dividers, and of the benefit of the Λ topology. In order to isolate the aliasing effect from other phenomena in the divider, we work with an artificially – and unrealistically – high level of white noise. This is done by attenuating and re-amplifying the clock signal (Fig. 4).

Flicker noise cannot be obtained in the same way. So, we use the phase-modulation feature of a commercial synthesizer driven by an audio-frequency flicker-noise generator.

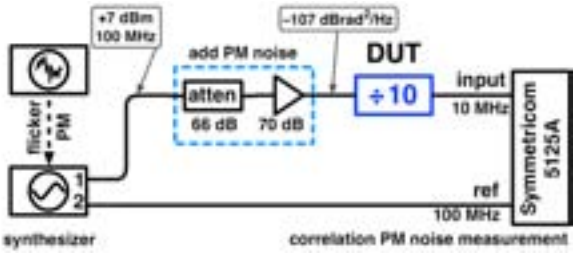

Fig. 4. Experimental setup.

The results of this first experiment are shown in Fig. 5. After waveform shaping, the phase noise is 4 dB higher. This is exactly what expected from the bandwidth of the front end.

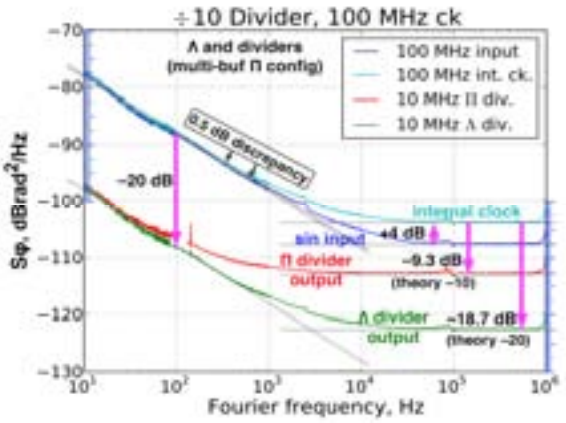

Fig. 5. Result on aliasing in case of flicker and white phase noise.

The flicker noise is scaled down by 20 dB in all cases. This confirms the theoretical prediction that the aliases of $1/f$ noise are too low to be visible on the output spectrum. At 100-1000 Hz, the spectrum differs by 0.5 dB from the straight-line approximation. This is still not explained, and left for future investigation.

The Π divider reduces the phase noise by 9.3 dB, which is close to the expected value of 10 dB. Similarly, the Λ divider reduces the input phase noise by 18.7 dB, close to the value of 20 dB predicted by the theory.

B. Residual Phase Noise of the Dividers

The second experiment is the measurement of the divider phase noise in real-life conditions, in order to demonstrate the practical usefulness of our solutions. The synthesizer is now replaced with a low-noise OCXO, manufactured by Wenzel Inc. [5]. The phase noise spectrum is shown in Fig. 6.

The 1-Hz phase-noise coefficient is $b_{-1}=10^{-12}$ rad^2/Hz (–120 dB rad^2/Hz) for the Π divider, and $b_{-1}=9\times10^{-14}$ rad^2/Hz (–130.5 dB rad^2/Hz) for the Λ divider. Beyond 10 Hz, the flicker noise is 2–3 dB higher. This discrepancy could be an artifact, however the phenomenon is still unexplained.

The white noise is $b_0=2.5\times10^{-16}$ rad^2/Hz (–156 dB rad^2/Hz) for the Π divider, and $b_0=3.2\times10^{-17}$ rad^2/Hz (–165 dB rad^2/Hz) for the Λ divider.

The Allan deviation of the Λ divider is of 2×10^{-14} at 1s. This is equivalent to that of a DDS [6], yet at a way lower cost, complexity, size, and electrical power.

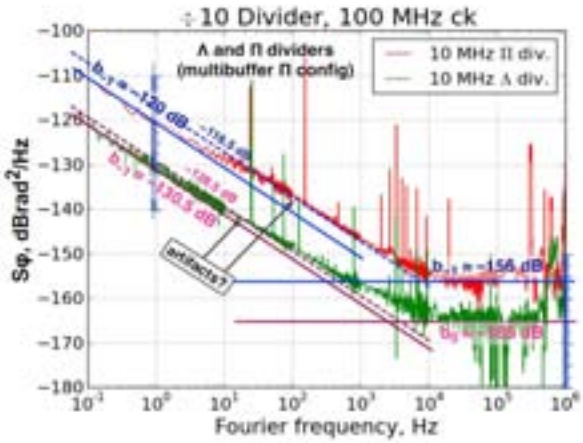

Fig. 6. Residual phase noise of the Π and Λ dividers we tested.

IV. Conclusions

We demonstrated theoretically and experimentally that the white noise of traditional digital frequency dividers (Π topology) is affected by aliasing, and that the new Λ topology fixes the problem.

The phase noise of the Λ divider sets the state of the art for digital dividers. Only the regenerative divider [7] performs lower noise. However, the Λ divider is a fully digital circuit, therefore simple, reproducible, and requires no tuning or adjustment. Thus it is suitable to straightforward integration in larger blocks.

Trim Effect Compensation Using an Artificial Neural Network

John C. Esterline
Greenray Industries
Mechanicsburg, PA USA
jesterline@greenrayindustries.com

Abstract— **Trim effect is a skewing of the frequency versus temperature performance of a crystal oscillator as the frequency is pulled (trimmed) away from the oscillator's nominal frequency. As TCXO (Temperature Compensated Crystal Oscillator) frequency versus temperature stabilities have improved to ppb (part per billion) levels trim effect has become more of a concern. Even though unwanted, the degradation of performance from trim effect is something generally accepted as a characteristic of TCXOs. This paper focuses on a method of compensating crystal oscillator trim effect. Through the use of an artificial neural network, trim effect compensation of AT cut crystal oscillators can be achieved with better than +/-15ppb stability over the industrial temperature range (-40 to +85 °C). This is more than a 10 fold improvement over the inherent trim effect found using state of the art polynomial function generator compensation. The theory of this compensation method with be discussed, and data showing the results of trim effect compensation on actual oscillators will be presented.**

I. INTRODUCTION

Trim effect is a skewing of the frequency versus temperature performance of a crystal oscillator as the frequency is pulled (trimmed) away from the oscillator's nominal frequency. This effect is well known, but mostly ignored, due to an inability to reduce or eliminate the skewing. Trim effect manifests because the compensation voltage for the Temperature Compensated Crystal Oscillators (TCXOs) is derived with the control voltage (or EFC) at a fixed value (generally ½ of the supply voltage) and applied to a varactor. The varactor's reactance varies with the voltage applied, which results in a change in load capacitance (C_L). The frequency versus C_L relationship is nonlinear.

This nonlinear relationship leads to degradation in frequency versus temperature performance when the TCXO's control voltage is changed to a value that is different than what it was compensated with. In practical use TCXO's are commonly adjusted for aging drift. The recalibration of the TCXO for aging will inadvertently cause the TCXO's frequency versus temperature performance to be degraded.

The following paper will discuss a trim effect compensation scheme using an Artificial Neural Network (ANN). The method developed by Greenray Industries, has successfully compensated Statek AT-cut strip crystals to stabilities of better than +/- 15 ppb over the industrial temperature range of -40 to +85 °C (including a +/-5ppm trim range).

Using an ANN for temperature compensation has been discussed in literature [2-4]. [2] is a review of the subject matter and asserts that ANN technology would be suited for environmental compensation of crystal oscillators. [3] describes an attempt to compensate the temperature performance of a crystal oscillator using an ANN. The oscillator in [3] was only compensated over a 6 °C range (21 - 27 °C), and the training of the network took 21 days. The conclusion drawn in [3] was that the technology could achieve compensation but the training time at that time (1994) was prohibitive for manufacturing. [4] describes preceding work from Greenray Industries, that compensated a TCXO to better than +/- 10ppb over the industrial temperature range of -40 to +85 °C.

Trim effect has been covered extensively in literature, however compensation of trim effect has been covered to a much lesser extent. [5] describes a TCXO compensation incorporated into a custom TCXO ASIC

In Section II, the basics of ANN technology and how this can be implemented as a curve fitter will be discussed. Section III describes the configuration of the Greenray Industries oscillator employing the ANN temperature compensation and trim effect compensation schema. Section IV summarizes the performance of the ANN compensated oscillator over temperature and trim. Section V, concludes with a discussion of the new compensation methodology.

II. ARTIFICIAL NEURAL NETWORK OVERVIEW

The following is a very brief overview of ANN theory. It is intended to give the unfamiliar reader enough understanding of the topic to comprehend the remainder of this text. For a more in depth discussion of neural network technology, [7] is an excellent source. Being the preceding work to this text, [4] is also a good source as it describes the ANN temperature compensation being employed in this work.

A neural network can be described in general as a "machine that is designed to model the way in which the brain performs a particular task or function of interest [7]." This "machine" achieves this modeling through the interconnections of many simple processing units or neurons. In nature the neurons are biological nerve cells which have electrical and chemical responses to given stimuli. In an artificial neural network the neuron is modeled in hardware and/or software. Figure 1 below shows a non-linear model of a neuron.

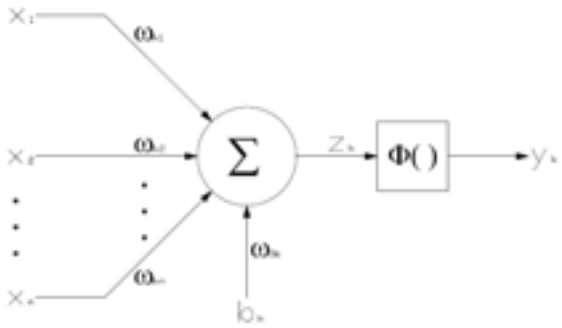

Figure 1: Nonlinear model of a neuron [4]

Starting at the left side of Figure 1, one can see the input vector of input(s) x_1 through x_n. These inputs are then multiplied by the individual synaptic weights ω_{k1} through ω_{kn}. There is a bias b_k, which can have its own weight ω_{0b}. These products are summed together, before being subjected to the activation function. The activation function (Φ) can be nearly any function the designer sees fit to use, and are often chosen to suit the application. The purpose of the activation function is to limit the amplitude of the output to some finite value [7]. Equations (1) and (2) show the neuron in mathematical terms.

$$z_k = \left(\sum_{i=1}^{n} \omega_{ki} x_i \right) + \omega_{0b} b_k \qquad (1)$$

and

$$y_k = \Phi(z_k) \qquad (2)$$

For simplicity, many times Figure 1 is condensed so that the summation and the activation function are both contained in the bubble as can be seen in the remainder of neural network figures in this text.

Activation Function

As mentioned above the activation function (Φ) can be any function the designer desires. The activation function selected for the task of oscillator temperature compensation is the unipolar sigmoid function, shown in (3). In equation (3), α is a slope control variable, and z_k is defined in (1).

$$\Phi = \frac{1}{1 + e^{-\alpha(z_k)}} \qquad (3)$$

For a two input network the sigmoid function becomes a three dimensional sigmoid sheet as seen in Figure 2. The variables affect the three dimensional sigmoid in the same way as its two dimensional counterpart except that there are now two inputs each with independent weights. These two independent weights can rotate or twist the sigmoid sheet in three dimensional space.

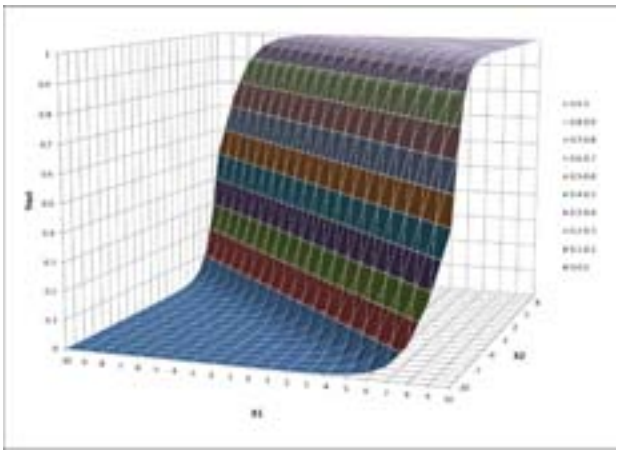

Figure 2: Three dimensional sigmoid

For trim effect compensation the ANN needs to have two inputs, x_1 and x_2. The input x_1 is a voltage that corresponds to the temperature of the oscillator. The input x_2 is the user applied control voltage. This two input network is shown in Figure 3 below.

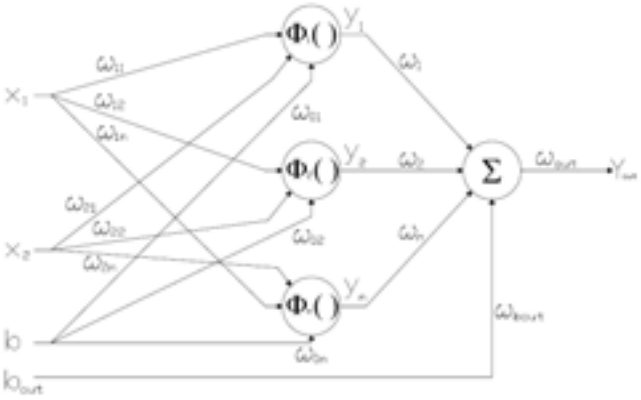

Figure 3: Two input network for trim effect compensation

The network structure in Figure 3 can be described by (4).

$$Y_{out} = \omega_{out} \left[\left(\sum_{i=1}^{n} \omega_i y_i \right) + \omega_{bout} b_{out} \right] \qquad (4)$$

Each neuron (y through y_n) in the input layer has a sigmoid activation function as shown in (3). The input x is a voltage representing temperature, and the output will be a representation of the deviation in ppm.

Network Training/Learning

The weights of the ANN structure are what ultimately determines its response and therefore must be determined in some fashion. In the neural network field the process of

"solving" for these weights is referred to as learning or training. The learning can be defined as "a process by which the free parameters of a neural network are adapted through a process of stimulation by the environment in which the network is embedded [7]." There are many different ways to "train" neural networks and most have applications where one method is preferred over another. For this application, the well-known method of least squares was implemented using a gradient reduction search.

III. ANN OSCILLATORTRIM EFFECT COMPENSATION

To implement trim effect compensation using an ANN two neural networks are implemented. The first network is responsible for compensating the oscillator at center control voltage. The second network is responsible for the trim effect compensation. The trim effect compensation network is placed in parallel to the temp compensation network, and the two compensation voltages are summed together. Figure 4 shows the block diagram of this dual network configuration. Theoretically speaking both the center temperature compensation and the trim effect compensation could be accomplished by the same ANN, however in practical application the complexity of the network to solve the higher deviation three dimensional trim effect solution space makes it more impractical. The gradient reduction solver can easily become "stuck" in a local minima, degrading the level of fit for the solution. Better results have been achieved by first compensating the oscillator at center control voltage, and then applying a secondary trim effect compensation ANN.

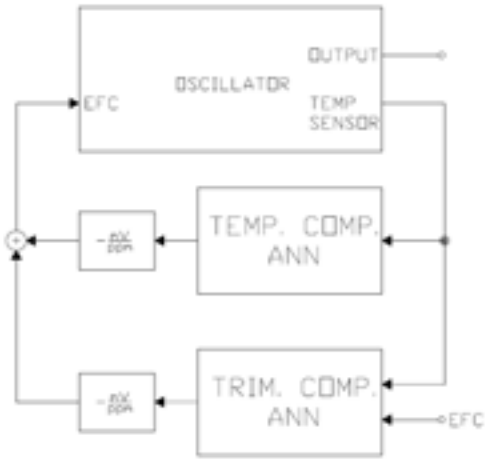

Figure 4: ANN trim effect compensation block diagram

The hardware needed to accomplish the temperature and trim compensations can be seen in Figure 5. The trained weights for the ANN are stored in the EEPROM. Each neuron has 4 variables that are being trained (ω_1, ω_2, b, and α). However from the equation of the sigmoid in (3), one can see that α is distributed in the quantity z_k . After training, this distribution can be done so that what is stored in the EEPROM are the quantities $\alpha\,\omega_1$, $\alpha\,\omega_2$, and α b. This reduces the storage requirements for each neuron down to three quantities. The network as a whole will have a ω_{bout} and ω_{out} that also need to be stored.

The microprocessor samples the temp sensor using the ADC. It then applies that input to the microprocessor which calculates the ANN's response, and the output is converted back into a voltage using the DAC. With the current hardware, seven corrections a second can be applied to the oscillator providing excellent tracking under fast temperature ramp conditions. The low pass filter is to prevent the output frequency from having a step function response to the corrections.

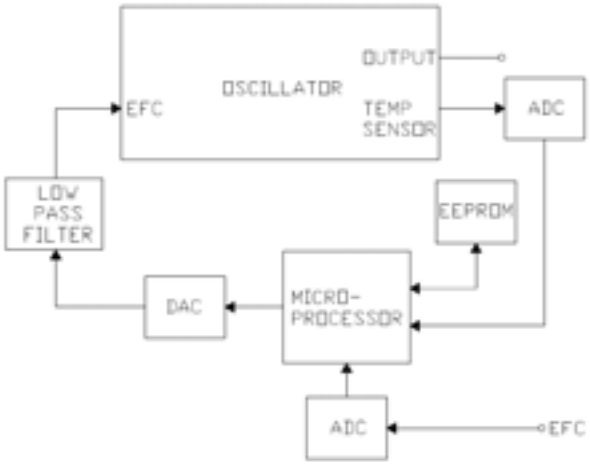

Figure 5: Block diagram of hardware for ANN trim effect compensation

Prototype Testing

Two different compensations were performed in the initial evaluation of the technology. The first compensation was to use one of Greenray Industries 10MHz ANN100-1 oscillator. This oscillator was designed around the ANN hardware in Figure 5. The ANN100 series uses a Greenray Industries T70 TCXO as the oscillator. The T70 was chosen because the oscillator die is in a ceramic package with a Statek AT strip crystal, which is also in a ceramic package, mounted on top. This construction provides a very good thermal design, which has excellent thermal coupling between the temperature sensor on the die and the crystal. Also the Statek AT Cut crystals have proven to be very good for low perturbations and low thermal hysteresis.

The first compensation done in evaluation of the hardware was to use the TCXO's internal compensation followed by a secondary compensation using the ANN methodology described above(with the control voltage set to ½ V_{cc}). This was done to provide a low deviation frequency versus temperature performance at center control voltage, which makes the solution space for the trim effect compensation easier to fit. The second compensation employed was another ANN to provide the trim effect compensation as described in Figure 4 above.

IV. ANN COMPENSATION RESULTS

The below section details the results of the trials described above. Figure 6 below shows the results of the center control voltage frequency versus temperature compensation and the resulting trim effect.

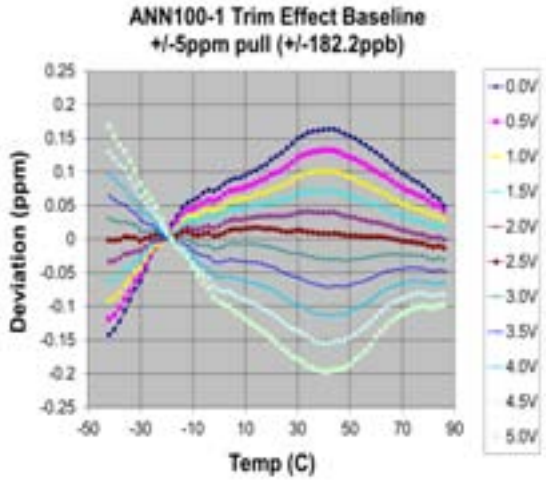

Figure 6: ANN100 frequency versus temperature compensation

In Figure 6 it can be seen that the center control voltage of +2.5V provides a very flat response over temperature and as the voltage is trimmed the deviation becomes increasingly worse. Figure 7 shows the results after implementing the trim effect compensation ANN. It can be seen that the deviation after the ANN trim effect compensation is applied is +/- 10.7ppb including trim effect. This is a compensation of 17 to 1. To achieve this compensation 10 neurons were used.

By implementing these two compensations, a TCXO has been created that has a frequency versus temperature performance of +/- 10.7ppb over the industrial temperature range (-40 to +85 C). This is inclusive of the trim effect generated by trimming the oscillator +/- 5ppm. This performance rivals that of many OCXOs, however the power consumption of the ANN100 is less than 100mW.

The addition of the trim effect compensation to the ANNCXO demonstrates the technology's robustness as a curve fitter improves the performance of the oscillator beyond what is achievable with other traditionally employed compensation methods.

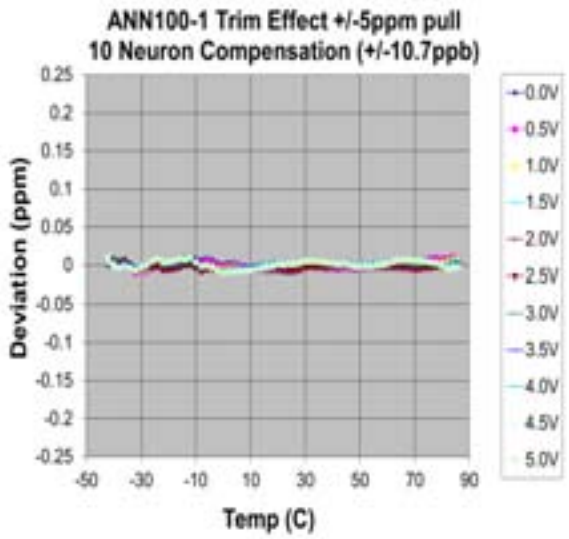

Figure 7: ANN trim effect compensation

V. CONCLUSION

The approach shown above outlines a means for using an ANN to provide temperature compensation and trim effect compensation for a crystal oscillator. From the above data it can be seen that the ANN provides a medium with which to fit very complex multidimensional data. This allows for an embeddable compensation schema to be employed that can improve the frequency versus temperature performance beyond what is achievable with traditional methods. It also allows for the compensation of trim effect which is present in all TCXOs (that have a control voltage).

ANN compensation provides greater than an order of magnitude improvement over the 5th order polynomial compensation. This realized performance improvement over the polynomial style of compensation allows a very low power consumption and relatively small device to have temperature stabilities that rival many OCXOs. A drawback to this approach is that the phase noise performance is that of a TCXO. This could limit the applications that it is ultimately suitable for. However, the advantage in footprint and power consumption (<100mW) will allow the ANNCXO to replace OCXO's in applications that are primarily concerned with temperature performance and not necessarily phase noise.

Building on the ANN temperature compensation described in [4], the trim effect compensation demonstrates how more complex multidimensional environmental effects can be compensated. This insight would allow ANNs to be designed that could compensate for thermal hysteresis, warm-up, and possibly aging. The superior curve fitting nature of the ANN effectively allows the designer to fit and compensate for any frequency deviation that can be sensed. The limit on this statement would be memory for storing weights. As the solution space becomes more complex and spans more dimensions the number of neurons needed to effectively fit that space will grow drastically.

Status of the Flight Model of the Cold Atoms Space Clock PHARAO

Igor Moric, Philippe Laurent
Observatoire de Paris, SYRTE
Paris, FRANCE

***Abstract*—PHARAO (Projet d'Horloge Atomique par Refroidissement d'Atomes en Orbite), which is being developed by the French space agency CNES, is the first Primary Frequency Standard (PFS) specially designed for operation in space. PHARAO is a main instrument of the ACES (Atomic Clock Ensemble in Space) mission. ACES is being developed by ESA and the payload will be installed on-board the International Space Station. The mission is based on comparisons with ground based clocks to perform fundamental physics experiments: gravitational redshift measurements, analysis of the stability of the fundamental constants and anisotropy of light. Planned duration of the mission is 18 months with a possible extension to 36 months. The frequency accuracy requirement for PHARAO is less than 3 x 10^{-16} and the expected frequency stability is $10^{-13}\tau^{-1/2}$. An engineering model of PHARAO has been constructed and fully tested to validate the clock architecture. Two sub-systems for the flight model FM) have been delivered: the cesium tube where the atoms are manipulated and the microwave source which generates the 9.2 GHz signals. The other sub-systems, the laser source and the computer, will be delivered this year. Some performances tests have been performed on the microwave source and on the cesium tube assembled with the other EM sub-systems. The whole FM clock will be assembled in 2013.**

I. INTRODUCTION

ACES (Atomic Clock Ensemble in Space) [1] is an ESA mission in fundamental physics which is based on time and frequency comparisons between high performances space clocks and ground based clocks. The space segment will operate a new type of atomic clocks in microgravity environment. The payload (Figure 1.) will be installed on the NASA developed External Payload Facility pallet of the Columbus laboratory (CEPF) on-board the ISS (International Space Station). The station is orbiting at a mean elevation of 400 km with about a 90 min rotation period and an inclination angle of 51.6 degrees. The Number of ISS passes over a European ground station is 5 per day.

The clock signal is obtained from the combination of two atomic clocks: a cold cesium clock PHARAO as a primary frequency standard [2] and an active hydrogen maser [3] as a freewheel oscillator. The comparison with earth based clocks is performed by two way time transfer links operating in the microwave domain (MWL) [4] and in the optical domain (ELT) [5]. Ground terminals will mainly be located in time and frequency laboratories, while the mission will be operated from the ACES User Support and Operation Center (USOC), installed at CADMOS (Centre d'Aide au Developement de la Micrograviteet aux Operations Spatiales) in France.

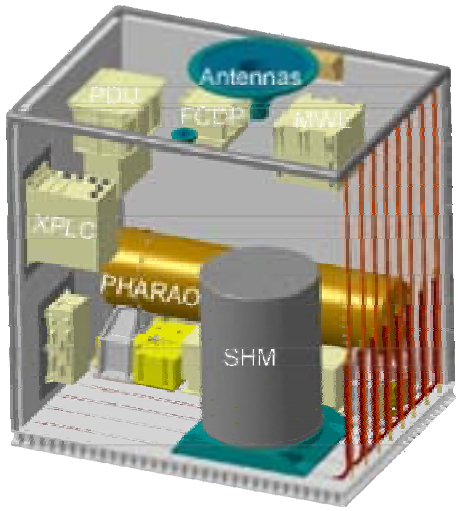

Fig. 1. – Scheme of the ACES payload. PHARAO: the cold cesium clock. SHM: the active hydrogen maser. FCDP: the frequency comparison and distribution package. MWL: the microwave link. ELT: the optical link. GNSS receiver, a computer (XPLC) and a power supply (PDU). The ACES payload has a volume of about $1m^3$, a total mass of 227 kg and a power consumption of 450 W.

The launch is scheduled on 2016. Planned duration of the mission is 36 months. First 6 months are reserved for functionality verification of instruments and performances evaluation. The first objectives are to study the performances of this first cold atom space clock and reach a frequency accuracy lower than 3 x10^{-16} and deliver a timescale with a 25ps/day stability. The microwave link will have to demonstrate the capability to perform phase comparisons between space and ground clocks with a resolution at the level of 0.3 ps over one ISS pass (300s), 7 ps over 1 day, and 23 ps over 10 days.

II. THE COLD ATOM CLOCK PHARAO

CNES is the prime contractor of the PHARAO clock. The clock architecture is shown in Figure 2. It is composed of 4 connected sub-systems. Diagram of the cesium tube is shown in Figure 3.

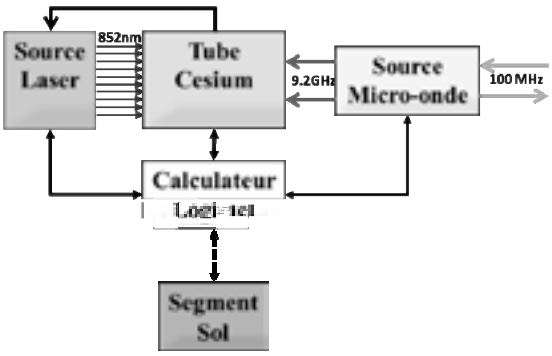

Fig. 2. – The PHARAO clock includes 4 sub-systems: the laser source provides laser beams to the cesium tube to manipulate the atoms. The microwave source provides two 9.2 GHz signals to the cesium tube and a 100MHz signal to the ACES payload. It can also receive a 100 MHz to generate the microwave signals. The computer manages the clock operation, sends data and receives telecommand from the ground segment.

The cold atoms are manipulated inside a titanium vacuum chamber. The pressure of 10^{-8} Pa is maintained by an ion pump and 6 getters. A reservoir with adjustable temperature and aperture provides the cesium flux to the capture zone. The atoms are captured and cooled at the intersection of 6 laser beams that have a diameter of 21 mm (capture cavity). The atomic cloud is then launched at a velocity which can be adjusted between 5 to 500 cm/s.

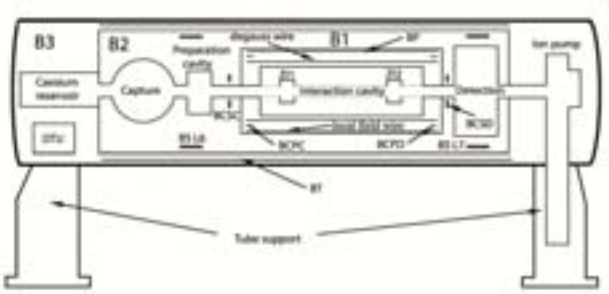

Fig. 3. – Diagram of the PHARAO cesium tube. Labeled are the external shields B1, B2, B3, the DTU magnetometer, ion pump, cesium reservoir, different cavities and coils. From the reservoir cesium atoms are released towards detection passing the capture cavity (where they are cooled), preparation cavity (where F = 3 atoms are selected) and interaction cavity (where the Ramsey interrogation is performed). In the detection zone, ratio of the two populations is obtained. The three Mumetal shields are used to reduce the magnetic oscillations the atoms experience in flight due to the Earth orbit field. The coils are used to improve field homogeneity, separate magnetic Zeeman levels by providing a static magnetic field and for active compensation (BT).

Next, two laser beams inside a microwave cavity (preparation cavity) select the atoms in a pure quantum state and can slice the atomic cloud to reduce the longitudinal expansion. The atoms enter in the interrogation region (interrogation cavity) where they are submitted to a Ramsey interaction inside a ring cavity. The temperature of the cavity is measured by using two calibrated probes placed on the vacuum chamber. After the microwave interaction, the atomic cloud passes through 4 laser beams in order to calculate the population in each hyperfine level from the measurement of the fluorescence signals.

The vacuum chamber is surrounded by 3 magnetic shields where a solenoid and 5 coils provide the magnetic field bias. A second solenoid and a magnetic probe are used for an active magnetic compensation. Two wires pass through the inner shield. One is used to degauss the shields and the other to induce Zeeman transitions in the atoms in order to deduce the local magnetic field. The cesium tube weighs 46 kg, the volume is 47 L and the power consumption is 5W.

A. The microwave source

The microwave source synthesizes two independent 9.2 GHz signals from an ultra stable quartz oscillator. One signal feeds the preparation cavity and the second feeds the Ramsey cavity. Both signals can be tuned over 10 kHz with a 10^{-7} Hz frequency resolution. The power can be adjusted between -20 to -80 dBm with a resolution of 0.02 dB. The signals can also be switched off by 80dB. The switching is mainly used to only feed the preparation cavity when the atoms are inside. In nominal operation the USO is phase locked on the 100 MHz H-maser signal. The microwave source can also use an external 100 MHz signal to generate the microwave signals. The weight of the microwave source is 7 kg, volume is 8 L and the power consumption is 25W.

B. The laser source

The laser source provides 6 laser beams to capture the atoms, 2 laser beams to select the atoms and two laser beams to detect the atoms. It contains two extended cavity diode lasers (with backup) frequency locked on cesium lines. One ECDL injects locked two slave diode lasers (with backup). Each slave laser beam is split in 3 to provide the capture beams. 2 acousto-optic modulators are used to change the laser frequencies and 4 are used to control the laser power. In addition, 6 mechanical shutters switch off the laser powers. The laser beams are injected into maintaining polarizing optical fibers. In order to ensure an optimum coupling or to balance the laser power for the capture beams, the beam alignment can be changed by means of mirrors mounted on PZT transducers. The optical set-up takes place on a double sided optical bench fixed by four 4 damped supports. All electronic drivers are mounted on the baseplate underneath the optical bench.

C. The computer and software

The computer is based on a 32 bits, 20MHz processor with 8 Mo flash memory and 8 Mo RAM memory and on a programmable microcontroller which provides 24 digital lines

to trigger the events of the clock cycle. The computer drives the servo-loops for thermal stabilization, the active magnetic compensation, the degaussing and Zeeman process. A multiplexed analogic digital converter reads physical values for housekeeping and for the determination of the transition probability of the cesium hyperfine transition. The computer also has several serial lines to command the sub-systems and to exchange data and telecommands with the ACES computer XPLC. The weight is 5 kg, the volume is 7 L and the power consumption is 30W. The software is based on 350 sequences dedicated to specific task.

Three different models of the clock have been constructed: the mechanical and thermal model (MSTH) to test the environments (vibrations 20g rms and temperature -40, +60°C), the engineering model to test the operation and the performances, and the flight model which has the benefits of the improvements deduced from the previous results.

D. The performances of the Engineering model

The phase noise and the spectral purity of the microwave source signals are in agreement with the expected performances of the clock. To complete these measurements the microwave source has been used by the SYRTE fountain F02 and the resulting frequency stability is $7.2 \times 10^{-14}\ \tau^{-1/2}$. During these measurements we have detected a transient effect on the 100 MHz signal due to the switching of the preparation cavity signal. As this signal is phase locked to the H-maser, this transient which is a phase jump of 10 µrd leads to a phase drift of the 9.2 GHz interrogation signal. The clock frequency shift can reach 6×10^{-16}.

Among all the optical performances of the laser source, only two are not in agreement with our requirement: the power of each capture laser beam is low, 5mW and the laser spectra are widened by a too large modulation index used by the frequency servo loops. In addition, although the vibration tests on the MSTH have been successful, the thermal tests have shown a sensitivity of the optical alignment with the temperature.

Concerning the cesium tube, the MSTH vibration and thermal tests have demonstrated the robustness, but without sufficient margins. The tests have also highlighted an inaccuracy in the temperature determination of the Ramsey cavity (to evaluate the blackbody frequency shift). The uncertainty can reach 400mK (100mK is required).

The tests of the clock have given a frequency stability of $3.3 \times 10^{-13}\ t^{-1/2}$. The frequency stability is obviously degraded by the ground operation since the interrogation time is only 90 ms. The Ramsey fringes are shown in the Figure 4. and the result is in agreement with a Monte-Carlo simulation. The main systematic effects have been studied. The second order Zeeman shift uncertainty is limited by an inhomogeneity of the magnetic field shown in the Figure 5. Consequently, the Ramsey pattern of the hyperfine resonance between m = 1 sub-levels shown in Figure 6. has a low contrast. Another issue comes from the magnetic field attenuation. In orbit, the magnetic field fluctuations due to the Earth field have an amplitude of about 30µT. The attenuation of the shields is 12000 in the interrogation zone and the active compensation adds a gain of about 5. The total attenuation (60000) is far too low to be sufficient to evaluate the second order Zeeman shift with a required accuracy.

