It's important to notice that in these circumstances, avoiding the caching of the database engine saves time and memory. The library doesn't have to use extra memory for the cache and doesn't need to waste time storing data (and duplicating information). Over the last couple of years, many programmers moved from BDE-based cached updates to the ClientDataSet component, which provides more flexibility in managing the content of the data and updating information they keep in memory. However, using a ClientDataSet on top of the BDE (or ADO) exposes you to the risk of having two separate caches, which wastes a lot of memory.

Another advantage of using the ClientDataSet component is that its cache supports editing operations, and the updates stored in this cache can be applied to the original database server by the DataSetProvider component. This component can generate the proper SQL `update` statements, and can do so in a more flexible way than the BDE (although ADO is powerful in this respect). In general, the provider can also use a dataset for the updates, but this isn't directly possible with the dbExpress dataset components.

### Platforms and Databases

A key element of the dbExpress library is its availability for both Windows and Linux, in contrast to the other database engines available for Delphi (BDE and ADO), which are available only for Windows. However, some of the database-specific components, such as InterBase Express, are also available on multiple platforms.

When you use dbExpress, you are provided with a common framework, which is independent of the SQL database

server you are planning to use. dbExpress comes with drivers for MySQL, InterBase, Oracle, Informix, Microsoft SQL Server, and IBM DB2.

**Note** It is possible to write custom drivers for the dbExpress architecture. This is documented in detail in the paper "dbExpress Draft Specification," published on the Borland Community website. At the time of this writing, this document is at <http://community.borland.com/article/0,1410,22495,00.html>. You'll probably be able to find third-party drivers. For example, there is a free driver that bridges dbExpress and ODBC. A complete list is hosted in the article at <http://community.borland.com/article/0,1410,28371,00.html>.

## Driver Versioning Troubles and Embedded Units

Technically, the dbExpress drivers are available as separate DLLs you have to deploy along with your program. This was the case with Delphi 6 and is still the case with Delphi 7. The problem is, these DLLs' names haven't changed. So, if you install a Delphi 7 compiled application on a machine that has the dbExpress drivers found in Delphi 6, the application will apparently work, open a connection to the server, and then fail when retrieving data. At that point you'll see the error "SQL Error: Error mapping failed." This is not a good hint that there is a version mismatch in the dbExpress driver!

To verify this problem, look at whether the DLL has any version information—it was missing from the Delphi 6 drivers. To make your applications more robust, you can provide a similar check within your code, accessing the version information using the related Windows APIs:

```
function GetDriverVersion (strDriverName: string): Integer;
var
    nInfoSize, nDetSize: DWord;
    pVInfo, pDetail: Pointer;
begin
    // the default, in case there is no version information
    Result := 6;

    // read version information
    nInfoSize := GetFileVersionInfoSize (pChar(strDriverName), nDetSize);
    if nInfoSize > 0 then
        begin
            GetMem (pVInfo, nInfoSize);
            try
                GetFileVersionInfo (pChar(strDriverName), 0, nInfoSize, pVInfo);
                VerQueryValue (pVInfo, '\', pDetail, nDetSize);
                Result := HiWord (TVSFixedFileInfo(pDetail^).dwFileVersionMS);
            finally
                FreeMem (pVInfo);
            end;
        end;
    end;
end;
```

This code snippet is taken from the DbxMulti example discussed later. The program uses it to raise an exception if the version is incompatible:

```
if GetDriverVersion ('dbexpint.dll') <> 7 then
    raise Exception.Create (
        'Incompatible version of the dbExpress driver "dbexpint.dll" found');
```

If you try to put the driver found in Delphi 6's bin folder in the application folder, you'll see the error. You'll have to modify this extra safety check to account for updated versions of the drivers or libraries, but this step should help you avoid the installation troubles dbExpress meant to solve in the first place.

You also have an alternative: You can statically link the dbExpress drivers' code into your application. To do so, include

a given unit (like `dbexpint.dcu` or `dbexpora.dcu`) in your program, listing it in one of the `uses` statements.

**Warning** Along with one of these units you need to include the `MidasLib` unit and link the code of the `MIDAS.DLL` into your program. If you fail to do so, the linker of Delphi 7 will stop showing an internal error, which is rather pointless information. Notice also that the embedded `dbExpress` drivers don't work properly with the international character set.

## The dbExpress Components

The VCL components used to interface the dbExpress library encompass a group of dataset components plus a few ancillary ones. To differentiate these components from other database-access families, the components are prefixed with the letters *SQL*, underlining the fact that they are used for accessing RDBMS servers.

These components include a database connection component, a few dataset components (a generic one; three specific versions for tables, queries, and stored procedures; and one encapsulating a ClientDataSet component), and a monitor utility.

## The SQLConnection Component

The `TSQLConnection` class inherits from the `TCustomConnection` component. It handles database connections, the same as its sibling classes (the `Database`, `ADOConnection`, and `IBConnection` components).

**Tip** Unlike other component families, in dbExpress the connection is compulsory. In the dataset components, you cannot specify directly which database to use, but can only refer to a `SQLConnection`.

The connection component uses the information available in the `drivers.ini` and `connections.ini` files, which are dbExpress's only two configuration files (these files are saved by default under `Common Files\Borland Shared\DBExpress`). The `drivers.ini` file lists the available dbExpress drivers, one for each supported database. For each driver there is a set of default connection parameters. For example, the `InterBase` section reads as follows:

```
[Interbase]
GetDriverFunc=getSQLDriverINTERBASE
LibraryName=dbexpint.dll
VendorLib=GDS32.DLL
BlobSize=-1
CommitRetain=False
Database=database.gdb
Password=masterkey
RoleName=RoleName
ServerCharSet=ASCII
SQLDialect=1
Interbase TransIsolation=ReadCommitted
User_Name=sysdba
WaitOnLocks=True
```

The parameters indicate the dbExpress driver DLL (the `LibraryName` value), the entry function to use (`GetDriverFunc`), the vendor client library, and other specific parameters that depend on the database. If you read the entire `drivers.ini` file, you'll see that the parameters are really database-specific. Some of these parameters don't make a lot of sense at the driver level (such as the database to connect to), but the list includes all the available parameters, regardless of their usage.

The `connections.ini` file provides the database-specific description. This list associates settings with a name, and you can enter multiple connection details for every database driver. The connection describes the physical database you want to connect to. As an example, this is the portion for the default `IBLocal` definition:

```
[IBLocal]
BlobSize=-1
CommitRetain=False
Database=C:\Program Files\Common Files\Borland Shared\Data\employee.gdb
DriverName=Interbase
Password=masterkey
RoleName=RoleName
ServerCharSet=ASCII
```

```
SQLDialect=1
Interbase TransIsolation=ReadCommitted
User_Name=sysdba
WaitOnLocks=True
```

As you can see by comparing the two listings, this is a subset of the driver's parameters. When you create a new connection, the system will copy the default parameters from the driver; you can then edit them for the specific connection—for example, providing a proper database name. Each connection relates to the driver for its key attributes, as indicated by the `DriverName` property. Notice also that the database referenced here is the result of my editing, corresponding to the settings I'll use in most examples.

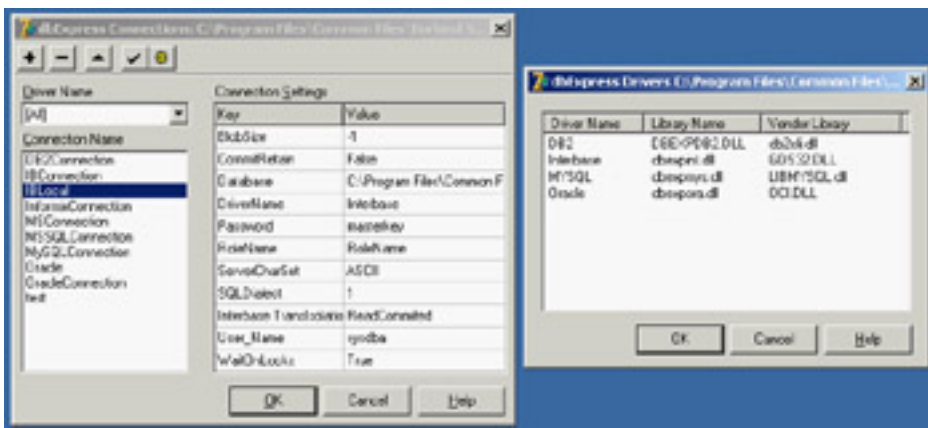

It's important to remember that these initialization files are used only at design time. When you select a driver or a connection at design time, the values of these files are copied to corresponding properties of the `SQLConnection` component, as in this example:

```
object SQLConnection1: TSQLConnection
  ConnectionName = 'IBLocal'
  DriverName = 'Interbase'
  GetDriverFunc = 'getSQLDriverINTERBASE'
  LibraryName = 'dbexpint.dll'
  LoginPrompt = False
  Params.Strings = (
    'BlobSize=-1'
    'CommitRetain=False'
    'Database=C:\Program Files\Common Files\Borland Shared\Data\employee.gdb'
    'DriverName=Interbase'
    'Password=masterkey'
    'RoleName=RoleName'
    'ServerCharSet=ASCII'
    'SQLDialect=1'
    'Interbase TransIsolation=ReadCommitted'
    'User_Name=sysdba'
    'WaitOnLocks=True' )
  VendorLib = 'GDS32.DLL'
end
```

At run time, your program will rely on the properties to have all the required information, so you don't need to deploy the two configuration files along with your programs. In theory, the files will be required if you want to change the `DriverName` or `ConnectionName` properties at run time. However, if you want to connect your program to a new database, you can set the relevant properties directly.

When you add a new `SQLConnection` component to an application, you can proceed in different ways. You can set up a driver using the list of values available for the `DriverName` property and then select a predefined connection by selecting one of the values available in the `ConnectionName` property. This second list is filtered according to the driver you've already selected. As an alternative, you can begin by selecting the `ConnectionName` property directly; in this case it includes the entire list.

Instead of hooking up an existing connection, you can define a new one (or see the details of the existing connections) by double-clicking the `SQLConnection` component and launching the dbExpress Connection Editor (see [Figure 14.4](#)). This editor lists on the left all the predefined connections (for a specific driver or all of them) and allows you to edit the connection properties using the grid on the right. You can use the toolbar buttons to add, delete, rename, and test connections, and to open the read-only dbExpress Drivers Settings window (also shown in [Figure 14.4](#)).

**Figure 14.4:** The dbExpress Connection Editor with the dbExpress Drivers Settings dialog box

In addition to letting you edit the predefined connection settings, the dbExpress Connection Editor allows you to select a connection for the SQLConnection component by clicking the OK button. Note that if you change any settings, the data is immediately written to the configuration files—clicking the Cancel button doesn't undo your editing!

To define access to a database, editing the connection properties is certainly the suggested approach. This way, when you need to access the same database from another application or another connection within the same application, all you need to do is select the connection. However, because this operation copies the connection data, updating the connection doesn't automatically refresh the values within other SQLConnection components referring to the same named connection: You must reselect the connection to which these other components refer.

What really matters for the SQLConnection component is the value of its properties. Driver and vendor libraries are listed in properties you can freely change at design time (although you'll rarely want to do this), whereas the database and other database-specific connection settings are specified in the `Params` properties. This is a string list including information such as the database name, the username and password, and so on. In practice, you could set up a SQLConnection component by setting up the driver and then assigning the database name directly in the `Params` property, forgetting about the predefined connection. I'm not suggesting this as the best option, but it is certainly a possibility; the predefined connections are handy, but when the data changes, you still have to manually refresh every SQLConnection component.

To be complete, I have to mention that there is an alternative. You can set the `LoadParamsOnConnect` property to indicate that you want to refresh the component parameters from the initialization files every time you open the connection. In this case, a change in the predefined connections will be reloaded when you open the connection, at either design time or run time. At design time, this technique is handy (it has the same effect as reselecting the connection); but using it at run time means you'll also have to deploy the `connections.ini` file, which can be a good idea or inconvenient, depending on your deployment environment.

The only property of the SQLConnection component that is not related to the driver and database settings is `LoginPrompt`. Setting it to `False` allows you to provide a password among the component settings and skip the login request dialog box, both at design time and at run time. Although this is handy for development, it can reduce the security of your system. Of course, you should also use this option for unattended connections, such as on a web server.

## The dbExpress Dataset Components

The dbExpress component's family provides four different dataset components: a generic dataset, a table, a query, and a stored procedure. The latter three components are provided for compatibility with the equivalent BDE components and have similarly named properties. If you don't have to port existing code, you should generally use the general `SQLDataSet` component, which lets you execute a query and also access a table or a stored procedure.

The first important thing to notice is that all these datasets inherit from a new special base class, `TCustomSQLDataSet`. This class and its derived classes represent unidirectional datasets, with the key features I've already described. In practice, this means that the browse operations are limited to calling `First` and `Next; Prior`,

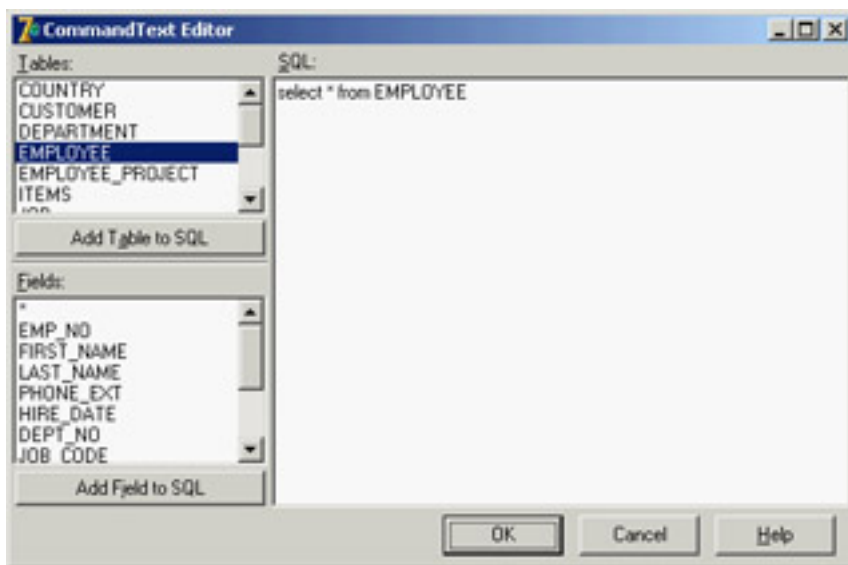

Last, Locate, the use of bookmarks, and all other navigational features are disabled.

**Note** Technically, some of the moving operations call the *CheckBiDirectional* internal function and eventually raise an exception. *CheckBiDirectional* refers to the public *IsUnidirectional* property of the *TDataSet* class, which you can eventually use in your own code to disable operations that are illegal on unidirectional datasets.

In addition to having limited navigational capabilities, these datasets have no editing support, so a lot of methods and events common to other datasets are not available. For example, there is no *AfterEdit* or *BeforePost* event.

As I mentioned earlier, of the four dataset components for dbExpress, the fundamental one is *TSQLDataSet*, which can be used both to retrieve a dataset and to execute a command. The two alternatives are activated by calling the *Open* method (or setting the *Active* property to *True*) and by calling the *ExecSQL* method.

The *SQLDataSet* component can retrieve an entire table, or it can use a SQL query or a stored procedure to read a dataset or issue a command. The *CommandType* property determines one of the three access modes. The possible values are *ctQuery*, *ctStoredProc*, and *ctTable*, which determine the value of the *CommandText* property (and also the behavior of the related property editor in the Object Inspector). For a table or stored procedure, the *CommandText* property indicates the name of the related database element, and the editor provides a drop-down list containing the possible values. For a query, the *CommandText* property stores the text of the SQL command, and the editor provides a little help in building the SQL query (in case it is a *SELECT* statement). You can see the editor in [Figure 14.5](#).

**Figure 14.5:** The *CommandText* Editor used by the *SQLDataSet* component for queries

When you use a table, the component will generate a SQL query for you, because dbExpress targets only SQL databases. The generated query will include all the fields of the table, and if you specify the *SortFieldNames* property, it will include a *sort by* directive.

The three *specific* dataset components offer similar behavior, but you specify the SQL query in the *SQL* string list property, the stored procedure in the *StoredProcName* property, and the table name in the *TableName* property (as in the three corresponding BDE components).

## The Delphi 7 SimpleDataSet Component

The *SimpleDataSet* component is new in Delphi 7. It is a combination of four existing components: *SQLConnection*, *SQLDataSet*, *DataSetProvider*, and *ClientDataSet*. The component is meant to be a helper—you need only one component instead of four (which must also be connected). The component is basically a client dataset with two compound components (the two dbExpress ones), plus a hidden provider. (The fact that the provider is hidden is odd, because it is created as a compound component.)

The component allows you to modify the properties and events of the compound components (besides the provider) and replace the internal connection with an external one, so that multiple datasets share the same database connection. In addition to this issue, the component has other limitations, including difficulty manipulating the dataset fields of the data access dataset (which is important for setting key fields and can affect the way updates are generated) and unavailability of some provider events. So, other than for simple applications, I don't recommend using the SimpleDataSet component.

**Note** Delphi 6 shipped with an even simpler and more limited component called SQLClientDataSet. Similar components were available for the BDE and IBX data access technologies. Now Borland has indicated that all these components are obsolete. However, the directory *Demos\Db\SQLClientDataSet* contains a copy of the original component, and you can install it in Delphi 7 for compatibility purposes. But just as the SimpleDataSet component is somewhat limited, I found the SQLClientDataSet component totally unusable.

## The SQLMonitor Component

The final component in the dbExpress group is SQLMonitor, which is used to log requests sent from dbExpress to the database server. This monitor lets you see the commands sent to the database and the low-level responses you receive, monitoring the client/server traffic at a low level.

---

### The TimeStamp Field Type

Along with dbExpress, Delphi 6 introduced the `TSQLTimeStampField` field type, which is mapped to the time stamp data type that many SQL servers have (InterBase included). A *time stamp* is a record-based representation of a date or time, and it's quite different from the floating-point representation used by the `TDateTime` data type. A time stamp is defined as follows:

```
TSQLTimeStamp = packed record
  Year : SmallInt;
  Month : Word;
  Day : Word;
  Hour : Word;
  Minute : Word;
  Second : Word;
  Fractions : LongWord;
end;
```

A time stamp field can automatically convert standard date and time values using the `AsDateTime` property (as opposed to the native `AsSQLTimeStamp` property). You can also do custom conversions and further manipulation of time stamps using the routines provided by the `SqITimSt` unit, including functions like `DateTimeToSQLTimeStamp`, `SQLTimeStampToStr`, and `VarSQLTimeStampCreate`.

---

## A Few dbExpress Demos

Let's look at a demonstration that highlights the key features of these components and shows how to use the `ClientDataSet` to provide caching and editing support for the unidirectional datasets. Later, I'll show you an example of native use of the unidirectional query, with no caching and editing support required.

The standard visual application based on dbExpress uses this series of components:

- The `SQLConnection` component provides the connection with the database and the proper dbExpress driver.
- The `SQLDataSet` component, which is hooked to the connection (via the `SQLConnection` property), indicates which SQL query to execute or table to open (using the `CommandType` and `CommandText` properties discussed earlier).
- The `DataSetProvider` component, connected with the dataset, extracts the data from the `SQLDataSet` and can generate the proper SQL update statements.
- The `ClientDataSet` component reads from the data provider and stores all the data (if its `PacketRecords` property is set to `-1`) in memory. You'll need to call its `ApplyUpdates` method to send the updates back to the database server (through the provider).
- The `DataSource` component allows you to surface the data from the `ClientDataSet` to the visual data-aware controls.

As I mentioned earlier, the picture can be simplified by using the `SimpleDataSet` component, which replaces the two datasets and the provider (and possibly even the connection). The `SimpleDataSet` component combines most of the properties of the components it replaces.

## Using a Single Component or Many Components

For this first example, drop a `SimpleDataSet` component on a form and set the connection name of its `Connection` subcomponent. Set the `CommandType` and `CommandText` properties to specify which data to fetch, and set the `PacketRecords` property to indicate how many records to retrieve in each block.

These are the key properties of the component in the `DbxSingle` example:

```
object SimpleDataSet1: TSimpleDataSet
  Connection.ConnectionName = 'IBLocal'
  Connection.LoginPrompt = False
  DataSet.CommandText = 'EMPLOYEE'
  DataSet.CommandType = ctTable
end
```

As an alternative, the `DbxMulti` example uses the entire sequence of components:

```
object SQLConnection1: TSQLConnection
  ConnectionName = 'IBLocal'
  LoginPrompt = False
end
object SQLDataSet1: TSQLDataSet
  SQLConnection = SQLConnection1
  CommandText = 'select * from EMPLOYEE'
end
object DataSetProvider1: TDataSetProvider
  DataSet = SQLDataSet1
end
object ClientDataSet1: TClientDataSet
```

```

    ProviderName = 'DataSetProvider1'
end
object DataSource1: TDataSource
    DataSet = ClientDataSet1
end

```

Both examples include some visual controls: a grid and a toolbar based on the action manager architecture.

## Applying Updates

In every example based on a local cache, like the one provided by the ClientDataSet and SimpleDataSet components, it's important to write the local changes back to the database server. This is typically accomplished by calling the `ApplyUpdates` method. You can either keep the changes in the local cache for a while and then apply multiple updates at once, or you can post each change right away. In these two examples, I've gone for the latter approach, attaching the following event handler to the `AfterPost` (fired after an edit or an insert operation) and `AfterDelete` events of the ClientDataSet components:

```

procedure TForm1.DoUpdate(DataSet: TDataSet);
begin
    // immediately apply local changes to the database
    SQLClientDataSet1.ApplyUpdates(0);
end;

```

If you want to apply all the updates in a single batch, you can do so either when the form is closed or when the program ends, or you can let a user perform the update operation by selecting a specific command, possibly using the corresponding predefined action provided by Delphi 7. We'll explore this approach when discussing the update caching support of the ClientDataSet component in more detail later in this chapter.

## Monitoring the Connection

Another feature I've added to the DbxSingle and DbxMulti examples is the monitoring capability offered by the SQLMonitor component. In the example, the component is activated as the program starts. In the DbxSingle example, because the SimpleDataSet embeds the connection, the monitor cannot be hooked to it at design time, but only when the program starts:

```

procedure TForm1.FormCreate(Sender: TObject);
begin
    SQLMonitor1.SQLConnection := SimpleDataSet1.Connection;
    SQLMonitor1.Active := True;
    SimpleDataSet1.Active := True;
end;

```

Every time a tracing string is available, the component fires the `OnTrace` event to let you choose whether to include the string in the log. If the `LogTrace` parameter of this event is `True` (the default value), the component logs the message in the `TraceList` string list and fires the `OnLogTrace` event to indicate that a new string has been added to the log.

The component can also automatically store the log into the file indicated by its `FileName` property, but I haven't used this feature in the example. All I've done is handle the `OnTrace` event, copying the entire log in the memo with the following code (producing the output shown in [Figure 14.6](#)):

```

procedure TForm1.SQLMonitor1Trace(Sender: TObject;
    CBIInfo: pSQLTRACEDesc; var LogTrace: Boolean);
begin
    Mem1.Lines := SQLMonitor1.TraceList;
end;

```

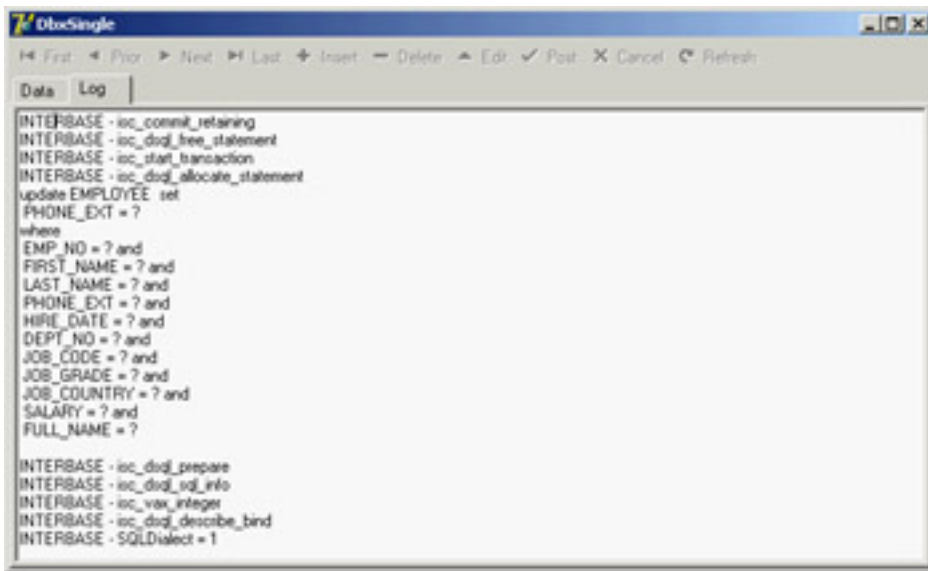

Figure 14.6: A sample log obtained by the SQLMonitor in the DbxSingle example

## Controlling the SQL Update Code

If you run the DbxSingle program and change, for example, an employee's telephone number, the monitor will log this update operation:

```
update EMPLOYEE set
  PHONE_EXT = ?
where
  EMP_NO = ? and
  FIRST_NAME = ? and
  LAST_NAME = ? and
  PHONE_EXT = ? and
  HIRE_DATE = ? and
  DEPT_NO = ? and
  JOB_CODE = ? and
  JOB_GRADE = ? and
  JOB_COUNTRY = ? and
  SALARY = ? and
  FULL_NAME = ?
```

By setting the SimpleDataSet's properties there is no way to change how the update code is generated (which happens to be worse than with the SQLClientDataSet component, which had the UpdateMode you could use to tweak the update statements).

In the DbxMulti example, you can use the UpdateMode property of the DataSetProvider component, setting the value to upWhereChanged or upWhereKeyOnly. In this case you'll get the following two statements, respectively:

```
update EMPLOYEE set
  PHONE_EXT = ?
where
  EMP_NO = ? and
  PHONE_EXT = ?

update EMPLOYEE set
  PHONE_EXT = ?
where
  EMP_NO = ?
```

**Tip** This result is much better than in Delphi 6 (without the patches applied), in which this operation caused an error because the key field was not properly set.

If you want more control over how the update statements are generated, you need to operate on the fields of the underlying dataset, which are available also when you use the all-in-one SimpleDataSet component (which has two field editors, one for the base ClientDataSet component it inherits from and one for the SQLDataSet component it embeds). I have made similar corrections in the DbxMulti example, after adding persistent fields for the SQLDataSet component and modifying the provider options for some of the fields to include them in the key or exclude them from updates.

**Note** We'll discuss this type of problem again when we examine the details of the ClientDataSet component, the provider, the resolver, and other technical details later in this chapter and in [Chapter 16](#).

## Accessing Database Metadata with *SetSchemaInfo*

All RDBMS systems use special-purpose tables (generally called *system tables*) for storing metadata, such as the list of the tables, their fields, indexes, and constraints, and any other system information. Just as dbExpress provides a unified API for working with different SQL servers, it also provides a common way to access metadata. The SQLDataSet component has a *SetSchemaInfo* method that fills the dataset with system information. This *SetSchemaInfo* method has three parameters:

*SchemaType* Indicates the type of information requested. Values include *stTables*, *stSysTables*, *stProcedures*, *stColumns*, and *stProcedureParams*.

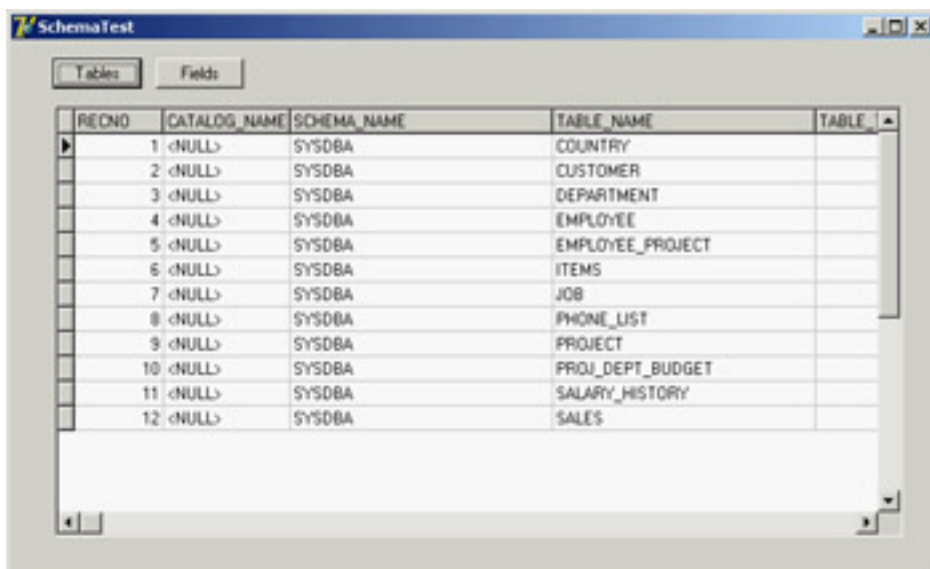

*SchemaObject* Indicates the object you are referring to, such as the name of the table whose columns you are requesting.

*SchemaPattern* A filter that lets you limit your request to tables, columns, or procedures starting with the given letters. This is handy if you use prefixes to identify groups of elements.

For example, in the SchemaTest program, a Tables button reads into the dataset all of the connected database's tables:

```
ClientDataSet1.Close;  
SQLDataSet1.SetSchemaInfo (stTables, '', '');  
ClientDataSet1.Open;
```

The program uses the usual group of dataset provider, client dataset, and data source component to display the resulting data in a grid, as you can see in [Figure 14.7](#). After you're retrieved the tables, you can select a row in the grid and click the Fields button to see a list of the fields of this table:

The screenshot shows a window titled "SchemaTest" with two buttons: "Tables" and "Fields". Below the buttons is a grid displaying the following data:

RECNO	CATALOG_NAME	SCHEMA_NAME	TABLE_NAME	TABLE
1	<NULL>	SYSDBA	COUNTRY	
2	<NULL>	SYSDBA	CUSTOMER	
3	<NULL>	SYSDBA	DEPARTMENT	
4	<NULL>	SYSDBA	EMPLOYEE	
5	<NULL>	SYSDBA	EMPLOYEE_PROJECT	
6	<NULL>	SYSDBA	ITEMS	
7	<NULL>	SYSDBA	JOB	
8	<NULL>	SYSDBA	PHONE_LIST	
9	<NULL>	SYSDBA	PROJECT	
10	<NULL>	SYSDBA	PROJ_DEPT_BUDGET	
11	<NULL>	SYSDBA	SALARY_HISTORY	
12	<NULL>	SYSDBA	SALES	

**Figure 14.7:** The SchemaTest example allows you to see a database's tables and the columns of a given table.

```
SQLDataSet1.SetSchemaInfo (stColumns, ClientDataSet1['Table_Name'], '');  
ClientDataSet1.Close;  
ClientDataSet1.Open;
```

In addition to letting you access database metadata, dbExpress provides a way to access its own configuration information, including the installed drivers and the configured connections. The unit `DbConnAdmin` defines a `TConnectionAdmin` class for this purpose, but the aim of this support is limited to dbExpress add-on utilities for developers (end users aren't commonly allowed to access multiple databases in a totally dynamic way).

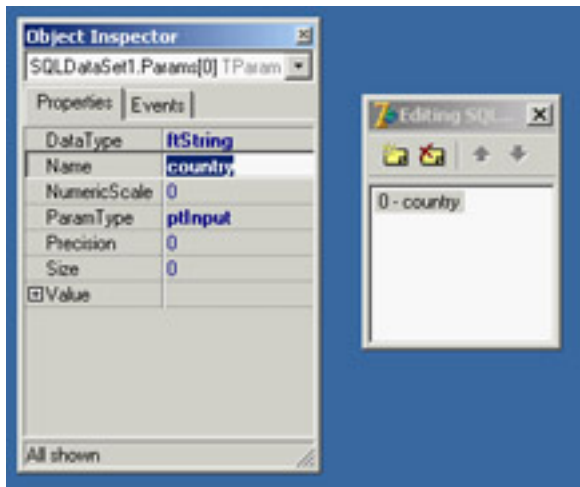

**Tip** The `DbxExplorer` demo included in Delphi shows how to access both dbExpress administration files and schema information. Also check the help file under "The structure of metadata datasets" within the section "Developing database applications."

## A Parametric Query

When you need slightly different versions of the same SQL query, instead of modifying the text of the query itself each time, you can write a query with a parameter and change the value of the parameter. For example, if you decide to have a user choose the employees in a given country (using the `employee` table), you can write the following parametric query:

```
select *  
from employee  
where job_country = :country
```

In this SQL clause, `:country` is a parameter. You can set its data type and startup value using the editor of the `SQLDataSet` component's `Params` property collection. When the `Params` collection editor is open, as shown in [Figure 14.8](#), you see a list of the parameters defined in the SQL statement; you can set the data type and the initial value of these parameters in the Object Inspector.

**Figure 14.8:** Editing a query component's collection of parameters

The form displayed by this program, called `ParQuery`, uses a combo box to provide all the available values for the parameters. Instead of preparing the combo box items at design time, you can extract the available contents from the same database table as the program starts. This is accomplished using a second query component, with this SQL statement:

```
select distinct job_country  
from employee
```

After activating this query, the program scans its result set, extracting all the values and adding them to the list box:

```

procedure TQueryForm.FormCreate(Sender: TObject);
begin
  SqlDataSet2.Open;
  while not SqlDataSet2.EOF do
  begin
    ComboBox1.Items.Add (SqlDataSet2.Fields [0].AsString);
    SqlDataSet2.Next;
  end;
  ComboBox1.Text := ComboBox1.Items[0];
end;

```

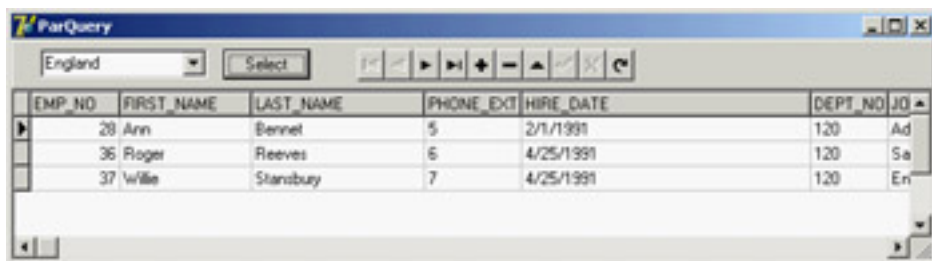

The user can select a different item in the combo box and then click the Select button (Button1) to change the parameter and activate (or re-activate) the query:

```

procedure TQueryForm.Button1Click(Sender: TObject);
begin
  SqlDataSet1.Close;
  ClientDataSet1.Close;
  Query1.Params[0].Value := ListBox1.Items [ListBox1.ItemIndex];
  SqlDataSet1.Open;
  ClientDataSet1.Open;
end;

```

This code displays the employees from the selected country in the DBGrid, as you can see in [Figure 14.9](#). As an alternative to using the elements of the Params array by position, you should consider using the ParamByName method, to avoid any problem in case the query gets modified over time and the parameters end up in a different order.

**Figure 14.9:** The ParQuery example at run time

By using parametric queries, you can usually reduce the amount of data moved over the wire from the server to the client and still use a DBGrid and the standard user interface common in local database applications.

**Tip** Parametric queries are generally also used to obtain master-detail architectures with SQL queries—at least, this is what Delphi tends to do. The *DataSource* property of the SQLDataSet component, automatically replaces parameter values with the fields of the master dataset having the same name as the parameter.

## When One-Way Is Enough: Printing Data

You have seen that one of the key elements of the dbExpress library is that it returns unidirectional datasets. In addition, you can use the ClientDataSet component (in one of its incarnations) to store the records in a local cache. Now, let's discuss an example in which a unidirectional dataset is all you need.

Such a situation is common in *reporting*—that is, producing information for each record in sequence without needing any further access to the data. This broad category includes producing printed reports (via a set of reporting components or using the printer directly), sending data to another application such as Microsoft Excel or Word, saving data to files (including HTML and XML formats), and more.

I don't want to delve into HTML and XML, so I'll present an example of printing—nothing fancy and nothing based on reporting components, just a way to produce a draft report on your monitor and printer. For this reason, I've used

Delphi's most straightforward technique to produce a printout: assigning a file to the printer with the `AssignPrn` RTL procedure.

The example, called `UniPrint`, has a unidirectional `SQLDataSet` component hooked to an `InterBase` connection and based on the following SQL statement, which joins the employee table with the department table to display the name of the department where each employee works:

```
select d.DEPARTMENT, e.FULL_NAME, e.JOB_COUNTRY, e.HIRE_DATE
from EMPLOYEE e
inner join DEPARTMENT d on d.DEPT_NO = e.DEPT_NO
```

To handle printing, I've written a somewhat generic routine, requiring as parameters the data to print, a progress bar for status information, the output font, and the maximum format size of each field. The entire routine uses file-print support and formats each field in a fixed-size, left-aligned string, to produce a columnar type of report. The call to the `Format` function has a parametric format string that's built dynamically using the size of the field.

In [Listing 14.1](#) you can see the code of the core `PrintOutDataSet` method, which uses three nested `try/finally` blocks to release all the resources properly:

### Listing 14.1: The Core Method of the UniPrint Example

---

```
procedure PrintOutDataSet (data: TDataSet;
    progress: TProgressBar; Font: TFont; toFile: Boolean; maxSize: Integer = 30);
var
    PrintFile: TextFile;
    I: Integer;
    sizeStr: string;
    oldFont: TFontRecall;
begin
    // assign the output to a printer or a file
    if toFile then
    begin
        SelectDirectory ('Choose a folder', '', strDir);
        AssignFile (PrintFile,
            IncludeTrailingPathDelimiter(strDir) + 'output.txt');
    end
    else
        AssignPrn (PrintFile);
    // assign the printer to a file
    AssignPrn (PrintFile);
    Rewrite (PrintFile);

    // set the font and keep the original one
    oldFont := TFontRecall.Create (Printer.Canvas.Font);
    try
        Printer.Canvas.Font := Font;
        try
            data.Open;
            try
                // print header (field names) in bold
                Printer.Canvas.Font.Style := [fsBold];
                for I := 0 to data.FieldCount - 1 do
                begin
                    sizeStr := IntToStr (min (data.Fields[I].DisplayWidth, maxSize));
                    Write (PrintFile, Format ('%-' + sizeStr + 's',
                        [data.Fields[I].FieldName]));
                end;
                Writeln (PrintFile);
            end;
        end;
    end;
```

```

// for each record of the dataset
Printer.Canvas.Font.Style := [];
while not data.EOF do
begin
  // print out each field of the record
  for I := 0 to data.FieldCount - 1 do
  begin
    sizeStr := IntToStr (min (data.Fields[i].DisplayWidth, maxSize));
    Write (PrintFile, Format ('%-' + sizeStr + 's',
      [data.Fields[i].AsString]));
  end;
  Writeln (PrintFile);
  // advance ProgressBar
  progress.Position := progress.Position + 1;
  data.Next;
end;
finally
  // close the dataset
  data.Close;
end;
finally
  // reassign the original printer font
  oldFont.Free;
end;
finally
  // close the printer/file
  CloseFile (PrintFile);
end;
end;

```

---

The program invokes this routine when you click the Print All button. It executes a separate query (`select count(*) from EMPLOYEE`), which returns the number of records in the employee table. This query is necessary to set up the progress bar (the unidirectional dataset has no way of knowing how many records it will retrieve until it has reached the last one). Then it sets the output font, possibly using a fixed-width font, and calls the `PrintOutDataSet` routine:

```

procedure TNavigator.PrintAllButtonClick(Sender: TObject);
var
  Font: TFont;
begin
  // set ProgressBar range
  EmplCountData.Open;
  try
    ProgressBar1.Max := EmplCountData.Fields[0].AsInteger;
  finally
    EmplCountData.Close;
  end;

  Font := TFont.Create;
  try
    Font.Name := 'Courier New';
    Font.Size := 9;
    PrintOutDataSet (EmplData, ProgressBar1, Font, cbFile.Checked);
  finally
    Font.Free;
  end;
end;

```

## The Packets and the Cache

The `ClientDataSet` component reads data in packets containing the number of records indicated by the `PacketRecords` property. The default value of this property is `-1`, which means the provider will pull all the records at once (this is reasonable only for a small dataset). Alternatively, you can set this value to zero to ask the server for only the field descriptors and no data, or you can use any positive value to specify a number.

If you retrieve only a partial dataset, then as you browse past the end of the local cache, if the `FetchOnDemand` property is set to `True` (the default value), the `ClientDataSet` component will get more records from its source. This property also controls whether BLOB fields and nested datasets of the current records are fetched automatically (these values might not be part of the data packet, depending on the dataset provider's `Options` value).

If you turn off this property, you'll need to fetch more records manually by calling the `GetNextPacket` method until the method returns zero. (You call `FetchBlobs` and `FetchDetails` for these other elements.)

**Warning** Notice, by the way, that before you set an index for the data, you should retrieve the entire dataset (either by going to its last record or by setting the `PacketRecords` property to `-1`). Otherwise you'll have an odd index based on partial data.

## Manipulating Updates

One of the core ideas behind the `ClientDataSet` component is that it is used as a local cache to collect input from a user and then send a batch of update requests to the database. The component has both a list of the changes to apply to the database server, stored in the same format used by the `ClientDataSet` (accessible through the `Delta` property), and a complete update log that you can manipulate with a few methods (including an Undo capability).

**Tip** In Delphi 7, the `ClientDataSet` component's `ApplyUpdates` and `Undo` operations are also accessible through predefined actions.

## The Status of the Records

The component lets you monitor what's going on within the data packets. The `UpdateStatus` method returns one of the following indicators for the current record:

```
type TUpdateStatus = (usUnmodified, usModified, usInserted, usDeleted);
```

To easily check the status of every record in the client dataset, you can add a string-type calculated field to the dataset (I've called it `ClientDataSet1Status`) and compute its value with the following `OnCalcFields` event handler:

```
procedure TForm1.ClientDataSet1CalcFields(DataSet: TDataSet);  
begin  
    ClientDataSet1Status.AsString := GetEnumName (TypeInfo(TUpdateStatus),  
        Integer (ClientDataSet1.UpdateStatus));  
end;
```

This method (based on the RTTI `GetEnumName` function) converts the current value of the `TUpdateStatus` enumeration to a string, with the effect you can see in [Figure 14.10](#).

The screenshot shows a window titled "Client 3 Tier" with buttons for "Update", "Show Delta", and "Undo". Below the buttons is a "Data" tab and a table with the following columns: Status, DEPT\_NO, EMP\_NO, FIRST\_NAME, LAST\_NAME, PHONE\_EXT, and SALARY. The table contains 10 rows of employee data.

Status	DEPT_NO	EMP_NO	FIRST_NAME	LAST_NAME	PHONE_EXT	SALARY
usUnmodified	115	118	Takashi	Yanamoto	23	
usUnmodified	125	121	Roberto	Fenali	1	
usUnmodified	100	127	Michael	Yanowski	492	
usModified	123	134	Jacques	Glon	937	
usUnmodified	623	136	Scott	Johnson	265	
usUnmodified	621	138	T.J.	Green	218	
usUnmodified	672	144	John	Montgomery	820	
usModified	622	145	Mark	Guckenheimer	931	
usInserted	622	146	John	Roland	932	

Figure 14.10: The CdsDelta program displays the status of each record of a ClientDataSet.

## Accessing the Delta

Beyond examining the status of each record, the best way to understand which changes have occurred in a given ClientDataSet (but haven't been uploaded to the server) is to look at the *delta*—the list of changes waiting to be applied to the server. This property is defined as follows:

```
property Delta: OleVariant;
```

The format used by the `Delta` property is the same as that used for the data of a client dataset. You can add another ClientDataSet component to an application and connect it to the data in the `Delta` property of the first client dataset:

```
if ClientDataSet1.ChangeCount > 0 then
begin
  ClientDataSet2.Data := ClientDataSet1.Delta;
  ClientDataSet2.Open;
```

In the CdsDelta example, I've added a data module with the two ClientDataSet components and a source of data: a SQLDataSet mapped to InterBase's EMPLOYEE demo table. Both client datasets have the extra status calculated field, with a slightly more generic version than the code discussed earlier, because the event handler is shared between them.

**Tip** To create persistent fields for the ClientDataSet hooked to the delta (at run time), I've temporarily connected it at design time to the main ClientDataSet's provider. The delta's structure is the same as the dataset it refers to. After creating the persistent fields, I removed the connection.

The application's form has a page control with two pages, each of which has a DBGrid, one for the data and one for the delta. Code hides or shows the second tab depending on the existence of data in the change log, as returned by the `ChangeCount` method, and updates the delta when the corresponding tab is selected. The core of the code used to handle the delta is similar to the previous code snippet, and you can study the example source code on the CD to see more details.

Figure 14.11 shows the change log of the CdsDelta application. Notice that the delta dataset has two entries for each modified record (the original values and the modified fields) unless this is a new or deleted record, as indicated by its status.

Status	DEPT_NO	EMP_NO	FIRST_NAME	LAST_NAME	PHONE_EXT	SALARY
usUnmodified	600	2	Robert	Nelson	250	105900
usModified					251	
usInserted	622	146	John	Poland	532	32000
usUnmodified	622	145	Mark	Guckenheimer	321	32000
usModified					531	
usDeleted	121	141	Piers	Osborne		110000
usUnmodified	123	134	Jacques	Glen		390500
usModified					537	

**Figure 14.11:** The CdsDelta example allows you to see the temporary update requests stored in the `Delta` property of the `ClientDataSet`.

**Tip** You can filter the delta dataset (or any other `ClientDataSet`) depending on its update status, using the `StatusFilter` property. This property allows you to show new, updated, and deleted records in separate grids or in a grid filtered by selecting an option in a `TabControl`.

## Updating the Data

Now that you have a better understanding of what goes on during local updates, you can try to make this program work by sending the local update (stored in the delta) back to the database server. To apply all the updates from a dataset at once, pass `-1` to the `ApplyUpdates` method.

If the provider (or the Resolver component inside it) has trouble applying an update, it triggers the `OnReconcileError` event. This can take place because of a concurrent update by two different people. We tend to use optimistic locking in client/server applications, so this should be regarded as a normal situation.

The `OnReconcileError` event allows you to modify the `Action` parameter (passed by reference), which determines how the server should behave:

```
procedure TForm1.ClientDataSet1ReconcileError(DataSet: TClientDataSet;
  E: EReconcileError; UpdateKind: TUpdateKind; var Action: TReconcileAction);
```

This method has three parameters: the client dataset component (in case there is more than one client dataset in the current application), the exception that caused the error (with the error message), and the kind of operation that failed (`ukModify`, `ukInsert`, or `ukDelete`). The return value, which you'll store in the `Action` parameter, can be any one of the following:

```
type TReconcileAction = (raSkip, raAbort, raMerge, raCorrect, raCancel,
  raRefresh);
```

**raSkip** Specifies that the server should skip the conflicting record, leaving it in the delta (this is the default value).

**raAbort** Tells the server to abort the entire update operation and not try to apply the remaining changes listed in the delta.

**raMerge** Tells the server to merge the client data with the data on the server, applying only the modified fields of this client (and keeping the other fields modified by other clients).

**raCorrect** Tells the server to replace its data with the current client data, overriding all field changes already made by other clients.

**raCancel** Cancels the update request, removing the entry from the delta and restoring the values originally fetched from the database (thus ignoring changes made by other clients).

**raRefresh** Tells the server to dump the updates in the client delta and to replace them with the values currently on the server (thus keeping the changes made by other clients).

To test a collision, you can launch two copies of the client application, change the same record in both clients, and then post the updates from both. We'll do this later to generate an error, but let's first see how to handle the `OnReconcileError` event.

Handling this event is not too difficult, but only because you'll receive a little help. Because building a specific form to handle an `OnReconcileError` event is common, Delphi provides such a form in the Object Repository (available with the File → New → Other menu command of the Delphi IDE). Go to the Dialogs page and select the Reconcile Error Dialog item. This unit exports a function you can use directly to initialize and display the dialog box, as I've done in the `CdsDelta` example:

```
procedure TDmCds.cdsEmployeeReconcileError (DataSet: TCustomClientDataSet;
  E: EReconcileError; UpdateKind: TUpdateKind; var Action: TReconcileAction);
begin
  Action := HandleReconcileError(DataSet, UpdateKind, E);
end;
```

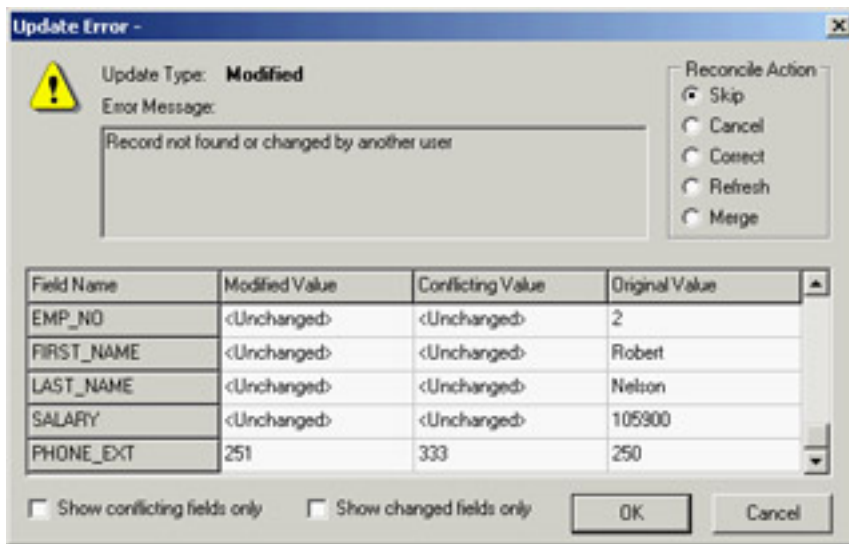

**Warning** As the source code of the Reconcile Error Dialog unit suggests, you should use the Project Options dialog to remove this form from the list of automatically created forms (if you don't, an error will occur when you compile the project). Of course, you need to do this only if you haven't set up Delphi to skip the automatic form creation.

The `HandleReconcileError` function creates the dialog box form and shows it, as you can see in the code provided by Borland:

```
function HandleReconcileError(DataSet: TDataSet; UpdateKind: TUpdateKind;
  ReconcileError: EReconcileError): TReconcileAction;
var
  UpdateForm: TReconcileErrorForm;
begin
  UpdateForm := TReconcileErrorForm.CreateForm(DataSet, UpdateKind,
    ReconcileError);
  with UpdateForm do
  try
    if ShowModal = mrOK then
    begin
      Result := TReconcileAction(ActionGroup.Items.Objects[
        ActionGroup.ItemIndex]);
      if Result = raCorrect then
        SetFieldValues(DataSet);
    end
    else
      Result := raAbort;
  finally
    Free;
  end;
end;
```

The `Reconc` unit, which hosts the Reconcile Error dialog (a window titled Update Error to be more understandable by end-users of your programs), contains more than 350 lines of code, so I can't describe it in detail. However, you should be able to understand the source code by studying it carefully. Alternatively, you can use it without caring how everything works.

The dialog box will appear in case of an error, reporting the requested change that caused the conflict and allowing the user to choose one of the possible `TReconcileAction` values. You can see this form at run time in [Figure 14.12](#).

**Figure 14.12:** The Reconcile Error dialog provided by Delphi in the Object Repository and used by the CdsDelta example

**Tip** When you call *ApplyUpdates*, you start a complex update sequence, which is discussed in more detail in [Chapter 16](#) for multitier architectures. In short, the delta is sent to the provider, which fires the *OnUpdateData* event and then receives a *BeforeUpdateRecord* event for every record to update. These are two chances you have to look at the changes and force specific operations on the database server.

## Using Transactions

Whenever you are working with a SQL server, you should use *transactions* to make your applications more robust. You can think of a transaction as a series of operations that are considered a single, "atomic" whole that cannot be split.

An example may help to clarify the concept. Suppose you have to raise the salary of each employee of a company by a fixed rate, as you did in the Total example in [Chapter 13](#). A typical program would execute a series of SQL statements on the server, one for each record to update. If an error occurred during the operation, you might want to undo the previous changes. If you consider the operation "raise the salary of each employee" as a single transaction, it should either be completely performed or completely ignored. Or, consider the analogy with financial transactions—if an error causes only part of the operation to be performed, you might end up with a missed credit or with some extra money.

Working with database operations as transactions serves a useful purpose. You can start a transaction and do several operations that should all be considered parts of a single larger operation; then, at the end, you can either commit the changes or *roll back* the transaction, discarding all the operations done up to that moment. Typically, you might want to roll back a transaction if an error occurred during its operations.

There is another important element to underline: Transactions also serve a purpose when reading data. Until data is committed by a transaction, other connections and/or transactions should not see it. Once the data is committed from a transaction, others should see the change when reading the data—that is, unless you need to open a transaction and read the same data over and over for data analysis or complex reporting operations. Different SQL servers allow you to read data in transaction according to some or all of these alternatives, as you'll see when we discuss transaction isolation levels.

Handling transactions in Delphi is simple. By default, each edit/post operation is considered a single *implicit* transaction, but you can alter this behavior by handling the operations explicitly. Use the following three methods of the dbExpress SQLConnection component (other database connection components have similar methods):

*StartTransaction* Marks the beginning of a transaction

*Commit* Confirms all the updates to the database done during the transaction

*Rollback* Returns the database to its state prior to starting the transaction

You can also use the `InTransaction` property to check whether a transaction is active. You'll often use a `try` block to roll back a transaction when an exception is raised, or you can commit the transaction as the last operation of the `try` block, which is executed only when there is no error. The code might look like this:

```
var
    TD: TTransactionDesc;
begin
    TD.TransactionID := 1;
    TD.IsolationLevel := xilREADCOMMITTED;
    SQLConnection1.StartTransaction(TD);
    try
        // -- operations within the transaction go here --
        SQLConnection1.Commit(TD);
    except
        SQLConnection1.Rollback(TD);
    end;
```

Each transaction-related method has a parameter describing the transaction it is working with. The parameter uses the record type `TTransactionDesc` and accounts for a transaction isolation level and a transaction ID. The transaction isolation level is an indication of how the transaction should behave when other transactions make changes to the data. The three predefined values are as follows:

**tiDirtyRead** Makes the transaction's updates immediately visible to other transactions, even before they are committed. This is the only possibility in a few databases and corresponds to the behavior of databases with no transaction support.

**tiReadCommitted** Makes available to other transactions only the updates already committed by this transaction. This setting is recommended for most databases, to preserve efficiency.

**tiRepeatableRead** Hides changes made by every transaction started after the current one, even if the changes have been committed. Subsequent repeat calls within a transaction will always produce the same result, as if the database took a snapshot of the data when the current transaction started. Only InterBase and few other database servers work efficiently with this model.

**Tip** As a general suggestion, for performance reasons transactions should involve a minimal number of updates (only those strictly related and part of a single atomic operation) and should be kept short in time. You should avoid transactions that wait for user input to complete them, because the user might be temporarily gone, and the transaction might remain active for a long time. Caching changes locally, as the `ClientDataSet` allows, can help you make the transactions small and fast, because you can open a transaction for reading, close it, and then open a transaction for writing out the entire batch of changes.

The other field of the `TTransactionDesc` record holds a transaction ID. It is useful only in conjunction with a database server supporting multiple concurrent transactions over the same connection, like InterBase does. You can ask the connection component whether the server supports multiple transactions or doesn't support transactions at all, using the `MultipleTransactionsSupported` and `TransactionsSupported` properties.

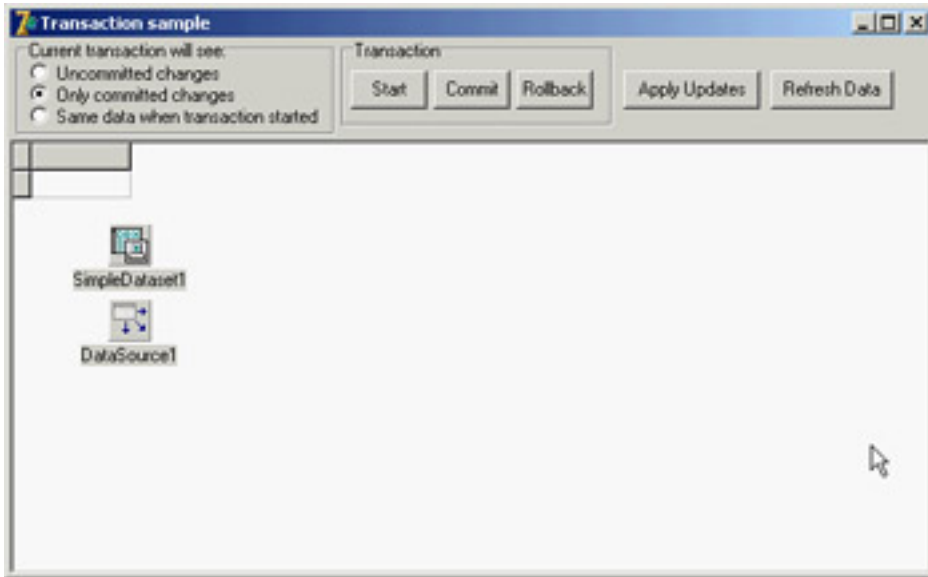

When the server supports multiple transactions, you must supply each transaction with a unique identifier when calling the `StartTransaction` method:

```
var
    TD: TTransactionDesc;
begin
    TD.TransactionID := GetTickCount;
    TD.IsolationLevel := xilREADCOMMITTED;
    SQLConnection1.StartTransaction(TD);
```

```
SQLDataSet1.TransactionLevel := TD.TransactionID;
```

You can also indicate which datasets belong to which transaction by setting the `TransactionLevel` property of each dataset to a transaction ID, as shown in the last statement.

To further inspect transactions and to experiment with transaction isolation levels, you can use the `TranSample` application. As you can see in [Figure 14.13](#), radio buttons let you choose the various isolation levels and buttons let you work on the transactions and apply updates or refresh data. To get a real idea of the different effects, you should run multiple copies of the program (provided you have enough licenses on your InterBase server).

**Figure 14.13:** The form of the `TranSample` application at design time. The radio buttons let you set different transaction isolation levels.

**Note** InterBase doesn't support the "dirty read" mode, so in the `TranSample` program you cannot use the last option unless you work with a different server.

## Using InterBase Express

The examples built earlier in this chapter were created with the new dbExpress database library. Using this server-independent approach allows you to switch the database server used by your application, although in practice doing so is often far from simple. If the application you are building will invariably use a given database, you can write programs that are tied directly to the API of the specific database server. This approach will make your programs intrinsically non-portable to other SQL servers.

Of course, you won't generally use these APIs directly, but rather base your development on dataset components that wrap these APIs and fit into Delphi and the architecture of its class library. An example of such a family of components is InterBase Express (IBX). Applications built using these components should work better and faster (even if only marginally), giving you more control over the specific features of the server. For example, IBX provides a set of administrative components specifically built for InterBase 6.

**Note** I'll examine the IBX components because they are tied to InterBase (the database server discussed in this chapter) and because they are the only set of components available in the standard Delphi installation. Other similar sets of components (for InterBase, Oracle, and other database servers) are equally powerful and well regarded in the Delphi programmers' community. A good example (and an alternative to IBX) is InterBase Objects ([www.ibobjects.com](http://www.ibobjects.com)).

## IBX Dataset Components

The IBX components include custom dataset components and a few others. The dataset components inherit from the base `TDataSet` class, can use all the common Delphi data-aware controls, and provide a field editor and all the usual design-time features. You can choose among multiple dataset components. Three IBX datasets have a role and a set of properties similar to the table/query/storedproc components in the dbExpress family:

- `IBTable` resembles the `Table` component and allows you to access a single table or view.
- `IBQuery` resembles the `Query` component and allows you to execute a SQL query, returning a result set. The `IBQuery` component can be used together with the `IBUpdateSQL` component to obtain a live (or editable) dataset.
- `IBStoredProc` resembles the `StoredProc` component and allows you to execute a stored procedure.

These components, like the related dbExpress ones, are intended for compatibility with older BDE components you might have used in your applications. For new applications, you should generally use the `IBDataSet` component, which allows you to work with a live result set obtained by executing a `select` query. It basically merges `IBQuery` with `IBUpdateSQL` in a single component. The three components in the previous list are provided mainly for compatibility with existing Delphi BDE applications.

Many other components in InterBase Express don't belong to the dataset category, but are still used in applications that need to access to a database:

- `IBDatabase` acts like the `DBX SQLConnection` component and is used to set up the database connection. The BDE also uses the specific `Session` component to perform some global tasks done by the `IBDatabase` component.
- `IBTransaction` allows complete control over transactions. It is important in InterBase to use transactions explicitly and to isolate each transaction properly, using the `Snapshot` isolation level for reports and the `Read Committed` level for interactive forms. Each dataset explicitly refers to a given transaction, so you can have multiple concurrent transactions against the same database and choose which datasets take part in which transaction.
- `IBSQL` lets you execute SQL statements that don't return a dataset (for example, DDL requests, or `update` and `delete` statements) without the overhead of a dataset component.
- `IBDatabaseInfo` is used for querying the database structure and status.

- IBSQLMonitor is used for debugging the system, because the SQL Monitor debugger provided by Delphi is a BDE-specific tool.
- IBEvents receives events posted by the server.