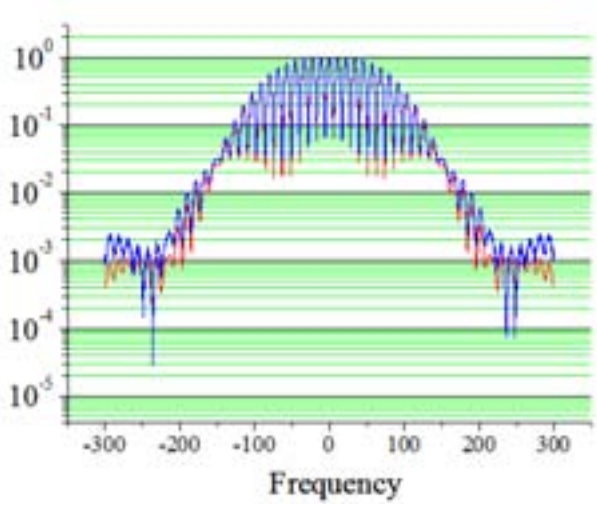

Fig 4. The Ramsey fringes for m = 0 transition in log scale. In blue are the experimental results, in red the simulation.

The frequency accuracy of the engineering model is evaluated at 1.6×10^{-15}. By comparing the clock with the FOM primary frequency standard of SYRTE we obtain frequency differences within 2.10^{-15}, in agreement with the evaluation budget.

From all these tests some modifications have been made on the clock design to build the flight model.

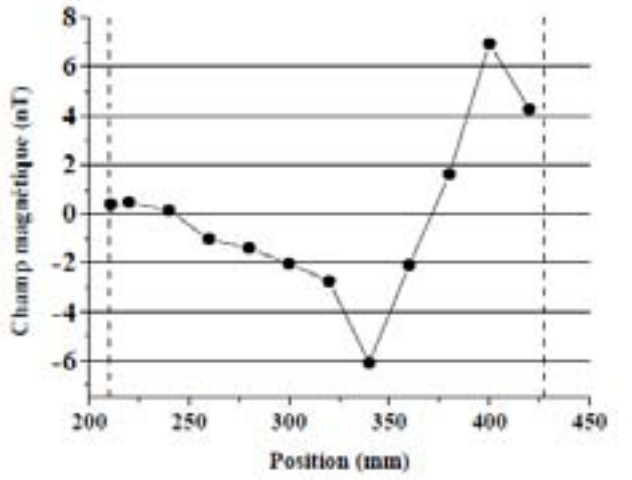

Fig 5. The EM magnetic field inhomogeneity inside the interrogation cavity obtained using a wire placed parallel to the atom path that invokes m = 1 transitions.

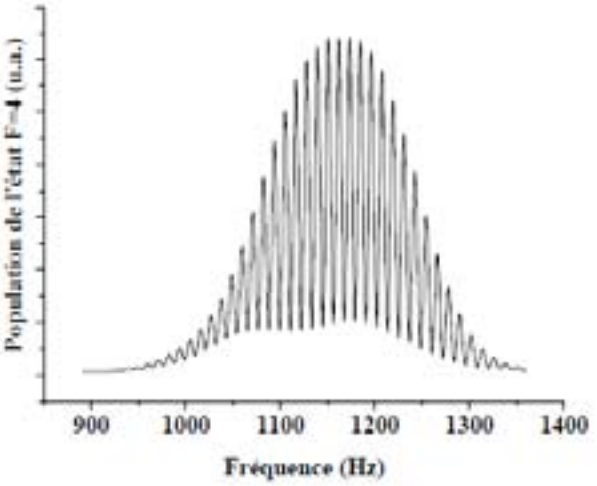

Fig 6. The EM Ramsey fringes for m = 1 transition. Observe the shape dissymmetry.

III. FM STATUS

Based on the experience gathered from the MSTH and EM, various improvements have been made on the FM. Mechanical structure and design improvements have been performed for the laser source and the cesium tube. As a result, the power of the laser source was increased to 15 mW/beam (a factor of 3 improvement over the EM) and a better optical alignment stability was ensured. Cesium tube has a better robustness and temperature accuracy. In order to improve the field homogeneity magnetic shield design was changed. Additionally, the assembly process and software were modified.

Change in the microwave synthesis reduced the transient effect present on the EM microwave source by a factor of 10 (Figure 7.). The phase noise spectral density and spectral purity are as per specification.

The cesium tube was qualified and delivered in March 2013. The laser source is now fully assembled and is to be qualified in August 2013.

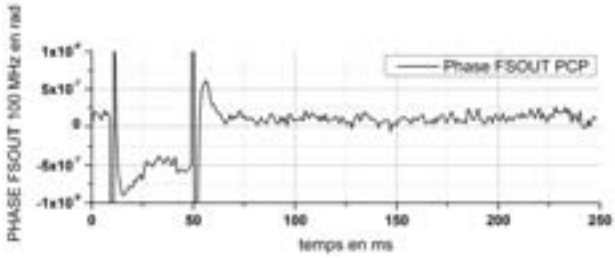

Fig 7. Microwave source transient effect on the FM microwave source. The amplitude jump caused by the turning on and off of the device was reduced by a factor of 10 compared to the EM.

IV. FM PRELIMINARY RESULTS

The FM cesium tube has been assembled with the EM subsystems to verify its operation and magnetic homogeneity improvements. Figure 8. shows the m = 1 hyperfine transition for the FM. The shape is much more symmetrical than on the EM indicating better homogeneity. This has been confirmed by using the Zeeman wire.

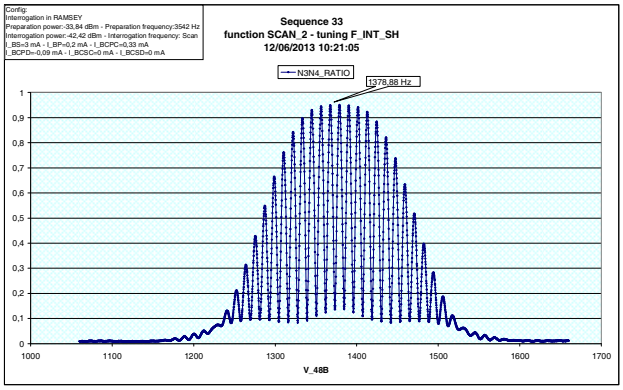

Fig 8. The FM Ramsey fringes for m = 1 transition. Compared to Fig 6. the shape is much more symmetric indicating better homogeneity.

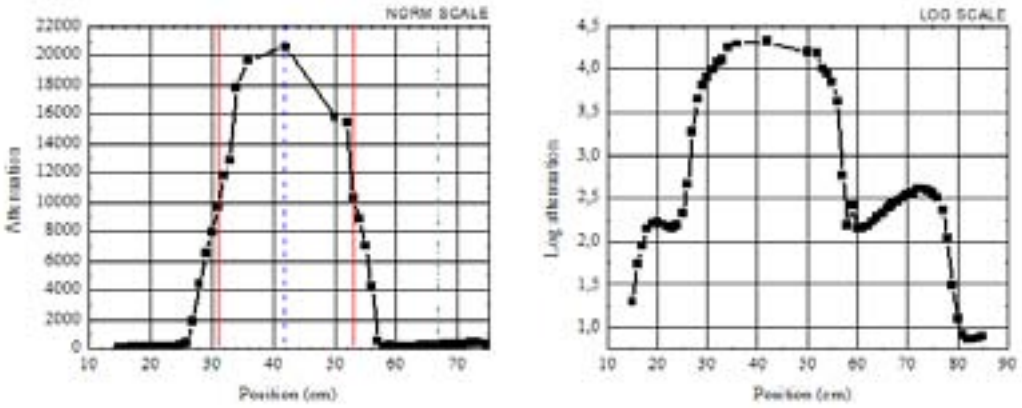

Fig 9. Summary of attenuation results as a function of position along the atom path inside all three shields combined in normal scale (left) and log scale (right). Values were obtained using the peak to peak method. Full vertical lines (red) represent the position of the interaction zones, dashed line (blue) is the center of interaction cavity and the dash-dotted line (green) is the center of preparation cavity. An external field with amplitude of ± 31 μT was used (representing the real peak to peak variation the shield will experience in orbit) and the period was 100 s. An attenuation of 9633 was measured at ZI2, 20550 at the center, 10275 at ZI1 and 250 inside preparation zone.

V. MAGNETIC SHIELDS IMPROVEMENTS

Experiments have been performed to verify the attenuation improvements of the FM shields. Two Helmholtz coils were used to simulate an axial external field around the shields positioned in the center and a fluxgate Mag-01 magnetic probe manufactured by Bartington Instruments was used to measure the internal field. The measurements show an improvement of the EM by a factor of 1.5. The attenuation is 20 550 at the center, 10 250 at the ZI1 (zone interaction 1) and 9650 at the ZI2 (zone interaction 2). On average, the attenuation in the interaction zone is around 18 000 (compared to 12 000 on the EM). For more detail see Figure 9.

Additionally, a new active attenuation system was implemented. It is a feed-forward system composed of a magnetometer (DTU) and a compensating coil (BT). Using the DTU measurements and a model, the field inside the interrogation cavity is calculated. Current is then sent inside the coil to compensate this field. Development of a model was necessary due to a presence of a position dependent hysteresis inside the B3 shield.

Experimental results show that the model performs as expected. The attenuation for the axial component of the orbital field inside the interrogation cavity reaches a value of 100. This can be seen on Figure 4. However, due to the transverse component of the orbital field, the total attenuation is reduced by a factor of around 5. The problem is that the magnetometer installed in the cesium tube cannot separate the axial and the transverse component of the orbital field and the transverse component has a different effect on the device and on the atoms. Additionally, a temperature dependency of the magnetometer has been noticed further reducing the attenuation. Therefore, to reach the required attenuation in order to reduce the quadratic Zeeman effect and have the required frequency accuracy another system composed of measuring the magnetic field (m = 1 transition) every 300s for 10s will be added.

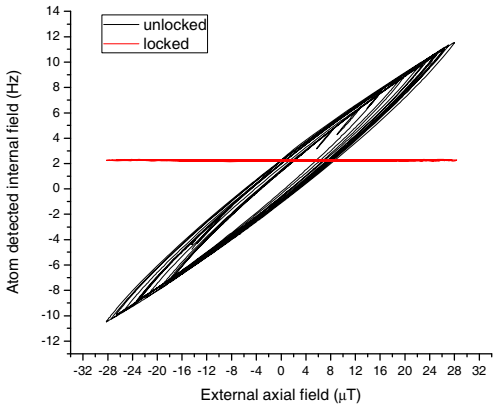

Fig 10. m = 1 hyperfine transition frequency fluctuation with (in red) and without the active attenuation (in black) for an axial component of the orbit field as the external field.

VI. CONCLUSION

In conclusion, the microwave source is ready. The cesium tube magnetic homogeneity and static and active attenuation achieved combined with the m = 1 field measuring system is enough to evaluate the effect of the second order Zeeman effect to a required accuracy.

What remains is to perform the cesium tube thermal analysis and verify the temperature determination accuracy. After the FM laser source is delivered in November 2013, the FM clock will be assembled with all the FM subsystems. During 2 months cold atoms number and temperature, cavity phase shift and cold collision will be evaluated with an objective to reach the total frequency accuracy of 3×10^{-16} . Finally, ACES will be assembled in spring of 2014. The launch is envisioned in 2016 by SpaceX.

Lifetime of Space Passive Hydrogen Maser

Qinghua Wang, Pierre Mosset, Fabien Droz, Pascal Rochat
Orolia Switzerland Inc.
Neuchâtel, Switzerland
qinghua@spectratime.com

Abstract—**Accurate and ultra-stable space qualified atomic clocks represent critical equipment for the precision Global Navigation Satellite Systems (GNSS). The Passive Hydrogen Maser (PHM), with its excellent frequency stability performance, is the master clock for European Navigation satellite payload, and is the most stable clock ever flown for GNSS. Nine PHMs have been flying onboard Galileo satellites (GIOVE-B and four IOV satellites) since Apr. 2008. More than 35 PHM flight Physics Packages (PP) have been manufactured and characterized by Orolia Switzerland SA (Spectratime), under the industrial consortium led by Selex ES S.p.A.**

Besides radiation effects on electronic components, lifetime on PHM depends mainly on which of PP. In the frame of the "Lifetime Qualification of the PHM" supported by ESA, two Qualification Model (QM) units had been subjected to test under vacuum since 2008. After the first 1.5-year test period as reported in previously published papers [1][2], one QM has been extended for another 2-year lifetime test. This paper provides test results over the overall period of QM1, and gives further comparison and analysis of key PP parameters over 3.5 years of operation (or 4.1 years including the stay-alive period). The extended test enhances the on-ground test statistics and provides better confidences in the PHM lifetime evaluation, which shows the instrument capability to comply with the lifetime requirement of 12 years.

Keywords-Hydrogen maser; lifetime; space atomic clock; GNSS

I. INTRODUCTION

Accurate and ultra-stable space qualified atomic clocks represent critical equipment for the precision Global Navigation Satellite Systems (GNSS).

The Rubidium Atomic Frequency Standard (RAFS) and Passive Hydrogen Maser (PHM) are the baseline clock technologies for the European Navigation satellite payload. The adoption of a "dual technology" for the onboard clocks is dictated by the need to insure a sufficient degree of reliability (technology diversity) and to comply with the lifetime requirement of 12 years. The PHM with its excellent frequency stability performance has been chosen as the master clock.

After almost 10 years of continuous development in Europe the first space PHM has been launched onboard GIOVE-B (Galileo In-Orbit Validation Element) spacecraft on 27 April 2008. The mission of GIOVE-B has proved that PHM is the most stable clock ever flown in space for navigation applications and this clock technology is suitable for the harsh environment of space [3]. Four IOV (In-Orbit Validation) satellites were launched by pair on 21.10.2011 and 12.10.2012, each carrying two PHMs.

II. DEVELOPMENT HISTORY OF PHM

The development of the PHM has been funded continuously by ESA. The first space PHM development activity tailored to navigation applications was kicked off in 2000, led by Observatory of Neuchatel with Selex ES (SES) as subcontractor for Electronics Package (EP).

The industrialization activity aimed at PHM design consolidation for flight production was started in 2003. The industrial consortium is led by SES in charge of the instrument integration and EP design, and Spectratime is responsible for redesign and manufacturing the Physics Package (PP) [4][5]. The overall structure and design were reviewed in order to increase compactness and robustness. Strong efforts have been devoted to further improve both performances and manufacturing processes of the PHM from GSTB-V2 to IOV phases.

From 2009, the production and tests capability have been set up to 2 space PHM PPs per month at Spectratime. More than 35 flight PPs have been delivered, 9 of them have been flying onboard Galileo satellites.

A further development of a miniaturized PHM has been carrying out in the frame of the ESA European GNSS Evolutions Program. The main target is to preserve the excellent PHM frequency stability performance with reduction of the overall mass from present 18 kg down to 12 kg [6]. To achieve this goal, the physics package weight has been realized by Spectratime at 8 kg and demonstrated very similar performance [7].

III. LIFETIME TEST AND EXTRAPOLATION

Besides radiation effects on electronic components, lifetime on PHM depends mainly on which of PP. In order to highlight potential lifetime limitations, in the frame of the "Lifetime Qualification of the PHM" supported by ESA, two Qualification Model units (QM1 and QM2) were subjected to test continuously under vacuum from 05.06.2008 to 04.12.2009. The 1.5-year test results were published in papers [1] and [2], in which the comparison with related telemetries from the early 690-day in-orbit operation of GIOVE-B PHM demonstrated the consistency between the on-ground and in-orbit observations.

Seven months later QM1 was extended for a second 2-year lifetime test period (14.07.2010 – 13.07.2012). A third 1-year lifetime test on QM1 initiated on 06.02.2013 is in progress.

This paper provides test results over the first two test periods on QM1. Further analysis of key PP parameters over 3.5 years (1280 days) of operation (or 4.1 years if including the Stay-Alive period) is presented, which improves the statistical confidence for the lifetime extrapolation.

Fig. 1 illustrates the overall layout of the test bench. In addition to frequency stability performances, about 30 parameters have been measured. Most of them do not present measurable ageing effects. In this paper PP telemetries (Microwave cavity frequency, hydrogen supply tank temperature, high vacuum pressure), and master oscillator frequency, which are more relevant or affected by long term operation, therefore on which the lifetime of the PHM is more dependent, are discussed. The overall characteristics (atomic signal level, frequency stability) are also provided,

A. Microwave Cavity Frequency Drift

The cavity varactor, as part of Automatic Cavity Tuning (ACT) servo loop, is aimed at tuning the microwave cavity resonance frequency to the atomic transition frequency. For an easy and reliable comparison between the PHM units, the varactor voltage has been converted to the equivalent cavity frequency shift wrt the initial frequency.

Fig. 2 shows the cavity frequency shift observed on PHM QM1 during 1280 days (3.5 years) of operation, two curve fittings, and corresponding extrapolations over 12 years.

The least squares fitting of the cavity frequency shift consists in an exponential function of time, which has been also demonstrated during the PHM PP final tests. A square root fit is performed as well in the whole period in an attempt to estimate the drift trend in worse case.

It has to be noted that according the on-ground PHM PP acceptance tests, lifetime tests on QM1&QM2, and in-orbit data from GIOVE-B, the frequency drifts in all cases decease with time reaching an asymptotic value.

By two fitting models, the extrapolated values reach around 60 to 85 kHz in 12 years, which are within the maximum adjustable cavity frequency tuning range, equal to 150 kHz. This considerable margin, with respect to the measured and predicted cavity drift, can be achieved by the combination of the ACT and the fine adjustment of the cavity temperature (by tiny steps of few mK each). Such approach, as demonstrated by test, does not affect the PHM frequency stability.

B. Hydrogen Consumption

Another key aspect that has been monitored is the hydrogen consumption over the time. PHM uses the hydride to store in a tank of 0.1 liters 25 bar*liter of hydrogen, with internal pressure below 5 bars. During the instrument operation, the hydrogen is consumed and the tank temperature is automatically increased by a servo control loop in order to maintain the internal hydrogen pressure at a constant level required for maser operation. Therefore, the temperature

Figure 1. PHM QM Lifetime test bench

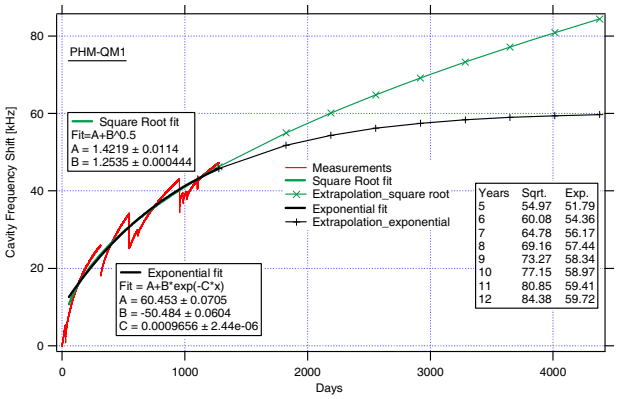

Figure 2. Cavity frequency shift measured during 3.5 years, curve fitting, and extrapolation over 12 year

variation over the time is a good indication of the Hydrogen consumption.

Fig. 3 shows the hydrogen tank temperature variations observed on PHM QM1 during 1280 days (3.5 years) of operation, the curve fitting and the trend extrapolation over 12 years. A square root fit has been used, which is a realistic approach based on hydride properties and its characterization. It can be noticed that the container temperature increasing rate is higher during first few weeks after the switch-on, which could be interpreted by the solid-state hydride transition phase.

The predication based on 3.5 years' data is remarkably similar as the results obtained during first 1.5-year period, which confirms the consistent behavior of the hydrogen tank.

As having highlighted in [1] and [2], the maximum reachable hydrogen tank temperature is limited to 50°C due to the available heating power. A recovery action has been carried out on all PHM models from QM2 on. A new type of hydride (higher purity LN5) achieving lower maximum pressure and more constant pressure plateau has been adopted. Thanks to this, the end of life temperature needed to keep the constant pressure is considerably lower than in the QM1, as demonstrated in the QM2 lifetime test [2].

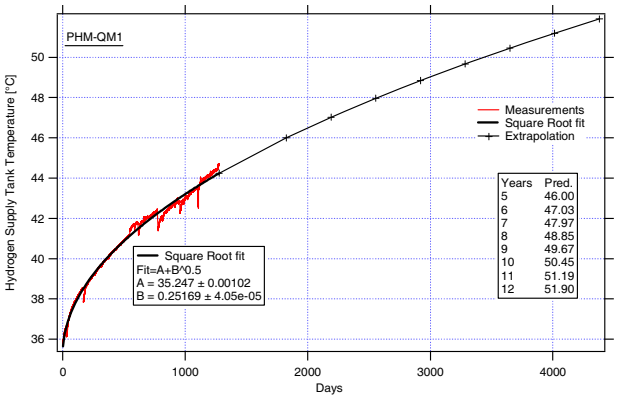

Figure 3. Hydrogen tank temperature measured during 3.5 years, curve fitting, and extrapolation over 12 year

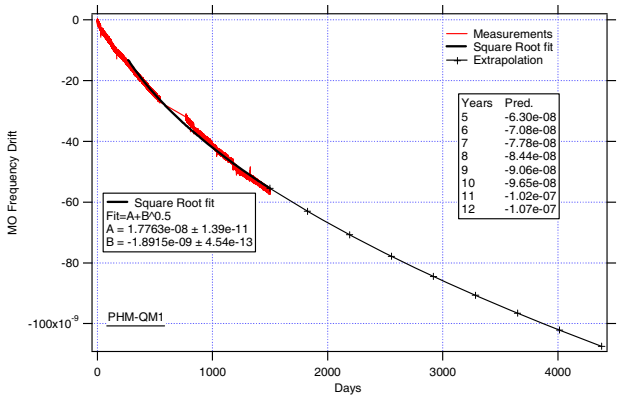

Figure 4. Master oscillator frequency drift measured during 3.5 years of operation (plus 7 months of Stay-Alive in-between), curve fitting, and prediction over 12 years

C. *Master Oscillator Frequency Drift*

The PHM 10 MHz output signal is provided by a crystal Master Oscillator (MO), whose frequency is locked to the atomic hyperfine transition by the varactor voltage. Therefore it is possible to assess the crystal frequency drift and servo loop capability in maintain the oscillator locked for the whole mission lifetime.

As done for the microwave cavity frequency drift, the varactor voltage change is converted to the MO fractional frequency drift.

Fig. 4 shows the MO frequency drift observed on PHM QM1 during 4.1 years, including the stay-alive period when the PHM QM1 was not operating. It's very interesting to note that even during this 7 months, the frequency drifting of the MO was still following the same trend. The figure shows also the simple square root fitting, which allows a very good confidence. The prediction over 12 years indicates the frequency change around -1e-7 in the end of the life.

The worst case analysis performed at PHM instrument level considers an overall frequency drift of the MO equal to ± 2.1e-7. As shown above, this limit is respected with almost 100% of margin. Besides such margin, further 2~3e-7 compensation can be achieved by telecommand. Therefore, the risk to lose a PHM as consequence of unexpected MO frequency drift is negligible.

D. *High Vacuum Pressure*

Fig. 5 shows the high vacuum pressure during 4.1 years (including the 'no-record' 7 months between two test periods). In this STAY-ALIVE mode, only external power was provided to the ion pump to prevent PHM performance degradation during long storage/ OFF periods. The high vacuum pressure had maintained at a reasonable level between 3.4e-7 to 3.6e-7 mbar over 4.1 years.

E. *Atomic Signal Amplitude*

The atomic signal amplitude telemetry provides the most relevant indication of PHM healthy operation.

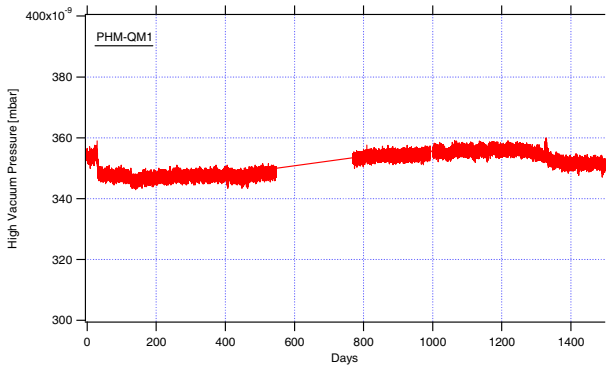

Figure 5. High vacuum pressure measured during 3.5 years of operation (plus 7 months of Stay-Alive in-between)

This telemetry is sensitive to any degradation as internal coating, out-gassing, leakage, dissociation efficiency, quality factor of the microwave cavity, interrogation power instability, receiver electronic degradation, temperature instability, etc. It is therefore of primary importance to verify that its decay over the life time stays below acceptable limits.

Fig. 6 shows the atomic signal amplitude measured during 3.5 years of operation under the same operation condition. The data show a fairly stable behavior as expectation.

F. *Frequency Performances*

Frequency stability and trend evolution is the most fundamental aspect for a clock assessment. Fig. 7 reports the frequency data and the frequency drift evolution over 4.1 years. The frequency offset due to the cavity temperature change experiment during the 1st period [1][2] is corrected in order to compare the overall data under same operation condition. The values show that the frequency drift is improving with the continuation of the operation, finally stabilized below 1e-16/day.

Fig. 8 compares the frequency stabilities for every 3-month, which demonstrates the excellent flicker floor around 3e-15 from 1 day to more than 10 days.

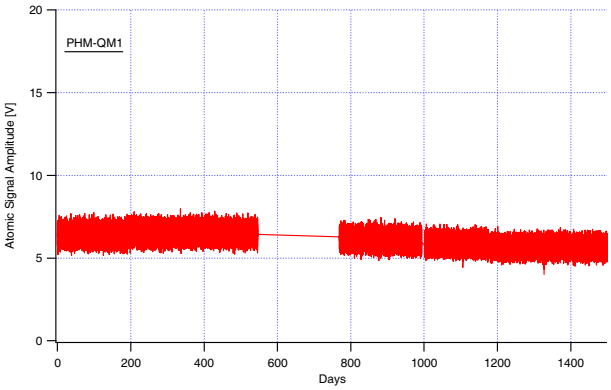

Figure 6. Atomic signal amplitude measured on OM1 during 3.5 years of operation (plus 7 months of Stay-Alive in-between)

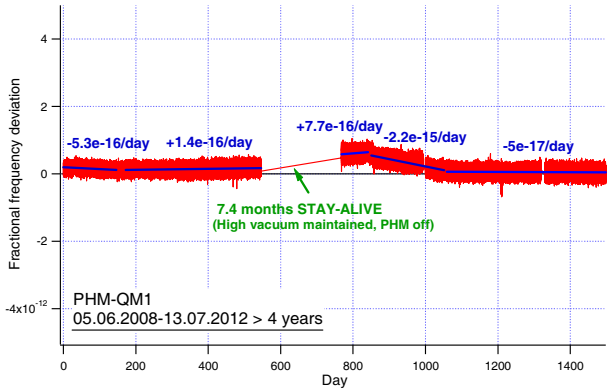

Figure 7. PHM frequency data and drift evolution during during 3.5 years of operation (plus 7 months of Stay-Alive in-between)

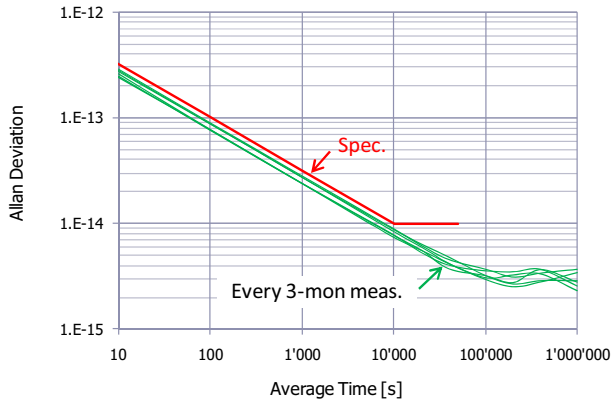

Figure 8. Frequency stabilities of every 3-month

IV. Conclusions

The extended 24-month test enhances the first 18-month test statistics. The comparison and correlation with previous data provides improved confidence in the PHM lifetime evaluation.

The life-demonstration testing on ground is confirming the capability of the PHM to operate in vacuum over the required life time of 12 years. The operational data so far collected for 30'700 h show no appreciable degradation.

***Abstract*-In the field of aviation and aerospace engine, monitoring of the vibration of the engine in situ directly in the high temperature part is of great importance for the safe and performance of the engine. So there is demanding for sensors that can stand for high temperature of 645ºC or above temperature. Recently, the crystals of langasite and ReCOB family are found to be good candidate for this application through the study of basic properties of crystals at high temperature. But there is few reports about the acceleration sensors made of these crystals. In this work, the single crystals of $La_3Ga_5SiO_{14}$ (LGS), $La_3Ga_{5.5}Ta_{0.5}O_{14}$ (LGT), $YCa_4O(BO_3)_3$ (YCOB) and $SmCa_4O(BO_3)_3$ (SmCOB) were grown by Czochralski method respectively, and the basic properties of these crystals were characterized. The acceleration sensors with LGT as sensitive components were successfully made and characterized up to 700ºC. The results show that sensors made by these crystals can be used at the high temperature circumstance above 645ºC and under the vibration with frequency in the range of ten Hz to several thousands Hz.**

I. INTRODUCTION

Piezoelectric acceleration sensors that could stand environment temperature above 645ºC (1200ºF) are of great important to the field of vibration monitoring of aviation and aerospace engine. The traditional piezoelectric materials used in this area include lithium niobate crystal, bismuth layer structure system piezoelectric ceramics. But the issue of the lower electric resistivity limits their application of temperature higher than 645 ºC. $GaPO_4$ crystal which is grown by hydrothermal method could be used up to 900 ºC. However, the difficulty in crystal growth of $GaPO_4$ crystal makes it very expensive and limits its application [1].

ReCOB (Re= La, Y, Sm, Nd, Lu) crystals and LGX crystals including LGT, LGN and LGS are piezoelectric crystals with high melting points above 1400ºC and without phase transition from room temperature to their melting points. All of these crystals can be grown by common Czochralski method up to 4 inches. They are all good candidates for high temperature application. This work is aim to explore the possibility of LGS, LGT, YCOB and SmCOB crystals for application for high temperature acceleration sensors by characterization the basic properties and sensors performance after crystals being grown.

II. EXPERIMENTAL

A. Single Crystal Growth

The raw materials of LGS crystals are the mixing of powders of La_2O_3, Ga_2O_3, SiO_2 in the ration of stoichiometry, while LGT are of La_2O_3, Ga_2O_3 and Ta_2O_5, YCOB are of Y_2O_3, $CaCO_3$, H_3BO_3, SmCOB are of Sm_2O_3, $CaCO_3$, H_3BO_3. All these powders are of purity of 99.99%. Then the raw materials were mixed by 3D mixing machine and pressed into cylindrical blocks and sintered in the oven under the temperature of 1200~1300ºC. After that, the blocks of raw materials were put into iridium crucible and heated to the temperature dozens degrees higher than their melting temperature in vacuum Czochralski furnace with the growth atmosphere of 99% nitrogen and 1% oxygen. The growth rate and rotation rate of the crystals were 0.5~2 mm/hr and 5~20 rpm respectively.

The LGS and LGT crystals had strong growth habits, i.e., the facet faces of specific crystallographic face appeared in the shape. And they were in red brown. The diameter of LGS boule was of 4 inches and that of LGT was 3 inches. YCOB and SmCOB crystals had weak growth habits and were apt to crack along cleavage plane of (20-1) or (202). YCOB was transparent and colorless, while SmCOB was in light-yellow. The former can be grown into 4 inches boule in diameter. The later can be grown into 2 inches boule. The pictures of these four crystals are shown in Fig 1.

(a) LGS (b) LGT (c) YCOB (d) SmCOB

Fig. 1. The as-grown LGS, LGT, YCOB and SmCOB single crystals.

B. Crystals Processing and Characterization

For LGS and LGT crystals, the rectangular plates with the planes perpendicular to X-axis and Z-axis were cut and fine grinded. For YCOB and SmCOB crystals, the rectangular plates with the planes perpendicular to Y-axis were cut and fine grinded. The two sides were coated with Ag or Au platings.

Also the rings with outer diameter of 10 mm and inner diameter of 5 mm and thickness of 1.0 mm were processed for using as the sensitive components. The two sides were coated with Cr-Au films of about 200 nm thick by CVD.

The resistance was measured using a source meter (Keithley 2410C, MetricTest, Hayward, CA) and the dielectric properties were determined using a multifrequency LCR meter (HP 4284A, Hewlett-Packard, Palo Alto, CA). The piezoelectric coefficient was obtained from a Berlincourt type d33 meter (ZJ-2, Institute of Acoustic, Chinese Academy of Sciences, Beijing, China). The resonance and anti-resonance frequencies were obtained from an Impedance-Phase Gain Analyzer (HP4194A, Hewlett-Packard). The effective electromechanical coupling factors and mechanical quality factors were calculated according to IEEE standards. Based upon the potential to operate YCOB crystals at very high temperatures, it was worthy to explore the properties as a function of temperature. In this work, the properties were measured as a function of temperature up to 777ºC, above which, the Au electrodes were subject to degradation.

C. Sensors Fabrication and Characterization

The acceleration sensors were fabricated according to the standard compress mode design. In order to improve the sensitivity of the sensors, multi-piece of piezoelectric rings were used in each sensors.

The acceleration sensors were characterized in a standard acceleration sensors evaluation system. The sensors were put into a temperature controlled oven which can be vibrated in high acceleration and frequency. The sensitivity vs different temperature from 20 to 777ºC and acceleration from 0 to 40 g was tested. The phase of the sensors under different temperatures was also characterized.

III. RESULTS

A. Basic Properties

Table I lists some data of the electrical properties of YCOB and LGT crystals between room temperature and 800ºC, respectively. The dielectric loss were measured at a frequency of 100kHz for Y– cut YCOB samples and found to be on the order of 11 and <0.1% at room temperature, respectively. The piezoelectric strain coefficient d_{26} was measured to be about 7.8 pC/N, comparable to the values of other piezoelectric crystals. It is shown that the crystal YCOB is promising for applications requiring a large voltage output of piezoelectric sensors. The mechanical quality factor Q was found to be on the order of 9000 for YCOB crystals at room temperature, comparable to other piezoelectric crystals.