This group of components provides greater control over the database server than you can achieve with dbExpress. For example, having a specific transaction component allows you to manage multiple concurrent transactions over one or multiple databases, as well as a single transaction spanning multiple databases. The IBDatabase component allows you to create databases, test the connection, and generally access system data, something the Database and Session BDE components don't fully provide.

**Tip** IBX datasets let you set up the automatic behavior of a generator as a sort of auto-increment field. You do so by setting the *GeneratorField* property using its specific property editor. An example is discussed later in this chapter in the section "[Generators and IDs.](#)"

## IBX Administrative Components

The InterBase Admin page of Delphi's Component Palette hosts InterBase administrative components. Although your aim is probably not to build a full InterBase console application, including some administrative features (such as backup handling or user monitoring) can make sense in applications meant for power users.

Most of these components have self-explanatory names: IBConfigService, IBBackupService, IBRestoreService, IBValidationService, IBStatisticalService, IBLogService, IBSecurityService, IBServerProperties, IBInstall, and IBUninstall. I won't build any advanced examples that use these components, because they are more focused toward the development of server management applications than client programs. However, I'll embed a couple of them in the IbxMon example discussed later in this chapter.

## Building an IBX Example

To build an example that uses IBX, you'll need to place in a form (or data module) at least three components: an IBDatabase, an IBTransaction, and a dataset component (in this case an IBQuery). Any IBX application requires at least an instance of the first two components. You cannot set database connections in an IBX dataset, as you can do with other datasets. And, at least a transaction object is required even to read the result of a query.

Here are the key properties of these components in the IbxEmp example:

```
object IBTransaction1: TIBTransaction
  Active = False
  DefaultDatabase = IBDatabase1
end
object IBQuery1: TIBQuery
  Database = IBDatabase1
  Transaction = IBTransaction1
  CachedUpdates = False
  SQL.Strings = (
    'SELECT * FROM EMPLOYEE')
end
object IBDatabase1: TIBDatabase
  DatabaseName = 'C:\Program Files\Common Files\Borland Shared\Data\employee.gdb'
  Params.Strings = (
    'user_name=SYSDBA'
    'password=masterkey')
  LoginPrompt = False
  SQLDialect = 1
end
```

Now you can hook a DataSource component to IBQuery1 and easily build a user interface for the application. I had to

type in the pathname of the Borland sample database. However, not everyone has the `Program Files` folder, which depends on the local version of Windows, and the Borland sample data files could be installed elsewhere on the disk. You'll solve these problems in the next example.

**Warning** Notice that I've embedded the password in the code—a naïve approach to security. Not only can anyone run the program, but someone can extract the password by looking at the hexadecimal code of the executable file. I used this approach so I wouldn't need to keep typing in my password while testing the program, but in a real application you should require your users to do so to ensure the security of their data.

## Building a Live Query

The `IbxEmp` example includes a query that doesn't allow editing. To activate editing, you need to add an `IBUpdateSQL` component to the query, even if the query is trivial. Using an `IBQuery` that hosts the SQL `select` statement together with an `IBUpdateSQL` component that hosts the `insert`, `update`, and `delete` SQL statements is a typical approach from BDE applications. The similarities among these components make it easier to port an existing BDE application to this architecture. Here is the code for these components (edited for clarity):

```
object IBQuery1: TIBQuery
  Database = IBDatabase1
  Transaction = IBTransaction1
  SQL.Strings = (
    'SELECT Employee.EMP_NO, Department.DEPARTMENT, Employee.FIRST_NAME, '+
    ' Employee.LAST_NAME, Job.JOB_TITLE, Employee.SALARY, Employee.DEPT_NO, '+
    ' Employee.JOB_CODE, Employee.JOB_GRADE, Employee.JOB_COUNTRY'
    'FROM EMPLOYEE Employee'
    ' INNER JOIN DEPARTMENT Department'
    ' ON (Department.DEPT_NO = Employee.DEPT_NO) '
    ' INNER JOIN JOB Job'
    ' ON (Job.JOB_CODE = Employee.JOB_CODE) '
    ' AND (Job.JOB_GRADE = Employee.JOB_GRADE) '
    ' AND (Job.JOB_COUNTRY = Employee.JOB_COUNTRY) '
    'ORDER BY Department.DEPARTMENT, Employee.LAST_NAME')
  UpdateObject = IBUpdateSQL1
end
object IBUpdateSQL1: TIBUpdateSQL
  RefreshSQL.Strings = (
    'SELECT Employee.EMP_NO, Employee.FIRST_NAME, Employee.LAST_NAME, '+
    ' Department.DEPARTMENT, Job.JOB_TITLE, Employee.SALARY, Employee.DEPT_NO, '+
    ' Employee.JOB_CODE, Employee.JOB_GRADE, Employee.JOB_COUNTRY'
    'FROM EMPLOYEE Employee'
    'INNER JOIN DEPARTMENT Department'
    'ON (Department.DEPT_NO = Employee.DEPT_NO)'
    'INNER JOIN JOB Job'
    'ON (Job.JOB_CODE = Employee.JOB_CODE)'
    'AND (Job.JOB_GRADE = Employee.JOB_GRADE)'
    'AND (Job.JOB_COUNTRY = Employee.JOB_COUNTRY)'
    'WHERE Employee.EMP_NO=:EMP_NO')
  ModifySQL.Strings = (
    'update EMPLOYEE'
    'set'
    ' FIRST_NAME = :FIRST_NAME,'
    ' LAST_NAME = :LAST_NAME,'
    ' SALARY = :SALARY,'
    ' DEPT_NO = :DEPT_NO,'
    ' JOB_CODE = :JOB_CODE,'
    ' JOB_GRADE = :JOB_GRADE,'
    ' JOB_COUNTRY = :JOB_COUNTRY'
```

```

'where'
  ' EMP_NO = :OLD_EMP_NO')
InsertSQL.Strings = (
  'insert into EMPLOYEE'
  '(FIRST_NAME, LAST_NAME, SALARY, DEPT_NO, JOB_CODE, JOB_GRADE, JOB_COUNTRY)'
  'values'
  '(:FIRST_NAME, :LAST_NAME, :SALARY, :DEPT_NO, :JOB_CODE, :JOB_GRADE, :JOB_COUNTRY)')
DeleteSQL.Strings = (
  'delete from EMPLOYEE '
  'where EMP_NO = :OLD_EMP_NO')
end

```

For new applications, you should consider using the `IBDataSet` component, which sums up the features of `IBQuery` and `IBUpdateSQL`. The differences between using the two components and the single component are minimal. Using `IBQuery` and `IBUpdateSQL` is a better approach when you're porting an existing application based on the two equivalent BDE components, even if porting the program directly to the `IBDataSet` component doesn't require much extra work.

In the `lbxUpdSql` example, I've provided both alternatives so you can test the differences yourself. Here is the skeleton of the DFM description of the single dataset component:

```

object IBDataSet1: TIBDataSet
  Database = IBDatabase1
  Transaction = IBTransaction1
  DeleteSQL.Strings = (
    'delete from EMPLOYEE'
    'where EMP_NO = :OLD_EMP_NO')
  InsertSQL.Strings = (
    'insert into EMPLOYEE'
    ' (FIRST_NAME, LAST_NAME, SALARY, DEPT_NO, JOB_CODE, JOB_GRADE, ' +
    ' JOB_COUNTRY)'
    'values'
    ' (:FIRST_NAME, :LAST_NAME, :SALARY, :DEPT_NO, :JOB_CODE, ' +
    ' :JOB_GRADE, :JOB_COUNTRY)')
  SelectSQL.Strings = (...)
  UpdateRecordTypes = [cusUnmodified, cusModified, cusInserted]
  ModifySQL.Strings = (...)
end

```

If you connect the `IBQuery1` or the `IBDataSet1` component to the data source and run the program, you'll see that the behavior is identical. Not only do the components have a similar effect; the available properties and events are also similar.

In the `lbxUpdSql` program, I've also made the reference to the database a little more flexible. Instead of typing in the database name at design time, I've extracted the Borland shared data folder from the Windows Registry (where Borland saves it while installing Delphi). Here is the code executed when the program starts:

```

uses
  Registry;

procedure TForm1.FormCreate(Sender: TObject);
var
  Reg: TRegistry;
begin
  Reg := TRegistry.Create;
  try
    Reg.RootKey := HKEY_LOCAL_MACHINE;
    Reg.OpenKey('\Software\Borland\Borland Shared\Data', False);
    IBDatabase1.DatabaseName := Reg.ReadString('Rootdir') + '\employee.gdb';
  finally

```

```

finally
  Reg.Free;
end;
  EmpDS.DataSet.Open;
end;

```

**Note** For more information about the Windows Registry and INI files, see the related sidebar in [Chapter 8](#), "The Architecture of Delphi Applications."

Another feature of this example is the presence of a transaction component. As I've said, the InterBase Express components make the use of a transaction component compulsory, explicitly following a requirement of InterBase. Simply adding a couple of buttons to the form to commit or roll back the transaction would be enough, because a transaction starts automatically as you edit any dataset attached to it.

I've also improved the program by adding an ActionList component. This component includes all the standard database actions and adds two custom actions for transaction support: Commit and Rollback. Both actions are enabled when the transaction is active:

```

procedure TForm1.ActionUpdateTransactions(Sender: TObject);
begin
  acCommit.Enabled := IBTransaction1.InTransaction;
  acRollback.Enabled := acCommit.Enabled;
end;

```

When executed, they perform the main operation but also need to reopen the dataset in a new transaction (which can also be done by "retaining" the transaction context). `CommitRetaining` doesn't really reopen a new transaction, but it allows the current transaction to remain open. This way, you can keep using your datasets, which won't be refreshed (so you won't see edits already committed by other users) but will keep showing the data you've modified. Here is the code:

```

procedure TForm1.acCommitExecute(Sender: TObject);
begin
  IBTransaction1.CommitRetaining;
end;

procedure TForm1.acRollbackExecute(Sender: TObject);
begin
  IBTransaction1.Rollback;
  // reopen the dataset in a new transaction
  IBTransaction1.StartTransaction;
  EmpDS.DataSet.Open;
end;

```

**Warning** Be aware that InterBase closes any opened cursors when a transaction ends, which means you have to reopen them and refetch the data even if you haven't made any changes. When committing data, however, you can ask InterBase to retain the *transaction context*—not to close open datasets—by issuing a `CommitRetaining` command, as mentioned before. InterBase behaves this way because a transaction corresponds to a snapshot of the data. Once a transaction is finished, you are supposed to read the data again to refetch records that may have been modified by other users. Version 6.0 of InterBase includes a `RollbackRetaining` command, but I've decided not to use it because in a rollback operation, the program should refresh the dataset data to show the original values on screen, not the updates you've discarded.

The last operation refers to a generic dataset and not a specific one, because I'm going to add a second alternate dataset to the program. The actions are connected to a text-only toolbar, as you can see in [Figure 14.14](#). The program opens the dataset at startup and automatically closes the current transaction on exit, after asking the user what to do, with the following `OnClose` event handler:

EMP_NO	FIRST_NAME	LAST_NAME	DEPARTMENT	JOB_TITLE	SALARY
05	Sue Anne	O'Brien	Consumer Electronics Div.	Administrative Assistant	31275 6
107	Kevin	Cook	Consumer Electronics Div.	Director	111262 5 6
105	Oliver H.	Bender	Corporate Headquarters	Chief Executive Officer	212650 0
12	Terri	Lee	Corporate Headquarters	Administrative Assistant	53793 0
144	John	Montgomery	Customer Services	Engineer	35000 6
94	Randy	Williams	Customer Services	Manager	56295 6
25	Roger	De Souza	Customer Support	Engineer	59482 63 6
44	Leslie	Phong	Customer Support	Engineer	56034 38 6
114	Bill	Parker	Customer Support	Engineer	35000 6
15	Katherine	Young	Customer Support	Manager	67241 25 6
136	Scott	Johnson	Customer Support	Technical Writer	60000 6
2	Robert	Nelson	Engineering	Vice President	105900 6
105	Kelly	Brown	Engineering	Administrative Assistant	27000 6
36	Roger	Reeves	European Headquarters	Sales Co-ordinator	33620 63 1
26	Ann	Bennet	European Headquarters	Administrative Assistant	22335 1
37	Wille	Stansbury	European Headquarters	Engineer	35224 06 1

Figure 14.14: The output of the IbxUpdSql example

```

procedure TForm1.FormClose(Sender: TObject; var Action: TCloseAction);
var
    nCode: Word;
begin
    if IBTransaction1.InTransaction then
    begin
        nCode := MessageDlg ('Commit Transaction? (No to rollback)',
            mtConfirmation, mbYesNoCancel, 0);
        case nCode of
            mrYes: IBTransaction1.Commit;
            mrNo: IBTransaction1.Rollback;
            mrCancel: Action := caNone; // don't close
        end;
    end;
end;

```

## Monitoring InterBase Express

Like the dbExpress architecture, IBX also allows you to monitor a connection. You can embed a copy of the IBSQLMonitor component in your application and produce a custom log.

You can even write a more generic monitoring application, as I've done in the IbxMon example. I've placed in its form a monitoring component and a RichEdit control, and written the following handler for the OnSQL event:

```

procedure TForm1.IBSQLMonitor1SQL(EventText: String);
begin
    if Assigned (RichEdit1) then
        RichEdit1.Lines.Add (TimeToStr (Now) + ': ' + EventText);
    end;

```

The `if Assigned` test can be useful when receiving a message during shutdown, and it is required when you add this code directly inside the application you are monitoring.

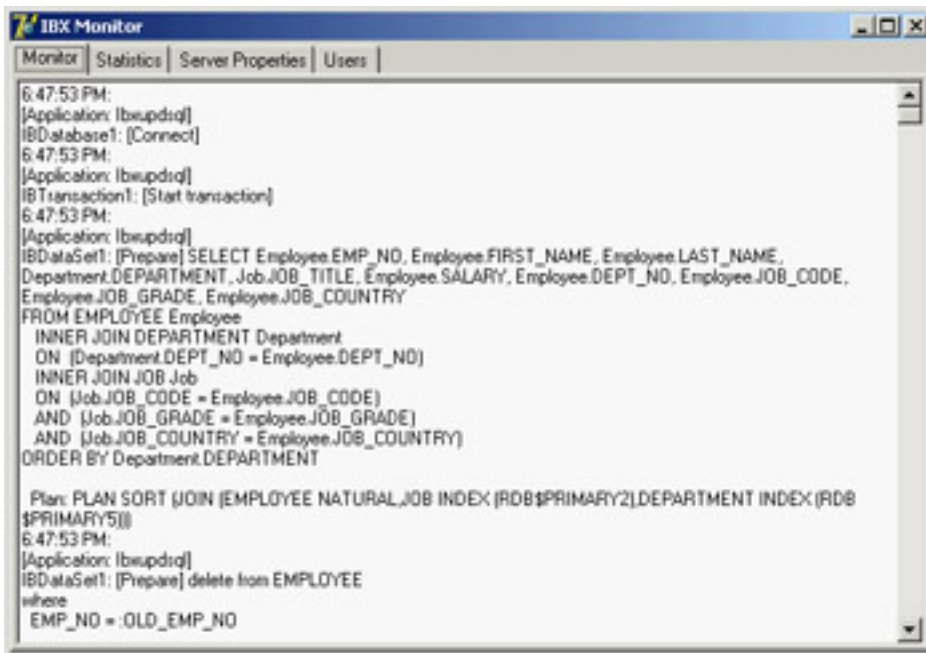

To receive messages from other applications (or from the current application), you have to turn on the IBDatabase component's tracing options. In the IbxUpdSql example (discussed in the preceding section, "[Building a Live Query](#)"), I turned them all on:

```

object IBDatabase1: TIBDatabase
    ...
    TraceFlags = [tfQPrepare, tfQExecute, tfQFetch, tfError, tfStmt,
        tfConnect, tfTransact, tfBlob, tfService, tfMisc]

```

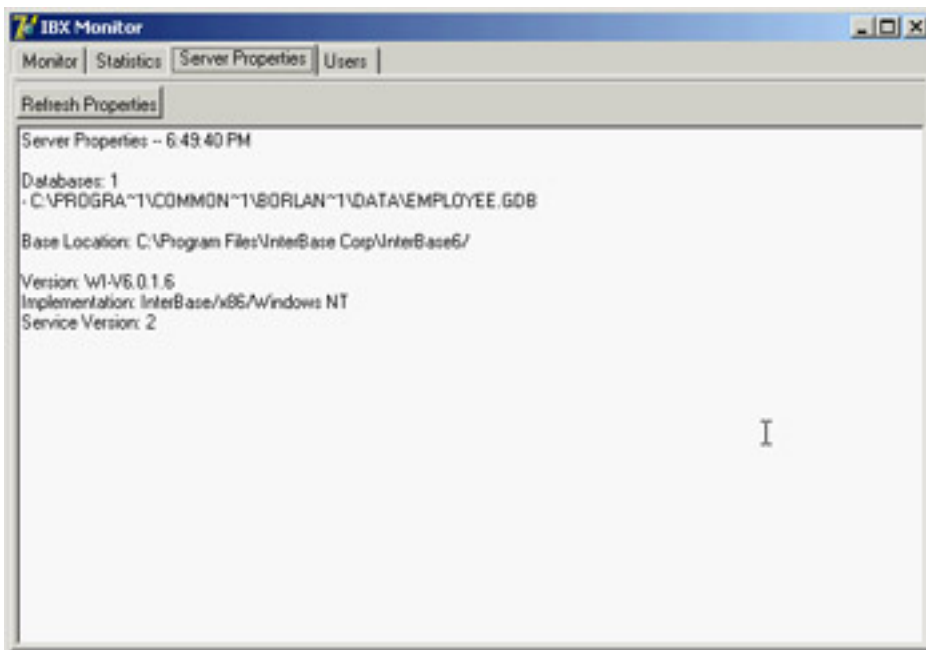

If you run the two examples at the same time, the output of the IbxMon program will list details about the IbxUpdSql program's interaction with InterBase, as you can see in [Figure 14.15](#).

**Figure 14.15:** The output of the IbxMon example, based on the IBMonitor component

## Getting More System Data

In addition to letting you monitor the InterBase connection, the IbxMon example allows you to query some server settings using the various tabs on its page control. The example embeds a few IBX administrative components, showing server statistics, server properties, and all connected users. You can see an example of the server properties in [Figure 14.16](#). The code for extracting the users appears in the following code fragment.

**Figure 14.16:** The server information displayed by the IbxMon application

```
// grab the user's data
IBSecurityService1.DisplayUsers;
```

```
// display the name of each user
for i := 0 to IBSecurityService1.UserInfoCount - 1 do
  with IBSecurityService1.UserInfo[i] do
    RichEdit4.Lines.Add (Format ('User: %s, Full Name: %s, Id: %d',
      [UserName, FirstName + ' ' + LastName, UserId]));
```

## Real-World Blocks

Up to now, we've discussed specific techniques related to InterBase programming, but we haven't delved into the development of an application and the problems this presents in practice. In the following subsections, I'll discuss a few practical techniques, in no specific order.

Nando Dessena (who knows InterBase much better than I do) and I have used all of these techniques in a seminar discussing the porting of an internal Paradox application to InterBase. The application we discussed in the seminar was large and complex, and I've trimmed it down to only a few tables to make it fit into the space I have for this chapter.

**Tip** The database discussed in this section is called *mastering.gdb*. You can find it in the *data* subfolder of the code folder for this chapter. You can examine it using InterBase Console, possibly after making a copy to a writable drive so that you can fully interact with it.

## Generators and IDs

I mentioned in [Chapter 13](#) that I'm a fan of using IDs extensively to identify the records in each table of a database.

**Note** I tend to use a single sequence of IDs for an entire system, something often called an Object ID (OID) and discussed in a sidebar earlier in this chapter. In such a case, however, the IDs of the two tables must be unique. Because you might not know in advance which objects could be used in place of others, adopting a global OID allows you more freedom later. The drawback is that if you have lots of data, using a 32-bit integer as the ID (that is, having only 4 billion objects) might not be sufficient. For this reason, InterBase 6 supports 64-bit generators.

How do you generate the unique values for these IDs when multiple clients are running? Keeping a table with a *latest* value will create troubles, because multiple concurrent transactions (from different users) will see the same values. If you don't use tables, you can use a database-independent mechanism, including the rather large Windows GUIDs or the so-called *high-low technique* (the assignment of a base number to each client at startup—the high number—that is combined with a consecutive number—the low number—determined by the client).

Another approach, bound to the database, is the use of internal mechanisms for sequences, indicated with different names in each SQL server. In InterBase they are called *generators*. These sequences operate and are incremented outside of transactions, so that they provide unique numbers even to concurrent users (remember that InterBase forces you to open a transaction to read data).

You've already seen how to create a generator. Here is the definition for the one in my demo database, followed by the definition of the view you can use to query for a new value:

```
create generator g_master;

create view v_next_id (
    next_id
) as
select gen_id(g_master, 1) from rdb$database
;
```

Inside the RWBlocks application, I've added an IBQuery component to a data module (because I don't need it to be an editable dataset) with the following SQL:

```
select next_id from v_next_id;
```

The advantage, compared to using the direct statement, is that this code is easier to write and maintain, even if the underlying generator changes (or you switch to a different approach behind the scenes). Moreover, in the same data module, I've added a function that returns a new value for the generator:

```
function TDmMain.GetNewId: Integer;
begin
```

```

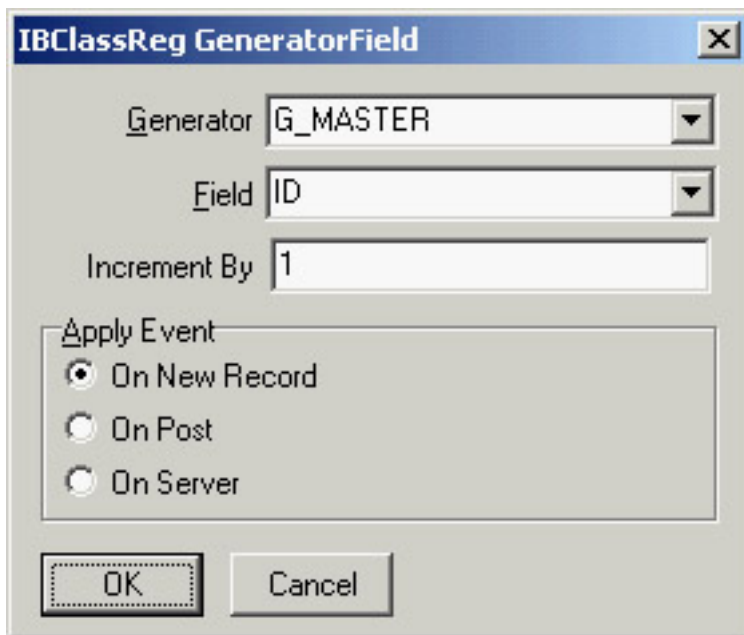

// return the next value of the generator
QueryId.Open;
try
    Result := QueryId.Fields[0].AsInteger;
finally
    QueryId.Close;
end;
end;

```

This method can be called in the `AfterInsert` event of any dataset to fill in the value for the ID:

```
mydataset.FieldName ('ID').AsInteger := data.GetNewId;
```

As I've mentioned, the IBX datasets can be tied directly to a generator, thus simplifying the overall picture. Thanks to the specific property editor (shown in [Figure 14.17](#)), connecting a field of the dataset to the generator becomes trivial.

**Figure 14.17:** The editor for the `GeneratorField` property of the IBX datasets

Notice that both these approaches are much better than the approach based on a server-side trigger, discussed earlier in this chapter. In that case, the Delphi application didn't know the ID of the record sent to the database and so was unable to refresh it. Not having the record ID (which is also the only key field) on the Delphi side means it is almost impossible to insert such a value directly inside a `DBGrid`. If you try, you'll see that the value you insert gets lost, only to reappear in case of a full refresh.

Using client-side techniques based on the manual code or the `GeneratorField` property causes no trouble. The Delphi application knows the ID (the record key) before posting it, so it can easily place it in a grid and refresh it properly.

## Case-Insensitive Searches

An interesting issue with SQL servers in general, not specifically InterBase, has to do with case-insensitive searches. Suppose you don't want to show a large amount of data in a grid (which is a bad idea for a client/server application). You instead choose to let the user type the initial portion of a name and then filter a query on this input, displaying only the smaller resulting record set in a grid. I've done this for a table of companies.

This search by company name will be executed frequently and will take place on a large table. However, if you search using the `starting with` or `like` operator, the search will be case sensitive, as in the following SQL statement:

```
select * from companies
where name starting with 'win';
```

To make a case-insensitive search, you can use the `upper` function on both sides of the comparison to test the uppercase values of each string, but a similar query will be very slow, because it won't be based on an index. On the other hand, saving the company names (or any other name) in uppercase letters would be silly, because when you print those names, the result will be unnatural (even if common in old information systems).

If you can trade off some disk space and memory for the extra speed, you can use a trick: Add an extra field to the table to store the uppercase value of the company name, and use a server-side trigger to generate it and update it. You can then ask the database to maintain an index on the uppercase version of the name, to speed the search operation even further.

In practice, the table definition looks like this:

```
create domain d_uid as integer;
create table companies
(
  id          d_uid not null,
  name       varchar(50),
  tax_code   varchar(16),
  name_upper varchar(50),
  constraint companies_pk primary key (id)
);
```

To copy the uppercase name of each company into the related field, you cannot rely on client-side code, because an inconsistency would cause problems. In a case like this, it is better to use a trigger on the server, so that each time the company name changes, its uppercase version is updated accordingly. Another trigger is used to insert a new company:

```
create trigger companies_bi for companies
active before insert position 0
as
begin
  new.name_upper = upper(new.name);
end;
```

```
create trigger companies_bu for companies
active before update position 0
as
begin
  if (new.name <> old.name) then
    new.name_upper = upper(new.name);
  end;
```

Finally, I've added an index to the table with this DDL statement:

```
create index i_companies_name_upper on companies(name_upper);
```

With this structure behind the scenes, you can now select all the companies starting with the text of an edit box (`edSearch`) by writing the following code in a Delphi application:

```
dm.DataCompanies.Close;
dm.DataCompanies.SelectSQL.Text :=
  'select c.id, c.name, c.tax_code,' +
  ' from companies c ' +
  ' where name_upper starting with ''' +
  UpperCase (edSearch.Text) + ''';
dm.DataCompanies.Open;
```

**Tip** Using a prepared parametric query, you might be able to make this code even faster.

As an alternative, you could create a server-side calculated field in the table definition, but doing so would prevent you from having an index on the field, which speeds up your queries considerably:

```
name_upper varchar(50) computed by (upper(name))
```

## Handling Locations and People

You might notice that the table describing companies is quite bare. It has no company address, nor any contact information. The reason is that I want to be able to handle companies that have multiple offices (or locations) and list contact information about multiple employees of those companies.

Every location is bound to a company. Notice, though, that I've decided not to use a location identifier related to the company (such as a progressive location number for each company), but rather a global ID for all the locations. This way, I can refer to a location ID (let's say, for shipping goods) without having to also refer to the company ID. This is the definition of the table that stores company locations:

```
create table locations
(
  id            d_uid not null,
  id_company   d_uid not null,
  address      varchar(40),
  town         varchar(30),
  zip          varchar(10),
  state        varchar(4),
  phone        varchar(15),
  fax          varchar(15),
constraint locations_pk primary key (id),
constraint locations_uc unique (id_company, id)
);

alter table locations add constraint locations_fk_companies
foreign key (id_company) references companies (id)
on update no action on delete no action;
```

The final definition of a foreign key relates the `id_company` field of the `locations` table with the `ID` field of the `companies` table. The other table lists names and contact information for people at specific company locations. To follow the database normalization rules, I should have added to this table only a reference to the location, because each location relates to a company. However, to make it simpler to change the location of a person within a company and to make my queries much more efficient (avoiding an extra step), I've added to the `people` table both a reference to the location and a reference to the company.

The table has another unusual feature: One of the people working for a company can be set as the key contact. You obtain this functionality with a Boolean field (defined with a domain, because the Boolean type is not supported by InterBase) and by adding triggers to the table so that only one employee of each company can have this flag active:

```
create domain d_boolean as char(1)
default 'F'
check (value in ('T', 'F')) not null

create table people
(
  id            d_uid not null,
  id_company   d_uid not null,
  id_location  d_uid not null,
  name         varchar(50) not null,
  phone        varchar(15),
  fax          varchar(15),
```

```

email          varchar(50),
key_contact    d_boolean,
constraint people_pk primary key (id),
constraint people_uc unique (id_company, name)
);

alter table people add constraint people_fk_companies
foreign key (id_company) references companies (id)
on update no action on delete cascade;
alter table people add constraint people_fk_locations
foreign key (id_company, id_location)
references locations (id_company, id);

create trigger people_ai for people
active after insert position 0
as
begin
  /* if a person is the key contact, remove the
     flag from all others (of the same company) */
  if (new.key_contact = 'T') then
    update people
    set key_contact = 'F'
    where id_company = new.id_company
    and id <> new.id;
end;

create trigger people_au for people
active after update position 0
as
begin
  /* if a person is the key contact, remove the
     flag from all others (of the same company) */
  if (new.key_contact = 'T' and old.key_contact = 'F') then
    update people
    set key_contact = 'F'
    where id_company = new.id_company
    and id <> new.id;
end;

```

## Building a User Interface

The three tables discussed so far have a clear master/detail relation. For this reason, the RWBlocks example uses three IBDataSet components to access the data, hooking up the two secondary tables to the main one. The code for the master/detail support is that of a standard database example based on queries, so I won't discuss it further (but I suggest you study the example's source code).

Each of the datasets has a full set of SQL statements, to make the data editable. Whenever you enter a new detail element, the program hooks it to its master tables, as in the two following methods:

```

procedure TDmCompanies.DataLocationsAfterInsert(DataSet: TDataSet);
begin
  // initialize the data of the detail record
  // with a reference to the master record
  DataLocationsID_COMPANY.AsInteger := DataCompaniesID.AsInteger;
end;

procedure TDmCompanies.DataPeopleAfterInsert(DataSet: TDataSet);

```

```

begin
  // initialize the data of the detail record
  // with a reference to the master record
  DataPeopleID_COMPANY.AsInteger := DataCompaniesID.AsInteger;
  // the suggested location is the active one, if available
  if not DataLocations.IsEmpty then
    DataPeopleID_LOCATION.AsInteger := DataLocationsID.AsInteger;
  // the first person added becomes the key contact
  // (checks whether the filtered dataset of people is empty)
  DataPeopleKEY_CONTACT.AsBoolean := DataPeople.IsEmpty;
end;

```

As this code suggests, a data module hosts the dataset components. The program has a data module for every form (hooked up dynamically, because you can create multiple instances of each form). Each data module has a separate transaction so that the various operations performed in different pages are totally independent. The database connection, however, is centralized. A main data module hosts the corresponding component, which is referenced by all the datasets. Each of the data modules is created dynamically by the form referring to it, and its value is stored in the form's dm private field:

```

procedure TFormCompanies.FormCreate(Sender: TObject);
begin
  dm := TDmCompanies.Create (Self);
  dsCompanies.Dataset := dm.DataCompanies;
  dsLocations.Dataset := dm.DataLocations;
  dsPeople.Dataset := dm.DataPeople;
end;

```

This way, you can easily create multiple instances of a form, with an instance of the data module connected to each of them. The form connected to the data module has three DBGrid controls, each tied to a data module and one of the corresponding datasets. You can see this form at run time, with some data, in [Figure 14.18](#).

ID	ID_COMPANY	ADDRESS	FAX	PHONE	STATE	TOWN
11	9	100, Barland Way			CA	Scotts Valley
12	9	Fryland			UK	Reading

ID	ID_COMPANY	ID_LOCATION	KEY_CONTACT	NAME	EMAIL
12	9	11	F	Chuck J	
14	9	11	F	David I	

**Figure 14.18:** A form showing companies, office locations, and people (part of the RWBlocks example)

The form is hosted by a main form, which in turn is based on a page control, with the other forms embedded. Only the form connected with the first page is created when the program starts. The ShowForm method I've written takes care of parenting the form to the tab sheet of the page control, after removing the form border:

```

procedure TFormMain.FormCreate(Sender: TObject);
begin

```

```

ShortDateFormat := 'dd/mm/yyyy';
ShowForm (TFormCompanies.Create (Self), TabCompanies);
end;

procedure TFormMain.ShowForm (Form: TForm; Tab: TTabSheet);
begin
  Form.BorderStyle := bsNone;
  Form.Align := alClient;
  Form.Parent := Tab;
  Form.Show;
end;

```

The other two pages are populated at run time:

```

procedure TFormMain.PageControllChange(Sender: TObject);
begin
  if PageControll.ActivePage.ControlCount = 0 then
    if PageControll.ActivePage = TabFreeQ then
      ShowForm (TFormFreeQuery.Create (self), TabFreeQ)
    else if PageControll.ActivePage = TabClasses then
      ShowForm (TFormClasses.Create (self), TabClasses);
end;

```

The companies form hosts the search by company name (discussed in the [previous section](#)) plus a search by location. You enter the name of a town and get back a list of companies having an office in that town:

```

procedure TFormCompanies.btnTownClick(Sender: TObject);
begin
  with dm.DataCompanies do
    begin
      Close;
      SelectSQL.Text :=
        'select c.id, c.name, c.tax_code' +
        ' from companies c ' +
        ' where exists (select loc.id from locations loc ' +
        ' where loc.id_company = c.id and upper(loc.town) = ''' +
        UpperCase(edTown.Text) + ''' )';
      Open;
      dm.DataLocations.Open;
      dm.DataPeople.Open;
    end;
  end;

```

The form includes a lot more source code. Some of it is related to closing permission (as a user cannot close the form while there are pending edits not posted to the database), and quite a bit relates to the use of the form as a lookup dialog, as described later.

## Booking Classes

Part of the program and the database involves booking training classes and courses. (Although I built this program as a showcase, it also helps me run my own business.) The database includes a classes table that lists all the training courses, each with a title and the planned date. Another table hosts registration by company, including the classes registered for, the ID of the company, and some notes. Finally, a third table lists people who've signed up, each hooked to a registration for his or her company, with the amount paid.

The rationale behind this company-based registration is that invoices are sent to companies, which book the classes for programmers and can receive specific discounts. In this case the database is more normalized, because the people registration doesn't refer directly to a class, but only to the company registration for that class. Here are the definitions

of the tables involved (I've omitted foreign key constraints and other elements):

```
create table classes
(
  id            d_uid not null,
  description   varchar(50),
  starts_on    timestamp not null,
constraint classes_pk primary key (id)
);
create table classes_reg
(
  id            d_uid not null,
  id_company   d_uid not null,
  id_class     d_uid not null,
  notes        varchar(255),
constraint classes_reg_pk primary key (id),
constraint classes_reg_uc unique (id_company, id_class)
);
create domain d_amount as numeric(15, 2);
create table people_reg
(
  id            d_uid not null,
  id_classes_reg d_uid not null,
  id_person     d_uid not null,
  amount        d_amount,
constraint people_reg_pk primary key (id)
);
```

The data module for this group of tables uses a master/detail/detail relationship, and has code to set the connection with the active master record when a new detail record is created. Each dataset has a generator field for its ID, and each has the proper update and insert SQL statements. These statements are generated by the corresponding component editor using only the ID field to identify existing records and updating only the fields in the original table. Each of the two secondary datasets retrieves data from a lookup table (either the list of companies or the list of people). I had to edit the RefreshSQL statements manually to repeat the proper inner join. Here is an example:

```
object IBClassReg: TIBDataSet
  Database = DmMain.IBDatabase1
  Transaction = IBTransaction1
  AfterInsert = IBClassRegAfterInsert
  DeleteSQL.Strings = (
    'delete from classes_reg'
    'where id = :old_id')
  InsertSQL.Strings = (
    'insert into classes_reg (id, id_class, id_company, notes)'
    'values (:id, :id_class, :id_company, :notes)')
  RefreshSQL.Strings = (
    'select reg.id, reg.id_class, reg.id_company, reg.notes, c.name '
    'from classes_reg reg'
    'join companies c on reg.id_company = c.id'
    'where id = :id')
  SelectSQL.Strings = (
    'select reg.id, reg.id_class, reg.id_company, reg.notes, c.name '
    'from classes_reg reg'
    'join companies c on reg.id_company = c.id'
    'where id_class = :id')
  ModifySQL.Strings = (
    'update classes_reg'
```

```

'set'
' id = :id,'
' id_class = :id_class,'
' id_company = :id_company,'
' notes = :notes'
'where id = :old_id')
GeneratorField.Field = 'id'
GeneratorField.Generator = 'g_master'
DataSource = dsClasses
end

```

To complete the discussion of IBClassReg, here is its only event handler:

```

procedure TDmClasses.IBClassRegAfterInsert(DataSet: TDataSet);
begin
  IBClassReg.FieldName ('id_class').AsString :=
    IBClasses.FieldName ('id').AsString;
end;

```

The IBPeopleReg dataset has similar settings, but the IBClasses dataset is simpler at design time. At run time, this dataset's SQL code is dynamically modified, using three alternatives to display scheduled classes (whenever the date is after today's date), classes already started or finished in the current year, and classes from past years. A user selects one of the three groups of records for the table with a tab control, which hosts the DBGrid for the main table (see [Figure 14.19](#)).

ID	DESCRIPTION	STARTS_ON
18	Learning 201	11/10/2002

ID	NAME
19	Buford Cop
20	Whitech Lake St

ID	NAME	AMOUNT
21	David J	300
24	Chuck J	300

**Figure 14.19:** The RWBlocks example form for class registrations

The three alternative SQL statements are created when the program starts, or when the class registrations form is created and displayed. The program stores the final portion of the three alternative instructions (the *where* clause) in a string list and selects one of the strings when the tab changes:

```

procedure TFormClasses.FormCreate(Sender: TObject);
begin
  dm := TDmClasses.Create (Self);
  // connect the datasets to the data sources
  dsClasses.Dataset := dm.IBClasses;
  dsClassReg.DataSet := dm.IBClassReg;
  dsPeopleReg.DataSet := dm.IBPeopleReg;

```

```

// open the datasets
dm.IBClasses.Active := True;
dm.IBClassReg.Active := True;
dm.IBPeopleReg.Active := True;

// prepare the SQL for the three tabs
SqlCommands := TStringList.Create;
SqlCommands.Add (' where Starts_On > ''now'' ');
SqlCommands.Add (' where Starts_On <= ''now'' and ' +
  ' extract (year from Starts_On ) >= extract(year from current_timestamp)');
SqlCommands.Add (' where extract (year from Starts_On) < ' +
  ' extract(year from current_timestamp)');
end;
procedure TFormClasses.TabChange(Sender: TObject);
begin
  dm.IBClasses.Active := False;
  dm.IBClasses.SelectSQL [1] := SqlCommands [Tab.TabIndex];
  dm.IBClasses.Active := True;
end;

```

## Building a Lookup Dialog

The two detail datasets of this class registration form display lookup fields. Instead of showing the ID of the company that booked the class, for example, the form shows the company name. You obtain this functionality with an inner join in the SQL statement and by configuring the DBGrid columns so they don't display the company ID. In a local application, or one with a limited amount of data, you could use a lookup field. However, copying the entire lookup dataset locally or opening it for browsing should be limited to tables with about 100 records at most, embedding some search capabilities.

If you have a large table, such as a table of companies, an alternative solution is to use a secondary dialog box to perform the lookup selection. For example, you can choose a company by using the form you've already built and taking advantage of its search capabilities. To display this form as a dialog box, the program creates a new instance of it, shows some hidden buttons already there at design time, and lets the user select a company to refer to from the other table.

To simplify the use of this lookup, which can happen multiple times in a large program, I've added to the companies form a class function that has as output parameters the name and ID of the selected company. An initial ID can be passed to the function to determine its initial selection. Here is the complete code of this class function, which creates an object of its class, selects the initial record if requested, shows the dialog box, and finally extracts the return values:

```

class function TFormCompanies.SelectCompany (
  var CompanyName: string; var CompanyId: Integer): Boolean;
var
  FormComp: TFormCompanies;
begin
  Result := False;
  FormComp := TFormCompanies.Create (Application);
  FormComp.Caption := 'Select Company';
  try
    // activate dialog buttons
    FormComp.btnCancel.Visible := True;
    FormComp.btnOK.Visible := True;
    // select company
    if CompanyId > 0 then
      FormComp.dm.DataCompanies.SelectSQL.Text :=
        'select c.id, c.name, c.tax_code' +
        ' from companies c ' +

```

```

    ' where c.id = ' + IntToStr (CompanyId)
else
    FormComp.dm.DataCompanies.SelectSQL.Text :=
        'select c.id, c.name, c.tax_code' +
        ' from companies c ' +
        ' where name_upper starting with ''a''';
FormComp.dm.DataCompanies.Open;
FormComp.dm.DataLocations.Open;
FormComp.dm.DataPeople.Open;

if FormComp.ShowModal = mrOK then
begin
    Result := True;
    CompanyId := FormComp.dm.DataCompanies.FieldByName ('id').AsInteger;
    CompanyName := FormComp.dm.DataCompanies.FieldByName ('name').AsString;
end;
finally
    FormComp.Free;
end;
end;
end;

```

Another slightly more complex class function (available with the example's source code, but not listed here) lets you select a person from a given company to register people for classes. In this case, the form is displayed after disallowing searching another company or modifying the company's data.

In both cases, you trigger the lookup by adding an ellipsis button to the column of the DBGrid—for example, the grid column listing the names of companies registered for classes. When this button is clicked, the program calls the class function to display the dialog box and uses its result to update the hidden ID field and the visible name field:

```

procedure TFormClasses.DBGridClassRegEditButtonClick(Sender: TObject);
var
    CompanyName: string;
    CompanyId: Integer;
begin
    CompanyId := dm.IBClassReg.FieldByName ('id_Company').AsInteger;
    if TFormCompanies.SelectCompany (CompanyName, CompanyId) then
    begin
        dm.IBClassReg.Edit;
        dm.IBClassReg.FieldByName ('Name').AsString := CompanyName;
        dm.IBClassReg.FieldByName ('id_Company').AsInteger := CompanyId;
    end;
end;

```

## Adding a Free Query Form

The program's final feature is a form where a user can directly type in and run a SQL statement. As a helper, the form lists in a combo box the available tables of the database, obtained when the form is created by calling

```
DmMain.IBDatabase1.GetTableNames (ComboTables.Items);
```

Selecting an item from the combo box generates a generic SQL query:

```
MemoSql.Lines.Text := 'select * from ' + ComboTables.Text;
```

The user (if an expert) can then edit the SQL, possibly introducing restrictive clauses, and then run the query:

```

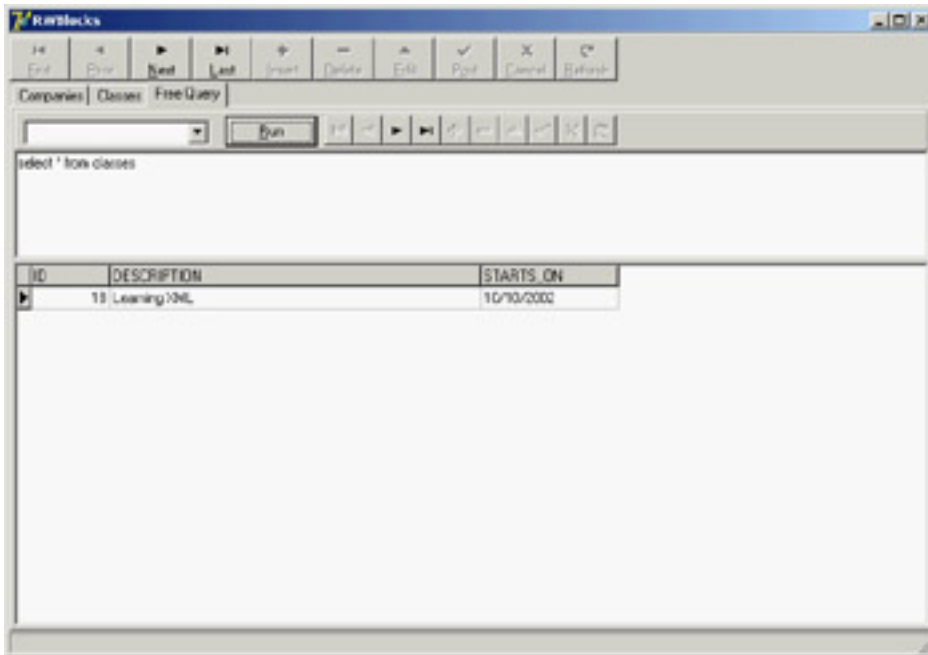

procedure TFormFreeQuery.ButtonRunClick(Sender: TObject);
begin

```

```
QueryFree.Close;  
QueryFree.SQL := MemoSql.Lines;  
QueryFree.Open;  
end;
```

You can see this third form of the RWBlocks program in [Figure 14.20](#). Of course, I'm not suggesting that you add SQL editing to programs intended for all your users—this feature is intended for power users or programmers. I basically wrote it for myself!

**Figure 14.20:** The free query form of the RWBlocks example is intended for power users.

## What's Next?

This chapter has presented a detailed introduction to client/server programming with Delphi. We discussed the key issues and delved a little into interesting areas of client/server programming. After a general introduction, I discussed the use of the dbExpress database library. I also briefly covered the InterBase server and the InterBase Express (IBX) components. At the end of the chapter I presented a real-world example, going beyond the typical examples in the book to focus on a single feature at a time.

There is more I can say about client/server programming in Delphi. [Chapter 15](#) will focus on Microsoft's ADO database engine. It's followed by a chapter on Delphi's multitier architecture, DataSnap; this chapter highlights the use of the dbExpress library and the ClientDataSet component, although in a slightly different context.

## Chapter 15: Working with ADO

### Overview

Since the mid-1980s, database programmers have been on a quest for the "holy grail" of *database independence*. The idea is to use a single API that applications can use to interact with many different sources of data. The use of such an API would release developers from dependence on a single database engine and allow them to adapt to the world's changing demands. Vendors have produced many solutions to this goal, the two most notable early solutions being Microsoft's Open Database Connectivity (ODBC) and Borland's Integrated Database Application Programming Interface (IDAPI), more commonly known as the Borland Database Engine (BDE).

Microsoft started to replace ODBC with OLE DB in the mid-1990s with the success of the Component Object Model (COM). However, OLE DB is what Microsoft would class a *system-level* interface and is intended to be used by system-level programmers. It is very large, complex, and unforgiving. It makes greater demands on the programmer and requires a higher level of knowledge in return for lower productivity. ActiveX Data Objects (ADO) is a layer on top of OLE DB and is referred to as an *application-level* interface. It is considerably simpler than OLE DB and more forgiving. In short, it is designed for use by application programmers.

As you saw in [Chapter 14](#), "Client/Server with dbExpress," Borland has also replaced the BDE with a newer technology called dbExpress. ADO shares greater similarities with the BDE than with the lightweight dbExpress technology. BDE and ADO support navigation and manipulation of datasets, transaction processing, and cached updates (called *batch updates* in ADO), so the concepts and issues involved in using ADO are similar to those of the BDE.

**Note** I wish to acknowledge and thank Guy Smith-Ferrier for originally writing this chapter for *Mastering Delphi 6*. Guy is a programmer, author, and speaker. He is the author of several commercial software products and countless internal systems for independent and blue-chip companies alike. He has written many articles for *The Delphi Magazine* and for others on topics beyond Delphi, and he has spoken at numerous conferences in North America and Europe. Guy lives in England with his wife, his son, and his cat.

In this chapter we will look at ADO. We will also discuss *dbGo*—a set of Delphi components initially called ADOExpress, but renamed in Delphi 6 because Microsoft objects to the use of the term *ADO* in third-party product names. It is possible to use ADO in Delphi without using dbGo. By importing the ADO type library, you can gain direct access to the ADO interfaces; this is how Delphi programmers used ADO before the release of Delphi 5. However, this path bypasses Delphi's database infrastructure and ensures that you are unable to make use of other Delphi technologies such as the data-aware controls or DataSnap. This chapter uses dbGo for all of its examples, not only because it is readily available and supported but also because it is a very viable solution. Regardless of your final choice, you will find the information here useful.

**Note** Alternatively, you can turn to Delphi's active third-party market for other ADO component suites such as Adonis, AdoSolutio, Diamond ADO, and Kamiak.

## Microsoft Data Access Components (MDAC)

ADO is part of a bigger picture called Microsoft Data Access Components (MDAC). MDAC is an umbrella for Microsoft's database technologies and includes ADO, OLE DB, ODBC, and RDS (Remote Data Services). Often you will hear people use the terms MDAC and ADO interchangeably, but incorrectly. Because ADO is only distributed as part of MDAC, we talk of ADO versions in terms of MDAC releases. The major releases of MDAC have been versions 1.5, 2.0, 2.1, 2.5, and 2.6. Microsoft releases MDAC independently and makes it available for free download and virtually free distribution (there are distribution requirements, but most Delphi developers will have no trouble meeting them). MDAC is also distributed with most Microsoft products that have database content. Delphi 7 ships with MDAC 2.6.

There are two consequences of this level of availability. First, it is highly likely that your users will already have MDAC installed on their machines. Second, whatever version your users have, or you upgrade them to, it is also virtually certain that someone—you, your users, or other application software—will upgrade their existing MDAC to the current release of MDAC. You can't prevent this upgrade, because MDAC is installed with such commonly used software as Internet Explorer. Add to this the fact that Microsoft supports only the current release of MDAC and the release before it, and you arrive at this conclusion: Applications must be designed to work with the current release of MDAC or the release before it.

As an ADO developer, you should regularly check the MDAC pages on Microsoft's website at [www.microsoft.com/data](http://www.microsoft.com/data). From there you can download the latest version of MDAC for free. While you are on this website, you should take the opportunity to download the MDAC SDK (13 MB) if you do not already have it or the Platform SDK (the MDAC SDK is part of the Platform SDK). The MDAC SDK is your bible: Download it, consult it regularly, and use it to answer your ADO questions. You should treat it as your first port of call when you need MDAC information.

## OLE DB Providers

OLE DB providers enable access to a source of data. They are ADO's equivalent to the dbExpress drivers and the BDE SQL Links. When you install MDAC, you automatically install the OLE DB providers shown in [Table 15.1](#):

**Table 15.1: OLE DB Providers Included with MDAC**

Driver	Provider	Description
MSDASQL	ODBC Drivers	ODBC drivers (default)
Microsoft.Jet.OLEDB.3.5	Jet 3.5	MS Access 97 databases only
Microsoft.Jet.OLEDB.4.0	Jet 4.0	MS Access and other databases
SQLOLEDB	SQL Server	MS SQL Server databases
MSDAORA	Oracle	Oracle databases
MSOLAP	OLAP Services	Online Analytical Processing
SampProv	Sample provider	Example of an OLE DB provider for CSV files
MSDAOXP	Simple provider	For creating your own providers for simple text data

- The ODBC OLE DB provider is used for backward compatibility with ODBC. As you learn more about ADO, you will discover the limitations of this provider.
- The Jet OLE DB providers support MS Access and other desktop databases. We will return to these providers later.
- The SQL Server provider supports SQL Server 7, SQL Server 2000, and Microsoft Database Engine (MSDE). MSDE is a reduced version of SQL Server, with most of the tools removed and some code added to deliberately

degrade performance when there are more than five active connections. MSDE is important because it is free and it is fully compatible with SQL Server.

- The OLE DB provider for OLAP can be used directly but is more often used by ADO Multi-Dimensional (ADOMD). ADOMD is an additional ADO technology designed to provide Online Analytical Processing (OLAP). If you have used Delphi's Decision Cube, Excel's Pivot Tables, or Access's Cross Tabs, then you have used some form of OLAP.

In addition to these MDAC OLE DB providers, Microsoft supplies other OLE DB providers with other products or with downloadable SDKs:

- The Active Directory Services OLE DB provider is included with the ADSI SDK; the AS/400 and VSAM OLE DB provider is included with SNA Server; and the Exchange OLE DB provider is included with Microsoft Exchange 2000.
- The OLE DB provider for Indexing Service is part of Microsoft Indexing Service, a Windows mechanism that speeds up file searches by building catalogs of file information. Indexing Service is integrated into IIS and, consequently, is often used for indexing websites.
- The OLE DB provider for Internet Publishing allows developers to manipulate directories and files using HTTP.
- Still more OLE DB providers come in the form of *service providers*. As their name implies, OLE DB service providers provide a service to other OLE DB providers and are often invoked automatically as needed without programmer intervention. The Cursor Service, for example, is invoked when you create a client-side cursor, and the Persisted Recordset provider is invoked to save data locally.

MDAC includes many providers that I'll discuss, but many more are available from Microsoft and from the third-party market. It is impossible to reliably list all available OLE DB providers, because the list is so large and changes constantly. In addition to independent third parties, you should consider most database vendors, because the majority now supply their own OLE DB providers. For example, Oracle supplies the ORAOLEDB provider.

**Tip** A notable omission from the vendors that supply OLE DB providers is InterBase. In addition to accessing it using the ODBC driver, you can use Dmitry Kovalenko's IBProvider ([www.lcpi.lipetsk.ru/prog/eng/index.html](http://www.lcpi.lipetsk.ru/prog/eng/index.html)). Also check Binh Ly's OLE DB Provider Development Toolkit ([www.techvanguards.com/products/optk/install.htm](http://www.techvanguards.com/products/optk/install.htm)). If you want to write your own OLE DB provider, this tool is easier to use than most.

## Using dbGo Components

Programmers familiar with the BDE, dbExpress, or IBExpress should recognize the set of components that make up dbGo ([Table 15.2](#)).

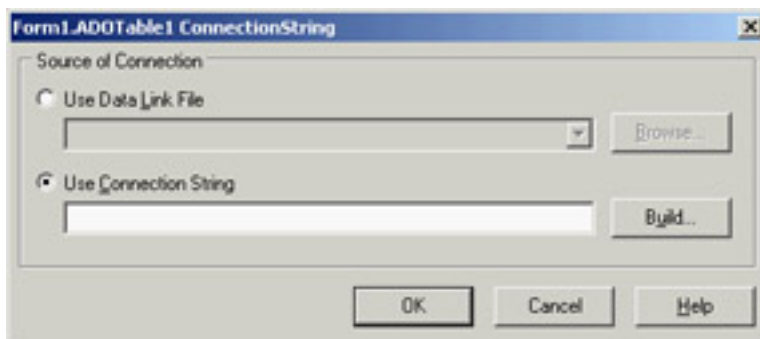

**Table 15.2: dbGo Components**

dbGo Component	Description	BDE Equivalent Component
ADOConnection	Connection to a database	Database
ADOCommand	Executes an action SQL command	No equivalent
ADODataset	All-purpose descendant of TDataSet	No equivalent
ADOTable	Encapsulation of a table	Table
ADOQuery	Encapsulation of SQL <code>SELECT</code>	Query
ADOStoredProc	Encapsulation of a stored procedure	StoredProc
RDSCConnection	Remote Data Services connection	No equivalent

The four dataset components (ADODataset, ADOTable, ADOQuery, and ADOStoredProc) are implemented almost entirely by their immediate ancestor class, TCustomADODataset. This component provides the majority of dataset functionality, and its descendants are mostly thin wrappers that expose different features of the same component. As such, the components have a lot in common. In general, however, ADOTable, ADOQuery, and ADOStoredProc are viewed as "compatibility" components and are used to aid the transition of knowledge and code from their BDE counterparts. Be warned, though: These compatibility components are similar to their counterparts but not identical. You will find differences in any application except the most trivial. ADODataset is the component of choice partly because of its versatility but also because it is closer in appearance to the ADO Recordset interface upon which it is based. Throughout this chapter, I'll use all the dataset components to give you the experience of using each.

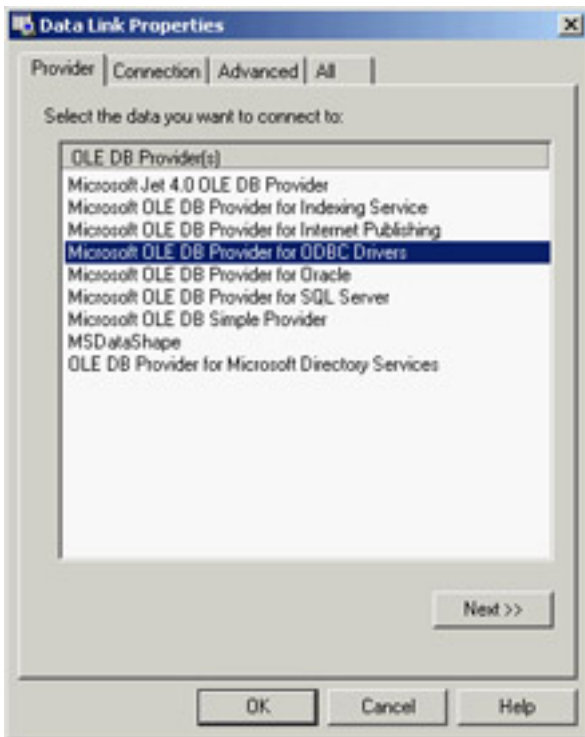

## A Practical Example

Enough theory: Let's see some action. Drop an ADOTable onto a form. To indicate the database to connect to, ADO uses *connection strings*. You can type in a connection string by hand if you know what you are doing. In general, you'll use the connection string editor (the property editor of the `ConnectionString` property), shown in [Figure 15.1](#).

**Figure 15.1:** Delphi's connection string editor

This editor adds little value to the process of entering a connection string, so you can click Build to go straight to Microsoft's connection string editor, shown in [Figure 15.2](#).

**Figure 15.2:** The first page of Microsoft's connection string editor

This is a tool you need to understand. The first tab shows the OLE DB providers and service providers installed on your computer. The list will vary according to the version of MDAC and other software you have installed. In this example, select the Jet 4.0 OLE DB provider. Double-click Jet 4.0 OLE DB Provider, and you will be presented with the Connection tab. This page varies according to the provider you select; for Jet, it asks you for the name of the database and your login details. You can choose an Access MDB file installed by Borland with Delphi 7: the `dbdemos.mdb` file available in the shared data folder (by default, `C:\Program Files\Common Files\Borland Shared\Data\dbdemos.mdb`). Click the Test Connection button to test the validity of your selections.

The Advanced tab handles access control to the database; here you specify exclusive or read-only access to the database. The All tab lists all the parameters in the connection string. The list is specific to the OLE DB provider you selected on the first page. (You should make a mental note of this page, because it contains many parameters that are the answers to many problems.) After closing the Microsoft connection string editor you'll see in the Borland ConnectionString property editor the value that will be returned to the ConnectionString property (here split on multiple lines for readability):

```
Provider=Microsoft.Jet.OLEDB.4.0;
Data Source=C:\Program Files\Common Files\Borland Shared\Data\dbdemos.mdb;
Persist Security Info=False
```

Connection strings are just strings with many parameters delimited by semicolons. To add, edit, or delete any of these parameter values programmatically, you must write your own routines to find the parameter in the list and amend it appropriately. A simpler approach is to copy the string into a Delphi string list and use its name/value pairs capability: This technique will be demonstrated in the JetText example covered in the section "[Text Files through Jet.](#)"

Now that you have set the connection string, you can select a table. Drop down the list of tables using the `TableName` property in the Object Inspector. Select the Customer table. Add a `DataSource` component and a `DBGrid` control and connect them all together; you are now using ADO in an actual—though trivial—program (available in the source code as `FirstAdoExample`). To see the data, set the `Active` property of the dataset to `True` or open the dataset in the `FormCreate` event (as in the example) to avoid design-time errors if the database is not available.

**Tip** If you are going to use dbGo as your primary database access technology, you might want to move the DataSource component to the ADO page of the Component Palette to avoid moving back and forth between the ADO page and the Data Access page. If you use both ADO and another database technology, then you can simulate installing DataSource on multiple pages by creating a Component Template for a DataSource and installing it on the ADO page.

## The ADOConnection Component

When you use an ADOTable component this way, it creates its own connection component behind the scenes. You do not have to accept the default connection it creates. In general, you should create your own connection using the ADOConnection component, which has the same purpose as the dbExpress SQLConnection component and the BDE Database component. It allows you to customize the login procedure, control transactions, execute action commands directly, and reduce the number of connections in an application.

Using an ADOConnection is easy. Place one on a form and set its `ConnectionString` property the same way you would for the ADOTable. Alternatively, you can double-click an ADOConnection component (or use a specific item of its Component Editor, in its shortcut menu) to invoke the connection string editor directly. With the `ConnectionString` set to the proper database, you can disable the login dialog box by setting `LoginPrompt` to `False`. To use the new connection in the previous example, set the `Connection` property of `ADOTable1` to `ADOConnection1`. You will see `ADOTable1`'s `ConnectionString` property reset because the `Connection` and `ConnectionString` properties are mutually exclusive. One of the benefits of using an ADOConnection is that the connection string is centralized instead of scattered throughout many components. Another, more important, benefit is that all the components that share the ADOConnection share a single connection to the database server. Without your own ADOConnection, each ADO dataset has a separate connection.

## Data Link Files

So, an ADOConnection allows you to centralize the definition of a connection string within a form or data module. However, even though this is a worthwhile step forward from scattering the same connection string throughout all ADO datasets, it still suffers from a fundamental flaw: If you use a database engine that defines the database in terms of a filename, then the path to the database file(s) is hard-coded in the EXE. This makes for a fragile application. To overcome this problem, ADO uses Data Link files.

A Data Link file is a connection string in an INI file. For example, Delphi's installation adds to the system the `dbdemos.udl` file, with the following text:

```
[oledb]
; Everything after this line is an OLE DB initstring
Provider=Microsoft.Jet.OLEDB.4.0;
  Data Source=C:\Program Files\Common Files\Borland Shared\Data\dbdemos.mdb
```

Although you can give a Data Link file any extension, the recommended extension is `.UDL`. You can create a Data Link using any text editor, or you can right-click in Windows Explorer, select `New`, select `Text Document`, rename the file with a `.UDL` extension (assuming extensions are displayed in your configuration of Explorer), and then double-click the file to invoke the Microsoft connection string editor.

When you select a file in the Connection editor, the `ConnectionString` property will be set to `'FILE NAME ='` followed by the actual filename, as demonstrated by the `DataLinkFile` example. You can place your Data Link files anywhere on the hard disk, but if you are looking for a common, shared location, then you can use the `DataLinkDir` function in the `ADODB` Delphi unit. If you haven't altered MDAC's defaults, `DataLinkDir` will return the following:

```
C:\Program Files\Common Files\System\OLE DB\Data Links
```

## Dynamic Properties

Imagine that you are responsible for designing a new database middleware architecture. You have to reconcile two

opposing goals of a single API for all databases and access to database-specific features. You could take the approach of designing an interface that is the sum of all the features of every database ever created. Each class would have every property and method imaginable, but it would only use the properties and methods it had support for. It doesn't take much discussion to realize that this isn't a good solution. ADO has to solve these apparently mutually exclusive goals, and it does so using *dynamic properties*.

Almost all ADO interfaces and their corresponding dbGo components have a property called `Properties` that is a collection of database-specific properties. These properties can be accessed by their ordinal position, like this:

```
ShowMessage(ADOTable1.Properties[1].Value);
```

But they are more usually accessed by name:

```
ShowMessage(ADOConnection1.Properties['DBMS Name'].Value);
```

Dynamic properties depend on the type of object and also on the OLE DB providers. To give you an idea of their importance, a typical ADO Connection or Recordset has approximately 100 dynamic properties. As you will see throughout this chapter, the answers to many ADO questions lie in dynamic properties.

**Tip** An important event related to the use of dynamic properties is *OnRecordsetCreate*, which was introduced in a Delphi 6 update and is available in Delphi 7. *OnRecordsetCreate* is called immediately after the recordset has been created, but before it is opened. This event is useful when you're setting dynamic properties that can be set only when the recordset is closed.

## Getting Schema Information

In ADO, you can retrieve schema information using the `ADOConnection` component's `OpenSchema` method. This method accepts four parameters:

- The kind of data `OpenSchema` should return. It is a `TSchemaInfo` value: a set of 40 values including those for retrieving a list of tables, indexes, columns, views, and stored procedures.
- A filter to place on the data before it is returned. You will see an example of this parameter in a moment.
- A GUID for a provider-specific query. This parameter is used only if the first parameter is `siProviderSpecific`.
- An `ADODataset` into which the data is returned. This parameter illustrates a common theme in ADO: Any method that needs to return more than a small amount of data will return its data as a `Recordset`, or, in Delphi terms, an `ADODataset`.

To use `OpenSchema`, you need an open `ADOConnection`. The following code (part of the `OpenSchema` example) retrieves a list of primary keys for every table into an `ADODataset`:

```
ADOConnection1.OpenSchema(siPrimaryKeys, EmptyParam, EmptyParam, ADODataset1);
```

Each field in a primary key has a single row in the result set. So, a table with a composite key of two fields has two rows. The two `EmptyParam` values indicate that these parameters are given empty values and are ignored. The result of this code is shown in [Figure 15.3](#), after resizing the grid with some custom code.

The screenshot shows a Delphi dialog box titled 'TADOConnection.OpenSchema'. It has two buttons: 'Get Primary Keys' (selected) and 'Get Customer Primary Keys'. Below the buttons is a table with the following data:

TABLE_CATALOG	TABLE_SCHEMA	TABLE_NAME	COLUMN_NAME	COLUMN_GUID	COLUMN_PROPID	ORDIN
		country	Name			
		customer	CustNo			
		employee	EmpNo			
		items	ItemNo			
		items	OrderNo			
		MSysAccessObjects	ID			
		orders	OrderNo			
		parts	PartNo			
		vendors	VendorNo			

**Figure 15.3:** The OpenSchema example retrieves the primary keys of the database tables.

When `EmptyParam` is passed as the second parameter, the result set includes all information of the requested type for the entire database. For many kinds of information, you will want to filter the result set. You can, of course, apply a traditional Delphi filter to the result set using the `Filter` and `Filtered` properties or the `OnFilterRecord` event. However, doing so applies the filter on the client side in this example. Using the second parameter, you can apply a more efficient filter at the source of the schema information. The filter is specified as an array of values. Each element of the array has a specific meaning relevant to the kind of data being returned. For example, the filter array for primary keys has three elements: the catalog (*catalog* is ANSI-speak for the database), the schema, and the table name. This example returns a list of primary keys for the Customer table:

```
var
  Filter: OLEVariant;
begin
  Filter := VarArrayCreate([0, 2], varVariant);
  Filter[2] := 'CUSTOMER';
  ADOConnection1.OpenSchema(
    siPrimaryKeys, Filter, EmptyParam, ADODataSet1);
end;
```

**Note** You can retrieve the same information using ADOX, and this warrants a brief comparison between *OpenSchema* and ADOX. ADOX is an additional ADO technology that allows you to retrieve and update schema information. It is ADO's equivalent to SQL's Data Definition Language (DDL—*CREATE*, *ALTER*, *DROP*) and Data Control Language (DCL—*GRANT*, *REVOKE*). ADOX is not directly supported in dbGo, but you can import the ADOX type library and use it successfully in Delphi applications. Unfortunately, ADOX is not as universally implemented as *OpenSchema* so there are greater gaps. To just retrieve information and not update it, *OpenSchema* is usually a better choice.

## Using the Jet Engine

Now that you have some of the MDAC and ADO basics under your belt, let's take a moment out to look at the Jet engine. This engine is of great interest to some and of no interest to others. If you're interested in Access, Paradox, dBase, text, Excel, Lotus 1-2-3, or HTML, then this section is for you. If you have no interest in any of these formats, you can safely skip this section.

The Jet database engine is usually associated with Microsoft Access databases, and this is its forte. However, the Jet engine is also an all-purpose desktop database engine, and this lesser-known attribute is where much of its strength lies. Because using the Jet engine with Access is its default mode and is straightforward, this section mostly covers use of non-Access formats, which are not so obvious.

**Note** The Jet engine has been included in some (but not all) versions of MDAC. It is not included in version 2.6. There has been a long debate about whether programmers using a non-Microsoft development tool have the right to distribute the Jet engine. The official answer is positive, and the Jet engine is available as a free download (in addition to being distributed with many Microsoft software products).

There are two Jet OLE DB providers: the Jet 3.51 OLE DB provider and the Jet 4.0 OLE DB provider. The Jet 3.51 OLE DB provider uses the Jet 3.51 engine and supports Access 97 databases only. If you intend to use Access 97 and not Access 2000, then you will get better performance using this OLE DB provider in most situations than using the Jet 4.0 OLE DB provider.

The Jet 4.0 OLE DB provider supports Access 97, Access 2000, and Installable Indexed Sequential Access Method (IISAM) drivers. Installable ISAM drivers are those written specifically for the Jet engine to support access to ISAM formats such as Paradox, dBase, and text, and it is this facility that makes the Jet engine so useful and versatile. The complete list of ISAM drivers installed on your machine depends on what software you have installed. You can find this list by looking in the Registry at

```
HKEY_LOCAL_MACHINE\Software\Microsoft\Jet\4.0\ISAM Formats
```

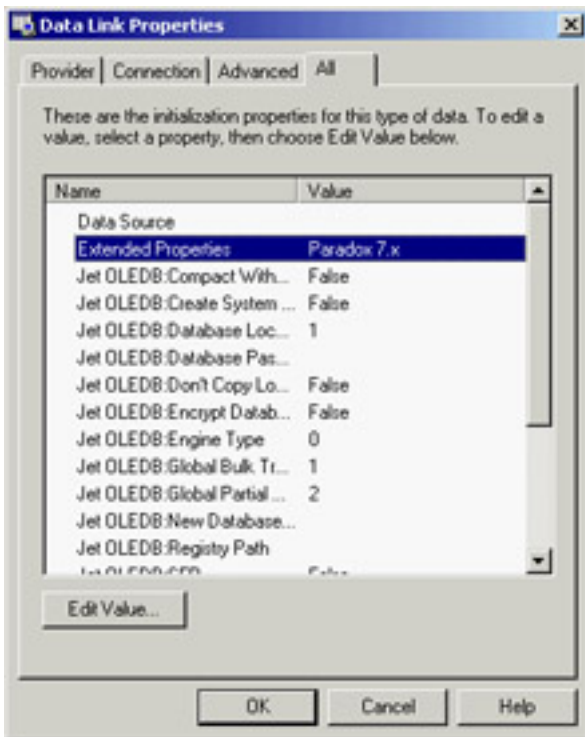

However, the Jet engine includes drivers for Paradox, dBase, Excel, text, and HTML.

## Paradox through Jet

The Jet engine expects to be used with Access databases. To use it with any database other than Access, you need to tell it which IISAM driver to use. This is a painless process that involves setting the Extended Properties connection string argument in the connection string editor. Let's work through a quick example.

Add an ADOTable component to a form and invoke the connection string editor. Select the Jet 4.0 OLE DB Provider. Select the All page, locate the Extended Properties property, and double-click it to edit its value.

Enter **Paradox 7.x** in the Property Value, as illustrated in [Figure 15.4](#), and click OK. Now go back to the Connection tab and enter the name of the directory containing the Paradox tables directly, because the Browse button won't help you (it lets you enter a filename, not a folder name). At this point you can select a table in the ADOTable's `TableName` and open it either at design time or at run time. You are now using Paradox through ADO, as demonstrated by the JetParadox example.

**Figure 15.4:** Setting extended properties

I have some bad news for Paradox users: Under certain circumstances, you will need to install the BDE in addition to the Jet engine. Jet 4.0 requires the BDE in order to be able to update Paradox tables, but it doesn't require the BDE just to read them. The same is true for most releases of the Paradox ODBC Driver. Microsoft has received justified criticism about this point and has made a new Paradox IISAM available that does not require the BDE; you can get these updated drivers from Microsoft Technical Support.

**Note** As you learn more about ADO, you will discover how much it depends on the OLE DB provider and the RDBMS (relational database management system) in question. Although you can use ADO with a local file format, as demonstrated in this and following examples, the general suggestion is to install a local SQL engine whenever possible. Access and MSDE are good choices if you have to use ADO; otherwise you might want to consider InterBase or Firebird as alternatives, as discussed in [Chapter 14](#).

## Excel through Jet

Excel is easily accessed using the Jet OLE DB provider. Once again, you set the Extended Properties property to Excel 8.0. Assume that you have an Excel spreadsheet called `ABCCompany.xls` with a sheet called `Employees`, and you want to open and read this file using Delphi. With a little knowledge of COM, you can do so by automating Excel. However, the ADO solution is considerably easier to implement and doesn't require Excel to be available on the computer.

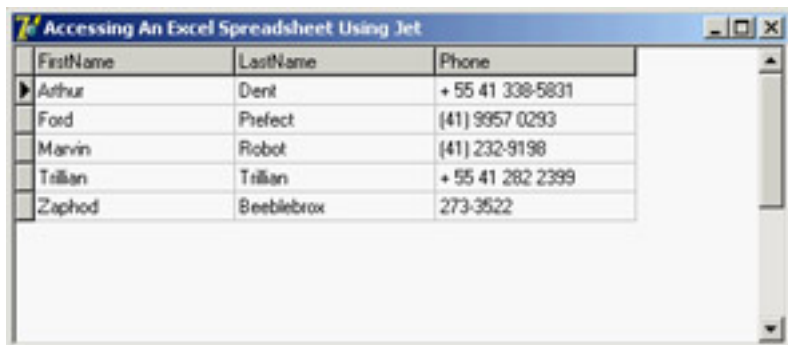

**Tip** You can also read an Excel file using the `XLSReadWrite` component (available from [www.axolot.com](http://www.axolot.com)). It doesn't require Excel to be available on the computer or the time to start it (like OLE Automation techniques do).

Ensure that your spreadsheet is not open in Excel, because ADO requires exclusive access to the file. Add an `ADODataset` component to a form. Set its `ConnectionString` to use the Jet 4.0 OLE DB provider and set Extended Properties to Excel 8.0. In the Connection tab, set the database name to the full file and path specification of the Excel spreadsheet (or use a relative path if you plan to deploy the file along with the program).

The `ADODataset` component works by opening or executing a value in its `CommandText` property. This value might be the name of a table, a SQL statement, a stored procedure, or the name of a file. You specify how this value is interpreted by setting the `CommandType` property. Set `CommandType` to `cmdTableDirect` to indicate that the value in `CommandText` is the name of a table and that all columns should be returned from this table. Select `CommandText` in

the Object Inspector, and you will see a drop-down arrow. Drop down the arrow and a single pseudo-table will be displayed: Employees\$. (Excel workbooks are suffixed with a \$.)

Add a DataSource and a DBGrid and connect them altogether, and you'll obtain the output of the JetExcel example, shown in [Figure 15.5](#) at design time. By default it would be a little difficult to view the data in the grid, because each column has a width of 255 characters. You can change the field display size either by adding columns to the grid and changing their width properties or by adding persistent fields and changing their Size or DisplayWidth properties.

FirstName	LastName	Phone
Arthur	Dent	+ 55 41 338-5831
Ford	Prefect	((41) 9957 0293
Marvin	Robot	((41) 232-9198
Trillian	Trillian	+ 55 41 282 2399
Zaphod	Beeblebrox	273-3522

**Figure 15.5:** ABCCompany.xls in Delphi—a small tribute to Douglas Adams

Notice that you cannot keep the dataset open at design time and run the program, because the Excel IISAM driver opens the XLS file in exclusive mode. Close the dataset and add to the program a line of code to open it at startup. When you run the program, you will notice another limitation of this IISAM driver: You can add new rows and edit existing rows, but you cannot delete rows.

Incidentally, you could have used either an ADOTable or an ADOQuery component, instead of the ADODataset, but you need to be aware of how ADO treats symbols in things like table names and field names. If you use an ADOTable and drop down the list of tables, you will see the Employees\$ table as you expect. Unfortunately, if you attempt to open the table, you will receive an error. The same is true for `SELECT * FROM Employees$` in a TADOQuery. The problem lies with the dollar sign in the table name. If you use characters such as dollar signs, dots, or, more importantly, spaces in a table name or field name, then you must enclose the name in square brackets (for example, [Employees\$]).

## Text Files through Jet

One of the most useful IISAM drivers that comes with the Jet engine is the Text IISAM. This driver allows you to read and update text files of almost any structured format. We will begin with a simple text file and then cover the variations.

Assume you have a text file called `NightShift.TXT` that contains the following text:

```
CrewPerson ,HomeTown
Neo ,Cincinnati
Trinity ,London
Morpheus ,Milan
```

Add an ADOTable component to a form, set its `ConnectionString` to use the Jet 4.0 OLE DB provider, and set `Extended Properties` to `Text`. The Text IISAM provider considers a directory a database, so you need to enter as the database name the directory that contains the `NightShift.TXT` file. In the Object Inspector and drop down the list of tables in the `TableName` property. You will notice that the dot in the filename has been converted to a hash, as in `NightShift#TXT`. Set `Active` to `True`, add a DataSource and a DBGrid and connect them altogether, and you will see the contents of the text file in a grid.

**Warning** If your computer's settings are such that the decimal separator is a comma instead of a period (so that 1,000.00 is displayed as 1.000,00), then you will need to either change your Regional Settings (Start → Settings → Control Panel → Regional Settings → Numbers) or take advantage of `SCHEMA.INI`, described shortly.

The grid indicates that the widths of the columns are 255 characters. You can change these values just as you did in the JetExcel program by adding persistent fields or columns to the grid and then setting the relevant width property. Alternatively, you can define the structure of the text file more specifically using `SCHEMA.INI`.

In the JetText example, the database folder is determined at run time depending on the folder hosting the program. To modify the connection string at run time, first load it into a string list (after converting the separators) and then use the `Values` property to change only one of the elements of the connection string. This is the code from the example:

```
procedure TForm1.FormCreate(Sender: TObject);  
var  
    sl: TStringList;  
begin  
    sl := TStringList.Create;  
    sl.Text := StringReplace (ADOTable1.ConnectionString,  
        ';', sLineBreak, [rfReplaceAll]);  
    sl.Values ['Data Source'] := ExtractFilePath (Application.ExeName);  
    ADOTable1.ConnectionString := StringReplace (sl.Text,  
        sLineBreak, ';', [rfReplaceAll]);  
    ADOTable1.Open;  
    sl.Free;  
end;
```

Text files come in all shapes and sizes. Often you do not need to worry about the format of a text file because the Text IISAM takes a peek at the first 25 rows to see whether it can determine the format for itself. It uses this information and additional information in the Registry to decide how to interpret the file and how to behave. If you have a file that doesn't match a regular format the Text IISAM can determine, then you can provide this information using a `SCHEMA.INI` file located in the same directory as the text files to which it refers. This file contains *schema* information, also called metadata, about any or all of the text files in the same directory. Each text file is given its own section, identified by the name of the text file, such as `[NightShift.TXT]`.

Thereafter you can specify the format of the file; the names, types, and sizes of columns; any special character sets to use; and any special column formats (such as date/time or currency). Let's assume that you change your `NightShift.TXT` file to the following format:

```
Neo           |Cincinnati  
Trinity       |London  
Morpheus      |Milan
```

In this example, the column names are not included in the text file, and the delimiter is a vertical bar. An associated `SCHEMA.INI` file might look something like the following:

```
[NightShift.TXT]  
Format=Delimited(|)  
ColNameHeader=False  
Col1=CrewPerson Char Width 10  
Col2=HomeTown Char Width 30
```

Regardless of whether you use a `SCHEMA.INI` file, you will encounter two limitations of the Text IISAM: Rows cannot be deleted, and rows cannot be edited.

## Importing and Exporting

The Jet engine is particularly adept at importing and exporting data. The process of exporting data is the same for each export format and consists of executing a `SELECT` statement with a special syntax. Let's begin with an example of exporting data from the Access version of the `DBDemos` database back to a Paradox table. You will need an active `ADOConnection`, called `ADOConnection1` in the `JetImportExport` example, which uses the Jet engine to open the database. The following code exports the `Customer` table to a Paradox `Customer.db` file:

```
SELECT * INTO Customer IN "C:\tmp" "Paradox 7.x;" FROM CUSTOMER
```

Let's look at the pieces of this `SELECT` statement. The `INTO` clause specifies the new table that will be created by the `SELECT` statement; this table must not already exist. The `IN` clause specifies the database to which the new table is added; in Paradox, this is a directory that already exists. The clause immediately following the database is the name of the IISAM driver to be used to perform the export. *You must include the trailing semicolon at the end of the driver name.* The `FROM` clause is a regular part of any `SELECT` statement. In the sample program, the operation is executed through the `ADOConnection` component and uses the program's folder instead of a fixed one:

```
ADOConnection1.Execute ('SELECT * INTO Customer IN "' +  
    CurrentFolder + '" "Paradox 7.x;" FROM CUSTOMER');
```

All export statements follow these same basic clauses, although IISAM drivers have differing interpretations of what a database is. Here, you export the same data to Excel:

```
ADOConnection1.Execute ('SELECT * INTO Customer IN "' +  
    CurrentFolder + 'dbdemos.xls" "Excel 8.0;" FROM CUSTOMER');
```

A new Excel file called `dbdemos.xls` is created in the application's current directory. A workbook called `Customer` is added, containing all the data from the `Customer` table in `dbdemos.mdb`.

This last example exports the same data to an HTML file:

```
ADOConnection1.Execute ('SELECT * INTO [Customer.htm] IN "' +  
    CurrentFolder + '" "HTML Export;" FROM CUSTOMER');
```

In this case, the database is the directory, as it was for Paradox but not for Excel. The table name must include the `.htm` extension and, therefore, it must be enclosed in square brackets. Notice that the name of the IISAM driver is `HTML Export`, not just `HTML`, because this driver can only be used for exporting to HTML.

The last IISAM driver we'll look at in this investigation of the Jet engine is the partner to HTML Export: HTML Import. Add an `ADOTable` to a form, set its `ConnectionString` to use the Jet 4.0 OLE DB provider, and set `Extended Properties` to HTML Import. Set the database name to the name of the HTML file created by the export a few moments ago—that is, `Customer.htm`. Now set the `TableName` property to `Customer`. Open the table—you have just imported the HTML file. Bear in mind, though, that if you attempt to update the data, you'll receive an error because this driver is intended for import only. Finally, if you create your own HTML files containing tables and want to open these tables using this driver, then remember that the name of the table is the value of the `caption` tag of the HTML table.

## Working with Cursors

Two properties of ADO datasets have a fundamental impact on your application and are inextricably linked with each other: `CursorLocation` and `CursorType`. If you want to understand your ADO dataset behavior, you must understand these two properties.

### Cursor Location

The `CursorLocation` property allows you to specify what is in control of the retrieval and update of your data. You have two choices: `client` (`clUseClient`) or `server` (`clUseServer`). Your choice affects your dataset's functionality, performance, and scalability.

A client cursor is managed by the ADO Cursor Engine. This engine is an excellent example of an OLE DB service provider: It provides a service to other OLE DB providers. The ADO Cursor Engine manages the data from the client side of the application. All data in the result set is retrieved from the server to the client when the dataset is opened. Thereafter, the data is held in memory, and updates and manipulation are managed by the ADO Cursor Engine. This is similar to using the `ClientDataSet` component in a `dbExpress` application. One benefit is that manipulation of the data, after the initial retrieval, is considerably faster. Furthermore, because the manipulation is performed in memory, the ADO Cursor Engine is more versatile than most server-side cursors and offers extra facilities. I'll examine these benefits later, as well as other technologies that depend on client-side cursors (such as disconnected and persistent recordsets).

A server-side cursor is managed by the RDBMS. In a client/server architecture based on a database such as SQL Server, Oracle, or InterBase, this means the cursor is managed physically on the server. In a desktop database such as Access or Paradox, the "server" location is a logical location, because the database is running on the desktop. Server-side cursors are often faster to load than client-side cursors because not all the data is transferred to the client when the dataset is opened. This behavior also makes them more suitable for very large result sets where the client has insufficient memory to hold the entire result set in memory. Often you can determine what kinds of features will be available to you with each cursor location by thinking through how the cursor works. Locking is a good example of how features determine the cursor type; I will discuss locking in more detail later. (To place a lock on a record requires a server-side cursor, because there must be a conversation between the application and the RDBMS.)

Another issue that will affect your choice of cursor location is scalability. Server-side cursors are managed by the RDBMS; in a client/server database, this will be located on the server. As more users use your application, the load on the server increases with each server-side cursor. A greater workload on the server means that the RDBMS becomes a bottleneck more quickly, so the application is less scalable. You can achieve better scalability by using client-side cursors. The initial hit on opening the cursor is often heavier, because all the data is transferred to the client, but the maintenance of the open cursor can be lower. As you can see, many conflicting issues are involved in choosing the correct cursor location for your datasets.

### Cursor Type

Your choice of cursor location directly affects your choice of cursor type. To all intents and purposes there are four cursor types, but one value is unused: a cursor type that means *unspecified*. Many values in ADO signify an unspecified value, and I will cover them all here and explain why you won't have much to do with them. They exist in Delphi because they exist in ADO. ADO was primarily designed for Visual Basic and C programmers. In these languages, you use objects directly without the assistance `dbGo` provides. As such, you can create and open *recordsets*, as they are called in ADO-speak, without having to specify every value for every property. The properties for which a value has not been specified have an unspecified value. However, in `dbGo` you use components. These components have constructors, and these constructors initialize the properties of the components. So, from the moment you create a `dbGo` component, it will usually have a value for every property. As a consequence, you have little need for the unspecified values in many enumerated types.

Cursor types affect how your data is read and updated. As I mentioned, there are four choices: forward-only, static, keyset, and dynamic. Before we get too involved in all the permutations of cursor locations and cursor types, you should be aware that there is only one cursor type available for client-side cursors: the static cursor. All other cursor

types are available only to server-side cursors. I'll return to the subject of cursor type availability after we have looked at the various cursor types, in increasing order of expense:

**Forward-Only Cursor** The forward-only cursor is the least expensive cursor type, and therefore the type with the best performance. As the name implies, the forward-only cursor lets you navigate forward. The cursor reads the number of records specified by `CacheSize` (default of 1); each time it runs out of records, it reads another `CacheSize` set. Any attempt to navigate backward through the result set beyond the number of records in the cache results in an error. This behavior is similar to that of a `dbExpress` dataset. A forward-only cursor is not suitable for use in the user interface where the user can control the direction through the result set. However, it is eminently suitable for batch operations, reports and stateless Web applications, because these situations start at the top of the result set and work progressively toward the end, and then the result set is closed.

**Static Cursor** A static cursor works by reading the complete result set and providing a window of `CacheSize` records into the result set. Because the complete result set has been retrieved by the server, you can navigate both forward and backward through the result set. However, in exchange for this facility, the data is static—updates, insertions, and deletions made by other users cannot be seen, because the cursor's data has already been read.

**Keyset Cursor** A keyset cursor is best understood by breaking *keyset* into the two words *key* and *set*. *Key*, in this context, refers to an identifier for each row. Often this will be a primary key. A keyset cursor, therefore, is a set of keys. When the result set is opened, the complete list of keys for the result set is read. If, for example, the dataset was a query like `SELECT * FROM CUSTOMER`, then the list of keys would be built from `SELECT CUSTID FROM CUSTOMER`. This set of keys is held until the cursor is closed. When the application requests data, the OLE DB provider reads the rows using the keys in the set of keys. Consequently, the data is always up to date. If another user changes a row in the result set, then the changes will be seen when the data is reread. However, the set of keys is static; it is read only when the result set is first opened. If another user adds new records, these additions will not be seen. Deleted records become inaccessible, and changes to primary keys (you don't let your users change primary keys, do you?) are also inaccessible.

**Dynamic Cursor** The most expensive cursor type, a dynamic cursor is almost identical to a keyset cursor. The sole difference is that the set of keys is reread when the application requests data that is not in the cache. Because the default for `ADODataset.CacheSize` is 1, such requests occur frequently. You can imagine the additional load this behavior places on the DBMS and the network, and why this is the most expensive cursor. However, the result set can see and respond to additions and deletions made by other users.

## Ask and Ye Shall Not Receive

Now that you know about cursor locations and cursor types, a word of warning: Not all combinations of cursor location and cursor type are possible. Usually, this limitation is imposed by the RDBMS and/or the OLE DB provider as a result of the functionality and architecture of the database. For example, client cursors always force the cursor type to static. You can see behavior this for yourself. Add an `ADODataset` component to a form, set its `ConnectionString` to any database, and set the `ClientLocation` property to `clUseCursor` and the `CursorType` property to `ctDynamic`. Now set `Active` to `True` and keep your eye on the `CursorType`; it changes to `ctStatic`. You learn an important lesson from this example: What you ask for is not necessarily what you get. Always check your properties after opening a dataset to see the actual effect of your requests.

Each OLE DB provider will make different changes according to different requests and circumstances, but here are a few examples to give you an idea of what to expect:

- The Jet 4.0 OLE DB provider changes most cursor types to keyset.
- The SQL Server OLE DB provider often changes keyset and static to dynamic.

- The Oracle OLE DB provider changes all cursor types to forward-only.
- The ODBC OLE DB provider makes various changes according to the ODBC driver in use.

## No Record Count

ADO datasets sometimes return `-1` for their `RecordCount`. A forward-only cursor cannot know how many records are in the result set until it reaches the end, so it returns `-1` for the `RecordCount`. A static cursor always knows how many records are in the result set, because it reads the entire set when it is opened, so it returns the number of records in its result set. A keyset cursor also knows how many records are in the result set, because it has to retrieve a fixed set of keys when the result set is opened, so it also returns a useful value for `RecordCount`. A dynamic cursor does not reliably know how many records are in the result set, because it is regularly rereading the set of keys, so it returns `-1`. You can avoid using `RecordCount` altogether and execute `SELECT COUNT(*) FROM tablename`, but the result will be an accurate reflection of the number of records in the database table—which is not necessarily the same as the number of records in the dataset.

## Client Indexes

One of the many benefits of client-side cursors is the ability to create local, or *client*, indexes. Assuming you have an ADO client-side dataset for the DBDemos Customer table, which has a grid attached to it, set the dataset's `IndexFieldNames` property to `CompanyName`. The grid will immediately show that the data is in `CompanyName` order. There is an important point here: In order to index the data, ADO did not have to reread the data from its source. The index was created from the data in memory. So, not only is the index created as quickly as possible, but the network and the DBMS are not overloaded by transferring the same data over and over in different orders.

The `IndexFieldNames` property has more potential. Set it to `Country;CompanyName` and you will see the data ordered first by country and then, within country, by company name. Now set `IndexFieldNames` to `CompanyName DESC`. Be sure to write `DESC` in capitals (and not `desc` or `Desc`). The data is now sorted in descending order.

This simple but powerful feature allows you to solve one of the great bugbears of database developers. Users ask the inevitable, and quite reasonable, question, "Can I click the columns of the grid to sort my data?" Answers like replacing grids with non-data-aware controls such as `ListView` that have the sorting built into the control or like trapping the `DBGrid`'s `OnTitleClick` event and reissuing the SQL `SELECT` statement after including an appropriate `ORDER BY` clause are far from satisfactory.

If you have the data cached on the client side (as you've also seen in the use of the `ClientDataSet` component), you can use a client index computed in memory. Add the following `OnTitleClick` event to the grid (the code is available in the `ClientIndexes` example):

```
procedure TForm1.DBGrid1TitleClick(Column: TColumn);
begin
    if ADODataSet1.IndexFieldNames = Column.Field.FieldName then
        ADODataSet1.IndexFieldNames := Column.Field.FieldName + ' DESC'
    else
        ADODataSet1.IndexFieldNames := Column.Field.FieldName
end;
```

This simple event checks to see whether the current index is built on the same field as the column. If it is, then a new index is built on the column, but in descending order. If not, then a new index is built on the column. When the user clicks the column for the first time, it is sorted in ascending order; when it is clicked for the second time, it is sorted in descending order. You could extend this functionality to allow the user to `Ctrl+click` several column titles to build up more complicated indexes.

**Note** All of this can be achieved using `ClientDataSet`, but that solution is not as elegant because `ClientDataSet` does not support the `DESC` keyword so you have to create an index collection item to obtain a descending index, something that requires more code. Moreover when changing an ascending index to a descending version, the `ClientDataSet` will rebuild the index, performing an unnecessary and possibly slow operation.

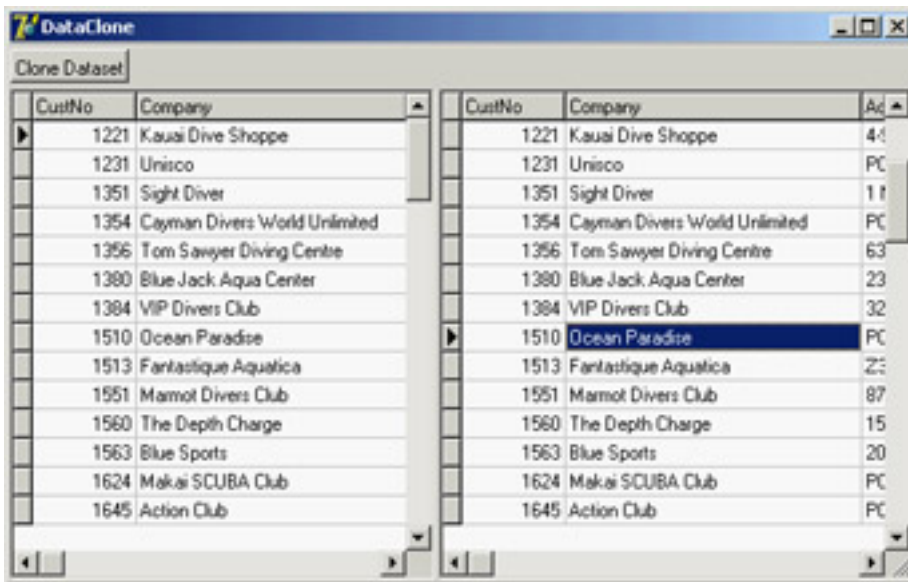

## Cloning

ADO is crammed with features. You can argue that *feature-rich* can translate into *footprint-rich*, but it also translates into more powerful and reliable applications. One such powerful feature is cloning. A cloned recordset is a new recordset that has all the same properties as the original from which it is cloned. First I'll explain how you can create and use a clone, and then I'll explain why clones are so useful.

**Note** The `ClientDataSet` also supports cloning; this feature was not discussed in [Chapter 13](#), "Delphi's Database Architecture."

You can clone a recordset (or, in dbGo-speak, a dataset) using the `Clone` method. You can clone any ADO dataset, but you will use `ADOTable` in this example. The `DataClone` example (see [Figure 15.6](#)) uses two `ADOTable` components, one hooked to database data and the other empty. Both datasets are hooked to a `DataSource` and grid. A single line of code, executed when the user clicks a button, clones the dataset:

```
ADOTable2.Clone(ADOTable1);
```

**Figure 15.6:** The form of the `DataClone` example, with two copies of a dataset (the original and a clone)

This line clones `ADOTable1` and assigns the clone to `ADOTable2`. In the program, you'll see a second view of the data. The two datasets have their own record pointers and other status information, so the clone does not interfere with its original copy. This behavior makes clones ideal for operating on a dataset without affecting the original data. Another interesting feature is that you can have multiple different active records, one for each of the clones—functionality you cannot achieve in Delphi with a single dataset.

**Tip** A recordset must support bookmarks in order to be cloned, so forward-only and dynamic cursors cannot be cloned. You can determine whether a recordset supports bookmarks using the `Supports` method (for example, `ADOTable1.Supports([coBookMark])`). One of the useful side effects of clones is that the bookmarks created by one clone are usable by all other clones.

## Transaction Processing

As we saw in section "[Using Transactions](#)" of [Chapter 14](#), transaction processing allows developers to group individual updates to a database into a single logical unit of work.

ADO's transaction processing support is controlled with the `ADOConnection` component, using the `BeginTrans`, `CommitTrans`, and `RollbackTrans` methods, which have effects similar to those of the corresponding `dbExpress` and `BDE` methods. To investigate ADO transaction processing support, you will build a test program called `TransProcessing`. The program has an `ADOConnection` component with the `ConnectionString` set to the Jet 4.0 OLE DB provider and the `dbdemos.mdb` file. It has an `ADOTable` component hooked to the `Customer` table and a `DataSource` and `DBGrid` for displaying the data. Finally, it has three buttons to execute the following commands:

```
ADOConnection1.BeginTrans;  
ADOConnection1.CommitTrans;  
ADOConnection1.RollbackTrans;
```

With this program, you can make changes to the database table and then roll them back, and they will be rolled back as expected. I emphasize this point because transaction support varies depending on the database and on the OLE DB provider you are using. For example, if you connect to Paradox using the ODBC OLE DB provider, you will receive an error indicating that the database or the OLE DB provider is not capable of beginning a transaction. You can find out the level of transaction processing support you have using the `Transaction DDL` dynamic property of the connection:

```
if ADOConnection1.Properties['Transaction DDL'].Value > DBPROPVAL_TC_NONE then  
    ADOConnection1.BeginTrans;
```

If you are trying to access the same Paradox data using the Jet 4.0 OLE DB provider, you won't receive an error but you also won't be able to roll back your changes, due to limitations of the OLE DB provider.

Another strange difference becomes evident when you're working with Access: If you use the ODBC OLE DB provider, you'll be able to use transactions—but not nested transactions. Opening a transaction when another is active will result in an error. Using the Jet engine, however, Access supports nested transactions.

## Nested Transactions

Using the `TransProcessing` program, you can try this test:

1. Begin a transaction.
2. Change the `ContactName` of the `Around The Horn` record from `Thomas Hardy` to `Dick Solomon`.
3. Begin a nested transaction.
4. Change the `ContactName` of the `Bottom-Dollar Markets` record from `Elizabeth Lincoln` to `Sally Solomon`.
5. Roll back the inner transaction.
6. Commit the outermost transaction.

The net effect is that only the change to the `Around The Horn` record is permanent. If, however, the inner transaction had been committed and the outer transaction rolled back, then the net effect would have been that *none* of the changes were permanent (even the changes in the inner transaction). This is as you would expect, with the only limit being that Access supports five levels of nested transactions.

ODBC does not support nested transactions, the Jet OLE DB provider supports up to five levels of nested transactions, and the SQL Server OLE DB provider doesn't support nesting at all. You might get a different result depending on the version of SQL server or the driver, but the documentation and my experiments with the servers seem to indicate that this is the case. Apparently only the outermost transaction decides whether all the work is committed or rolled back.

## ADOConnection Attributes

There is another issue you should consider if you intend to use nested transactions. The `ADOConnection` component has an `Attributes` property that determines how the connection should behave when a transaction is committed or rolled back. It is a set of `TXActAttributes` that, by default, is empty. `TXActAttributes` contains only two values: `xaCommitRetaining` and `xaAbortRetaining` (this value is often mistakenly written as `xaRollbackRetaining`—a more logical name for it). When `xaCommitRetaining` is included in `Attributes` and a transaction is committed, a new transaction is automatically started. When `xaAbortRetaining` is included in `Attributes` and a transaction is rolled back, a new transaction is automatically started. Thus if you include these values in `Attributes`, a transaction will always be in progress, because when you end one transaction another will always be started.

Most programmers prefer to be in greater control of their transactions and not to allow them to be automatically started, so these values are not commonly used. However, they have a special relevance to nested transactions. If you nest a transaction and set `Attributes` to `[xaCommitRetaining, xaAbortRetaining]`, then the outermost transaction can never be ended. Consider this sequence of events:

1. An outer transaction is started.
2. An inner transaction is started.
3. The inner transaction is committed or rolled back.
4. A new inner transaction is automatically started as a consequence of the `Attributes` property.

The outermost transaction can never be ended, because a new inner transaction will be started when one ends. The conclusion is that the use of the `Attributes` property and the use of nested transactions should be considered mutually exclusive.

## Lock Types

ADO supports four different approaches to locking your data for update: `ItReadOnly`, `ItPessimistic`, `ItOptimistic`, and `ItBatchOptimistic` (there is also an `ItUnspecified` option, but for the reasons mentioned earlier, we will ignore unspecified values). The four approaches are made available through the dataset's `LockType` property. In this section I will provide an overview of the four approaches, and in subsequent sections we will take a closer look at them.

The `ItReadOnly` value specifies that data is read-only and cannot be updated. As such, there is effectively no locking control required, because the data cannot be updated.

The `ItPessimistic` and `ItOptimistic` values offer the same pessimistic and optimistic locking control as the BDE. One important benefit that ADO offers over the BDE in this respect is that the choice of locking control remains yours. If you use the BDE, the decision to use pessimistic or optimistic locking is made for you by your BDE driver. If you use a desktop database such as dBase or Paradox, then the BDE driver uses pessimistic locking; if you use a client/server database such as InterBase, SQL Server, or Oracle, the BDE driver uses optimistic locking.

## Pessimistic Locking

The words *pessimistic* and *optimistic* in this context refer to the developer's expectation of conflict between user updates. Pessimistic locking assumes that there is a high probability that users will attempt to update the same records at the same time and that a conflict is likely. In order to prevent such a conflict, the record is locked when the edit begins. The record lock is maintained until the update is completed or cancelled. A second user who attempts to edit the same record at the same time will fail in their attempt to place their record lock and will receive a "Could not update; currently locked" exception.

This approach to locking will be familiar to developers who have worked with desktop databases such as dBase and Paradox. The benefit is that the user knows that if they can begin editing a record, then they will succeed in saving their update. The disadvantage of pessimistic locking is that the user is in control of when the lock is placed and when it is removed. If the user is skilled with the application, then this lock could be as short as a couple of seconds.

However, in database terms, a couple of seconds is an eternity. On the other hand, the user might begin an edit and go to lunch, and the record would be locked until the user returns. As a consequence, most proponents of pessimistic locking guard against this eventuality by using a Timer or other such device to time out locks after a certain amount of keyboard and mouse inactivity.

Another problem with pessimistic locking is that it requires a server-side cursor. Earlier we looked at cursor locations and saw that they have an impact on the availability of the different cursor types. Now you can see that cursor locations also have an impact on locking types. Later in this chapter, we will discuss more benefits of client-side cursors; if you choose to take advantage of these benefits, then you'll be unable to use pessimistic locking.

Pessimistic locking is an area of dbGo that changed in Delphi 6 (compared to Delphi 5). This section describes the way pessimistic locking works in versions 6 and 7. To highlight how it works, I've built the PessimisticLocking example. It is similar to other examples in this chapter, but the `CursorLocation` property is set to `clUseServer` and the `LockType` property is set to `ltPessimistic`. To use it, run two copies from Windows Explorer and attempt to edit the same record in both running instances of the program: You will fail because the record is locked by another user.

## Updating the Data

One of the reasons people use the ClientDataSet component (or turn to cached updates in the BDE) is to make a SQL join updatable. Consider the following SQL equi-join:

```
SELECT * FROM Orders, Customer
WHERE Customer.CustNo=Orders.CustNo
```

This statement provides a list of orders and the customers that placed those orders. The BDE considers any SQL join to be read-only because inserting, updating, and deleting rows in a join is ambiguous. For example, should the insert of a row into the previous join result in a new product and also a new supplier, or just a new product? The ClientDataSet/Provider architecture allows you to specify a primary update table (and advanced features actually not covered in the book) and also customize the updates' SQL, as we partially saw in [Chapter 14](#) and we'll further explore in [Chapter 16](#), "Multitier DataSnap Applications."

ADO supports an equivalent to cached updates called *batch updates*, which are similar to the BDE approach. In the [next section](#) we will take a closer look at ADO's batch updates, what they can offer you, and why they are so important. However, in this section you won't need them to solve the problem of updating a join, because in ADO, joins are naturally updatable.

For example, the JoinData example is built around an ADODataset component that uses the previous SQL join. If you run it, you can edit one of the fields and save the changes (by moving off the record). No error occurs, because the update has been applied successfully. ADO, compared to the BDE, has taken a more practical approach to the problem. In an ADO join, each field object knows which underlying table it belongs to. If you update a field in the Products table and post the change, then a SQL UPDATE statement is generated to update the field in the Products table. If you change a field in the Products table and a field in the Suppliers table, then two SQL UPDATE statements are generated, one for each table.

The insertion of a row into a join follows a similar behavior. If you insert a row and enter values for the Products table only, then a SQL INSERT statement is generated for the Products table. If you enter values for both tables, two SQL INSERT statements are generated, one for each table. The order in which the statements are executed is important, because the new product might relate to the new supplier, so the new supplier is inserted first.

The biggest problem with the ADO solution can be seen when a row in a join is deleted. The deletion attempt will appear to fail. The exact message you see depends on the version of ADO you are using and the database, but it will be along the lines that you cannot delete the row because other records relate to it. The error message can be confusing. In the current scenario, the error message implies that a product cannot be deleted because there are records that relate to the product, but the error occurs whether the product has any related records or not. The explanation can be found by following the same logic for deletions as for insertions. Two SQL DELETE statements are generated: one for the Suppliers table and then another for the Products table. Contrary to appearances, the DELETE statement for the Products table succeeds. It is the DELETE statement for the Suppliers table that fails, because the supplier cannot be deleted while it still has dependent records.

**Tip** If you are curious about the SQL statements that are generated, and you use SQL Server, you can see these statements using SQL Server Profiler.

Even if you understand how this process works, it's helpful to look at this problem through the users' eyes. From their point of view, when users delete a row in the grid, I would wager that 99 percent of them intend to delete just the product—not both the product and the supplier. Fortunately, you can achieve this result using another dynamic property—in this case, the Unique Table dynamic property. You can specify that deletes refer to just the Products table and not to Suppliers using the following line of code:

```
ADOQuery1.Properties['Unique Table'].Value := 'Products';
```

This value cannot be assigned at design time, so the next best alternative is to place this line in the form's OnCreate event.

## Batch Updates

When you use batch updates, any changes you make to your records can be made in memory; later, the entire "batch" of changes can be submitted as one operation. This approach offers some performance benefits, but there are more practical reasons why this technology is a necessity: The user might not be connected to the database at the time they make their updates. This would be the case in a briefcase application (which we will return to in the section "[The Briefcase Model](#)"), but it can also be the case in web applications that use another ADO technology, Remote Data Services (RDS).

You can enable batch updates in any ADO dataset by setting `LockType` to `ltBatchOptimistic` before the dataset is opened. In addition, you will need to set the `CursorLocation` to `clUseClient`, because batch updates are managed by ADO's cursor engine. Hereafter, changes are all made to a *delta* (a list of changes). The dataset looks to all intents and purposes as if the data has changed, but the changes have only been made in memory; they have not been applied to the database. To make the changes permanent, use `UpdateBatch` (equivalent to cached updates' `ApplyUpdates`):

```
ADODataset1.UpdateBatch;
```

To reject the entire batch of updates, use either `CancelBatch` or `CancelUpdates`. There are many similarities in method and property names between ADO batch updates, BDE cached updates, and `ClientDataSet.UpdateStatus`, for example, can be used exactly the same way as for cached updates to identify records according to whether they have been inserted, updated, deleted, or unmodified. This approach is particularly useful for highlighting records in different colors in a grid or showing their status on a status bar. Some differences between the syntaxes are slight, such as changing `RevertRecord` to `CancelBatch(arCurrent)`; others require more effort.

One useful cached update feature that is not present in ADO batch updates is the dataset's `UpdatesPending` property. This property is true if changes have been made but not yet applied. It's particularly useful in a form's `OnCloseQuery` event:

```
procedure TForm1.FormCloseQuery(  
    Sender: TObject; var CanClose: Boolean);  
begin  
    CanClose := True;  
    if ADODataset1.UpdatesPending then  
        CanClose := (MessageDlg('Updates are still pending' #13 +  
            'Close anyway?', mtConfirmation, [mbYes, mbNo], 0) = mrYes);  
end;
```

However, with a little knowledge and ingenuity you can implement a suitable `ADOUpdatesPending` function. The necessary knowledge is that ADO datasets have a property called `FilterGroup`, which is a kind of filter. Unlike a dataset's `Filter` property, which filters the data based on a comparison of the data against a condition, `FilterGroup` filters based on the status of the record. One such status is `fgPendingRecords`, which includes all records that have been modified but not yet applied. So, to allow the user to look through all the changes they have made so far, you need only execute two lines:

```
ADODataset1.FilterGroup := fgPendingRecords;  
ADODataset1.Filtered := True;
```

Naturally, the result set will now include the records that have been deleted. The effect you will see is that the fields are left blank, which is not very helpful because you don't know which record has been deleted. (This was not the behavior in the first version of ADOExpress, which displayed the field values of deleted records.)

The ingenuity you need in order to solve the `UpdatesPending` problem involves clones, discussed earlier. The `ADOUpdatesPending` function will set the `FilterGroup` to restrict the dataset to only those changes that have not yet been applied. All you need to do is see whether there are any records in the dataset once the `FilterGroup` has been applied. If there are, then some updates are pending. However, if you do this with the actual dataset, then the setting of the `FilterGroup` will move the record pointer, and the user interface will be updated. The best solution is to

use a clone:

```
function ADOUpdatesPending(ADODataset: TCustomADODataset): boolean;  
var  
    Clone: TADODataset;  
begin  
    Clone := TADODataset.Create(nil);  
    try  
        Clone.Clone(ADODataset);  
        Clone.FilterGroup := fgPendingRecords;  
        Clone.Filtered := True;  
        Result := not (Clone.BOF and Clone.EOF);  
        Clone.Close;  
    finally  
        Clone.Free;  
    end;  
end;
```

In this function, you clone the original dataset, set the `FilterGroup`, and check to see whether the dataset is at both beginning of the file and also the end of the file. If it is, then no records are pending.

## Optimistic Locking

Earlier we looked at the `LockType` property and saw how pessimistic locking works. In this section, we'll look at optimistic locking, not only because it is the preferred locking type for medium- to high-throughput transactions, but also because it is the locking scheme employed by batch updates.

Optimistic locking assumes there is a low probability that users will attempt to update the same records at the same time and that a conflict is unlikely. As such, the attitude is that all users can edit any record at any time, and you deal with the consequences of conflicts between different users' updates to the same records when the changes are saved. Thus, conflicts are considered an exception to the rule. This means there are no controls to prevent two users from editing the same record at the same time. The first user to save their changes will succeed; the second user's attempt to update the same record might fail. This behavior is essential for briefcase applications (discussed later in the chapter) and web applications, where there is no permanent connection to the database and, therefore, no way to implement pessimistic locking. In contrast with pessimistic locking, optimistic locking has the additional considerable benefit that resources are consumed only momentarily; therefore, the average resource usage is much lower, making the database more scalable.

Let's consider an example. Assume you have an `ADODataset` connected to the `Customer` table of the `dbdemos.mdb` database, with `LockType` set to `ltBatchOptimistic`, and the contents are displayed in a grid. Assume that you also have a button to call `UpdateBatch`. Run the program twice (it is the `BatchUpdates` example if you don't want to rebuild it) and begin editing a record in the first copy of the program. Although for the sake of simplicity I'll demonstrate a conflict using just a single machine, the scenario and subsequent events are unchanged when using multiple machines:

1. Choose the Bottom-Dollar Markets company in Canada and change the name to Bottom-Franc Markets.
2. Save the change, move off the record to post it, and click the button to update the batch.
3. In the second copy of the program, locate the same record and change the company name to Bottom-Pound Markets.
4. Move off the record and click the button to update the batch. It will fail.

As with many ADO error messages, the exact message you receive will depend not only on the version of ADO you are using but also on how closely you followed the example. In ADO 2.6, the error message is "Row cannot be located for updating. Some values may have been changed since it was last read." This is the nature of optimistic locking. The update to the record is performed by executing the following SQL statement:

```
UPDATE CUSTOMER SET CompanyName="Bottom-Pound Markets"
```

```
WHERE CustomerID="BOTTM" AND CompanyName="Bottom-Dollar Markets"
```

The number of records affected by this `UPDATE` statement is expected to be one, because it locates the original record using the primary key and the contents of the `CompanyName` field as it was when the record was first read. In this example, however, the number of records affected by the `UPDATE` statement is zero. This result can occur only if the record has been deleted, the record's primary key has changed, or the field that you are changing was changed by someone else. Hence, the update fails.

If the "second user" had changed the `ContactName` field and not the `CompanyName` field, then the `UPDATE` statement would have looked like this:

```
UPDATE CUSTOMER SET ContactName="Liz Lincoln"  
WHERE CustomerID="BOTTM" AND ContactName="Elizabeth Lincoln"
```

In the example scenario, this statement would have succeeded because the other user didn't change the primary key or the contact name. This behavior is similar to the BDE with the *update where changed* update mode. The `UpdateMode` property of the BDE in ADO is replaced by the `Update Criteria` dynamic property of a dataset. The following list shows the possible values that can be assigned to this dynamic property:

Constant	Locate Records By
<code>adCriteriaKey</code>	Primary key columns only
<code>adCriteriaAllCols</code>	All columns
<code>adCriteriaUpdCols</code>	Primary key columns and changed columns only
<code>adCriteriaTimeStamp</code>	Primary key columns and a timestamp column only

Don't fall into the trap of thinking that one of these settings is better than another for your whole application. In practice, your choice of setting will be influenced by the contents of each table. Say that the `Customer` table has just `CustomerID`, `Name`, and `City` fields. In this case, the update of any one of these fields is logically not mutually exclusive with the update of any of the other fields, so a good choice for this table would be `adCriteriaUpdCols` (the default). If, however, the `Customer` table included a `PostalCode` field, then the update of a `PostalCode` field would be mutually exclusive with the update of the `City` field by another user (because if the city changes, then so should the postal code, and possibly vice versa). In this case, you could argue that `adCriteriaAllCols` would be a safer solution.

Another issue to be aware of is how ADO deals with errors during the update of multiple records. Using the BDE's cached updates and `ClientDataSet`, you can use the `OnUpdateError` event to handle each update error as the error occurs and resolve the problem before moving on to the next record. In ADO, you cannot establish such a dialog. You can monitor the progress and success or failure of the updating of the batch using the dataset's `OnWillChangeRecord` and `OnRecordChangeComplete`, but you cannot revise the record and resubmit it during this process as you can with the BDE and `ClientDataSet`. There's more: If an error occurs during the update process, the updating does not stop. It continues to the end, until all updates have been applied or have failed. This process can produce an unhelpful and incorrect error message. If more than one record cannot be updated, or the single record that failed is not the last record to be applied, then the error message in ADO 2.6 is "Multiple-step OLE DB operation generated errors. Check each OLE DB status value, if available. No work was done." The last sentence is the problem; it states that "No work was done," but this is incorrect. It is true that no work was done on the record that failed, but other records were successfully applied, and their updates stand.

## Resolving Update Conflicts

As a consequence of the nature of applying updates, the approach that you need to take to update the batch is to update the batch, let the individual records fail, and then deal with the failed records once the process is over. You can determine which records have failed by setting the dataset's `FilterGroup` to `fgConflictingRecords`:

```
ADODataset1.FilterGroup := fgConflictingRecords;  
ADODataset1.Filtered := True;
```

For each failed record, you can inform the user of three critical pieces of information about each field using the

following TField properties:

Property	Description
NewValue	The value this user changed it to
CurValue	The new value from the database
OldValue	The value when first read from the database

Users of the ClientDataSet component will be aware of the handy `ReconcileErrorForm` dialog, which wraps up the process of showing the user the old and new records and allows them to specify what action to take. Unfortunately, there is no ADO equivalent to this form, and `TReconcileErrorForm` has been written with `ClientDataSet` so much in mind that it is difficult to convert it for use with ADO datasets.

I'll point out one last gotcha about using these `TField` properties: They are taken straight from the underlying ADO Field objects to which they refer. This means, as is common in ADO, that you are at the mercy of your chosen OLE DB provider to support the features you hope to use. All is well for most providers, but the Jet OLE DB provider returns the same value for `CurValue` as it does for `OldValue`. In other words, if you use Jet, you cannot determine the value to which the other user changed the field unless you resort to your own measures. Using the OLEDB provider for SQL Server, however, you can access the `CurValue` only after calling the `Resync` method of the dataset with the `AffectRecords` parameter set to `adAffectGroup` and `ResyncValues` set to `adResyncUnderlyingValues`, as in the following code:

```
adoCustomers.FilterGroup := fgConflictingRecords;  
adoCustomers.Filtered := true;  
adoCustomers.Recordset.Resync(adAffectGroup, adResyncUnderlyingValues);
```

## Disconnected Recordsets

This knowledge of batch updates allows you to take advantage of the next ADO feature: disconnected recordsets. A *disconnected recordset* is a recordset that has been disconnected from its connection. This feature is impressive because the user cannot tell the difference between a regular recordset and a disconnected one; their feature sets and behavior are almost identical. To disconnect a recordset from its connection, you must set the `CursorLocation` to `clUseClient` and the `LockType` to `ltBatchOptimistic`. You then tell the dataset that it no longer has a connection:

```
ADODataset1.Connection := nil;
```

Hereafter, the recordset will continue to contain the same data, support the same navigational features, and allow records to be added, edited, and deleted. The only relevant difference is that you cannot update the batch because you need to be connected to the server to update the server. You can reconnect the connection (and use `UpdateBatch`) as follows:

```
ADODataset1.Connection := ADOConnection1;
```

This feature is also available to the BDE and other database technologies by switching over to `ClientDataSets`, but the beauty of the ADO solution is that you can build your entire application using `dbGo` dataset components and be unaware of disconnected recordsets. When you discover this feature and want to take advantage of it, you can continue to use the same components you always used.

You might want to disconnect your recordsets for two reasons:

- To keep the total number of connections lower
- To create a briefcase application

I'll discuss keeping down the number of connections in this section and return to briefcase applications later.

Most regular client/server business applications open tables and maintain a permanent connection to their database while the table is open. However, there are usually only two reasons to be connected to the database: to retrieve data and to update data. Suppose you change your regular client/server application so that after the table is opened and the data is retrieved, the dataset is disconnected from the connection and the connection is dropped; your user will be none the wiser, and the application will not need to maintain an open database connection. The following code shows the two steps:

```
ADODataset1.Connection := nil;  
ADOConnection1.Connected := False;
```

The only other point at which a connection is required is when the batch of updates needs to be applied. The update code looks like this:

```
ADOConnection1.Connected := True;  
ADODataset1.Connection := ADOConnection1;  
try  
    ADODataset1.UpdateBatch;  
finally  
    ADODataset1.Connection := nil;  
    ADOConnection1.Connected := False;  
end;
```

If you followed this approach throughout the application, the average number of open connections at any one time would be minimal—the connections would be open only for the brief time they were required. The consequence of this change is scalability; the application can cope with significantly more simultaneous users than an application that maintains an open connection. The downside is that reopening the connection can be a lengthy process on some (but not all) database engines, so the application will be slower to update the batch.

## Connection Pooling

All this talk about dropping and reopening connections brings us to the subject of connection pooling. Connection pooling—not to be confused with session pooling—allows connections to a database to be reused once you have finished with them. This process happens automatically; if your OLE DB provider supports it and it is enabled, no action is necessary for you to take advantage of connection pooling.

There is a single reason to pool your connections: performance. The problem with database connections is that it can take time to establish a connection. In a desktop database such as Access, this time is typically brief. However, in a client/server database such as Oracle used on a network, this time could be measured in seconds. It makes sense to promote the reuse of such an expensive (in performance terms) resource.

With ADO connection pooling enabled, ADO Connection objects are placed in a pool when the application "destroys" them. Subsequent attempts to create an ADO connection will automatically search the connection pool for a connection with the same connection string. If a suitable connection is found, it is reused; otherwise, a new connection is created. The connections themselves stay in the pool until they are reused, the application closes, or they time out. By default, connections will time out after 60 seconds, but from MDAC 2.5 onward you can set this time-out period using the `HKEY_CLASSES_ROOT\CLSID\ <ProviderCLSID>\SPTimeout` Registry key. The connection pooling process occurs seamlessly, without the intervention or knowledge of the developer. This process is similar to the BDE database pooling under Microsoft Transaction Server (MTS) and COM+, with the important exception that ADO performs its own connection pooling without the aid of MTS or COM+.

By default, connection pooling is enabled on all MDAC OLE DB providers for relational databases (including SQL Server and Oracle), with the notable exception of the Jet OLE DB provider. If you use ODBC, you should choose between ODBC connection pooling and ADO connection pooling, but you should not use both. From MDAC 2.1 on, ADO connection pooling is enabled and ODBC is disabled.

**Note** Connection pooling does not occur on Windows 95 regardless of the OLE DB provider.

To be comfortable with connection pooling, you need to see the connections being pooled and timed out. Unfortunately, no adequate ADO connection pool spying tools are available at the time of this writing; but you can use SQL Server's Performance Monitor, which can accurately spy on SQL Server database connections.

You can enable or disable connection pooling either in the Registry or in the connection string. The key in the Registry is `OLEDB_SERVICES`, which can be found at `HKEY_CLASSES_ROOT\CLSID\<ProviderCLSID>`. It is a bit mask that allows you to disable several OLE DB services, including connection pooling, transaction enlistment, and the cursor engine. To disable connection pooling using the connection string, include `" ;OLE DB Services=-2"` at the end of the connection string. To enable connection pooling for the Jet OLE DB provider, you can include `" ;OLE DB Services=-1"` at the end of the connection string, which enables all OLE DB services.

## Persistent Recordsets

The persistent recordset is a useful feature that contributes to the briefcase model (discussed in the [next section](#)). Persistent recordsets allow you to save the contents of any recordset to a local file, which can be loaded later. In addition to aiding with the briefcase model, this feature allows developers to create true single-tier applications—you can deploy a database application without having to deploy a database. This makes for a very small footprint on your client's machine.

You can "persist" your datasets using the `SaveToFile` method:

```
ADODataset1.SaveToFile('Local.ADTG');
```

This method saves the data and its delta in a file on your hard disk. You can reload this file using the `LoadFromFile` method, which accepts a single parameter indicating the file to load. The format of the file is Advanced Data Table Gram (ADTG), which is a proprietary Microsoft format. It does, however, have the advantage of being very efficient. If you prefer, you can save the file as XML by passing a second parameter to `SaveToFile`:

```
ADODataset1.SaveToFile('Local.XML', pfXML);
```

However, ADO does not have a built-in XML parser (as the ClientDataSet does), so it must use the MSXML parser. Your user must either install Internet Explorer 5 or later or download the MSXML parser from the Microsoft website.

If you intend to persist your files locally in XML format, be aware of a few disadvantages:

- Saving and loading XML files is slower than saving and loading ADTG files.
- ADO's XML files (and XML files in general) are significantly larger than their ADTG counterparts (XML files are typically twice as large as their ADTG counterparts).
- ADO's XML format is specific to Microsoft, like most companies' XML implementations. This means the XML generated in ADO is not readable by the ClientDataSet and vice versa. Fortunately this problem can be overcome using Delphi's XMLTransform component, which can be used to translate between different XML structures.