TABLE I BASIC PROPERTIES OF YCOB AND LGS CRYSTALS

YCOB	20ºC	300 ºC	500 ºC	600 ºC	800 ºC
Resistivity (Ω• cm)	1×10^{17}		1.2×10^{11}	4×10^{9}	2×10^{8}
Dielectric Loss	<0.1%	0.01	0.01	0.01	0.03
d_{26} (pC/N)	7.8	5%	8%	12%	9.0
Q	~9000				
LGS	20ºC	300 ºC	500 ºC	600 ºC	800 ºC
Resistivity (Ω• cm)	1×10^{14}	8.0×10^{8}	9.0×10^{6}		3.6×10^{4}
Dielectric Loss	0.001	0.002	0.13	0.46	27
d_{11} (pC/N)	5.6	6.2	6.9	7.4	8.4
Q	14000	7300	500	450	5000

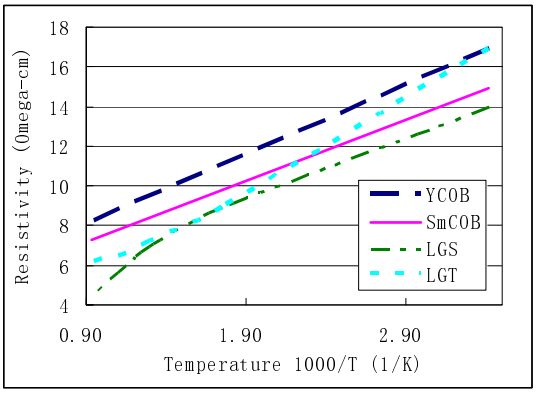

Fig.2 The electric resistivity of four crystals

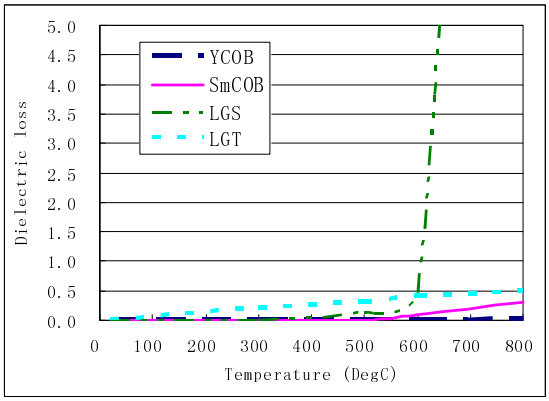

Fig.3 The dielectric loss of four crystals under different temperatures

Fig. 2 shows electrical resistivity as a function of temperature for all these four crystals. The resistivity value of YCOB at 800ºC was found to be $2x10^{8}$Ohm.cm, two order higher than LGT crystals ($1.8x10^{6}$Ohm.cm) and more

than three orders higher than the value of LGS crystals ($3.6x10^4$Ohm.cm). The oxyborate crystals of YCOB and SmCOB exhibited similar slopes, demonstrating they have similar activation energies, which was found to be on the order of 1.6eV. The high electrical resistivity at elevated temperature is desirable for the possible application of BAW resonator and sensors. Similarly, the dielectric loss for YCOB crystal was found to be 3% at 800ºC, while the value of LGT at the same temperature was on the order of 50%, demonstrating that YCOB crystals possess stable dielectric behavior at elevated temperature. The dielectric loss of these four crystals in the temperature range of 20 to 800ºC was shown in Fig. 3.

B. The Properties of the Acceleration Sensors

Fig. 4 and Fig. 5 shown the sensitivity and phase stability of the acceleration sensors made of LGT crystals. It is found it could work until 649ºC with the sensitivity of 1.046 pC/g by less than 5% deviation. And also the sensitivity is quite stable under various vibration frequencies from 10 Hz to 2500 Hz and acceleration from 0 to 40 g.

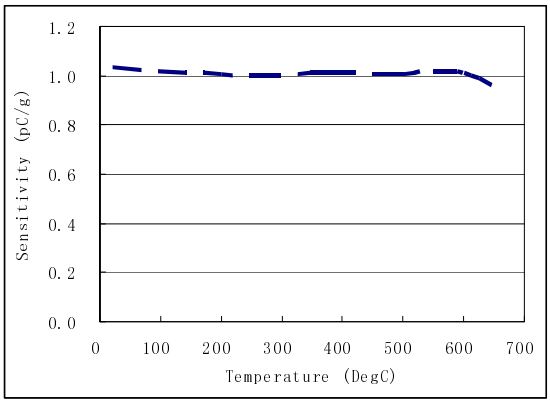

Fig.4 The sensitivity of the sensors under different temperatures

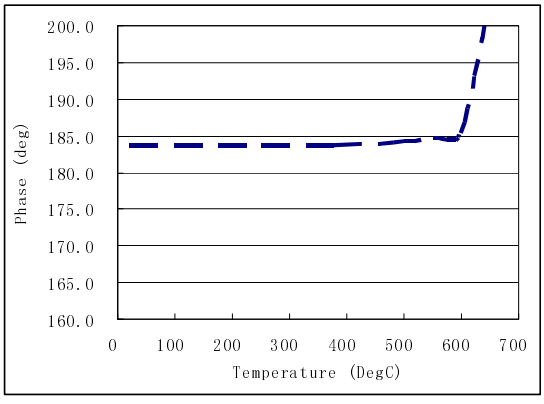

Fig.5 The phase of the sensors under different temperatures

IV. DISCUSION

The acceleration sensors made of LGT crystals can be used up to temperature of 649ºC. It is shown that the ReCOB family crystal has more high stability than LGX crystals. So they may be used under higher temperature. More work has to be done to explore the much high temperature application of these excellent crystals.

V. CONCLUSIONS

LGT, LGS, YCOB and SmCOB were grown successfully, LGS and YCOB with diameter of 4 inches, LGT of 3 inches and SmCOB of 2 inches. The rocking curve of high-resolution X-ray diffraction (HRXRD) of these crystals shown that they were of high quality. Piezoelectric acceleration sensors used the X-cut rings of 10 mm diameter based on these crystals were fabricated and tested. It was shown that our as-grown LGT crystal could be used up to 645 ºC with very steady sensitivity. YCOB and SmCOB crystals could be used to higher temperature up to 900 ºC after overcoming the issue of pyroelectric effect..

***Abstract*—In this paper, we present a wafer level approach to fabricate SAW pressure sensors on a single crystal AT-cut Quartz film transferred onto a bulk Silicon substrate. The final thickness of the quartz active layer was obtained using a combination of coarse mechanical thinning and fine polishing. Isolated Quartz membranes with a controlled thickness were then released by DRIE of the Silicon substrate. Details of the sensor fabrication process, modeling and electrical measurements are presented. In addition, theoretical considerations in good agreement with experimental results are disclosed.**

Keywords: Quartz-On-Silicon (QOS); direct wafer bonding; Surface Acoustic Wave; SAW resonator; pressure sensor

I. INTRODUCTION

Surface Acoustic Wave (SAW) devices are extensively used for high frequency wireless telecommunications and various other applications such as high quality resonators, IF bandpass filters and similar RF signal processing [1-2]. Nowadays, they are becoming increasingly popular for passive sensing applications. Indeed, SAW resonators are particularly well adapted for sensing applications since their resonance frequency is directly affected by external parameters such as pressure [3], strain/stress [4], temperature [5] or mass load of chemical species adsorption [6]. By estimating the shift of resonance frequency, one can easily assess the value of the monitored physical parameter. The accuracy of the measurement for its part depends on the quality factor of the resonator. Despite remarkable characteristics SAW devices implementation is limited to essential applications. Indeed, most of available commercial solutions are discrete, implying a significant rise of fabrication cost or complex integration [7].

In this paper, we depict a wafer level approach to transfer single-crystal Quartz layer onto a Silicon substrate. This allows the batch production of SAW resonators for pressure sensing. The process relies on low-temperature direct wafer bonding technology and customized thinning processes. Utmost care was taken to ensure the homogeneity and the integrity of the Quartz film. Thereby, in addition to the benefits of collective fabrication such as cost reduction and high throughput, a silicon based technology simplifies the integration and guarantees a perfect control of all the sensors characteristics. As a first proof of concept, we fabricated a 100mm diameter quartz/silicon hybrid wafers hosting SAW resonators with a quality factor exceeding 12500 when operating at 430 MHz. A linear pressure sensitivity of 25.8 kHz/bar of the sensor was experimentally observed.

This paper is organized as follows: section II of this work presents the clean-room fabrication process to achieve collective realization of SAW pressure sensors. Section III details a previously developed model of inhomogeneous stress distribution in the resonator when pressure is applied on the Quartz membrane. Measurements of the resonators are presented in section IV and compared with theoretical analysis. Section V focuses on conclusions and perspectives.

II. SENSOR FABRICATION

The use of a direct wafer bonding technology for piezoelectric substrates like Quartz material is of great interest as this approach allows for a collective and precise production of sensors which sensitivity is being controlled by the membrane thickness and diameter. The SAW pressure sensors and wafer bonding process are schematically summarized in Fig. 1.

The sensor is composed of a Quartz wafer and a Silicon oxidized wafer. An (*YXl*)/37° AT-cut Quartz substrate was chosen because of its well-known temperature stability. The wafers are cleaned to remove any kind of organic or particular contaminants.

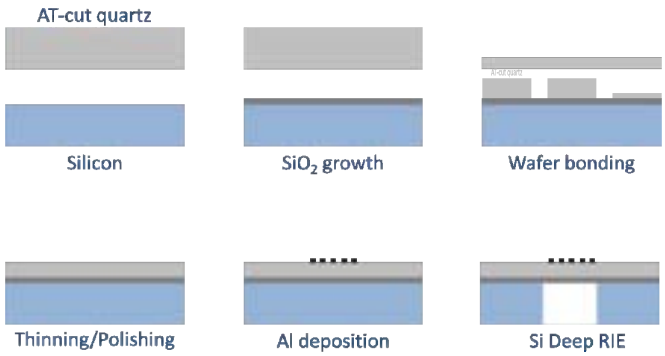

Fig. 1. SAW pressure sensor fabrication process flow

This work was partly supported by the French Direction Générale pour l'Armement (DGA).

We developed a low-temperature direct bonding process based on chemical surface hydrophilization followed by plasma activation. The Quartz wafer is then bonded onto the oxidized Silicon wafer at room temperature and atmospheric pressure. This process was already employed in a previous work [8] and leads to a homogenous and high quality bonding. After bonding, the assembled wafers are annealed at 200°C for 2 hours to strengthen the bond. Figure 2 shows optical and infrared images of the bonded wafer after annealing. It reveals an excellent bonding quality without bonding defect apparition during processing, implying an adequate surface preparation before direct bonding.

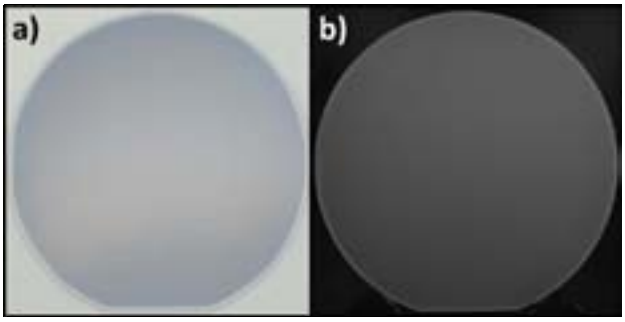

Fig. 2. Optical (a) and InfraRed (b) images of the Quartz-On-Silicon hybrid wafer

The Quartz wafer is then subsequently thinned by coarse mechanical thinning step to an overall thickness of 100 µm, followed by a final polishing step. Aluminum electrodes are deposited on the thinned Quartz plate surface using a lift-off process to achieve single-port SAW resonators. Inter Digitated Transducers (IDT) were designed to generate Rayleigh waves at 430 MHz. Finally, a Deep Reactive Ion Etching (DRIE) of the Silicon wafer is achieved to form the membranes. Figure 3 shows the resonators obtained on the hybrid Quartz/Silicon wafer at the end of the process. Sensors are then cut in individual parts. A photo of a tested SAW pressure sensor is shown in fig. 4.

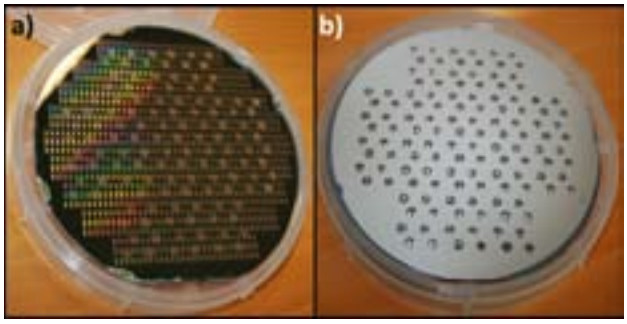

Fig. 3. SAW pressure sensor based on Quartz/Silicon direct wafer bonding: a) top side of the wafer showing SAW resonators; b) back side of the wafer showing the membrane locations

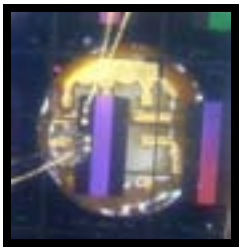

Fig. 4. A SAW pressure sensor ready to be tested

III. SENSOR MODELING

The fabrication of membrane-based SAW pressure sensors has received a strongly interest due to the wave frequency dependence versus stress at the surface of the membrane when bent by pressure [9-11]. The purpose of this section is to model the behavior of surface acoustic waves under stress.

A. Sensor description

The sensor consists of a clamped Quartz circular membrane that is free to move and suspended over on a bulk micromachined silicon wafer. A SAW resonator is then placed on top of it and its resonance frequency is a measure of the tensile stress produced by the membrane bending under pressure effect [11].

B. The Perturbation Method

The behavior of surface acoustic wave under static stress can be modeled using the celebrated Sinha-Tiersten perturbation method [12]. It consists in determining the velocity change of surface acoustic waves under static stress. Frequency variation due to stress is given by (1).

$$\left(\frac{\Delta f}{f_0}\right) = S_{\alpha_{ij}} T_{ij} = S_{\alpha_{11}} T_{11} + S_{\alpha_{33}} T_{33} \qquad (1)$$

where $S_{\alpha 11}$ and $S_{\alpha 33}$ represent the linear sensitivity stress coefficients (in ppm.MPa^{-1}) for radial and ortho-radial stress seen by Rayleigh waves. These coefficients depend only on the Quartz cut choice and are intrinsic characteristics of the material. T_{11} and T_{33} correspond to the in-plane stress associated to these directions (in Pa).

C. Stress and Sensor

We now consider the case where the stress is completely inhomogeneous under the resonator and where the membrane of the sensor is assumed as an isotropic material [13]. Locally, tangential and radial stress to the surface of the membrane are given by (2) and (3) [14].

$$\sigma_r(p) = \frac{p}{h^2} \cdot \frac{3}{8}[R^2(1+\nu) - r^2(3+\nu)] \qquad (2)$$

$$\sigma_\theta(p) = \frac{p}{h^2} \cdot \frac{3}{8}[R^2(1+\nu) - r^2(1+3\nu)] \qquad (3)$$

In these equations, P is the pressure applied on the membrane, h corresponds to the thickness, R is the membrane radius, r the distance from the center and ν is the Quartz Poisson's ratio.

One can note that the induced stress field is linear with the applied pressure P, which means that the resonant frequency shift seen by the resonator is also linear with the applied pressure. The thickness of the Quartz plate as well as the radius of the membrane will also directly influence the pressure sensitivity of the sensor. Thus, these two parameters must be controlled precisely during the fabrication process. A schematic structure of an individual pressure SAW sensor is shown in figure 5.

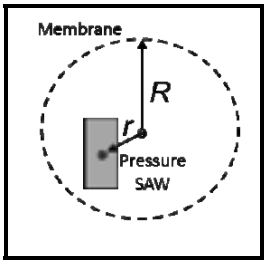

Fig. 5. Schematic structure of the modeled device

IV. ELECTRICAL RESULTS

The electrical characterization was achieved by measuring the reflection coefficient S_{11} of the SAW resonator. The Figure 6 shows the evolution of the electrical conductance and susceptance of a single-port SAW resonator. It exhibits a quality factor around 12500 at 430 MHz, yielding Q×f product of about 0.5×10^{13}. This high Q-factor attests the preservation of the single-crystal quartz bulk material properties through all the steps of our developed process. The design of the resonator did not exhibit enough electrodes, yielding a weak dynamic of the S_{11} parameter.

We also studied the temperature sensitivity of the Rayleigh fundamental mode. The resonator was measured for temperatures ranging from -5 to +70°C. Figure 7 shows the relative frequency drifts as a function of temperature. A first order TCF_1 of -4ppm/°C and a second order TCF_2 of -62ppb/°C² were obtained. This non-zero temperature coefficient of frequency could be attributed to an excessive metal thickness from the electrodes.

A test chamber was used in order to measure the sensor response under pressure effects. It allows for applying pressure (from 0 to 4.8 bar) directly to the membrane. Figure 8 compares theoretical and experimental shifts of the SAW sensor versus the applied pressure. As predicted, the frequency shift dependence is linear versus pressure. The measured pressure sensitivity is about 25.8 kHz/bar and is in excellent agreement with the theory developed in section III. It means that a very good control in term of radius and diaphragm has been achieved during the process, matching the expected geometric values.

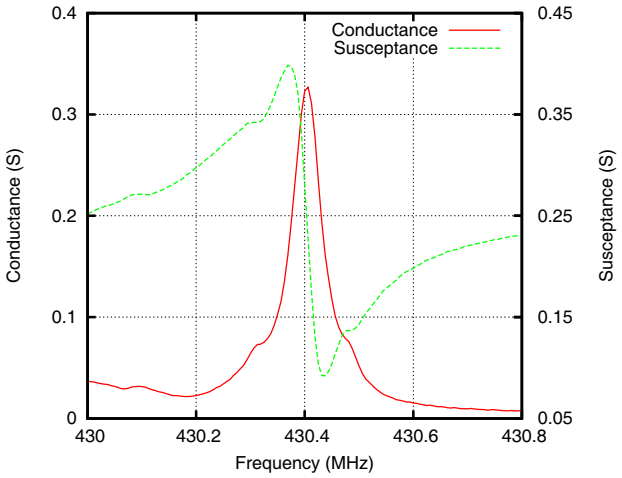

Fig. 6. Admittance measurement of a single-port SAW resonator

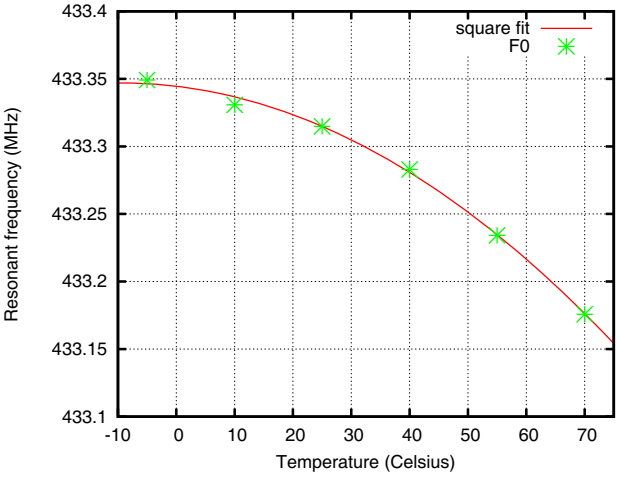

Fig. 7. Variation of the SAW resonance frequency according to the temperature change. The square fit indicates a TCF_1 value of -4ppm/°C and a TCF_2 value of -63ppb/°C²

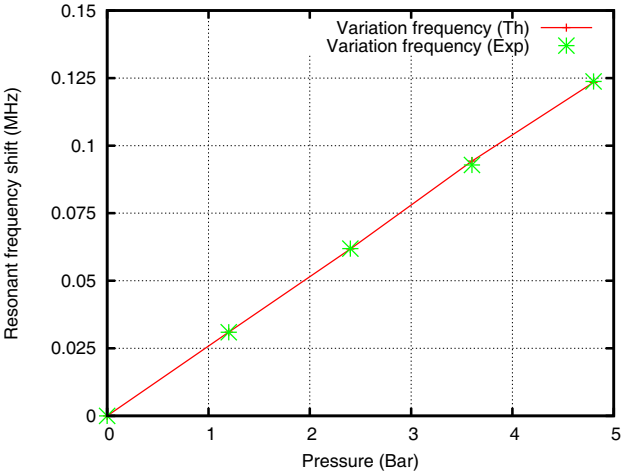

Fig. 8. Comparison of frequency shift under pressure with developed model and experimental data

V. CONCLUSIONS

This work reports the transfer of a thinned Quartz layer onto a Silicon substrate through low-temperature direct wafer bonding and thinning process for a collective manufacturing of Quartz crystal/Si-based SAW pressure sensors. A quality factor as high as 12500 was measured at 430 MHz and a first order temperature dependence of frequency of -4ppm/°C. Notably, a pressure sensitivity of 25.8 kHz/bar was measured and fits very well the expected theory value. Our developed process is generic enough to be applied to different Quartz crystal orientations to satisfy a large variety of applications.

Further developments now will be dedicated to estimate the pressure sensitivity of the sensors depending on their position on the membrane and to compare theoretical optimization with experimental measurements.

ACKNOWLEDGMENT

The authors would like to thank J.-M. Friedt and Sébastien Alzuaga for electrical measurements under pressure and Alexandre Reinhardt for fruitful discussions. This work was partly supported by the French Renatech network and its FEMTO-ST technological facility.

***Abstract*— In this paper the acoustic characterization of a layer of carbon nanotubes (CNT) deposited on AlN solidly mounted resonators is described. The structure of the CNT layer is analyzed by scanning electron microscopy and Raman spectroscopy. The electrical sheet resistance is derived from 4 point probe measurements and from the fitting of the electrical response of the resonators. Values of sheet resistance around 100 Ω/□ are measured. The longitudinal acoustic velocity is derived from the fitting of the electrical response of the resonators using Mason's model, by adjusting the overtones produced in the CNT layer. A mean value of 62000 $m \cdot s^{-1}$ is obtained, although some devices show values around 90000 $m \cdot s^{-1}$, close to the theoretical value of 100000 $m \cdot s^{-1}$. Some results on the deposition of CNT layers on metallic top electrodes and their influence on the performance of the resonator are also presented.**

Keywords*— Carbon nanotubes (CNT); bio-chemical sensors; BAW resonators; top electrodes

I. INTRODUCTION

During the last few years, the increasing demand for highly sensitive biosensors for real-time monitoring has boosted the development of new devices and materials. Most of the studies have especially focused on the functionalization of sensors and the improvement of their performances [1]. Due to the recent progress achieved in the field of the piezoelectric resonators for communication electronics, acoustic wave devices have become one of the most promising technologies for sensing applications. In particular, bulk acoustic wave (BAW) sensors have been shown to have excellent potential in diagnosis applications [2]. Despite the progress made in this type of resonators, additional work is still required to improve their quality factor (*Q*) and to optimize the sensing layer needed for specific detection.

The top electrode of BAW resonators intended for sensing applications needs special attention, since it strongly affects both their electrical performance and sensing ability [3]. From an electrical perspective, the desired properties for the top electrode material are low mass, high conductivity, and high acoustic impedance. Carbon nanotubes (CNTs) have emerged as good candidates to act as biosensors electrodes or sensing layer. Since their discovery in 1991 by Sumio Iijima [4], they have been widely investigated due to their ultra-light weight, mechanical strength, high chemical resistance, high thermal conductivity, high surface to volume ratio and high electrical conductivity [5]. Among their many applications, CNTs can be used in the microelectronics field as vertical interconnections, conductive flexible composites, low-k dielectrics or as part of transistors, diodes [6] or bio and chemical sensors [7].

The use of CNTs in sensors can be found in many recent studies [8-10]. The main advantage they offer is the possibility of being functionalized to act both as sensing layer and electrode. Their high conductivity is an encouraging prospect to act as a good electrode; additionally, they can be treated to make them sensitive to specific molecules by an adequate functionalization, which can be achieved by chemical methods [11].

Carbon nanotubes are commonly grown by catalytic vapor phase deposition of carbon, being iron and nickel, among others [12], the most frequently used catalysts [8]. The choice of the substrate to grow CNTs is another interesting issue that has been studied recently. It has been demonstrated that CNTs can grow on different materials [13], but the possibility of an optimal growth on metals is still a pending matter.

The final motivation of this work is to develop high sensitive sensors using BAW resonators. To achieve this, CNTs are proposed as sensing top electrode, since they possess an effective surface area which is much greater than that of the standard metallic electrodes. Their light weight also provides advantages to the electrical performance of the resonator. In this paper, the growth of CNT layers on different types of substrates (insulators and metals) using Fe as catalyst has been studied. We have assessed their acoustic, electric and structural properties and evaluated the improvement of their sheet conductivity when grown on metallic surfaces.

II. EXPERIMENTAL

The CNT layers were deposited at temperatures ranging from 600ºC to 750ºC by the pyrolytic decomposition of acetylene (C_2H_2) diluted in ammonia (NH_3) using Fe nanoparticles as catalyst agent. The process was carried out at a total pressure of 300 mTorr. The reaction chamber was evacuated with a two stages mechanical pump and cleaned

before deposition by several purges with high purity nitrogen to ensure very low oxygen content. After the cleaning, NH_3 was fed to the chamber. The substrates, which were previously pre-coated with an evaporated Fe layer, were then heated to the process temperature by a pyrolytic carbon heater at a rate of 5ºC/s. Fe nanoparticles were formed in this step by annealing the substrates in the reducing atmosphere of NH_3. Their size depended on the thickness of the Fe layer, which ranged from 3 nm to 7 nm. After the formation of the nanoparticles, C_2H_2 was fed to the chamber without stopping the NH_3 supply. After the deposition, the samples were cooled down under vacuum at a rate of 1ºC/s.

CNT layers were deposited as top electrode of solidly mounted resonators (SMR) composed of an acoustic reflector, an iridium bottom electrode and a 2 µm-thick piezoelectric AlN layer. All the layers of the piezoelectric stack were deposited by pulsed-DC reactive sputtering in an UHV system. The acoustic reflectors were made of five alternating layers of low acoustic impedance porous-SiO_2 [14] and high acoustic impedance Mo, with thicknesses adjusted for a center resonance frequency of 2.5 GHz. These had been carefully designed to withstand the high temperatures required for CNTs deposition without delamination. The area of the resonators was set by defining the Fe layer through a photoresist lift-off process before the formation of the nanoparticles, which provided the substrate areas for the selective growth of the CNT-top electrode. In some samples, a Mo or Al layer was deposited before the Fe and CNTs layers. Figure 1 shows a SEM image of a typical device after being measured. The indentations in the contact pads are due to the RF test probes.

The electrical impedance spectra of the resonators, measured with an Agilent network analyzer PNA N5230A between 100 MHz and 10 GHz, were fitted with Mason's model to determine the acoustic velocity of the CNT layers. The acoustic properties of the different materials used for the simulations are summarized in Table I.

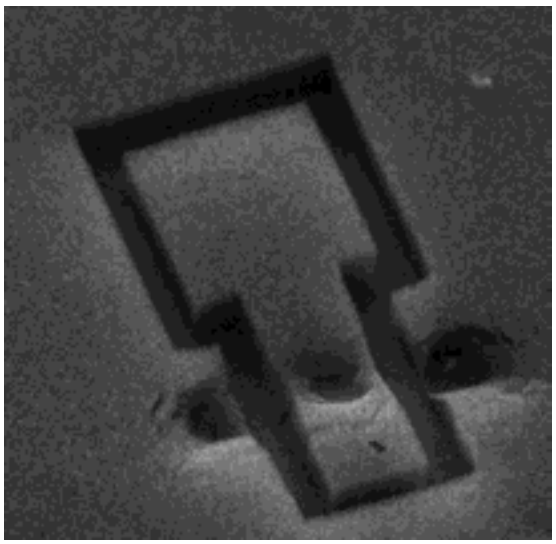

Figure 1. Plan view of a typical test resonator after being measured.

TABLE I. Acoustic impedance of the materials used in this work.

MATERIAL	MASS DENSITY ($kg \cdot m^{-3}$)	SOUND VELOCITY ($m \cdot s^{-1}$)	ACOUSTIC IMPEDANCE ($kg \cdot m^{-2} \cdot s^{-1}) \times 10^{-6}$
Al	2700	5100	13.77
p-SiO_2	1800	5450	9.81
AlN	3300	11000	36.30
Mo	10300	6190	63.76
Ir	22500	5300	119.25

The dimensions of the resonators (thicknesses and areas) were carefully assessed. The thickness of the CNT layers was measured on cleaved samples in a scanning electron microscope (SEM). Mass density was calculated by weighting large substrates before and after deposition of the CNT layer. The structure of the CNTs was assessed by Raman spectroscopy using B&BTek S415-532S spectrometer. The sheet resistance of the CNT carpet was measured by the four point probe method.

III. RESULTS AND DISCUSSION

The Raman spectrum of a typical CNT layer is depicted in figure 2, which indicates that the CNT layers are composed by multiwall nanotubes with relatively high defect content, as determined by the ratio between D and G bands, which is around 1.

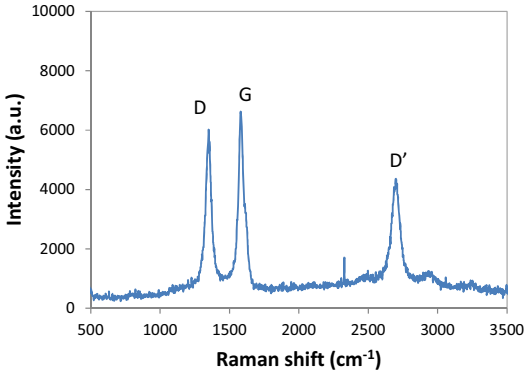

Figure 2. Raman spectrum of a typical CNT layer.

Figure 3 shows a SEM image of the cross section of a typical stack, showing the sequence of the different layers composing the resonator: i) the CNT layer (top layer), ii) the AlN active layer, iii) the Ir bottom electrode and 4) the acoustic reflector.

Firstly, in order to investigate the effect of the high temperature needed to grow the CNTs on the integrity of the piezoelectric stack, the frequency response of conventional SMRs (without CNTs) was assessed before and after a thermal treatment in NH_3 atmosphere similar to that used to deposit the CNT layers; the variations of the coupling factor and the resonant frequency were negligible. However, the parasitic

series resistance slightly increased. We attribute this effect to an increase of the resistivity of the Mo top electrode used in these test devices during the high temperature process. The possibility of some diffusion of the metal atoms into the AlN film was discarded as the resonant frequency did not vary.

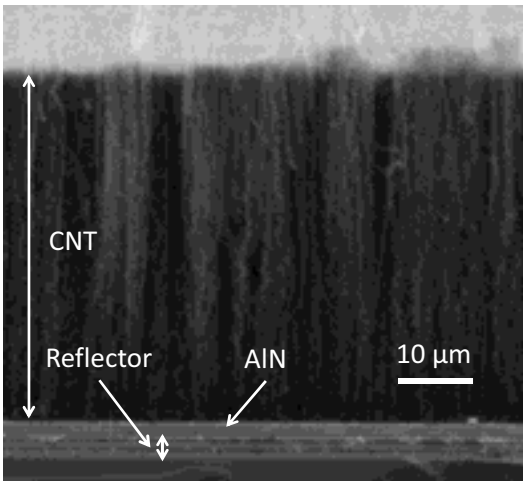

Figure 3. Cross section image of a typical device.

The sound velocity of the CNTs was assessed trough the frequency response of SMRs containing CNTs as top electrode. The frequency response of a typical test device with a 30 µm-thick CNT top electrode is shown in figure 4(b). The frequency response exhibits three clear resonances associated to the main λ/2 longitudinal mode in the AlN film and two secondary overtones in the acoustic reflector. These features also appear in resonators without CNT electrode. In addition, some tiny resonances due to overtones in the CNT layer can also be observed. The fact that these resonances appear so weak can be attributed to a loss of coherence in the reflection of the acoustic waves in the interface between the CNT layer and the air, because of its roughness, which makes it difficult to detect them in some devices. Figure 5 shows the SEM images of two CNT layers with very different roughness. The electrical response of samples with roughness similar to that of figure 5(top) corresponds to figure 4(a) spectrum, which does not show any feature attributable to overtones in the CNT layer.

The fitting of the electrical response of the test devices using Mason's model allowed us to obtain the acoustic velocity in the CNT layer, providing that its density and the properties and thicknesses of all the materials involved in the device are well known. The density of the CNT layers was derived by weighting, with a precision of 10^{-4} g, large substrates (2x3 cm^2) before and after the deposition of the CNTs, and dividing the weight change by the volume of the layer whose thickness was obtained through the SEM picture. The resulting mean density was 100 kg/m^3 with a dispersion of ±30 kg/m^3.

The overtones in the CNT layer could be fitted by varying the sound velocity. The frequency response of the thinner samples did not exhibit overtones, even the smoother ones, but, if the thickness of the layer was large enough (more than 20 µm), the number of overtones was sufficient to determine the sound velocity. The average value obtained after analyzing more than 30 samples is around 62000 $m \cdot s^{-1}$ with a dispersion of around 10% attributable to the dispersion in the value of the mass density and in the thickness of the layers. A few samples exhibited velocity values up to 90000 $m \cdot s^{-1}$, but we cannot attribute these high values to any special feature.

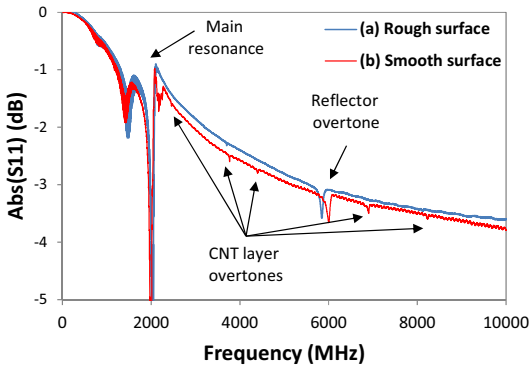

Figure 4. Electrical response of typical devices with CNT exhibiting (a) rough (a) and smooth (b) surfaces

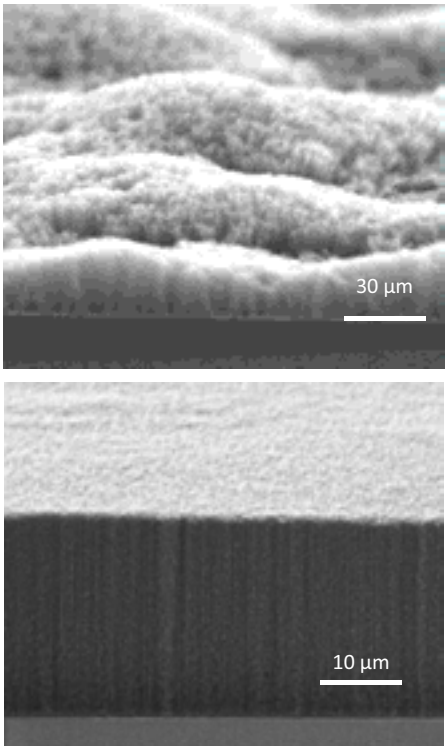

Figure 5. SEM images of two CNT layers with different roughness. The picture on top corresponds to significantly rough layer, in which overtones are barely detected.

Theoretically, the sound velocity can be estimated as the square root of the ratio between the stiffness coefficient and the mass density. The stiffness coefficient of a single CNT is around 1TPa [15] and the resulting velocity is 100000 $m \cdot s^{-1}$ considering a density of 100 $kg \cdot m^{-3}$. There is an interesting

issue that should be set out. The mass density considered above is that of the propagating medium. However, in a CNT carpet, the waves should travel along the nanotubes. Therefore the mass density to be considered would be that of the tubes, regardless of their surface density, which fixes the mass density of the entire film. Thus, the previous theoretical prediction could be incorrect since the measured density depends greatly on the number of CNTs per unit area.

One of the main drawbacks of using CNTs top electrodes is that the devices show large parasitic series resistance, which can rise tens of ohms. The origin of this high sheet resistance is the lateral interconnections between the carbon nanotubes. It is well-established that MWCNT have a very large conductivity in the axial direction [16]. However, the sheet resistance shown by a carpet of well-aligned CNTs appears to be very high. The assessment of a continuous CNT layer using the four point probe method yields a sheet resistance of 100 Ω/□, which represents around 200 Ω of series resistance in a resonator with an area of 15000 μm^2. However, the fitting of the frequency spectra yields a parasitic resistance of only 25 Ω. This aspect, which should be improved in practical devices, is not a drawback for characterizing test devices such as those used in this work.