If you intend to use these features solely for single-tier applications and not as part of the briefcase model, then you can use an ADODataset component and set its `CommandType` to `cmdFile` and its `CommandText` to the name of the file. Doing so will save you the effort of calling `LoadFromFile` manually. However, you will still have to call `SaveToFile`. In a briefcase application this approach is too limiting, because the dataset can be used in two different modes.

## The Briefcase Model

Using this knowledge of batch updates, disconnected recordsets, and persistent recordsets, you can take advantage of the *briefcase model*. The idea behind the briefcase model is that your users want to be able to use your application while they are on the road—they want to take the same application they use on their office desktops and use it on their laptops at client sites. Traditionally, the problem with this scenario is that when your users are at client sites, they are not connected to the database server, because the database server is running on the network back at their office. Consequently, there is no data on the laptop (and the data cannot be updated anyway).

This is where your newfound understanding comes in handy. Assume the application has been written; the user has requested a new briefcase enhancement, and you have to retrofit it into your existing application. You need to add a new option for your users to allow them to prepare the briefcase application by executing `SaveToFile` for every table in the database. The result is a collection of ADTG or XML files that mirror the contents of the database. These files are then copied to the laptop, where a copy of the application has previously been installed.

The application needs to be sensitive to whether it is running locally or connected to the network. You can determine this by attempting to connect to the database and seeing whether the connection fails, by detecting the presence of a local briefcase file, or by creating a flag of your own design. If the application is running in briefcase mode, then it needs to use `LoadFromFile` for each table instead of setting `Connected` to `True` for the ADOConnections and `Active` to `True` for the ADO datasets. Thereafter, the briefcase application needs to use `SaveToFile` instead of `UpdateBatch` whenever data is saved. When the user returns to the office, they need to follow an update process that loads each table from its local file, connects the dataset to the database, and applies the changes using `UpdateBatch`.

**Tip** To see a complete implementation of the briefcase model, refer to the BatchUpdates example mentioned earlier.

## A Word on ADO.NET

ADO.NET is part of Microsoft's new .NET architecture—the company's redesign of application development tools to better suit the needs of web development. ADO.NET is a significant evolution of ADO. It looks at the problems of web development and addresses shortcomings of ADO's solution. The problem with ADO's solution is that it is based on COM. For one- and two-tier applications, COM imposes few problems, but in the world of web development, it is unacceptable as a transport mechanism. COM suffers from three primary problems that limit its use in web development: It (mostly) runs only on Windows, the transmission of recordsets from one process requires COM marshalling, and COM calls cannot penetrate corporate firewalls. ADO.NET's solution to all these problems is to use XML.

Some other redesign issues focus on breaking the ADO recordset into separate classes. The resulting classes are adept at solving a single problem instead of multiple problems. For example, the ADO.NET class currently called `DataSetReader` is similar to a read-only, forward-only, server-side recordset and, as such, is best suited to reading a result set very quickly. A `DataTable` is most like a disconnected, client-side recordset. A `DataRelation` shares similarities with the `MSDataShape` OLE DB provider. You can see that your knowledge of how ADO works is of great benefit in understanding the basic principles of ADO.NET.

## What's Next?

This chapter described ActiveX Data Objects (ADO) and dbGo, the set of Delphi components for accessing the ADO interfaces. You've seen how to take advantage of Microsoft Data Access Components (MDAC) and various server engines, and I've described some of the benefits and hurdles you'll encounter in using ADO.

[Chapter 16](#) will take you into the world of Delphi's DataSnap architecture, which is used to develop custom client and server applications in a three-tier environment. You can do this using ADO, but because this is a book about Delphi I prefer to show you the *native* solution to the problem. After we delve into DataSnap, we will continue examining Delphi's database architecture by covering the development of custom data-aware controls and dataset components.

## Chapter 16: Multitier DataSnap Applications

### Overview

Large companies often have needs that are broader than applications using local database and SQL servers can meet. In the past few years, Borland Software Corporation has been addressing the needs of large corporations, and it even temporarily changed its own name to Inprise to underline this enterprise focus. The name was eventually changed back to Borland, but the focus on enterprise development remains.

Delphi targets many different technologies: three-tier architectures based on Windows NT and DCOM, TCP/IP and socket applications, and—most of all—SOAP- and XML-based web services. This chapter focuses on database-oriented multitier architectures; XML-oriented solutions will be discussed in [Chapters 22](#) and [23](#), which are devoted to XML, SOAP, and web services.

Before proceeding, I should emphasize two important elements. First, the tools to support this kind of development are available only in the Enterprise version of Delphi; and second, with Delphi 7 you don't have to pay a deployment fee for DataSnap applications. You buy the development environment and then deploy your programs on as many servers as you want, without owing Borland any money. This is a very significant change (the most significant in Delphi 7) to the distribution policy of DataSnap, which used to require a per-server fee (initially very high, then significantly lowered over time). This new deployment license will certainly increase the appeal of DataSnap to developers, which is a good reason to cover it in some detail.

## One, Two, Three Levels in Delphi's History

Initially, database PC applications were client-only solutions: The program and the database files were on the same computer. From there, adventuresome programmers moved the database files onto a network file server. The client computers still hosted the application software and the entire database engine, but the database files were now accessible to several users at the same time. You can still use this type of configuration with a Delphi application and Paradox files (or, of course, Paradox itself), but the approach was much more widespread just few years ago.

The next big transition was to client/server development, embraced by Delphi since its first version. In the client/server world, the client computer requests the data from a server computer, which hosts both the database files and a database engine to access them. This architecture downplays the role of the client, but it also reduces the requirements for processing power on the client machine. Depending on how the programmers implement client/server, the server can do most (if not all) of the data processing. In this way, a powerful server can provide data services to several less powerful clients.

Naturally, there are many other reasons for using centralized database servers, such as concern for data security and integrity, simpler backup strategies, central management of data constraints, and so on. The database server is often called a SQL server, because SQL is the language most commonly used for making queries into the data; but it may also be called a RDBMS (relational database management system), reflecting the fact that the server provides tools for managing the data, such as support for backup and replication.

Of course, some applications you build may not need the benefits of a full RDBMS, so a simple client-only solution might be sufficient. On the other hand, you might need some of the robustness of a RDBMS system, but on a single, isolated computer. In this case, you can use a local version of a SQL server, such as InterBase. Traditional client/server development is done with a two-tier architecture. However, if the RDBMS is primarily performing data storage instead of data- and number-crunching, the client might contain both user interface code (formatting the output and input with customized reports, data-entry forms, query screens, and so on) and code related to managing the data (also known as *business rules*). In this case, it's generally a good idea to try to separate these two sections of the program and build a logical three-tier architecture. The term *logical* here means that there are still just two computers (that is, two physical tiers), but you've now partitioned the application into three distinct elements.

Delphi 2 introduced support for a logical three-tier architecture with data modules. As you should know by now, a *data module* is a nonvisual container for the data access components of an application (or indeed any other nonvisual components), but it often includes several handlers for database-related events. You can share a single data module among several different forms and provide different user interfaces for the same data; there might be one or more data-input forms, reports, master/detail forms, and various charting or dynamic output forms.

The logical three-tier approach solves many problems, but it also has a few drawbacks. First, you must replicate the data-management portion of the program on different client computers; doing so may hamper performance, but the bigger issue is the complexity it adds to code maintenance. Second, when multiple clients modify the same data, there's no simple way to handle the resulting update conflicts. Finally, for logical three-tier Delphi applications, you must install and configure the database engine (if any) and SQL server client library on every client computer.

The next logical step up from client/server is to move the data-module portion of the application to a separate server computer and design all the client programs to interact with it. This is exactly the purpose of remote data modules, which were introduced in Delphi 3. Remote data modules run on a server computer—generally called the *application server*. The application server in turn communicates with the DBMS (which can run on the application server or on another dedicated computer). Therefore, the client machines don't connect to the SQL server directly, but indirectly via the application server.

At this point there is a fundamental question: Do we still need to install the database access software? The traditional Delphi client/server architecture (even with three logical tiers) requires you to install the database access on each client, which is quite troublesome when you must configure and maintain hundreds of machines. In the physical three-tier architecture, you need to install and configure the database access only on the application server, not on the client computers. Because the client programs have only user interface code and are extremely simple to install, they now fall into the category of so-called *thin clients*. To use marketing-speak, we might even call this a *zero-configuration thin-client architecture*. But let's focus on technical issues instead of marketing terminology.

## The Technical Foundation of DataSnap

When Borland introduced this physical multitier architecture in Delphi, it was called MIDAS (Middle-tier Distributed Application Services). For example, Delphi 5 included the third version of this technology, MIDAS 3. Afterward Borland renamed the technology *DataSnap* and extended its capabilities.

DataSnap requires the installation of specific libraries on the server (actually the middle-tier computer), which provides your client computers with the data extracted from the SQL server database or other data sources. DataSnap does not require a SQL server for data storage. DataSnap can serve up data from a wide variety of sources, including SQL, other DataSnap servers, or data computed on the fly.

As you would expect, the client side of DataSnap is extremely thin and easy to deploy. The only file you need is `Midas.dll`, a small DLL that implements the `ClientDataSet` and `RemoteServer` components and provides the connection to the application server. As an alternative to distributing the DLL, you can embed the code of this library in your executable file by including the `MidasLib` unit in your `uses` statements, as discussed in [Chapter 13](#), "Delphi's Database Architecture."

## The IAppServer Interface

The two sides of a DataSnap application communicate using the `IAppServer` interface; this interface's definition appears in [Listing 16.1](#). You'll seldom need to call the methods of the `IAppServer` interface directly, because Delphi includes components implementing this interface on the server side applications and components calling the interface on the client side applications. These components simplify the support of the `IAppServer` interface and at times even hide it completely. In practice, the server will make objects implementing this interface available to the client, possibly along with other custom interfaces.

### Listing 16.1: The Definition of the IAppServer Interface

---

```
type
  IAppServer = interface(IDispatch)
    ['{1AEFCC20-7A24-11D2-98B0-C69BEB4B5B6D}']
    function AS_ApplyUpdates(const ProviderName: WideString; Delta: OleVariant;
      MaxErrors: Integer; out ErrorCount: Integer;
      var OwnerData: OleVariant): OleVariant; safecall;
    function AS_GetRecords(const ProviderName: WideString; Count: Integer;
      out RecsOut: Integer; Options: Integer; const CommandText: WideString;
      var Params: OleVariant; var OwnerData: OleVariant): OleVariant; safecall;
    function AS_DataRequest(const ProviderName: WideString;
      Data: OleVariant): OleVariant; safecall;
    function AS_GetProviderNames: OleVariant; safecall;
    function AS_GetParams(const ProviderName: WideString;
      var OwnerData: OleVariant): OleVariant; safecall;
    function AS_RowRequest(const ProviderName: WideString; Row: OleVariant;
      RequestType: Integer; var OwnerData: OleVariant): OleVariant; safecall;
    procedure AS_Execute(const ProviderName: WideString;
      const CommandText: WideString; var Params: OleVariant;
      var OwnerData: OleVariant); safecall;
  end;
```

---

**Note** A DataSnap server exposes an interface using a COM type library, a technology covered in [Chapter 12](#), "From COM to COM+."

## The Connection Protocol

DataSnap defines only the higher-level architecture and can use different technologies for moving the data from the middle tier to the client side. DataSnap supports many different protocols, including the following:

**Distributed COM (DCOM) and Stateless COM (MTS or COM+)** DCOM is directly available in Windows NT/2000/XP and 98/Me, and it requires no additional run-time applications on the server. DCOM is basically an extension of COM technology that allows a client application to use server objects that exist and execute on a separate computer. The DCOM infrastructure allows you to use stateless COM objects, available in the COM+ and in the older MTS (Microsoft Transaction Server) architectures. Both COM+ and MTS provide features such as security, component management, and database transactions, and are available in Windows NT/2000/XP and in Windows 98/Me.

Due to the complexity of DCOM configuration and its problems in passing through firewalls, even Microsoft is abandoning DCOM in favor of SOAP-based solutions.

**TCP/IP Sockets** These are available on most systems. Using TCP/IP, you might distribute clients over the Web, where DCOM cannot be taken for granted, and you'll have far fewer configuration headaches. To use sockets, the middle-tier computer must run the `ScktSrvr.exe` application provided by Borland, a single program that can run either as an application or as a service. This program receives the client requests and forwards them to the remote data module (executing on the same server) using COM. Sockets provide no protection against failure on the client side, because the server is not informed and might not release resources when a client unexpectedly shuts down.

**HTTP and SOAP** The use of HTTP as a transport protocol over the Internet simplifies connections through firewalls or proxy servers (which generally don't like custom TCP/IP sockets). You need a specific web server application, `httpsrvr.dll`, which accepts client requests and creates the proper remote data modules using COM. These web connections can also use SSL security. Finally, web connections based on HTTP transport can use DataSnap object-pooling support.

**Note** The DataSnap HTTP transport can use XML as the data packet format, enabling any platform or tool that can read XML to participate in a DataSnap architecture. This is an extension of the original DataSnap data packet format, which is also platform independent. The use of XML over HTTP is also the foundation of SOAP. There's more on SOAP in DataSnap in [Chapter 23](#), "Web Services and SOAP."

Until Delphi 6, you could also use CORBA (Common Object Request Broker Architecture) as a transport mechanism for DataSnap applications. Due to compatibility issues with the newer versions of Borland's VisiBroker CORBA solution, this feature has been discontinued in Delphi 7.

Finally, notice that as an extension to this architecture, you can transform the data packets into XML and deliver them to a web browser. In this case, you basically have one extra tier: the web server gets the data from the middle tier and delivers it to the client. I'll discuss this architecture, called Internet Express, in [Chapter 22](#), "Using XML Technologies."

## Providing Data Packets

The entire Delphi multitier data-access architecture centers around the idea of *data packets*. In this context, a data packet is a block of data that moves from the application server to the client or from the client back to the server. Technically, a data packet is a sort of subset of a dataset. It describes the data it contains (usually a few records of data), and it lists the names and types of the data fields. Even more important, a data packet includes the constraints—that is, the rules to be applied to the dataset. You'll typically set these constraints in the application server, and the server sends them to the client applications along with the data.

All communication between the client and the server occurs by exchanging data packets. The provider component on the server manages the transmission of several data packets within a big dataset, with the goal of responding faster to the user. As the client receives a data packet in a `ClientDataSet` component, the user can edit the records it contains. As mentioned earlier, during this process the client also receives and checks the constraints, which are applied during the editing operations.

When the client has updated the records and sends back a data packet, that packet is known as a *delta*. The delta packet tracks the difference between the original records and the updated ones, recording all the changes the client requested from the server. When the client asks to apply the updates to the server, it sends the delta to the server, and the server tries to apply each of the changes. I say *tries* because if a server is connected to several clients, the data may have changed already, and the update request may fail.

Because the delta packet includes the original data, the server can quickly determine if another client has already changed the data. If so, the server fires an `OnReconcileError` event, which is one of the vital elements for thin-client applications. In other words, the three-tier architecture uses an update mechanism similar to the one Delphi uses for cached updates. As you saw in [Chapter 14](#), "Client/Server with dbExpress," the `ClientDataSet` manages data in a memory cache; it typically reads only a subset of the records available on the server side, loading more elements only as they're needed. When the client updates records or inserts new ones, it stores these pending changes in another local cache on the client, the *delta cache*.

The client can also save the data packets to disk and work offline, thanks to the MyBase support discussed in [Chapter 13](#). Even error information and other data moves using the data packet protocol, so it is truly one of the foundation elements of this architecture.

**Note** It's important to remember that data packets are protocol-independent. A data packet is merely a sequence of bytes, so anywhere you can move a series of bytes, you can move a data packet. This functionality was provided to make the architecture suitable for multiple transport protocols (including DCOM, HTTP, and TCP/IP) and for multiple platforms.

## Delphi Support Components (Client-Side)

Now that we've examined the general foundations of Delphi's three-tier architecture, let's focus on the components that support it. For developing client applications, Delphi provides the `ClientDataSet` component, which provides all the standard dataset capabilities and embeds the client side of the `IAppServer` interface. In this case, the data is delivered through the remote connection.

The connection to the server application is made via another component you'll also need in the client application. You should use one of the three specific connection components (available in the [DataSnap](#) page):

- The `DCOMConnection` component can be used on the client side to connect to a DCOM and MTS server, located either on the current computer or on another computer indicated by the `ComputerName` property. The connection is with a registered object having a given `ServerGUID` or `ServerName`.
- The `SocketConnection` component can be used to connect to the server via a TCP/IP socket. You should indicate the IP address or the host name, and the GUID of the server object (in the `InterceptGUID` property). This connection component has an extra property, `SupportCallbacks`, which you can disable if you are not using callbacks and want to deploy your program on Windows 95 client computers that don't have Winsock 2 installed.

**Note** In the [WebServices](#) page, you can also find the `SoapConnection` component, which requires a specific type of server and will be discussed in [Chapter 23](#).

- The `WebConnection` component is used to handle an HTTP connection that can easily get through a firewall. You should indicate the URL where your copy of `httpsrvr.dll` is located and the name or GUID of the remote object on the server.

A few more client-side components were added to the [DataSnap](#) architecture in Delphi 6, mainly for managing connections:

- The `ConnectionBroker` component can be used as an alias of an actual connection component, which is useful when you have a single application with multiple client datasets. To change the physical connection of each dataset, you only need to change the `Connection` property of the `ConnectionBroker`. You can also use the events of this virtual connection component in place of those of the actual connections, so you don't have to change any code if you change the data transport technology. For the same reason, you can refer to the

`AppServer` object of the `ConnectionBroker` instead of the corresponding property of a physical connection.

- The `SharedConnection` component can be used to connect to a secondary (or child) data module of a remote application, piggy-backing on an existing physical connection to the main data module. In other words, an application can connect to multiple data modules of the server with a single, shared connection.
- The `LocalConnection` component can be used to target a local dataset provider as the source of the data packet. The same effect can be obtained by hooking the `ClientDataSet` directly to the provider. However, using the `LocalConnection`, you can write a local application with the same code as a complete multitier application, using the `IAppServer` interface of the "fake" connection. Doing so will make the program easier to scale up, compared to a program with a direct connection.

A few other components of the `DataSnap` page relate to the transformation of the `DataSnap` data packet into custom XML formats. These components (`XMLTransform`, `XMLTransformProvider`, and `XMLTransformClient`) will be discussed in [Chapter 22](#).

## Delphi Support Components (Server-Side)

On the server side (actually the middle tier), you'll need to create an application or a library that embeds a remote data module, a special version of the `TDataModule` class. A second alternative is the use of a specialized remote data module for transactional COM. In the Multitier page of the New Items dialog box (obtained from the File → New → Other menu) there are specific wizards to create both types of remote data module.

The only specific component you need on the server side is the `DataSetProvider`. You need one of these components for every table or query you want to make available to the client applications, which will then use a separate `ClientDataSet` component for every exported dataset. The `DataSetProvider` was introduced in [Chapter 13](#).

## Building a Sample Application

Now you're ready to build a sample program. Doing so will let you observe some of the components I've just described in action, and will also allow you to focus on some other problems, shedding light on other pieces of the Delphi multitier puzzle. I'll build the client and application server portions of a three-tier application in two steps. The first step will simply test the technology using a minimum of elements. These programs will be very simple.

From that point, I'll add more power to the client and the application server. In each example, I'll display data from a local InterBase table using dbExpress and set up everything to allow you to test the programs on a stand-alone computer. I won't cover the steps you have to follow to install the examples on multiple computers with various technologies—that would be the subject of at least one other book.

### The First Application Server

The server side of the basic example is easy to build. Simply create a new application and add a remote data module to it using the corresponding icon in the Multitier page of the Object Repository. The Remote Data Module Wizard (see [Figure 16.1](#)) will ask you for a class name and the instancing style. When you enter a class name, such as `TAppServerOne`, and click the OK button, Delphi will add a data module to the program. This data module will have the usual properties and events, but its class will have the following Delphi language declaration:

```
type
  TAppServerOne = class(TRemoteDataModule, IAppServerOne)
  private
    { Private declarations }
  protected
    class procedure UpdateRegistry(Register: Boolean;
      const ClassID, ProgID: string); override;
  public
    { Public declarations }
  end;
```

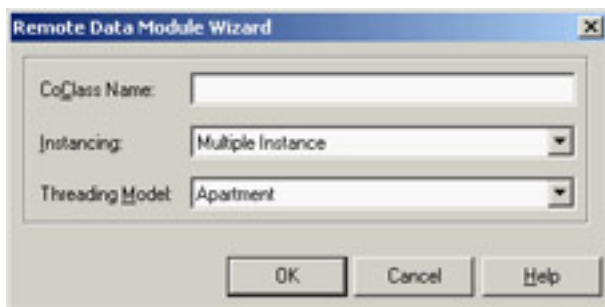

Figure 16.1: The Remote Data Module Wizard

In addition to inheriting from the `TRemoteDataModule` base class, this class implements the custom `IAppServerOne` interface, which derives from the standard `DataSnap` interface (`IAppServer`). The class also overrides the `UpdateRegistry` method to add support for enabling the socket and web transports, as you can see in the code generated by the wizard. At the end of the unit, you'll find the class factory declaration, which should be clear if you read [Chapter 12](#):

#### initialization

```
TComponentFactory.Create(ComServer, TAppServerOne,
  Class_AppServerOne, ciMultiInstance, tmApartment);
end.
```

Now you can add a dataset component to the data module (I've used the dbExpress `SQLDataSet`), connect it to a database and a table or query, activate it, and finally add a `DataSetProvider` and hook it to the dataset component.

You'll obtain a DFM file like this:

```
object AppServerOne: TAppServerOne
  object SQLConnection1: TSQLConnection
    ConnectionName = 'IBLocal'
    LoginPrompt = False
  end
  object SQLDataSet1: TSQLDataSet
    SQLConnection = SQLConnection1
    CommandText = 'select * from EMPLOYEE'
  end
  object DataSetProvider1: TDataSetProvider
    DataSet = SQLDataSet1
    Constraints = True
  end
end
```

The main form of this program is almost useless, so you can simply add a label to it indicating that it's the form of the server application. When you've built the server, you should compile it and run it once. This operation will automatically register it as an Automation server on your system, making it available to client applications. Of course, you should register the server on the computer where you want it to run, either the client or the middle tier.

## The First Thin Client

Now that you have a working server, you can build a client that will connect to it. You'll again begin with a standard Delphi application and add a DCOMConnection component to it (or the proper component for the specific type of connection you want to test). This component defines a `ComputerName` property that you'll use to specify the computer that hosts the application server. If you want to test the client and application server from the same computer, you can leave this property blank.

Once you've selected an application server computer, you can simply display the `ServerName` property's combo box list to view the available DataSnap servers. This combo box shows the servers' registered names, by default the name of the executable file of the server followed by the name of the remote data module class, as in `AppServ1.AppServerOne`. Alternatively, you can enter the GUID of the server object as the `ServerGUID` property. Delphi will automatically fill this property as you set the `ServerName` property, determining the GUID by looking it up in the Registry.

At this point, if you set the DCOMConnection component's `Connected` property to `True`, the server form will appear, indicating that the client has activated the server. You don't usually need to perform this operation, because the `ClientDataSet` component typically activates the `RemoteServer` component for you. I've suggested this step simply to emphasize what's happening behind the scenes.

**Tip** You should generally leave the DCOMConnection component's `Connected` property set to `False` at design time, so you can open the project in Delphi even on a computer where the DataSnap server is not already registered.

As you might expect, the next step is to add a `ClientDataSet` component to the form. You must connect the `ClientDataSet` to the `DCOMConnection1` component via the `RemoteServer` property, and thereby to one of the providers it exports. You can see the list of available providers in the `ProviderName` property, via the usual combo box. In this example, you'll be able to select only `DataSetProvider1`, because it is the only provider available in the server you've just built. This operation connects the dataset in the client's memory with the dbExpress dataset on the server. If you activate the client dataset and add a few data-aware controls (or a `DBGrid`), you'll immediately see the server data appear in them, as illustrated in [Figure 16.2](#).

**Figure 16.2:** When you activate a ClientDataSet component connected to a remote data module at design time, the data from the server becomes visible as usual.

Here is the DFM file for the minimal client application, ThinCli1:

```

object Form1: TForm1
  Caption = 'ThinClient1'
  object DBGrid1: TDBGrid
    Align = alClient
    DataSource = DataSource1
  end
  object DCOMConnection1: TDCOMConnection
    ServerGUID = '{09E11D63-4A55-11D3-B9F1-00000100A27B}'
    ServerName = 'AppServ1.AppServerOne'
  end
  object ClientDataSet1: TClientDataSet
    Aggregates = <>
    Params = <>
    ProviderName = 'DataSetProvider1'
    RemoteServer = DCOMConnection1
  end
  object DataSource1: TDataSource
    DataSet = ClientDataSet1
  end
end

```

Obviously, the programs for this first three-tier application are quite simple, but they demonstrate how to create a dataset viewer that splits the work between two different executable files. At this point, the client is only a viewer. If you edit the data on the client, it won't be updated on the server. To accomplish this, you'll need to add more code to the client. However, before you do that, let's add some features to the server.

## Adding Constraints to the Server

When you write a traditional data module in Delphi, you can easily add some of the application logic, or business rules, by handling the dataset events and by setting field object properties and handling their events. You should avoid doing this work on the client application; instead, write your business rules on the middle tier.

In the DataSnap architecture, you can send some constraints from the server to the client and let the client program impose those constraints during the user input. You can also send field properties (such as minimum and maximum values and the display and edit masks) to the client and (using some of the data access technologies) process updates through the dataset used to access the data (or a companion UpdateSql object).

### Field and Dataset Constraints

When the provider interface creates data packets to send to the client, it includes the field definitions, the table and field constraints, and one or more records (as requested by the ClientDataSet component). This implies that you can customize the middle tier and build distributed application logic by using SQL-based constraints.

The constraints you create using SQL expressions can be assigned to an entire dataset or to specific fields. The provider sends the constraints to the client along with the data, and the client applies them before sending updates back to the server. This process reduces network traffic, compared to having the client send updates back to the application server and eventually up to the SQL server, only to find that the data is invalid. Another advantage of coding the constraints on the server side is that if the business rules change, you need to update the single server application and not the many clients on multiple computers.

But how do you write constraints? You can use several properties:

- BDE datasets have a `Constraints` property, which is a collection of `TCheckConstraint` objects. Every object has a few properties, including the expression and the error message.
- Each field object defines the `CustomConstraint` and `ConstraintErrorMessage` properties. There is also an `ImportedConstraint` property for constraints imported from the SQL server.
- Each field object has a `DefaultExpression` property, which can be used locally or passed to the `ClientDataSet`. This is not an actual constraint; it's only a suggestion to the end user.

The next example, `AppServ2`, adds a few constraints to a remote data module connected to the sample `EMPLOYEE` InterBase database. After connecting the table to the database and creating the field objects for it, you can set the following special properties:

```
object SQLDataSet1: TSQLDataSet
...
object SQLDataSet1EMP_NO: TSmallintField
  CustomConstraint = 'x > 0 and x < 10000'
  ConstraintErrorMessage =
    'Employee number must be a positive integer below 10000'
  FieldName = 'EMP_NO'
end
object SQLDataSet1FIRST_NAME: TStringField
  CustomConstraint = 'x <> '#39#39
  ConstraintErrorMessage = 'The first name is required'
  FieldName = 'FIRST_NAME'
  Size = 15
end
object SQLDataSet1LAST_NAME: TStringField
  CustomConstraint = 'not x is null'
  ConstraintErrorMessage = 'The last name is required'
  FieldName = 'LAST_NAME'
```

```
end
end
```

**Note** The expression `'x <> '#39#39` is the DFM transposition of the string `x <> ' '`, indicating that you don't want to have an empty string. The final constraint, *not x is null*, instead allows empty strings but not null values.

## Including Field Properties

You can control whether the properties of the field objects on the middle tier are sent to the `ClientDataSet` (and copied into the corresponding field objects of the client side) by using the `polncFieldProps` value of the `Options` property of the `DataSetProvider`. This flag controls the download of the field properties `Alignment`, `DisplayLabel`, `DisplayWidth`, `Visible`, `DisplayFormat`, `EditFormat`, `MaxValue`, `MinValue`, `Currency`, `EditMask`, and `DisplayValues`, if they are available in the field. Here is an example of another field of the `AppServ2` example with some custom properties:

```
object SQLDataSet1SALARY: TBCDField
  DefaultExpression = '10000'
  FieldName = 'SALARY'
  DisplayFormat = '#,###'
  EditFormat = '####'
  Precision = 15
  Size = 2
end
```

With this setting, you can write your middle tier the way you usually set the fields of a standard client/server application. This approach also makes it faster to move existing applications from a client/server to a multitier architecture. The main drawback of sending fields to the client is that transmitting all the extra information takes time. Turning off `polncFieldProps` can dramatically improve network performance of datasets with many columns.

A server can generally filter the fields sent to the client; it does so by declaring persistent field objects with the `Fields` editor and omitting some of the fields. Because a field you're filtering out might be required to identify the record for future updates (if the field is part of the primary key), you can also use the field's `ProviderFlags` property on the server to send the field value to the client but make it unavailable to the `ClientDataSet` component (this provides some extra security, compared to sending the field to the client and hiding it there).

## Field and Table Events

You can write middle-tier dataset and field event handlers as usual and let the dataset process the updates received by the client in the traditional way. This means updates are considered to be operations on the dataset, exactly as when a user is directly editing, inserting, or deleting fields locally.

This update process is requested by setting the `ResolveToDataSet` property of the `TDataSetProvider` component, again connecting either the dataset used for input or a second dataset used for the updates. This approach is possible with datasets supporting editing operations. These include BDE, ADO, and InterBase Express datasets, but not those of the new `dbExpress` architecture.

With this technique, the updates are performed by the dataset, which implies a lot of control (the standard events are being triggered) but generally slower performance. Flexibility is much greater, because you can use standard coding practices. Also, porting existing local or client/server database applications, which use dataset and field events, is much more straightforward with this model. However, keep in mind that the user of the client program will receive your error messages only when the local cache (the delta) is sent back to the middle tier. Saying to the user that some data prepared half an hour ago is not valid might be a little awkward. If you follow this approach, you'll probably need to apply the updates in the cache at every `AfterPost` event on the client side.

Finally, if you decide to let the dataset and not the provider do the updates, Delphi helps you a lot in handling possible exceptions. Any exceptions raised by the middle-tier update events (for example, `OnBeforePost`) are automatically transformed by Delphi into update errors, which activate the `OnReconcileError` event on the client side (more on

this event later in this chapter). No exception is shown on the middle tier, but the error travels back to the client.

## Adding Features to the Client

After adding some constraints and field properties to the server, let's return our attention to the client application. The first version was very simple, but now you can add several features to make it work well. In the ThinCli2 example, I've embedded support for checking the record status and accessing the delta information (the updates to be sent back to the server), using some of the ClientDataSet techniques already discussed in [Chapter 13](#). The program also handles reconcile errors and supports the briefcase model.

Keep in mind that while you're using this client to edit the data locally, you'll be reminded of any failure to match the business rules of the application, which are set up on the server side using constraints. The server will also provide you with a default value for the Salary field of a new record and pass along the value of its `DisplayFormat` property. In [Figure 16.3](#), you can see one of the error messages this client application can display, which it receives from the server. This message is displayed when you're editing the data locally, not when you send it back to the server.

**Figure 16.3:** The error message displayed by the ThinCli2 example when the employee ID is too large

## The Update Sequence

This client program includes a button to apply the updates to the server and a standard reconcile dialog. Here is a summary of the complete sequence of operations related to an update request and the possible error events:

1. The client program calls the `ApplyUpdates` method of a `ClientDataSet`.
2. The delta is sent to the provider on the middle tier. The provider fires the `OnUpdateData` event, where you have a chance to look at the requested changes before they reach the database server. At this point you can modify the delta, which is passed in a format compatible with the data of a `ClientDataSet`.
3. The provider (technically, a part of the provider called the *resolver*) applies each row of the delta to the database server. Before applying each update, the provider receives a `BeforeUpdateRecord` event. If you've set the `ResolveToDataSet` flag, this update will eventually fire local events of the dataset in the middle tier.
4. In case of a server error, the provider fires the `OnUpdateError` event (on the middle tier) and the program has a chance of fixing the error at that level.
5. If the middle-tier program doesn't fix the error, the corresponding update request remains in the delta. The error is returned to the client side at this point or after a given number of errors have been collected, depending on the value of the `MaxErrors` parameter of the `ApplyUpdates` call.
6. The delta packet with the remaining updates is sent back to the client, firing the `OnReconcileError` event of the `ClientDataSet` for each remaining update. In this event handler, the client program can try to fix the problem (possibly prompting the user for help), modifying the update in the delta, and later reissuing it.

## Refreshing Data

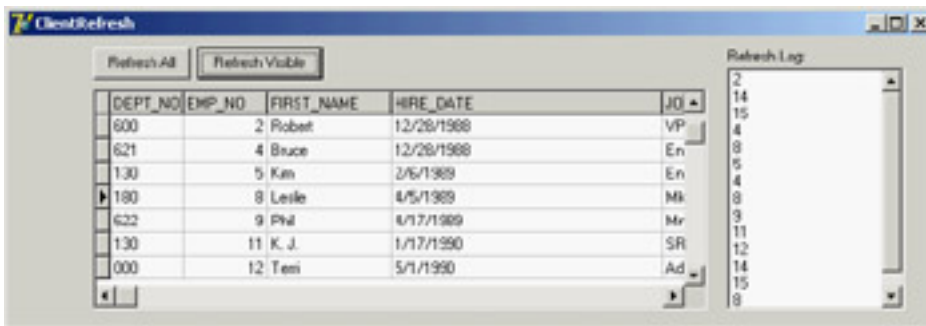

You can obtain an updated version of the data, which other users might have modified, by calling the `Refresh` method of the `ClientDataSet`. However, this operation can be done only if there are no pending update operations in the cache, because calling `Refresh` raises an exception when the change log is not empty:

```
if cds.ChangeCount = 0 then
    cds.Refresh;
```

If only some records have been changed, you can refresh the others by calling `RefreshRecords`. This method refreshes only the current record, but it should be used only if the user hasn't modified the current record. In this case, `RefreshRecords` leaves the unapplied changes in the change log. As an example, you can refresh a record every time it becomes the active one, unless it has been modified and the changes have not yet been posted to the server:

```
procedure TForm1.cdsAfterScroll(DataSet: TDataSet);
begin
    if cds.UpdateStatus = usUnModified then
        cds.RefreshRecord;
end;
```

When the data is subject to frequent changes by many users and each user should see changes right away, you should apply any change immediately in the `AfterPost` and `AfterDelete` methods, and call `RefreshRecords` for the active record (as shown previously) or each of the records visible inside a grid. This code is part of the `ClientRefresh` example, connected to the `AppServ2` server. For debugging purposes, the program also logs the `EMP_NO` field for each record it refreshes, as you can see in [Figure 16.4](#).

**Figure 16.4:** The form of the `ClientRefresh` example, which automatically refreshes the active record and allows more extensive updates by clicking the buttons

I've done this by adding a button to the `ClientRefresh` example. The handler of this button moves from the current record to the first visible record of the grid and then to the last visible record. This is accomplished by noting that there are `RowCount - 1` rows visible, assuming that the first row is the fixed one hosting the field names. The program doesn't call `RefreshRecord` every time, because each movement will trigger an `AfterScroll` event with the code shown previously. The following code refreshes the visible rows, which might be triggered by a timer:

```
// protected access hack
type
    TMyGrid = class (TDBGrid)
    end;

procedure TForm1.Button2Click(Sender: TObject);
var
    i: Integer;
    bm: TBookmarkStr;
begin
    // refresh visible rows
```

```

cds.DisableControls;
// start with the current row
i := TMyGrid (DbGrid1).Row;
bm := cds.Bookmark;
try
  // get back to the first visible record
  while i > 1 do
    begin
      cds.Prior;
      Dec (i);
    end;
  // return to the current record
  i := TMyGrid(DbGrid1).Row;
  cds.Bookmark := bm;
  // go ahead until the grid is complete
  while i < TMyGrid(DbGrid1).RowCount do
    begin
      cds.Next;
      Inc (i);
    end;
  finally
    // set back everything and refresh
    cds.Bookmark := bm;
    cds.EnableControls;
  end;
end;

```

This approach generates a huge amount of network traffic, so you might want to trigger updates only when there are actual changes. You can implement this process by adding a callback technology to the server, so that it can inform all connected clients that a given record has changed. The client can determine whether it is interested in the change and eventually trigger the update request.

## Advanced DataSnap Features

DataSnap includes many more features than I've covered up to now. Here is a quick tour of some of the more advanced features of the architecture, partially demonstrated by the AppSPlus and ThinPlus examples. Unfortunately, demonstrating every piece of functionality would turn this chapter into an entire book, so I'll limit myself to an overview.

**Warning** The ThinPlus example requires Delphi's socket server (provided in Delphi's *bin* folder) to run. Without this program, you'll see a socket error when the client tries to connect with the server. The plus side is that you can easily deploy the program over a network by modifying the IP address of the server in the client program.

Besides the features discussed in the following sections, the AppSPlus and ThinPlus examples demonstrate the use of a socket connection, limited logging of events and updates on the server side, and direct fetching of a record on the client side. The last feature is accomplished with this call:

```
procedure TClientForm.ButtonFetchClick(Sender: TObject);  
begin  
    ButtonFetch.Caption := IntToStr (cds.GetNextPacket);  
end;
```

This allows you to get more records than are required by the client user interface (the DBGrid). In other words, you can fetch records directly, without waiting for the user to scroll down in the grid. I suggest you study the details of these complex examples after reading the rest of this section.

## Parametric Queries

If you want to use parameters in a query or stored procedure, then instead of building a custom solution (with a custom method call to the server), you can let Delphi help you. First define the query on the middle tier with a parameter:

```
select * from customer where Country = :Country
```

Use the `Params` property to set the type and default value of the parameter. On the client side, you can use the `Fetch Params` command from the `ClientDataSet`'s shortcut menu, after connecting the component to the proper provider. At run time, you can call the equivalent `FetchParams` method of the `ClientDataSet` component.

Now you can provide a local default value for the parameter by acting on the `Params` property. The value of the parameter will be sent to the middle tier when you fetch the data. The ThinPlus example refreshes the parameter with the following code:

```
procedure TFormQuery.btnParamClick(Sender: TObject);  
begin  
    cdsQuery.Close;  
    cdsQuery.Params[0].AsString := EditParam.Text;  
    cdsQuery.Open;  
end;
```

You can see the secondary form of this example, which shows the result of the parametric query in a grid, in [Figure 16.5](#). The figure also shows some custom data sent by the server, as explained in the section "[Customizing the Data Packets](#)."

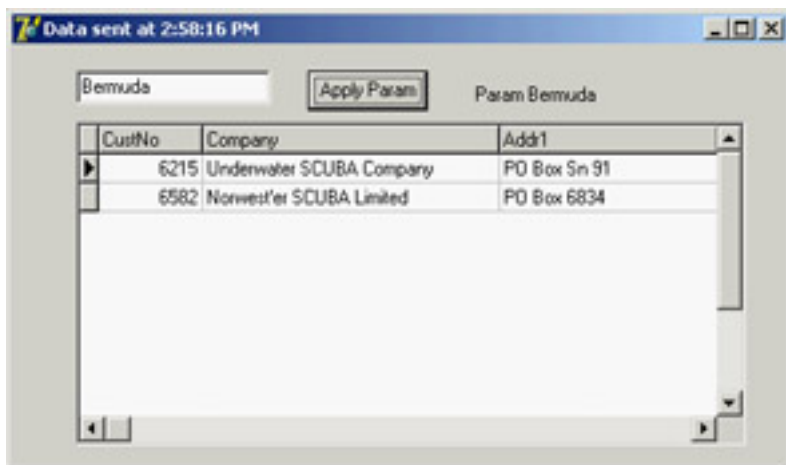

Figure 16.5: The secondary form of the ThinPlus example, showing the data of a parametric query

## Custom Method Calls

Because the server has a normal COM interface, you can add more methods or properties to it and call them from the client. Simply open the server's type library editor and use it as with any other COM server. In the AppSPlus example, I've added a custom `Login` method with the following implementation:

```
procedure TAppServerPlus.Login(const Name, Password: WideString);
begin
  // TODO: add actual login code...
  if Password <> Name then
    raise Exception.Create ('Wrong name/password combination received')
  else
    Query.Active := True;
    ServerForm.Add ('Login:' + Name + '/' + Password);
end;
```

The program performs a simple test, instead of checking the name/password combination against a list of authorizations as a real application should do. Also, disabling the `Query` doesn't really work, because it can be activated by the provider; disabling the `DataSetProvider` is a more robust approach. The client has a simple way to access the server: the `AppServer` property of the remote connection component. Here is a sample call from the ThinPlus example, which takes place in the `AfterConnect` event of the connection component:

```
procedure TClientForm.ConnectionAfterConnect(Sender: TObject);
begin
  Connection.AppServer.Login (Edit2.Text, Edit3.Text);
end;
```

Note that you can call extra methods of the COM interface through DCOM and also using a socket-based or HTTP connection. Because the program uses the `safecall` calling convention, the exception raised on the server is automatically forwarded and displayed on the client side. This way, when a user selects the `Connect` check box, the event handler used to enable the client datasets is interrupted, and a user with the wrong password won't be able to see the data.

**Note** Besides direct method calls from the client to the server, you can also implement callbacks from the server to the client. You can use this approach, for example, to notify every client of specific events. COM events are one way to do this. As an alternative, you can add a new interface, implemented by the client, which passes the implementation object to the server. This way, the server can call the method on the client computer. Callbacks are not possible with HTTP connections, though.

## Master/Detail Relations

If your middle-tier application exports multiple datasets, you can retrieve them using multiple `ClientDataSet`

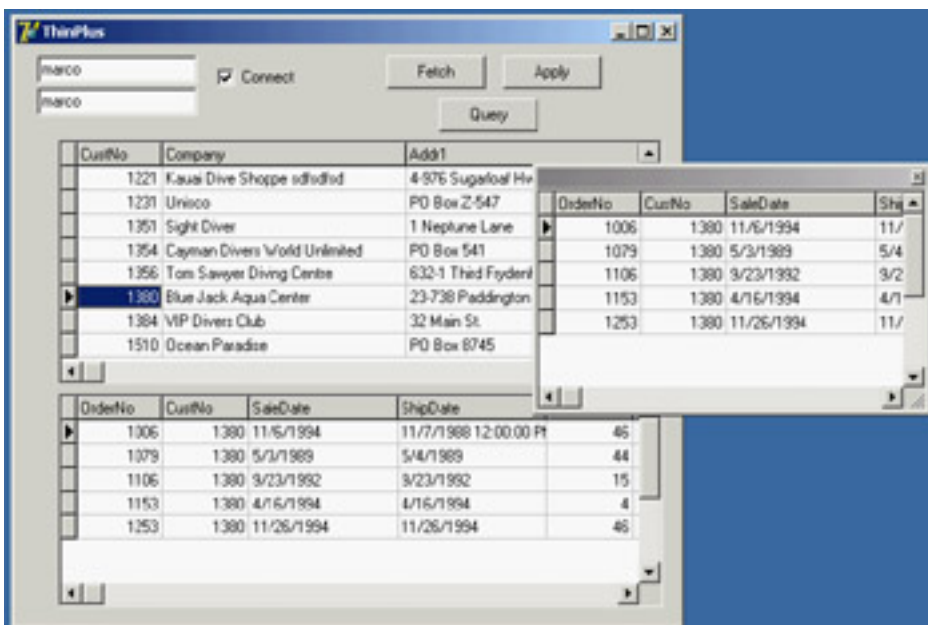

components on the client side and connect them locally to form a master/detail structure. This approach will create quite a few problems for the detail dataset unless you retrieve all the records locally.

This solution also makes it quite complex to apply the updates; you cannot usually cancel a master record until all related detail records have been removed, and you cannot add detail records until the new master record is properly in place. (Different servers handle this situation differently, but in most cases where a foreign key is used, this is the standard behavior.) To solve this problem, you can write complex code on the client side to update the records of the two tables according to the specific rules.

A completely different approach is to retrieve a single dataset that already includes the detail as a dataset field, a field of type `TDataSetField`. To accomplish this, you need to set up the master/detail relation on the server application:

```
object TableCustomer: TTable
  DatabaseName = 'DBDEMOS'
  TableName = 'customer.db'
end
object TableOrders: TTable
  DatabaseName = 'DBDEMOS'
  MasterFields = 'CustNo'
  MasterSource = DataSourceCust
  TableName = 'ORDERS.DB'
end
object DataSourceCust: TDataSource
  DataSet = TableCustomer
end
object ProviderCustomer: TDataSetProvider
  DataSet = TableCustomer
end
```

On the client side, the detail table will show up as an extra field of the `ClientDataSet`, and the `DBGrid` control will display it as an extra column with an ellipsis button. Clicking the button will display a secondary form with a grid presenting the detail table (see [Figure 16.6](#)). If you need to build a flexible user interface on the client, you can then add a secondary `ClientDataSet` connected to the dataset field of the master dataset, using the `DataSetField` property. Simply create persistent fields for the main `ClientDataSet` and then hook up the property:

**Figure 16.6:** The ThinPlus example shows how a dataset field can either be displayed in a grid in a floating window or extracted by a `ClientDataSet` and displayed in a second form. You'll generally do one of the two things, not both!

```

object cdsDet: TClientDataSet
    DataSetField = cdsTableOrders
end

```

With this setting, you can show the detail dataset in a separate DBGrid placed as usual in the form (the bottom grid of [Figure 16.6](#)) or any other way you like. Note that with this structure, the updates relate only to the master table, and the server should handle the proper update sequence even in complex situations.

## Using the Connection Broker

I've already mentioned that the ConnectionBroker component can be helpful in case you might want to change the physical connection used by many ClientDataSet components of a single program. By hooking each ClientDataSet to the ConnectionBroker, you can change the physical connection of all the ClientDataSets by updating the physical connection of the broker.

The ThinPlus example uses these settings:

```

object Connection: TSocketConnection
    ServerName = 'AppSPlus.AppServerPlus'
    AfterConnect = ConnectionAfterConnect
    Address = '127.0.0.1'
end
object ConnectionBroker1: TConnectionBroker
    Connection = Connection
end
object cds: TClientDataSet
    ConnectionBroker = ConnectionBroker1
end
// in the secondary form
object cdsQuery: TClientDataSet
    ConnectionBroker = ClientForm.ConnectionBroker1
end

```

That's basically all you have to do. To change the physical connection, drop a new DataSnap connection component to the main form and set the Connection property of the broker to it.

## More Provider Options

I've already mentioned the Options property of the DataSetProvider component, noting that you can use it to add the field properties to the data packet. There are several other options you can use to customize the data packet and the behavior of the client program. Here is a short list:

- You can minimize downloading BLOB data with the poFetchBlobsOnDemand option. In this case, the client application can download BLOBs by setting the FetchOnDemand property of the ClientDataSet to True or by calling the FetchBlobs method for specific records. Similarly, you can disable the automatic downloading of detail records by setting the poFetchDetailsOnDemand option. Again, the client can use the FetchOnDemand property or call the FetchDetails method.
- When you are using a master/detail relation, you can control cascades with either of two options. The poCascadeDeletes flag controls whether the provider should delete detail records before deleting a master record. You can set this option if the database server performs cascaded deletes for you as part of its referential integrity support. Similarly, you can set the poCascadeUpdates option when the server can automatically update key values of a master/detail relation.
- You can limit the operations on the client side. The most restrictive option, poReadOnly, disables any update. If you want to give the user a limited editing capability, use poDisableInserts, poDisableEdits, or poDisableDeletes.

- You can use `poAutoRefresh` to resend to the client a copy of the records the client has modified; doing so is useful in case other users have simultaneously made other, nonconflicting changes. You can also specify the `poPropagateChanges` option to send back to the client changes done in the `BeforeUpdateRecord` or `AfterUpdateRecord` event handler. This option is also handy when you are using autoincrement fields, triggers, and other techniques that modify data on the server or middle tier beyond the changes requested from the client tier.
- Finally, if you want the client to drive the operations, you can enable the `poAllowCommandText` option. It lets you set the SQL query or table name of the middle tier from the client, using the `GetRecords` or `Execute` method.

## The Simple Object Broker

The `SimpleObjectBroker` component provides an easy way to locate a server application among several server computers. You provide a list of available computers, and the client will try each of them in order until it finds one that is available.

Moreover, if you enable the `LoadBalanced` property, the component will randomly choose one of the servers; when many clients use the same configuration, the connections will be automatically distributed among the multiple servers. If this seems like a "poor man's" object broker, consider that some highly expensive load-balancing systems don't offer much more than this.

## Object Pooling

When multiple clients connect to your server at the same time, you have two options. The first is to create a remote data module object for each of them and let each request be processed in sequence (the default behavior for a COM server with the `ciMultiInstance` style). Alternatively, you can let the system create a different instance of the server application for every client (`ciSingleInstance`). This approach requires more resources and more SQL server connections (and possibly licenses).

An alternate approach is offered by `DataSnap`'s support for object pooling. All you need to do to request this feature is add a call to `RegisterPooled` in the overridden `UpdateRegistry` method. Combined with the stateless support built in to this architecture, the pooling capability allows you to share some middle-tier objects among a much larger number of clients. A pooling mechanism is built in to COM+, but `DataSnap` makes it available for HTTP and socket-based connections as well.

The users on the client computers will spend most of their time reading data and typing in updates, and they generally don't continue asking for data and sending updates. When the client is not calling a method of the middle-tier object, this same remote data module can be used for another client. Being stateless, every request reaches the middle tier as a brand-new operation, even when a server is dedicated to a specific client.

## Customizing the Data Packets

There are many ways to include custom information within the data packet handled by the `IAppServer` interface. The simplest is to handle the `OnGetDataSetProperties` event of the provider. This event has a `Sender` parameter, a dataset parameter indicating where the data is coming from, and an `OleVariant` array `Properties` parameter, in which you can place the extra information. You need to define one variant array for each extra property and include the name of the extra property, its value, and whether you want the data to return to the server along with the update delta (the `IncludeInDelta` parameter).

Of course, you can pass properties of the related dataset component, but you can also pass any other value (extra fake properties). In the `AppSPlus` example, I pass to the client the time the query was executed and its parameters:

```
procedure TAppServerPlus.ProviderQueryGetDataSetProperties(
  Sender: TObject; DataSet: TDataSet; out Properties: OleVariant);
begin
  Properties := VarArrayCreate([0,1], varVariant);
```

```
Properties[0] := VarArrayOf(['Time', Now, True]);
Properties[1] := VarArrayOf(['Param', Query.Params[0].AsString, False]);
end;
```

On the client side, the `ClientDataSet` component has a `GetOptionalParameter` method to retrieve the value of the extra property with the given name. The `ClientDataSet` also has the `SetOptionalParameter` method to add more properties to the dataset. These values will be saved to disk (in the briefcase model) and eventually sent back to the middle tier (by setting the `IncludeInDelta` member of the variant array to `True`). Here is a simple example of the retrieval of the dataset in the previous code:

```
Caption := 'Data sent at ' + TimeToStr (TDateTime (
    cdsQuery.GetOptionalParam('Time')));
Label1.Caption := 'Param ' + cdsQuery.GetOptionalParam('Param');
```

The effect of this code was visible in [Figure 16.5](#). An alternative and more powerful approach for customizing the data packet sent to the client is to handle the `OnGetData` event of the provider, which receives the outgoing data packet in the form of a client dataset. Using the methods of this client dataset, you can edit data before it is sent to the client. For example, you might encode some of the data or filter out sensitive records.

## What's Next?

Borland originally introduced its multitier technology in Delphi 3 and has kept extending it from version to version. In addition to further updates and the change of the MIDAS name to DataSnap, Delphi 6 saw the introduction of SOAP support, introducing an alternate and extended architecture for multitier applications. We'll fully explore this topic in [Chapter 23](#). Delphi 7, on the other hand, cut back on CORBA support.

However, with the introduction of a new licensing scheme (basically, *free deployment*), Delphi 7 has paved the way for increased adoption of this technology. This is particularly true of DataSnap's SOAP variant, but socket connections also provide a very good balance of data transfer efficiency and ease of deployment.

For the moment, we'll continue with database programming, discussing data-aware controls and custom datasets. In the final part of the book we'll explore sockets, Internet programming, and SOAP, so you'll have a complete picture of possible multitier architectures based on Delphi—not to mention the availability of third-party tools providing features similar to DataSnap.

## Chapter 17: Writing Database Components

### Overview

In [Chapter 9](#), "Writing Delphi Components," we explored the development of Delphi components in depth. Now that I've discussed database programming, we can get back to the earlier topic and focus on the development of database-related components.

There are basically two families of such components: data-aware controls you can use to present the data of a field or an entire record to the users of a program; and dataset components you can define to provide data to existing data-aware controls, reading the data from a database or any other data source. In this chapter, I'll cover both topics.

## The Data Link

When you write a Delphi database program, you generally connect some data-aware controls to a `DataSource` component, and then connect the `DataSource` component to a dataset. The connection between the data-aware control and the `DataSource` is called a *data link* and is represented by an object of class `TDataLink` or descendant. The data-aware control creates and manages this object and represents its only connection to the data. From a more practical perspective, to make a component data-aware, you need to add a data link to it and surface some of the properties of this internal object, such as the `DataSource` and `DataField` properties.

Delphi uses the `DataSource` and `DataLink` objects for bidirectional communication. The dataset uses the connection to notify the data-aware controls that new data is available (because the dataset has been activated, or the current record has changed, and so on). Data-aware controls use the connection to ask for the current value of a field or to update it, notifying the dataset of this event.

The relations among all these components are complicated by the fact that some of the connections can be one-to-many. For example, you can connect multiple data sources to the same dataset, you generally have multiple data links to the same data source (simply because you need one link for every data-aware component), and in most cases you connect multiple data-aware controls to each data source.

### The `TDataLink` Class

We'll work for much of this chapter with `TDataLink` and its derived classes, which are defined in the `DB` unit. This class has a set of protected virtual methods, which have a role similar to events. They are "almost-do-nothing" methods you can override in a specific subclass to intercept user operations and other data-source events. Here is a list, extracted from the class's source code:

**type**

```
TDataLink = class(TPersistent)
protected
  procedure ActiveChanged; virtual;
  procedure CheckBrowseMode; virtual;
  procedure DataSetChanged; virtual;
  procedure DataSetScrolled(Distance: Integer); virtual;
  procedure FocusControl(Field: TFieldRef); virtual;
  procedure EditingChanged; virtual;
  procedure LayoutChanged; virtual;
  procedure RecordChanged(Field: TField); virtual;
  procedure UpdateData; virtual;
```

All these virtual methods are called by the `DataEvent` private method, which is a sort of window procedure for a data source, triggered by several data events (see the `TDataEvent` enumeration). These events originate in the dataset, fields, or data source, and are generally applied to a dataset. The `DataEvent` method of the dataset component dispatches the events to the connected data sources. Each data source calls the `NotifyDataLinks` method to forward the event to each connected data link, and then the data source triggers its own `OnDataChange` or `OnUpdateData` event.

### Derived Data Link Classes

The `TDataLink` class is not technically an abstract class, but you'll seldom use it directly. When you need to create data-aware controls, you'll need to use one of its derived classes or derive a new one yourself. The most important class derived from `TDataLink` is the `TFieldDataLink` class, which is used by data-aware controls that relate to a single field of the dataset. Most data-aware controls fall into this category, and the `TFieldDataLink` class solves the most common problems of this type of component.

All the table- or record-oriented data-aware controls define specific subclasses of `TDataLink`, as we'll do later. The `TFieldDataLink` class has a list of events corresponding to the virtual methods of the base class it overrides. This makes the class simpler to customize, because you can use event handlers instead of having to inherit a new class from it. Here's an example of an overridden method, which fires the corresponding event, if available:

```
procedure TFieldDataLink.ActiveChanged;  
begin  
    UpdateField;  
    if Assigned(FOnActiveChange) then FOnActiveChange(Self);  
end;
```

The `TFieldDataLink` class also contains the `Field` and `FieldName` properties that let you connect the data-aware control to a specific field of the dataset. The link keeps a reference to the current visual component, using the `Control` property.

## Writing Field-Oriented Data-Aware Controls

Now that you understand the theory of how the data link classes work, let's begin building some data-aware controls. The first two examples are data-aware versions of the `ProgressBar` and `TrackBar` common controls. You can use the first to display a numeric value, such as a percentage, in a visual way. You can use the second to allow a user to change the numeric value.

**Note** The code for all of the components built in this chapter is in the `MdDataPack` folder, which also includes a similarly named package for installing them all. Other folders include sample programs that use these components.

### A Read-Only ProgressBar

A data-aware version of the `ProgressBar` control is a relatively simple case of a data-aware control, because it is read-only. This component is derived from the version that's not data-aware and adds a few properties of the data link object it encapsulates:

```
type
  TMdDbProgress = class(TProgressBar)
  private
    FDataLink: TFieldDataLink;
    function GetDataField: string;
    procedure SetDataField (Value: string);
    function GetDataSource: TDataSource;
    procedure SetDataSource (Value: TDataSource);
    function GetField: TField;
  protected
    // data link event handler
    procedure DataChange (Sender: TObject);
  public
    constructor Create (AOwner: TComponent); override;
    destructor Destroy; override;
    property Field: TField read GetField;
  published
    property DataField: string read GetDataField write SetDataField;
    property DataSource: TDataSource read GetDataSource write SetDataSource;
  end;
```

As with every data-aware component that connects to a single field, this control makes available the `DataSource` and `DataField` properties. There is little code to write; simply export the properties from the internal data link object, as follows:

```
function TMdDbProgress.GetDataField: string;
begin
  Result := FDataLink.FieldName;
end;

procedure TMdDbProgress.SetDataField (Value: string);
begin
  FDataLink.FieldName := Value;
end;

function TMdDbProgress.GetDataSource: TDataSource;
begin
  Result := FDataLink.DataSource;
end;
```

```

procedure TMdDbProgress.SetDataSource (Value: TDataSource);
begin
    FDataLink.DataSource := Value;
end;

function TMdDbProgress.GetField: TField;
begin
    Result := FDataLink.Field;
end;

```

Of course, to make this component work, you must create and destroy the data link when the component itself is created or destroyed:

```

constructor TMdDbProgress.Create (AOwner: TComponent);
begin
    inherited Create (AOwner);
    FDataLink := TFieldDataLink.Create;
    FDataLink.Control := Self;
    FDataLink.OnDataChange := DataChange;
end;

destructor TMdDbProgress.Destroy;
begin
    FDataLink.Free;
    FDataLink := nil;
    inherited Destroy;
end;

```

In the preceding constructor, notice that the component installs one of its own methods as an event handler for the data link. This is where the component's most important code resides. Every time the data changes, you modify the output of the progress bar to reflect the value of the current field:

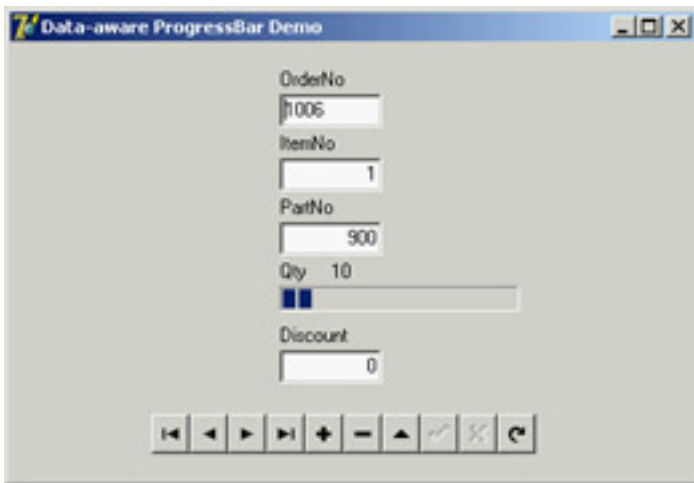

```

procedure TMdDbProgress.DataChange (Sender: TObject);
begin
    if FDataLink.Field is TNumericField then
        Position := FDataLink.Field.AsInteger
    else
        Position := Min;
end;

```

Following the convention of the VCL data-aware controls, if the field type is invalid, the component doesn't display an error message—it disables the output. Alternatively, you might want to check the field type when the `SetDataField` method assigns it to the control.

In [Figure 17.1](#) you can see an example of the DbProgr application's output, which uses both a label and a progress bar to display an order's quantity information. Thanks to this visual clue, you can step through the records and easily spot orders for many items. One obvious benefit to this component is that the application contains almost no code, because all the important code is in the MdProgr unit that defines the component.

**Figure 17.1:** The data-aware ProgressBar in action in the DbProgr example

As you've seen, a read-only data-aware component is not difficult to write. However, it becomes extremely complex to use such a component inside a `DBCtrlGrid` container.

**Note** If you remember the discussion of the *Notification* method in [Chapter 9](#), you might wonder what happens if the data source referenced by the data-aware control is destroyed. The good news is that the data source has a destructor that removes itself from its own data links. So, there is no need for a *Notification* method for data-aware controls, although you'll see books and articles suggesting it, and VCL includes plenty of this useless code.

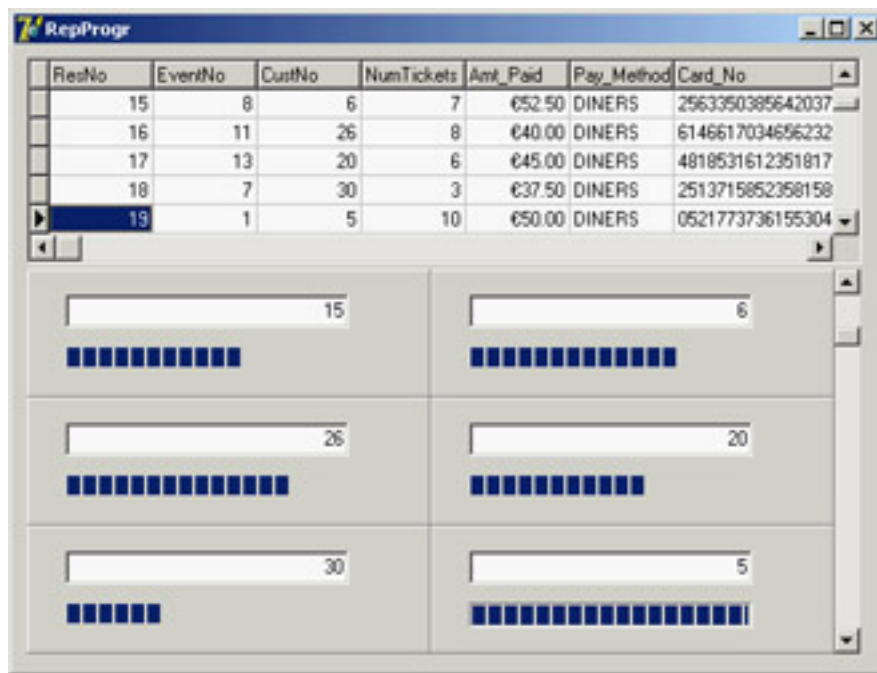

---

### Replicable Data-Aware Controls

Extending a data-aware control to support its use inside a `DBCtrlGrid` component is complex and not well documented. You can find a complete replicable version of the progress bar in the `MdRepPr` unit of the `MdDataPack` package and an example of its use in the `RepProgr` folder, along with an HTML file describing its development. The `DBCtrlGrid` component has a peculiar behavior: It displays on screen multiple versions of the same physical control, using smoke and mirrors. The grid can attach the control to a data buffer other than the current record and redirects the control paint operations to another portion of the monitor.

In short, to appear in the `DBCtrlGrid`, a component's `csReplicable` control style must be set; this flag indicates that your component supports being hosted by a control grid. First, the component must respond to the `cm_GetDataLink` Delphi message and return a pointer to the data link, so that the control grid can use and change it. Second, it needs a custom `Paint` method to draw the output in the appropriate canvas object, which is provided in a parameter of the `wm_Paint` message if the `ControlState` property's `csPaintCopy` flag is set.

The example code is involved, and the `DBCtrlGrid` component is not heavily used, so I decided not to give you full details here; you can find the full code and more information in the source code. Here's the output of a test program that uses this component:

## A Read-Write TrackBar

The next step is to write a component that allows a user to modify the data in a database, not just browse it. The overall structure of this type of component isn't very different from the previous version, but there are a few extra elements. In particular, when the user begins interacting with the component, the code should put the dataset into edit mode and then notify the dataset that the data has changed. The dataset will then use a `FieldDataLink` event handler to ask for the updated value.

To demonstrate how you can create a data-aware component that modifies the data, I extended the `TrackBar` control. This isn't the simplest example, but it demonstrates several important techniques.

Here's the definition of the component's class (from the `MdTrack` unit of the `MdDataPack` package):

```

type
  TMdDbTrack = class(TTrackBar)
  private
    FDataLink: TFieldDataLink;
    function GetDataField: string;
    procedure SetDataField (Value: string);
    function GetDataSource: TDataSource;
    procedure SetDataSource (Value: TDataSource);
    function GetField: TField;
    procedure CNHScroll(var Message: TWMHScroll); message CN_HSCROLL;
    procedure CNVScroll(var Message: TWMVScroll); message CN_VSCROLL;
    procedure CMExit(var Message: TCMExit); message CM_EXIT;
  protected
    // data link event handlers
    procedure DataChange (Sender: TObject);
    procedure UpdateData (Sender: TObject);
    procedure ActiveChange (Sender: TObject);
  public
    constructor Create (AOwner: TComponent); override;
    destructor Destroy; override;
    property Field: TField read GetField;

```

```

published
  property DataField: string read GetDataField write SetDataField;
  property DataSource: TDataSource read GetDataSource write SetDataSource;
end;

```

Compared to the read-only data-aware control you built earlier, this class is more complex, because it has three message handlers, including component notification handlers, and two new event handlers for the data link. The component installs these event handlers in the constructor, which also disables the component:

```

constructor TMDbTrack.Create (AOwner: TComponent);
begin
  inherited Create (AOwner);
  FDataLink := TFieldDataLink.Create;
  FDataLink.Control := Self;
  FDataLink.OnDataChange := DataChange;
  FDataLink.OnUpdateData := UpdateData;
  FDataLink.OnActiveChange := ActiveChange;
  Enabled := False;
end;

```

The get and set methods and the `DataChange` event handler are similar to those in the `TMDbProgress` component. The only difference is that whenever the data source or data field changes, the component checks the current status to see whether it should enable itself:

```

procedure TMDbTrack.SetDataSource (Value: TDataSource);
begin
  FDataLink.DataSource := Value;
  Enabled := FDataLink.Active and (FDataLink.Field <> nil) and
    not FDataLink.Field.ReadOnly;
end;

```

This code tests three conditions: the data link should be active, the link should refer to an actual field, and the field shouldn't be read-only.

When the user changes the field, the component should consider that the field name might be invalid; to test for this condition, the component uses a `try/finally` block:

```

procedure TMDbTrack.SetDataField (Value: string);
begin
  try
    FDataLink.FieldName := Value;
  finally
    Enabled := FDataLink.Active and (FDataLink.Field <> nil) and
      not FDataLink.Field.ReadOnly;
  end;
end;

```

The control executes the same test when the dataset is enabled or disabled:

```

procedure TMDbTrack.ActiveChange (Sender: TObject);
begin
  Enabled := FDataLink.Active and (FDataLink.Field <> nil) and
    not FDataLink.Field.ReadOnly;
end;

```

The most interesting portion of this component's code is related to its user interface. When a user begins moving the scroll thumb, the component puts the dataset into edit mode, lets the base class update the thumb position, and alerts the data link (and therefore the data source) that the data has changed. Here's the code:

```

procedure TMDbTrack.CNHScroll(var Message: TWMHScroll);
begin

```

```

// enter edit mode
FDataLink.Edit;
// update data
inherited;
// let the system know
FDataLink.Modified;
end;

procedure TMdDbTrack.CNVScroll(var Message: TWMVScroll);
begin
    // enter edit mode
    FDataLink.Edit;
    // update data
    inherited;
    // let the system know
    FDataLink.Modified;
end;

```

When the dataset needs new data—for example, to perform a `Post` operation—it requests it from the component via the `TFieldDataLink` class's `OnUpdateData` event:

```

procedure TMdDbTrack.UpdateData (Sender: TObject);
begin
    if FDataLink.Field is TNumericField then
        FDataLink.Field.AsInteger := Position;
end;

```

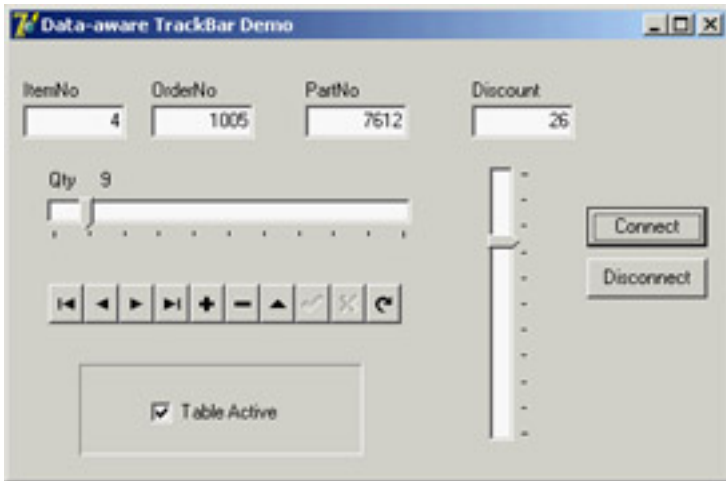

If the proper conditions are met, the component updates the data in the proper table field. Finally, if the component loses the input focus, it should force a data update (if the data has changed) so that any other data-aware components showing the value of that field will display the correct value as soon as the user moves to a different field. If the data hasn't changed, the component doesn't bother updating the data in the table. This is the standard `CMExit` code for components used by VCL and borrowed for this component:

```

procedure TMdDbTrack.CMExit(var Message: TCMExit);
begin
    try
        FDataLink.UpdateRecord;
    except
        SetFocus;
        raise;
    end;
    inherited;
end;

```

A demo program is available for testing this component; you can see its output in [Figure 17.2](#). The `DbTrack` program contains a check box to enable and disable the table, the visual components, and a couple of buttons you can use to detach the vertical `TrackBar` component from the field it relates to. I placed these on the form to test enabling and disabling the track bar.

**Figure 17.2:** The DbTrack example's track bars let you enter data in a database table. The check box and buttons test the enabled status of the components.

## Creating Custom Data Links

The data-aware controls I've built up to this point all refer to specific fields of the dataset, so I used a `TFieldDataLink` object to establish the connection with a data source. Now let's build a data-aware component that works with a dataset as a whole: a record viewer.

Delphi's database grid shows the value of several fields and several records simultaneously. My record viewer component lists all the fields of the current record, using a customized grid. This example will show you how to build a customized grid control and a custom data link to go with it.

### A Record Viewer Component

In Delphi there are no data-aware components that manipulate multiple fields of a single record without displaying other records. The only two components that display multiple fields from the same table are the `DBGrid` and the `DbCtrlGrid`, which generally display multiple fields and multiple records.

The record viewer component I'll describe in this section is based on a two-column grid; the first column displays the table's field names, and the second column displays the corresponding field values. The number of rows in the grid corresponds to the number of fields, with a vertical scroll bar in case they can't fit in the visible area.

The data link you need in order to build this component is a class connected only to the record viewer component and declared directly in the implementation portion of its unit. This is the same approach used by VCL for some specific data links. Here's the definition of the new class:

```
type
  TMdRecordLink = class (TDataLink)
  private
    RView: TMdRecordView;
  public
    constructor Create (View: TMdRecordView);
    procedure ActiveChanged; override;
    procedure RecordChanged (Field: TField); override;
  end;
```

As you can see, the class overrides the methods related to the principal event—in this case, the activation and data (or record) change. Alternatively, you could export events and then let the component handle them, as the `TFieldDataLink` does.

The constructor requires the associated component as its only parameter:

```
constructor TMdRecordLink.Create (View: TMdRecordView);
begin
  inherited Create;
  RView := View;
end;
```

After you store a reference to the associated component, the other methods can operate on it directly:

```
procedure TMdRecordLink.ActiveChanged;
var
  I: Integer;
begin
  // set number of rows
  RView.RowCount := DataSet.FieldCount;
  // repaint all...
  RView.Invalidate;
end;
```

```

procedure TMdRecordLink.RecordChanged;
begin
    inherited;
    // repaint all...
    RView.Invalidate;
end;

```

The record link code is simple. Most of the difficulties in building this example result from the use of a grid. To avoid dealing with useless properties, I derived the record viewer grid from the `TCustomGrid` class. This class incorporates much of the code for grids, but most of its properties, events, and methods are protected. For this reason, the class declaration is quite long, because it needs to publish many existing properties. Here is an excerpt (excluding the base class properties):

```

type
    TMdRecordView = class(TCustomGrid)
    private
        // data-aware support
        FDataLink: TDataLink;
        function GetDataSource: TDataSource;
        procedure SetDataSource (Value: TDataSource);
    protected
        // redefined TCustomGrid methods
        procedure DrawCell (ACol, ARow: Longint; ARect: TRect;
            AState: TGridDrawState); override;
        procedure ColWidthsChanged; override;
        procedure RowHeightsChanged; override;
    public
        constructor Create (AOwner: TComponent); override;
        destructor Destroy; override;
        procedure SetBounds (ALeft, ATop, AWidth, AHeight: Integer); override;
        // public parent properties (omitted...)
    published
        // data-aware properties
        property DataSource: TDataSource read GetDataSource write SetDataSource;
        // published parent properties (omitted...)
    end;

```

In addition to redeclaring the properties to publish them, the component defines a data link object and the `DataSource` property. There's no `DataField` property for this component, because it refers to an entire record. The component's constructor is very important. It sets the values of many unpublished properties, including the grid options:

```

constructor TMdRecordView.Create (AOwner: TComponent);
begin
    inherited Create (AOwner);
    FDataLink := TMdRecordLink.Create (self);
    // set numbers of cells and fixed cells
    RowCount := 2; // default
    ColCount := 2;
    FixedCols := 1;
    FixedRows := 0;
    Options:= [goFixedVertLine, goFixedHorzLine,
        goVertLine, goHorzLine, goRowSizing];
    DefaultDrawing := False;
    ScrollBars := ssVertical;
    FSaveCellExtents := False;
end;

```

The grid has two columns (one of them fixed) and no fixed rows. The fixed column is used for resizing each row of the grid. Unfortunately, a user cannot drag the fixed row to resize the columns, because you can't resize fixed elements,

and the grid already has a fixed column.

**Note** An alternative approach could be to have an extra empty column, like the DBGrid control. You could resize the two other columns after adding a fixed row. Overall, though, I prefer my implementation.

I used an alternative approach to resize the columns. The first column (holding the field names) can be resized either using programming code or visually at design time, and the second column (holding the values of the fields) is resized to use the remaining area of the component:

```
procedure TMDRecordView.SetBounds (ALeft, ATop, AWidth, AHeight: Integer);  
begin  
    inherited;  
    ColWidths [1] := ClientWidth - ColWidths[0];  
end;
```

This resizing takes place when the component size changes and when either of the columns change. With this code, the `DefaultColWidth` property of the component becomes, in practice, the fixed width of the first column.

After everything has been set up, the key method of the component is the overridden `DrawCell` method, detailed in [Listing 17.1](#). In this method, the control displays the information about the fields and their values. It needs to draw three things. If the data link is not connected to a data source, the grid displays an *empty element* sign ([ ]). When drawing the first column, the record viewer shows the `DisplayName` of the field, which is the same value used by the DBGrid for the heading. When drawing the second column, the component accesses the textual representation of the field value, extracted with the `DisplayText` property (or with the `AsString` property for memo fields).

### **Listing 17.1: The *DrawCell* Method of the Custom RecordView Component**

---

```
procedure TMDRecordView.DrawCell(ACol, ARow: Longint; ARect: TRect;  
    AState: TGridDrawState);  
var  
    Text: string;  
    CurrField: TField;  
    Bmp: TBitmap;  
begin  
    CurrField := nil;  
    Text := '[]'; // default  
    // paint background  
    if (ACol = 0) then  
        Canvas.Brush.Color := FixedColor  
    else  
        Canvas.Brush.Color := Color;  
    Canvas.FillRect (ARect);  
    // leave small border  
    InflateRect (ARect, -2, -2);  
    if (FDataLink.DataSource <> nil) and FDataLink.Active then  
    begin  
        CurrField := FDataLink.DataSet.Fields[ARow];  
        if ACol = 0 then  
            Text := CurrField.DisplayName  
        else if CurrField is TMemoField then  
            Text := TMemoField (CurrField).AsString  
        else  
            Text := CurrField.DisplayText;  
    end;  
    if (ACol = 1) and (CurrField is TGraphicField) then  
    begin  
        Bmp := TBitmap.Create;  
        try
```

```

    Bmp.Assign (CurrField);
    Canvas.StretchDraw (ARect, Bmp);
finally
    Bmp.Free;
end;
end
else if (ACol = 1) and (CurrField is TMemoField) then
begin
    DrawText (Canvas.Handle, PChar (Text), Length (Text), ARect,
        dt_WordBreak or dt_NoPrefix)
end
else // draw single line vertically centered
    DrawText (Canvas.Handle, PChar (Text), Length (Text), ARect,
        dt_vcenter or dt_SingleLine or dt_NoPrefix);
if gdFocused in AState then
    Canvas.DrawFocusRect (ARect);
end;

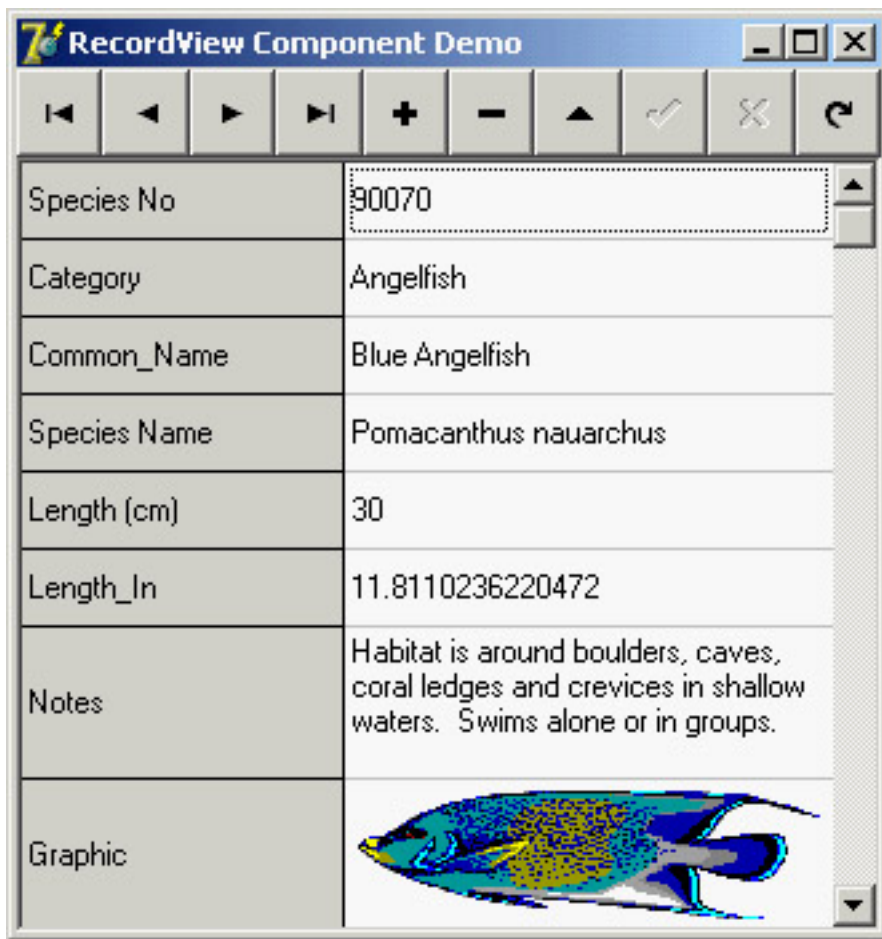

```

---

In the final portion of the method, the component considers memo and graphic fields. If the field is a `TMemoField`, the `DrawText` function call doesn't specify the `dt_SingleLine` flag, but uses `dt_WordBreak` flag to wrap the words when there's no more room. For a graphic field, the component uses a completely different approach, assigning the field image to a temporary bitmap and then stretching it to fill the surface of the cell.

Notice that the component sets the `DefaultDrawing` property to `False`, so it's also responsible for drawing the background and the focus rectangle, as it does in the `DrawCell` method. The component also calls the `InflateRect` API function to leave a small area between the cell border and the output text. The output is produced by calling another Windows API function, `DrawText`, which centers the text vertically in its cell.

This drawing code works both at run time, as you can see in [Figure 17.3](#), and at design time. The output may not be perfect, but this component can be useful in many cases. To display the data for a single record, instead of building a custom form with labels and data-aware controls, you can easily use this record viewer grid. It's important to remember that the record viewer is a read-only component. It's possible to extend it to add editing capabilities (they're already part of the `TCustomGrid` class); however, instead of adding this support, I decided to make the component more complete by adding support for displaying BLOB fields.

**Figure 17.3:** The ViewGrid example demon-strates the output of the RecordView component, using Borland's sample BioLife database table.

To improve the graphical output, the control makes the lines for BLOB fields twice as high as those for plain text fields. This operation is accomplished when the dataset connected to the data-aware control is activated. The data link's `ActiveChanged` method is also triggered by the `RowHeightsChanged` methods connected to the `DefaultRowHeight` property of the base class:

```

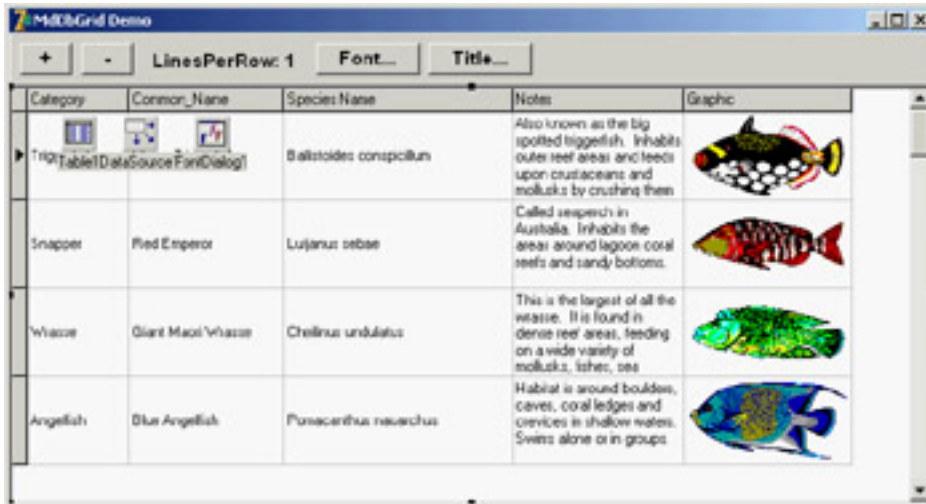

procedure TMdRecordLink.ActiveChanged;
var
    I: Integer;
begin
    // set number of rows
    RView.RowCount := DataSet.FieldCount;
    // double the height of memo and graphics
    for I := 0 to DataSet.FieldCount - 1 do
        if DataSet.Fields [I] is TBlobField then
            RView.RowHeights [I] := RView.DefaultRowHeight * 2;
    // repaint all...
    RView.Invalidate;
end;

```

At this point, you stumble into a minor problem. In the `DefineProperties` method, the `TCustomGrid` class saves the values of the `RowHeights` and `ColHeights` properties. You could disable this streaming by overriding the method and not calling `inherited` (which is generally a bad technique), but you can also toggle the `FSaveCellExtents` protected field to disable this feature (as I've done in the component's code).

## Customizing the DBGrid Component

In addition to writing new, custom, data-aware components, Delphi programmers commonly customize the DBGrid control. The goal for the next component is to enhance the DBGrid with the same kind of custom output I used for the RecordView component, directly displaying graphic and memo fields. To do this, the grid needs to make the row height resizable, to allow space for graphics and a reasonable amount of text. You can see an example of this grid at design time in [Figure 17.4](#).

**Figure 17.4:** An example of the MdDbGrid component at design time. Notice the output of the graphics and memo fields.

Although creating the output was a simple matter of adapting the code used in the record viewer component, setting the height of the grid cells ended up being a difficult problem to solve. The lines of code for that operation may be few, but they cost me hours of work!

**Note** Unlike the generic grid used earlier, a DBGrid is a virtual view on the dataset—there is no relation between the number of rows shown on the screen and the number of rows of data in the dataset. When you scroll up and down through the data records of the dataset, you are not scrolling through the rows of the DBGrid; the rows are stationary, and the data moves from one row to the next to give the appearance of movement. For this reason, the program doesn't try to set the height of an individual row to suit its data; it sets the height of all the data rows to a multiline height value.

This time the control doesn't have to create a custom data link, because it is deriving from a component that already has a complex connection with the data. The new class has a new property to specify the number of lines of text for each row and overrides a few virtual methods:

```
type
  TMdDbGrid = class(TDbGrid)
  private
    FLinesPerRow: Integer;
    procedure SetLinesPerRow (Value: Integer);
  protected
    procedure DrawColumnCell(const Rect: TRect; DataCol: Integer;
      Column: TColumn; State: TGridDrawState); override;
    procedure LayoutChanged; override;
  public
    constructor Create (AOwner: TComponent); override;
  published
    property LinesPerRow: Integer
      read FLinesPerRow write SetLinesPerRow default 1;
  end;
```

The constructor sets the default value for the `FLinesPerRow` field. Here is the set method for the property:

```
procedure TMdDbGrid.SetLinesPerRow(Value: Integer);  
begin  
  if Value <> FLinesPerRow then  
    begin  
      FLinesPerRow := Value;  
      LayoutChanged;  
    end;  
end;
```

The side effect of changing the number of lines is a call to the `LayoutChanged` virtual method. The system calls this method frequently when one of the many output parameters changes. In the method's code, the component first calls the inherited version and then sets the height of each row. As a basis for this computation, it uses the same formula as the `TCustomDBGrid` class: The text height is calculated using the sample word *Wg* in the current font (this text is used because it includes both a full-height uppercase character and a lowercase letter with a descender). Here's the code:

```
procedure TMdDbGrid.LayOutChanged;  
var  
  PixelsPerRow, PixelsTitle, I: Integer;  
begin  
  inherited LayOutChanged;  
  
  Canvas.Font := Font;  
  PixelsPerRow := Canvas.TextHeight('Wg') + 3;  
  if dgRowLines in Options then  
    Inc (PixelsPerRow, GridLineWidth);  
  
  Canvas.Font := TitleFont;  
  PixelsTitle := Canvas.TextHeight('Wg') + 4;  
  if dgRowLines in Options then  
    Inc (PixelsTitle, GridLineWidth);  
  
  // set number of rows  
  RowCount := 1 + (Height - PixelsTitle) div (PixelsPerRow * FLinesPerRow);  
  
  // set the height of each row  
  DefaultRowHeight := PixelsPerRow * FLinesPerRow;  
  RowHeights [0] := PixelsTitle;  
  for I := 1 to RowCount - 1 do  
    RowHeights [I] := PixelsPerRow * FLinesPerRow;  
  
  // send a WM_SIZE message to let the base component recompute  
  // the visible rows in the private UpdateRowCount method  
  PostMessage (Handle, WM_SIZE, 0, MakeLong(Width, Height));  
end;
```

**Warning** `Font` and `TitleFont` are the grid defaults, which can be overridden by properties of the individual `DBGrid` column objects. This component currently ignores those settings.

The difficult part of this method was getting the final statements right. You can set the `Default-RowHeight` property, but in that case the title row will probably be too high. First I tried setting the `DefaultRowHeight` and then the height of the first row, but this approach complicated the code used to compute the number of visible rows in the grid (the read-only `VisibleRowCount` property). If you specify the number of rows (to avoid having rows hidden beneath the lower edge of the grid), the base class keeps recomputing it. Here's the code used to draw the data, ported from the `RecordView` component and adapted slightly for the grid:

```
procedure TMdDbGrid.DrawColumnCell (const Rect: TRect; DataCol: Integer;
```

```

Column: TColumn; State: TGridDrawState);
var
  Bmp: TBitmap;
  OutRect: TRect;
begin
  if FLinesPerRow = 1 then
    inherited DrawColumnCell(Rect, DataCol, Column, State)
  else
    begin
      // clear area
      Canvas.FillRect (Rect);
      // copy the rectangle
      OutRect := Rect;
      // restrict output
      InflateRect (OutRect, -2, -2);
      // output field data
      if Column.Field is TGraphicField then
        begin
          Bmp := TBitmap.Create;
          try
            Bmp.Assign (Column.Field);
            Canvas.StretchDraw (OutRect, Bmp);
          finally
            Bmp.Free;
          end;
        end
      else if Column.Field is TMemoField then
        begin
          DrawText (Canvas.Handle, PChar (Column.Field.AsString),
            Length (Column.Field.AsString), OutRect, dt_WordBreak or dt_NoPrefix)
        end
      else // draw single line vertically centered
        DrawText (Canvas.Handle, PChar (Column.Field.DisplayText),
          Length (Column.Field.DisplayText), OutRect,
            dt_vcenter or dt_SingleLine or dt_NoPrefix);
    end;
  end;
end;

```

In this code you can see that if the user displays a single line, the grid uses the standard drawing technique with no output for memo and graphic fields. However, as soon as you increase the line count, you'll see better output.

To see this code in action, run the GridDemo example. This program has two buttons you can use to increase or decrease the row height of the grid, and two more buttons to change the font. This is an important test because the height in pixels of each cell is the height of the font multiplied by the number of lines.

## Building Custom Datasets

When discussing the `TDataSet` class and the alternative families of dataset components available in Delphi in [Chapter 13](#), "Delphi's Database Architecture," I mentioned the possibility of writing a custom dataset class. Now it's time to look at an example. The reasons for writing a custom dataset relate to the fact that you won't need to deploy a database engine, but you'll still be able to take full advantage of Delphi's database architecture, including things like persistent database fields and data-aware controls.

Writing a custom dataset is one of the most complex tasks for a component developer, so this is one of the most advanced areas (as far as low-level coding practices, including tons of pointers) in the book. Moreover, Borland hasn't released any official documentation about writing custom datasets. If you are early in your experience with Delphi, you might want to skip the rest of this chapter and come back later.

`TDataSet` is an abstract class that declares several virtual abstract methods—23 in Delphi 5, now only a handful, as most have been replaced by empty virtual methods (which you still have to override). Every subclass of `TDataSet` must override all those methods.

Before discussing the development of a custom dataset, we need to explore a few technical elements of the `TDataSet` class—in particular, record buffering. The class maintains a list of buffers that store the values of different records. These buffers store the data, but they also usually store further information for the dataset to use when managing the records. These buffers don't have a predefined structure, and each custom dataset must allocate the buffers, fill them, and destroy them. The custom dataset must also copy the data from the record buffers to the various fields of the dataset, and vice versa. In other words, the custom dataset is entirely responsible for handling these buffers.

In addition to managing the data buffers, the component is responsible for navigating among the records, managing the bookmarks, defining the structure of the dataset, and creating the proper data fields. The `TDataSet` class is nothing more than a framework; you must fill it with the appropriate code. Fortunately, most of the code follows a standard structure, which the `TDataSet`-derived VCL classes use. Once you've grasped the key ideas, you'll be able to build multiple custom datasets borrowing quite a lot of code.

To simplify this type of reuse, I've collected the common features required by any custom dataset in a `TMdCustomDataSet` class. However, I'm not going to discuss the base class first and the specific implementation later, because it would be difficult to understand. Instead, I'll detail the code required by a dataset, presenting methods of the generic and specific classes at the same time, according to a logical flow.

### The Definition of the Classes

The starting point, as usual, is the declaration of the two classes discussed in this section: the generic custom dataset I've written and a specific component storing data in a file stream. The declaration of these classes is available in [Listing 17.2](#). In addition to virtual methods, the classes contain a series of protected fields used to manage the buffers, track the current position and record count, and handle many other features. You'll also notice another record declaration at the beginning: a structure used to store the extra data for every data record you place in a buffer. The dataset places this information in each record buffer, following the data.

#### Listing 17.2: The Declaration of `TMdCustomDataSet` and `TMdDataSetStream`

    function GetFieldData(Field: TField; Buffer: Pointer): Boolean; override;
  published
    property TableName: string read FTableName write SetTableName;
  end;

```

---

When I divided the methods into sections (as you can see by looking at the source code files), I marked each one with a roman number. You'll see those numbers in a comment describing the method, so that while browsing this long listing you'll immediately know which of the four sections you are in.

## Section I: Initialization, Opening, and Closing

The first methods I'll examine are responsible for initializing the dataset and for opening and closing the file stream used to store the data. In addition to initializing the component's internal data, these methods are responsible for initializing and connecting the proper `TFields` objects to the dataset component. To make this work, all you need to do is to initialize the `FieldsDef` property with the definitions of the fields for your dataset, and then call a few standard methods to generate and bind the `TField` objects. This is the general `InternalOpen` method:

```
procedure TMdCustomDataSet.InternalOpen;
begin
    InternalPreOpen; // custom method for subclasses

    // initialize the field definitions
    InternalInitFieldDefs;

    // if there are no persistent field objects, create the fields dynamically
    if DefaultFields then
        CreateFields;
    // connect the TField objects with the actual fields
    BindFields (True);

    InternalAfterOpen; // custom method for subclasses

    // sets cracks and record position and size
    BofCrack := -1;
    EofCrack := InternalRecordCount;
    FCurrentRecord := BofCrack;
    FRecordBufferSize := FRecordSize + sizeof (TMdRecInfo);
    BookmarkSize := sizeof (Integer);

    // everything OK: table is now open
    FIsTableOpen := True;
end;
```

You'll notice that the method sets most of the local fields of the class, and also the `BookmarkSize` field of the base `TDataSet` class. Within this method, I call two custom methods I introduced in my custom dataset hierarchy: `InternalPreOpen` and `InternalAfterOpen`. The first, `InternalPreOpen`, is used for operations required at the very beginning, such as checking whether the dataset can be opened and reading the header information from the file. The code checks an internal version number for consistency with the value saved when the table is first created, as you'll see later. By raising an exception in this method, you can eventually stop the open operation.

Here is the code for the two methods in the derived stream-based dataset:

```
const
    HeaderVersion = 10;

procedure TMdDataSetStream.InternalPreOpen;
begin
    // the size of the header
    FDataFileHeaderSize := sizeof (TMdDataFileHeader);

    // check if the file exists
```

```

if not FileExists (FTableName) then
    raise EMdDataSetError.Create ('Open: Table file not found');

// create a stream for the file
FStream := TFileStream.Create (FTableName, fmOpenReadWrite);

// initialize local data (loading the header)
FStream.ReadBuffer (FDataFileHeader, FDataFileHeaderSize);
if FDataFileHeader.VersionNumber <> HeaderVersion then
    raise EMdDataSetError.Create ('Illegal File Version');
// let's read this, double check later
FRecordCount := FDataFileHeader.RecordCount;
end;

procedure TMdDataSetStream.InternalAfterOpen;
begin
    // check the record size
    if FDataFileHeader.RecordSize <> FRecordSize then
        raise EMdDataSetError.Create ('File record size mismatch');
    // check the number of records against the file size
    if (FDataFileHeaderSize + FRecordCount * FRecordSize) <> FStream.Size then
        raise EMdDataSetError.Create ('InternalOpen: Invalid Record Size');
end;

```

The second method, `InternalAfterOpen`, is used for operations required after the field definitions have been set and is followed by code that compares the record size read from the file against the value computed in the `InternalInitFieldDefs` method. The code also checks that the number of records read from the header is compatible with the size of the file. This test can fail if the dataset wasn't closed properly: You might want to modify this code to let the dataset refresh the record size in the header anyway.

The `InternalOpen` method of the custom dataset class is specifically responsible for calling `InternalInitFieldDefs`, which determines the field definitions (at either design time or run time). For this example, I decided to base the field definitions on an external file—an INI file that provides a section for every field. Each section contains the name and data type of the field, as well as its size if it is string data. [Listing 17.3](#) shows the `Contrib.INI` file used in the component's demo application.

### **Listing 17.3: The *Contrib.INI* File for the Demo Application**

---

```

[Fields]
Number = 6

[Field1]
Type = ftString
Name = Name
Size = 30

[Field2]
Type = ftInteger
Name = Level

[Field3]
Type = ftDate
Name = BirthDate

[Field4]
Type = ftCurrency
Name = Stipend

```

```
[Field5]
Type = ftString
Name = Email
Size = 50
```

```
[Field6]
Type = ftBoolean
Name = Editor
```

---

This file, or a similar one, must use the same name as the table file and must be in the same directory. The `InternalInitFieldDefs` method (shown in [Listing 17.4](#)) will read it, using the values it finds to set up the field definitions and determine the size of each record. The method also initializes an internal `TList` object that stores the offset of every field inside the record. You use this `TList` to access fields' data within the record buffer, as you can see in the code listing.

#### **Listing 17.4: The `InternalInitFieldDefs` Method of the Stream-Based Dataset**

---

```
procedure TmDataSetStream.InternalInitFieldDefs;
var
  IniFileName, FieldName: string;
  IniFile: TIniFile;
  nFields, I, TmpFieldOffset, nSize: Integer;
  FieldType: TFieldType;
begin
  FFieldOffset := TList.Create;
  FieldDefs.Clear;
  TmpFieldOffset := 0;
  IniFilename := ChangeFileExt(FTableName, '.ini');
  Inifile := TIniFile.Create (IniFilename);
  // protect INI file
  try
    nFields := IniFile.ReadInteger (' Fields', 'Number', 0);
    if nFields = 0 then
      raise EDataSetOneError.Create (' InitFieldsDefs: 0 fields?');
    for I := 1 to nFields do
      begin
        // create the field
        FieldType := TFieldType (GetEnumValue (TypeInfo (TFieldType),
          IniFile.ReadString ('Field' + IntToStr (I), 'Type', '')));
        FieldName := IniFile.ReadString ('Field' + IntToStr (I), 'Name', '');
        if FieldName = '' then
          raise EDataSetOneError.Create (
            'InitFieldsDefs: No name for field ' + IntToStr (I));
        nSize := IniFile.ReadInteger ('Field' + IntToStr (I), 'Size', 0);
        FieldDefs.Add (FieldName, FieldType, nSize, False);
        // save offset and compute size
        FFieldOffset.Add (Pointer (TmpFieldOffset));
        case FieldType of
          ftString:           Inc (TmpFieldOffset, nSize + 1);
          ftBoolean, ftSmallInt, ftWord:  Inc (TmpFieldOffset, 2);
          ftInteger, ftDate, ftTime:     Inc (TmpFieldOffset, 4);
          ftFloat, ftCurrency, ftDateTime:  Inc (TmpFieldOffset, 8);
        else
          raise EDataSetOneError.Create (
```

```

        'InitFieldsDefs: Unsupported field type');
    end;
end; // for
finally
    IniFile.Free;
end;
FRecordSize := TmpFieldOffset;
end;

```

---

Closing the table is a matter of disconnecting the fields (using some standard calls). Each class must dispose of the data it allocated and update the file header, the first time records are added and each time the record count has changed:

```

procedure TmdCustomDataSet.InternalClose;
begin
    // disconnect field objects
    BindFields (False);
    // destroy field object (if not persistent)
    if DefaultFields then
        DestroyFields;
    // close the file
    FIsTableOpen := False;
end;

procedure TmdDataSetStream.InternalClose;
begin
    // if required, save updated header
    if (FDataFileHeader.RecordCount <> FRecordCount) or
        (FDataFileHeader.RecordSize = 0) then
        begin
            FDataFileHeader.RecordSize := FRecordSize;
            FDataFileHeader.RecordCount := FRecordCount;
            if Assigned (FStream) then
                begin
                    FStream.Seek (0, soFromBeginning);
                    FStream.WriteBuffer (FDataFileHeader, FDataFileHeaderSize);
                end;
            end;
        end;
    // free the internal list field offsets and the stream
    FFieldOffset.Free;
    FStream.Free;
    inherited InternalClose;
end;

```

Another related function is used to test whether the dataset is open, something you can solve using the corresponding local field:

```

function TmdCustomDataSet.IsCursorOpen: Boolean;
begin
    Result := FIsTableOpen;
end;

```

These are the opening and closing methods you need to implement in any custom dataset. However, most of the time, you'll also add a method to create the table. In this example, the `CreateTable` method creates an empty file and inserts information in the header: a fixed version number, a dummy record size (you don't know the size until you initialize the fields), and the record count (which is zero to start):

```

procedure TmdDataSetStream.CreateTable;

```

```

begin
  CheckInactive;
  InternalInitFieldDefs;

  // create the new file
  if FileExists (FTableName) then
    raise EMdDataSetError.Create ('File ' + FTableName + ' already exists');
  FStream := TFileStream.Create (FTableName, fmCreate or fmShareExclusive);
  try
    // save the header
    FDataFileHeader.VersionNumber := HeaderVersion;
    FDataFileHeader.RecordSize := 0;    // used later
    FDataFileHeader.RecordCount := 0;  // empty
    FStream.WriteBuffer (FDataFileHeader, FDataFileHeaderSize);
  finally
    // close the file
    FStream.Free;
  end;
end;

```

## Section II: Movement and Bookmark Management

As mentioned earlier, every dataset must implement *bookmark management*, which is necessary for navigating through the dataset. Logically, a bookmark is a reference to a specific dataset record, something that uniquely identifies the record so a dataset can access it and compare it to other records. Technically, bookmarks are pointers. You can implement them as pointers to specific data structures that store record information, or you can implement them as record numbers. For simplicity, I'll use the latter approach.

Given a bookmark, you should be able to find the corresponding record; but given a record buffer, you should also be able to retrieve the corresponding bookmark. This is the reason for appending the `TMdRecInfo` structure to the record data in each record buffer. This data structure stores the bookmark for the record in the buffer, as well as some bookmark flags defined as follows:

```

type
  TBookmarkFlag = (bfCurrent, bfBOF, bfEOF, bfInserted);

```

The system will request that you store these flags in each record buffer and will later ask you to retrieve the flags for a given record buffer.

To summarize, the structure of a record buffer stores the record data, the bookmark, and the bookmark flags, as you can see in [Figure 17.5](#).

**Figure 17.5:** The structure of each buffer of the custom dataset, along with the various local fields referring to its subportions

To access the bookmark and flags, you can use as an offset the size of the data, casting the value to the `PMdRecInfo` pointer type, and then access the proper field of the `TMdRecInfo` structure via the pointer. The two methods used to set and get the bookmark flags demonstrate this technique:

```
procedure TMdCustomDataSet.SetBookmarkFlag (Buffer: PChar;
    Value: TBookmarkFlag);
begin
    PMdRecInfo(Buffer + FRecordSize).BookmarkFlag := Value;
end;

function TMdCustomDataSet.GetBookmarkFlag (Buffer: PChar): TBookmarkFlag;
begin
    Result := PMdRecInfo(Buffer + FRecordSize).BookmarkFlag;
end;
```

The methods you use to set and get a record's current bookmark are similar to the previous two, but they add complexity because you receive a pointer to the bookmark in the `Data` parameter. Casting the value referenced by this pointer to an integer, you obtain the bookmark value:

```
procedure TMdCustomDataSet.GetBookmarkData (Buffer: PChar; Data: Pointer);
begin
    Integer(Data^) := PMdRecInfo(Buffer + FRecordSize).Bookmark;
end;

procedure TMdCustomDataSet.SetBookmarkData (Buffer: PChar; Data: Pointer);
begin
    PMdRecInfo(Buffer + FRecordSize).Bookmark := Integer(Data^);
end;
```

The key bookmark management method is `InternalGotoBookmark`, which your dataset uses to make a given record the current one. This isn't the standard navigation technique—it's much more common to move to the next or previous record (something you can accomplish using the `GetRecord` method presented in the [next section](#)), or to move to the first or last record (something you'll accomplish using the `InternalFirst` and `InternalLast` methods described shortly).

Oddly enough, the `InternalGotoBookmark` method doesn't expect a bookmark parameter, but a pointer to a bookmark, so you must dereference it to determine the bookmark value. You use the following method, `InternalSetToRecord`, to jump to a given bookmark, but it must extract the bookmark from the record buffer passed as a parameter. Then, `InternalSetToRecord` calls `InternalGotoBookmark`. Here are the two methods:

```
procedure TMdCustomDataSet.InternalGotoBookmark (Bookmark: Pointer);
var
    ReqBookmark: Integer;
begin
    ReqBookmark := Integer (Bookmark^);
    if (ReqBookmark >= 0) and (ReqBookmark < InternalRecordCount) then
        FCurrentRecord := ReqBookmark
    else
        raise EMdDataSetError.Create ('Bookmark ' +
            IntToStr (ReqBookmark) + ' not found');
end;

procedure TMdCustomDataSet.InternalSetToRecord (Buffer: PChar);
var
    ReqBookmark: Integer;
begin
    ReqBookmark := PMdRecInfo(Buffer + FRecordSize).Bookmark;
    InternalGotoBookmark (@ReqBookmark);
```

```
end;
```

In addition to the bookmark management methods just described, you use several other navigation methods to move to specific positions within the dataset, such as the first or last record. These two methods don't really move the current record pointer to the first or last record, but move it to one of two special locations before the first record and after the last one. These are not actual records: Borland calls them *cracks*. The beginning-of-file crack, or `BofCrack`, has the value `-1` (set in the `InternalOpen` method), because the position of the first record is zero. The end-of-file crack, or `EofCrack`, has the value of the number of records, because the last record has the position `FRecordCount - 1`. I used two local fields, called `EofCrack` and `BofCrack`, to make this code easier to read:

```
procedure TMdCustomDataSet.InternalFirst;
begin
    FCurrentRecord := BofCrack;
end;
```

```
procedure TMdCustomDataSet.InternalLast;
begin
    EofCrack := InternalRecordCount;
    FCurrentRecord := EofCrack;
end;
```

The `InternalRecordCount` method is a virtual method introduced in my `TMdCustomDataSet` class, because different datasets can either have a local field for this value (as in case of the stream-based dataset, which has an `FRecordCount` field) or compute it on the fly.

Another group of optional methods is used to get the current record number (used by the `DBGrid` component to show a proportional vertical scroll bar), set the current record number, or determine the number of records. These methods are easy to understand, if you recall that the range of the internal `FCurrentRecord` field is from 0 to the number of records minus 1. In contrast, the record number reported to the system ranges from 1 to the number of records:

```
function TMdCustomDataSet.GetRecordCount: Longint;
begin
    CheckActive;
    Result := InternalRecordCount;
end;
```

```
function TMdCustomDataSet.GetRecNo: Longint;
begin
    UpdateCursorPos;
    if FCurrentRecord < 0 then
        Result := 1
    else
        Result := FCurrentRecord + 1;
end;
```

```
procedure TMdCustomDataSet.SetRecNo(Value: Integer);
begin
    CheckBrowseMode;
    if (Value > 1) and (Value <= FRecordCount) then
        begin
            FCurrentRecord := Value - 1;
            Resync([]);
        end;
end;
```

Notice that the generic custom dataset class implements all the methods of this section. The derived stream-based dataset doesn't need to modify any of them.

## Section III: Record Buffers and Field Management

Now that we've covered all the support methods, let's examine the core of a custom dataset. In addition to opening and creating records and moving around between them, the component needs to move the data from the stream (the persistent file) to the record buffers, and from the record buffers to the `TField` objects that are connected to the data-aware controls. The management of record buffers is complex, because each dataset also needs to allocate, empty, and free the memory it requires:

```
function TmCustomDataSet.AllocRecordBuffer: PChar;
begin
    GetMem (Result, FRecordBufferSize);
end;

procedure TmCustomDataSet.FreeRecordBuffer (var Buffer: PChar);
begin
    FreeMem (Buffer);
end;
```

You allocate memory this way because a dataset generally adds more information to the record buffer, so the system has no way of knowing how much memory to allocate. Notice that in the `AllocRecordBuffer` method, the component allocates the memory for the record buffer, including both the database data and the record information. In the `InternalOpen` method, I wrote the following:

```
FRecordBufferSize := InternalRecordSize + sizeof (TmRecInfo);
```

The component also needs to implement a function to reset the buffer (`InternalInitRecord`), usually filling it with numeric zeros or spaces.

Oddly enough, you must also implement a method that returns the size of each record, but only the data portion—not the entire record buffer. This method is necessary for implementing the read-only `RecordSize` property, which is used only in a couple of peculiar cases in the entire VCL source code. In the generic custom dataset, the `GetRecordSize` method returns the value of the `FRecordSize` field.

Now we've reached the core of the custom dataset component. The methods in this group are `GetRecord`, which reads data from the file; `InternalPost` and `InternalAddRecord`, which update or add new data to the file; and `InternalDelete`, which removes data and is not implemented in the sample dataset.

The most complex method of this group is `GetRecord`, which serves multiple purposes. The system uses this method to retrieve the data for the current record, fill a buffer passed as a parameter, and retrieve the data of the next or previous records. The `GetMode` parameter determines its action:

```
type
    TGetMode = (gmCurrent, gmNext, gmPrior);
```

Of course, a previous or next record might not exist. Even the current record might not exist—for example, when the table is empty (or in case of an internal error). In these cases you don't retrieve the data but return an error code. Therefore, this method's result can be one of the following values:

```
type
    TGetResult = (grOK, grBOF, grEOF, grError);
```

Checking to see if the requested record exists is slightly different than you might expect. You don't have to determine if the current record is in the proper range, only if the requested record is. For example, in the `gmCurrent` branch of the case statement, you use the standard expression `CurrentRecord >= InternalRecordCount`. To fully understand the various cases, you might want to read the code a couple of times.

It took me some trial and error (and system crashes caused by recursive calls) to get the code straight when I wrote my first custom dataset a few years back. To test it, consider that if you use a `DBGrid`, the system will perform a series of `GetRecord` calls, until either the grid is full or `GetRecord` return `grEOF`. Here's the entire code for the `GetRecord`

method:

```
// III: Retrieve data for current, previous, or next record
// (moving to it if necessary) and return the status
function TmdCustomDataSet.GetRecord(Buffer: PChar;
  GetMode: TGetMode; DoCheck: Boolean): TGetResult;
begin
  Result := grOK; // default
  case GetMode of
    gmNext: // move on
      if FCurrentRecord < InternalRecordCount - 1 then
        Inc (FCurrentRecord)
      else
        Result := grEOF; // end of file
    gmPrior: // move back
      if FCurrentRecord > 0 then
        Dec (FCurrentRecord)
      else
        Result := grBOF; // begin of file
    gmCurrent: // check if empty
      if FCurrentRecord >= InternalRecordCount then
        Result := grError;
  end;
  // load the data
  if Result = grOK then
    InternalLoadCurrentRecord (Buffer)
  else if (Result = grError) and DoCheck then
    raise EMdDataSetError.Create ('GetRecord: Invalid record');
end;
```

If there's an error and the DoCheck parameter was True, GetRecord raises an exception. If everything goes fine during record selection, the component loads the data from the stream, moving to the position of the current record (given by the record size multiplied by the record number). In addition, you need to initialize the buffer with the proper bookmark flag and bookmark (or record number) value. This is accomplished by another virtual method I introduced, so that derived classes will only need to implement this portion of the code, while the complex GetRecord method remains unchanged:

```
procedure TmdDataSetStream.InternalLoadCurrentRecord (Buffer: PChar);
begin
  FStream.Position := FDataFileHeaderSize + FRecordSize * FCurrentRecord;
  FStream.ReadBuffer (Buffer^, FRecordSize);
  with PMdRecInfo(Buffer + FRecordSize)^ do
    begin
      BookmarkFlag := bfCurrent;
      Bookmark := FCurrentRecord;
    end;
end;
```

You move data to the file in two different cases: when you modify the current record (that is, a post after an edit) or when you add a new record (a post after an insert or append). You use the InternalPost method in both cases, but you can check the dataset's State property to determine which type of post you're performing. In both cases, you don't receive a record buffer as a parameter; so, you must use the ActiveRecord property of TDataSet, which points to the buffer for the current record:

```
procedure TmdDataSetStream.InternalPost;
begin
  CheckActive;
  if State = dsEdit then
```

```

begin
    // replace data with new data
    FStream.Position := FDataFileHeaderSize + FRecordSize * FCurrentRecord;
    FStream.WriteBuffer (ActiveBuffer^, FRecordSize);
end
else
begin
    // always append
    InternalLast;
    FStream.Seek (0, soFromEnd);
    FStream.WriteBuffer (ActiveBuffer^, FRecordSize);
    Inc (FRecordCount);
end;
end;

```

In addition, there's another related method: `InternalAddRecord`. This method is called by the `AddRecord` method, which in turn is called by `InsertRecord` and `AppendRecord`. These last two are public methods a user can call. This is an alternative to inserting or appending a new record to the dataset, editing the values of the various fields, and then posting the data, because the `InsertRecord` and `AppendRecord` calls receive the values of the fields as parameters. All you must do at that point is replicate the code used to add a new record in the `InternalPost` method:

```

procedure TMDDataSetOne.InternalAddRecord(Buffer: Pointer; Append: Boolean);
begin
    // always append at the end
    InternalLast;
    FStream.Seek (0, soFromEnd);
    FStream.WriteBuffer (ActiveBuffer^, FRecordSize);
    Inc (FRecordCount);
end;

```

I should also have implemented a file operation that removes the current record. This operation is common, but it is complex. If you take a simple approach, such as creating an empty spot in the file, then you'll need to keep track of that spot and make the code for reading or writing a specific record work around that location. An alternate solution is to make a copy of the entire file without the given record and then replace the original file with the copy. Given these choices, I felt that for this example I could forgo supporting record deletion.

## Section IV: From Buffers to Fields

In the last few methods, you've seen how datasets move data from the data file to the memory buffer. However, there's little Delphi can do with this record buffer, because it doesn't yet know how to interpret the data in the buffer. You need to provide two more methods: `GetData`, which copies the data from the record buffer to the field objects of the dataset, and `SetData`, which moves the data back from the fields to the record buffer. Delphi will automatically move the data from the field objects to the data-aware controls and back.

The code for these two methods isn't difficult, primarily because you saved the field offsets inside the record data in a `TList` object called `FFieldOffset`. By incrementing the pointer to the initial position in the record buffer of the current field's offset, you can get the specific data, which takes `Field.DataSize` bytes.

A confusing element of these two methods is that they both accept a `Field` parameter and a `Buffer` parameter. At first, you might think the buffer passed as a parameter is the record buffer. However, I found out that the `Buffer` is a pointer to the field object's raw data. If you use one of the field object's methods to move that data, it will call the dataset's `GetData` or `SetData` method, probably causing an infinite recursion. Instead, you should use the `ActiveBuffer` pointer to access the record buffer, use the proper offset to get to the data for the current field in the record buffer, and then use the provided `Buffer` to access the field data. The only difference between the two methods is the direction you move the data:

```

function TmDataSetOne.GetFieldData (Field: TField; Buffer: Pointer): Boolean;
var
    FieldOffset: Integer;
    Ptr: PChar;
begin
    Result := False;
    if not IsEmpty and (Field.FieldNo > 0) then
        begin
            FieldOffset := Integer (FFieldOffset [Field.FieldNo - 1]);
            Ptr := ActiveBuffer;
            Inc (Ptr, FieldOffset);
            if Assigned (Buffer) then
                Move (Ptr^, Buffer^, Field.DataSize);
            Result := True;
            if (Field is TDateTimeField) and (Integer(Ptr^) = 0) then
                Result := False;
            end;
        end;

procedure TmDataSetOne.SetFieldData(Field: TField; Buffer: Pointer);
var
    FieldOffset: Integer;
    Ptr: PChar;
begin
    if Field.FieldNo >= 0 then
        begin
            FieldOffset := Integer (FFieldOffset [Field.FieldNo - 1]);
            Ptr := ActiveBuffer;
            Inc (Ptr, FieldOffset);
            if Assigned (Buffer) then
                Move (Buffer^, Ptr^, Field.DataSize)
            else
                raise Exception.Create (
                    'Very bad error in TmDataSetStream.SetField data');
                DataEvent (deFieldChange, Longint(Field));
            end;
        end;

```

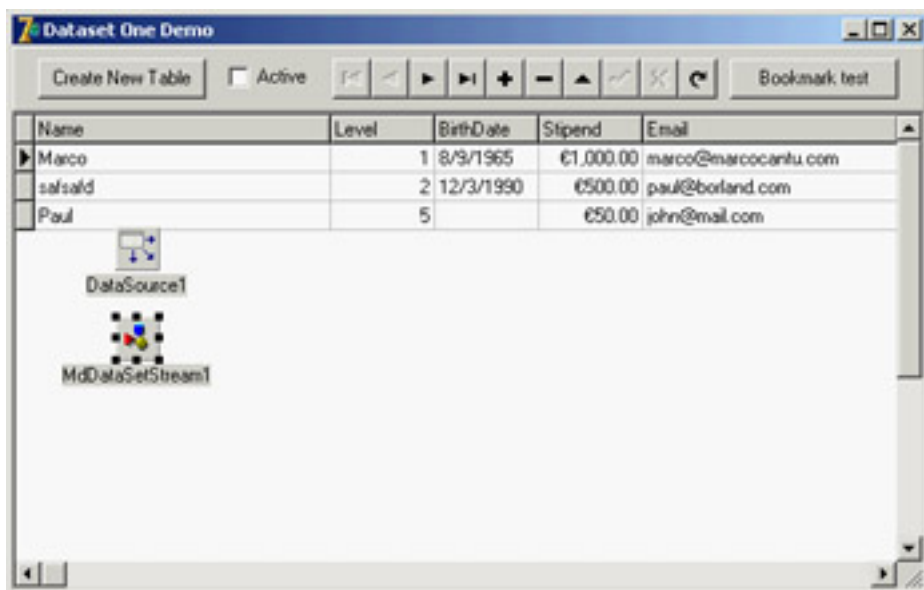

The `GetField` method should return `True` or `False` to indicate whether the field contains data or is empty (a null field, to be more precise). However, unless you use a special marker for blank fields, it's difficult to determine this condition, because you're storing values of different data types. For example, a test such as `Ptr^<>#0` makes sense only if you are using a string representation for all the fields. If you use this test, zero integer values and empty strings will show as null values (the data-aware controls will be empty), which may be what you want. The problem is that `Boolean False` values won't show up. Even worse, floating-point values with no decimals and few digits won't be displayed, because the exponent portion of their representation will be zero. However, to make this example work, I had to consider as empty each date/time field with an initial zero. Without this code, Delphi tries to convert the illegal *internal* zero date (internally, date fields don't use a `TDateTime` data type but a different representation), raising an exception. The code used to work with past versions of Delphi.

**Warning** While trying to fix this problem, I also found out that if you call `IsNull` for a field, this request is resolved by calling `GetFieldData` without passing any buffer to fill but looking only for the result of the function call. This is the reason for the `if Assigned (Buffer)` test within the code.

There's one final method, which doesn't fall into any category: `InternalHandleException`. Generally, this method silences the exception, because it is activated only at design time.

## Testing the Stream-Based DataSet

After all this work, you're ready to test an application example of the custom dataset component, which is installed in the component's package for this chapter. The form displayed by the StreamDSDemo program is simple, as you can see in [Figure 17.6](#). It has a panel with two buttons, a check box, and a navigator component, plus a DBGrid filling its client area.

**Figure 17.6:** The form of the StreamDSDemo example. The custom dataset has been activated, so you can already see the data at design time.

[Figure 17.6](#) shows the example's form at design time, but I activated the custom dataset so that its data is visible. I already prepared the INI file with the table definition (the file listed earlier when discussing the dataset initialization), and I executed the program to add some data to the file.

You can also modify the form using Delphi's Fields editor and set the properties of the various field objects. Everything works as it does with one of the standard dataset controls. However, to make this work, you must enter the name of the custom dataset's file in the `TableName` property, using the complete path.

**Warning** The demo program defines the absolute path of the table file at design time, so you'll need to fix it if you copy the examples to a different drive or directory. In the example, the `TableName` property is used only at design time. At run time, the program looks for the table in the current directory.

The example code is simple, especially compared to the custom dataset code. If the table doesn't exist yet, you can click the Create New Table button:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
    MdDataSetStream1.CreateTable;
    MdDataSetStream1.Open;
    CheckBox1.Checked := MdDataSetStream1.Active;
end;
```

You create the file first, opening and closing it within the `CreateTable` call, and then open the table. This is the same behavior as the `TTable` component (which accomplishes this step using the `CreateTable` method). To open or close the table, you can click the check box:

```
procedure TForm1.CheckBox1Click(Sender: TObject);
begin
    MdDataSetStream1.Active := CheckBox1.Checked;
end;
```

Finally, I created a method that tests the custom dataset's bookmark management code (it works).

## A Directory in a Dataset

An important idea related to datasets in Delphi is that they represent a set of data, regardless of where this data comes from. A SQL server and a local file are examples of traditional datasets, but you can use the same technology to show a list of a system's users, a list of a folder's files, the properties of objects, XML-based data, and so on.

As an example, the second dataset presented in this chapter is a list of files. I've built a generic dataset based on a list of objects in memory (using a `TObjectList`), and then derived a version in which the objects correspond to a folder's files. The example is simplified by the fact that it is a read-only dataset, so you might find it more straightforward than the previous dataset.

**Note** Some of the ideas presented here were discussed in an article I wrote for the Borland Community website, published in June 2000 at the URL [bdn.borland.com/article/0,1410,20587,00.html](http://bdn.borland.com/article/0,1410,20587,00.html).

## A List as a Dataset

The generic list-based dataset is called `TMDListDataSet` and contains the list of objects, a list that is created when you open the dataset and freed when you close it. This dataset doesn't store the record data within the buffer; rather, it saves in the buffer only the position in the list of the entry corresponding to the record's data. This is the class definition:

```
type
  TMDListDataSet = class (TMDCustomDataSet)
  protected
    // the list holding the data
    FList: TObjectList;
    // dataset virtual methods
    procedure InternalPreOpen; override;
    procedure InternalClose; override;
    // custom dataset virtual methods
    function InternalRecordCount: Integer; override;
    procedure InternalLoadCurrentRecord (Buffer: PChar); override;
  end;
```

You can see that by writing a generic custom data class, you can override a few virtual methods of the `TDataSet` class and of this custom dataset class, and have a working dataset (although this is still an abstract class, which requires extra code from subclasses to work). When the dataset is opened, you have to create the list and set the record size, to indicate you're saving the list index in the buffer:

```
procedure TMDListDataSet.InternalPreOpen;
begin
  FList := TObjectList.Create (True); // owns the objects
  FRecordSize := 4; // an integer, the list item id
end;
```

Further derived classes at this point should also fill the list with objects.