To prevent the high parasitic series resistance that worsens the resonator response, CNT layers were deposited on a metal layer acting as top electrode. The deposition of CNT on metals is not straightforward because the metals used as catalytic agent (iron or nickel) can diffuse into the substrate during the heat treatments, thus inhibiting the nanoparticles formation. This is the case of Mo, which is the typical top electrode used in BAW devices. CNT layers have been deposited on different metallic thin films, such as Mo, Ti, Au, and Al, but only Al substrates thinner than 70 nm did provide good results. The use of Al reduced the series resistance of the BAW resonators from 25 Ω to 10 Ω, which is still not sufficiently low. More work is required to optimize this aspect.

IV. Conclusions

The acoustic characteristics of CNT layers have been derived from the electric characterization of BAW resonators containing CNT layers as top electrode. The overtones generated in this layer were fitted with Mason's model, which allowed us deriving the CNT's sound velocity. A mean value of 62000 $m \cdot s^{-1}$ ±10% was obtained. The error arises from inaccuracies in the determination of the mass density and the thickness.

The sheet resistance exhibited by the CNT layers suggests that, in their present form, they are not suitable as top electrode for BAW resonators. However, their low density and hence, low mass, provide very thick layers (30 µm) that do not disturb the response of the resonators, since they barely load them. Therefore, CNTs can be very useful as sensing layers on top of BAW resonators, as long as they are grown on metallic electrodes of low sheet resistance. CNT carpets have been successfully grown on thin Al substrates although additional work is still required to achieve optimally-performing devices.

***Abstract*—In this paper, a kind of fully ordered langasite family crystals $Ca_3TaGa_3Si_2O_{14}$ (CTGS) were grown by the Czochralski pulling method and cut into lateral mode. The dielectric, elastic and piezoelectric properties of them were investigated as functions of temperature (up to 1073.15 K) and pressure (up to E-7 torr). It was found that all the crystals exhibited pressure stability properties and temperature dependent characteristics. According to the calculation, the dielectric permittivity, elastic coefficient and piezoelectric coefficient were about 17.66, 9.06 pm^2/N and 3.77 pC/N, respectively. The good properties make CTGS promising candidates for sensing applications at high temperature and high vacuum conditions.**

Keywords—langasite; high temperature; high vacuum

I. INTRODUCTION

High temperature sensors for harsh environments are of major importance to the aerospace and energy industries [1]. For example, high temperature sensors that could bear high vacuum and high radiation of the space environment and work in a wide temperature range are needed for the health monitoring of the aerospace industry.

To date, many kinds of materials have been investigated for the application at elevated temperatures. However, most of them are restricted in use. Currently, quartz (α-SiO_2) crystals are widely used in sensing applications, due to its thermally stable properties (zero temperature coefficient of frequency (TCF)), high mechanical Q, and high electrical resistivity. However, the maximum operating temperature of quartz-based devices is limited by the low α-β phase transition temperature at 573 °C and further restricted by the crystal twinning occurring at 300 °C [1]. Similar to quartz, $GaPO_4$ has been reported to be an excellent candidate for high temperature sensors due to the relatively high resistivity, low dielectric loss and high mechanical Q with α-β phase transition temperature at ~970 °C [2-7]. Unfortunately, the costly raw materials and achievable small crystal size limit the applications [8]. The disordered langasite family crystals (general formula $A_3BC_3D_2O_{14}$) exhibit no phase transitions prior to their respective melting points T_m (T_m = 1300 ~ 1500 °C) and can be readily grown using the Czochralski (CZ) method. Moreover, their piezoelectric coefficient d_{11} and electromechanical coupling factor k_{26} are significantly higher than those of quartz (7.0 pC/N versus 2~3 pC/N) and comparable to $GaPO_4$. However, their electrical resistivity is several orders of magnitudes lower than those of quartz and GaPO4 [9-11].

Recently, a kind of fully ordered langasite family crystals $Ca_3TaGa_3Si_2O_{14}$ (CTGS) have attracted considerable attention for high-temperature applications. Compared to disordered langasite family crystals, CTGS crystals have greatly improved resistivity. At the same time, they exhibit thermal stability of dielectric and electromechanical properties [12-13]. However, the properties of these crystals under high-vacuum conditions have not been studied.

In this paper, we investigated CTGS lateral mode resonators, by looking into the properties of the resonators as functions of temperature (from room temperature to 1073 K) and vacuum condition (from E-2 torr to E-7 torr).

II. EXPERIMENTAL

CTGS piezoelectric crystals were grown by the Czochralski (CZ) technique using iridium crucibles with an atmosphere of N_2 plus 1 vol% O_2. The combination of N_2/O_2 was used to protect the Ir crucibles while avoiding oxygen defects in the grown crystals. The crystals were grown along the crystallographic <100> direction [12]. The crystals were cut into lateral mode (XY-cut).

All the samples were with the dimensions of 0.64 × 3.99 × 13.99 mm^3 and polished using 15-μm SiC powder. The electrodes of the samples were vacuum-sputtered Au thin film (200 nm) and the surfaces of the electrodes were perpendicular to the thickness (0.64 mm) direction. The relative dielectric permittivity $\varepsilon^T/\varepsilon_0$ was determined from capacitance measurements using a multi-frequency LCR meter (Agilent 4284A, precision LCR meter, 20 Hz – 1 MHz). The elastic compliance s and the electromechanical coupling factor k were calculated based on the resonance/anti-resonance frequencies,

measured using an Agilent 4294A precision impedance analyzer (40 Hz – 110 MHz). The piezoelectric coefficient d was calculated using the dielectric, elastic and coupling parameters. During measurement, the samples were put in the chamber of a sputtering system (ATC 1300-F, AJA International, Inc.) with different temperatures (from room temperature to 1073.15 K) and different vacuum conditions (from E-2 torr to E-7 torr).

III. Methods of Calculating Parameters of Lateral Mode Resonators

CTGS is a trigonal crystal belonging to the space group 32. So the dielectric, piezoelectric and elastic constants matrices are as follows:

$$\varepsilon_{ij} = \begin{bmatrix} \varepsilon_{11} & 0 & 0 \\ 0 & \varepsilon_{11} & 0 \\ 0 & 0 & \varepsilon_{33} \end{bmatrix}$$

$$d_{ij} = \begin{bmatrix} d_{11} & -d_{11} & 0 & d_{14} & 0 & 0 \\ 0 & 0 & 0 & 0 & -d_{14} & -2d_{11} \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

$$s_{ij} = \begin{bmatrix} s_{11} & s_{12} & s_{13} & s_{14} & 0 & 0 \\ s_{12} & s_{11} & s_{13} & -s_{14} & 0 & 0 \\ s_{13} & s_{13} & s_{33} & 0 & 0 & 0 \\ s_{14} & -s_{14} & 0 & s_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{44} & 2s_{14} \\ 0 & 0 & 0 & 0 & 2s_{14} & s_{66} \end{bmatrix}$$

From the above matrices, it is easy to obtain the following relationships:

$$\varepsilon_{11} = \varepsilon_{22}, d_{11} = -d_{12}, s_{11} = s_{22} \quad (1)$$

Where ε_{11} and ε_{22} are dielectric permittivity, d_{11} and d_{12} are piezoelectric coefficient and s_{11} and s_{22} are elastic coefficient.

According to d-type piezoelectric equations:

$$S_2 = s_{22}^E T_2 + d_{12} E_1, \; D_1 = d_{12} T_2 + \varepsilon_{11}^T E_1 \quad (2)$$

In (2), S_2, T_2, E_1, D_1, s_{22}, $d_{12,}$ and ε_{11} are strain, stress, electric field, electric displacement, elastic constant, piezoelectric constant and dielectric constant, respectively. And the electric admittance can be given by:

$$Y = j\omega C^T [(1 - k_{12}^2) + k_{12}^2 \frac{\tan(kl/2)}{kl/2}] \quad (3)$$

And:

$$C^T = \frac{wl\varepsilon_{11}^T}{t}, \quad k = \frac{\omega}{v}, \quad v = \sqrt{\frac{1}{\rho s_{11}^E}}, \quad k_{12}^2 = \frac{d_{12}^2}{s_{22}^E \varepsilon_{11}^T} \quad (4)$$

Where w, l, t and ρ are the width, length, thickness and density (= 4.63 g/cm^3) of the CTGS crystal sample, respectively. ω, k, v, and k_{12} are angular frequency, wave number, acoustic velocity and electromechanical coupling factor, respectively. C^T is the low frequency capacitance (measured at 1KHz).

From (3), when tan(kl/2) goes to infinity, Y goes to infinity. Thus, it could be obtained:

$$f_r = \frac{v}{2l} \quad (5)$$

Where fr is the resonant frequency.

In (3), if Y=0, the following relationship could be got:

$$\frac{k_{12}^2 - 1}{k_{12}^2} = \frac{\tan(kl/2)}{kl/2} \quad (6)$$

That means:

$$\frac{k_{12}^2 - 1}{k_{12}^2} = \frac{\tan[\frac{\pi}{2}(f_a / f_r)]}{\frac{\pi}{2}(f_a / f_r)} \quad (7)$$

In (7), fa is the anti-resonant frequency.

Thus, from equations (1), (4) and (5), the following relationships can be calculated:

$$\varepsilon_{11}^T = \varepsilon_{22}^T = \frac{C^T t}{wl} \quad (8)$$

$$s_{11}^E = s_{22}^E = \frac{1}{4\rho(lf_r)^2} \quad (9)$$

$$d_{11}^2 = d_{12}^2 = k_{12}^2 \varepsilon_{11}^T s_{22}^E, \quad d_{11} = -d_{12} \tag{10}$$

Therefore, if t, w, l, ρ, C^T, fr and fa are known, the dielectric constants, piezoelectric constants, elastic constants and electromechanical coupling factor can be obtained by using (7) - (10).

IV. Results and Discussion

Fig. 1 shows that at the same temperature, with the change of pressure, the resonant frequency of CTGS lateral mode crystal stayed stable.

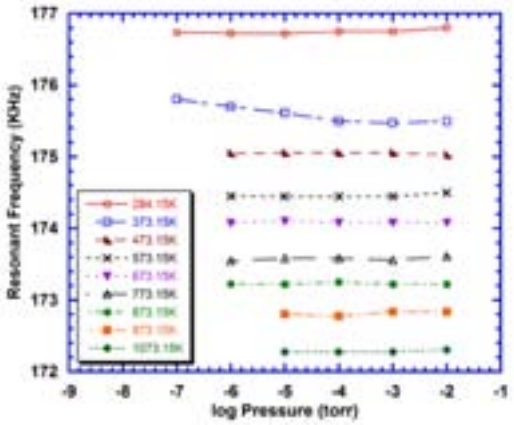

Fig. 1. Resonant frequency as a function of pressure for CTGS lateral mode crystal at different temperatures.

From Fig. 2, it can be seen that the resonant frequency as a function of temperature exhibited linear temperature/frequency characteristics over a wide temperature range. The temperature coefficient of the resonant frequency was found to be -5.1Hz/K. The inset in Fig. 2 presents the impedance as a function of temperature when the pressure is 1.0 E-4 torr, from which it can be seen that the resonant frequency (together with anti-resonant frequency) shifted downward with increasing temperature.

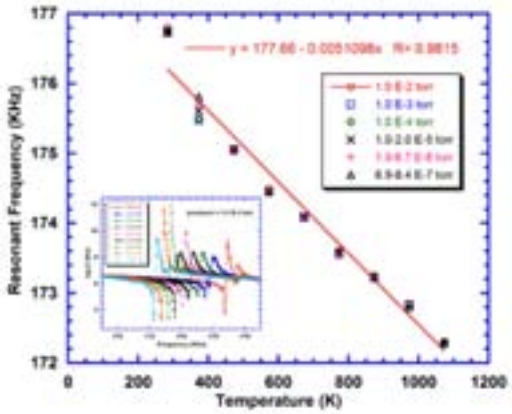

Fig. 2. Resonant frequency as a function of temperature for CTGS lateral mode crystal at different pressures.

Fig. 3 gives the elastic constant (s_{11}^E, s_{22}^E) as a function of temperature. It was found that the values increased almost linearly with the increasing temperature. It was 9.29 pm^2/N at 1073.15K and the temperature coefficient was found to be 0.00053 $(pm^2/N)/K$.

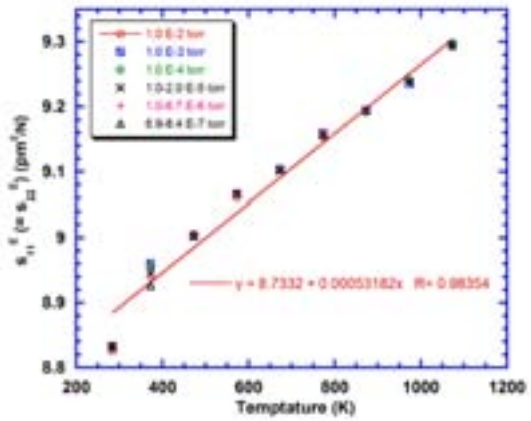

Fig. 3. Elastic constant variation as a function of temperature for CTGS lateral mode crystal at different pressure.

It was observed from Fig. 4 that the dielectric permittivity ($\varepsilon_{11}^T / \varepsilon_0, \varepsilon_{22}^T / \varepsilon_0$) and piezoelectric constant (d_{11}, d_{22}), to some extent, exhibited thermal stability and the values were within the range of ±3.57% around 17.66 and ±2.11% around 3.77 pC/N, respectively. According to the measurement, pressure almost didn't affect the capacitance. So, the dielectric permittivity didn't change with pressure.

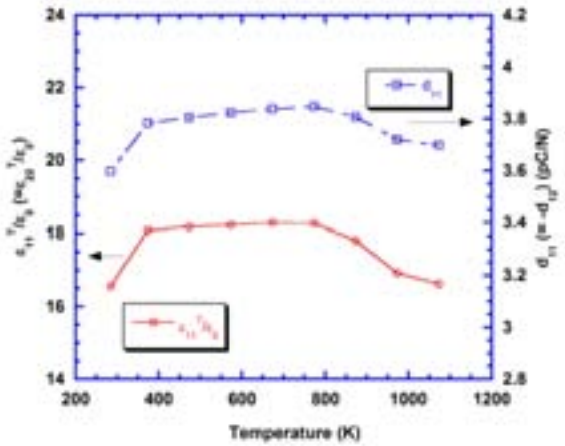

Fig. 4. Dielectric and piezoelectric constant variation as a function of temperature for CTGS lateral mode crystal.

V. Conclusion

In summary, high-quality piezoelectric single crystals CTGS were grown using the Czochralski pulling technique. By specially cut, we obtained lateral mode CTGS resonators

and investigated the dielectric, elastic and piezoelectric properties of them as functions of temperature and pressure. It was found that all the samples exhibited pressure stable properties (up to E-7 torr), which means that the crystals could work well under very high vacuum condition. Moreover, the crystals showed temperature dependent characteristics (up to 1073.15K). According to the calculation, the dielectric permittivity, elastic coefficient and piezoelectric coefficient were about 17.66 (±3.75%), 8.83~9.29 pm^2/N and 3.77 (±2.11%) pC/N, respectively. Thus, the CTGS crystals are promising candidates for sensing applications under high-temperature and high-vacuum conditions.

Abstract — **High overtone Bulk Acoustic Resonators have been developed for radio-frequency application such as oscillator stabilization, but also as an alternative to surface acoustic wave resonator for sensor development. In the present work, the possibility to operate such devices at temperature up to 800°C is investigated experimentally. Devices built using Aluminum Nitride deposited on Silicon with Platinum electrodes have been manufactured and resonance frequencies near the 434-MHz centered ISM band have been characterized from room conditions to 800°C. Although the exposition to such a temperature yields changes in the device response, it turns out that the operation is partly reversible and that these HBARs could operate without major defects for several tens of hours at such regimes. The development of wireless temperature sensors on this base then reveals accessible.**

I. INTRODUCTION

The development of elastic wave sensors capable to be remotely interrogated without on-board energy has yield new markets rise. The corresponding users challenge these sensors for several extreme applications such as operation at temperature above 500°C. Although the use of Langasite was the most promising approach, Aluminum Nitride (AlN)-based structures were also considered as a potential solution [1]. It was demonstrated that high overtone bulk acoustic resonators (HBARs) can be applied for wireless sensing as an alternative to SAW resonators [2]. As AlN is well-suited for such devices and exhibit a melting point in excess of 2000°C, the idea to exploit AlN-based HBAR for high temperature operation was considered in the present work.

AlN-based HBARs have been manufactured in a Sigma-Trikon sputtering machine, depositing 1µm thick layers onto a (111) Ti/Pt backside electrode deposited atop 530µm thick Sapphire and 400µm thick Silicon substrates. The classical figure of HBAR response was observed, with a frequency separation of about 8 to 9 MHz depending on the substrate and a maximum resonance of the layer alone near 2 GHz. The resonances between 400 and 500 MHz (close to the 434 MHz centered ISM band) have been focused for assessing the operation of the devices at temperature larger than 500°C.

These devices have been submitted to temperature cycles up to 600°C for 48 hours in an oven developed at IMTEK for calibrating acoustic devices [3], and their electrical response were monitored at various frequencies during the experiment. The observation of the device showed minimal de-wetting effects in form of single droplets atop the surface, as it is currently the case for inter-digitated-based transducer devices. The material lattice was found stable enough to withstand the temperature induced tensions as the thermal grooving and the resulting forming of droplets leaving micro cavities in the metallization layer is observed but limited and do not prevent the device operation. The experiments then were extended successfully up to 800°C.

In the first section of the paper, basic considerations on materials and sensor structure are discussed. The fabrication of the test vehicles then is described and finally test results of the HBAR under temperature ranging from room to 600°C and 800°C are reported.

II. HBAR MATERIALS AND STRUCTURE FOR HIGH TEMPERATURE APPLICATION

A. *Materials*

Quartz, Lithium Tantalate ($LiTaO_3$) and Lithium Niobate ($LiNbO_3$) are currently the most common piezoelectric crystals for the development of acoustic wave sensors. However, their maximum admissible operation temperature is limited by intrinsic properties, i.e. phase transitions and material decomposition (see for instance [4]). Gallium Orthophosphate and Langasite have both been used for high temperature purposes and revealed their robustness at temperature in excess of 800°C. The main point is that the SAW devices built on such materials suffer from important degradation when exposed for several tens of hours to temperature in excess of 600°C [3][4].

On the other hand, Aluminum Nitride (like all III-V nitrides) exhibits a high thermal conductivity and a high stability at elevated temperatures. Patel et al. [1] were able to measure an ultrasonic response of AlN at temperatures up to 1150°C, whereas a constant signal strength was observed up to 900°C. AlN exhibits the highest bulk acoustic wave velocity of all known piezoelectric materials, as well as an electromechanical coupling high enough for the generation of high overtones in HBAR structures. The basic idea then is to use such a structure which does not suffer from electrode fragility as it is the case for SAW to operate it at temperature in excess of 600°C. Platinum was considered specifically here as top and bottom electrodes because of its compatibility with high quality AlN deposition and its well known resilience to temperature.

B. Device characteristics

The schematic cross section with the specific stack details of this kind of HBAR is given in Figure 1 as well as the metallization layers and thicknesses. For the processing of the layers themselves, standard processes as described in section III where the buried electrode and top electrode layers were vapor deposited and the transducer layer was sputtered. A standard (100) silicon substrate was used for this type of HBAR. The main electrode layouts are also depicted in Figure 1. The top electrode was not protected anyhow as there were no fine electrode design structures but only plain surface area.

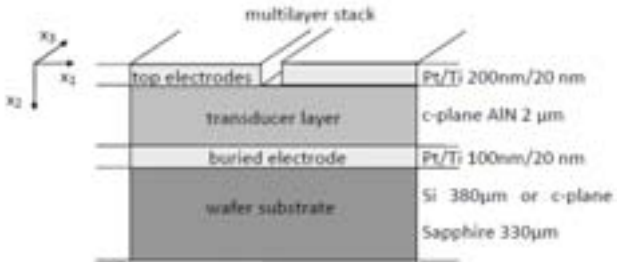

Figure 1 Scheme of HBAR stack structure with design and material parameters for the specific stack used in this work

III. FABRICATION OF THE RESONATORS

AlN-based HBARs have been manufactured in a Sigma-Trikon sputtering machine, depositing 1µm thick layers onto a (111) Ti/Pt backside electrode deposited atop 530µm thick Sapphire and 400µm thick Silicon substrates. The qualitative observation of the layer (**Figure 2**) indicates a dense layer with the expected textured columnar structure.

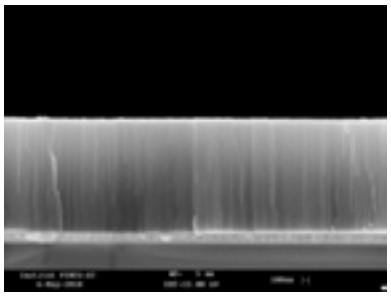

Figure 2 SEM observation of the trench of an AlN layer deposited on a Ti/Pt electrode on silicon

The Ti/Pt bottom electrode was deposited by sputtering and then thermally annealed to obtain proper orientation promoting the AlN deposition. This thermal process was achieved in the sputtering machine just before the AlN deposition to minimize potential surface pollution. Figure 3 shows a view of the devices after top electrode patterning. Although these devices were built for double-port laterally coupled HBAR application, they could be used without difficulties as single port resonators by simply leaving one of the port open.

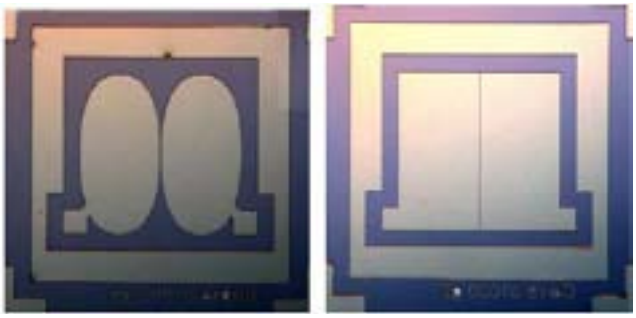

Figure 3 Photos of two top electrode designs for the manufactured HBAR devices, here, devices processed atop c-plane AlN on (100) silicon

IV. EXPERIMENTAL CHARACTERIZATION OF HBAR AT HIGH TEMPERATURE

The classical figure of HBAR response was observed, with a frequency separation of about 8 to 9 MHz depending on the substrate and a maximum resonance of the layer alone near 2 GHz. The resonances between 400 and 500 MHz (close to the 434 MHz centered ISM band) have been focused for assessing the operation of the devices versus temperature. The devices were first exposed to 500°C for tempering the platinum layer and for the following high-temperature measurements at 600°C and 800°C (along the profile of **Figure 4**), the different devices and their frequency characteristics were measured afterwards and evaluated in comparison to un-tempered devices.

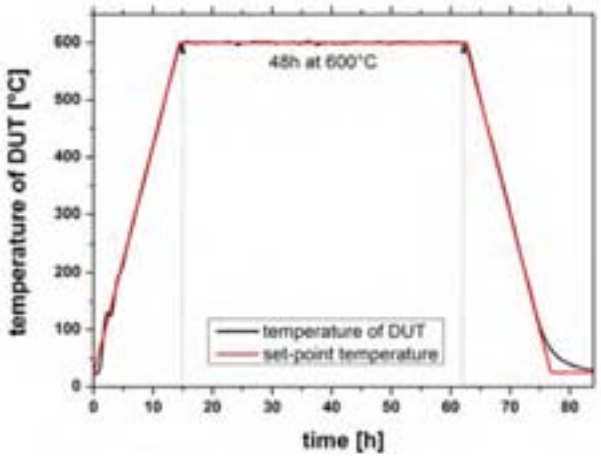

Figure 4 Temperature profile for the characterization of the temperature behavior and stability, the set-point temperature measured by a PT100 is the oven temperature

The on-wafer level measured conductance of the two test designs of HBARs are shown in Figure 5. In the frequency band of interest from 400 to 450 MHz (including the 433MHz-centered ISM band), five well-defined longitudinal mode signatures are observed as well as six very weak signals attributed to shear polarized modes. The resonance frequency of the different modes of one device at one frequency clearly does not change before and after being exposed to 600°C for 48h. Only the amplitude as a figure for the quality factor decreased, possibly due to thermal induced defects at the interfaces between the transducer, layer adhesion and the device surface degradation (not protected during the tests).

During the this first temperature test up to 600°C, the devices were continuously measured by acquiring the resonance frequency measuring the S_{11} parameters automatically every 15 min. using a specific but un-calibrated high-temperature resistant device holder. Therefore one recognizes a varying frequency dependant offset of electrical parasitic effects (see Figure 6).

As the devices did operate well during the whole thermo cycle, the characterization experiment has been extended to 800°C. The devices were heated-up to 800°C and hold at this temperature again for 48h and cooled-down to room-temperature. Comparing the linearity of the frequency of the heating-up phase to the cooling down phase, the frequency shift is about 110 kHz. This corresponds to relative aging rate of 5.3 ppm per hour at 800°C. The linearity during heat-up and cool-down phases and the steadiness of the resonance frequency at the maximum temperature during the hold phase were also evaluated. The results are shown in Figure 7. The temperature coefficient of the frequency (TCF, in some way the sensor "sensitivity") was measured as shown in Figure 8. The TCF then is estimated between -40 and -42 ppm/K for the complete temperature range and -49 ppm/K at 800°C.

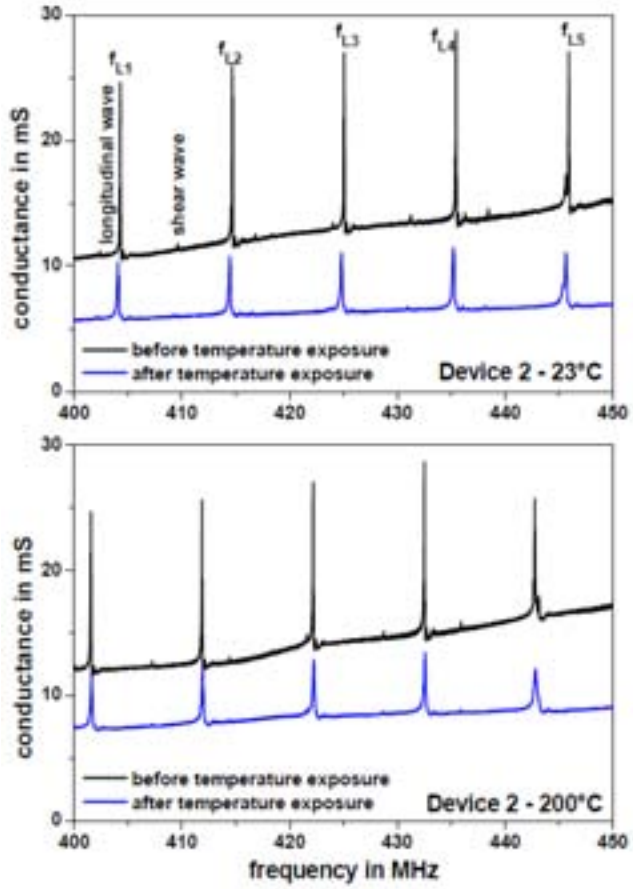

Figure 5 On-wafer measured conductance of the tested HBARs before and after being exposed to 600°C for 48h at room condition and 200°C

At platinum surfaces, as shown in Figure 9, minimal de-wetting effects in form of single droplets atop the surface are observable, showing that the (111) orientation is not fully homogeneous but the lattice is stable enough to withstand the temperature induced tensions as the thermal grooving and the resulting forming of droplets leaving micro cavities in the metallization layer is limited.

VI Conclusion

It has been demonstrated that AlN/Si-based HBARs with Ti-Pt electrodes are capable to operate at temperature up to 800°C for several tens of hours. Some signal characteristics are of course observed as the direct observation of the device reveals obvious but limited defects compared to SAW devices operated at such temperature. The importance of an initial tempering process (electrode annealing) has been emphasized to keep a stable device response on the whole temperature range. An almost linear average TCF was measured near -45 ppm.K^{-1} representative of Silicon thermal sensitivity. Furthermore, as the use of HBAR for wireless applications was already reported, future work will be engaged to develop remotely controlled passive sensors based on the presented principles.

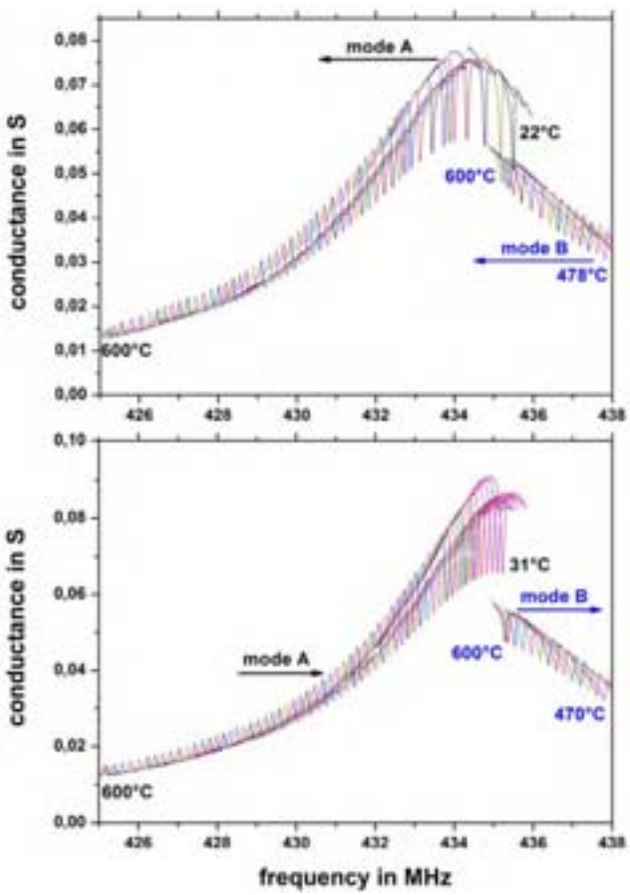

Figure 6 Measured conductance of a test HBAR during heating-up to 600°C (upper graph) Measured conductance of a test HBAR during heating-up to 600°C (upper graph) and cooling down again to room temperature (lower graph) around the 433 MHz ISM band showing two different modes marked as A and B. The flashes indicate the direction in dependence of the temperature gradient

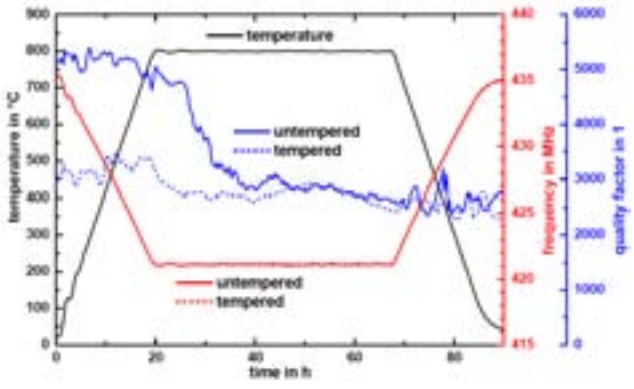

Figure 7 Frequency response and quality factor of un-tempered and tempered HBAR test devices versus time during a measurement cycle of 90 hours with a rising temperature up to 800°C. The quality factor of the tempered devices decreases by a value of about 800 whereas for the un-tempered device the value decreases by 2500

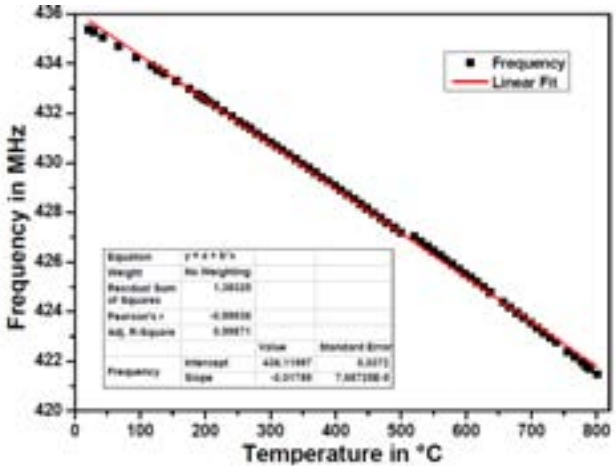

Figure 8 Measured device frequency characteristics of the test device up to 800°C resonance frequency in dependence of temperature with the corresponding linear fit, evaluating the frequency-temperature behavior and its linearity

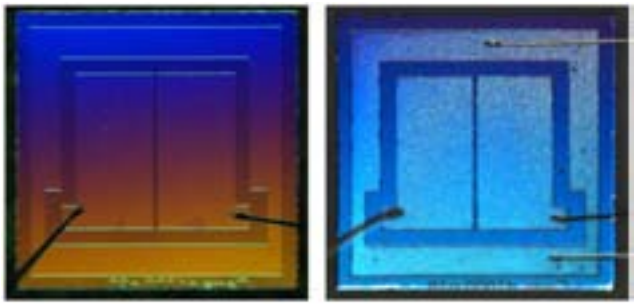

Figure 9 Differential interference contrast LM-micrographs for a visualized surface topography of test devices exposed to temperature. Left-hand side: after being exposed for to 600°C for 48h. Right-hand side: after being exposed to 800°C for 48h.

Langatate Temperature-Compensated BAW Orientations Identified Using High-Temperature Constants

Peter Davulis, Mauricio Pereira da Cunha
Electrical and Computer Engineering Dept., University of Maine, Orono, ME, USA
Email: mdacunha@maine.edu

***Abstract*— LGT BAW orientations are investigated up to 900°C for temperature-compensated orientations targeting harsh-environment applications. The study utilizes recently published LGT elastic, piezoelectric, and dielectric constants extracted by the authors using resonant ultrasound spectroscopy (RUS) up to 900°C based on the resonances of bulk crystal samples. Temperature-compensated LGT BAW orientations have been identified for operation at high temperatures. The orientations disclosed in this work have turnover temperatures between 100°C and 550°C for the one quasi-shear mode and up to 150°C for the other quasi-shear mode. Additionally, orientations were identified with pure transverse-shear modes that are selectively excitable and have temperature compensation up to 550°C. These orientations can be readily applied for both frequency control and sensor applications in harsh environments.**

Keywords—Langatate, BAW, high temperature, temperature compensation

I. INTRODUCTION

There is a growing demand for high-temperature (>200°C) sensors and frequency control devices. Langatate (LGT) crystal is a prime candidate substrate for surface acoustic wave (SAW) and bulk acoustic wave (BAW) devices to address high-temperature sensing applications due to demonstrated harsh-environment operation and the availability of recently published acoustic wave constants up to 900°C [1]-[4]. While prior work by the authors on LGT has focused on orientations for high-temperature SAW devices [1], LGT BAW devices capable of operating in harsh-environments also have very attractive applications, such as deposition rate monitoring; high-temperature timing devices; gas, chemical, and physical sensors.

While temperature compensated langasite (LGS) BAW orientations have been reported using extracted LGS constants up to 900°C [5], no such study has been reported on LGT due to the absence of high-temperature constants. Langatate orientations were investigated in [6] for temperature-compensated length extensional, flexural, and torsional cylinder resonators up to 250°C, although the study utilized constants extracted below 150°C from [7], [8] for their predictions. Temperature-compensated thickness shear BAW orientations were predicted to several hundred degrees Celsius in [9] using constants extracted below 150°C [8]. Selected rotated Y-cut BAW orientations were fabricated using LGT crystals grown by Yu, et al., with experimentally identified turnover temperatures as high as 350°C [9], [10].