**Tip** Like the `ClientDataSet`, my list dataset keeps its data in memory. However, using some smart techniques, you can also create a list of fake objects and then load the actual objects only when you are accessing them.

Closing is a matter of freeing the list, which has a record count corresponding to the list size:

```
function TMDListDataSet.InternalRecordCount: Integer;
begin
  Result := fList.Count;
end;
```

The only other method saves the current record's data in the record buffer, including the bookmark information. The core data is the position of the current record, which matches the list index (and also the bookmark):

```
procedure TMdListDataSet.InternalLoadCurrentRecord (Buffer: PChar);  
begin  
  PInteger (Buffer)^ := fCurrentRecord;  
  with PMdRecInfo(Buffer + FRecordSize)^ do  
    begin  
      BookmarkFlag := bfCurrent;  
      Bookmark := fCurrentRecord;  
    end;  
end;
```

## Directory Data

The derived directory dataset class has to provide a way to load the objects in memory when the dataset is opened, to define the proper fields, and to read and write the value of those fields. It also has a property indicating the directory to work on—or, to be more precise, the directory plus the file mask used for filtering the files (such as `c:\docs\*.txt`):

```
type  
  TMdDirDataset = class(TMdListDataSet)  
    private  
      FDirectory: string;  
      procedure SetDirectory(const NewDirectory: string);  
    protected  
      // TDataSet virtual methods  
      procedure InternalInitFieldDefs; override;  
      procedure SetFieldData(Field: TField; Buffer: Pointer); override;  
      function GetCanModify: Boolean; override;  
      // custom dataset virtual methods  
      procedure InternalAfterOpen; override;  
    public  
      function GetFieldData(Field: TField; Buffer: Pointer): Boolean; override;  
    published  
      property Directory: string read FDirectory write SetDirectory;  
    end;
```

The `GetCanModify` function is another virtual method of `TDataSet`, used to determine if the dataset is read-only. In this case, it returns `False`. You don't have to write any code for the `SetFieldData` procedure, but you must define it because it is an abstract virtual method.

Because you are dealing with a list of objects, the unit includes a class for those objects. In this case, the file data is extracted from a `TSearchRec` buffer by the `TFileData` class constructor:

```
type  
  TFileData = class  
    public  
      ShortFileName: string;  
      Time: TDateTime;  
      Size: Integer;  
      Attr: Integer;  
      constructor Create (var FileInfo: TSearchRec);  
    end;  
  
constructor TFileData.Create (var FileInfo: TSearchRec);  
begin  
  ShortFileName := FileInfo.Name;  
  Time := FileDateToDateTime (FileInfo.Time);
```

```

Size := FileInfo.Size;
Attr := FileInfo.Attr;
end;

```

This constructor is called for each folder while opening the dataset:

```

procedure TMdDirDataset.InternalAfterOpen;
var
  Attr: Integer;
  FileInfo: TSearchRec;
  FileData: TFileData;
begin
  // scan all files
  Attr := faAnyFile;
  FList.Clear;
  if SysUtils.FindFirst(fDirectory, Attr, FileInfo) = 0 then
  repeat
    FileData := TFileData.Create (FileInfo);
    FList.Add (FileData);
  until SysUtils.FindNext(FileInfo) <> 0;
  SysUtils.FindClose(FileInfo);
end;

```

The next step is to define the fields of the dataset, which in this case are fixed and depend on the available directory data:

```

procedure TMdDirDataset.InternalInitFieldDefs;
begin
  if fDirectory = '' then
    raise EMdDataSetError.Create ('Missing directory');

  // field definitions
  FieldDefs.Clear;
  FieldDefs.Add ('FileName', ftString, 40, True);
  FieldDefs.Add ('TimeStamp', ftDateTime);
  FieldDefs.Add ('Size', ftInteger);
  FieldDefs.Add ('Attributes', ftString, 3);
  FieldDefs.Add ('Folder', ftBoolean);
end;

```

Finally, the component has to move the data from the list object referenced by the current record buffer (the `ActiveBuffer` value) to each field of the dataset, as requested by the `GetFieldData` method. This function uses either `Move` or `StrCopy`, depending on the data type, and it does some conversions for the attribute codes (*H* for hidden, *R* for read-only, and *S* for system) extracted from the related flags and used to determine whether a file is a folder. Here is the code:

```

function TMdDirDataset.GetFieldData (Field: TField; Buffer: Pointer): Boolean;
var
  FileData: TFileData;
  Bool1: WordBool;
  strAttr: string;
  t: TDateTimeRec;
begin
  FileData := fList [Integer(ActiveBuffer^)] as TFileData;
  case Field.Index of
    0: // filename
      StrCopy (Buffer, pchar(FileData.ShortFileName));
    1: // timestamp

```

```

begin
  t := DateTimeToNative (ftdatetime, FileData.Time);
  Move (t, Buffer^, sizeof (TDateTime));
end;
2: // size
  Move (FileData.Size, Buffer^, sizeof (Integer));
3: // attributes
begin
  strAttr := '   ';
  if (FileData.Attr and SysUtils.faReadOnly) > 0 then
    strAttr [1] := 'R';
  if (FileData.Attr and SysUtils.faSysFile) > 0 then
    strAttr [2] := 'S';
  if (FileData.Attr and SysUtils.faHidden) > 0 then
    strAttr [3] := 'H';
  StrCopy (Buffer, pchar(strAttr));
end;
4: // folder
begin
  Bool1 := FileData.Attr and SysUtils.faDirectory > 0;
  Move (Bool1, Buffer^, sizeof (WordBool));
end;
end; // case
Result := True;
end;

```

The tricky part in writing this code was figuring out the internal format of dates stored in date/time fields. This is not the common TDateTime format used by Delphi, and not even the internal TTimeStamp, but what is internally called the *native date and time format*. I've written a conversion function by cloning one I found in the VCL code for the date/time fields:

```

function DateTimeToNative(DataType: TFieldType; Data: TDateTime): TDateTimeRec;
var
  TimeStamp: TTimeStamp;
begin
  TimeStamp := DateTimeToTimeStamp(Data);
  case DataType of
    ftDate: Result.Date := TimeStamp.Date;
    ftTime: Result.Time := TimeStamp.Time;
  else
    Result.DateTime := TimeStampToMsecs(TimeStamp);
  end;
end;

```

With this dataset available, building the demo program (shown in [Figure 17.7](#)) was just a matter of connecting a DBGrid component to the dataset and adding a folder-selection component, the sample ShellTreeView control. This control is set up to work only on files, by setting its Root property to C:\. When the user selects a new folder, the OnChange event handler of the ShellTreeView control refreshes the dataset:

```

procedure TForm1.ShellTreeView1Change(Sender: TObject; Node: TTreeNode);
begin
  MdDirDataset1.Close;
  MdDirDataset1.Directory := ShellTreeView1.Path + '\*.*';
  MdDirDataset1.Open;
end;

```

FileName	TimeStamp	Size	Attributes	Folder
.	9/19/2002 13:49:18 AM			True
..	9/19/2002 13:49:18 AM			True
delphi32.bpl	8/9/2002 2:30:00 PM	14,272		False
delphi32.exe	8/9/2002 2:30:00 PM	545,792		False
DELPHI32.BCF	8/9/2002 2:30:00 PM	6,644		False
delphi32.dac	9/14/2002 6:28:32 PM	3,742		False
delphi32.dcl	8/9/2002 4:30:00 PM	66,560		False
delphi32.exe_80_70.bpl	8/9/2002 4:30:00 PM	140,256		False
TIIDelphi32.dac	8/9/2002 4:30:00 PM	4,449		False
Delphi.vpp	8/9/2002 4:30:00 PM	3,320		False
ETH1-arcoc.dcl	8/9/2002 4:30:00 PM	18,796		False
ETH2.dcl	8/9/2002 4:30:00 PM	19,340		False
ETH3.2.dcl	8/9/2002 4:30:00 PM	21,076		False
ETH.lan1.exe	8/9/2002 4:30:00 PM	11,564		False
ETH-special.exe	8/9/2002 4:30:00 PM	4,114		False
ETH-special.exe	8/9/2002 4:30:00 PM	14,447		False

**Figure 17.7:** The output of the DirDemo example, which uses an unusual dataset that shows directory data

**Warning** If your version of Windows has problems with the sample shell controls available in Delphi, you can use the DirDemoNoShell version of the example, which uses the old-fashioned Windows 3.1-compatible Delphi file controls.

## A Dataset of Objects

As you saw in the previous example, a list of objects is conceptually similar to the rows of a table in a dataset. In Delphi, you can build a dataset wrapping a list of objects, as in the case of the `TFileData` class. It's intriguing to extend this example to build a dataset that supports generic objects, which you can do thanks to the extended RTTI available in Delphi.

This dataset component inherits from `TMDListDataSet`, as in the previous example. You must provide a single setting: the target class, stored in the `ObjClass` property (see the complete definition of the `TMdObjDataSet` class in [Listing 17.5](#)).

### Listing 17.5: The Complete Definition of the *TMdObjDataSet* Class

```

type
  TMdObjDataSet = class(TMDListDataSet)
  private
    PropList: PPropList;
    nProps: Integer;
    FObjClass: TPersistentClass;
    ObjClone: TPersistent;
    FChangeToClone: Boolean;
    procedure SetObjClass (const Value: TPersistentClass);
    function GetObjects (I: Integer): TPersistent;
    procedure SetChangeToClone (const Value: Boolean);
  protected
    procedure InternalInitFieldDefs; override;
    procedure InternalClose; override;
    procedure InternalInsert; override;
    procedure InternalPost; override;
    procedure InternalCancel; override;
    procedure InternalEdit; override;
    procedure SetFieldData(Field: TField; Buffer: Pointer); override;
    function GetCanModify: Boolean; override;
    procedure InternalPreOpen; override;
  public
    function GetFieldData(Field: TField; Buffer: Pointer): Boolean; override;
    property Objects [I: Integer]: TPersistent read GetObjects;
    function Add: TPersistent;
  published
    property ObjClass: TPersistentClass read FObjClass write SetObjClass;
    property ChangesToClone: Boolean read FChangeToClone
      write SetChangeToClone default False;
  end;

```

The class is used by the `InternalInitFieldDefs` method to determine the dataset fields based on the published properties of the target class, which are extracted using RTTI:

```

procedure TMdObjDataSet.InternalInitFieldDefs;
var
  i: Integer;
begin
  if FObjClass = nil then
    raise Exception.Create ('TMdObjDataSet: Unassigned class');

  // field definitions

```

```

FieldDefs.Clear;
nProps := GetTypeData(fObjClass.ClassInfo)^.PropCount;
GetMem(PropList, nProps * SizeOf(Pointer));
GetPropInfos (fObjClass.ClassInfo, PropList);

for i := 0 to nProps - 1 do
  case PropList [i].PropType^.Kind of
    tkInteger, tkEnumeration, tkSet:
      FieldDefs.Add (PropList [i].Name, ftInteger, 0);
    tkChar: FieldDefs.Add (PropList [i].Name, ftFixedChar, 0);
    tkFloat: FieldDefs.Add (PropList [i].Name, ftFloat, 0);
    tkString, tkLString:
      FieldDefs.Add (PropList [i].Name, ftString, 50); // TODO: fix size
    tkWString: FieldDefs.Add (PropList [i].Name, ftWideString, 50);
      // TODO: fix size
  end;
end;

```

Similar RTTI-based code is used in the `GetFieldData` and `SetFieldData` methods to access the properties of the current object when a dataset field access operation is requested. The huge advantage in using properties to access the dataset data is that read and write operations can be mapped directly to data but also use the corresponding method. This way, you can write the *business rules* of your application by implementing rules in the read and write methods of the properties—definitely a sounder OOP approach than hooking code to field objects and validating them.

Here is a slightly simplified version of `GetFieldData` (the other method is symmetric):

```

function TObjDataSet.GetFieldData (
  Field: TField; Buffer: Pointer): Boolean;
var
  Obj: TPersistent;
  TypeInfo: PTypeInfo;
  IntValue: Integer;
  FlValue: Double;
begin
  if FList.Count = 0 then
    begin
      Result := False;
      exit;
    end;
  Obj := fList [Integer(ActiveBuffer^)] as TPersistent;
  TypeInfo := PropList [Field.FieldNo-1]^ .PropType^;
  case TypeInfo.Kind of
    tkInteger, tkChar, tkWChar, tkClass, tkEnumeration, tkSet:
      begin
        IntValue := GetOrdProp(Obj, PropList [Field.FieldNo-1]);
        Move (IntValue, Buffer^, sizeof (Integer));
      end;
    tkFloat:
      begin
        FlValue := GetFloatProp(Obj, PropList [Field.FieldNo-1]);
        Move (FlValue, Buffer^, sizeof (Double));
      end;
    tkString, tkLString, tkWString:
      StrCopy (Buffer, pchar(GetStrProp(Obj, PropList [Field.FieldNo-1])));
  end;
  Result := True;
end;

```

This pointer-based code may look terrible, but if you've endured the discussion of the technical details of developing a custom dataset, it won't add much complexity to the picture. It uses some of the data structures defined (and briefly commented) in the `TTypeInfo` unit, which should be your reference for any questions about the previous code.

Using this naïve approach of editing the object's data directly, you might wonder what happens if a user cancels the editing operation (something Delphi generally accounts for). My dataset provides two alternative approaches, controlled by the `ChangesToClone` property and based on the idea of cloning objects by copying their published properties. The core `DoClone` procedure uses RTTI code similar to what you have already seen to copy all the published data of an object into another object, creating an effective copy (or a clone).

This cloning takes place in both cases. Depending on the value of the `ChangesToClone` property, either the edit operations are performed on the clone object, which is then copied over the actual object during the Post operation; or the edit operations are performed on the actual object, and the clone is used to get back the original values if editing terminates with a Cancel request. This is the code of the three methods involved:

```
procedure TObjDataSet.InternalEdit;
begin
    DoClone (fList [FCurrentRecord] as TDbPers, ObjClone);
end;

procedure TObjDataSet.InternalPost;
begin
    if FChangeToClone and Assigned (ObjClone) then
        DoClone (ObjClone, TDbPers (fList [fCurrentRecord]));
end;

procedure TMdObjDataSet.InternalCancel;
begin
    if not FChangeToClone and Assigned (ObjClone) then
        DoClone (ObjClone, TPersistent(fList [fCurrentRecord]));
end;
```

In the `SetFieldData` method, you have to modify either the cloned object or the original instance. To make things more complicated, you must also consider this difference in the `GetFieldData` method: If you are reading fields from the current object, you might have to use its modified clone (otherwise, the user's changes to other fields will disappear).

As you can see in [Listing 17.5](#), the class also has an `Objects` array that accesses the data in an OOP way and an `Add` method that's similar to the `Add` method of a collection. By calling `Add`, the code creates a new empty object of the target class and adds it to the internal list:

```
function TMdObjDataSet.Add: TPersistent;
begin
    if not Active then
        Open;
    Result := fObjClass.Create;
    fList.Add (Result);
end;
```

To demonstrate the use of this component, I wrote the `ObjDataSetDemo` example. It has a demo target class with a few fields and buttons to create objects automatically, as you can see in [Figure 17.8](#). The most interesting feature of the program, however, is something you have to try for yourself. Run the program and look at the `DbGrid` columns. Then edit the target class, `TDemo`, adding a new published property to it. Run the program again, and the grid will include a new column for the property.

The screenshot shows a window titled "ObjDataSetDemo" with a toolbar containing buttons for "Add Object", "Descriptions", and navigation controls. Below the toolbar is a table with the following data:

Name	Age	Amount	Value
John	21	3242.43	12
Mark	33	6716.54	32
Joseph	28	3722.38	33
Bill	24	4747.94	23
John	62	597.24	14

Figure 17.8: The ObjDataSet-Demo example showcases a dataset mapped to objects using RTTI.

## What's Next?

In this chapter we've delved into Delphi's database architecture by first examining the development of data-aware controls and then studying the internals of the `TDataSet` class to write a couple of custom dataset components. With this information and the other ideas presented in this part of the book, you should be able to choose the architecture of your database applications, depending on your needs.

Database programming is a core element of Delphi, which is why I've devoted several chapters to this topic. I'll continue to cover it in the [next chapter](#), which is devoted to the new reporting engine available in Delphi 7. We'll get back to databases when focusing on presenting data over the Web in [Chapters 20](#) and [21](#), and also when discussing XML and SOAP in [Chapters 22](#) and [23](#).

## Chapter 18: Reporting with Rave

### Overview

Database applications let you view and edit data, but quite often their output should be physically printed to paper. Technically, Delphi supports printing in many different ways, from direct text output to the use of the printer `Canvas`, from sophisticated database reporting to the generation of documents in various formats (from Microsoft's Word to Sun's OpenOffice). In this chapter we'll focus exclusively on reports and in particular on the use of the third-party reporting Rave engine included in Delphi 7. If you are interested in other Delphi techniques for driving the printer, see the related material on my website (discussed in [Appendix C](#), "Free Companion Books on Delphi").

Reporting tools are important because they can perform complex processing by themselves: the reporting subsystem can become a stand-alone application. Although this chapter focuses on how you can produce a report from the dataset within your Delphi programs, you should always keep in mind the autonomous nature of reports evaluating such a tool.

Reports must be created with care, because they represent a user interface for your applications that goes beyond and is sometimes more significant than the software itself. Many more people will probably look at the printed reports than just the users who produce the reports using the programs. For this reason, it's important to have good-quality reports and a flexible architecture to let users customize them.

**Note** This chapter was written with the help of Jim Gunkel of Nevrona Designs, the company that developed the Rave engine.

## Introducing Rave

Reports are a primary means of retrieving information from the data being managed by an application. To solve the problems associated with presenting a visual report of data in a meaningful and informative manner, traditional visual reporting applications have offered banded layout tools geared toward table-style data listings. Today, however, more complex reporting requirements exist that are not easily handled by banded layout tools.

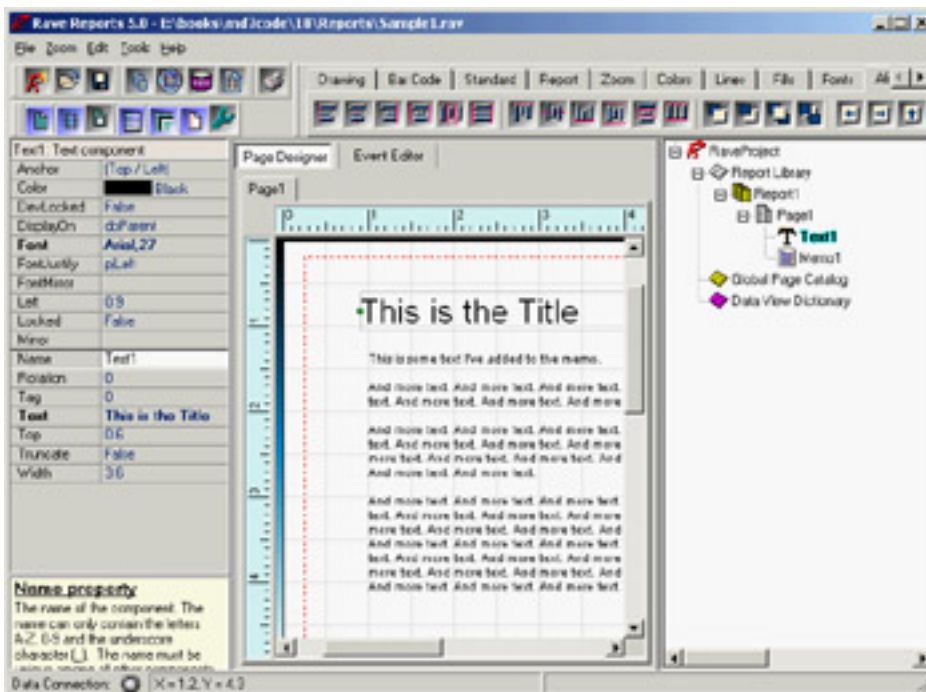

Rave Reports is a visual report design environment offering many unique features that help make the reporting process simpler, quicker, and more efficient. Rave can handle a wide variety of report formats and includes advanced technologies such as mirroring, to encourage the reuse of report contents for quicker changes and easier maintenance.

This chapter presents a brief introduction to Rave's features. Additional information about Rave can be found in the online Help files, in the PDF documentation on Delphi's CD, in several demo projects, and on the producer's website, [www.nevrona.com](http://www.nevrona.com).

**Note** A key feature of Rave—and one of the reasons Borland chose it over other solutions—is that it is a completely cross-platform solution you can use on both Windows and Linux. Not only do Rave components integrate with both the VCL and CLX, but the Rave Designer is itself a cross-platform application written in CLX.

## Rave: The Report Authoring Visual Environment

To start the Rave visual report design environment, double-click on a `TRvProject` component dropped on a form or select `Tools` → `Rave Designer` in the Delphi IDE. When you activate this environment, you'll see a window like that shown in [Figure 18.1](#). As you can see, the Rave Designer includes several sections: the Page Designer, Event Editor, Property panel, Project Tree panel, toolbars, Toolbar Palette, and status bar.

**Figure 18.1:** The Rave Designer with a simple report

**Note** Any time you want to see the result of your efforts, press F9 in the Rave Designer for a preview of the current report.

Keep in mind that Rave allows your end users to create or modify their own reports. You can set the Rave Designer level to Beginner, Intermediate, or Advanced in the `Edit` → `Preferences` dialog box (in the `Environment` section) so your

end users will be working at the level they're comfortable with and won't have more power than you want to give them. You can also lock features of the report so they cannot be modified.

## Page Designer and Event Editor

The central portion of the Rave Designer window hosts the Page Designer (where you lay out the report) and the Event Editor (where you can provide scripts to customize the report at run time).

The Page Designer is the most noticeable aspect of Rave. This page is the foundation of a report, where you perform all the designing actions. The page displays a grid pattern, although you can change the look and feel of the page with the preference settings. The names of the current pages being designed appear in the tabs above the Page Designer (*Page1* in the figure).

The Event Editor allows you to define custom scripting code for the report components. Each component has several different types of events that can be used for calculations, string manipulation, or custom report logic. The Event Editor is an advanced feature of Rave; I'll cover it briefly at the end of this chapter.

## The Property Panel

The Property panel at left in the Rave Designer helps you customize the way components appear or behave. This panel has a role similar to that of Delphi's Object Inspector: When a component is selected on the page, the Property panel reflects the selection by displaying the different properties associated with that component. If no component is selected, the Property panel is blank.

Also as in the Delphi IDE, you can change a property value by editing the contents of the edit box, selecting an option from a drop-down list, or bringing up an editor dialog. You can double-click on any property that has a list of choices (instead of clicking on the down arrow button and selecting the option) to advance to the next item in the list.

## The Project Tree Panel

The Project Tree panel on the right side of the designer is very informative. It also provides an easy way to navigate a report project's structure. The Project Tree contains three main nodes: Report Library, Global Page Catalog, and Data View Dictionary:

**Report Library** Contains all the reports within the project. Each report has one or more pages. Each of those pages will normally include one or more components.

**Global Page Catalog** Manages reporting templates. The reporting templates can contain one or more components and can then be reused via Rave's mirroring technology. They can include items such as letter headings and footers, pre-printed forms, watermark designs, or complete page definitions that can be the foundation for other reports. You can think of the Global Page Catalog as a repository—a central location for you to store reporting items you want to be able to access from multiple reports.

**Data View Dictionary** Defines all the data views and other data-related objects for reports.

## Toolbars and the Toolbar Palette

As in Delphi, Rave includes two types of toolbars: component toolbars and IDE toolbars. However, unlike in Delphi (which uses the tabbed Component Palette exclusively for components), in Rave you can place either type of toolbar in the open area at the top of the designer or dock them in the tabbed Toolbar Palette. At first this process can be confusing, but after you arrange the toolbars to suit your needs (using the Dock and Undock shortcut menu commands, and not by dragging them as you'd expect) you'll probably find it quite flexible.

The default component toolbars in Rave are Standard, Drawing, Report, and Bar Code. I'll describe the component toolbars in more detail later in this chapter. For the moment, suffice to say that other component toolbars may be present if you've installed add-on packages in the Rave Designer, and that components can be rearranged in the

toolbars.

Editor toolbars have the ability to change or modify the project or existing components. Here is summary of the commands they host:

**Project Toolbar** Similar to a component toolbar, because it lets you create new report, page, and data object components in the report project. The Project toolbar can also be used to create new report projects, save and load existing report projects, and send the current report to the printer or preview.

**Alignment Toolbar** Has numerous tools for aligning and positioning components on a page. The first component selected often determines the benchmark for an alignment operation. You can change the printing order of components using the order buttons: Move Forward, Move Behind, Bring to Front, and Send to Back. The tap buttons let you move components in very small increments.

**Fonts Toolbar** Can be used to change font attributes such as Name, Size, Style, and Alignment.

**Fills Toolbar** Provides the fill style for shapes such as rectangles and circles.

**Lines Toolbar** Allows you to change the border widths and styles of lines and borders.

**Colors Toolbar** Determines primary and secondary colors (normally foreground and background, respectively). The left mouse button selects the primary color, and the right mouse button selects the secondary color. Eight custom color boxes are available for commonly used custom colors. Double-clicking on the primary or secondary color box at right on the toolbar opens the Color Editor dialog, which provides additional color selection tools.

**Zoom Toolbar** Provides many tools that allow the Page Designer to zoom in or out for easier editing.

**Designer Toolbar** Lets you customize the Page Designer and the Rave Designer through the preferences dialog.

## The Status Bar

At the bottom of the Rave Designer is the status bar. The status bar provides information about the direct data view connection status and the mouse position and sizing. The data connection LED's color tells you the status of the Rave data system (DirectDataViews): gray and green indicate an inactive or active connection, respectively; yellow and red indicate specific data access situations (respectively, waiting for response or a time-out).

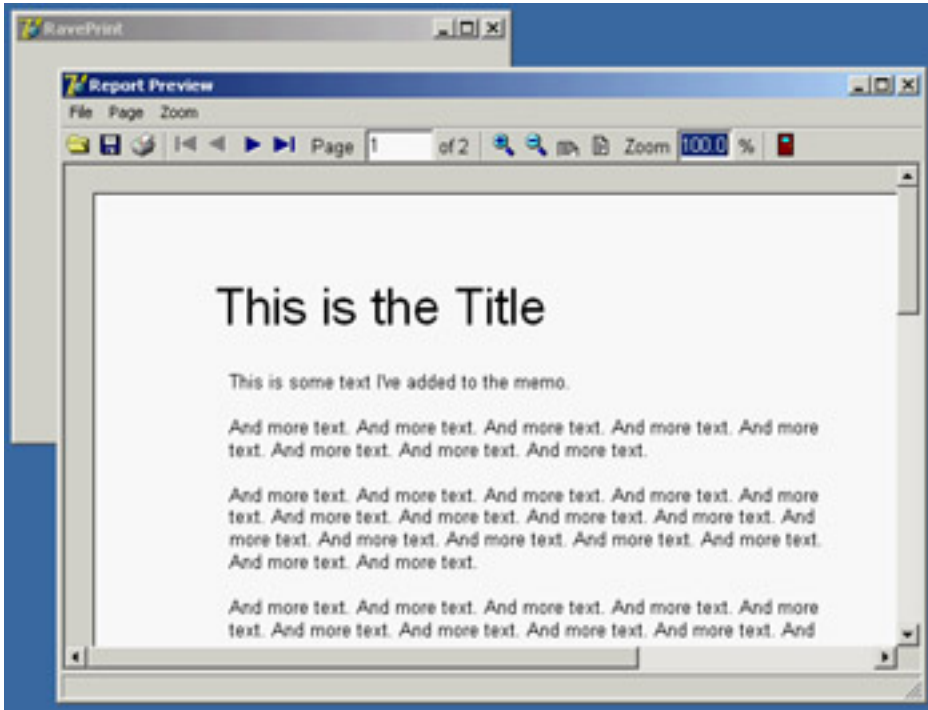

The X and Y values are the coordinates of the mouse pointer in page units. When you're dropping a component on the page, if you don't release the mouse button, the size of the component will be shown by the dX and dY values (*d* stands for *delta*).

## Using the RvProject Component

[Figure 18.1](#) shows a trivial Rave report, which is stored in a `.rav` file. To connect this report to your Delphi 7 application you use the Rave page, which provides a series of components. The central component is RvProject. Place this component on a form or data module, set its `ProjectFile` property to a Rave file, and write this event handler code for a button:

```
RvProject1.Execute;
```

You now have a working application (the RavePrint example among the source code files) that can print a report and that includes an embedded print preview feature, as you can see in [Figure 18.2](#). The referenced file should be distributed separately, and can be modified without having to change the Delphi program. As an alternative, you can also embed the `.rav` file into the Delphi executable by loading it in the DFM file. To accomplish this, use the `StoreRAV` property of the Rave project component.

**Figure 18.2:** The Rave Report Preview window for a report

**Note** As I mentioned earlier, the RvProject component, as well as all the components available in Rave Reports, can be used in either a VCL or a CLX application. The entire Rave engine is fully cross-platform.

To control the most important settings of the report and the preview, you can hook an RvNDRWriter or an RvSystem component to the `Engine` property of the RvProject component:

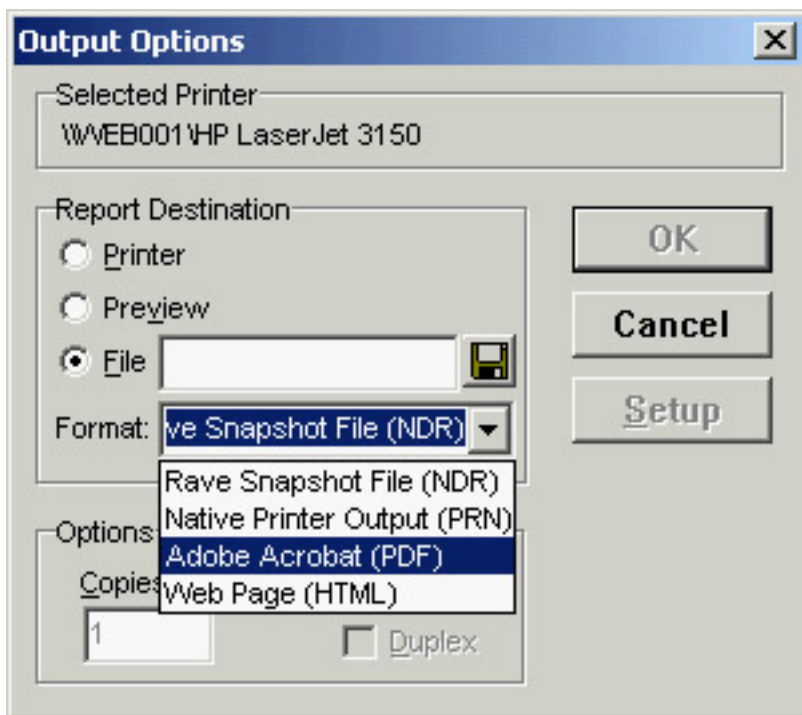

**RvNDRWriter Component** Generates an NDR formatted file when the report is executed. NDR formatted files are of a proprietary binary format and store all information needed by the rendering components to reproduce the report in a wide variety of formats.

**RvSystem Component** Combines the RvNDRWriter component with a standard print, preview, and rendering user interface. Many properties are available to customize the user interface, and override events can be defined to replace the standard dialogs with custom versions.

## Rendering Formats

The Rave engine produces an NDR file or stream, generated by the RvNDRWriter. Rave's rendering engine can convert this internal representation to a wide variety of formats. To let a user choose one of the target file formats, drop the desired render components within a form of your Delphi program. When running the RvProject component's `Execute` method (as in the RavePrint example), you can choose one of the file formats in the dialog box displayed by Rave and visible in [Figure 18.3](#).

**Figure 18.3:** After executing a Rave project, a user can choose the output format or rendering engine.

These are the available rendering components on the Rave page of Delphi's Component Palette:

**RvRenderPreview** Can be used to display an NDR file or stream to the screen. A ScrollBox component is used to display the report pages, and many methods and properties are available to create custom preview dialogs. Unless you need a custom print preview, you should use the RvSystem component for previewing instead of RvRenderPreview.

**RvRenderPrinter** Sends an NDR file or stream to the printer. Unless you need a custom printing or previewing interface, you do not need to use this component—RvSystem provides standard printing functionality.

**RvRenderPDF** Converts an NDR file or stream to PDF (Adobe Acrobat) form. You can use properties and events to customize the type of output that is created and to provide compression support.

**RvRenderHTML** Converts an NDR file or stream to HTML (DHTML) form. Each page is rendered to a separate page and can be combined with templates for greater output control.

**RvRenderRTF** Converts an NDR file or stream to RTF form. The RTF format uses field areas for accurate positioning and reproduction of the report.

**RvRenderText** Converts an NDR file or stream to text form. Many graphical commands and components, such as lines and rectangles, are ignored during text rendering.

In addition to letting a user choose a file format in the dialog, rendering can be done programmatically. For example, to convert a report to a PDF file directly, you can write the following code (taken again from the RavePrint example):

```

procedure TFormRave.btnPdfClick(Sender: TObject);
begin
  RvSystem1.DefaultDest := rdFile;
  RvSystem1.DoNativeOutput := False;
  RvSystem1.RenderObject := RvRenderPDF1;
  RvSystem1.OutputFileName := 'Simple2.pdf';
  RvSystem1.SystemSetups := RvSystem1.SystemSetups - [ssAllowSetup];
  RvProject1.Engine := RvSystem1;
  RvProject1.Execute;

```

end;

## Data Connections

Data connection components provide a link between data contained in a Delphi application and the DirectDataViews available in the Rave Designer. Notice that the value defined in the `Name` property for each data connection component is used to provide the link with the Rave report. For this reason, take care to avoid changing the component names after the DirectDataViews are created in Rave.

The data connection components are as follows:

**RvCustomConnection** Provides data to Rave reports using programmed events and can be used to send non-database data to a visual report.

**RvDataSetConnection** Connects any `TDataSet` class descendent component to a Rave DirectDataView. Using the `FieldAliasList` property, you can also modify the names of the dataset fields, replacing them with more legible names for the developers or end users building the report. If you need sorting or filtering for lookups or master-detail relationships within the Rave reports, you can handle the `OnSetSort` and `OnSetFilter` events.

**RvTableConnection and RvQueryConnection** Connect BDE Table and Query components to a Rave DirectDataView. Rave natively provides sorting and filtering support for table connections.

As a first example of how to construct a database-related report, I've created the RaveSingle example, which is an update of the DbxSingle program (built in [Chapter 14](#), "Client/ Server with dbExpress") with a Rave project and a connection:

```
object RvDataSetConnection1: TRvDataSetConnection
  RuntimeVisibility = rtDeveloper
  DataSet = SimpleDataSet1
end
object RvProject1: TRvProject
  ProjectFile = 'RaveSingle.rav'
end
```

In the Rave Designer, I created a new project, the file `RaveSingle.rav` in the `RaveSingle` folder. To refer to the data exposed by the Delphi program, you need to add a data view by clicking the New Data Object button on the Project toolbar, selecting the Direct Data View option (more details on the other alternatives later), and choosing an available connection. The list you'll see depends on the connections available in the project currently active in the Delphi IDE.

You can now create a report with the help of a wizard. From the Rave Designer menu, choose Tools → Report Wizards → Simple Table. Select the data view (you should have only one if you've followed these steps), and in the following window choose the dataset fields you want to include in your report. You should see a report like the one shown in [Figure 18.4](#).

**Figure 18.4:** The RaveSingle report (generated with the help of a wizard) at design time

As you can see in the Project Tree, the wizard generated a report page with a Region containing three Band components: one for the title, one for the table header, and a data-aware band for the items. I'll cover the details of using these components in the section "[Regions and Bands](#)," later in this chapter; for the moment, I wanted to build and let you experiment with a working example.

## Components of the Rave Designer

The [previous section](#) discussed the Rave components available in Delphi, because when you use this reporting engine you'll do most of your work in the report designer. The core element of a report (available at the top of the Project Tree view) is the RaveProject component, also called the Project Manager. This is not a component you drop on a report, because there is always only one object of this type in every report (as there is one global `Application` object in a Delphi program).

The RaveProject component is the owner of all the other report components. Like every component in Rave, the Project Manager has properties. To see them, select RaveProject in the Project Tree, and then look in the Property panel. To create a new RaveProject, click the New Project button on the Project toolbar. Doing so will create a new file, as well as the new Project Manager.

Every project can host multiple reports, represented by the Report component. A Report component contains the pages of a report. There can be multiple Reports in one project, and each Report can have multiple Pages. The Page component is the base visual component upon which you can place the report's visual components. You complete the designing and layout of a report here.

In addition to the list of reports available under the Report Library node, a Rave project has a Global Page Catalog, introduced earlier, and a Data View Dictionary. The Data View Dictionary is a detailed list of the data conduits made available by the hosting Delphi application (using the Delphi Rave connection components covered earlier) or activated directly from the report to a database.

You design the report by placing visual components directly on the page or on another container, such as a Band or a Region. Some of these components are not connected with database data—for example, the Text, Memo, and Bitmap components in the designer's Standard toolbar. Other components can be connected with a field in a database table (or are *data-aware*, to use a Delphi term), such as the DataText and DataMemo components on the Report toolbar.

### Basic Components

The Standard toolbar contains seven components: Text, Memo, Section, Bitmap, Metafile, FontMaster, and PageNumInit. Many of the standard components are used frequently when designing reports.

#### Text and Memo Components

The Text component is useful for displaying a single line of text on the report. It acts like a label that can contain simple text (not data). When placed on the report, the Text box is surrounded by a box that indicates its boundaries.

Memo components are similar to Text components, but they can contain multiple lines of text. When you set the Memo's font, all text in the Memo will have the same font, as in a Delphi Memo component. Once you've entered the text, the Memo box can be resized, and the text within the Memo box will be repositioned accordingly. If text seems to be missing from the Memo box after it has been entered in the Memo Editor, resize the box to allow all text to be visible.

#### The Section Component

The Section component is used to group components, like a Panel in Delphi. It provides advantages such as letting you move all components that form part of the Section with one mouse click, as opposed to making you move each component individually or try to select all components before moving.

The Project Tree is helpful when you're dealing with the Section component. From an expanded node, it is easy to see what components are in each Section, because compound components can form a tree with parent-child relationships.

**Tip** The Section component is important when you're mirroring, which allows visual design inheritance within your report designs.

### Graphical Components

The Bitmap and Metafile components let you place images in a report. Bitmap supports raster image files with the extension `.bmp`, and Metafile supports vector image files with the extensions `.wmf` and `.emf`. Metafiles are not supported when you use Rave in a CLX application, because they are based on a specific Windows technology.

## The FontMaster Component

Each Text component in a report has a `Font` property. By setting this property, you can assign a specific font to the component. In many cases, it may be useful and necessary to set the same font properties for more than one object. Although you can do so by selecting more than one component at a time, this method has a drawback: You have to keep track of which fonts must be the same typeface, size, and style, which is not an easy task for more than one report.

The FontMaster component lets you define standard fonts for different parts of the report, such as the headers, body, and footers. The FontMaster is a non-visual component (designated by the button's green color), so there will be no visual reference to it on the page (unlike in Delphi); and, like other non-visual components, it can only be accessed using the Project Tree.

Once you've set the FontMaster component's `Font` property, linking it to a body of text is simple. On the report, select a Text/Memo component, and then use the down arrow button by the `FontMirror` property in the Property panel to choose a FontMaster link. Any component whose `FontMirror` property is set to the FontMaster will be affected by and changed to the FontMaster's `Font` property.

When you set a component's `FontMirror` property, the component's `Font` property will be overridden by the FontMaster's `Font` property. Another side effect of using the FontMaster is that the Font toolbar is disabled when the `FontMirror` property is set for that component.

There can be more than one FontMaster per page; however, it is good practice to rename FontMaster components to describe their function. You should also locate them on a Global Page, so they can be used by all reports within the project and provide a more consistent typographical layout.

## Page Numbers

`PageNumInit` is a non-visual component that lets you restart page numbering within a Report. Its use is similar to that of other non-visual components. You use `PageNumInit` when more advanced formatting is required.

For example, consider a customer statement report for a checking account. The account statements customers receive every month may vary in the number of pages. Suppose the first page defines the account summary page layout, the second defines the customer's credits/deposits, and the third defines withdrawals and debits. The first two reports may need only one page; but if account activity is high for a customer, then the withdrawals section may be several pages long. If the user producing the report wants each section's pages numbered individually, the summary and deposits pages should both be marked "1 of 1". If an active customer account has three pages of withdrawals and debits, this section of the statement should be numbered "1 of 3", "2 of 3", and "3 of 3". `PageNumInit` comes in handy for this kind of page numbering.

## Drawing Components

Like the standard components, drawing components aren't related to data. Rave reports can include three components for lines: Generic lines are drawn in any direction and include angled lines; horizontal and vertical lines have a fixed direction. Available geometric shapes include squares, rectangles, circles, and ellipses. You can drop a shape on a report and then move it behind another element. For example, you can place a rectangle around a `DataBand`, set it so that it is sized to completely fill the band, and then move it behind the other components placed in the band.

## Bar Code Components

Bar code components are used to create many different kinds of bar codes in a report. Bar codes are for users who know exactly what they need, you must have background knowledge about bar codes and how they are used. To

define a bar code value, go to the Property panel and type the value in the `Text` property box.

Rave bar codes support includes the following:

- POSTNET (POSTal Numeric Encoding Technique) bar code, specifically used by the U.S. Postal Service
- I2of5BarCode (interleaved 2 of 5), for numeric information only
- Code39BarCode, an alphanumeric bar code that can encode decimal numbers, the uppercase alphabet, and a few special symbols
- Code128BarCode, a high-density alphanumeric bar code designed to encode all 128 ASCII characters
- UPCBarCode (Universal Product Code), which has a fixed length of 12 digits and was designed for coding products
- EANBarCode (European Article Numbering System), which is identical to the UPC but has 13 digits, 10 numeric characters, 2 country code characters, and a check digit

## Data Access Objects

In most cases, a report will be based on a data feed, either directly from a database or from a Delphi application. The data might come from a dataset connected to a database or from some internal processing of a Delphi program. When you choose the New Data Object button on the Project toolbar, you'll see the alternatives shown here and described in the following list:

**RaveDatabase Component (Database Connection)** Provides database connection parameters for the DriverDataView component. Only database connections for which DataLink drivers are installed will be allowed.

**RaveDirectDataView Component (Direct Data View)** Provides a means to retrieve data from a data connection component located within the hosting Delphi application, as in the last example. (The selection is called Direct Data View even if this is not the direct database connection from the report, but is instead the indirect connection based on data fetched from the database by a hosting application.)

**RaveDriverDataView Component (Driver Data View)** Provides a means to define a query for a specific database connection using a query language such as SQL. A query builder will be displayed to define the query.

**RaveSimpleSecurity Component (Simple Security Controller)** Implements the most basic form of security by using a simple list of username and password pairs in the `UserList` property. `UserList` contains one username and password pair per line in this format: `Username = password`. `CaseMatters` is a Boolean property that controls whether the password is case sensitive.

**RaveLookupSecurity Component (Data Lookup Security)** Allows username and password pairs to be checked against entries in a database table. The `DataView` property specifies the `DataView` to use to look up the username and password. The `UserField` and `PasswordField` properties are used to look up the username and the password to verify against.

## Regions and Bands

A Region component is a container for Band components. In its simplest form, the Region could be the whole Page component. This would be true for a report that is a list type. Many master-detail reports could be made to fit a single-Region design. However, do not be limited by thinking of a Region as being the entire Page; the properties for a Region deal with its size and location on the Page. Creative use of Regions will give you more flexibility when you're designing complex reports. Multiple Regions can be placed on a single Page; they can be side-by-side, one above the other, or staggered about the Page.

**Tip** Do not confuse a Region with a Section. Region components contain Bands and only Bands. A Section component can contain any group of components, including Region components, but cannot directly contain Bands.

When you're working with Bands, you must follow a simple rule: Bands must be in a Region. Notice that the number of Regions on a Page is not limited, nor is the number of Bands within a Region. As long as you can visualize the report mentally, you can use a combination of Regions and Bands to solve any difficulties faced when putting those thoughts into design. There are two band types:

**DataBand** Used to display iterating information from a `DataView`. In general, a `DataBand` will contain several `DataText` components. A `DataBand`'s `DataView` property must be set to the `DataView` component over which it will iterate and will typically contain other data-aware components that operate on that same `DataView`.

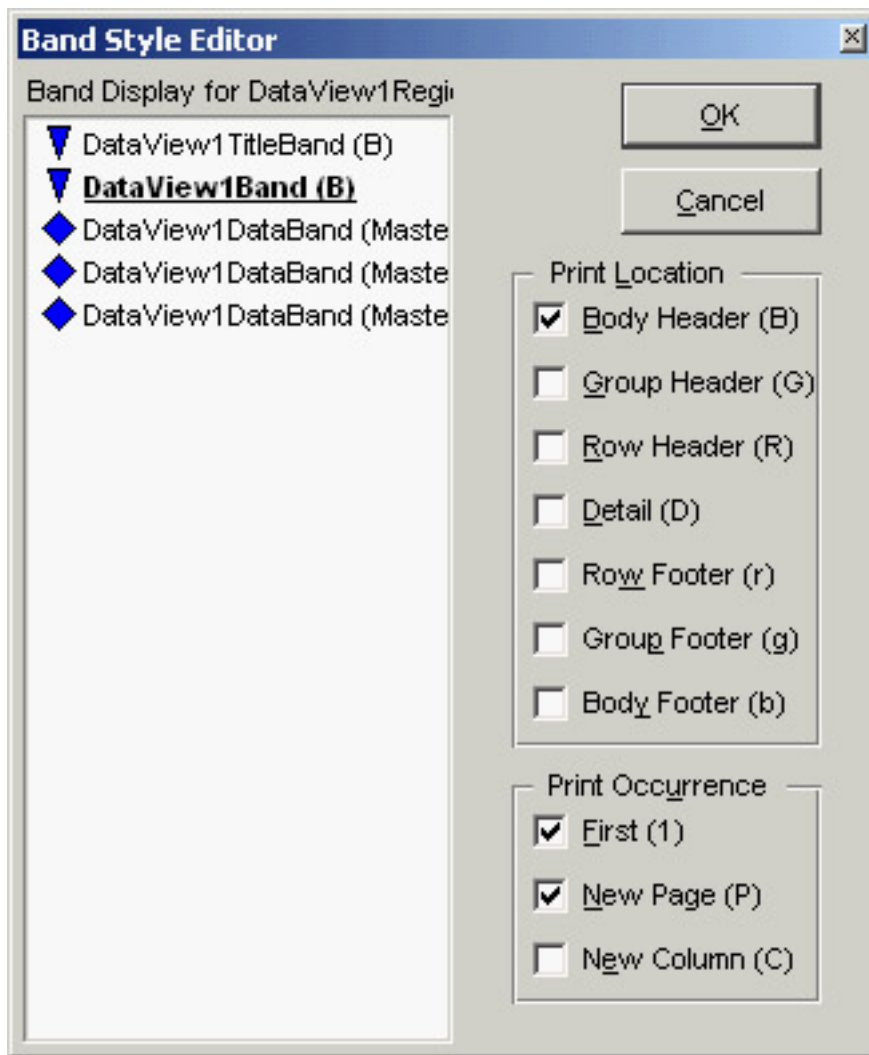

**Band** Used to print header and footer bands within a Region. Supported header and footer types include Body, Group, and Row; they are selected using the `BandStyle` property. Page headers and footers are not needed in a Band because you can drop them directly on the page outside the Region component.

`ControllingBand` is an important property for the Band component. This property determines which `DataBand` a Band belongs to (or is controlled by). When the controlling `DataBand` has been set, notice that the graphics symbol on the Band points in the direction of that controlling Band and that the color of the symbols matches. The letter codes shown on the Band are explained in the following section, "[The Band Style Editor](#)."

## The Band Style Editor

Go to the `BandStyle` property of a Band or `DataBand` component and click the ellipsis button to open the Band Style Editor:

This editor provides a simple method to select the features you want for a Band by using the check boxes. Note that a Band can have several different features active at a time. This means it is possible for a Band to be both a Body Header and Body Footer simultaneously.

The display area in the Band Style Editor is designed to represent the flow of a report in pseudo-layout style. DataBands are duplicated three times to show that they are repeated. The current Band that is being edited is highlighted: Although you see the other Bands in the editor, you can only modify the settings of the current one.

The Band Style Editor uses symbols and letters in the display area and in the Page Layout area (for example, see [Figure 18.6](#)) to inform you about each Band's behavior. The major difference between these two representations is that the Band Style Editor display arranges the bands in a pseudo flow according to the definition of each Band. In the Band Style Editor the Bands are arranged according to the logical flow and the order they are placed in the report at design time. The Bands sequence in the report's output is mainly controlled by this order.

Headers (capital letters *BGR*, which stand for Body, Group, and Row, respectively) will print first, followed by the DataBand, and then the footers (lower case letters *bgr*) for each level. However, if more than one header is defined for a particular level, then the header Bands are processed in the order they are arranged in the Region. So, it is possible to put all the headers at the top, all the DataBands in the middle, and all the footers at the bottom of a Region for all levels of a master-detail report. Alternatively, you can group each level, with the appropriate headers, footers, and DataBands together for each level. Rave lets you use the Region layout in a way that makes the most sense to the design flow. Just remember that the order of precedence for Bands at the same level is controlled by their order within the Region.

Two symbols show the parent/child or master/detail relationships of the various bands:

- The *triangle* symbol (up/down arrows) indicates that the band is controlled by a master band with the same color (level), which can be found in the direction of the arrow.

- The *diamond* symbol represents a master or controlling band.

These symbols are both color-coded and indented to represent the level of master-detail flow. Remember that you can have a master/detail/detail relationship in which both details are both controlled by the same master or one of the details is controlled by the other detail.

## Data-Aware Components

You can place different data-aware Rave components within a DataBand. The most common choice is the DataText component, used to display a text field from a dataset, as you saw in the RaveSingle example.

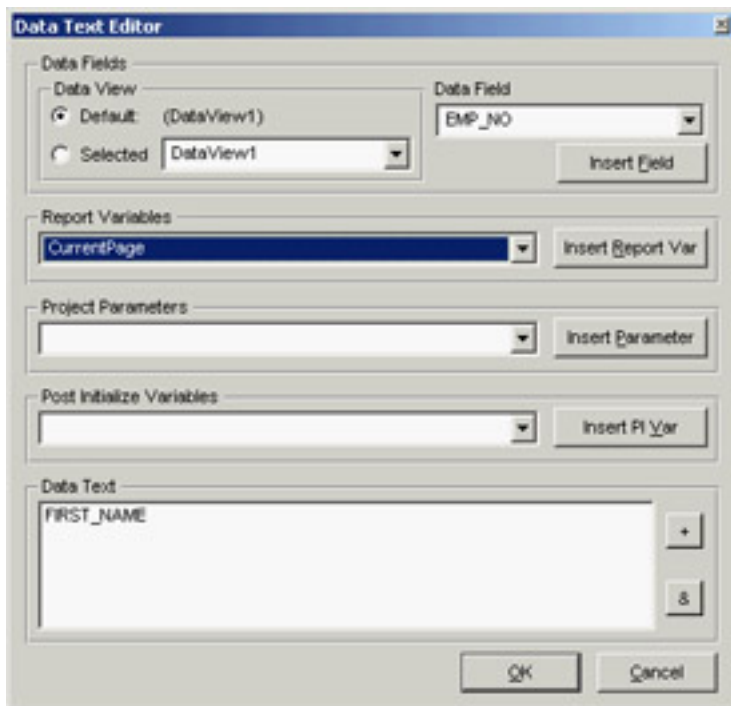

Two options are available for entering data in a DataField property. The first is to select a single field using the drop-down list; this approach is fine for normal database reporting where only a single data field for each DataText item may be needed. The second is to use the Data Text Editor.

### The Data Text Editor

Many reports require various fields to be combined. Two common examples are city, state, and zip code, or first name and last name combinations. In code, you can accomplish these combinations using statements like the following:

```
City + ', ' + State + ' ' + Zip
FirstName & LastName
```

The DataField property has a Data Text Editor, shown in [Figure 18.5](#), which assists you in building composite fields. Click on the ellipsis to open the DataText Editor; it gives you the power to concatenate fields, parameters, or variables to build a complex data-aware text field by selecting items from the list boxes. This editor includes a lot of combinations; I will cover them quickly here, and you can try them in practice.

**Figure 18.5:** The Rave Designer's Data Text Editor

Note that the dialog box is divided into five groups: Data Fields, Report Variables, Project Parameters, Post Initialize Variables, and Data Text. Data Text is the result window: Watch this window when you're inserting items. The two buttons on the right side of this window are plus (+) and ampersand (&). The + button adds two items together with no spaces, and the & button concatenates them with a single space (as long as the previous field was not blank). So, the first step is to decide whether you want to use + or &, and then select the text from one of the three groups above the

Data Text window.

The DataText component is not limited to printing database data: You can also use project parameters and report variables. Go to the Report Variables group, look in the list box, note the variables that are available. The Project Parameters list could contain `UserName`, `ReportTitle`, or `UserOption` parameters initialized by the application. To create the list of project parameters, select the Project node in the Project Tree (the top item). Then, in the Properties panel, click the ellipsis button by the Parameters property to open typical string editor, where you can enter the different parameters you want to pass to Rave from the application (such as the `UserName`).

## From Text to Memo

The DataMemo component displays a memo field from a DataView. The main difference between the DataMemo component and the DataText component is that the DataMemo component is used to print text that may require more than one line and will thus need to be wrapped. For example, it could be used to print remarks about a customer at the bottom of each Page of an invoice.

One use for the DataMemo component is mail-merge functions. The easiest way to accomplish this is to set the `DataView` and `DataField` properties to the source of the Memo field. Then, launch the Mail Merge Editor by clicking the ellipsis button by the `MailMergeItems` property. This editor lets you set the items in the Memo that will be changed.

To use the Mail Merge Editor, click the Add button. In the Search Token window, type the item that is in the Memo and that will be replaced. Then, either type the replacement string in the Replacement window or click the Edit button to start the Data Text Editor that will help you select different DataViews and fields.

## Calculating Totals

The CalcText component is a data-aware totaling component. The main difference between the DataText component and the CalcText component is that the CalcText component is specially designed to perform calculations and display the results.

The `CalcType` property determines the type of calculation being performed; values include Average, Count, Maximum, Minimum, and Sum. For example, you can use this component to print the totals of an invoice at the top of each page.

The `CountBlanks` property determines whether blank field values are included in the Average and Count calculation methods. If `RunningTotal` is True, then the calculation will not be reset to 0 each time it is printed.

## Cycling on Data inside Pages

The DataCycle component is basically an invisible DataBand that adds data-iterating capabilities directly to a Page. This component is useful for form-style reports where using Regions and Band components would be cumbersome. It is important to make sure the DataCycle component appears before any components on the Page that process information from the same DataView.

## Advanced Rave

In this long introduction to Rave, you've seen that this reporting system is so complex I could devote an entire book to it. I've already built a couple of examples, and I could continue by showing a master/detail relationship or other reports with a complex structure. However, with the wizards available and the information provided so far, you should be able to build similar examples yourself. So, in this section I'll build only one example of this type, and then provide information about a few relevant features of Rave that aren't easy to understand by trial and error.

**Note** Among other features of Rave not discussed here is one that allows you to distribute the report designer to end users (to let them customize the reports), either bound to a Delphi program or as a stand-alone tool. Rave also has a server version that allows you to surface reports from a web server.

**Tip** You can learn more about these features and other aspects of Rave on Nevrona's website. Specifically, you should browse the tip collection located at [www.nevrona.com/rave/tips.shtml](http://www.nevrona.com/rave/tips.shtml).

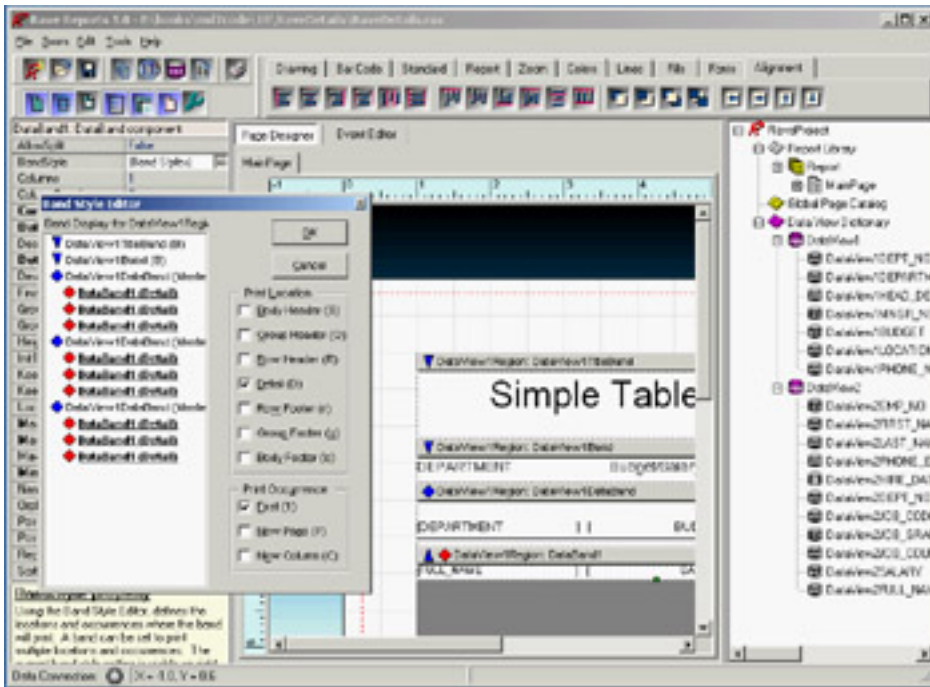

## Master/Detail Reports

To create a master/detail report in Rave, you need two datasets in the corresponding Delphi application, but these datasets don't need to have a master/detail relationship defined in the program—the report can define such a relationship. In the RaveDetails demo program, each of the two datasets is exposed through a Rave connection:

```
object dsDepartments: TSimpleDataSet
  Connection = SQLConnection1
  DataSet.CommandText = 'select * from DEPARTMENT'
end
object dsEmployee: TSimpleDataSet
  Connection = SQLConnection1
  DataSet.CommandText = 'select * from EMPLOYEE'
end
object RvConnectionDepartments: TRvDataSetConnection
  DataSet = dsDepartments
end
object RvConnectionEmployee: TRvDataSetConnection
  DataSet = dsEmployee
end
```

The report has two corresponding data views, each connected to a DataBand component (both hosted within a Region). The first DataBand, used for the main dataset, has no special settings. The secondary DataBand defines the master/detail relationship using a few properties. The `MasterDataView` property refers to the data view of the master dataset, and the `MasterKey` and `DetailKey` properties refer to the fields that define the join (in this case, they both refer to the field `DEPT_NO`). The `ControllerBand` property refers to the DataBand showing the data of the master dataset.

In case master/details report, the most important settings are managed by the Band Style Editor, where you must set the band as a detail. You can see this editor for the RaveDetails example in [Figure 18.6](#). The master data view's `KeepRowTogether` property is set to `True`, to avoid having details end up in a different page than the master.

**Figure 18.6:** The master/detail report. The Band Style Editor appears in front of it.

**Warning** To create a master/detail report, you may want to use the corresponding wizard available in Rave. In the version shipping with Delphi 7, this wizard doesn't work. At the time of this writing an update to fix this and other issues is still not available.

## Scripting Reports

At the beginning of this chapter I mentioned the Event Editor window of the Rave Designer, but so far I haven't used it. This tool is used to write code (scripts) within a report, responding to events of the various components as you'd do in Delphi. Writing scripts in the Rave Designer allows you to customize, or fine-tune, the output of a report in sophisticated ways. The language Rave uses for the scripts is Pascal based and a variation of the Delphi language, so you should be able to pick it up easily.

The RaveDetails example shows in bold font salaries that are greater than a specified amount. The obvious way to accomplish this is to write scripting code to be executed for each instance of the detail band—that is, for each record in the employee database. Instead of modifying the `Font` property directly, I decided to add two different `FontManager` components to the report page and name them to make their role understandable: `fmPlainFont` and `fmBoldFont`. You can open the report to see their properties and layout.

In the report, to highlight values outside a given range, you handle the `DataText` component's `BeforePrint` event. To do so, move to the Event Editor page, choose the `DataText` component connected to the Salary field, and select the event. In the event's code editor window, write the following code:

```
if DataView2Salary.AsFloat > 100000 then
  self.FontMirror := fmBoldFont;
else
  self.FontMirror := fmPlainFont;
end if;
```

The script changes the `FontMirror` property of the current object (`self`) to refer to one of the two `FontManager` components on the page, depending on the field value. Notice that `DataView2Salary` is a reference to one of the fields of the data view—the one connected to the current `DataText` component. Compile the script and run the report to see its effect, shown in [Figure 18.7](#).