In this work, LGT BAW orientations are investigated up to 900°C for temperature-compensated orientations targeting harsh-environment applications. In order to predict the high-temperature properties of BAW devices, this study utilizes recently published LGT elastic, piezoelectric, and dielectric constants extracted by the authors using resonant ultrasound spectroscopy (RUS) up to 900°C [3], [4] and the thermal expansion and density up to 1200°C from [11]. These constants and temperature coefficients were validated by high-temperature SAW device measurements in [1], [3], [4], thus suggesting adequate prediction of the BAW properties including turnover temperatures.

Temperature-compensated LGT BAW orientations were investigated based on the analysis of the temperature coefficient of frequency (TCF), the turnover temperature (TCF=0) and the piezoelectric coupling for both thickness-field and lateral-field excitation of the three bulk wave modes. Turnover temperature orientations were identified for both quasi-shear (*QS*) BAWs. Turnover temperatures up to 150°C have been predicted in this work for one of the QS modes, and identified between 100°C and 550° for the other. For this second quasi-shear mode the turnover temperatures are mapped with respect to the crystallographic angles, thus allowing the selection of an orientation with a particular turnover temperature within the range mentioned above. In addition, pure-shear (*PS*) orientations, important for sensor and frequency control applications, are also reported with turnover temperatures up to 550°C.

The LGT BAW properties investigated and the calculation method used are described in Section II. Section III presents LGT BAW orientations and respective properties for high-temperature harsh-environment applications. Section IV discusses pure-shear LGT orientations that are temperature compensated at high temperature. Section V concludes the paper.

II. CALCULATION PROCEDURE & NOMENCLATURE

The identification of BAW orientations for high-temperature operation involved the calculation and analysis of the phase velocity, temperature coefficient of frequency (TCF), thickness field excitation (TFE) piezoelectric coupling (k_{TE})

This work is supported by U.S. Department of Energy Award #: DE-FE0007379TDD. A disclaimer statement is included in the Acknowledgement Section as required by the sponsor.

using the process described in [12], [13], and lateral field excitation (LFE) piezoelectric coupling (k_{LE}) using the procedure outlined in [14]. For each mode there is a single value of k_{TE} but k_{LE} depends on the angle of the lateral electric field [14]. Therefore the lateral-excitation coupling is calculated by rotating the electric field around the cut plane. For the rotated Cartesian coordinate system, using Euler Angles nomenclature, and assuming propagation along the X''' axis, the angle of the lateral electric field, $\Psi_E = 0°$, is defined as coincident with the rotated Y''' axis, and Ψ_E increases in going from the positive Y''' axis towards the positive Z''' axis in the plane normal to propagation. In this work, unless otherwise specified, the k_{LE} given for a particular mode is the maximum lateral field coupling for the orientation found by sweeping Ψ_E.

The BAW properties were calculated for each of the three BAW modes: (*QL*) quasi-longitudinal, (*QS1*) first quasi-shear, and (*QS2*) second quasi-shear. The denomination "quasi" (*Q*) is dropped along orientations where pure shear or pure longitudinal modes take place. The modes are ordered in this work by the eigenvectors (particle polarization) [12], [13], and not by velocity [15]. For this reason the nomenclature "first" and "second" quasi-shear modes were selected, since *QS1*, for instance, can start as the fast shear mode in a plane sweep and then turn into the slow shear mode, after the mode velocities cross each other (mode degeneracy orientation).

The BAW orientations can be given by (YXwl)φ,θ in the BAW rotated plate nomenclature [15], [16] or by [φ, θ, ψ] = [φ, θ, 90°] in Euler angle notation [16]. The BAW properties were calculated in this work for a range of orientations by sweeping the angles 0°≤φ≤60° and −90°≤θ≤90°. These calculations were performed at every 100°C between 100°C and 900°C, and sometimes at smaller temperature intervals. The TCF was numerically determined from the discrete derivatives calculated 5°C above and below the target temperature.

III. LGT BAW High-Temperature Performance

The BAW TCF calculations for the three BAW modes from 100°C to 900°C along LGT [φ, θ, 90°] revealed temperature-compensated orientations for modes *QS1* and *QS2*, but not for the *QL* mode. The *QS2* mode was found to have TCF=0 orientations as high as 550°C and the *QS1* mode had TCF=0 orientations up to 150°C. The k_{TE}, k_{LE}, and TCF are plotted for the *QS1* mode at 150°C in Fig. 1, and for the *QS2* mode at 550°C in Fig. 2.

For the *QS1* mode, LGT orientations in the range [0°≤φ≤5°, −15°≤θ≤0°, 90°], and [55°≤φ≤60°, 0°≤θ≤15°, 90°] were identified with TCF=0 at 150°C, the highest turnover temperature found for this mode. Along these orientations, k_{TE} is less than 0.04. However, k_{LE} reaches values between 0.06 and 0.08 for this same region.

The k_{TE} and k_{LE} coupling and TCF are plotted for the *QS2* mode at 550°C in Fig. 2. The *QS2*-mode shows values of TCF=0 with k_{TE} of 0.04 to 0.14 and k_{LE} up to 0.1 for each temperature investigated between 100°C and 550°C. The turnover temperatures of the LGT *QS2*-mode are plotted in Fig. 3, showing the orientations with TCF=0 between 100°C and 550°C. This particular plot can be used to select an LGT BAW orientation for a desired turnover temperature. The value k_{TE} and k_{LE} decreased by about 15% from 25°C to 550°C for the orientations shown. Therefore, Figs. 2a and 2b can also be used as a guide for the TFE and LFE coupling at lower temperatures.

For the *QS2* mode, orientations in the range [0°≤ ϕ≤10°, −58°≤θ≤−40°, 90°], and [50°≤φ≤60°, 40°≤θ≤58°, 90°], were identified with TCF=0 at 550°C. These orientations have coupling $0.04 \le k_{TE} \le 0.1$ and $k_{LE} \approx 0.1$; for comparison, SC-cut quartz has coupling of $k_{TE} = 0.051$ and AT-cut quartz can coupling of $k_{TE} = 0.063$ [13], [17] at room temperatures. There are also 550°C turnover temperature orientations in the range [25°≤φ≤35°, 5°≤θ≤5°, 90°] with coupling $k_{LE} \approx 0.14$ and $k_{LE} \le 0.02$.

In addition, the temperature compensated orientations identified experimentally in [9], [10] for the *QS2*-mode on (YXl)θ plates, orientations [0°, θ, 90°], were consistent with predictions made in this work. Measurements of a LGT (YXl) −30° plate, Euler angle [0°, −30°, 90°] in [10] found a turnover temperature at between 350°C and 400°C [10, Fig. 7], slightly lower than turnover temperature of around 450°C predicted in this work (Fig. 3). Additionally, the measured turnover temperature LGT (YXl) −10° plates in [10] were found to be around 250°C, whereas the predicted turnover temperature in this work is 300°C. While the measurements from [10] confirm the existence of the predicted LGT orientations with TCF=0 at high temperature made in this work, the identified discrepancies between the predictions in this work and the reported values from [10] are around 15% and call for investigation to identify the source of these differences. Possible causes for the discrepancies include: constants and temperature coefficients inaccuracies; crystal differences due to different suppliers; crystals or wafers being under stress, crystal cut precision, and measurement inaccuracies.

IV. LGT BAW Orientations with Transverse-Shear Modes

Bulk acoustic wave devices that utilize pure-shear BAW, also labeled as transverse-shear modes (TSM), are useful for frequency control and sensor applications, since this mode is selectively excited without exciting the other BAW modes [17]. In addition, the *PS* BAW is important for sensor applications in which the sensor is exposed to viscous media, since these modes have purely shear particle displacements parallel to the device's surface (no longitudinal component), thus not suffering significant attenuation due to the presence of the media.

The LGT orientations [0°, θ, 90°] are Symmetry 4 orientations [18], where a pure shear stiffened BAW mode (*PS2*) exists and uncouples from the unstiffened *QL* and *QS1* modes. Orientations along this plane can be selected with turnover temperatures between 100°C and 550°C, as observed in Fig. 3. For the LGT BAW orientations [0°, −50°→25°, 90°], the *PS2* mode also possesses $0.06 \le k_{TE} \le 0.14$ at 550°C. For lateral field excitation, the *PS2* mode has maximum k_{LE} when $\Psi_E = 90°$, assuming values $0.05 \le k_{LE} \le 0.1$ at 550°C. Therefore the *PS2* can be strongly and selectively excited on LGT with

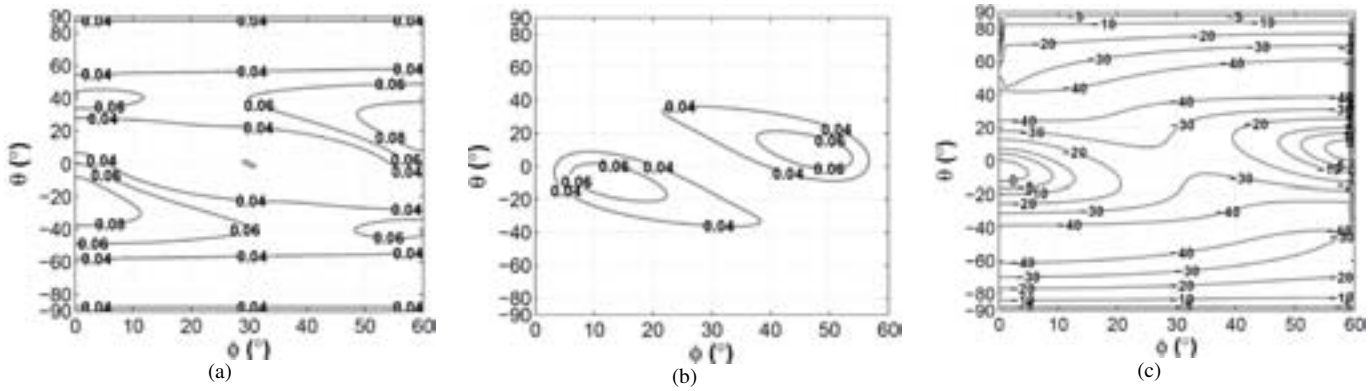

Fig. 1. LGT BAW *QS1* properties at 150°C: (a) max k_{LE} *of the orientation*, (b) k_{TE}, (c) TCF (ppm/°C).

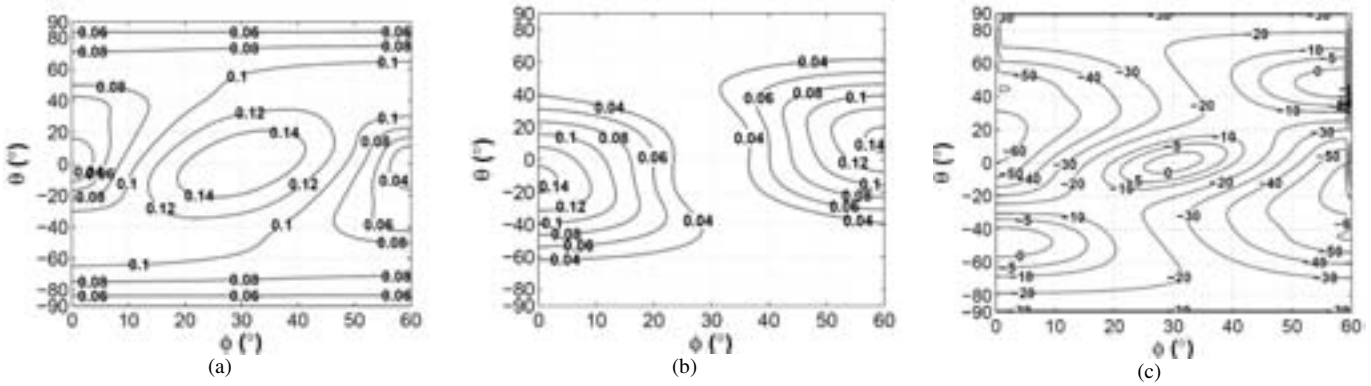

Fig. 2. LGT BAW *QS2* properties at 550°C: (a) max k_{LE} *of the orientation*, (b) k_{TE}, (c) TCF (ppm/°C).

either thickness or lateral electric field excitation along orientations with turnover temperature between 100°C and 550°C.

In addition, modes with a predominantly pure shear particle polarization can be found by searching for quasi-shear modes for which the longitudinal component of the normalized eigenvector is less than 0.01 (i.e. less than 1% of the shear component). Fig. 4 plots the ratio of longitudinal to shear eigenvector components for both *QS1* and *QS2* at room temperature, noting that the eigenvector components do not significantly change for the investigated LGT orientations over the temperature range of 25 to 900°C. Fig. 4 reveals the existence of additional close-to-pure-shear mode orientations with turnover temperatures between 100°C and 550°C. An important observation is that, differently from the Symmetry 4 orientations previously mentioned, these orientations may have significant coupling to more than one mode.

V. CONCLUSIONS

Temperature-compensated LGT BAW orientations have been identified for operation at high temperatures, based on the use of constants extracted up to 900°C and validated by SAW measurements. Orientations with turnover temperatures up to 550°C for the *QS2* mode and up to 150°C for the *QS1* mode have been presented and discussed. Pure transverse-shear mode orientations with temperature compensation up to 550°C have also been disclosed. In addition, the coupling coefficients for both TFE and LFE have been presented at high temperatures. For the *QS2*, in particular, turnover temperature orientations have been mapped between 100°C and 550°C to allow the selection orientations for a targeted turnover temperature. The identified orientations are expected to enable new and diverse high-temperature applications in sensing and frequency control, due to the identified existence of appropriate temperature compensated orientations to suit the particular harsh environment application.

Abstract—**We demonstrate a 30-km-long optical fiber link for frequency comparison between two strontium optical lattice clocks being developed at Riken and the University of Tokyo. We use a transfer laser at 1397 nm which is twice the wavelength of the clock transition of strontium clocks. The link stability is estimated to be 1×10^{-17} for an averaging time $\tau = 1$ s, which is in good agreement with the theoretical limit calculated from the fiber noise spectrum. We discuss a remote clock comparison with stability of $10^{-17}(\tau/s)^{-1/2}$ by synchronously operating the two distant clocks.**

I. Introduction

Recently, frequency comparison between two Sr optical lattice clocks demonstrated the quantum projection noise (QPN) limited stability of a few times $10^{-16}(\tau/s)^{-1/2}$ for an averaging time τ either by operating two clocks synchronously [1] or by using stable clock lasers [2]. Such a high clock stability enables to probe the relativistically-curved space-time in real time. Because of its sensitivity to the gravitational potential, frequency comparison between two clocks operating at distant sites allows monitoring temporal fluctuation of the gravitational potential difference, which can lead to new applications in relativistic geodesy [3,4].

Coherent optical frequency transfer via optical fibers [5] serves as an essential technique for frequency link of accurate optical clocks operating at distant sites, though the link stability may deteriorate as the fiber length increases. The limit of stability is mainly because the actual phase noise in the forward and return paths are not equal due to a finite time delay [6]. The residual one-way phase-noise power spectrum density (PSD) for a stabilized fiber is given by [6]

$$S_\phi^{\mathrm{stab}}(f) = (1/3)\,(2\pi f\tau_d)^2\, S_\phi^{\mathrm{free}}(f) \qquad (1)$$

for the Fourier frequency $f < 1/(4\tau_d)$. Here $S_\phi^{\mathrm{free}}(f)$ is the one-way phase-noise PSD for a free-running fiber. Assuming the fiber noise to be uncorrelated with position, $S_\phi^{\mathrm{free}}(f)$ is estimated to be [7]

$$S_\phi^{\mathrm{free}}(f) = \{2[1+\mathrm{sinc}(4\pi f\tau_d)]\}^{-1}\, S_\phi^{\mathrm{free,RT}}(f) \qquad (2)$$

by measuring the round-trip phase-noise PSD with free-running fiber $S_\phi^{\mathrm{free,RT}}(f)$. As the free-running fiber noise is proportional to the fiber length L [7], the residual fiber noise with stabilization $S_\phi^{\mathrm{stab}}(f)$ increases as L^3 by (1).

In order to demonstrate frequency comparison between distant clocks at the stability of $10^{-17}(\tau/s)^{-1/2}$, we have developed a 30-km-long optical fiber link between Riken and the University of Tokyo. According to the fiber noise spectrum measurement, the theoretical limit of the link stability is calculated to be 1×10^{-17} at 1 s. We partly confirm the link stability by implementing a 60-km-long fiber link which includes the 30-km-long fiber. We discuss about the synchronous operation of two distant clocks that will allow measuring clock shift with $10^{-17}(\tau/s)^{-1/2}$ stability.

Since we focus on frequency comparison between two Sr optical lattice clocks operating with 698 nm clock lasers, we implemented a novel scheme utilizing a 1397 nm transfer light which directly links to the clock frequency by the second harmonic generation (SHG) without the help of optical frequency combs. The water-peak attenuation due to the presence of OH radical in the fiber core material centers at around 1383 nm [8] and is not a serious problem for fiber length up to ~60 km (typically 0.2 dB/km at 1397 nm). OH-free fiber is expected to become more popular for coarse wavelength division multiplexing (CWDM) applications [8], which allows extending the frequency transfer at 1397 nm to longer distances. Our transfer scheme will provide a convenient and simple platform for networking Sr optical lattice clock which has become the most widespread optical clock around the world.

II. Experiment

A. 30-km-long optical fiber link between Riken and UT

A schematic of the experimental setup of 30-km-long optical fiber link is shown in Fig. 1. Two clock lasers at 698 nm for Sr optical lattice clocks were developed at Riken (local site) and the University of Tokyo (UT, remote site), a line-of-sight distance between which is 15 km. They were stabilized to high finesse cavities made of ultralow-expansion (ULE) glasses. A transfer laser at 1397 nm was phase locked to the clock laser via SHG by a periodically poled lithium niobate (PPLN) waveguide at the local site (a) and sent to the remote

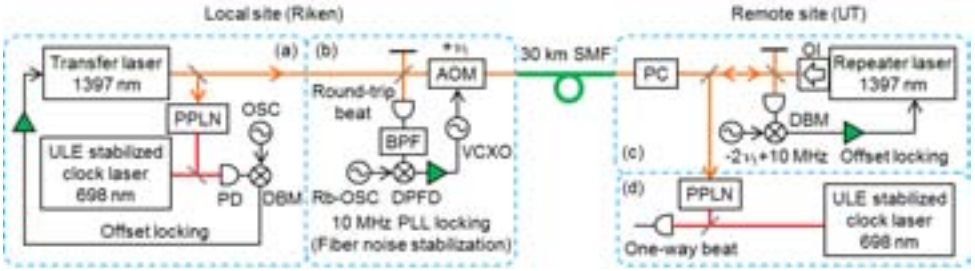

Figure 1. Experimental setup of 30-km-long optical fiber link. A transfer laser at 1397 nm was phase locked to the clock laser at the local site (a) and sent to the remote site. At the remote site, a repeater laser was offset locked to the received signal (c) and was sent back to the local site to measure round-trip fiber noise by a Michelson interferometer (b). A part of the repeater laser is frequency doubled to measure a beat signal with a clock laser at the remote site (d). PPLN, periodically poled lithium niobate waveguide; AOM, acousto-optic modulator; SMF, single-mode optical fiber; PD, photo diode; DBM, double balanced mixer; DPFD, digital phase-frequency discriminator; BPF, band-pass filter; OSC, RF oscillator; OI, optical isolator; VCXO, voltage controlled crystal oscillator; PLL, phase-locked loop; and PC, polarization controller.

site through the 30-km-long telecom fiber. The optical transmission loss of the fiber was 30.4 dB, which was 7 dB larger than that measured at 1550 nm partly due to the water-peak attenuation centered at 1383 nm [8]. To compensate the fiber transmission loss, we used a repeater laser at the remote site (c), by which we boosted and sent back the signal to the local site to measure the round-trip fiber noise by a Michelson interferometer (b). The round-trip beat signal was phase compared with a rubidium oscillator by a digital phase-frequency discriminator (DPFD). The obtained phase error signal was fed back to a voltage controlled crystal oscillator (VCXO) that drove an acousto-optic modulator (AOM) to compensate the round-trip fiber noise. The servo bandwidth was limited to $1/(4\tau_d)$ = 1.7 kHz given by the one-way light propagation time τ_d = 0.15 ms for the 30-km-long fiber. A part of the repeater laser is frequency doubled to measure a beat signal with the clock laser at the remote site (d), which can be used to phase lock the clock laser to the repeater laser for synchronous operation of the two optical lattice clocks.

B. 60-km-long optical fiber link

The one-way beat signal obtained in Fig. 1(d) includes phase noise of two clock lasers, which prevents accessing the potential stability of the frequency link. In order to evaluate the link stability experimentally, we implemented a 60-km-long fiber link by connecting two 30-km-long fibers in series at the remote site as shown in Fig. 2 so that we received the transferred light at the local site where we operated the repeater laser. The total optical transmission loss of the fiber was 61 dB. The propagation time of 0.3 ms limited the servo bandwidth of the fiber noise stabilization by about 800 Hz. With the stabilization, the beat signal between the transfer and repeater lasers was measured to evaluate the link stability. The theoretical limit of the stabilized one-way fiber noise should be 8 times larger than that of 30-km-long fiber by (1).

III. RESULTS AND DISCUSSIONS

A. Performance of the optical fiber link

The round-trip phase noise for the 30-km-long fiber was measured by the phase error signal of the round-trip beat signal

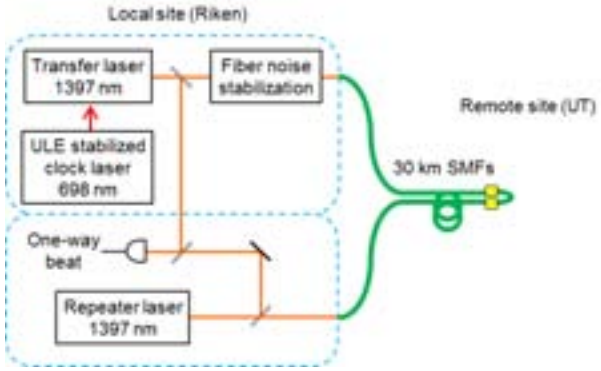

Figure 2. A schematic of a 60-km-long optical fiber link using two 30-km-long fibers connected at the remote site. Both the transfer and repeater laser were operated at the local site, and the link stability was evaluated by measuring a beat signal between them.

(see Fig. 1(b)) as shown in Fig. 3. The $S_\phi^{\text{free,RT}}(f)$ measured at 3 am (b: solid blue line) was an order of magnitude better than that measured at 3 pm (a: solid red line) especially around 100 Hz, which decreased as $S_\phi^{\text{free,RT}}(f) \sim 2\text{x}10^3 f^{-2}$ up to $f < 100$ Hz and decreased even rapidly as f^{-4} for higher frequencies in agreement with observations elsewhere [6]. By activating the PLL for the fiber noise stabilization, the round-trip phase noise was suppressed to the level indicated by the solid black line (c). The residual one-way fiber noise for the stabilized fiber $S_\phi^{\text{stab}}(f)$ at 3 pm and 3 am were calculated by applying (1) and (2) and are shown by dashed red (d) and blue (e) lines, respectively. The solid green line (f) shows the residual one-way fiber noise measured with stabilized 60-km-long fiber at 3 am, which is consistent with the calculation which should be 8 times larger than (e). The dashed green line (g) represents the phase noise of the clock lasers $S_\phi^{\text{laser}}(f) = 0.15\, f^{-3} + 0.02\, f^{-2}$ assuming a thermal noise of the ULE cavities, which corresponds to a frequency stability of $1\text{x}10^{-15}$ at 0.1 s.

Figure 4 shows the fiber link stability evaluated by the modified Allan deviation (MDEV) [9], which was calculated from the one-way beat note (see Fig. 1(d) and Fig. 2) measured by a Λ-type frequency counter with zero dead time (Agilent, 53230A). The open squares (red) and circles (blue) represent

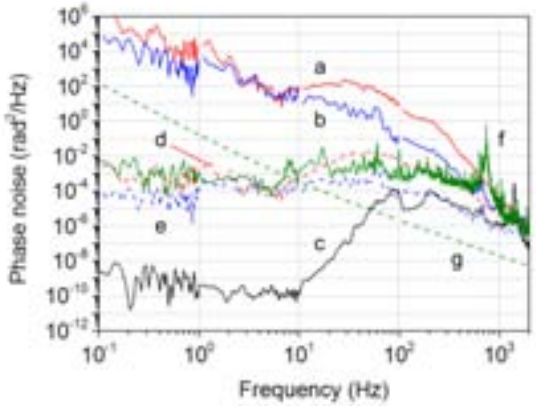

Figure 3. Power spectrum density of the free-running round-trip fiber noise $S_\phi^{\text{free,RT}}(f)$ at 3 pm in the daytime (a: solid red) and at 3 am in the night (b: solid blue) and that of the stabilized round-trip fiber noise (c: solid black). The stabilized one-way fiber noise $S_\phi^{\text{stab}}(f)$ at 3 pm (d: dashed red) and at 3 am (e: dashed blue) were calculated from $S_\phi^{\text{free,RT}}(f)$. The one-way fiber noise measured with stabilized 60-km-long fiber at 3 am (f: solid green) was consistent with the culculation. Phase noise of the clock laser $S_\phi^{\text{lasr}}(f)$ operated at $1\text{x}10^{-15}$ frequency stability at 0.1 s is shown by green dashed-line (g).

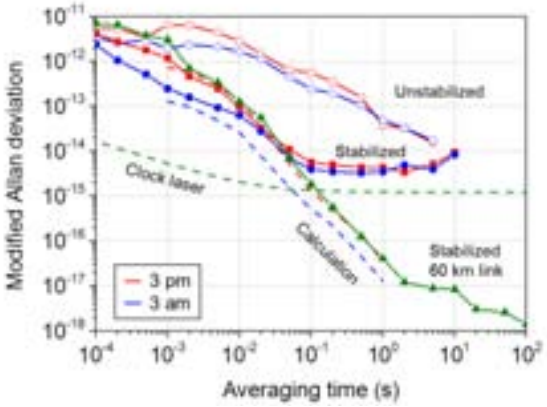

Figure 4. Modified Allan deviations (MDEV) for the fiber link stabilities. Open squares and circles show stabilities of the one-way beat frequency measured with the 30-km-long free-running fiber, while closed ones show that for the stabilized fiber, which include noise of the clock lasers. Those measured at 3 pm and 3 am are shown in red and blue, respectively. Corresponding MDEVs calculated from the one-way fiber noise $S_\phi^{\text{stab}}(f)$ are shown by dashed lines. Closed triangles (green) show the stability of the 60-km-long fiber link at 3 am. The thermal noise limit of clock lasers calculated from $S_\phi^{\text{laser}}(f)$ is shown by a dashed green line.

the stabilities for the free-running 30-km-long fiber at 3 pm and 3 am, respectively, while the closed ones represent those for the stabilized fiber. The MDEV calculated from the estimated one-way fiber noise $S_\phi^{\text{stab}}(f)$ at 3 pm and 3 am (as given in Fig. 3(d) and (e)) are shown by the dashed red and blue lines, which have $\tau^{-3/2}$ slopes for the averaging time $\tau > 0.01$ s because of their white phase noise features for $f < 100$ Hz and reached a few times of 10^{-17} at 1 s. The measured stabilities deviate from the calculated ones for $\tau > 0.1$ s and reach a floor, which is mainly set by the thermal noise of the clock lasers especially for $f < 10$ Hz as shown in Fig. 3(g). The dashed green line in Fig. 4 shows the stabilities of the two clock lasers assuming $S_\phi^{\text{laser}}(f)$, which reasonably explains the measured stability floor. The closed green triangles represent the stability of the 60-km-long fiber link at 3 am, which decreases as $4\text{x}10^{-17}\tau^{-3/2}$ for the averaging time up to $\tau < 2$ s. It corresponds to $1.4\text{x}10^{-17}\tau^{-3/2}$ for the 30 km one-way stability and is in good agreement with the calculation (dashed blue line). For longer averaging time $\tau > 2$ s the MDEV has $\tau^{-1/2}$ slope, which is possibly responsible for the white frequency noise caused by mechanical instability of the heterodyne interferometer.

B. Application to remote clock comparison

We have established a frequency link as stable as $1\text{x}10^{-17}$ at 1 s. The actual stability for clock comparison, however, may be severely limited by the stability of atomic clocks that is about $10^{-16}(\tau/\text{s})^{-1/2}$ even with the best clocks available to date [2]. Here we discuss about synchronous operation [1] of two remote clocks to fully exploit the link stability. We speculate that frequency comparison with stability of $10^{-17}(\tau/\text{s})^{-1/2}$ will be achievable with a clock laser having $1\text{x}10^{-16}$ stability at 1 s. The scheme, therefore, allows comparing two remote clocks at 10^{-18} uncertainty in about 100 s, which will find applications in relativistic geodesy to measure 1 cm height differences every 100 s.

Consider a clock operation with an interrogation time $T_\text{i} = 0.5$ up to 2 s that is well supported by a clock laser having $1\text{x}10^{-16}$ stability at 1 s. Correspondingly, we assume a cycle time $T_\text{c} = T_\text{i} + 0.5$ s, where 0.5 s includes atom loading and state manipulation time. Allan deviation (ADEV) for the clock stability at the QPN limit is given by

$$\sigma_\text{y}^{\text{QPN}}(\tau) = (\gamma/\nu_0\kappa)(T_\text{c}/N\tau)^{1/2}, \quad (3)$$

where $\gamma = 0.8/T_\text{i}$ is the full-width at half-maximum (FWHM) linewidth of the Rabi spectrum, N is the number of interrogated atoms in a cycle, and κ is a coefficient around 1 for Rabi excitation.

In optical lattice clocks that interrogate a large number of atoms, the most severe constraint on the clock stability is imposed by the Dick effect [1]. ADEV for the Dick effect limit is given by [10]

$$\sigma_\text{y}^{\text{Dick}}(\tau) = \Sigma_\text{n}\,[(g_n^{\text{s}}/g_0)^2 + (g_n^{\text{c}}/g_0)^2]\,S_y(n/T_\text{c})\,(\tau/\text{s})^{-1}]^{1/2} \quad (4)$$

where $g_n^{\text{s,c}}$ and g_0 are the Fourier coefficients for sine and cosine components and the mean value of the sensitivity function for the clock sequence, and $S_y(n/T_\text{c})$ is the PSD of fractional frequency noise of the clock laser sampled at frequencies n/T_c with integer n. As both the QPN and the Dick effect introduce white frequency noise on the clock frequency, the clock stability shows $\tau^{-1/2}$ dependence on averaging time τ either in ADEV or MDEV but with a factor of 2 difference [9].

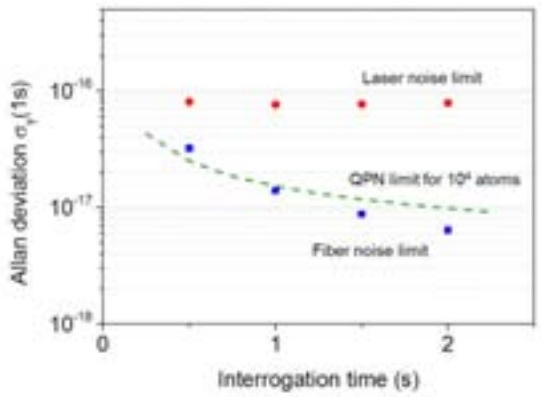

Figure 5. Clock stabilities at an averaging time of 1 s as a function of the interrogation time T_i, assuming a cycle time $T_c = T_i + 0.5$ s. Dick effects are calculated for a laser noise with frequency stability of 10^{-16} (circles) and for the white phase noise of the fiber (squares). Dashed line indicates QPN limit with $N = 10^4$ atoms.

Figure 5 shows the clock stability at $\tau = 1$ s as a function of the interrogation time T_i. Red circles assume a laser nose corresponding to the laser stability of $1\text{x}10^{-16}$ at 0.1 s. It is noteworthy that the clock stability of $0.8\text{x}10^{-16}$ is nearly independent of the interrogation time as frequency noise components lower than $1/T_i$ predominantly determine the Dick effect limit. Blue squares show the Dick effect limit assuming the white phase noise $S_\phi = 1.5\text{x}10^{-4}$ (see Fig. 3(e)) of the fiber at 3 am. As a result of the white phase noise character of the fiber, the longer T_i successfully improves the stability, which reaches $6\text{x}10^{-18}$ for $T_i = 2$ s. It would, therefore, be ideal if we could compare the clocks by rejecting the frequency noise of the clock laser. In addition, in order to set the QPN limit below the Dick effect limit of the fiber, $N = 10^4$ atoms need to be interrogated in a cycle, which is well within the reach of the experiments.

Figure 6 depicts a schematic of the frequency comparison between synchronously operated clocks. A clock laser at a remote site is generated by frequency doubling the repeater laser. Atoms at both sites are thus synchronously interrogated by the local clock laser $f_0(t)$ by taking a time delay τ_d at the remote clock, then the two clocks are independently stabilized by steering AOMs by applying correction frequencies $\delta f_{LO}(t_n)$ and $\delta f_{RE}(t_n+\tau_d)$ for local and remote clocks, respectively, after n-th interrogation period at $t = t_n$. By communicating data series $\delta f_{LO}(t_n)$ and $\delta f_{RE}(t_n+\tau_d)$ via a global area network, the clock shift is obtained as $\Delta\nu(t_n) = \delta f_{RE}(t_n+\tau_d) - \delta f_{LO}(t_n)$. In this scheme, stability of the frequency comparison is solely limited by the Dick effect originating from the residual fiber noise as shown by blue squares in Fig. 5 as long as the QPN (dashed line) is small enough. The stability improves as $\sim 1/T_i$ and can be better than $10^{-17}(\tau/\text{s})^{-1/2}$ for $T_i > 1.5$ s.

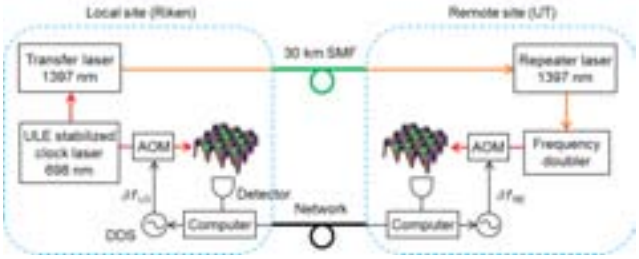

Figure 6. A schematic of frequency comparison of synchronously operated optical lattice clocks via fiber link. A clock laser at the remote site is phase locked to that in the local site. Correction frequencies for AOMs, $\delta f_{LO}(t_n)$ and $\delta f_{RE}(t_n+\tau_d)$, are exchanged via a global area network. Clock shift is given by $\Delta\nu(t_n) = \delta f_{RE}(t_n+\tau_d) - \delta f_{LO}(t_n)$. DDS, direct digital synthesizer.

***Abstract*—We demonstrate optical frequency transfer over an 1840 km underground optical fiber link using a single-span stabilization. To compensate for more than 420 dB of optical attenuation of the light we use twenty Erbium doped fiber amplifiers along the entire link and two additional fiber Brillouin amplifiers. The good passive stability of our fiber link allows us to reach short term instabilities expressed as the modified Allan deviation of 3×10^{-15} for a gate time τ of 1 s reaching 4×10^{-19} in just 100 s. By comparing the sent and transferred frequencies we find no systematic offset within the statistical uncertainty of about 3×10^{-19}. The spectral noise distribution of our fiber link at low Fourier frequencies leads to a τ^{-2} slope in the modified Allan deviation.**

I. Introduction

The development of optical frequency standards [1], [2] raises a demand for transferring highly stable optical signals over continental distances. Such transfer would enable new experiments in fundamental physics such as in quantum electrodynamics or to verify the constancy of fundamental constants. Also applications in navigation or relativistic geodesy will strongly benefit from those stable frequency references. Besides this, the transfer of highly stable optical signals will be mandatory for a future redefinition of the SI-second based on an optical atomic transition. Well-established satellite-based techniques for frequency comparisons and dissemination do not reach the required stability and accuracy to compare optical clocks. In recent years, optical fiber links have been investigated extensively [3]–[7] and are considered as a possible transfer medium for stable optical signals.

II. Experimental Setup

We investigate an optical frequency transfer over an 1840 km fiber link connecting the Max-Planck-Institut für Quantenoptik (MPQ) and the Physikalisch-Technische Bundesanstalt (PTB). The link spans a significant part of Germany and consists of a dedicated fiber which is set up in a loop configuration with sender and receiver being located at MPQ. We use a commercial cw fiber laser emitting at 1542.5 nm that is stabilized to a high-finesse optical reference cavity made from ultra-low expansion (ULE) material to transfer an optical carrier at 194 THz over the fiber link. To overcome the optical attenuation of more than 420 dB of the light in the fiber we use twenty Erbium-doped fiber amplifiers (EDFA) that are distributed equally along the entire link and a fiber Brillouin amplifier (FBA) [8] at each institute. The EDFAs are remotely controlled by using an amplitude modulated 1310 nm communication signal that is sent simultaneously through the same fiber. Additionally, the EDFAs are fully bi-directional and specially designed for low input signal powers. The fiber link is subject to temperature induced optical path length variations and acoustic noise that impose Doppler frequency shifts on the transmitted signals. An interferometric stabilization scheme similar to the one described in [9] is used to detect and compensate for those Doppler shifts.

In contrast to cascading multiple fiber links where each section is phase stabilized separately [4], [10] we investigate a long-distance fiber link by using a single-span stabilization of the whole 1840 km link. While the latter approach comprises a simpler setup as no stable lasers or intermediate regeneration stations have to be installed and operated along the link, the large propagation delay of the light in the fiber yields a strongly reduced bandwidth for the suppression of fiber-induced noise. The round-trip time of the light for the 1840 km loop is close to 18 ms, limiting the noise suppression bandwidth to < 27 Hz.

To characterize the performance of the frequency transfer over the fiber link we generate a heterodyne beat note at MPQ between the sent light and light that has been transferred through the fiber link. To record the beat note we use dead time free frequency counters [11], that can operate in two different modes: the so called Π- and Λ-modes [12]. In contrast to a Π-type counter, a Λ-type counter averages many frequency samples within a gate time, thus noise is effectively suppressed and more accurate data is produced.

III. Results

Figure 1 shows the stability of the transferred frequency after 1840 km of fiber when the link transfer is stabilized. The stability is expressed as the Allan deviation (ADEV) measured with a Π-type counter as well as the modified ADEV measured with a Λ-type counter. Despite the severely reduced servo bandwidth for the suppression of fiber-induced noise, the low intrinsic noise of the fiber link together with active noise cancellation allows for 1-s instabilities of a few parts in 10^{15} and about 4×10^{-19} after 100 s of measurement time. It can be seen that even todays most stable optical clocks can be compared over the distance of 1840 km within a few minutes

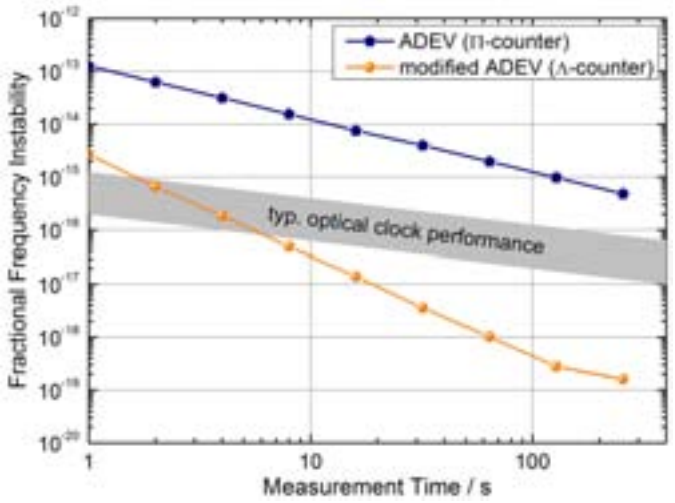

Fig. 1. Fractional frequency instability of the 1840 km fiber link. ADEV measured with a Π-type counter and modified ADEV measured with a Λ-type counter when the link transfer is stabilized. For comparison the instability of state-of-the-art optical clocks is depicted.

of measurement time using our fiber link. The noise of our link peaks at around 15 Hz and is lower at smaller frequencies which leads to a τ^{-2} dependency in the modified ADEV as shown in Figure 1. We attribute the noise maximum around 15 Hz to building and ground vibrations.

To assess potential systematic frequency shifts, we analyzed the mean deviation of the transferred frequency from the input frequency, and found agreement within the statistical uncertainty of 2.6×10^{-19}. The results illustrate that for a remote comparison of state-of-the-art optical clocks, the short-term instability contribution of the stabilized $\approx$ 2000 km link is negligible within one minute of measurement time.

IV. Conclusion

We demonstrated optical frequency transfer along an 1840 km optical fiber link with an instability of 2.7×10^{-15} at 1 s reaching 4×10^{-19} after 100 s of measurement time. The residual uncertainty exceeds the requirements for a comparison of todays most stable clocks by more than one order of magnitude. Our fiber link is provided by a commercial telecommunication supplier and passes several metropolitan areas and computing centers. Despite these environmental conditions active noise cancellation and carefully adjusted in-line amplification can yet provide high-performance frequency transfer over continental distances. We demonstrate that remote comparisons of state-of-the-art optical clocks are possible even if the clocks are separated by nearly 2000 kilometers. This work can be seen as a testbed for a European wide fiber link network to connect metrology institutes across Europe. The ability to compare those modern optical frequency standards opens a variety of applications, including relativistic geodesy [13], tests of the constancy of fundamental constants and quantum electrodynamics.

***Abstract*— This work describes the use of Distributed optical Raman Amplification for the realization of coherent optical fiber links for frequency dissemination. The main advantages of this technique are high gain and feasibility of long fiber spans with a simple apparatus, without degrading the link stability.**

Keywords-fiber links, optical amplifiers, Raman amplification

I. INTRODUCTION

In recent years, phase-compensated optical links proved to be the most performing technique to disseminate optical frequencies on a continental scale [1,2]. Most National Metrology Institutes are thus cooperating to realize a pan-European fiber network, that will enable optical clocks comparisons at unprecedented levels of accuracy and stability. The ultrastable frequency transfer via optical fiber requires that the fiber phase noise is compensated. This is done by reflecting a portion of the transferred light from the user end back to the transmitter end, and by comparing it to the original light. The double pass allows to cancel the phase noise accumulated along the fiber, provided that the optical path is exactly the same in both directions.

Dedicated amplification systems are thus needed, that must be fully bidirectional and symmetrical in the two directions. Bidirectional Erbium Doped Fiber Amplifiers are typically used, but their gain is limited by the back-reflections along the path, that may lead the amplifier to oscillate and may limit the achievable gain to about 20 dB. Distributed amplification is quite promising from this point of view, and offers several advantages compared to BEDFA. Distributed Brillouin Amplifiers (DBA) have recently been demonstrated and fruitfully used in coherent optical links [3]. We demonstrate that Distributed Raman Amplification (DRA) is a reliable technique as well: it does not degrade the transfer of the optical carrier at the 10^{-19} level of stability, and allows to bridge hauls of up to 60 dB losses without intermediate stations [4].

Raman amplification is based on the power transfer between two optical beams, the pump and the signal, through stimulated scattering of light with optical phonons [5]. Since the power transfer is distributed along the fiber, with an effective length of about 20 km, DRA can provide a very high gain without the onset of lasing or oscillations, even for high pump powers [6]. The gain is maximum when the signal is downshifted ~13.2 THz from the pump light, and the bandwidth is several THz wide around the gain peak. DRA requires pump power levels on the order of ~1 W, that is rather high, especially if compared to those required in DBA (~10 mW). On the other hand, DRA is intrinsically bidirectional, i.e. it amplifies signals that propagate in the opposite or in the same direction as the pump (hereafter indicated as counter- and co-pumped), whilst DBA only amplifies counter-propagating signals. Also, thanks to the large gain bandwidth, DRA does not require a frequency control of the pump laser to ensure a stable gain. Thus, DRA technology could help to simplify long haul optical links and to increase the reliability of the whole infrastructure.

In this work, we propose an analysis of the gain, the optical signal to noise ratio (OSNR) and the phase noise of the amplified optical carrier, and report on the use of DRA in a coherent optical link based on 200 km of fiber spools, both in a counter-pumped and in a co-pumped scheme.

II. THE EXPERIMENT

A. Optical Instrumentation and Experimental Apparatus

The laboratory test-bed we used is sketched in Fig. 1. An ultrastable laser radiation at 1542 nm is generated by locking a fiber laser through the Pound-Drever-Hall technique to a Fabry-Perot high finesse (120,000) cavity made of Corning Ultra Low Expansion (ULE) glass. The resulting laser linewidth is smaller than 30 Hz (details in [7]), with OSNR~56 dB in 0.1 nm resolution bandwidth. Light is coupled into a standard SMF-28 single mode fiber, with a total length of up to 200 km. The light power at fiber input is 0.5 mW; total losses due to fiber and connectors amount to ~45 dB. To

achieve phase noise cancellation, two acousto-optic modulators (AOM) are employed. AOM1 is placed before the fiber link and used as actuator to compensate the fiber phase noise. AOM2 is placed after the fiber link to shift the back-reflected radiation and allows to distinguish the real signal from stray reflections. Photodiode PD1 detects the fiber noise from an interferometric scheme [7] and a phase-locked-loop (PLL) feeds AOM1 with the correction signal. The bandwidth of the PLL loop filter is 20 kHz, and a minimum round-trip optical signal power of at least -70 dBm has to combine to the original light on PD1 to phase-lock the optical carrier. Photodiode PD2 is used to compare the phase noise of the radiation transferred through the fiber to that injected at the input.

We tested both co-and counter-pumped DRA, by coupling the pump light into the fiber trough wavelength-division multiplexers WDM1 or WDM2 respectively. Two different pump lasers at 1450 nm were used. The first is a depolarized fiber Raman laser (FRL) delivering up to ~800 mW into the fiber (OSNR >50 dB in 0.1 nm resolution bandwidth). The other Fabry-Pérot laser (FPL) depolarized pump is composed of two polarization-multiplexed Fabry-Perot diode lasers at the same wavelength, providing ~260 mW (OSNR ~58 dB in 0.1 nm resolution bandwidth) at the fiber input [8]. The depolarization of the pump laser is mandatory, as the Raman gain is maximum for co-polarized pump and signal, whilst it is minimum when pump and signal are orthogonally polarized. Therefore, care must be devoted to minimize gain fluctuations associated to polarization mode dispersion in the fiber.

Also, to avoid the transfer of Relative Intensity Noise (RIN) from pump to signal, we used the higher-RIN (~-110 dB/Hz) FRL pump at frequencies lower than 10 MHz) for counter-pumping, and the lower-RIN (~-140 dB/Hz) FPL for co-pumping. Indeed, counter-pumped DRA is known to be less affected by pump-to-signal RIN transfer than co-pumped DRA [9], since the RIN transfer is averaged out by the large difference in the group velocities of counter-propagating pump and signal. Being the signal RIN level <-141 dB/Hz, Raman amplification leads to an expected added signal RIN of ~-134.7 dB/Hz in co-pumping, and ~ -95.3 dB/Hz in counter-pumping, whose cross-talk values are extremely low when integrated over the narrow signal bandwidth (30 Hz).

B. Measurements and Discussion

We initially evaluated the DRA impact with a counter-pump scheme. On-off gain, OSNR and the phase noise of the amplified radiation have been measured by performing on PD2 the heterodyne beatnote between the signal travelling along the link and the light from the short reference arm. Fig. 2 (circles) shows the measured gain after 200 km propagation, versus the fiber-coupled pump power. The gain increases with pump power and attains the maximum value of 23 dB, limited by the effective power available with the FRL (800 mW). The measured OSNR is 106 dB/Hz, and is limited by the amplified spontaneous emission at pump powers higher than 600 mW, whilst it is degraded at lower pump powers due to the electrical noise of PD2.

This work has been partly funded by Compagnia di San Paolo, by the Italian Ministry of Research, contract PRIN09, and by Ente Cassa di Risparmio di Firenze.

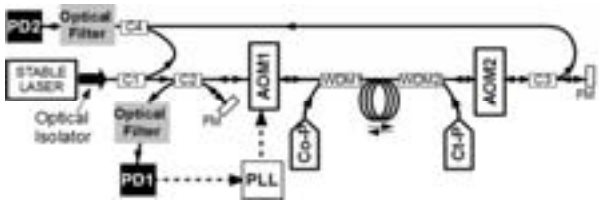

Fig. 1. Set up of the coherent fiber link with DRA. PD Photodiodes, C Couplers, FM Faraday Mirrors, WDM Wavelength Division Multiplexers, Co-P Co-propagating Pump, Ct-P Counter-propagating Pump, AOM Acousto-Optic Modulators, PLL Phase Locked Loop.

To investigate the maximum link length achievable without intermediate stations, the FPL as well was coupled into the fiber as a co-pump. The overall gain then increased to 32 dB, equivalent to a single stage DRA with a 1 W single counter-pump [8], limited by the power available with our FPL. The double stage pump allows to phase-compensate a link with up to 60 dB losses in a single span with our setup.

To test the flexibility of the amplifiers chain, we tried the high-power FRL as co-pump and the low-power FPL as counter-pump. We measured the co-propagating signal gain, as a function of the pump power while keeping a constant counter-pump gain of 9 dB, and with an input signal of ~0.5 mW. At high co-pump power levels, we observed degrading effects on the signal, and a strong gain reduction, as shown in Fig. 2 (squares). This is expected to be due to the power level of the amplified signal, that increases beyond the SBS threshold in the co-pumped scheme. When the gain reaches ~13 dB, the amplified signal achieves 10 mW, i.e. the SBS threshold. The net gain is then reduced by almost 10 dB with respect to the counter-pump scheme. This did not happen in the previous scheme, in which the signal amplified by the counter-pumped FRL was much weaker due to the fiber losses. As a result, in that scheme, the amplified signal never exceeded the SBS threshold [5]. Such detrimental effects can be reduced by a careful design of the amplifier chain whenever intermediate stations are required along the path.

Figure 3 shows the phase noise power spectral density $S_\phi(f)$ of a 100 km compensated link without (dashed grey line) and

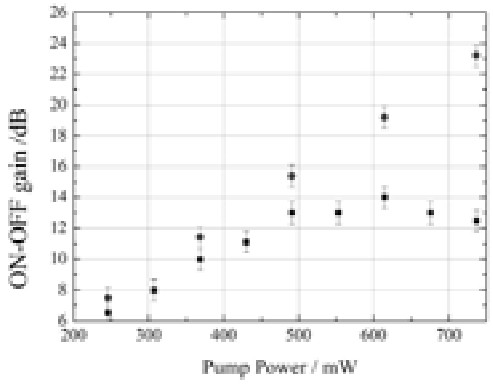

Fig. 2. Raman gain versus pump power in an optimized counter-pumped scheme (circles) and in a not optimized co-pumped scheme (squares).

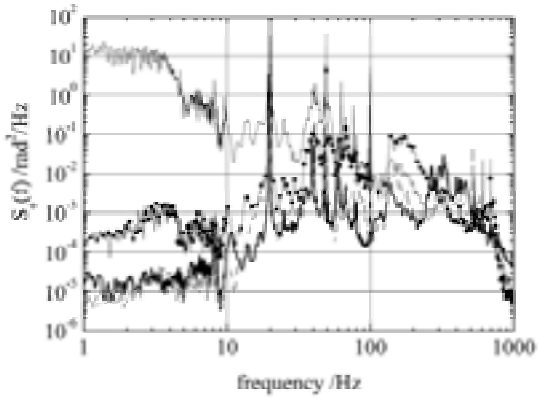

Fig. 3. Phase noise density $S_\phi(f)$ of the free running (thin black line) and compensated link (black line, filled circles) at 200 km, and $S_\phi(f)$ of a 100 km link without amplification (dashed grey line) and with an amplification of 22 dB (thick black line).

with (solid black line) an optical amplification of 22 dB. The spikes observed at frequencies within the link servo bandwidth (500 Hz) are mainly due to acoustic noise on the spooled fiber. The residual noise of the compensated link agrees with the expected limit due to the fiber delay [10], and there is no evidence of phase noise degradation due to DRA. Fig. 3 also shows the phase noise power spectral density of the free-running link at 200 km (thin black line) and of the compensated link (black line, filled circles). Again, the noise of the 200 km agreed with the expectations, considering the phase noise of the free running link and the fiber delay [10].

Link stability over long averaging times was calculated by counting the beatnote on PD2 with a high resolution Λ-type counter [11]. The data frequency instability $\sigma_\Lambda(\tau)$ obtained by processing data from Λ-counters can be converted into the Modified Allan deviation for common phase noises [11]. Fig. 4 shows $\sigma_\Lambda(\tau)$ of the link at 100 km (circles), at 200 km (squares) and of the interferometer without fiber spools (diamonds, grey line). Up to 20 s the link noise is dominant,

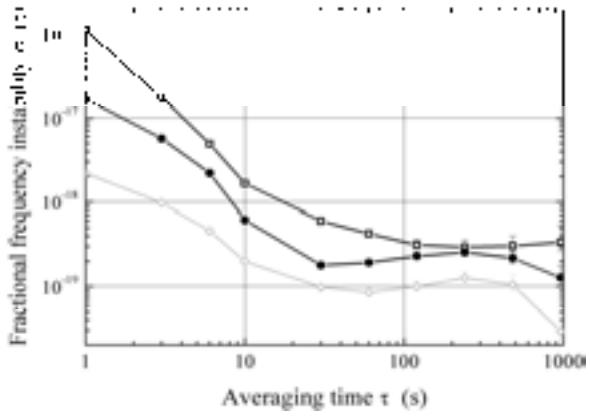

Fig. 4. Fiber link frequency instability on a 100 km link(filled circles), on the 200 km link using ROA (empty squares), and the interferometer noise floor (grey line, empty diamonds).

whilst at longer times the stability reaches a floor of $\sigma_\Lambda(\tau) \sim 3 \cdot 10^{-19}$. We attribute this limit to random, not reciprocal phase variations related to the fiber birefringence. Nevertheless, these results show that DRA enables coherent amplification in phase-compensated optical links.

III. Conclusions and Outlooks

We demonstrate that DRA is suitable for amplification in phase coherent optical links, allowing to bridge hauls of 200 km with a single fiber span, with a frequency instability of $3 \cdot 10^{-19}$ at 100-1000 s. DRA offers several advantages in terms of link maintenance and reliability with respect to discrete amplification techniques, providing a high gain with a simple apparatus. However, care should be devoted to the design of links involving both counter- and co-pumping, to avoid nonlinearities affecting the ultimate performances of the amplifier. We plan to investigate the use of DRA on a 650 km optical link that is under development between INRIM in Turin and LENS-UNIFI in Firenze, Italy [12]. DRA could improve the present design, reducing the number of amplifiers, as nine BEDFA amplifiers are used at the moment.

sven-christian.ebenhag@sp.se

***Abstract*—SP Technical Research Institute of Sweden has previously presented results with a two color one- way method. This method is an alternative method to two-way time and frequency transfer that is useful if there are unknown asymmetries in the connection. The method is possible to use in existing infrastructure and is able to coexist with data channels for example in WDM systems, which make it possible to broadcast to multiple users and enables the user to be anonymous to the time or frequency transfer.**

This paper will present the results from the analysis when implementing the technique in an urban commercial optical fiber data communication WDM network between two clock labs in Sweden connecting two cesium clocks to each other for frequency comparison. The evaluation is performed with two wavelengths 8 nm apart on 6 km of installed fiber in an urban city network.

The transmitter and the receiver are installed in an electromagnetically shielded room several meters below ground, and the fiber runs to a building at a distance of 3 km, and then back again. The comparison will be within the laboratory, eliminating any errors from a reference system. Results and conclusion from this evaluation reveals the propagation delay variations in the propagation distance and will display the need of compensation for these variations

Keywords — Optical fiber network, optical fiber, frequency transfer, two color.

I. INTRODUCTION

The last decade has the need for high accuracy frequency and time transfer has significantly increased and due to that has the users with the most demanding requirements for comparisons of remotely located frequency and time standards been investigating the use of optical fibers.

Recent work in the field of optical frequency transfer shows results with potential accuracies below 10^{-17} obtained in less than a day, demonstrating that the technique is useful for the comparison of optical frequency standards [1, 2].

Several of the optical frequency transfer methods focus on two-way frequency transfer, whether it uses the optical phase or intensity modulation at microwave frequencies, dark fiber, or wavelength division multiplexing channels [1 - 14]. When two-way frequency transfer methods are used, there is a presumption that the signal delays are equivalent (symmetrical) in both directions, but in several cases the two transmission paths are asymmetrical and this introduces a varying error. Solutions that use bidirectional signals in a single fiber results in a close to perfect match, but other limitations still occur [11]. For a solution utilizing one-way frequency transfer, it is therefore beneficial if the delay variations can be sufficiently compensated. Recent results have been presented using either a fiber based pre-compensation [15 - 17], or an electronic post-compensation [18]. The pre-compensation uses a temperature controlled fiber as a part of the transmission and a feedback signal that adjusts the temperature to keep the phase difference constant between two propagated frequencies. The electronic post-compensation utilizes a model of the fiber to translate a phase difference between the two wavelengths into the corresponding delay in the fiber, and then adjusts an in-line delay unit accordingly.

The results section of this paper presents three different setups of measurement and the first presents the frequency stability of measurements using signals with two wavelengths separated by 8 nm propagated through a 3-km fiber in a commercial metropolitan fiber network. The frequency stability is presented for transmission time using both compensated and uncompensated optical fiber. The second part presents measurements of the varying transmission time due to varying ambient temperature, and for this setup the 3 km optical fiber was looped to a distance of 6 km, which includes that the transmitter and receiver are located at the same place in an electromagnetically shielded room several meters below ground. The last measurements of the result section present measurements performed in a controlled laboratory environment for evaluation of error sources.

A Cesium beam frequency standards were used as primary source to evaluate the system.

II. Method Description

The successful distribution of a proposed phase stabilized frequency over a one-way fiber optic connection relies on the unambiguous correlation between the dispersion and the group velocity in a single mode optical fiber. The variation in dispersion, as is detectable at the receiver, can be transformed to a corresponding change in delay through the fiber. When distance increases, and especially when a significant amount of the transmission media is outdoors, the temperature variations will affect the propagation properties of the media.

Polarization mode dispersion and polarization dependent losses are small and the influence is minimized when using a polarization scrambler. Furthermore, the waveguide dispersion is negligible in standard single mode fiber, even though this also could be added if implemented in networks of dispersion shifted fiber.

The proposed method to solve for constant and varying transfer time (τ and $\tau_{det}(t)$) is to transmit two wavelengths through the same fiber and then detect the propagation delay differences between them [19 - 21]. The difference is then applied as a correction term for the delay variations in $\tau_{det}(t)$.

Furthermore, the proposed method operates within the C-band of commercial Dense Wavelength Division Multiplexing (DWDM) networks. The motive for using the C-band is that the commonly used Erbium Doped Fiber Amplifier (EDFA) has a flat gain spectrum between 1530 nm and 1560 nm that includes the C-band frequencies. The effect is larger when the two transmitted wavelength are far apart, while the availability to access channels in bright DWDM-fibers improves when the spacing is narrow.

In a fully operational solution, the time or frequency from the master clock can be distributed to a network of slave clocks, with an uncertainty smaller than what would be the case if only a single wavelength was transmitted.

The feasibility of this transfer technique is supported by previous presented experimental results [16 - 18].

III. Frequency transfer setup

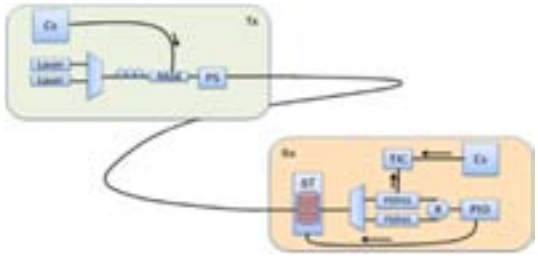

Fig. 1. Frequency transfer setup. The transmitter includes a Cesium standard (Cs), two tunable lasers, a WDM multiplexer, a Mach-Zehnder optical modulator (Mod) which is preceded by a polarization controller (three circles) and followed by a polarization scrambler (PS). At the receiving end, *ΔT* illustrates a temperature controlled fiber spool, followed by a WDM demultiplexer, photo-detection, filter, amplification and splitting (PDFAS). The two outputs are mixed to achieve a difference signal for the PID regulator (PID) which controls the temperature box. The output characterizes the local Cs utilizing a time interval counter (TIC).

This paper is based on a previous experiment with the following setup presented in Fig. 1 and further in the text.

Two tunable lasers emitting light at different wavelengths 8 nm apart (1551 nm and 1559 nm) are combined in a WDM multiplexer and modulated by a 10 MHz sinusoidal signal from the Cesium clock (Cs). The modulated light is transmitted through a polarization scrambler, which varies the output polarization state controlled by four uncorrelated frequencies. The 3 km fiber between the transmitter and receiver is installed in tubing a few meters below city streets. At the receiver, the light is propagated through a 500 m standard single mode fiber (SMF) placed in a thermally controlled box. At the output of this fiber, the light is split in a WDM demultiplexer and connected to P-I-N photodiodes for conversion to electrical signals. These signals are connected in parallel paths at equal length and attenuation to amplifiers and power splitters (PDFAS), and finally combined in a mixer to generate phase-difference detection (PDD) signal.

If the fiber in the temperature controlled box has the same characteristics as the fiber used in the transmission, the phase of the transferred signal is stable when the PDD signal is constant. The PDD signal is therefore connected to a proportional-integral-derivative (PID) regulator which controls the temperature of the box.

Both the master oscillator and slave oscillator are cesium beam frequency standards with high-performance beam tubes. The PDD signal emits a phase corresponding to the difference in the arrival time of the two signals.

To further evaluate the sources of error and the need for transfer time compensation the fiber was looped to begin and end in the same place with a total distance of 6 km and the transfer time was measured continuously. The results are presented in Fig.3.

Since the experiment is based on a field environment a similar setup was mounted in a controlled environment with a few minor changes that the distance was changed to 16 km of which 8 km located outdoors and 8 km in a temperature cabinet and the frequency was increased to 100 MHz, all this to further evaluate the error sources.

IV. Results

The frequency stabilities of the previous transfers in an urban fiber network, as estimated with the Overlapping Allan deviation, is shown in Fig. 2.

Time interval measurements for the compensated and uncompensated frequency transmissions are assembled with an existing multi-channel TIC with the measurement interval of 1 s at the receiver end. External temperature influence of an optical fiber is a slower process than 1 s, which means that if the time between measurements is in the 60 s range is it enough to create good propagation variation compensations.

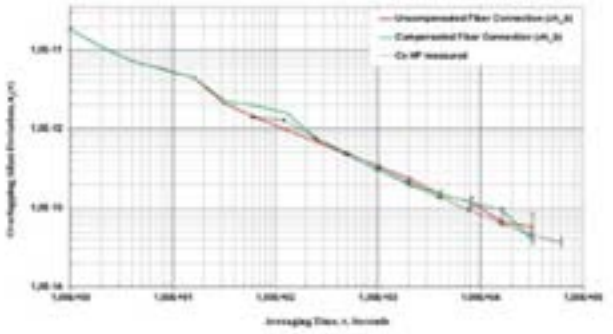

Fig. 2. The frequency stability of the uncompensated frequency transfer utilizing fiber is presented in red and the real-time compensated frequency transfer utilizing fiber is presented in green. The black Overlapping Allan Deviation line presents data sampled every 60 s between two high performance Cesium standards of the same type as used in the experiment.

From the Overlapping Allan deviation graph shown in Fig. 2, it is evident that improving the stability of the compensated fiber connection is small. A small degradation at an averaging period of 100 s is expected, caused by the bandwidth of the feedback loop. The frequency stability of the link is approximately 3×10^{-13} for an average period of about 1000 s. The main improvement is expected over 10 000 s, which is slightly indicated in Fig. 2, but measurements over a longer period will be necessary to prove the full performance of the technique and would also serve the same purpose as more stable clocks to some extent.

The fiber network is placed in tubes below the surface which makes the network less affected by temperature changes but nevertheless is it still affected.

For an evaluation of the temperature impact on the urban fiber network the transit time was measured through a 6 km roundtrip fiber path and is shown in Fig. 3. The used frequency is measured and distributed through a frequency distribution amplifier (FDA) and its impact on the measurement is also presented in Fig. 3.

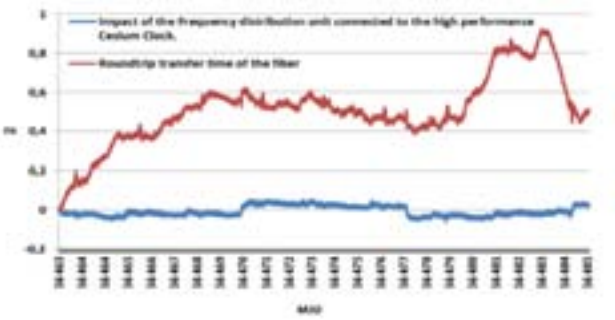

Fig. 3. In red the varying transfer time through 6 km of fiber in tubing below ground during 22 days in June and July is presented and as can be seen it does vary more than 900 ps. For these measurements a FDA is used and it s impact on the measurements is shown in blue. The impact of the FDA regarding the measurement is neglible. The small steps in the FDA data is due to change of climate control of the room. There are redundant climate control and every 7th day master system is changed.

To evaluate most of the error sources an equal system was setup in a controlled environment with the exception that the modulation frequency and distance was increased. In this case the distance was 16 km of which 8 km was located outdoors and the other 8 km was placed in the Peltier regulated temperature chamber. The modulation frequency was increased to 100 MHz.

In this setup the signal was optical split after 8 km to be used as reference of the outdoor temperature impact of the fiber. Transfer time measurements of the compensated fiber and the reference fiber are presented in Fig. 4.

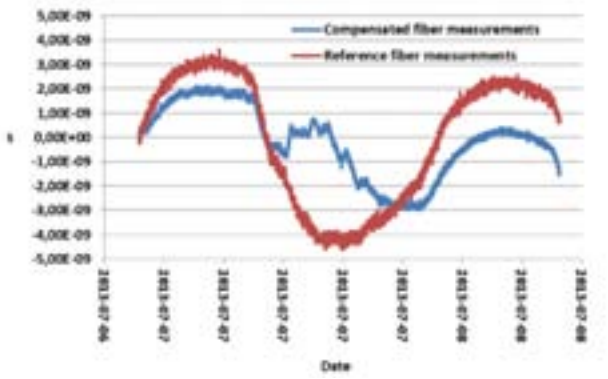

Fig. 4. In red is the varying transfer time through 8 km of fiber located in a box oudoors during 1.5 day and as can be seen it does vary more than 7 ns. In blue are the same measurements performed but through the whole compensated distance of 16 km and as can be seen the variation is reduced. The reason for the short dataset is that the used temperature chamber is limited to work in a region of ± 10˚C from it initial value which limits the compensation algorithm and measurements for proof where only performed. The slightly less short term noise for the compensated measurements are to some extemt due to the use of filtered Avalanche Photo Diodes for conversion between optical and electrical domain instead of P-I-N photodides.

The stability of the frequency for both the reference and the compensated are presented in Fig. 5.

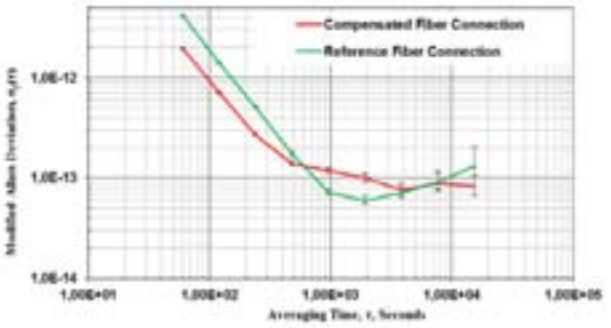

Fig. 5. The data from Fig. 4 are used to plot he frequency stability both the reference and compensated measurements. It is a short dataset, but still do the the compensated fiber (red) perform better than the uncompensated (green) for short term but perform worse for average times between 600 – 4000 s.The data set is too short to be able to perform a fair evaluation of the daily variations, but idicates that with a good temperature regulation the system should be sufficiently stable to support a stable output phase for clocks that perform better than cesium beam frequency standards.

V. CONCLUSION

Measurements in urban optical fiber network as well as in controlled environment are performed. One major conclusion is that even though your fiber is placed in tubing below the ground it is still affected by temperature changes (Fig. 3). For short distances as 3-6 km the transfer time is varying in the region of 900ps during three weeks.

In conclusion, the experiment has been successful and has shown that the compensated one-way way fiber solution can be implemented in an existing metropolitan data network. Future improvements are related to size-reduction of the hardware and increased reliability of the transmitter, receiver and temperature tuning.

***Abstract*—We demonstrate a fiber-based multiple-access ultra-stable frequency dissemination scheme for both radio frequency modulated on the optical carrier and optical frequency. Relative frequency stabilities of 7×10^{-14}/s and 5×10^{-18}/day for radio frequency, 3×10^{-16}/s and $4 \times 10^{-18}/10^4$s for optical frequency have been obtained, respectively. Using this method, highly synchronized radio-frequency modulation signal or the optical signal itself can be regenerated along the entire fiber link and it is expected to have potential applications.**

I. Introduction

Along with the significant progress of modern atomic frequency standards in recent years[1], the transfer and synchronization of ultra-stable frequency signals is required by more and more applications. Due to its properties of low attenuation, high reliability and continuous availability, frequency dissemination via fiber link has been actively studied[2]. Different schemes, such as fiber based radio frequency (RF) dissemination[3], [4], optical frequency dissemination[5], [6], [7], and even optical frequency comb signal dissemination[8], [9] have been proposed and demonstrated, respectively. All of these schemes have much higher dissemination stability than that of the conventional frequency dissemination via satellite link, which has a limited stability of 10^{-15}/day[10], [11]. Ultra-long distance frequency dissemination has also been demonstrated by cascaded frequency dissemination method[7], [12], [13]. However, at present, almost all of the frequency dissemination fiber links are built between precision laboratories and used for atomic clock comparisons[14]. Most of the application areas, such as distributed synthetic aperture radar[15], very-long-baseline interferometry (VLBI)[16], and particle accelerators[17], still use satellite links to synchronize time and frequency. It is mainly due to the frequency accessing limitation of the fiber link. For satellite link, it can disseminate time and frequency signal to cover essentially the entire globe; for fiber link, the point to point frequency dissemination protocol limits its coverage area.

In this paper, we demonstrate a multiple-access dissemination scheme which can reproduce the stably disseminated radio or optical frequency signal at arbitrary node along the entire fiber pathway. For the radio frequency dissemination, we build up a time and frequency dissemination system via a 80 km urban telecommunication fiber network between Tsinghua University (THU) and the National Institute of Metrology (NIM)[4]. We reproduce the disseminated 9.1GHz modulation signal at an arbitrary node[18]. For the optical frequency, Grosche proposed a technique for multiple access optical frequency dissemination in 2010[19]. However, the user at an arbitrary node along the pathway needs a highly stable laser source of same wavelength to reproduce the disseminated signal, which makes the system costly and technically complex. We propose a more convenient and efficient idea to solve this problem[20]. Relative frequency stabilities of 7×10^{-14}/s and 5×10^{-18}/day for radio frequency, 3×10^{-16}/s and $4 \times 10^{-18}/10^4$s for optical frequency have been obtained, respectively. Optical frequency transfer can provide better stability while the RF dissemination is relatively simple for practical applications. Using this method, we can regenerate the highly synchronized radio-frequency modulation signal or the optical signal itself along the entire fiber link and it is expected to have potential applications such as a large area branching fiber network for frequency synchronization.

II. Multiple-access radio frequency dissemination

The schematic diagram of the multiple-access radio frequency dissemination system based on 80 km urban fiber link is shown in Figure 1. During the performance test, for the convenience of phase difference measurement, we connected two parallel 40 km fiber links at the NIM site. Consequently, the local and remote sites of the 80 km fiber link are both placed in the same lab at THU. The experimental setup is almost the same as that of [4], except that a 3 km fiber spool is connected to the 80 km urban fiber link at the local site, which is used to demonstrate the multiple-access frequency dissemination. A 9.1 GHz frequency signal $V_r = cos(\omega t + \phi_r)$ (without considering its amplitude) from an oscillator referenced to an atomic clock is used as the reference frequency signal. The phase noise compensation system is composed of a voltage controlled crystal oscillator (VCXO), electro-absorption modulated 1547 nm diode laser, erbium-doped fiber amplifiers (EDFA), optical circulator, fast photo-detector, and a feedback locking loop. It generates a 9.1 GHz phase-compensated frequency signal $V_0 = cos(\omega t + \phi_0)$ and modulates the amplitude of the 1547 nm laser carrier. Through round-trip phase noise detection and active phase noise compensation, the phase of the transmitted signal, $\phi_0(t)$,

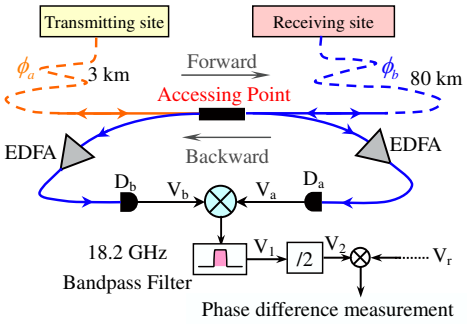

Fig. 1. Schematic diagram of the multiple-access RF dissemination system.

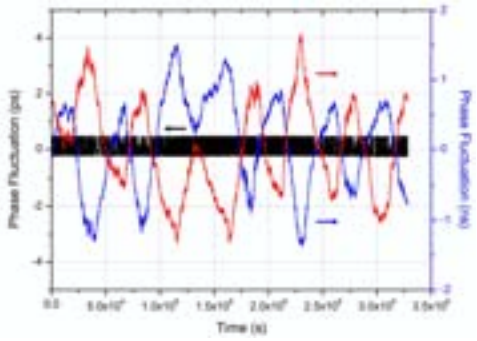

Fig. 2. Measured relative phase fluctuations of the reproduced frequency signals at an arbitrary accessing node of the fiber link.

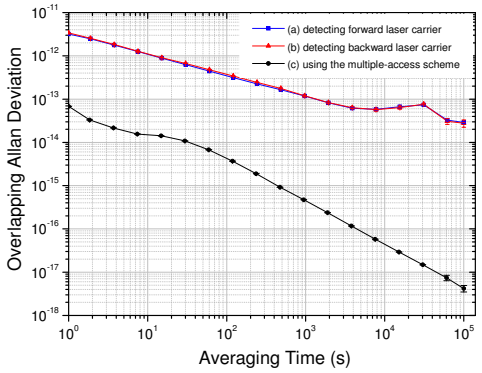

Fig. 3. Measured relative frequency stability of the reproduced frequency signal at an arbitrary accessing node of the fiber link. (a) forward signal; (b) backward signal; and (c) signal obtained using the multiple-access rf dissemination method.

will follow the phase offset of the reference frequency signal ϕ_r, together with the phase fluctuation $\phi_p(t)$ introduced during transmission in the 83 km fiber link, giving the relation,

$$\phi_0 = \phi_r - \phi_p. \quad (1)$$

Here, to maintain consistency with the published papers[3], [4] and for the convenience of presentation, we neglect the time item of phase part. Consequently, the received frequency signal at the receiving (remote) site becomes $V_1 = cos(\omega t + \phi_0 + \phi_p) = V_1 cos(\omega t + \phi_r)$, which is phase-locked to that of the reference signal, V_r.

From the principle of the applied phase noise compensation scheme, the highly stable 9.1 GHz microwave signal can only be reproduced at the "remote" end without any degradation in frequency stability. We take the connecting point (marked by a red star in Fig. 1) of a 3 km fiber spool and the 80 km urban fiber link as the example of an arbitrary accessing node. One can splice a 2×2 fiber coupler to couple out the 1547 nm laser carrier transferring forward and backward in the fiber link. The frequency signal modulated on the laser carrier can be detected and reproduced by two fast photo-detectors D_a and D_b, and can be expressed as $V_a = cos(\omega t + \phi_0 + \phi_a)$, and $V_b = cos(\omega t + \phi_0 + \phi_a + 2\phi_b)$, respectively. Here, ϕ_a and ϕ_b are the phase fluctuations induced by transits in the 3 km fiber spool and the 80 km urban fiber link, respectively. They have the relationship of $\phi_a + \phi_b = \phi_p$. When the round-trip phase noise compensation loop is closed, considering Eq. (1), the two received signals can be written as:

$$V_a = cos(\omega t + \phi_0 + \phi_p - \phi_b) = cos(\omega t + \phi_r - \phi_b) \quad (2)$$

$$V_b = cos(\omega t + \phi_0 + \phi_p + \phi_b) = cos(\omega t + \phi_r + \phi_b). \quad (3)$$

They both carry the phase fluctuation ϕ_b of the 80 km fiber link which is located between the accessing node and the remote end.

To demonstrate it, we measure the relative phase fluctuations and frequency stability of the intermediate signals V_a and V_b compared with the frequency reference V_r, simultaneously. The results are shown in Fig. 2 and Fig. 3. From Fig. 2, we can see that their phase fluctuation terms are complementary to each other. Therefore, a summing operation on phase terms of these two rf signals will cancel out this fluctuation. From Fig. 2, we can see that they show very similar behaviors and stabilities of 3.5×10^{-12}/s and 3×10^{-14}/day, respectively. Consequently, if we directly access the dissemination channel at a given point in the fiber link, even if using the round-trip phase noise compensation method, the reproduced frequency signal will carry the phase fluctuations of the remainder of the fiber link. That is to say, the closer to the local site, the more noise it will have gathered. For this reason, we choose a node very close to the sending site, and therefore having maximal noise, as a typical case for a demonstration. Figure 1 shows the schematic diagram of the multiple-access rf dissemination scheme we implemented. The out-coupled 1547 nm laser carriers received from both directions are amplified by two EDFAs and detected by two fast photo detectors D_a and D_b, respectively. Two intermediate signals V_a and V_b, with power of 5 dBm and 10 dBm respectively, are then mixed by a frequency mixer and filtered by a 18.2 GHz bandpass filter. An 18.2 GHz (2ω) frequency signal

$$V_2 = cos(2\omega t + 2\phi_r), \quad (4)$$

is generated. It does not carry the phase fluctuation term ϕ_b and is phase-locked to the frequency reference V_r. Using a divide-by-2 pre-scaling frequency divider, V_2 is down-converted to

$$V_3 = cos(\omega t + \phi_r). \quad (5)$$

This way, an rf signal V_3 whose phase and frequency are locked to the reference signal V_r, is reproduced at the accessing node. We measure the relative frequency stability of V_3 compared to V_r (with 3Hz effective measurement bandwidth), and the relative frequency stabilities of 7×10^{-14}/s and 5×10^{-18}/day have been obtained (Fig. 3). We emphasize that there are several orders of magnitude in improvement on

the relative stability compared to those of directly obtained frequency signals V_a and V_b. Furthermore, we note that a 10^{-18}/day fiber-based, multiple-access rf dissemination system can fulfill the needs of essentially any practical applications of present time.

III. Multiple-Access Optical Frequency Dissemination

Figure 4 shows the schematic diagram of the fiber based multiple-access optical frequency dissemination experiment. The whole system is separated into three parts, which are the local site, remote site and download site, respectively. For the convenience of phase stability measurement, they are located in the same lab. The arbitrary frequency accessing point is chosen as being 1.5 km away from the sending site. As a performance test, a commercial 1550nm laser module (RIO ORION Laser Module) is used as the reference resource at the local site. Its frequency signal can be expressed as $E_0 = V_0 cos(\omega t + \phi_0)$. After passing a circulator and an 80MHz fiber-couple acoustic optical modulator AOM1 (+1st order Bragg shift), the 10 mW laser signal is coupled into the fiber link. A phase fluctuation ϕ_p of the signal E_0 will be induced during its propagation. At the remote site, another 80MHz AOM2 (+1st order Bragg shift) is employed as a frequency shifter for optical beating at the download site. The received signal E_1 at the remote site can be expressed as

$$E_1 = V_1 cos(\omega t + \Omega_1 t + \Omega_2 t + \phi_0 + \phi_p + \phi_{AOM1}). \quad (6)$$

Here, $\Omega_1 \approx \Omega_2 \approx 2\pi\times 80$ MHz are the frequency offsets induced by AOM1 and AOM2, ϕ_{AOM1} is the correction phase modulated on AOM1, and the fixed phase shift induced by AOM2 is neglected. To compensate the phase fluctuations induced during fiber dissemination, at remote site, a fraction of the received optical signal is sent back (via an optical circulator) to beat with E_0 at the local site. The round-trip signal E_2 can be expressed as

$$E_2 = V_2 cos(\omega t + 2\Omega_1 t + 2\Omega_2 t + \phi_0 + 2\phi_p + 2\phi_{AOM1}), \quad (7)$$

and the beating signal is proportional to $cos(2\Omega_1 t + 2\Omega_2 t + 2\phi_p + 2\phi_{AOM1})$. The beating signal is processed by the phase noise compensation system, and the generated error signal is fed to control the phase of AOM1. It is the same way as that of conventional optical-stabilization techniques[21]. Once the phase-locking loop is closed, without loss of generality, we can get:

$$\phi_p + \phi_{AOM1} = 0. \quad (8)$$

Consequently, the phase noise compensation is accomplished and the received frequency signal E_1 is phase locked to E_0 at the local site. To overcome the phase fluctuations induced by the single trip elements in local and remote sites, these elements have been temperature controlled.

In order to download the disseminated frequency signal at an arbitrary accessing point, using a 2×2 fiber coupler (80/20 ratio), we can easily couple out the forward and backward propagating optical signal from the fiber link. Due to the existence of AOM2, there is a frequency difference of 160 MHz between the two signals. Consequently, they can be

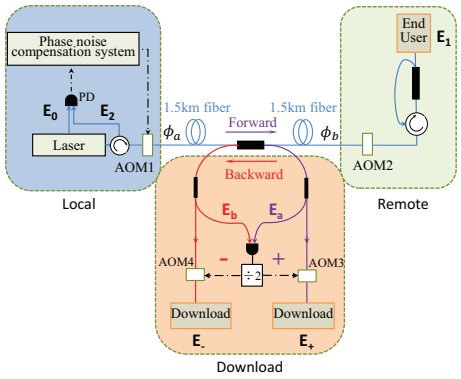

Fig. 4. Schematic diagram of the fiber based multiple-access optical frequency dissemination system.

expressed as

$$\begin{aligned} E_a &= V_a cos(\omega t + \Omega_1 t + \phi_0 + \phi_a + \phi_{AOM1}) \\ &= V_a cos(\omega t + \Omega_1 t + \phi_0 - \phi_b), \end{aligned} \quad (9a)$$

$$\begin{aligned} E_b &= V_b cos(\omega t + \Omega_1 t + 2\Omega_2 t + \phi_0 + \phi_p + \phi_b + \phi_{AOM1}) \\ &= V_b cos(\omega t + \Omega_1 t + 2\Omega_2 t + \phi_0 + \phi_b). \end{aligned} \quad (9b)$$

Here, ϕ_a and ϕ_b are the phase fluctuations induced by the fiber links before and behind the accessing point, respectively. They obviously have the relationship of $\phi_a + \phi_b = \phi_p$. From Eq. (9), we can see the phase fluctuation terms of these two directly accessing frequency signals E_a and E_b are complementary to each other. By beating E_a and E_b with E_0 respectively, we can get the relative frequency stabilities of the directly accessing signals. As shown in Fig. 5(curve (a), (b)), they are $1\times 10^{-14}/s$, $6\times 10^{-15}/10^4 s$ for the forward signal and $1\times 10^{-14}/s$, $4\times 10^{-15}/10^4 s$ for the backward signal. To cancel the phase fluctuations ϕ_a and ϕ_b of the two directly accessing optical signals, we simply beat 20% of the forward and backward transmitted signals E_a and E_b, and get

$$V_{beat} \propto cos(2\Omega_2 t + 2\phi_b). \quad (10)$$

Two more accousic optical modulators AOM3(+1st order Bragg shift) and AOM4(-1st order Bragg shift) are further employed as shown in Fig. 4. The beat signal V_{beat} is discriminated and digitally divided by 2. The resulting 80MHz RF signal with phase ϕ_b is then bandpass filtered, amplified, and fed to AOM3 and AOM4. The modulated, download signals of the forward and backward directions can be written as:

$$E_+ = E_- \propto cos(\omega t + \Omega_1 t + \Omega_2 t + \phi_0). \quad (11)$$

Therefore, the reproduced signals E_+ and E_- have exactly the same form as E_1 received at the remote site. As shown in Fig. 5(curve (c), (d)), relative frequency stabilities can be improved to $3\times 10^{-16}/s$, $4\times 10^{-18}/10^4 s$ for the forward signal, and $2\times 10^{-16}/s$, $4\times 10^{-18}/10^4 s$ for the backward signal. As a preliminary demonstration, we emphasize the advantages of this method - there is no requirement of any additional laser source at the download site, and the apparatus is as simple as that of remote site. This feature will greatly improve the feasibility of a branching fiber network for optical frequency dissemination. However, there are still many challenges ahead to realize its practical application in

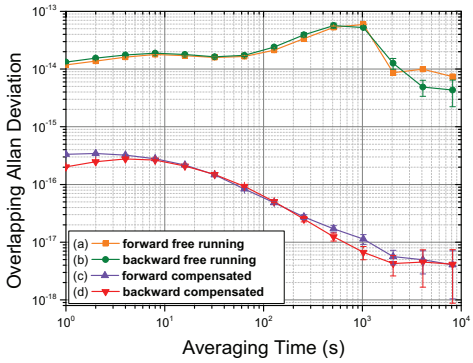

Fig. 5. Measured relative frequency stabilities of frequency signals at the download site with and without phase noise compensation. (a) forward signal directly accessing; (b) backward signal directly accessing; and (c) forward signal with compensation; (d) backward signal with compensation.

non-dedicated telecommunication networks, such as a reliable Hertz-level narrow linewidth laser module, universal interface of the download module, and automatic parameter optimization of the compensation system.

IV. Conclusion

In summary, we have demonstrated a fiber-based, multiple-access optical frequency dissemination scheme for both radio and optical frequency. Using the method, ultra-stable, distributed radio and optical frequency signals can be accessed conveniently at an arbitrary point along the entire fiber link of the dissemination system. The relative frequency stability is at the same level with the dissemination stability of the whole fiber link. A branching fiber network for high-precision synchronization of frequency standards is thus enabled by this method, which will not only cover the research labs with high quality frequency resources, but also cover different industrial users which need precision time and frequency service.

***Abstract*—According to Friedrich Robert Helmert geodesy is the science of the measurement and mapping of the figure of the Earth. With the advent of the space age it was possible to establish a global reference frame, which can relate different locations across the entire Earth with an accuracy of currently about 1 cm with respect to each other. A rapid development of highly precise and stable frequency standards took place at the same time and is an important prerequisite for the actual quality of this global terrestrial reference frame. In fact all measurement techniques in modern space geodesy are based on precise time and frequency. Growing demands for the monitoring of global change as one of several examples of the importance of a highly resolved reference frame require more than one order of magnitude improvement over the existing level of quality. Optical clocks, optical frequency combs and near lossless time and frequency transfer have the potential to provide significant improvements of the individual techniques of space geodesy. This talk reviews how time and frequency impacts space geodesy and how the observation techniques may benefit from the recent progress in this field.**

I. Introduction

With the advent of the space age, the tool box of geodesy has changed considerably. With the classical methods, such as triangulation, distance measurements and astronomical observations a consistent reference frame on a global scale remained a dream. With the help of dedicated satellite missions, highly precise time and frequency standards and broadband data acquisition techniques, an entirely new scenario emerges, which allows to reference any event on the body of the Earth to another location with 1 cm of accuracy in a global scale. Space geodesy today contributes to Earth sciences in several ways by

- providing 3-D coordinates in a local, regional and global scale (terrestrial reference frame).
- measuring the precise coordinates of extra galactic radio sources (quasars) and their structure as a function of time (celestial reference frame).
- the determination of the rotation rate of the Earth and polar motion, in order to provide the transformation between these two frames of reference.
- establishing the gravity field of the Earth precisely.

In order to gain access to the continuous evolution of the Earth from variations of the global mass transport, tectonic motion and other mechanisms, the geodetic measurements are repeated frequently. The most prominent measurement concepts are the Very Long Baseline Interferometry (VLBI), Satellite Laser Ranging (SLR), the Global Navigation Satellite System (GNSS) and Doppler Orbitography and Radiopositioning Integrated by Satellite (DORIS). A network of continuously operating globally distributed observing stations forms the backbone of space geodesy.

Apart from high precision navigation, the establishment of a highly precise terrestrial reference frame and for that matter also an equally precise celestial reference frame serves as an underlying metric for models and measurements on climate change, sea level rise, seismic activity and mass loss in the cryosphere of the Earth. For the lithosphere the rate of change reaches from highly dynamic earthquake activities with velocities of km/s to the very slow tectonic plate motions over millions of years with velocities of a few cm per year. The extreme positions of the rate of change for the hydrosphere are given by the current rate of sea level rise of 3 mm per year up to highly dynamical tsunamis with velocities of up to 300 m/s. While weather patterns are typically changing over hours up to days, variations in the global climate are happening over secular periods down to decades. These requirements between very small and slow processes and highly dynamic realtime events are placing severe constraints on the measurement techniques of space geodesy, demanding a terrestrial reference frame of extremely high resolution and stability over at least 9 orders of magnitude of dynamic range and with high spatial and temporal resolution. The Global Geodetic Observing System (GGOS), an initiative within the International Association of Geodesy (IAG), has formulated these requirements in order to integrate GGOS as an important contributor into the Earth System research, which attempts to measure and model the ongoing physical, chemical and biological processes [1].

II. The role of time and frequency in geodesy

In order to establish a maximum in sensitivity and stability all precise ranging techniques in space geodesy are based on the measurement of intervals of time. GNSS, VLBI and DORIS are one-way measurement techniques, while SLR uses a two-way approach. The advantage of SLR is the fact, that the range measurement is based on a precisely detected interval of time on the same clock. The one-way measurement techniques on the other side always rely on the precise synchronization of the two clocks, one at each end of the distance of interest.

978-1-4799-0342-9/13/$31.00 ©2013 IEEE

The process of synchronizing the two sensor clocks therefore is an integrated part of the data reduction procedure in space geodesy. As a matter of fact, one-way geodetic measurement techniques are well suited for precise time and frequency transfer.

The need for precise time as an independent geodetic observable in itself is not given so far. To realize accurate ephemerides of fast moving satellites as part of the data reduction process, an accuracy of the applied timescale of the order of 1 μs is required. The reason for not using precise absolute time is the inherent difficulty of transfering and comparing time experimentally due to the finite velocity of electromagnetic signals, acting as the carrier of time and the difficulty of controlling the entire delays on the signal path up to the point of reference of time. In this context we are not even touching any aspects of the theory of relativity, which will need additional careful consideration for a complete treatment of the time transfer. Time transfer in the microwave regime requires some sort of code measurements in order to transfer time tags and to resolve the ambiguity inherently related to phase measurements. For the GNSS technique, as an example, the code measurement is about a hundred times less precise than the phase measurement, requiring extended filtering techniques to reach a high accuracy. On top of that and even more important, time transfer requires calibrated and temperature stable antennas, cables as well as electronic circuits, such as signal conditioners and amplifiers, of similar quality. Compared to the desirable level of performance of $\Delta t \approx 1$ ps, a viable concept has not yet been demonstrated.

The situation is very different for time transfer in the optical regime, both for the ground to space application as well as for the actively controlled fiber links on the ground. Both applications are utilizing a two-way measurement concept, using essentially a single local timescale to establish the round-trip time as a precisely determined time interval. An additional detector at the single path distance is then used for the timescale comparison, while the round-trip measurement determines the delays, or in the case of the fiber link is used to stabilize the transit delay to a constant value. Neither the optical two-way time transfer from ground to space, nor the two-way compensated fiber link from ground to ground are common or well established techniques in space geodesy today. This may change with the advent of highly precise optical clocks, demonstrating a relative stability approaching $\delta f/f \approx 10^{-18}$ and making gravity field estimates based on exploiting the gravitational redshift by clock comparisons possible in the future. If we are taking the current GGOS goals as the baseline for the requirements for today's space geodesy, this would mean that a remaining uncertainty of 1 mm in the position accuracy from phase measurements would require $\Delta_c = 1$ mm/$c = 3$ ps for the granularity of the applied clocks and $\Delta_v = 1$ mm/$v_{sat} = 0.3$ μs for the accuracy of the applied timescale. In summary time itself needs to be 5 orders of magnitude less precise than the measured time intervals for a given observable. This is another way to express the difficulties that come about with actually measuring time itself as a quantity. How is space geodesy dealing with these difficulties?

All one-way measurement techniques require clocks on both ends of the measured distance that are synchronized at the ps-level in order to derive accurate signal travel times. For GNSS a typical measurement scenario means that every receiver observes more than one satellite that are measured simultaneously. At the same time every satellite is observed by more than one permanent receiving station. As a result one can synchronize all clocks for each measurement epoch from this redundancy, so that no stable clocks are required within the network. However this does not preclude, that the geodetic products would gain, if the clocks would be stable and this stability would be exploited in the data analysis.

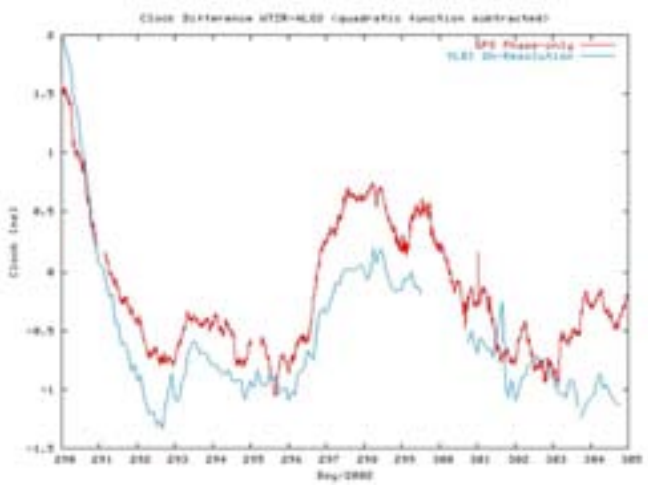

Fig. 1. Transatlantic Clock comparison between the Algonquin and Wettzell observatory. The diagram shows the residual clock drift between the GNSS and VLBI clock synchronization after a common linear and quadratic trend has been removed.

For the VLBI operations a similar situation is given. There is more than one quasar observed and a redundant number of telescopes are participating in the measurement campaign. As the quasars are, however, measured by the parabolic dishes one after the other, the station clock needs to be modeled for an observation session. In the processing procedure usually one set of clock corrections is computed for all systems after every 2 hours in addition to a quadratic clock drift. The clock of one of the stations is selected as the reference clock. Figure 1 shows an illustrating example for a clock comparison based on data of the CONT'02 campaign during which a network of VLBI instruments were operated continuously during two weeks. The VLBI stations, namely Algonquin (Canada) and Wettzell (Germany) are operated from a H-maser each. The same masers are also used as a timing reference in the GNSS permanent receivers simultaneously operated on these observatories. In the absence of any other error source one would expect that the two one-way measurement techniques would provide the same relative clock drift. Once a linear and a quadratic trend, describing the relative drift between the two masers, has been removed, a small time varying discrepancy of the order of up to 1 ns remains. This indicates that small variable systematic biases from the station delays are contaminating the clock synchronization process and hence the measurement resolution.

DORIS is a one-way microwave technique, too. Ultra stable oscillators operated at the ground beacons as well as in the Earth observation satellites have to be synchronized

with master beacons equipped with H-masers. Also for DORIS the absolute timing requirement is at some 1 μs. One beacon observes in general only a single satellite while only the second generation satellite DORIS receivers are capable of observing up to seven beacons at the same time. As a consequence the satellite clocks have to be modeled and the beacon oscillator frequencies have to be estimated per satellite pass. In order to mitigate clock instabilities the phase measurements are converted to Doppler measurements. Precise synchronization of the ground beacon oscillators in conjunction with second generation DORIS satellites would allow to use the high precision phase measurements.

The two-way technique SLR observes time intervals and determines system delays from calibration measurements to local targets of known distance. The requirements for the correct epoch of measurements are comparatively low, since an error in time shifts the measurement along the track of the satellite orbit with the velocity of the satellite. Epoch corrections and range offsets are computed for all systems from a redundant number of observing stations.

III. Common Clock Concept

A clock comparison over large distances as shown in the above example for VLBI and GNSS is limited by a combination of errors. For the microwave techniques we find a high correlation between the refraction correction, phase center variation in the antenna, unaccounted for signal delays in the receiver chain and potentially geometrical instabilities of the entire measurement system. These accumulative error sources are exacerbated by additional delays in the process of synchronizing the clock to the VLBI and the GNSS receiver system independently. Usually the H-maser for the VLBI system is located in a temperature stabilized environment some distance away from the detection system. The same is normally true for the GNSS system. Since all the mentioned error sources are technique specific, part of the high correlation between all contributors can possibly be broken up, if all techniques would be operated on a common clock with lossless time and frequency distribution within each observatory. The lossless time and frequency distribution on the observatory however requires a closed loop locking scheme, where the variable delay on the transmission line is actively controlled and compensated.

For this purpose the classical two-way transfer concept can be employed, where an optical frequency travels back and forth on the identical optical fiber [2], [3]. The phase delay accumulated over this double pass is detected interferometrically and is subsequently stabilized in a closed loop by adjusting the outgoing frequency to provide a stable interferogram at the source at all times. In this way a de facto common clock can be realized for a distributed ensemble of instrumentation in space geodesy, removing the local clock error from the inter-technique comparison. While the viability of this frequency transfer concept has been demonstrated over distances of nearly 1000 km, the same concept does not work for the transfer of time to the same extend, because the frequency dispersion of the fibers do not support the necessary bandwidth for sub-picosecond laser pulses to travel large distances without decomposition. However the closed loop distribution of time over several hundred meters can be achieved with uncertainties of far less than 1 ps, which is enough to synchronize an entire observatory.

Precise optical time transfer over large distances with an accuracy of far less than a nanosecond has been proposed for the Atomic Clock Ensemble in Space (ACES) onboard the International Space Station (ISS) and the concept is currently under construction [4] with an expected launch date in 2015. The time transfer is based on SLR, where two-way time of flight measurements are used to establish the orbit of the ISS. Since the laser pulses are also detected and time tagged on the ACES timescale during the SLR measurement process, the timescale on the ground and the timescale of ACES can be synchronized with an expected accuracy of 100 ps [5]. The inherent high stability of the ACES clocks will also allow a non-common view time comparison, thus allowing to synchronize geodetic observatories over intercontinental baselines for demonstrating the common clock concept.

IV. Conclusion

Modern space geodesy has reached a point where the international terrestrial reference frame allows to relate globally distributed positions with about 1 cm of accuracy with respect to each other. While this falls short of the GGOS goals by about one order of magnitude, it is desirable to improve the situation by providing a lossless distributed common frequency source to all instrumentation on a geodetic Fundamental station. Closed loop fiber links for optical frequency distribution have been demonstrated to provide the necessary phase stability. They are also suitable for accurate time transfer over short distances. Eventually optical laser time transfer via satellites and stable clocks in space may demonstrate an improved accuracy for clock synchronization supporting the generation of highest-accuracy and long-term stable geodetic reference frames.

***Abstract*—This work describes the realization of a fiber optic gyroscope with a sensitivity of 10^{-8} (rad/s)/√Hz. Such a high sensitivity is obtained using a 47 km long single mode fiber of the urban optical telecommunication network, that is shared with other users and encloses an area of 20 km^2. This setup has been used to investigate ground motion in occurrence of earthquakes.**

Keywords-fiber optic gyroscope, optical links,fiber optics

I. INTRODUCTION

In recent years, the study of the rotational components of seismic events has received a great attention in seismology, as it can provide a deep insight in the investigation of ground motion. The key tools used to perform this research are optical gyroscopes based on the Sagnac effect. These instruments are the most performing rotation sensors available, and their reading is not corrupted by translational motion as in the rotation sensors based on inertial masses.

There are basically two kinds of optical gyroscopes: Ring Laser Gyroscopes (RLGs) are complex experiments, that require careful maintenance and sophisticated instrumentation, such as free-space optics and ultrastable lasers; they have a high sensitivity, that allows detection of rotation signals well below 10^{-9} (rad/s)/√Hz, such as those occurring during large teleseismic events [1-3]. On the converse, rotation sensors based on passive Fiber Optic Gyroscopes (FOGs) are not suitable for such demanding applications, as their sensitivity varies between 10^{-4} rad/s and 10^{-6} rad/s [4], with a single relevant exception in the 10^{-8} rad/s range [5]. However, they have a broader dynamic range, are transportable, and require only commercial components [6].

We realized a FOG that aims to combine the high sensitivity of RLGs with the robustness of FOGs. This has been done by implementing a Sagnac interferometer on a multiplexed telecom fiber that encloses a 20 km^2 urban area [7]. Our instrument can detect signals that exceed 10^{-8} (rad/s)/√Hz, without the need of ultrastable lasers or complex optics, and may offer new possibilities for the investigation of the rotational component of seismic events.

II. THE EXPERIMENT

A. How the fiber optic gyroscope works

Optical fiber gyroscopes are based on the Sagnac effect, i. e., two optical beams propagate in opposite directions over a closed fiber path enclosing an area; if the platform rotates with respect to an inertial frame, the two beams accumulate a phase difference φ_{nr}. To realize this interferometer and detect φ_{nr}, an optical source is split into two beams that are injected in a fiber loop in opposite directions, and are recombined on a photodiode PD after a round trip. φ_{nr} is related to the rotation rate of the platform $\boldsymbol{\Omega}$ through the relation::

$$\varphi_{nr}=8\pi(\nu/c^2)N\mathbf{A}\cdot\boldsymbol{\Omega} \quad (1)$$

where **A** is the area enclosed by one loop of the fiber spool, N the number of turns of the spool, c is the speed of light in vacuum, and ν is the optical frequency.

To improve the sensitivity of this scheme, we realized an interferometer that has one single loop enclosing a wider area rather than just increase the number of turns. In our setup, the beams are then injected in a 47 km single mode commercial fiber located in the urban area around the city of Turin (Italy, colatitude ~45°). This fiber is used for the Internet data traffic and is implemented on a Dense Wavelength Division Multiplexed (DWDM) architecture, with about 25 dB of optical losses. The 44th channel of the International Telecommunication Union (ITU) grid is dedicated to our

experiment, while Internet data are transmitted on the 21st and 22nd channels, 2 THz away. There is no evidence of any crosstalk between the channels. The shape of the fiber loop is an elongated triangle with an enclosed area of 20 km^2: the resulting phase due to the Earth rotation should be about 55 rad. The optical signal is a laser radiation at 1542 nm provided by a fiber laser with a linewidth of about 10 kHz and optical power of 6 mW . The beam polarization is randomized through a polarization scrambler PS, that reduces

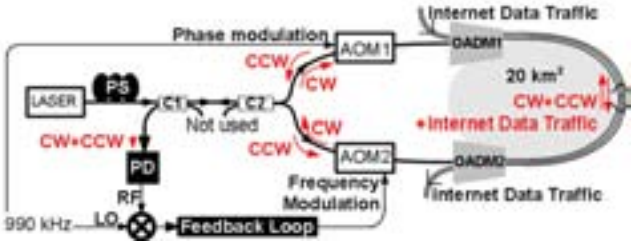

Fig. 1: The large area FOG setup: PS polarization scrambler, C couplers, AOM acousto-optic modulators, OADM Optical Add&Drop Multiplexers, CW (CCW) clockwise (counter clockwise) propagation direction

the effect of polarization mode dispersion along the fiber, i.e. a source of phase shifts between the two beams. Two Optical Add and Drop Multiplexers, OADM1 and OADM2, are used to inject and extract the two beams from the urban loop. In Figure 1, the experimental setup is sketched, in the typical minimum configuration scheme. This setup ensures that the two beams travel exactly the same optical distance [8]. A phase modulation stage is inserted in the loop in a position such that one of the two beams is phase-modulated at the beginning of the loop, whilst the other is modulated after a round trip. In our setup, the phase modulation is performed through an acousto-optic modulator AOM1. The delay in the phase modulation of the two beams enables the detection of an ac photocurrent on the photodiode PD, that varies with time at the phase modulation rate f_m:

$$I = I_0 + I_1 \sin \varphi_{nr} \cos[2\pi f_m t - \varphi_0] + f_m \text{ harmonics} \qquad (2)$$

where I_0 and I_1 are the amplitudes of dc and first harmonic signal; I_1 depends on the phase modulation depth and on the fiber length, and φ_0 is an arbitrary phase. We implemented a closed-loop system [8] in which the non-reciprocal phase shift φ_{nr} is compensated by a proper frequency offset Δ_f between the two counter-propagating beams, according to the relation:

$$\Delta_f = c/(2\pi L\eta)\Delta\varphi_{nr} + c/(L\eta)\kappa, \qquad (3)$$

being η the refractive index of the fiber and κ an integer. As actuator, we use another acousto-optic modulator, AOM2. The variations of the Earth rotation rate can be related to those of Δ_f, through the relation:

$$\Delta_f = 4(\eta v/c)\mathbf{A}\cdot\boldsymbol{\Omega} \quad . \qquad (4)$$

In principle, this interferometer is sensitive to the variations of both the orientation and the magnitude of $\boldsymbol{\Omega}$. However, the sensitivity to variations of tilt is ~10^4 times lower than the sensitivity to variations of spin, and can thus be neglected. Also, with this detection scheme there is an ambiguity in the definition of Δ_f and, for these reason, this setup is better suited to measure the variations of $\boldsymbol{\Omega}$, rather than its accurate value.

B. Measurements and Discussion

Several contributions may affect the phase reading, by inducing a phase noise that pollutes the Sagnac phase. The most relevant comes from the mechanical noise of the fiber originated by acoustic vibrations, human activity and temperature drifts. At first order, the interferometer is not sensitive to mechanical noise, since the optical length variations perturb the phase of the two beams of the same amount. However, the uncorrelated part of the noise $S_{\varphi,nr}(f)$ leads to a residual contribution, and this clearly depends on the Fourier components of the disturbance. We evaluated it by considering the phase noise of the fiber itself, its power spectral distribution $S_\varphi(f)$ and the round trip time of the radiation in the fiber. We estimated this contribution to be

$$S_{\varphi,nr}(f) = 1/3(2\pi fL/c)^2 S_\varphi(f), \qquad (5)$$

assuming that the noise is uniformly distributed along the fiber. It is interesting to note that the sensitivity of the gyroscope should improve using longer fibers, since $S_\varphi(f)$ scales as the fiber length L [9], and thus $S_{\varphi,nr}(f) \sim L^3$. In addition, the ratio A/L should be maximized in order to take full benefit from the available fiber loop. For instance, a factor 9 of improvement in our setup could be obtained simply by reshaping our triangular fiber loop into a circle, without changing the fiber length.

Fig. 2 shows the spectral density of the frequency correction signal Δ_f, that can be converted into the power

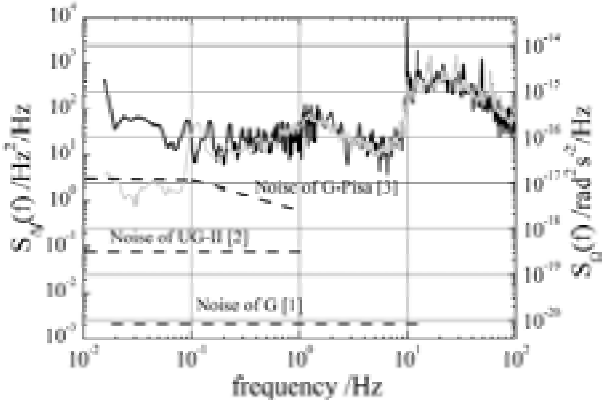

Fig. 2: Sensitivity of our FOG: black line, noise power spectral density of the frequency correction signal (left-hand axis) and of the equivalent rotation signal (right-hand axis); grey line, limitation by the mechanical noise of the fiber; dashed lines: sensitivity of some state-of-the-art RLGs.

This work has been partly funded by Compagnia di San Paolo

spectral density of the Earth's spin variations using eq. (4). The graph also shows the ultimate noise that can be obtained (grey line), considering the mechanical noise of the fiber loop used and the round-trip time. For comparison, the background noise of some state-of-the art RLGs is shown as well. The background noise of our FOG nicely agrees with the predictions down to Fourier frequencies of 0.1 Hz. The stability of our setup over longer averaging times was evaluated by counting Δ_f with a frequency counter and converting it into variations of the Earth rotation rate. It is shown in Fig. 3. On the medium and long term, the Sagnac phase instability is degraded due to linear or circular birefringence of the optical fiber (for instance, induced by stresses and Faraday effect), that varies with time due to slow and unpredictable drifts in the beams' polarization. This noise contribution should be averaged out if the two beams were completely depolarized, thus an improvement in our depolarization stage could help to decrease the long term noise. Nevertheless, the ultimate sensitivity already achieves $2 \cdot 10^{-9}$ rad/s for integration times of 1000 s.

Other noise contributions that may affect FOGs stability [6] are below our present noise. These include: backscattering, Kerr-based nonlinearities, and scale factor instability (i.e. variations in the length L or in the area A of the loop).

Backscattering occurs at the connectors and in the fiber itself; however, backscattered light passes two times through either AOM1 or AOM2, whilst the coherent signal passes only once in both AOMs. By adjusting the frequency difference between AOM1 and AOM2, the backscattered light can be overimposed to the coherent signal or pushed at a different frequency. We performed measurements both with a small (< 2 kHz) and with a large (>200 kHz) frequency offset, and could not detect any difference in the background noise. We conclude that this effect is still below the present sensitivity.

Variations of the optical power could affect the phase difference of the two beams through the Kerr effect. To quantify this contribution we changed the optical power of one of the two beams by about 20%, that is much higher than in normal operation (<5%), and looked for related variations in the non-reciprocal phase. We did not detect any difference, therefore we estimate this effect as well to be below the noise.

The detrimental effects of scale factor instability are more difficult to model. Nevertheless we can make some realistic assumptions based on the sensitivity of our interferometer: the dependence of the correction frequency Δ_f on variations of the fiber length is about 0.8 Hz/m, whilst the dependence on variations of the area is 2 mHz/m^2. Therefore, the response of the FOG to any reasonable geometrical variation of the loop should be negligible at the present state.

Table 1. Earthquakes occurred while the FOG was measuring.

C. *Earthquakes detection*

We let the gyroscope collect data uninterruptedly for several days, from December 23rd 2012 to January 8th, 2013. During acquisition some relevant seismic events happened, that are summarized in Table 1. They include one large and far earthquake and two small but close ones. In all cases, the estimated rotational sensitivity of our gyroscope was too low

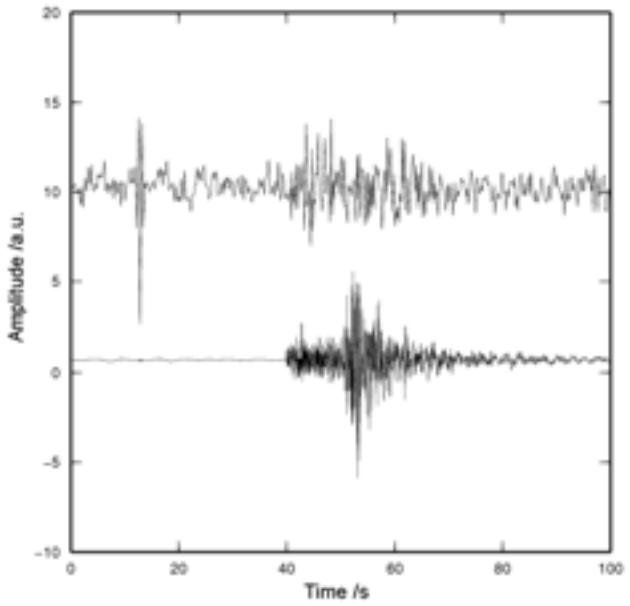

Fig. 4: The Gyroscope signal (top) and the seismometer signal (bottom) for the January 7th, 2013 earthquake in France (M_l = 3.5). Amplitudes have been arbitrarily scaled to compare. Seismogram (in velocity) has been recorded by station GU.LSD (Lago di Serrù, Latitude 45.4595°, Longitude 7.1343°) about 60 km North East from Torino.

to detect such events; however, our analysis was based on the model for small gyroscopes, as we still lack a model that predicts what kind of signal we should expect with this distributed sensor. Actually we could not detect any signal from the earthquakes of Italy and Alaska, but the FOG detected the earthquake occurring on January 7th in France.

In Fig. 4 both the signal from the gyroscope (top) and the signal from the closest available seismometer (GU.LSD) from the location of the gyroscope (bottom) related to this event are shown. The spectral components of the signal are between 0.1 Hz and 0.7 Hz. However, still we have no elements to conclude that this is a rotational signal rather just an increase of the background noise. This event was indeed very close to Turin (less than 100 km distance from the epicenter) and the seismic noise associated to the earthquake could have increased the fiber noise, with a subsequent increase in the noise of the instrument, that would lower the detection capability. Because of high frequency shaking, this would occur only for local earthquakes. This issue is still under investigation.

III. Conclusion and Outlooks

We realized a FOG on a multiplexed commercial fiber network that is 47 km long and has an enclosed area of 20 km^2. Its sensitivity is high enough to detect variations of the Earth rotation rate larger than 10^{-8} (rad/s)/√Hz without using complex optics nor ultrastable lasers; the potential of this technique is however not fully exploited yet. A better depolarization and a spectrally broader laser source could reduce the noise on the long term, whereas the sensitivity in the short and medium term (i.e. for frequencies higher than 0.1 Hz) is limited by the mechanical and temperature noise of the fiber. This could be improved on one hand by increasing the dimensions of the fiber loop, and on the other hand, by maximizing the area enclosed by the loop. For instance, the sensitivity could be improved of a factor 9 in our setup if the loop had not been an elongated triangle but a circle, with the same fiber length.

More sophisticated techniques have recently been proposed and can be implemented to improve the sensitivity [11].

We demonstrate that fiber networks used for the Internet data traffic could be suitable to realize optical fiber gyroscopes. An increasing number of telecom fiber loops are currently being used not only for telecommunications, but also for the coherent transfer of optical phase, and this could support the realization of a grid of such optical sensors distributed over large geographical areas [12, 13]. This setup could be helpful for the detection of teleseismic rotational signals, but novel applications could be envisaged as well, that could in principle support the research in rotational seismology. However, a deeper investigation on how the ground motion is detected over such a large area, and on the potential and feasibility of a distributed grid of such FOGs is still needed.

s-Wave Collisional Frequency Shift of a Fermion Clock

***Abstract*—We have experimentally observed a collisional frequency shift of trapped ultracold fermions. We probe the distinguishing features of s-wave collisional frequency shifts of fermions by stepping the atomic interactions through zero near an s-wave Feshbach resonance.**

Keywords—atomic clock, fermion, collision, frequency shift

I. SUMMARY

This paper summarizes our recent observations of an s-wave collisional frequency shift of an atomic clock based on fermions [1]. As the temperature of a gas is lowered to zero, collisions become *s*-wave, with no relative angular-momentum of the two particles. While *s*-wave collisions are allowed for bosons and are the most important limitation for the operation of Cs fountain clocks [2-6], they are forbidden for identical fermions. Even when dephasing made fermions distinguishable, collision shifts were absent [7]. Thus, fermions were thought to be immune to *s*-wave collisional frequency shifts (*s*CFS's), making them ideal for metrology. However, recent theoretical work predicted that fermions have *s*CFS's because the inhomogeneity of the excitation field makes particles distinguishable [8].

Here we experimentally observe *s*-wave collisional frequency shifts in a thermal gas of ultracold ^{6}Li fermions. Working near a Feshbach resonance, we tune the *s*-wave scattering length through zero around 528G to conclusively demonstrate that the shifts we observe are due to s-wave collisions. We show that Ramsey spectroscopy clearly distinguishes the novel behaviors of the *s*CFS, via unique dependences on the first and second Ramsey pulse areas, θ_1 and θ_2. We observe that the shift is insensitive to θ_1 and thereby the difference of the spin populations [8], in stark contrast with the shifts for bosons and the often-used mean-field expression. Instead, the fermion *s*CFS depends strongly on θ_2, which reads out the interaction-induced phase shifts of each atom. The shift is canceled if the atoms' phases are detected, on average, with equal sensitivity at $\theta_2=\pi/2$ [8]. Interestingly, we show that correlations in the sample perturb the null of the *s*CFS to θ_2 slightly greater than $\pi/2$. We explicitly see that the *s*CFS increases as expected with the independently characterized inhomogeneity of the clock excitation field. The fermion *s*CFS we observe in the resolved sideband regime is analogous to those for optical lattice clocks. Recently, the fermion *s*CFS was simulated with an ^{87}Rb Bose gas [9]. They observed the predicted dependence on θ_2, but an unexpected dependence on θ_1. They elegantly showed a direct link between spin-waves and the fermion *s*CFS, which we observe in the resolved sideband regime.

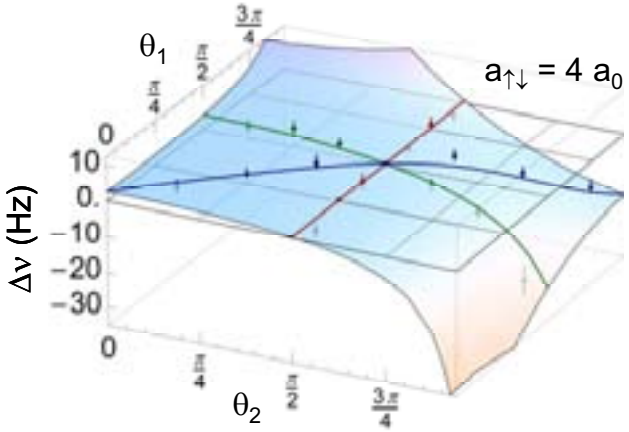

Fig. 1. Collisional frequency shift of ^{6}Li fermions as a function of the Ramsey pulse areas, θ_1 and θ_2 [1,8]. In contrast to bosons, the collision shift of fermions is not proportional to the difference of partial densities $n_\uparrow - n_\downarrow$, which would imply a strong dependence on θ_1. The shift depends strongly on the second Ramsey pulse area θ_2, going to 0 if the second pulse is a $\pi/2$ pulse.

***Abstract*—We present the results of the experimental investigation of ring lasers dynamics obtained by operating the G-Pisa gyroscope with the laser plane oriented almost perpendicularly to the local North direction. In this configuration, the Earth's rotation contribution to the Sagnac frequency is less sensitive to orientation errors, and more precise observations of the laser dynamical parameters can be achieved. Cavity losses and scattering parameters are monitored by observing the single beams intensity modulation at the Sagnac frequency while the active medium parameters are identified by a dedicated spectroscopic analysis of the plasma dispersion function. A summary of the performances of both the identification and the frequency denoising algorithm.**

I. Introduction

Active Sagnac interferometers, based on He-Ne ring laser technology [1], find applications in different areas of science as very sensitive gyroscopes. Depending on their scale-factor they can be used as inertial sensors for navigation, rotational seismometers, accurate detectors of geodetic signals modulating the Earth rotation vector. The outstanding stability of the large ring laser G [2], located at the geodetic observatory of of Wettzell, has recently triggered a collaboration for realizing an experiment for testing general relativity on ground, using an array of ultra sensitive ring lasers [3]. The project foresees the construction of a tri-axial gyroscope for the measurement of the Earth's rotation vector with an accuracy goal of at least 10^{-9}. This goal requires a strict control of all the systematics connected to the geometrical scale factor and to the nonlinear dynamics of the laser [6]. The frequency shift δf_S determined by the Sagnac effect on the two beams resonating on the same mode of wavelength λ in an optical cavity of area vector $\vec{A}$ side-length L, rotating at speed $\vec{\Omega}$ (see Fig.1) is:

$$\delta f_S = \frac{4\vec{A}}{L} \cdot \vec{\Omega}(1+\delta_S) + \delta f_{1-2} + \delta f_0 \qquad (1)$$

δ_S is a scale factor correction, due to geometry irregularities, δf_{1-2} is a frequency shift due to the coupling between the counter-propagating beams and the active medium, and δf_0 is a null-shift error coming from non-reciprocities of the active cavity.

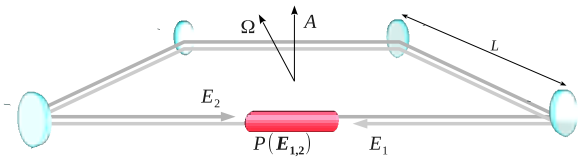

Fig. 1: Basic scheme of a square-cavity ring laser model. The nonlinear polarization $P_(E_{1,2})$ is the coupling function between the two counter-propagating beams 1 and 2.

A. Basics of the model

At the basis of the model we consider the Lamb-Aronowitz theory of ring laser [4], [5]. The electric fields resonating in the cavity are driven by a complex atomic polarization determining amplitudes and frequencies of the two counterpropagating modes. In their treatment the polarization $P(E_1, E_2)$ is expanded to the third order in the field amplitudes $E_{1,2}$:

$$P^{(3)}(E_{1,2}) = -\frac{2i|\mu_{ab}|^2}{\gamma_{ab}} \int_0^\infty \chi_{1,2}(v)\rho^{(2)}(v, E_{1,2})dv, \qquad (2)$$

where $|\mu_{ab}|$ is the atomic dipole amplitude of the laser transition, γ_{ab} is the homogeneous linewidth normalized to the Doppler linewidth, $\chi_{1,2}(v)$ is the complex susceptibility of the medium as a function of the atomic velocity class v, $\rho^{(2)}$ is the second order population inversion distribution. The calculation of the polarization is performed by means of the plasma dispersion function of the gas mixture which is typically composed by He, ^{20}Ne and ^{22}Ne at partial pressures of 7.3 mbar, 0.1 mbar and 0.1 mbar, respectively. In the model two kind of parameters can be distinguished: cold cavity parameters and active medium parameters. Relevant cold cavity parameters consist in the total losses of the two beams μ_1 and μ_2 and the backscattering coupling coefficients $r_1 e^{i\epsilon_1}$ and $r_2 e^{i\epsilon_2}$. The active medium parameters to be calibrated are related to the laser gain and dispersion. According to the Lamb formalism, the laser parameters to be calibrated and identified are:

$$\begin{aligned} \alpha_{1,2} &= G\frac{\Im[kZ(\xi_{1,2}) + k'Z(\xi'_{1,2})]}{\Im[Z(0)]} - \mu_{1,2} \\ \beta_{1,2} &= \alpha_{1,2} + \mu_{1,2}, \end{aligned} \qquad (3)$$

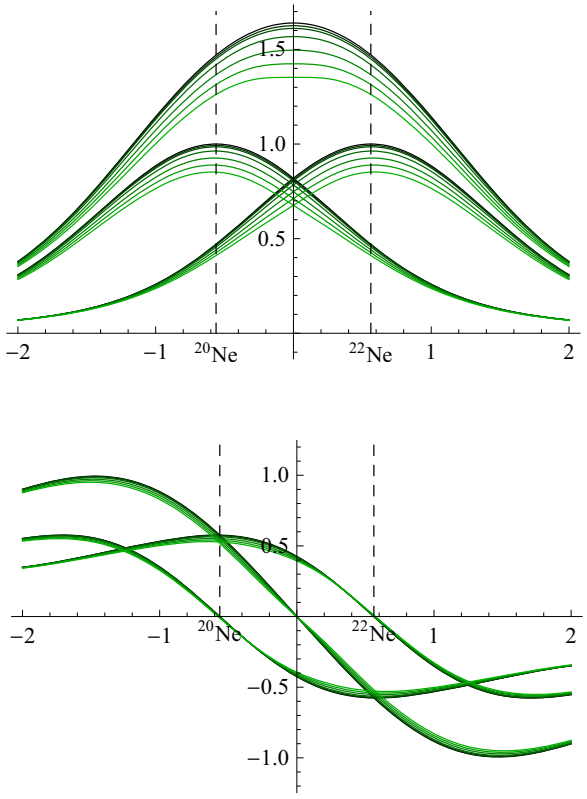

Fig. 2: Imaginary (upper) and real (lower) part of the plasma dispersion function versus normalized detuning. The two isotopic contributions ^{20}Ne and ^{22}Ne are also shown. Different curves correspond to different transition saturation parameters ranging from zero to 0.1 times the transition saturation intensity.

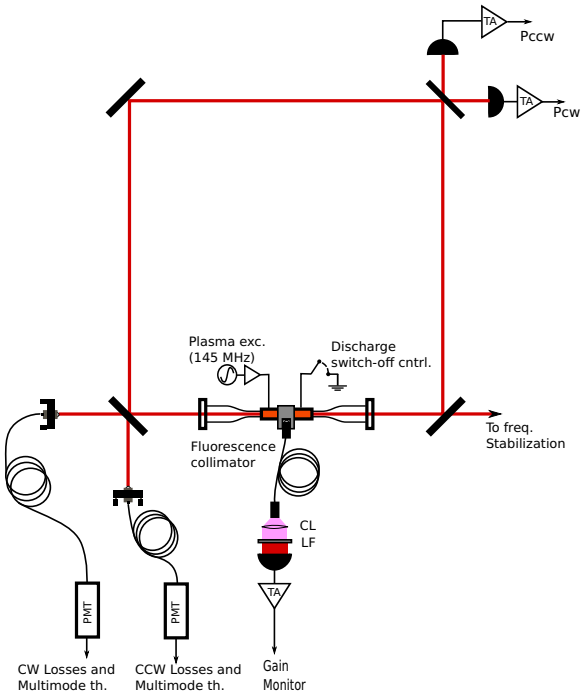

Fig. 3: The experimental setup for the calibration of the ring laser parameters. PMT: photomultiplier tube. TA: transimpedance Amplifier, LF:Line Filter. CL: Collimating Lens. TA Gain for G-Pisa is 1 GOhm.

where G is the single pass gain, $Z(\xi)$ is the plasma dispersion function of the detuning ξ, k and k' are the relative concentration of the two Ne isotopes.

B. Calibration of the ring laser parameters

The complete setup for the calibration of the laser parameters is presented in Fig. 3. The setup allows to perform essential observations on the active medium by accessing the plasma trough the laser capillary. By observing the single beams exiting one of the four cavity mirrors and the intensity of the spontaneous emission from the upper laser level in the plasma fluorescence, one can estimate the "cold cavity" parameters: cavity total losses, backscattering coupling amplitudes and backscattering phases. Other quantities related to the active medium, like the plasma temperature can be estimated by laser Doppler spectroscopy of a strong dipole transition (see Fig.4) by probing the plasma through the discharge capillary.

II. Experimental results

The information about rotation and laser systematics are obtained by sampling three optical outputs of the system: the Sagnac interferogram $S(t)$ and the two monobeams $V_1(t)$ and

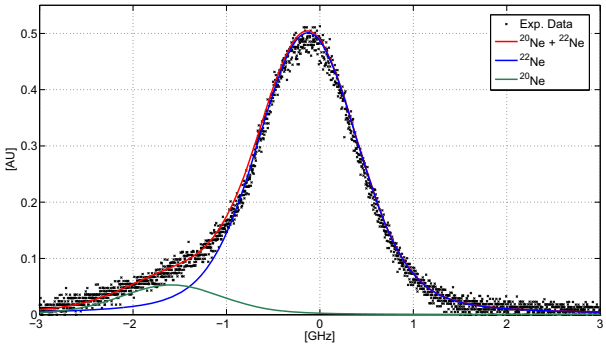

Fig. 4: Doppler profile of the closed optical transition in Neon at 640.2 nm, allowing for the Neon temperature estimation. The measurement is taken in typical operation conditions for a plasma of He-Ne standard mixture at 4.5 mbar. From the fit results, we get $T_{Ne} = \sqrt{\frac{\Gamma_{20}^2 * 20 m_p}{\lambda ln 2 K_B}} = (360 \pm 12) K$.

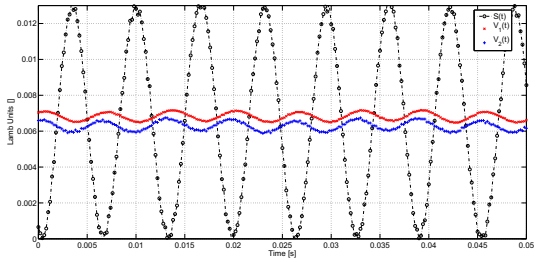

Fig. 5: Typical acquisition of the three main optical signals from G-Pisa. All the signals are sampled at 5kSample/s.

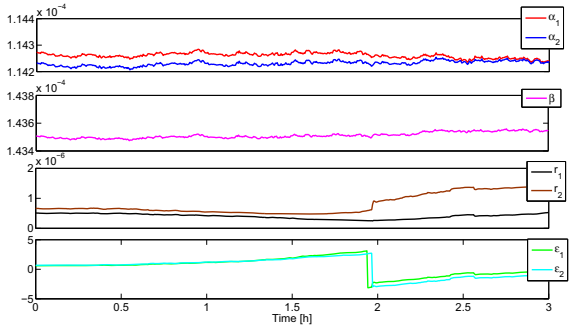

Fig. 6: Lamb parameters tracking obtained from 3 h of experimental data of G-Pisa. After about 2h of acquisition, one of two modes of the ring undergoes a multimode transition. The net effect on the laser dynamics is a sudden change in the amplitude and phases of the backscattering.

$V_2(t)$:

$$\begin{aligned} S(t) &= |a_1 E_1(t) + a_2 E_2(t)|^2 \\ V_1(t) &= |b_1 E_1(t) + c_{21} E_2(t)|^2 \\ V_2(t) &= |b_2 E_2(t) + c_{12} E_1(t)|^2 \end{aligned} \tag{4}$$

where the coefficients a_i, b_i, c_{ij} depend on the optical alignment, backscattering and electronics. Typical acquisition of the three optical signals are shown in Fig. 5.

A. Identification

After the initial calibration of the instrument, the laser parameters are estimated once per 10 second. The tracking of the main laser parameters for a run of 1 hour of operation of the gyro is sketched in Fig.6.

B. Rotation rate estimation

The parameter estimation procedure, based on the perturbative solutions of the laser dynamics, allow us to apply Kalman Filter theory for the estimation of the angular velocity. This method, already presented in [6] makes it possible to remove large part of the fluctuation of the measured Sagnac frequency.

In Fig. 7 is presented a preliminary result of the noise filtering.

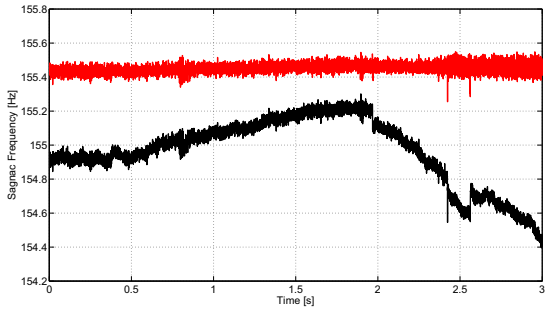

Fig. 7: Sagnac frequency estimation obtained from 3 h (same period of Fig.6) of experimental data of G-Pisa. The uncorrected frequency is plotted in comparison to demonstrate the effectiveness of the method.

III. Conclusion

We proposed a method for the cancellation of the laser dynamic induced drift from the Sagnac frequency of a large ring laser gyro. The method is based on the initial calibration of both passive cavity and active medium parameters. The parameters exhibiting the largest fluctuation are tracked along acquisition of the Sagnac frequency and subsequently exploited for the rotation rate estimation. A sensitive increment in rotation rate resolution and stability has been demonstrated. In order to set the actual limits of the method, further investigations have to be conducted over longer acquisition time periods.

***Abstract*— We propose employing an ultra-low thermal expansion ceramic for long cavity spacers that can reduce thermal noise effect on ultra-stable optical cavities relatively, since the high-rigidity ceramic should be insensitive to vibration. Thermal expansion properties are investigated using a prototype ceramic cavity. Simulation results show that responses of a long ceramic cavity to the vertical acceleration are similar to that of a short ultra-low expansion (ULE) glass cavity. Linewidth transfer technique based on an optical frequency comb combining with the narrow linewidth laser stabilized to the ceramic cavity would serve as a useful ultra-stable local oscillator for optical clocks.**

Keywords—ultra-stable laser, optical cavity, thermal noise, ultra-low expansion ceramic

I. INTRODUCTION

Lasers with high frequency stability and a narrow linewidth have been indispensable tools in various scientific fields. In the case of optical clocks, lasers locked to a longitudinal mode of an ultra-stable cavity are used to drive narrow-linewidth clock transitions in atoms/ions with a sub-hertz linewidth. Theoretical study shows that the frequency stabilities of ultra-stable lasers at a short averaging time are close to being limited by mechanical thermal fluctuations of the optical cavities [1]. To improve the short-term stabilities of the clock lasers, new high finesse cavities that reduce thermal noise should be necessary.

Thermal noise can be reduced by using an alternative mirror material with extremely low mechanical losses and cooling the optical cavity itself in a relatively large cryogenic system [2]. Furthermore, a large beam size on the highly reflective mirrors and a long spacer for the cavity should help to reduce the thermal noise relatively [3]. However, a long cavity could be sensitive to the vibration. To surmount the problems, there is a need for a new material, such as ceramic, with high specific rigidity and very low thermal expansion at room temperature.

As another important technique for the new clock laser system, laser linewidth transfer using high-speed controllable frequency comb stabilized to an ultra-stable laser is absolutory useful, because the ultra-stable optical cavity does not have to be operated at required wavelengths for optical transitions in atoms/ions [4-6]. Furthermore, it can be used to stabilize plural lasers with different wavelengths simultaneously using phase lock technique. In this case, even small frequency fluctuation of the resonant frequency of the ultra-stable cavity could be canceled, when the frequency ratio of the lasers stabilized to the same cavity via the comb is used for some experiments, such as frequency ratio measurements between ytterbium and strontium optical clock transitions.

In this proceeding, first we describe properties of the ceramic that will be employed as a spacer of the new long cavity. And then, laser linewidth transfer technique using our high-speed controllable fiber-based frequency comb is briefly explained.

II. DEVELOPMENT OF CERAMIC CAVITY

We have applied an ultra low thermal expansion ceramic based on poly-crystalline cordierite ceramics (‘NEXCERA’ Krosaki Harima [7]), which has a Young's modulus of ~ 130 GPa and a Poisson's ratio of ~ 0.30, to an optical cavity spacer. The ceramic is composed of cordierite grains with grain size of 0.5 to 2.0 μm and slight amorphous phases along the grain boundary. For manufacturing the cavity spacer, mixed raw powders were wet milled together with organic binder and deionized water. The slurry thus obtained was dried using a spray dryer and then isostatically pressed at room temperature into a cylindrical green compact. The green compact was annealed once in air to burn out the organic additives and then sintered at high temperature which is close to its melting point in an Ar-gas flow atmosphere. The sintered body was precisely ground and its both ends were polished to extremely smooth surfaces, thus enabling it to be connected to other materials, such as ULE glass, using the optical contact technique.

A. Thermal propertties of the ceramic

We produced a prototype optical cavity consisting of two ULE mirrors in optical contact with the ceramic spacer. The reflectivity of these mirrors was 99.5(1)% at 1064 nm, giving the cavity a finesse of about 600. The length and diameter of

the ceramic spacer were 75 and 25.4 mm, respectively. A Nd:YAG laser operated at 1064 nm was stabilized to the ceramic cavity and the resonant frequency of the cavity was measured by a fiber-based frequency comb system. We found that the ceramic cavity had a zero cross temperature at 16.4 (1) °C where the thermal expansion coefficient crosses zero [8].

We found that the thermal expansion coefficient of the ceramic cavity at around the zero cross temperature is about 5 times more sensitive to a temperature change than that of the ULE cavity. However, it should be possible to overcome this disadvantage by using a well-designed temperature controller.

B. Design of long ceramic cavities

A finite element based analysis has been employed to calculate the ceramic cavity deformation when loaded. A typical result is shown in figure 1. In this simulation, axial displacements at the end-face centre of the spacer are calculated, when a cut-out type long cavity spacer supported by four points is deformed by the gravity. A reduction in the response of the ceramic cavity to the vertical acceleration by a factor of 2 comparing with an ULE cavity has been shown (Fig. 1.). The estimated sensitivity of 13.6 kHz/(g mm) is same order to that of short (~ 0.1 m) cut-out cavities made by ULE glass [9].

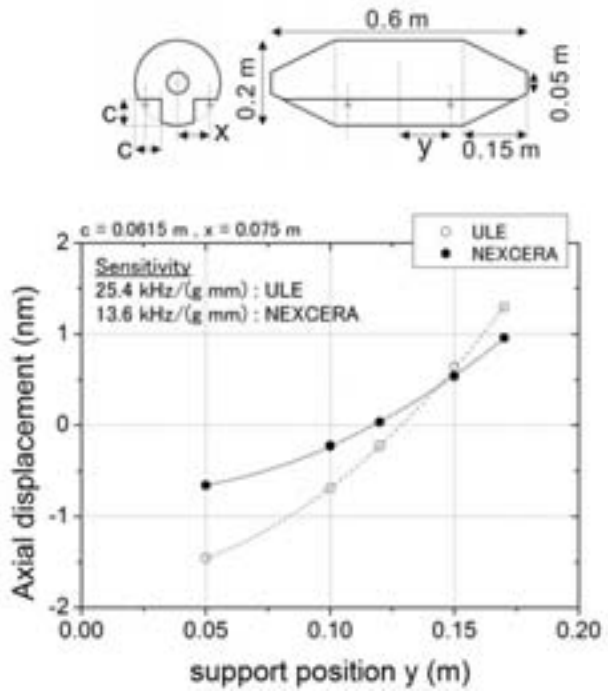

Fig. 1. A design of a long cavity and a calculated result of cavity length change under vertical acceleration as a function of the support position. In the figure of the assumed cavity spacer shape, gray triangles show support positions. In the graph, solid and open circles represent axial displacements of NEXCERA and ULE cavity spacers, respectively. This result shows that the NEXCERA cavity spacer is insensitive to the vibration in comparison with the ULE cavity spacer due to the high specific rigidity.

III. LASER LINEWIDTH TRANSFER TECHNIQUE

Recently, a high-speed controllable fiber comb has been developed at NMIJ. We have demonstrated that the fiber comb can transfer a linewidth of highly stable laser to other wavelength with mHz level [4,5]. The comb is composed of a mode-locked erbium-doped fiber laser with an intra-cavity electro-optic-modulator (EOM), which is inserted into a free space section of the cavity to change the effective cavity length with fast response. Output power from the mode-locked Er fiber oscillator is split into three branches. The first branch is used to stabilize the carrier-envelop offset (CEO) phase of the comb by controlling pump power for the oscillator. Using the second branch, a beat note between a component of the fiber comb and the ultra-stable laser at 1064 nm is observed. Repetition rate frequency of the comb is stabilized by locking the beat frequency to a reference through feedback to the EOM, so that the comb is stabilized to the reference laser. The third branch is used to observe a beat between the comb and light at 578 or 698 nm for our ytterbium or strontium optical lattice clocks [10, 11], respectively. To generate the comb at around 578 or 698 nm, periodically poled lithium niobates (PPLNs) were used. Then, these beat signals are used to stabilize the 578 or 698 nm light sources to the comb. If one would like to use the system for the optical clocks, the system needs to work continuously for a long time. That is one of the reason, why we employ the fiber comb in the experiment. The system has been working continuously for more than weeks. We have used the clock laser system for atomic spectroscopy and successfully observed the Zeeman components of ^{171}Yb and ^{87}Sr in a homogeneous magnetic field.

IV. SUMMARY

We have developed a ceramic cavity to investigate the thermal properties. Experimental results show that the ceramic has a zero cross temperature at room temperature. The sensitivity of the thermal expansion coefficient of the ceramic to temperature change is about five times greater than that of ULE glass at around the zero cross temperature. Furthermore, to calculate the ceramic cavity deformation, a finite element based analysis has been used. Simulation results show that responses of a long ceramic cavity to the vertical acceleration are similar to that of a short ULE glass cavity [9]. Owing to the high specific rigidity and relatively low thermal expansion at room temperature, the ceramic should be a promising material for long optical cavities that can reduce the effect of the thermal noise relatively. The new clock laser system with linewidth transfer scheme is absolutely attractive, because any ultra-stable lasers that would be easy to achieve narrow linewidth and great short-term stability can be used to stabilize other lasers operated at different wavelengths via the comb. By combining the long ceramic cavity with laser linewidth transfer technique, short-term stabilities and linewidth of clock lasers for ytterbium and strontium optical lattice clocks should be further improved.