DEPARTMENT	Budget/Salary	LOCATION
Corporate Headquarters	1,000,000.00	Monterey
Lee, Terri	53,793.00	
Bender, Oliver H.	<b>212,850.00</b>	
Sales and Marketing	2,000,000.00	San Francisco
MacDonald, Mary S.	<b>111,262.59</b>	
Yanowski, Michael	44,000.00	
Engineering	1,100,000.00	Monterey
Nelson, Robert	<b>105,960.00</b>	
Brown, Kelly	27,000.00	

**Figure 18.7:** The bold text in the report is determined at run time by a script.

**Warning** Every time you edit a script, remember to click the Compile button; otherwise your changes won't take effect!

## Mirroring

Reporting templates can contain one or more components and can be reused via Rave's mirroring technology. The DataMirrorSection component mirrors other Sections based on the contents of a DataField. The use of mirroring sections allows the DataMirrorSection to be very flexible. Remember that Sections can contain any other component including graphics, regions, text, and so on.

For example, you could use a DataMirrorSection component to make a single report produce different envelope formats for international or U.S. addresses. The template for international customers could include a line for the country have the text centered on the envelope, whereas the U.S. format would not include the country line would offset the text to the right of center and lower on the envelope.

Normally, one of the settings will be defined as the default. If a default is *not* defined and the field value does not match any of the other settings, then the format used will be the normal contents of the DataMirrorSection component.

## Calculations to the Max

In addition to the simple CalcText component discussed earlier, the Rave Designer includes three components for handling more complex situations: CalcTotal, CalcController, and CalcOp.

### CalcTotal

The CalcTotal is a non-visual version of the CalcText component. When this component is printed, its value is typically stored in a project parameter (defined by the DestParam property) and formatted according to the DisplayFormat property. It can be useful when you're performing totaling calculations that will be used by other calculations before being printed. If the value of the CalcTotal will only be used by other calculation components, such as CalcOp, you should leave the DestParam property blank.

### CalcController

CalcController is a non-visual component that acts as a controller for CalcText and CalcTotal components through their Controller properties. When the controller component is printed, it signals all calculation components that it controls to perform their operation. This process allows a report to recalculate totals on group bands, detail bands, or whole

pages depending upon the location of the CalcController component.

The CalcController component can also initialize a CalcText or CalcTotal component to a specific value (through the `InitCalcVar`, `InitDataField`, and `InitValue` properties). The CalcController component will initialize values only if it is used in the `Initializer` property of CalcText or CalcTotal components.

## CalcOp

CalcOp is a non-visual component that allows an operation (defined by the `Operator` property) to be performed on values from different data sources. The result can then be saved in a project parameter like CalcTotal, as indicated by the `DestParam` and `DisplayFormat` properties.

For example, suppose you need to add two DataText components, as in  $A + B = C$  (where A and B represent the two DataText component values and C represents the result stored in a project parameter). The three source types have many different values associated with them.

The calculation can start with different types of data sources:

- A DataField source is a field in a table, or a DataView in Rave terms. Thus in order to choose a field, you must first select a DataView.
- For a Value source, you fill in the property with a numeric value.
- A CalcVar source represents another calculation variable; you can choose one from the drop-down menu that lists all the calculation variables available in the page. This value can be from another CalcOp component or from some other calculation component.

After choosing the data sources, you select the operation to be used between them. The `Operator` property has a drop-down menu you can use to make the appropriate choice. In the example  $A + B = C$ , the operator is `coAdd`.

Sometimes a function needs to be performed on a value before it is processed with the second value. In this case the source's `Function` property is handy. With a function, you can converted a value (such as hours to minutes), compute a trigonometric function (like the sin of the value), or perform many others calculations (such as a square root or absolute value).

Just as it is important to do the calculations in order, it is important to make sure the components are in order in the Project Tree. A report executes components down the Project Tree. For CalcOp components or any calculation component, this means they must be in the correct order. It is also important to note that if a source value is dependent on any other components (like other CalcOp components or DataText components), those components must come first in the Project Tree.

## What's Next?

This chapter has focused using Rave to add reporting capabilities to Delphi applications. I've covered basic reports and data-driven reports, describing both the components you can use in a Delphi application to connect with a report and the components you can use in the report to display data passed by the application. I also touched on some of the more advanced features of Rave, like the use of the Band Style Editor, scripting, mirroring, calculations, and a few others.

If you are looking for more documentation, refer to the PDF files that are available with Delphi but not installed with the product. These manuals and many others are available on the Delphi 7 Companion CD.

This chapter ends the book's coverage of Delphi database technologies, although you'll also use databases in the following part of the book (devoted to Internet and web programming). I'll begin by covering core technologies, such as the use of sockets, and then proceed to HTML generation, traditional Delphi web development, and the use of IntraWeb. I'll then cover the XML and SOAP technologies.

## Part IV: Delphi, the Internet, and a .NET Preview

### Chapter List

[Chapter 19](#): Internet Programming: Sockets and Indy

[Chapter 20](#): Web Programming with WebBroker and WebSnap

[Chapter 21](#): Web Programming with IntraWeb

[Chapter 22](#): Using XML Technologies

[Chapter 23](#): Web Services and SOAP

[Chapter 24](#): The Microsoft .NET Architecture from the Delphi Perspective

[Chapter 25](#): Delphi for .NET Preview: The Language and the RTL

## Chapter 19: Internet Programming: Sockets and Indy

### Overview

With the advent of the Internet era, writing programs based on Internet protocols has become commonplace, so I've devoted five chapters to this topic. This chapter focuses on low-level socket programming and Internet protocols, [Chapter 20](#) is devoted to server-side web programming, [Chapter 21](#) covers IntraWeb, and [Chapters 22](#) and [23](#) discuss XML and web services.

In this chapter I'll begin by looking at the sockets technology in general; then I'll move to the use of the Internet Direct (Indy) components supporting both low-level socket programming and the most common Internet protocols. I will introduce some elements of the HTTP protocol, leading up to building HTML files from database data.

Although you probably just want to use a high-level protocol, the discussion of Internet programming starts from the core concepts and low-level applications. Understanding TCP/ IP and sockets will help you grasp most of the other concepts more easily.

## Building Socket Applications

Delphi 7 ships with two sets of TCP components—Indy socket components (IdTCPClient and IdTCPServer) and native Borland components—which are also available in Kylix and are hosted in the Internet page of the Component palette. The Borland components, TcpClient and TcpServer, were probably developed to replace the ClientSocket and ServerSocket components available in past versions of Delphi. However, now that the ClientSocket and ServerSocket components have been declared obsolete (although they are still available), Borland suggests using the corresponding Indy components instead.

In this chapter I'll focus on using Indy during my discussion of low-level socket programming, not only when I cover support for high-level Internet protocols. To learn more about the Indy project, refer to the sidebar "[Internet Direct \(Indy\) Open Source Components](#)"; keep reading to see how you can use these components for low-level socket programming.

Before I present an example of a low-level socket-based communication, let's take a tour of the core concepts of TCP/IP so you understand the foundations of the most widespread networking technology.

---

### Internet Direct (Indy) Open Source Components

Delphi ships with a collection of open-source Internet components called Internet Direct (Indy). The Indy components, previously called WinShoes (a pun on the term WinSock, the name of the Windows socket library), are built by a group of developers led by Chad Hower and are also available in Kylix. You can find more information and the most recent versions of the components at [www.nevrona.com/indy](http://www.nevrona.com/indy).

Delphi 7 ships with Indy 9, but you should check the website for updated versions. The components are free and are complemented by many examples and a reasonable help file. Indy 9 includes many more components than the previous version (Indy 8, available in Delphi 6), and it has two new pages on the component palette (Indy Intercepts and Indy I/O Handlers).

With more than 100 components installed on Delphi's palette, Indy has an enormous number of features, ranging from the development of client and server TCP/IP applications for various protocols to encoding and security. You can recognize Indy components from the Id prefix. Rather than list the various components here, I'll touch on a few of them throughout this chapter.

#### ***Blocking and Non-Blocking Connections***

When you're working with sockets in Windows, reading data from a socket or writing to it can happen asynchronously, so that it does not block the execution of other code in your network application. This is called a *non-blocking connection*. The Windows socket support sends a message when data is available. An alternative approach is the use of *blocking connections*, where your application waits for the reading or writing to be completed before executing the next line of code. When you're using a blocking connection, you must use a thread on the server, and you'll generally also use a thread on the client.

The Indy components use blocking connections exclusively. So, any client socket operation that might be lengthy should be performed within a thread or by using Indy's IdAntiFreeze component as a simpler but limited alternative. Using blocking connections to implement a protocol has the advantage of simplifying the program logic, because you don't have to use the state-machine approach of non-blocking connections.

All the Indy servers use a multithreaded architecture that you can control with the IdThreadMgrDefault and IdThreadMgrPool components. The first is used by default; the second supports thread pooling and should account for faster connections.

---

To understand the behavior of the socket components, you need to be confident with several terms related to the Internet in general and with sockets in particular. The heart of the Internet is the Transmission Control Protocol/Internet Protocol (TCP/IP), a combination of two separate protocols that work together to provide connections over the Internet (and that can also provide connection over a private intranet). In brief, IP is responsible for defining and routing the *datagrams* (Internet transmission units) and specifying the addressing scheme. TCP is responsible for higher-level transport services.

## Configuring a Local Network: IP Addresses

If you have a local network available, you'll be able to test the following programs on it; otherwise, you can use the same computer as both client and server. In this case, as I've done in the examples, use the address 127.0.0.1 (or *localhost*), which is invariably the address of the current computer. If your network is complex, ask your network administrator to set up proper IP addresses for you. If you want to set up a simple network with a couple of spare computers, you can set up the IP address yourself; it's a 32-bit number usually represented with each of its four components (called *octets*) separated by dots. These numbers have a complex logic underlying them, and the first octet indicates the class of the address.

Specific IP addresses are reserved for unregistered internal networks. Internet routers ignore these address ranges, so you can freely do your tests without interfering with an actual network. For example, the "free" IP address range 192.168.0.0 through 192.168.0.255 can be used for experiments on a network of fewer than 255 machines.

## Local Domain Names

How does the IP address map to a name? On the Internet, the client program looks up the values on a domain name server. But it is also possible to have a local *hosts* file, which is a text file you can easily edit to provide local mappings. Look at the `HOSTS.SAM` file (installed in a subdirectory of the `Windows` directory, depending on the version of Windows you have) to see a sample; you can eventually rename the file `HOSTS`, without the extension, to activate local host mapping.

You may wonder whether to use an IP or a hostname in your programs. Hostnames are easier to remember and won't require a change if the IP address changes (for whatever reason). On the other hand, IP addresses don't require any resolution, whereas hostnames must be resolved (a time-consuming operation if the lookup takes place on the web).

## TCP Ports

Each TCP connection takes place through a *port*, which is represented by a 16-bit number. The IP address and the TCP port together specify an Internet connection, or a *socket*. Different processes running on the same machine cannot use the same socket (the same port).

Some TCP ports have a standard usage for specific high-level protocols and services. In other words, you should use those port numbers when implementing those services and stay away from them in any other case. Here is a short list:

Protocol	Port
HTTP (Hypertext Transfer Protocol)	80
FTP (File Transfer Protocol)	21
SMTP (Simple Mail Transfer Protocol)	25
POP3 (Post Office Protocol, version 3)	110
Telnet	23

The `Services` file (another text file similar to the `Hosts` file) lists the standard ports used by services. You can add your own entry to the list, giving your service a name of your own choosing. Client sockets always specify the port number or the service name of the server socket to which they want to connect.

## High-Level Protocols

I've used the term *protocol* many times now. A protocol is a set of rules the client and server agree on to determine the communication flow. The low-level Internet protocols, such as TCP/IP, are usually implemented by an operating system. But the term *protocol* is also used for high-level Internet standard protocols (such as HTTP, FTP, or SMTP). These protocols are defined in standard documents available on the Internet Engineering Task Force website ([www.ietf.org](http://www.ietf.org)).

If you want to implement a custom communication, you can define your own (possibly simple) protocol, a set of rules determining which request the client can send to the server and how the server can respond to the various possible requests. You'll see an example of a custom protocol later. Transfer protocols are at a higher level than transmission protocols, because they abstract from the transport mechanism provided by TCP/IP. This makes the protocols independent not only from the operating system and the hardware but also from the physical network.

## Socket Connections

To begin communication through a socket, the server program starts running first; but it simply waits for a request from a client. The client program requests a connection indicating the server it wishes to connect to. When the client sends the request, the server can accept the connection, starting a specific server-side socket, which connects to the client-side socket.

To support this model, there are three types of socket connections:

- *Client connections* are initiated by the client and connect a local client socket with a remote server socket. Client sockets must describe the server they want to connect to, by providing its hostname (or its IP address) and its port.
- *Listening connections* are passive server sockets waiting for a client. Once a client makes a new request, the server spawns a new socket devoted to that specific connection and then gets back to listening. Listening server sockets must indicate the port that represents the service they provide. (The client will connect through that port.)
- *Server connections* are activated by servers; they accept a request from a client.

These different types of connections are important only for establishing the link from the client to the server. Once the link is established, both sides are free to make requests and to send data to the other side.

## Using Indy's TCP Components

To let two programs communicate over a socket (either on a local area network or over the Internet), you can use the `IdTCPClient` and `IdTCPServer` components. Place one of them on a program form and the other on another form in a different program; then, make them use the same port, and let the client program refer to the host of the server program, and you'll be able to open a connection between the two applications. For example, in the `IndySock1` project group, I've used the two components with these settings:

```
// server program
object IdTCPServer1: TIdTCPServer
  DefaultPort = 1050
end
// client program
object IdTCPClient1: TIdTCPClient
  Host = 'localhost'
  Port = 1050
end
```

**Note** The Indy server sockets allow binding to multiple IP addresses and/or ports, using the *Bindings* collection.

As this point, in the client program you can connect to the server by executing

```
IdTCPClient1.Connect;
```

The server program has a list box used to log information. When a client connects or disconnects, the program lists the

IP of that client along with the operation, as in the following `OnConnect` event handler:

```
procedure TFormServer.IdTCPServer1Connect(AThread: TIdPeerThread);  
begin  
  lbLog.Items.Add ('Connected from: ' +  
    AThread.Connection.Socket.Binding.PeerIP);  
end;
```

Now that you have set up a connection, you need to make the two programs communicate. Both the client and server sockets have read and write methods you can use to send data, but writing a multithreaded server that can receive many different commands (usually based on strings) and operate differently on each of them is far from trivial.

However, Indy simplifies the development of a server by means of its command architecture. In a server, you can define a number of commands, which are stored in the `CommandHandlers` collection of the `IdTCPServer`. In the `IndySock1` example the server has three handlers, all implemented differently to show you some of the possible alternatives.

The first server command, called `test`, is the simplest one, because it is fully defined in its properties. I've set the command string, a numeric code, and a string result in the `ReplyNormal` property of the command handler:

```
object IdTCPServer1: TIdTCPServer  
  CommandHandlers = <  
    item  
      Command = 'test'  
      Name = 'TIdCommandHandler0'  
      ParseParams = False  
      ReplyNormal.NumericCode = 100  
      ReplyNormal.Text.Strings = (  
        'Hello from your Indy Server')  
      ReplyNormal.TextCode = '100'  
    end
```

The client code used to execute the command and show its response is as follows:

```
procedure TFormClient.btnTestClick(Sender: TObject);  
begin  
  IdTCPClient1.SendCmd ('test');  
  ShowMessage (IdTCPClient1.LastCmdResult.TextCode + ' : ' +  
    IdTCPClient1.LastCmdResult.Text.Text);  
end;
```

For more complex cases, you should execute code on the server and read and write directly over the socket connection. This approach is shown in the second command of the trivial protocol I've come up with for this example. The server's second command is called `execute`; and it has no special property set (only the command name), but has the following `OnCommand` event handler:

```
procedure TFormServer.IdTCPServer1TIdCommandHandler1Command(  
  ASender: TIdCommand);  
begin  
  ASender.Thread.Connection.WriteLine ('This is a dynamic response');  
end;
```

The corresponding client code writes the command name to the socket connection and then reads a single-line response, using different methods than the first one:

```
procedure TFormClient.btnExecuteClick(Sender: TObject);  
begin  
  IdTCPClient1.WriteLine('execute');  
  ShowMessage (IdTCPClient1.ReadLn);  
end;
```

```
end;
```

The effect is similar to the previous example, but because it uses a lower-level approach, it should be easier to customize it to your needs. One such extension is provided by the third and last command in the example, which allows the client program to request a bitmap file from the server (in a sort of file-sharing architecture). The server command has parameters (the filename) and is defined as follows:

```
object IdTCPServer1: TIdTCPServer
  CommandHandlers = <
    item
      CmdDelimiter = ' '
      Command = 'getfile'
      Name = 'TIdCommandHandler2'
      OnCommand = IdTCPServer1TIdCommandHandler2Command
      ParamDelimiter = ' '
      ReplyExceptionCode = 0
      ReplyNormal.NumericCode = 0
      Tag = 0
    end>
```

The code uses the first parameter as filename and returns it in a stream. In case of error, it raises an exception, which will be intercepted by the server component, which in turn will terminate the connection (not a very realistic solution, but a safe approach and a simple one to implement):

```
procedure TFormServer.IdTCPServer1TIdCommandHandler2Command(
  ASender: TIdCommand);
var
  filename: string;
  fstream: TFileStream;
begin
  if Assigned (ASender.Params) then
    filename := HttpDecode (ASender.Params [0]);
  if not FileExists (filename) then
    begin
      ASender.Response.Text := 'File not found';
      lbLog.Items.Add ('File not found: ' + filename);
      raise EIdTCPServerError.Create ('File not found: ' + filename);
    end
  else
    begin
      fstream := TFileStream.Create (filename, fmOpenRead);
      try
        ASender.Thread.Connection.WriteStream(fstream, True, True);
        lbLog.Items.Add ('File returned: ' + filename +
          ' (' + IntToStr (fStream.Size) + ')');
      finally
        fstream.Free;
      end;
    end;
  end;
end;
```

The call to the `HttpDecode` utility function on the parameter is required to encode a pathname that includes spaces as a single parameter, at the reverse the client program calls `HttpEncode`. As you can see, the server also logs the files returned and their sizes, or an error message. The client program reads the stream and copies it into an `Image` component, to show it directly (see [Figure 19.1](#)):

```
procedure TFormClient.btnGetFileClick(Sender: TObject);
var
```

```

stream: TStream;
begin
  IdTCPClient1.WriteLine('getfile ' + HttpEncode (edFileName.Text));
  stream := TMemoryStream.Create;
  try
    IdTCPClient1.ReadStream(stream);
    stream.Position := 0;
    Image1.Picture.Bitmap.LoadFromStream (stream);
  finally
    stream.Free;
  end;
end;

```

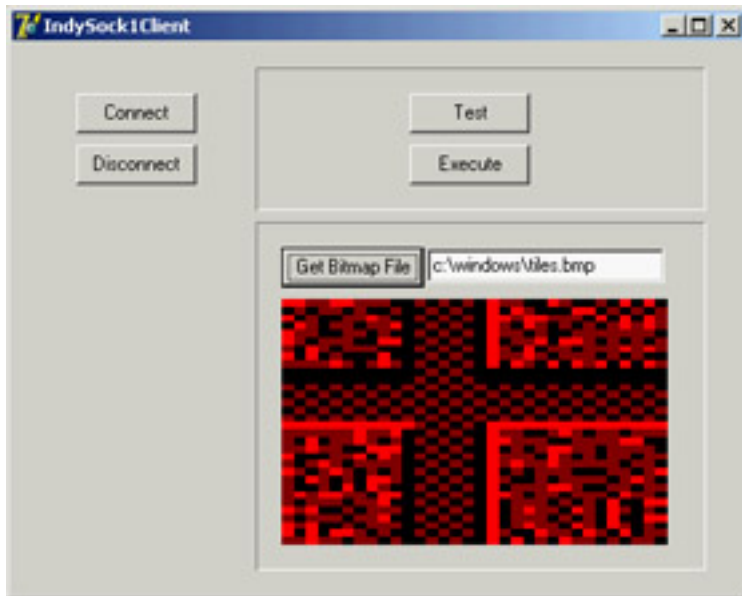

Figure 19.1: The client program of the IndySock1 example

## Sending Database Data over a Socket Connection

Using the techniques you've seen so far, you can write an application that moves database records over a socket. The idea is to write a front end for data input and a back end for data storage. The client application will have a simple data-entry form and use a database table with string fields for Company, Address, State, Country, Email, and Contact, and a floating-point field for the company ID (called CompID).

**Note** Moving database records over a socket is exactly what you can do with DataSnap and a socket connection component (as covered in [Chapter 16](#), "Multitier DataSnap Applications") or with SOAP support (discussed in [Chapter 23](#), "Web Services and SOAP").

The client program I've come up with works on a ClientDataSet with this structure saved in the current directory. (You can see the related code in the `OnCreate` event handler.) The core method on the client side is the handler of the Send All button's `OnClick` event, which sends all the new records to the server. A new record is determined by looking to see whether the record has a valid value for the CompID field. This field is not set up by the user but is determined by the server application when the data is sent.

For all the new records, the client program packages the field information in a string list, using the structure *FieldName=FieldValue*. The string corresponding to the entire list, which is a record, is then sent to the server. At this point, the program waits for the server to send back the company ID, which is then saved in the current record. All this code takes place within a thread, to avoid blocking the user interface during the lengthy operation. By clicking the Send button, a user starts a new thread:

```

procedure TForm1.btnSendClick(Sender: TObject);

```

```

var
    SendThread: TSendThread;
begin
    SendThread := TSendThread.Create(cds);
    SendThread.OnLog := OnLog;
    SendThread.ServerAddress := EditServer.Text;
    SendThread.Resume;
end;

```

The thread has a few parameters: the dataset passed in the constructor, the address of the server saved in the `ServerAddress` property, and a logging event to write to the main form (within a safe `Synchronize` call). The thread code creates and opens a connection and keeps sending records until it's finished:

```

procedure TSendThread.Execute;
var
    I: Integer;
    Data: TStringList;
    Buf: String;
begin
    try
        Data := TStringList.Create;
        fIdTcpClient := TIdTcpClient.Create (nil);
        try
            fIdTcpClient.Host := ServerAddress;
            fIdTcpClient.Port := 1051;
            fIdTcpClient.Connect;
            fDataSet.First;
            while not fDataSet.Eof do
                begin
                    // if the record is still not logged
                    if fDataSet.FieldName('CompID').IsNull or
                        (fDataSet.FieldName('CompID').AsInteger = 0) then
                        begin
                            FLogMsg := 'Sending ' + fDataSet.FieldName('Company').AsString;
                            Synchronize(DoLog);
                            Data.Clear;
                            // create strings with structure "FieldName=Value"
                            for I := 0 to fDataSet.FieldCount - 1 do
                                Data.Values [fDataSet.Fields[I].FieldName] :=
                                    fDataSet.Fields [I].AsString;
                            // send the record
                            fIdTcpClient.Writeln ('senddata');
                            fIdTcpClient.WriteString (Data, True);
                            // wait for reponse
                            Buf := fIdTcpClient.ReadLn;
                            fDataSet.Edit;
                            fDataSet.FieldName('CompID').AsString := Buf;
                            fDataSet.Post;
                            FLogMsg := fDataSet.FieldName('Company').AsString +
                                ' logged as ' + fDataSet.FieldName('CompID').AsString;
                            Synchronize(DoLog);
                        end;
                    fDataSet.Next;
                end;
            finally
                fIdTcpClient.Disconnect;
                fIdTcpClient.Free;
            end;

```

```

    Data.Free;
end;
except
    // trap exceptions in case of dataset errors
    // (concurrent editing and so on)
end;
end;
end;

```

Now let's look at the server. This program has a database table, again stored in the local directory, with two more fields than the client application's table: `LoggedBy`, a string field; and `LoggedOn`, a data field. The values of the two extra fields are determined automatically by the server as it receives data, along with the value of the `CompID` field. All these operations are done in the handler of the `senddata` command:

```

procedure TForm1.IdTCPServer1TIdCommandHandler0Command(
    ASender: TIdCommand);
var
    Data: TStrings;
    I: Integer;
begin
    Data := TStringList.Create;
    try
        ASender.Thread.Connection.ReadStrings(Data);
        cds.Insert;
        // set the fields using the strings
        for I := 0 to cds.FieldCount - 1 do
            cds.Fields [I].AsString :=
                Data.Values [cds.Fields[I].FieldName];
        // complete with ID, sender, and date
        Inc(ID);
        cdsCompID.AsInteger := ID;
        cdsLoggedBy.AsString := ASender.Thread.Connection.Socket.Binding.PeerIP;
        cdsLoggedOn.AsDateTime := Date;
        cds.Post;
        // return the ID
        ASender.Thread.Connection.WriteLine(cdsCompID.AsString);
    finally
        Data.Free;
    end;
end;

```

Except for the fact that some data might be lost, there is no problem when fields have a different order and if they do not match, because the data is stored in the *FieldName=FieldValue* structure. After receiving all the data and posting it to the local table, the server sends back the company ID to the client. When receiving feedback, the client program saves the company ID, which marks the record as sent. If the user modifies the record, there is no way to send an update to the server. To accomplish this, you might add a modified field to the client database table and make the server check to see if it is receiving a new field or a modified field. With a modified field, the server should not add a new record but update the existing one.

As shown in [Figure 19.2](#), the server program has two pages: one with a log and the other with a DBGrid showing the current data in the server database table. The client program is a form-based data entry, with extra buttons to send the data and delete records already sent (and for which an ID was received back).

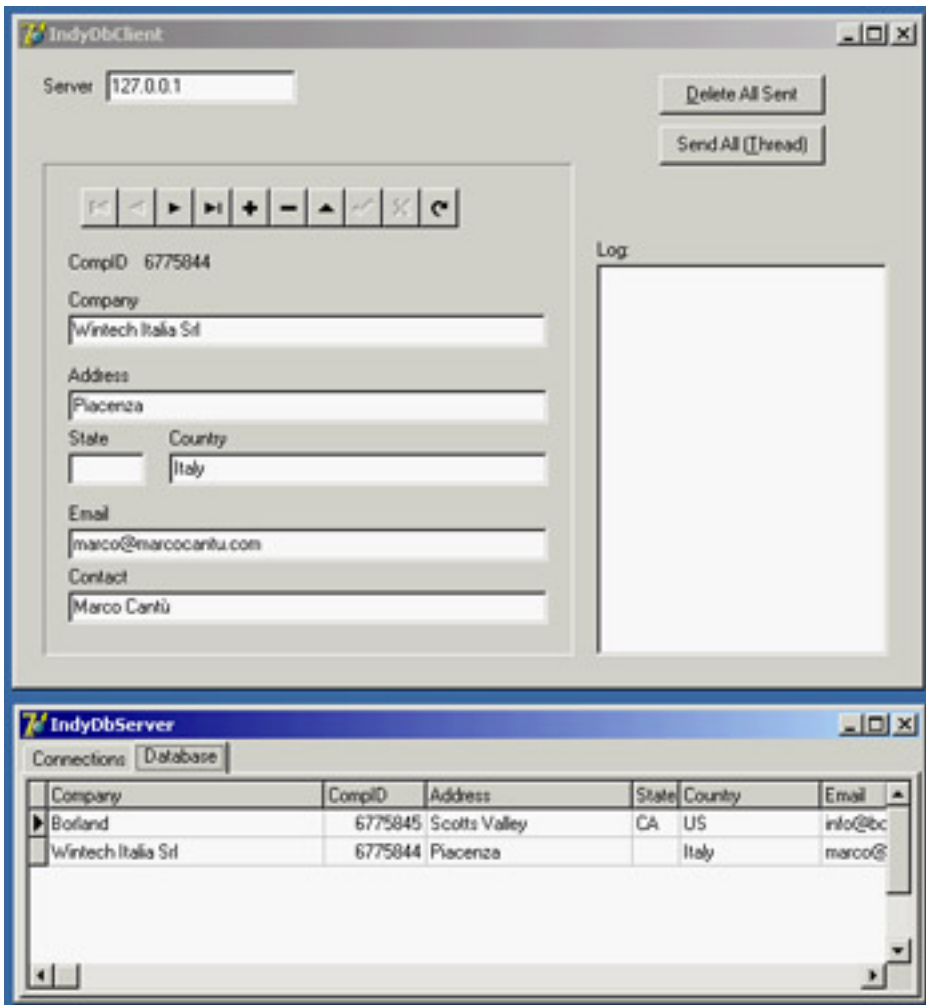

Figure 19.2: The client and server programs of the data-base socket example (IndyDbSock)

## Sending and Receiving Mail

Probably the most common operation you do on the Internet is to send and receive e-mail. There is generally little need to write a complete application to handle e-mail, because some of the existing programs are rather complete. For this reason, I have no intention of writing a general-purpose mail program here. You can find some examples of those among Indy demos. Other than creating a general-purpose mail application, you can do many things with the mail components and protocols; I've grouped the possibilities into two areas:

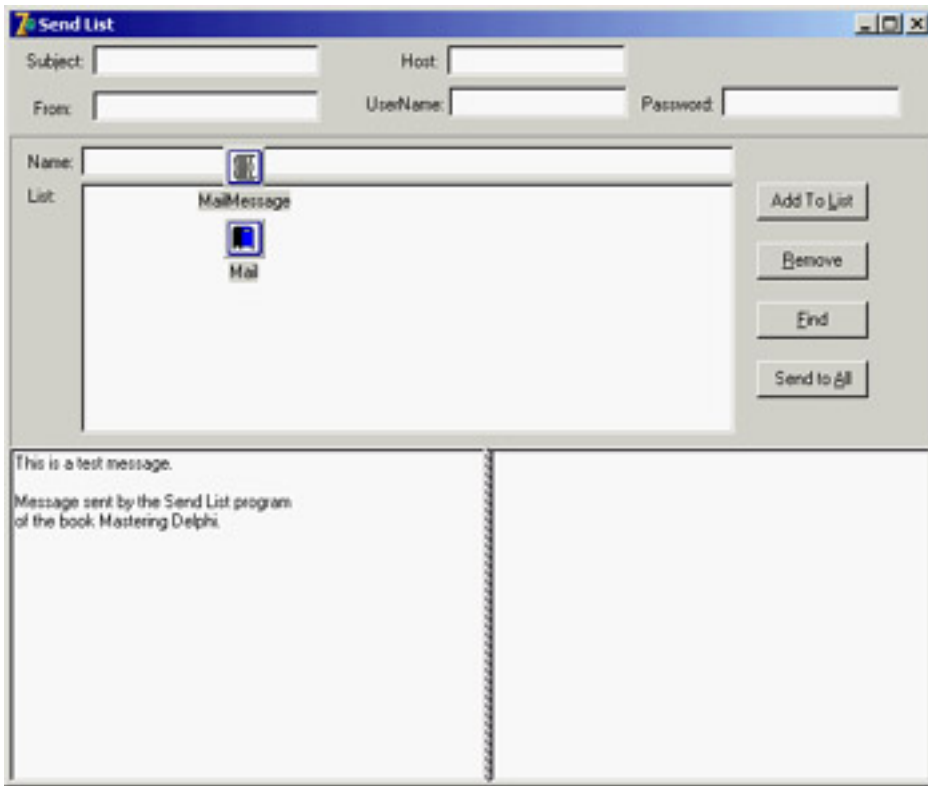

**Automatic Generation of Mail Messages** An application you've written can have an About box for sending a registration message back to your marketing department or a specific menu item for sending a request to your tech support. You might even decide to enable a tech-support connection whenever an exception occurs. Another related task could automate the dispatching of a message to a list of people or generate an automatic message from your website (an example I'll show you toward the end of this chapter).

**Use of Mail Protocols for Communication with Users Who Are Only Occasionally Online** When you must move data between users who are not always online, you can write an application on a server to synchronize among them, and you can give each user a specialized client application for interacting with the server. An alternative is to use an existing server application, such as a mail server, and write the two specialized programs based on the mail protocols. The data sent over this connection will generally be formatted in special ways, so you'll want to use a specific e-mail address for these messages (not your primary e-mail address). As an example, you could rewrite the earlier IndyDbSock example to dispatch mail messages instead of using a custom socket connection. This approach has the advantage of being firewall-friendly and allowing the server to be temporarily offline, because the requests will be kept on the mail server.

## Mail In and Out

Using the mail protocols with Indy means placing a message component (`IdMessage`) in your application, filling it with data, and then using the `IdSMTP` component to send the mail message. To *retrieve* a mail message from your mailbox, use the `IdPop3` component, which will return an `IdMessage` object. To give you an idea how this process works, I've written a program for sending mail to multiple people at once, using a list stored in an ASCII file. I originally used this program to send mail to people who sign up on my website, but later I extended the program by adding database support and the ability to read subscriber logs automatically. The original version of the program is still a good introduction to the use of the Indy SMTP component.

The `SendList` program keeps a list of names and e-mail addresses in a local file, which is displayed in a list box. A few buttons allow you to add and remove items, or to modify an item by removing it, editing it, and then adding it again. When the program closes, the updated list is automatically saved. Now let's get to the interesting portion of the program. The top panel, shown in [Figure 19.3](#) at design time, allows you to enter the subject, the sender address, and the information used to connect to the mail server (hostname, username, and eventually a password).

**Figure 19.3:** The SendList program at design time

You'll probably want to make the value of these edit boxes persistent, possibly in an INI file. I haven't done this, only because I don't want you to see my mail connection details! The value of these edit boxes, along with the list of addresses, allows you to send the series of mail messages (after customizing them) with the following code:

```

procedure TMainForm.BtnSendAllClick(Sender: TObject);
var
    nItem: Integer;
    Res: Word;
begin
    Res := MessageDlg ('Start sending from item ' +
        IntToStr (ListAddr.ItemIndex) + ' (' +
        ListAddr.Items [ListAddr.ItemIndex] + ')?'#13 +
        '(No starts from 0)', mtConfirmation, [mbYes, mbNo, mbCancel], 0);
    if Res = mrCancel then
        Exit;
    if Res = mrYes then
        nItem := ListAddr.ItemIndex
    else
        nItem := 0;
    // connect
    Mail.Host := eServer.Text;
    Mail.UserName := eUserName.Text;
    if ePassword.Text <> '' then
        begin
            Mail.Password := ePassword.Text;
            Mail.AuthenticationType := atLogin;
        end;
    Mail.Connect;
    // send the messages, one by one, prepending a custom message
    try
        // set the fixed part of the header
        MailMessage.From.Name := eFrom.Text;
        MailMessage.Subject := eSubject.Text;

```

```
MailMessage.Body.SetText (reMessageText.Lines.GetText);
MailMessage.Body.Insert (0, 'Hello');
while nItem < ListAddr.Items.Count do
begin
    // show the current selection
    Application.ProcessMessages;
    ListAddr.ItemIndex := nItem;
    MailMessage.Body [0] := 'Hello ' + ListAddr.Items [nItem];
    MailMessage.Recipients.EmailAddresses := ListAddr.Items [nItem];
    Mail.Send(MailMessage);
    Inc (nItem);
end;
finally // we're done
    Mail.Disconnect;
end;
end;
```

Another interesting example of using mail is to notify developers of problems within applications (a technique you might want to use in an internal application rather than in one you'll distribute widely). You can obtain this effect by modifying the [ErrorLog](#) example from [Chapter 2](#) and sending mail when an exception (or one of a given type only) occurs.

## Working with HTTP

Handling mail messages is certainly interesting, and mail protocols are probably still the most widespread Internet protocols. The other popular protocol is HTTP, which is used by web servers and web browsers. I'll devote the rest of this chapter to this protocol (along with a discussion of HTML); the following two chapters also discuss it.

On the client side of the Web, the main activity is browsing—reading HTML files. Besides building a custom browser, you can embed the Internet Explorer ActiveX control within your program (as I've done in the WebDemo example in [Chapter 12](#), "From COM to COM+"). You can also directly activate the browser installed on the user's computer—for example, opening an HTML page by calling the `ShellExecute` method (defined in the `ShellApi` unit):

```
ShellExecute(Handle, 'open', FileName, '', '', sw_ShowNormal);
```

Using `ShellExecute`, you can simply execute a document, such as a file. Windows will start the program associated with the `HTM` extension, using the action passed as the parameter (in this case, `open`, but passing `nil` would have invoked the standard action producing the same effect). You can use a similar call to view a website, by using a string like `'http://www.example.com'` instead of a filename. In this case, the system recognizes the `http` section of the request as requiring a web browser and launches it.

On the server side, you generate and make available the HTML pages. At times, it may be enough to have a way to produce static pages, occasionally extracting new data from a database table to update the HTML files as needed. In other cases, you'll need to generate pages dynamically based on a request from a user.

As a starting point, I'll discuss HTTP by building a simple but complete client and server; then I'll move on to discuss HTML producer components. In [Chapter 20](#), I'll move from this "core technology" level to the RAD development style for the web supported by Delphi, introducing the web server extension technologies (CGI, ISAPI, and Apache modules) and discussing the WebBroker and WebSnap architectures.

## Grabbing HTTP Content

As an example of the use of the HTTP protocols, I've written a specific search application. The program hooks onto the Google website, searches for a keyword, and retrieves the first 100 sites found. Instead of showing the resulting HTML file, the program parses it to extract only the URLs of the related sites to a list box. The description of these sites is kept in a separate string list and is displayed as you click a list-box item. So, the program demonstrates two techniques at once: retrieving a web page and parsing its HTML code.

To demonstrate how you should work with blocking connections, such as those used by Indy, I've implemented the program using a background thread for the processing. This approach also gives you the advantage of being able to start multiple searches at once. The thread class used by the WebFind application receives as input a URL to look for, `strUrl`.

The class has two output procedures, `AddToList` and `ShowStatus`, to be called inside the `Synchronize` method. The code of these two methods sends some results or some feedback to the main form, respectively adding a line to the list box and changing the status bar's `SimpleText` property. The key method of the thread is `Execute`. Before we look at it, however, here is how the thread is activated by the main form:

```
const
  strSearch = 'http://www.google.com/search?as_q=';

procedure TForm1.BtnFindClick(Sender: TObject);
var
  FindThread: TFindWebThread;
begin
  // create suspended, set initial values, and start
  FindThread := TFindWebThread.Create(True);
  FindThread.FreeOnTerminate := True;
```

```

// grab the first 100 entries
FindThread.strUrl := strSearch + EditSearch.Text + '&num=100';
FindThread.Resume;
end;

```

The URL string is made of the main address of the search engine, followed by some parameters. The first, `as_q`, indicates the words you are looking for. The second, `num=100`, indicates the number of sites to retrieve; you cannot use numbers at will but are limited to a few alternatives, with 100 being the largest possible value.

**Warning** The WebFind program works with the server on the Google website at the time this book was written and tested. The custom software on the site can change, however, which might prevent WebFind from operating correctly. This program was also in *Mastering Delphi 6*; however, it was missing the user agent HTTP header, and after a while Google changed its server software and blocked the requests. Adding any value for the user agent fixed the problem.

The thread's `Execute` method, activated by the `Resume` call, calls the two methods doing the work (shown in [Listing 19.1](#)). In the first, `GrabHtml`, the program connects to the HTTP server using a dynamically created `IdHttp` component and reads the HTML with the result of the search. The second method, `HtmlToList`, extracts the URLs referring to other websites from the result, the `strRead` string.

var
    Http1: TIdHTTP;
begin
    Status := 'Sending query: ' + StrUrl;
    Synchronize (ShowStatus);
    Http1 := TIdHTTP.Create (nil);
    try
        Http1.Request.UserAgent := 'User-Agent: NULL';
        Http1.OnWork := HttpWork;
        strRead := Http1.Get (StrUrl);
    finally
        Http1.Free;
    end;
end;

procedure TFindWebThread.HtmlToList;
var
    strAddr, strText: string;
    nText: integer;
    nBegin, nEnd: Integer;
begin
    Status := 'Extracting data for: ' + StrUrl;
    Synchronize (ShowStatus);
    strRead := LowerCase (strRead);
    repeat
        // find the initial part HTTP reference
        nBegin := Pos ('href=http', strRead);
        if nBegin <> 0 then
            begin
                // get the remaining part of the string, starting with 'http'
                strRead := Copy (strRead, nBegin + 5, 1000000);
                // find the end of the HTTP reference
                nEnd := Pos ('>', strRead);
                strAddr := Copy (strRead, 1, nEnd - 1);
                // move on
                strRead := Copy (strRead, nEnd + 1, 1000000);
                // add the URL if 'google' is not in it
                if Pos ('google', strAddr) = 0 then
                    begin
                        nText := Pos ('</a>', strRead);
                        strText := copy (strRead, 1, nText - 1);
                        // remove cached references and duplicates
                        if (Pos ('cached', strText) = 0) then

```

```

begin
  Addr := strAddr;
  Text := strText;
  AddToList;
end;
end;
end;
until nBegin = 0;
end;

procedure TFindWebThread.HttpWork(Sender: TObject; AWorkMode: TWorkMode;
  const AWorkCount: Integer);
begin
  Status := 'Received ' + IntToStr (AWorkCount) + ' for ' + strUrl;
  Synchronize (ShowStatus);
end;

procedure TFindWebThread.ShowStatus;
begin
  Form1.StatusBar1.SimpleText := Status;
end;

end.

```

---

The program looks for subsequent occurrences of the href=http substring, copying the text up to the closing > character. If the found string contains the word *google*, or its target text includes the word *cached*, it is omitted from the result. You can see the effect of this code in the output shown in [Figure 19.4](#). You can start multiple searches at the same time, but be aware that the results will be added to the same memo component.

**Figure 19.4:** The WebFind application can be used to search for a list of sites on the Google search engine.

## The WinInet API

When you need to use the FTP and HTTP protocols, as alternatives to using particular VCL components, you can use a specific API provided by Microsoft in the WinInet DLL. This library is part of the core operating system and implements the FTP and HTTP protocols on top of the Windows sockets API.

With just three calls—`InternetOpen`, `InternetOpenURL`, and `InternetReadFile`—you can retrieve a file corresponding to any URL and store a local copy or analyze it. Other simple methods can be used for FTP; I suggest you look for the source code of the `WinInet.pas` Delphi unit, which lists all the functions.

**Tip** The help file of the WinInet library is not part of the SDK Help shipping with Delphi, but can be found online on MSDN at [msdn.microsoft.com/library/en-us/wininet/wininet/wininet\\_reference.asp](http://msdn.microsoft.com/library/en-us/wininet/wininet/wininet_reference.asp).

The `InternetOpen` function establishes a generic connection and returns a handle you can use in the `InternetOpenURL` call. This second call returns a handle to the URL that you can pass to the `InternetReadFile` function in order to read blocks of data. In the following sample code, the data is stored in a local string. When all the data has been read, the program closes the connection to the URL and the Internet session by calling the `InternetCloseHandle` function twice:

```
var
  hHttpSession, hReqUrl: HInternet;
  Buffer: array [0..1023] of Char;
  nRead: Cardinal;
  strRead: string;
  nBegin, nEnd: Integer;
begin
  strRead := '';
  hHttpSession := InternetOpen ('FindWeb', INTERNET_OPEN_TYPE_PRECONFIG,
    nil, nil, 0);
  try
    hReqUrl := InternetOpenURL (hHttpSession, PChar(StrUrl), nil, 0,0,0);
    try // read all the data
      repeat
        InternetReadFile (hReqUrl, @Buffer, sizeof (Buffer), nRead);
        strRead := strRead + string (Buffer);
      until nRead = 0;
    finally
      InternetCloseHandle (hReqUrl);
    end;
  finally
    InternetCloseHandle (hHttpSession);
  end;
end;
```

## Browsing on Your Own

Although I doubt you are interested in writing a new web browser, it might be interesting to see how you can grab an HTML file from the Internet and display it locally, using the HTML viewer available in CLX (the `TextBrowser` control). Connecting this control to an Indy HTTP client, you can quickly come up with a simplistic text-only browser with limited navigation. The core is

```
TextBrowser1.Text := IdHttp1.Get (NewUrl);
```

where `NewUrl` is complete location of the web resource you want to access. In the `BrowseFast` example, this URL is entered in a combo box, which keeps track of recent requests. The effect of a similar call is to return the textual portion of a web page (see [Figure 19.5](#)), because grabbing the graphic content requires much more complex coding. The `TextBrowser` control really is better defined as a local file viewer than as a browser.

Figure 19.5: The output of the BrowseFast text-only browser

I've added to the program only very limited support for hyperlinks. When a user moves the mouse over a link, its link text is copied to a local variable (`NewRequest`), which is then used in case of a click on the control to compute the new HTTP request to forward. Merging the current address (`LastUrl`) with the request, though, is far from trivial, even with the help of the `IdUrl` class provided by Indy. Here is my code, which handles only the simplest cases:

```

procedure TForm1.TextBrowser1Click(Sender: TObject);
var
    Uri: TIdUri;
begin
    if NewRequest <> '' then
    begin
        Uri := TIdUri.Create (LastUrl);
        if Pos ('http:', NewRequest) > 0 then
            GoToUrl (NewRequest)
        else if NewRequest [1] = '/' then
            GoToUrl ('http://' + Uri.Host + NewRequest)
        else
            GoToUrl ('http://' + Uri.Host + Uri.Path + NewRequest);
    end;
end;

```

Again, this example is trivial and far from usable, but building a browser involves little more than the ability to connect via HTTP and display HTML files.

## A Simple HTTP Server

The situation with the development of an HTTP server is quite different. Building a server to deliver static pages based on HTML files is far from simple, although one of the Indy demos provides a good starting point. However, a custom HTTP server might be interesting when building a totally dynamic site, something I'll focus on in more detail in [Chapter 20](#).

To show you how to begin the development of a custom HTTP server, I've built the `HttpServ` example. This program has a form with a list box used for logging requests and an `IdHTTPServer` component with these settings:

```

object IdHTTPServer1: TIdHTTPServer
  Active = True
  DefaultPort = 8080
  OnCommandGet = IdHTTPServer1CommandGet
end

```

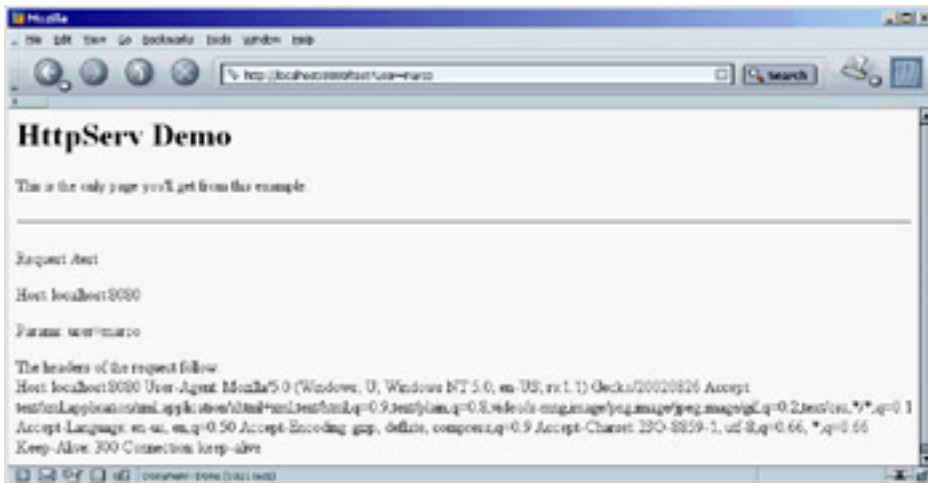

The server uses port 8080 instead of the standard port 80, so that you can run it alongside another web server. All the custom code is in the `OnCommandGet` event handler, which returns a fixed page plus some information about the request:

```

procedure TForm1.IdHTTPServer1CommandGet(AThread: TIdPeerThread;
  RequestInfo: TIdHTTPRequestInfo; ResponseInfo: TIdHTTPResponseInfo);
var
  HtmlResult: String;
begin
  // log
  Listbox1.Items.Add (RequestInfo.Document);
  // respond
  HtmlResult := '<h1>HttpServ Demo</h1>' +
    '<p>This is the only page you''ll get from this example.</p><hr>' +
    '<p>Request: ' + RequestInfo.Document + '</p>' +
    '<p>Host: ' + RequestInfo.Host + '</p>' +
    '<p>Params: ' + RequestInfo.UnparsedParams + '</p>' +
    '<p>The headers of the request follow: <br>' +
    RequestInfo.RawHeaders.Text + '</p>';
  ResponseInfo.ContentText := HtmlResult;
end;

```

By passing a path and some parameters in the command line of the browser, you'll see them reinterpreted and displayed. For example, [Figure 19.6](#) shows the effect of this command line:

**Figure 19.6:** The page displayed by connecting a browser to the custom `HttpServ` program

`http://localhost:8080/test?user=marco`

If this example seems too trivial, you'll see a slightly more interesting version in the [next section](#), where I discuss the generation of HTML with Delphi's producer components.

**Note** If you plan to build an advanced web server or other Internet servers with Delphi, then as an alternative to the Indy components, you should look at the `DXSock` components from Brain Patchwork DX ([www.dxsock.com](http://www.dxsock.com)).

## Generating HTML

The Hypertext Markup Language, better known by its acronym HTML, is the most widespread format for content on the Web. HTML is the format web browsers typically read; it is a standard defined by the W3C (World Wide Web Consortium, [www.w3.org](http://www.w3.org)), which is one of the bodies controlling the Internet. The HTML standard document is available on [www.w3.org/MarkUp](http://www.w3.org/MarkUp) along with and some interesting links.

### Delphi's HTML Producer Components

Delphi's HTML producer components (on the Internet page of the Component Palette) can be used to generate the HTML files and particularly to turn a database table into an HTML table. Many developers believe that the use of these components makes sense only when writing a web server extension. Although they were introduced for this purpose and are part of the WebBroker technology, you can still use three out of the five producer components in any application in which you must generate a static HTML file.

Before looking at the HtmlProd example, which demonstrates the use of these HTML producer components, let me summarize their role:

- The simplest HTML producer component is the PageProducer, which manipulates an HTML file in which you've embedded special tags. The HTML can be stored in an external file or an internal string list. The advantage of this approach is that you can generate such a file using the HTML editor you prefer. At run time, the PageProducer converts the special tags to HTML code, giving you a straightforward method for modifying sections of an HTML document. The special tags have the basic format `<#tagname>`, but you can also supply named parameters within the tag. You'll process the tags in the `OnTag` event handler of the PageProducer.
- The DataSetPageProducer extends the PageProducer by automatically replacing tags corresponding to field names of a connected data source.
- The DataSetTableProducer component is generally useful for displaying the contents of a table, query, or other dataset. The idea is to produce an HTML table from a dataset, in a simple yet flexible way. The component has a nice preview, so you can see how the HTML output will look in a browser directly at design time.
- The QueryTableProducer and the SQLQueryTableProducer components are similar to the DataSetTableProducer, but they are specifically tailored for building parametric queries (for the BDE or dbExpress, respectively) based on input from an HTML search form. This component makes little sense in a stand-alone program, and for this reason, I'll delay covering these components until [Chapter 20](#).

### Producing HTML Pages

A very simple example of using tags (introduced by the # symbol) is creating an HTML file that displays fields with the current date or a date computed relative to the current date, such as an expiration date. If you examine the HtmlProd example, you'll find a PageProducer1 component with internal HTML code, specified by the `HTMLDOC` string list:

```
<html>
<head>
<title>Producer Demo</title>
</head>
<body>
<h1>Producer Demo</h1>
<p>This is a demo of the page produced by the <b><#appname></b> application on
<b><#date></b>.</p>
<hr>
<p>The prices in this catalog are valid until <b><#expiration
days=21></b>.</p>
</body>
```

</html>

**Warning** If you prepare this file with an HTML editor (something I suggest you do), it may automatically place quotes around tag parameters, as in `days="21"`, because this format is required by HTML 4 and XHTML. The PageProducer component has a `StripParamQuotes` property you can activate to remove those extra quotes when the component parses the code (before calling the `OnHTMLTag` event handler).

The Demo Page button copies the PageProducer component's output to the `Text` of a Memo. As you call the `Content` function of the PageProducer component, it reads the input HTML code, parses it, and triggers the `OnTag` event handler for every special tag. In the handler for this event, the program checks the value of the tag (passed in the `TagString` parameter) and returns a different HTML text (in the `ReplaceText` reference parameter), producing the output shown in [Figure 19.7](#).

**Figure 19.7:** The output of the HtmlProd example, a simple demonstration of the Page-Producer component, when the user clicks the Demo Page button

```
procedure TFormProd.PageProducer1HTMLTag(Sender: TObject;
Tag: TTag; const TagString: String; TagParams: TStrings;
var ReplaceText: String);
var
nDays: Integer;
begin
if TagString = 'date' then
    ReplaceText := DateToStr (Now)
else if TagString = 'appname' then
    ReplaceText := ExtractFilename (Forms.Application.Exename)
else if TagString = 'expiration' then
begin
    nDays := StrToIntDef (TagParams.Values['days'], 0);
if nDays <> 0 then
        ReplaceText := DateToStr (Now + nDays)
    else
        ReplaceText := '<i>{expiration tag error}</i>';
    end;
end;
```

Notice in particular the code I've written to convert the last tag, `#expiration`, which requires a parameter. The PageProducer places the entire text of the tag parameter (in this case, `days=21`) in a string that's part of the `TagParams` list. To extract the value portion of this string (the portion after the equal sign), you can use the `Values` property of the `TagParams` string list and search for the proper entry at the same time. If it can't locate the parameter or if the parameter's value isn't an integer, the program displays an error message.

**Tip** The PageProducer component supports user-defined tags, which can be any string you like, but you should first review the special tags defined by the `TTags` enumeration. The possible values include `tgLink` (for the `link` tag), `tgImage` (for the `img` tag), `tgTable` (for the `table` tag), and a few others. If you create a custom tag, as in the PageProd example, the value of the `Tag` parameter to the HTMLTag handler will be `tgCustom`.

## Producing Pages of Data

The HtmlProd example also has a `DataSetPageProducer` component, which is connected with a database table and with the following HTML source code:

```
<html><head><title>Data for <#name></title></head>
<body>
<h1><center>Data for <#name></center></h1>
<p>Capital: <#capital></p>
<p>Continent: <#continent></p>
<p>Area: <#area></p>
<p>Population: <#population></p><hr>
<p>Last updated on <#date><br>
HTML file produced by the program <#program>.</p>
</body></html>
```

By using tags with the names of the connected dataset's fields (the usual `COUNTRY.DB` database table), the program automatically gets the value of the current record's fields and replaces them automatically. This produces the output shown in [Figure 19.8](#); the browser is connected to the HtmlProd example working as an HTTP server, as I'll discuss later. In the source code of the program related to this component, there is no reference to the database data:

```
procedure TFormProd.DataSetPageProducer1HTMLTag(Sender: TObject; Tag: TTag;
  const TagString: String; TagParams: TStrings; var ReplaceText: String);
begin
  if TagString = 'program' then
    ReplaceText := ExtractFilename (Forms.Application.Exename)
  else if TagString = 'date' then
    ReplaceText := DateToStr (Date);
end;
```

**Figure 19.8:** The output of the HtmlProd example for the Print Line button

## Producing HTML Tables

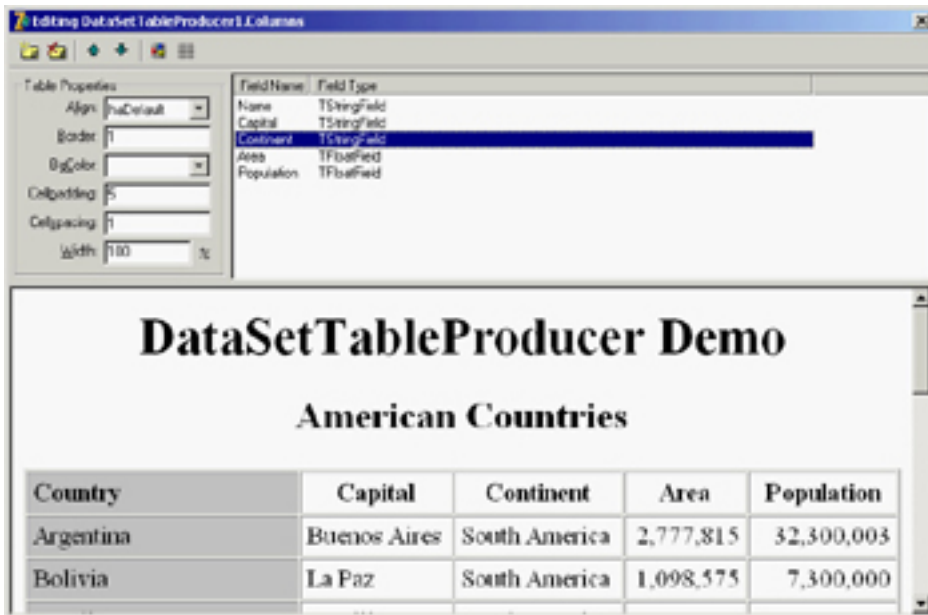

The third button in the HtmlProd example is Print Table. This button is connected to a DataSetTableProducer component, again calling its `Content` function and copying its result to the `Text` of the Memo. By connecting the `DataSet` property of the DataSetTableProducer to `ClientDataSet1`, you can produce a standard HTML table.

The component by default generates only 20 rows, as indicated by the `MaxRows` property. If you want to get all of the table's records, you can set this property to -1—a simple but undocumented setting.

**Tip** The DataSetTableProducer component starts from the current record rather than from the first one. So, the second time you click the Print Table button, you'll see no records in the output. Adding a call to the dataset's `First` method before calling the producer component's `Content` method fixes the problem.

To make the output of this producer component more complete, you can perform two operations. The first is to provide some `Header` and `Footer` information (to generate the HTML heading and closing elements) and add a `Caption` to the HTML table. The second is to customize the table by using the setting specified by the `RowAttributes`, `TableAttributes`, and `Columns` properties. The property editor for the columns, which is also the default component editor, allows you to set most of these properties, providing at the same time a nice preview of the output, as you can see in [Figure 19.9](#). Before using this editor, you can set up properties for the dataset's fields using the Fields editor. This is how, for example, you can format the output of the population and area fields to use thousands separators.

**Figure 19.9:** The editor of the DataSetTable-Producer component's Columns property provides you with a preview of the final HTML table (if the data-base table is active).

You can use three techniques to customize the HTML table, and it's worth reviewing each of them:

- You can use the table producer component's Column's property to set properties, such as the text and color of the title, or the color and the alignment for the cells in the rest of the column.
- You can use the TField properties, particularly those related to output. In the example, I've set the DisplayFormat property of the ClientDataSet1Area field object to ###,###,###. This is the approach to use if you want to determine the output of each field. You might go even further and embed HTML tags in the output of a field.
- You can handle the DataSetTableProducer component's OnFormatCell event to customize the output further. In this event, you can set the various column attributes uniquely for a given cell, but you can also customize the output string (stored in the CellData parameter) and embed HTML tags. You can't do this using the Columns property.

In the HtmlProd example, I've used a handler for this event to turn the text of the Population and Area columns to bold font and to a red background for large values (unless it is the header row). Here is the code:

```

procedure TFormProd.DataSetTableProducer1FormatCell(
  Sender: TObject; CellRow, CellColumn: Integer;
  var BgColor: THTMLBgColor; var Align: THTMLAlign;
  var VAlign: THTMLVAlign; var CustomAttrs, CellData: String);
begin
  if (CellRow > 0) and
    (((CellColumn = 3) and (Length (CellData) > 8)) or
    ((CellColumn = 4) and (Length (CellData) > 9))) then
    begin
      BgColor := 'red';
      CellData := '<b>' + CellData + '</b>';
    end;
end;

```

The rest of the code is summarized by the settings of the table producer component, including its header and footer, as you can see by opening the source code of the HtmlProd example.

## Using Style Sheets

The latest incarnations of HTML include a powerful mechanism for separating content from presentation: Cascading Style Sheets (CSS). Using a style sheet, you can separate the formatting of the HTML (colors, fonts, font sizes, and so on) from the text displayed (the content of the page). This approach makes your code more flexible and your website easier to update. In addition, you can separate the task of making the site graphically appealing (the work of a web designer) from automatic content generation (the work of a programmer). Style sheets are a complex technique, in which you give formatting values to the main types of HTML sections and to special "classes" (which have nothing to do with OOP). Again, see an HTML reference for the details.

You can update table generation in the `HtmlProd` example to include style sheets by providing a link to the style sheet in the `Header` property of a second `DataSetTableProducer` component:

```
<link rel="stylesheet" type="text/css" href="test.css">
```

You can then update the code of the `OnFormatCell` event handler with the following action (instead of the two lines changing the color and adding the bold font tag):

```
CustomAttrs := 'class="highlight"';
```

The style sheet I've provided (`test.css`, available in the source code of the example) defines a highlight style, which has the bold font and red background that were hard-coded in the first `DataSetTableProducer` component.

The advantage of this approach is that now a graphic artist can modify the CSS file and give your table a nicer look without touching its code. When you want to provide many formatting elements, using a style sheet can also reduce the total size of the HTML file. This is an important element that can reduce download time.

## Dynamic Pages from a Custom Server

The `HtmlProd` component can be used to generate static HTML files; it doubles as a web server, using an approach similar to that demonstrated in the `HttpServ` example, but in a more realistic context. The program accesses the request of one of the possible page producers, passing the name of the component in a request. This is a portion of the `IdHTTPServer` component's `OnCommandGet` event handler, which uses the `FindComponent` method to locate the proper producer component:

```
var
  Req, Html: String;
  Comp: TComponent;
begin
  Req := RequestInfo.Document;
  if Req [1] = '/' then
    Req := Copy (Req, 2, 1000); // skip '/'
  Comp := FindComponent (Req);
  if (Req <> '') and Assigned (Comp) and
    (Comp is TCustomContentProducer) then
    begin
      ClientDataSet1.First;
      Html := TCustomContentProducer (Comp).Content;
    end;
  ResponseInfo.ContentText := Html;
end;
```

In case the parameter is not there (or is not valid), the server responds with an HTML-based menu of the available components:

```
Html := '<h1>HtmlProd Menu</h1><p><ul>';
for I := 0 to ComponentCount - 1 do
  if Components [i] is TCustomContentProducer then
    Html := Html + '<li><a href="/" + Components [i].Name + "' +
      Components [i].Name + '</a></li>';
```

```
Html := Html + '</ul></p>';
```

Finally, if the program returns a table that uses CSS, the browser will request the CSS file from the server; so, I've added some specific code to return it. With the proper generalizations, this code shows how a server can respond by returning files, and also how to indicate the MIME type of the response (`ContentType`):

```
if Pos ('test.css', Req) > 0 then
begin
  CssTest := TStringList.Create;
  try
    CssTest.LoadFromFile(ExtractFilePath(Application.ExeName) + 'test.css');
    ResponseInfo.ContentText := CssTest.Text;
    ResponseInfo.ContentType := 'text/css';
  finally
    CssTest.Free;
  end;
  Exit;
end;
```

## What's Next?

In this chapter, I've focused on some core Internet technologies, including the use of sockets and core Internet protocols. I've discussed the main idea and shown a few examples of using the mail and HTTP protocols. You can find many more examples that use the Indy components in the demos written by their developers (which are not installed in Delphi 7).

After this introduction to the world of the Internet, you are now ready to delve into two key areas: the present and the future. The present is represented by the development of web applications, and I'll explore the development of dynamic websites in the next two chapters. I'll focus first on the old WebBroker technology and then move to the new WebSnap architecture. Then, in [Chapter 21](#), I'll discuss IntraWeb. The future is represented by the development of web services and the use of XML and related technology, discussed in [Chapters 22](#) and [23](#).

## Chapter 20: Web Programming with WebBroker and WebSnap

### Overview

The Internet has a growing role in the world, and much of it depends on the success of the World Wide Web, which is based on the HTTP protocol. In [Chapter 19](#), "Internet Programming: Sockets and Indy," we discussed HTTP and the development of client- and server-side applications based on it. With the availability of several high-performance, scalable, flexible web servers, you'll rarely want to create your own. Dynamic web server applications are generally built by integrating scripting or compiled programs within web servers, rather than by replacing them with custom software.

This chapter is entirely focused on the development of server-side applications, which extend existing web servers. I introduced the dynamic generation of HTML pages toward the end of the [last chapter](#). Now you will learn how to integrate this dynamic generation within a server. This chapter is a logical continuation of the last one, but it won't complete this book's coverage of Internet programming; [Chapter 21](#) is devoted to the IntraWeb technology available in Delphi 7, and [Chapter 22](#) gets back to Internet programming from the XML perspective.

**Warning** To test some of the examples in this chapter, you'll need access to a web server. The simplest solution is to use the version of Microsoft's IIS or Personal Web Server already installed on your computer. My personal preference, however, is to use the free open-source Apache Web Server available at [www.apache.org](http://www.apache.org). I won't spend much time giving you details of the configuration of your web server to enable the use of applications; you can refer to its documentation for this information.

## Dynamic Web Pages

When you browse a website, you generally download static pages—HTML-format text files—from the web server to your client computer. As a web developer, you can create these pages manually, but for most businesses, it makes more sense to build the static pages from information in a database (a SQL server, a series of files, and so on). Using this approach, you're basically generating a snapshot of the data in HTML format, which is reasonable if the data isn't subject to frequent changes. This approach was discussed in [Chapter 19](#).

As an alternative to static HTML pages, you can build dynamic pages. To do this, you extract information directly from a database in response to the browser's request, so that the HTML sent by your application displays current data, not an old snapshot of the data. This approach makes sense if the data changes frequently.

As mentioned earlier, there are a couple of ways you can program custom behavior at the web server, and these are ideal techniques you can use to generate HTML pages dynamically. In addition to script-based techniques, which are very popular, two common protocols for programming web servers are CGI (the Common Gateway Interface) and the web server APIs.

**Note** Keep in mind that Delphi's WebBroker technology (available in both the Enterprise Studio and Professional editions) flattens the differences between CGI and server APIs by providing a common class framework. This way, you can easily turn a CGI application into an ISAPI library or integrate it into Apache.

## An Overview of CGI

CGI is a standard protocol for communication between the client browser and the web server. It's not a particularly efficient protocol, but it is widely used and is not platform specific. This protocol allows the browser both to ask for and to send data, and it is based on the standard command-line input and output of an application (usually a console application). When the server detects a page request for the CGI application, it launches the application, passes command-line data from the page request to the application, and then sends the application's standard output back to the client computer.

You can use many tools and languages to write CGI applications, and Delphi is only one of them. Despite the obvious limitation that your web server must be an Intel-based Windows or Linux system, you can build some fairly sophisticated CGI programs in Delphi and Kylix. CGI is a low-level technique, because it uses the standard command-line input and output along with environment variables to receive information from the web server and pass it back.

To build a CGI program without using support classes, you can create a Delphi console application, remove the typical project source code, and replace it with the following statements:

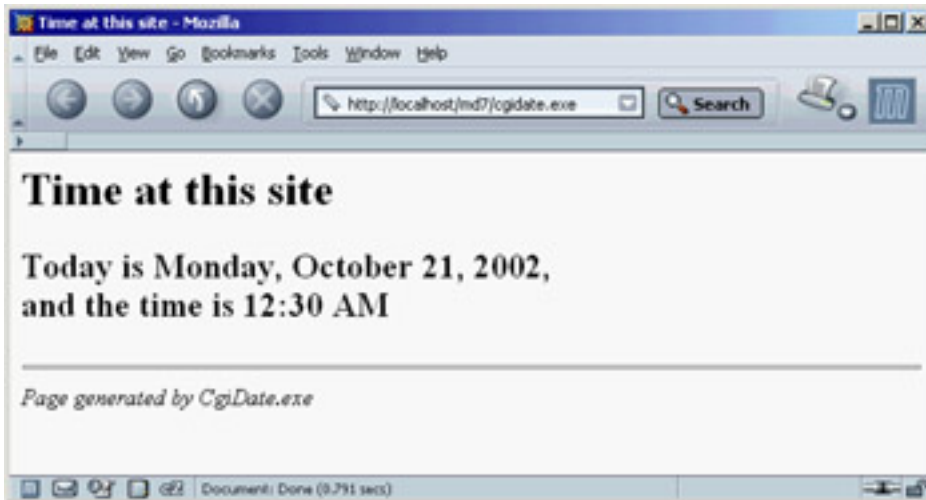

```
program CgiDate;
{$APPTYPE CONSOLE}

uses SysUtils;

begin
  writeln ('content-type: text/html');
  writeln;
  writeln ('<html><head>');
  writeln ('<title>Time at this site</title>');
  writeln ('</head><body>');
  writeln ('<h1>Time at this site</h1>');
  writeln ('<hr>');
  writeln ('<h3>');
  writeln (FormatDateTime('"Today is " dddd, mmmm d, yyyy,' +
    '"<br> and the time is" hh:mm:ss AM/PM', Now));
  writeln ('</h3>');
```

```
writeln ('<hr>');
writeln ('<i>Page generated by CgiDate.exe</i>');
writeln ('</body></html>');
end.
```

CGI programs produce a header followed by the HTML text using the standard output. If you execute this program directly, you'll see the text in a terminal window. If you run it instead from a web server and send the output to a browser, the formatted HTML text will appear, as shown in [Figure 20.1](#).

**Figure 20.1:** The output of the CgiDate application, as seen in a browser

Building advanced applications with plain CGI requires a lot of work. For example, to extract status information about the HTTP request, you need to access the relevant environment variables, as in the following:

```
// get the pathname
GetEnvironmentVariable ('PATH_INFO', PathName, sizeof (PathName));
```

## Using Dynamic Libraries

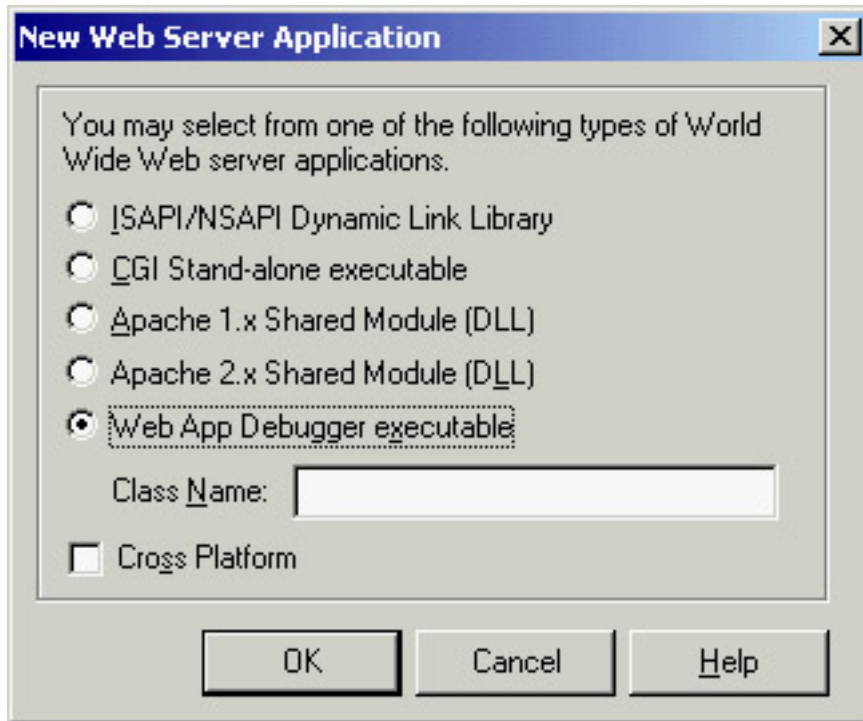

A completely different approach is the use of the web server APIs: the popular ISAPI (Internet Server API, introduced by Microsoft), the less common NSAPI (Netscape Server API), or the Apache API. These APIs allow you to write a library that the server loads into its own address space and keeps in memory. Once it loads the library, the server can execute individual requests via threads within the main process, instead of launching a new EXE for every request (as it must in CGI applications).

When the server receives a page request, it loads the DLL (if it hasn't done so already) and executes the appropriate code, which may launch a new thread or use an existing one to process the request. The library then sends the appropriate HTTP data back to the client that requested the page. Because this communication generally occurs in memory, this type of application tends to be faster than CGI.

## Delphi's WebBroker Technology

The CGI code snippet I've shown you demonstrates the plain, direct approach to this protocol. I could have provided similar low-level examples for ISAPI or Apache modules, but in Delphi it's more interesting to use the WebBroker technology. This comprises a class hierarchy within VCL and CLX (built to simplify server-side development on the Web) and a specific type of data modules called *WebModules*. Both the Enterprise Studio and Professional editions of Delphi include this framework (as opposed to the more advanced and newer WebSnap framework, which is available only in the Enterprise Studio version).

Using the WebBroker technology, you can begin developing an ISAPI or CGI application or an Apache module easily. On the first page (New) of the New Items dialog box, select the Web Server Application icon. The subsequent dialog box will offer you a choice among ISAPI, CGI, Apache 1 or 2 module, and the Web App Debugger:

In each case, Delphi will generate a project with a WebModule, which is a non-visual container similar to a data module. This unit will be identical, regardless of the project type; only the main project file changes. For a CGI application, it will look like this:

```

program Project2;

{$APPTYPE CONSOLE}

uses
  WebBroker,
  CGIApp,
  Unit1 in 'Unit1.pas' {WebModule1: TWebModule};

{$R *.res}

begin
  Application.Initialize;
  Application.CreateForm(TWebModule1, WebModule1);
  Application.Run;
end.

```

Although this is a console CGI program, the code looks similar to that of a standard Delphi application. However, it

uses a trick—the `Application` object used by this program is not the typical global object of class `TApplication` but an object of a new class. This `Application` object is of class `TCGIApplication` or another class derived from `TWebApplication`, depending on your web project type.

The most important operations take place in the `WebModule`. This component derives from `TCustomWebDispatcher`, which provides support for all the input and output of your programs. The `TCustomWebDispatcher` class defines `Request` and `Response` properties, which store the client request and the response you're going to send back to the client. Each of these properties is defined using a base abstract class (`TWebRequest` and `TWebResponse`), but an application initializes them using a specific object (such as the `TISAPIRequest` and `TISAPIResponse` subclasses). These classes make available all the information passed to the server, so you have a single approach to accessing all the information. The same is true of a response, which is easy to manipulate. The key advantage of this approach is that the code written with `WebBroker` is independent of the type of application (CGI, ISAPI, Apache module); you'll be able to move from one to the other, modifying the project file or switching to another one, but you won't need to modify the code written in a `WebModule`.

This is the structure of Delphi's framework. To write the application code, you can use the Actions editor in the `WebModule` to define a series of actions (stored in the `Actions` array property) depending on the *pathname* of the request:

This pathname is a portion of the CGI or ISAPI application's URL, which comes after the program name and before the parameters, such as `path1` in the following URL:

```
http://www.example.com/scripts/cgitest.exe/path1?param1=date
```

By providing different actions, your application can easily respond to requests with different pathnames, and you can assign a different producer component or call a different `OnAction` event handler for every possible pathname. Of course, you can omit the pathname to handle a generic request. Also consider that instead of basing your application on a `WebModule`, you can use a plain data module and add a `WebDispatcher` component to it. This is a good approach if you want to turn an existing Delphi application into a web server extension.

**Warning** The `WebModule` inherits from the base `WebDispatcher` class and doesn't require it as a separate component. Unlike `WebSnap` applications, `WebBroker` programs cannot have multiple dispatchers or multiple web modules. Also note that the actions of the `WebDispatcher` have nothing to do with the actions stored in an `ActionList` or `ActionManager` component.

When you define the accompanying HTML pages that launch the application, the links will make page requests to the URLs for each of those paths. Having a single library that can perform different operations depending on a parameter (in this case, the pathname) allows the server to keep a copy of this library in memory and respond much more quickly to user requests. The same is partially true for a CGI application: The server has to run several instances but can cache the file and make it available more quickly.

In the `OnAction` event, you write the code to specify the *response* to a given *request*, the two main parameters passed to the event handler. Here is an example:

```
procedure TWebModule1.WebModule1WebActionItem1Action(Sender: TObject;  
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);  
begin  
  Response.Content :=  
    '<html><head><title>Hello Page</title></head><body>' +  
    '<h1>Hello</h1>' +
```

```
'<hr><p><i>Page generated by Marco</i></p></body></html>';  
end;
```

In the `Content` property of the `Response` parameter, you enter the HTML code you want users to see. The only drawback of this code is that the output in a browser will be correctly displayed on multiple lines, but looking at the HTML source code, you'll see a single line corresponding to the entire string. To make the HTML source code more readable by splitting it onto multiple lines, you can insert the `#13` newline character (or, even better, the cross-platform `sLineBreak` value).

To let other actions handle this request, you set the last parameter, `Handled`, to `False`. The default value is `True`; if this value is set, then once you've handled the request with your action, the `WebModule` assumes you're finished. Most of a web application's code will be in the `OnAction` event handlers for the actions defined in the `WebModule` container. These actions receive a request from the client and return a response using the `Request` and `Response` parameters.

When you're using the producer components, your `OnAction` event often returns as `Response.Content` the `Content` of the producer component, with an assignment operation. You can shortcut this code by assigning a producer component to the `Producer` property of the action, and you won't need to write these event handlers any more (but don't do both things, because doing so might get you into trouble).

**Tip** As an alternative to the `Producer` property, you can use the `ProducerContent` property. This property allows you to connect custom producer classes that don't inherit from the `TCustomContentProducer` class but implement the `IProduceContent` interface. The `ProducerContent` property is almost an interface property: It behaves the same way, but this behavior is due to its property editor and is not based on Delphi's support for interfaced properties.

## Debugging with the Web App Debugger

Debugging web applications written in Delphi is often difficult. You cannot simply run the program and set breakpoints in it, but must convince the web server to run your CGI program or library within the Delphi debugger. You can do so by indicating a host application in Delphi's Run Parameters dialog box, but this approach implies letting Delphi run the web server (which is often a Windows service, not a stand-alone program).

To solve these issues, Borland has developed a specific Web App Debugger program. This program, which is activated by the corresponding item on the Tools menu, is a web server that waits for requests on a port you can set up (1024 by default). When a request arrives, the program can forward it to a stand-alone executable. In Delphi 6, this communication was based on COM techniques; in Delphi 7 it is based on Indy sockets. In both cases, you can run the web server application from within the Delphi IDE, set all the breakpoints you need, and then (when the program is activated through the Web App Debugger) debug the program as you would a plain executable file.

The Web App Debugger does a good job of logging all the received requests and the responses returned to the browser. The program also has a Statistics page that tracks the time required for each response, allowing you to test the efficiency of an application in different conditions. Another new feature of the Web App Debugger in Delphi 7 is that it is now a CLX application instead of a VCL application. This user interface change and the conversion from COM to sockets were both done to make the Web App Debugger available in Kylix.

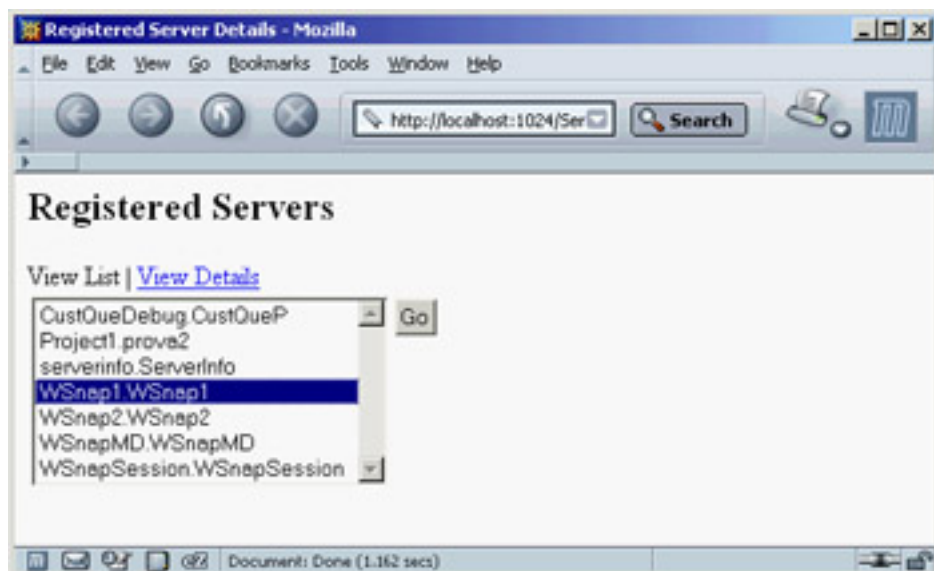

**Warning** Because the Web App Debugger uses Indy sockets, your application will receive frequent exceptions of type `EidConnClosedGracefully`. For this reason, this exception is automatically disabled in all Delphi 7 projects.

By using the corresponding option in the New Web Server Application dialog, you can easily create a new application compatible with the debugger. This option defines a standard project, which creates both a main form and a web module. The (useless) form includes code for providing initialization code and adding the application to the Windows Registry:

### initialization

```
TWebAppSockObjectFactory.Create('program_name');
```

The Web App Debugger uses this information to get a list of the available programs. It does so when you use the default URL for the debugger, indicated in the form as a link, as you can see (for example) in [Figure 20.2](#). The list includes all the registered servers, not only those that are running, and can be used to activate a program. This is not a good idea, though, because you have to run the program within the Delphi IDE to be able to debug it. (Notice that you can expand the list by clicking View Details; this view includes a list of the executable files and many other details.)

**Figure 20.2:** A list of applications registered with the Web App Debugger is displayed when you hook to its home page.

The data module for this type of project includes initialization code:

```
uses WebReq;
```

#### initialization

```
if WebRequestHandler <> nil then  
    WebRequestHandler.WebModuleClass := TWebModule2;
```

The Web App Debugger should be used only for debugging. To deploy the application, you should use one of the other options. You can create the project files for another type of web server program and add to the project the same web module as the debug application.

The reverse process is slightly more complex. To debug an existing application, you have to create a program of this type, remove the web module, add the existing one, and patch it by adding a line to set the `WebModuleClass` of the `WebRequestHandler`, as in the preceding code snippet.

**Warning** Although in most cases you'll be able to move a program from one web technology to another, this is not always the case. For example, in the `CustQueP` example (discussed later), I had to avoid the request's `ScriptName` property (which is fine for a CGI program) and use the `InternalScriptName` property instead.

There are two other interesting elements involved in using the Web App Debugger. First, you can test your program without having a web server installed and without having to tweak its settings. In other words, you don't have to deploy your programs to test them—you can try them right away. Second, instead of doing early development of an application as CGI, you can begin experimenting with a multithreaded architecture immediately, without having to deal with the loading and unloading of libraries (which often implies shutting down the web server and possibly even the computer).

## Building a Multipurpose WebModule

To demonstrate how easily you can build a feature-rich server-side application using Delphi's support, I created the

BrokDemo example. I built this example using the Web App Debugger technology, but it should be relatively simple to recompile as a CGI or a web server library.

A key element of the WebBroker example is the list of actions. The actions can be managed in the Actions editor or directly in the Object TreeView. Actions are also visible in the Designer page of the editor, so you can graphically see their relationship with database objects. If you examine the source code, you'll notice that every action has a specific name. I also gave meaningful names to the `OnAction` event handlers. For instance, `TimeAction` as a method name is much more understandable than the `WebModule1WebActionItem1Action` name automatically generated by Delphi.

Every action has a different pathname, and one is marked as a default and executed even if no pathname is specified. The first interesting idea in this program is the use of two `PageProducer` components, `PageHead` and `PageTail`, which are used for the initial and final portion of every page. Centralizing this code makes it easier to modify, particularly if it is based on external HTML files. The HTML produced by these components is added at the beginning and the end of the resulting HTML in the web module's `OnAfterDispatch` event handler:

```
procedure TWebModule1.WebModule1AfterDispatch(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
begin
  Response.Content := PageHead.Content + Response.Content + PageTail.Content;
end;
```

You add the initial and final HTML at the end of the page generation because doing so allows the components to produce the HTML as if they were making all of it. Starting with HTML in the `OnBeforeDispatch` event means that you cannot directly assign the producer components to the actions, or the producer component will override the `Content` you've already provided in the response.

The `PageTail` component includes a custom tag for the script name, replaced by the following code, which uses the current request object available in the web module:

```
procedure TWebModule1.PageTailHTMLTag(Sender: TObject; Tag: TTag;
  const TagString: String; TagParams: TStrings; var ReplaceText: String);
begin
  if TagString = 'script' then
    ReplaceText := Request.ScriptName;
end;
```

This code is activated to expand the `<#script>` tag of the `PageTail` component's `HTMLDoc` property.

The code for the time and date actions is straightforward. The really interesting part begins with the `Menu` path, which is the default action. In its `OnAction` event handler, the application uses a `for` loop to build a list of the available actions (using their names without the first two letters, which are always `wa` in this example), providing a link to each of them with an anchor (an `<a>` tag):

```
procedure TWebModule1.MenuAction(Sender: TObject; Request: TWebRequest;
  Response: TWebResponse; var Handled: Boolean);
var
  I: Integer;
begin
  Response.Content := '<h3>Menu</h3><ul>'#13;
  for I := 0 to Actions.Count - 1 do
    Response.Content := Response.Content + '<li> <a href="' +
      Request.ScriptName + Action[I].PathInfo + '"> ' +
      Copy(Action[I].Name, 3, 1000) + '</a>'#13;
  Response.Content := Response.Content + '</ul>';
end;
```

The BrokDemo example also provides users with a list of the system settings related to the request, which is useful for

debugging. It is also instructive to learn how much information (and exactly what information) the HTTP protocol transfers from a browser to a web server and vice versa. To produce this list, the program looks for the value of each property of the `TWebRequest` class, as this snippet demonstrates:

```
procedure TWebModule1.StatusAction(Sender: TObject; Request: TWebRequest;
Response: TWebResponse; var Handled: Boolean);
var
  I: Integer;
begin
  Response.Content := '<h3>Status</h3>'#13 +
    'Method: ' + Request.Method + '<br>'#13 +
    'ProtocolVersion: ' + Request.ProtocolVersion + '<br>'#13 +
    'URL: ' + Request.URL + '<br>'#13 +
    'Query: ' + Request.Query + '<br>'#13 + ...
```

## Dynamic Database Reporting

The BrokDemo example defines two more actions, indicated by the `/table` and `/record` pathnames. For these two last actions, the program produces a list of names and then displays the details of one record, using a `DataSetTableProducer` component to format the entire table and a `DataSetPageProducer` component to build the record view. Here are the properties of these two components:

```
object DataSetTableProducer1: TDataSetTableProducer
  DataSet = dataEmployee
  OnFormatCell = DataSetTableProducer1FormatCell
end
object DataSetPage: TDataSetPageProducer
  HTMLDoc.Strings = (
    '<h3>Employee: <#LastName></h3>'
    '<ul><li> Employee ID: <#EmpNo>'
    '<li> Name: <#FirstName> <#LastName>'
    '<li> Phone: <#PhoneExt>'
    '<li> Hired On: <#HireDate>'
    '<li> Salary: <#Salary></ul>')
  OnHTMLTag = PageTailHTMLTag
  DataSet = dataEmployee
end
```

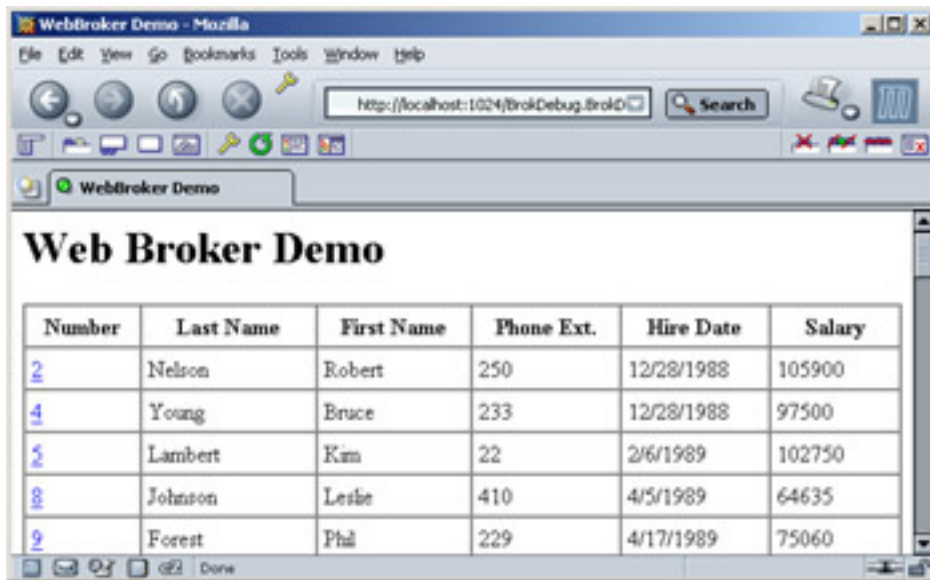

To produce the entire table, you connect the `DataSetTableProducer` to the `Producer` property of the corresponding actions without providing a specific event handler. The table is made more powerful by adding internal links to the specific records. The following code is executed for each cell of the table but a link is created only for the first column and not for the first row (the one with the title):

```
procedure TWebModule1.DataSetTableProducer1FormatCell(Sender: TObject;
  CellRow, CellColumn: Integer; var BgColor: THTMLBgColor;
  var Align: THTMLAlign; var VAlign: THTMLVAlign;
  var CustomAttrs, CellData: String);
begin
  if (CellColumn = 0) and (CellRow <> 0) then
    CellData := '<a href="' + ScriptName + '/record?LastName=' +
      dataEmployee['Last_Name'] + '&FirstName=' +
      dataEmployee['First_Name'] + '"> '
      + CellData + ' </a>';
end;
```

You can see the result of this action in [Figure 20.3](#). When the user selects one of the links, the program is called again, and it can check the `QueryFields` string list and extract the parameters from the URL. It then uses the values

corresponding to the table fields used for the record search (which is based on the `FindNearest` call):

```
procedure TWebModule1.RecordAction(Sender: TObject; Request: TWebRequest;
  Response: TWebResponse; var Handled: Boolean);
begin
  dataEmployee.Open;
  // go to the requested record
  dataEmployee.Locate ('LAST_NAME;FIRST_NAME',
    VarArrayOf([Request.QueryFields.Values['LastName'],
      Request.QueryFields.Values['FirstName']]), []);
  // get the output
  Response.Content := Response.Content + DataSetPage.Content;
end;
```

The screenshot shows a Mozilla browser window titled 'WebBroker Demo'. The address bar contains 'http://localhost:1024/BrokDebug.BrokD'. The main content area displays a table with the following data:

Number	Last Name	First Name	Phone Ext.	Hire Date	Salary
<a href="#">2</a>	Nelson	Robert	250	12/28/1988	105900
<a href="#">4</a>	Young	Bruce	233	12/28/1988	97500
<a href="#">5</a>	Lambert	Kim	22	2/6/1989	102750
<a href="#">8</a>	Johnson	Leslie	410	4/5/1989	64635
<a href="#">9</a>	Forest	Phil	229	4/17/1989	75060

**Figure 20.3:** The output corresponding to the table path of the BrokDemo example, which produces an HTML table with internal hyperlinks

## Queries and Forms

The previous example used some of the HTML producer components introduced earlier in this chapter. This group includes another component you haven't used yet: `QueryTableProducer` (for the BDE) and its sister `SQLQueryTableProducer` (for dbExpress). As you'll see in a moment, this component makes building even complex database programs a breeze.

Suppose you want to search for customers in a database. You might construct the following HTML form (embedded in an HTML table for better formatting):

```
<h4>Customer QueryProducer Search Form</h4>
<form action="<#script>/search" method="POST">
<table>
<tr><td>State:</td>
  <td><input type="text" name="State"></td></tr>
<tr><td>Country:</td>
  <td><input type="text" name="Country"></td></tr>
<tr><td></td>
  <td><center><input type="Submit"></center></td></tr>
</table></form>
```

**Note** As in Delphi, an HTML form hosts a series of controls. There are visual tools to help you design these forms, or you can manually enter the HTML code. The available controls include buttons, input text (or edit boxes), selections (or combo boxes), and input buttons (or radio buttons). You can define buttons as specific types, such as Submit or Reset, which imply standard behaviors. An important element of forms is the request method, which can be either *POST* (data is passed behind the scenes, and you receive it in the *ContentFields* property) or *GET* (data is passed as part of the URL, and you extract it from the *QueryFields* property).

You should notice a very important element in the form: the names of the input components (State and Country), which should match the parameters of a SQLQuery component:

```
SELECT Customer, State_Province, Country
FROM CUSTOMER
WHERE
    State_Province = :State OR Country = :Country
```

This code is used in the CustQueP (customer query producer) example. To build it, I placed a SQLQuery component inside the WebModule and generated the field objects for it. In the same WebModule, I added a SQLQueryTableProducer component connected to the *Producer* property of the */search* action. The program generates the proper response. When you activate the SQLQuery-TableProducer component by calling its *Content* function, it initializes the SQLQuery component by obtaining the parameters from the HTTP request. The component can automatically examine the request method and then use either the *QueryFields* property (if the request is a *GET*) or the *ContentFields* property (if the request is a *POST*).

One problem with using a static HTML form as you did earlier is that it doesn't tell you which states and countries you can search for. To address this issue, you can use a selection control instead of an edit control in the HTML form. However, if the user adds a new record to the database table, you'll need to update the element list automatically. As a final solution, you can design the ISAPI DLL to produce a form on-the-fly, and you can fill the selection controls with the available elements.

You'll generate the HTML for this page in the */form* action, which you connect to a PageProducer component. The PageProducer contains the following HTML text, which embeds two special tags:

```
<h4>Customer QueryProducer Search Form</h4>
<form action=" <#script>/search" method="POST">
<table>
<tr><td>State:</td>
    <td><select name="State"><option></option><#State_Province></select></td></tr>
<tr><td>Country:</td>
    <td><select name="Country"><option></option><#Country></select></td></tr>
<tr><td></td>
    <td><center><input type="Submit"></center></td></tr>
</table></form>
```

You'll notice that the tags have the same name as some of the table's fields. When the PageProducer encounters one of these tags, it adds an *<option>* HTML tag for every distinct value of the corresponding field. Here's the *OnTag* event handler's code, which is generic and reusable:

```
procedure TWebModule1.PageProducer1HTMLTag(Sender: TObject; Tag: TTag;
    const TagString: String; TagParams: TStrings; var ReplaceText: String);
begin
    ReplaceText := '';
    SQLQuery2.SQL.Clear;
    SQLQuery2.SQL.Add ('select distinct ' + TagString + ' from customer');
    try
        SQLQuery2.Open;
        try
            SQLQuery2.First;
            while not SQLQuery2.EOF do
```

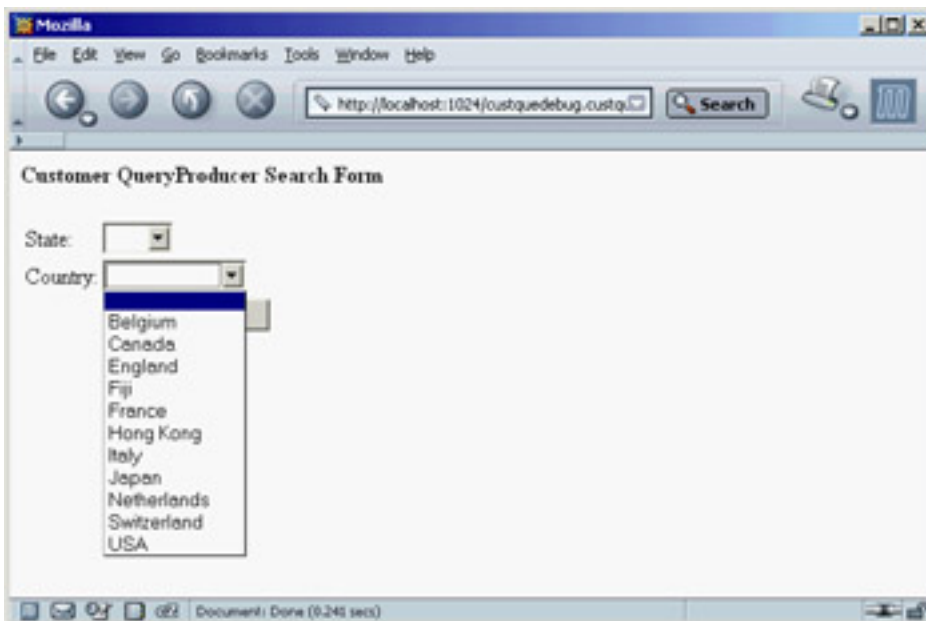

```

begin
  ReplaceText := ReplaceText +
    '<option>' + SQLQuery2.Fields[0].AsString + '</option>'#13;
  SQLQuery2.Next;
end;
finally
  SQLQuery2.Close;
end;
except
  ReplaceText := '{wrong field: ' + TagString + '}';
end;
end;

```

This method uses a second SQLQuery component, which I manually placed on the form and connected to a shared SQLConnection component. It produces the output shown in [Figure 20.4](#).

**Figure 20.4:** The form action of the CustQueP example produces an HTML form with a selection component dynamically updated to reflect the current status of the database.

This web server extension, like many others, allows the user to view the details of a specific record. As in the previous example, you can accomplish this by customizing the output of the first column (column zero), which is generated by the QueryTableProducer component:

```

procedure TWebModule1.QueryTableProducer1FormatCell(
  Sender: TObject; CellRow, CellColumn: Integer;
  var BgColor: THTMLBgColor; var Align: THTMLAlign;
  var VAlign: THTMLVAlign; var CustomAttrs, CellData: String);
begin
  if (CellColumn = 0) and (CellRow <> 0) then
    CellData := '<a href="' + Request.ScriptName + '/record?Company=' + CellData +
      '">' + CellData + '</a>'#13;
  if CellData = '' then
    CellData := '&nbsp;';
end;

```

**Tip** When you have an empty cell in an HTML table, most browsers render it without the border. For this reason, I added a *non-breaking* space symbol (&nbsp;) in each empty cell. You'll have to do this in each HTML table generated with Delphi's table producers.

The action for this link is `/record`, and you pass a specific element after the `?` parameter (without the parameter name, which is slightly nonstandard). The code you use to produce the HTML tables for the records doesn't use the producer components as you've been doing; instead, it shows the data of every field in a custom-built table:

```
procedure TWebModule1.RecordAction(Sender: TObject; Request: TWebRequest;
  Response: TWebResponse; var Handled: Boolean);
var
  I: Integer;
begin
  if Request.QueryFields.Count = 0 then
    Response.Content := 'Record not found'
  else
    begin
      Query2.SQL.Clear;
      Query2.SQL.Add ('select * from customer ' +
        'where Company="' + Request.QueryFields.Values['Company'] + '"');
      Query2.Open;
      Response.Content :=
        '<html><head><title>Customer Record</title></head><body>'#13 +
        '<h1>Customer Record: ' + Request.QueryFields[0] + '</h1>'#13 +
        '<table border>'#13;
      for I := 1 to Query2.FieldCount - 1 do
        Response.Content := Response.Content +
          '<tr><td>' + Query2.Fields [I].FieldName + '</td>'#13'<td>' +
          Query2.Fields [I].AsString + '</td></tr>'#13;
      Response.Content := Response.Content + '</table><hr>'#13 +
        // pointer to the query form
        '<a href="' + Request.ScriptName + '/form">' +
        ' Next Query </a>'#13 + '</body></html>'#13;
    end;
  end;
```

## Working with Apache

If you plan to use Apache instead of IIS or another web server, you can take advantage of the CGI technology to deploy your applications on almost any web server. However, using CGI means reduced speed and some trouble handling state information (because you cannot keep any data in memory). This is a good reason to write an ISAPI application or a dynamic Apache module. Using Delphi's WebBroker technology, you can also easily compile the same code for both technologies, so that moving your program to a different web platform becomes much simpler. You can also recompile a CGI program or a dynamic Apache module with Kylix and deploy it on a Linux server.

As I've mentioned, Apache can run traditional CGI applications but also has a specific technology for keeping the server extension program loaded in memory at all times for faster response. To build such a program in Delphi, you can use the Apache Shared Module option in the New Web Server Application dialog box; choose Apache 1 or Apache 2, depending on the version of the web server you plan to use.

**Warning** While D7 supports version 2.0.39 of Apache, it doesn't support the current popular version 2.0.40 due to a change in library interfaces. Use of version 2.0.39 is discouraged because it has a security problem. Information on how to fix the VCL code and make your modules compatible with Apache 2.0.40 and above have been posted by Borland R&D members on the newsgroups and are currently available also on Bob Swart's website at the URL [www.drbob42.com/delphi7/apache2040.htm](http://www.drbob42.com/delphi7/apache2040.htm).

If you choose to create an Apache module, you end up with a library having this type of source code for its project:

```
library Apache1;
```

```

uses
    WebBroker,
    ApacheApp,
    ApacheWm in 'ApacheWm.pas' {WebModule1: TWebModule};

{$R *.res}

exports
    apache_module name 'apache1_module';

begin
    Application.Initialize;
    Application.CreateForm(TWebModule1, WebModule1);
    Application.Run;
end.

```

Notice in particular the `exports` clause, which indicates the name used by Apache configuration files to reference the dynamic module. In the project source code, you can add two more definitions—the module name and the content type—in the following way:

```

ModuleName := 'Apache1_module';
ContentType:= 'Apache1-handler';

```

If you don't set these values, Delphi will assign them defaults, which are built adding the `_module` and `-handler` strings to the project name (resulting in the two names I used here).

An Apache module is generally not deployed within a script folder, but within the `modules` subfolder of the server (by default, `c:\Program Files\Apache\modules`). You have to edit the `http.conf` file, adding a line to load the module, as follows:

```
LoadModule apache1_module modules/apache1.dll
```

Finally, you must indicate when the module is invoked. The handler defined by the module can be associated with a given file extension (so that your module will process all the files having a given extension) or with a physical or virtual folder. In the latter case, the folder doesn't exist, but Apache pretends it is there. This is how you can set up a virtual folder for the Apache1 module:

```
<Location /Apache1>SetHandler Apache1-handler</Location>
```

Because Apache is inherently case sensitive (because of its Linux heritage), you also might want to add a second, lowercase virtual folder:

```
<Location /apache1>SetHandler Apache1-handler</Location>
```

Now you can invoke the sample application with the URL `http://localhost/Apache1`. A great advantage of using virtual folders in Apache is that a user doesn't really distinguish between the physical and dynamic portions of your site, as you can see by experimenting with the Apache1 example (which includes the code discussed here).

## Practical Examples

After this general introduction to developing server-side applications with WebBroker, I'll end this part of the chapter with two practical examples. The first is a classic web counter. The second is an extension of the WebFind program presented in [Chapter 19](#), which produces a dynamic page instead of filling a list box.

### A Graphical Web Hit Counter

The server-side applications you've built up to now were based only on text. Of course, you can easily add references to existing graphics files. What's more interesting, however, is to build server-side programs capable of generating graphics that change over time.

A typical example is a *page hit counter*. To write a web counter, you save the current number of hits to a file and then read and increase the value every time the counter program is called. To return this information, all you need is HTML text with the number of hits. The code is straightforward:

```

procedure TWebModule1.WebModule1WebActionItem1Action(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
var
  nHit: Integer;
  LogFile: Text;
  LogFileName: string;
begin
  LogFileName := 'WebCont.log';
  System.Assign (LogFile, LogFileName);
  try
    // read if the file exists
    if FileExists (LogFileName) then
      begin
        Reset (LogFile);
        Readln (LogFile, nHit);
        Inc (nHit);
      end
    else
      nHit := 0;
    // saves the new data
    Rewrite (LogFile);
    Writeln (LogFile, nHit);
  finally
    Close (LogFile);
  end;
  Response.Content := IntToStr (nHit);
end;

```

**Warning** This simple file handling does not scale. When multiple visitors hit the page at the same time, this code may return false results or fail with a file I/O error because a request in another thread has the file open for reading while this thread tries to open the file for writing. To support a similar scenario, you'll need to use a mutex (or a critical section in a multithreaded program) to let each subsequent thread wait until the thread currently using the file has completed its task.

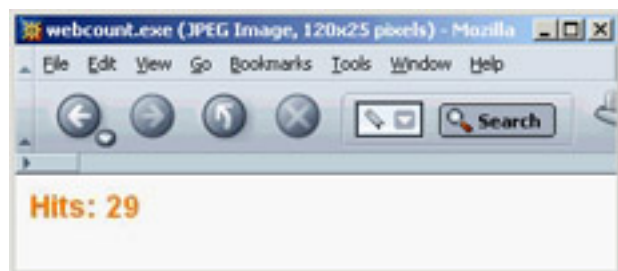

It's more interesting to create a graphical counter that can be easily embedded into any HTML page. There are two approaches to building a graphical counter: You can prepare a bitmap for each digit up front and then combine them in the program, or you can let the program draw over a memory bitmap to produce the graphic you want to return. In the WebCount program, I chose the second approach.

Basically, you can create an Image component that holds a memory bitmap, which you can paint on with the usual

methods of the `TCanvas` class. Then you can attach this bitmap to a `TJpegImage` object. Accessing the bitmap through the `JpegImage` component converts the image to the JPEG format. Then, you can save the JPEG data to a stream and return it. As you can see, there are many steps, but the code is not complicated:

```
// create a bitmap in memory
Bitmap := TBitmap.Create;
try
  Bitmap.Width := 120;
  Bitmap.Height := 25;
  // draw the digits
  Bitmap.Canvas.Font.Name := 'Arial';
  Bitmap.Canvas.Font.Size := 14;
  Bitmap.Canvas.Font.Color := RGB (255, 127, 0);
  Bitmap.Canvas.Font.Style := [fsBold];
  Bitmap.Canvas.TextOut (1, 1, 'Hits: ' +
    FormatFloat ('###,###,###', Int (nHit)));
  // convert to JPEG and output
  Jpeg1 := TJpegImage.Create;
  try
    Jpeg1.CompressionQuality := 50;
    Jpeg1.Assign(Bitmap);
    Stream := TMemoryStream.Create;
    Jpeg1.SaveToStream (Stream);
    Stream.Position := 0;
    Response.ContentStream := Stream;
    Response.ContentType := 'image/jpeg';
    Response.SendResponse;
    // the response object will free the stream
  finally
    Jpeg1.Free;
  end;
finally
  Bitmap.Free;
end;
```

The three statements responsible for returning the JPEG image are the two that set the `ContentStream` and `ContentType` properties of the `Response` and the final call to `SendResponse`. The content type must match one of the possible MIME types accepted by the browser, and the order of these three statements is relevant. The `Response` object also has a `SendStream` method, but it should be called only after sending the type of the data with a separate call. Here you can see the effect of this program:

To embed the program in a page, add the following code to the HTML:

```

```

## Searching with a Web Search Engine

In [Chapter 19](#), I discussed the use of the Indy HTTP client component to retrieve the result of a search on the Google

website. Let's extend the example, turning it into a server-side application. The WebSearcher program, available as a CGI application or a Web App Debugger executable, has two actions: The first returns the HTML retrieved by the search engine; and the second parses the HTML filling a client data set component, which is hooked to a table page producer for generating the final output. Here is the code for the second action:

```
const
  strSearch = 'http://www.google.com/search?as_q=borland+delphi&num=100';

procedure TWebModule1.WebModule1WebActionItem1Action(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
var
  I: integer;
begin
  if not cds.Active then
    cds.CreateDataSet
  else
    cds.EmptyDataSet;
  for i := 0 to 5 do // how many pages?
  begin
    // get the data form the search site
    GrabHtml (strSearch + '&start=' + IntToStr (i*100));
    // scan it to fill the cds
    HtmlStringToCds;
  end;
  cds.First;
  // return producer content
  Response.Content := DataSetTableProducer1.Content;
end;
```

The GrabHtml method is identical to the WebFind example. The HtmlStringToCds method is similar to the corresponding method of the WebFind example (which adds the items to a list box); it adds the addresses and their textual descriptions by calling

```
cds.InsertRecord ([0, strAddr, strText]);
```

The ClientDataSet component is set up with three fields: the two strings plus a line counter. This extra empty field is required in order to include the extra column in the table producer. The code fills the column in the cell-formatting event, which also adds the hyperlink:

```
procedure TWebModule1.DataSetTableProducer1FormatCell(Sender: TObject; CellRow,
  CellColumn: Integer; var BgColor: THTMLBgColor; var Align: THTMLAlign;
  var VAlign: THTMLVAlign; var CustomAttrs, CellData: String);
begin
  if CellRow <> 0 then
  case CellColumn of
    0: CellData := IntToStr (CellRow);
    1: CellData := '<a href="' + CellData + '">' + SplitLong(CellData) + '</a>';
    2: CellData := SplitLong (CellData);
  end;
end;
```

The call to SplitLong is used to add extra spaces in the output text, to avoid having grid columns that are too large—the browser won't split the text on multiple lines unless it contains spaces or other special characters. The result of this program is a rather slow application (because of the multiple HTTP requests it must forward) that produces output like that shown in [Figure 20.5](#).

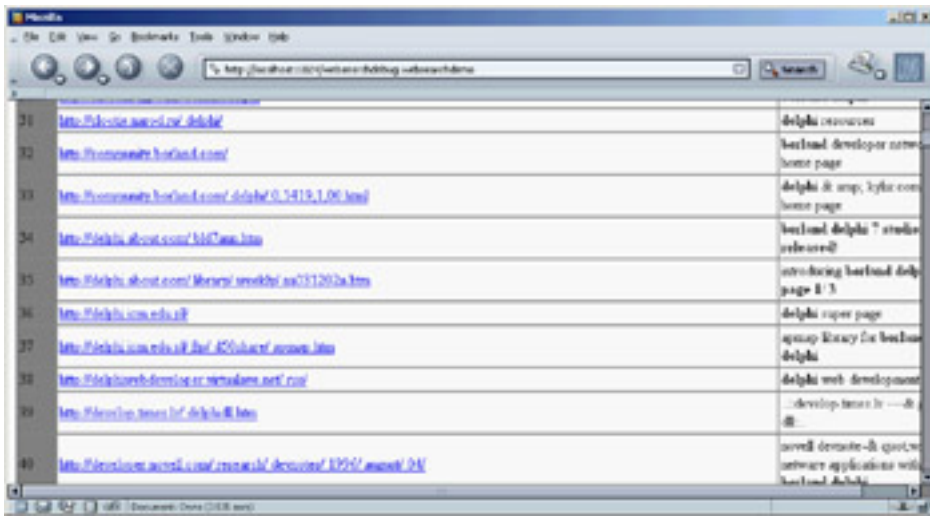

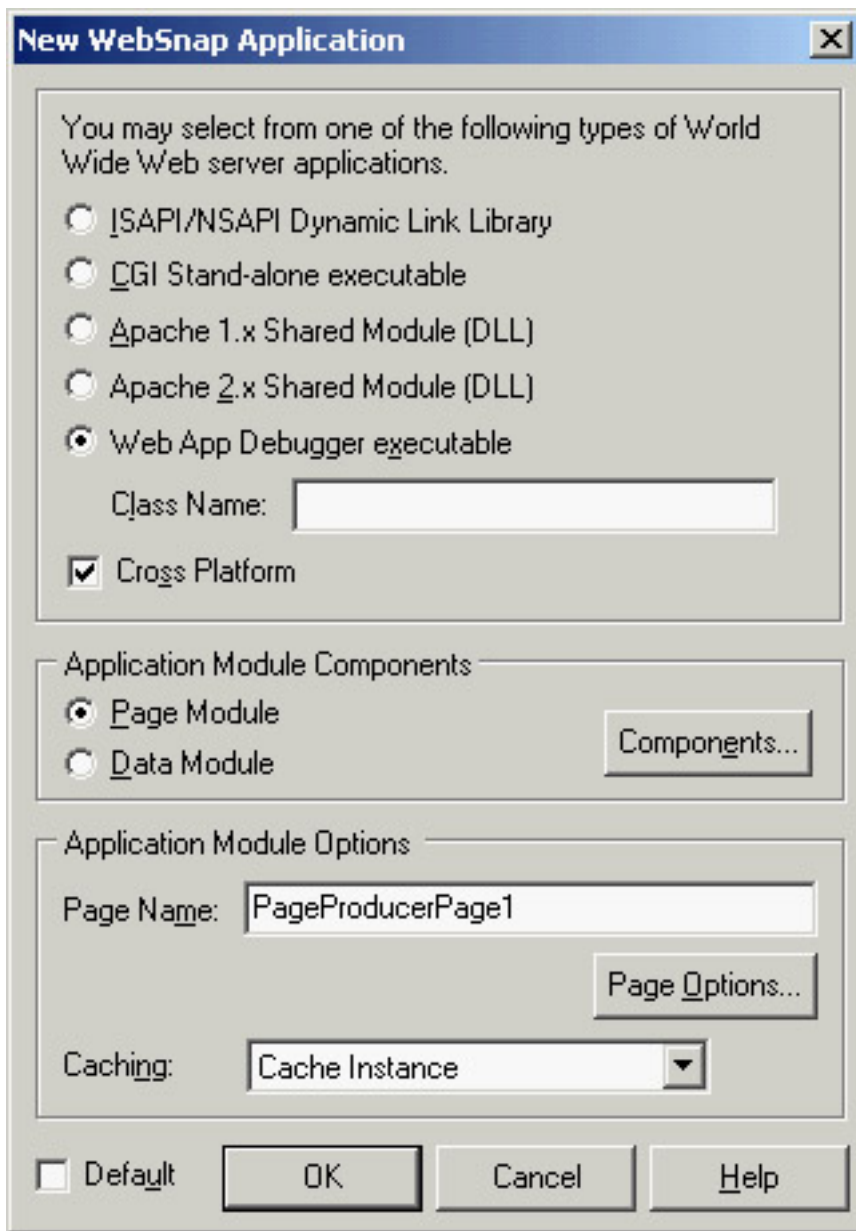

Figure 20.5: The WebSearch program shows the result of multiple searches done on Google.

Now that I've introduced the core elements of developing web server applications with Delphi, let's move to a more complex architecture available since Delphi 6: WebSnap. There are two good reasons I didn't jump into this topic at the beginning of this chapter. First, WebSnap builds on the foundation offered by WebBroker, so you cannot learn how to use the new features if you don't understand the underlying ones. For example, a WebSnap application is technically a CGI program, or an ISAPI or Apache module. Second, because WebSnap is included only in the Enterprise Studio version of Delphi, not all Delphi programmers have the chance to use it.

WebSnap has a few definite advantages over WebBroker, such as allowing for multiple web modules each corresponding to a page, integrating server-side scripting, XSL, and the Internet Express technology (these last two elements will be covered in [Chapter 22](#), "Using XML Technologies"). Moreover, many ready-to-use components are available for handling common tasks, such as user logins, session management, and so on. Instead of listing all the features of WebSnap, though, I've decided to cover them in a sequence of simple and focused applications. I built these applications using the Web App Debugger, for testing purposes, but you can easily deploy them using one of the other available technologies.

When you're developing a WebSnap application, the starting point is a dialog box you can invoke either in the WebSnap page of the New Items dialog box (File → New → Other) or using the Internet toolbar in the IDE (which is not visible by default). The resulting dialog box, shown in [Figure 20.6](#), allows you to choose the type of application (as in a WebBroker application) and to customize the initial application components (you'll be able to add more later). The bottom portion of the dialog determines the behavior of the first page (usually the default or home page of the program). A similar dialog box is displayed for subsequent pages.

**Figure 20.6:** The options offered by the New Web-Snap Application dialog box include the type of server and a button that lets you select the core application components.

If you choose the defaults and type in a name for the home page, the dialog box will create a project and open a `TWebAppPageModule`. This module contains the components you've chosen, by default:

- A `WebAppComponents` component is a container for all the centralized services of the WebSnap application, such as the user list, core dispatcher, session services, and so on. Not all of its properties must be set up, because an application might not need all the available services.
- One of these core services is offered by the `PageDispatcher` component, which (automatically) holds a list of the application's available pages and defines the default page.
- Another core service is given by the `AdapterDispatcher` component, which handles HTML form submissions and image requests.
- The `ApplicationAdapter` is the first component you encounter from the *adapters* family. These components offer fields and actions to the server-side scripts evaluated by the program. Specifically, the `ApplicationAdapter` is a field adapter that exposes the value of its own `ApplicationTitle` property. If you enter a value for this property, it will be made available to the scripts.
- The module hosts a `PageProducer` that includes the HTML code of the page—in this case, the program's default

page. Unlike in WebBroker applications, the HTML for this component is not stored inside its `HTMLDoc` string list property or referenced by its `HTMLFile` property. The HTML file is an external file, stored by default in the folder hosting the project's source code and referenced from the application using a statement similar to a resource include statement: `{*.html}`.

- Because the HTML file included by the PageProducer is kept as a separate file (the `LocateFileService` component will eventually help you for its deployment), you can edit it to change the output of a page of your program without having to recompile the application. These possible changes relate not only to the fixed portion of the HTML file but also to some of its dynamic content, thanks to the support for server-side scripting. The default HTML file, based on a standard template, already contains some scripting.

**Warning** The similarity between resource inclusion and HTML reference is mostly syntactical. The HTML reference is used only for the design-time location of the file, whereas a resource include directive links the data it refers into the executable file.

You can view the HTML file in the Delphi editor thanks to that directive (with reasonably good syntax highlighting) by selecting the corresponding lower tab. The editor also has pages for a WebSnap module, including by default an HTML Result page where you can see the HTML generated after evaluating the scripts, and a Preview page hosting what a user will see in a browser. The Delphi 7 editor for a WebSnap module includes a much more powerful HTML editor than Delphi 6 had; it includes better syntax highlighting and code completion. If you prefer to edit your web application's HTML with a more sophisticated editor, you can set up your choice in the Internet page of the Environment Options dialog box. Click the Edit button for the HTML extension, and you can choose an external editor from the editor's shortcut menu or a specific button on Delphi's Internet toolbar.

The standard HTML template used by WebSnap adds to any page of the program its title and the application title, using script lines such as these:

```
<h1><%= Application.Title %></h1>
<h2><%= Page.Title %></h2>
```

We'll get back to the scripting in a while; we'll begin developing the `WSnap1` example in the [next section](#) by creating a program with multiple pages. But first, I'll finish this overview by showing you the source code for a sample web page module:

```
type
  Thome = class(TWebAppPageModule)
    ...
  end;

function home: Thome;

implementation

{$R *.dfm} {*.html}

uses WebReq, WebCntxt, WebFact, Variants;

function home: Thome;

begin
  Result := Thome(WebContext.FindModuleClass(Thome));
end;

initialization
  if WebRequestHandler <> nil then

    WebRequestHandler.AddWebModuleFactory(TWebAppPageModuleFactory.Create(
      Thome, TWebPageInfo.Create([wpPublished {, wpLoginRequired}], '.html'),
      caCache));
```

end.

The module uses a global function instead of a form's typical global object to support page caching. This application also has extra code in the initialization section (particularly registration code) to let the application know the role of the page and its behavior.

**Tip** Unlike this chapter's WebBroker examples, the WebSnap examples compile each in its own folder. This is because the HTML files are needed at runtime and I preferred simplifying the deployment as much as possible.

## Managing Multiple Pages

The first notable difference between WebSnap and WebBroker is that instead of having a single data module with multiple actions eventually connected to producer components, WebSnap has multiple data modules, each corresponding to an action and having a producer component with an HTML file attached to it. You can add multiple actions to a page/module, but the idea is that you structure applications around pages rather than actions. As is the case with actions, the name of the page is indicated in the request path.

As an example, I added two more pages to the WebSnap application (which was built with default settings). For the first page, in the New WebSnap Page Module dialog (see [Figure 20.7](#)) choose a standard page producer and name it *date*. For the second, choose a DataSetPageProducer and name it *country*. After saving the files, you can begin testing the application. Thanks to some of the scripting I'll discuss later, each page lists all the available pages (unless you've unchecked the Published check box in the New WebSnap Page Module dialog).

**New WebSnap Page Module**

Producer

Type: PageProducer

Script Engine: JScript

HTML

New File:

Template: Standard

Page

Name: PageProducerPage1

Title: PageProducerPage1

Published:  Login Required:

Module Options

Creation: On Demand

Caching: Cache Instance

Default OK Cancel Help

**Figure 20.7:** The New WebSnap Page Module dialog box

The pages will be rather empty, but at least you have the structure in place. To complete the home page, you'll edit its linked HTML file directly. For the date page, use the same approach as a WebBroker application. Add some custom tags to the HTML text, like the following:

```
<p>The time at this site is <#time>.</p>
```

I also added code to the producer component's `OnTag` event handler to replace this tag with the current time.

For the third page (the country page), modify the HTML to include tags for the various fields of the country table, as in:

```
<h3>Country: <#name></h3>
```

Then attach the `ClientDataSet` to the page producer:

```
object DataSetPageProducer: TDataSetPageProducer
  DataSet = cdsCountry
end
object cdsCountry: TClientDataSet
  FileName = 'C:\Program Files\Common Files\Borland
  Shared\Data\country.cds'
end
```

To open this dataset when the page is first created and reset it to the first record in further invocations, you handle the `OnBeforeDispatchPage` event of the web page module, adding this code to it:

```
cdsCountry.Open;
cdsCountry.First;
```

The fact that a WebSnap page can be very similar to a portion of a WebBroker application (basically, an action tied to a producer) is important, if you want to port existing WebBroker code to this new architecture. You can even port your existing `DataSetTableProducer` components to the new architecture. Technically, you can generate a new page, remove its producer component, replace it with a `DataSetTableProducer`, and hook this component to the `PageProducer` property of the web page module. In practice, this approach would cut out the HTML file of the page and its scripts.

In the `WSnap1` program, I used a better technique. I added a custom tag (`<#htmltable>`) to the HTML file and used the `OnTag` event of the page producer to add to the HTML the result of the data set table:

```
if TagString = 'htmltable' then
  ReplaceText := DataSetTableProducer1.Content;
```

## Server-Side Scripts

Having multiple pages in a server-side program—each associated with a different page module—changes the way you write a program. Having the server-side scripts at hand offers an even more powerful approach. For example, the standard scripts of the `WSnap1` example account for the application and page titles, and for the index of the pages. This index is generated by an *enumerator*, the technique used to scan a list from within WebSnap script code. Let's look at it:

```
<table cellpadding="0" cellspacing="0"><td>
<% e = new Enumerator(Pages)
   s = ''
   c = 0
   for (; !e.atEnd(); e.moveNext())
   {
     if (e.item().Published)
     {
       if (c > 0) s += '&nbsp;|&nbsp;';
```

```

    if (Page.Name != e.item().Name)
        s += '<a href="' + e.item().HREF + '">' + e.item().Title + '</a>'
    else
        s += e.item().Title
    c++
}
}
if (c>1) Response.Write(s)
%>
</td></table>

```

**Note** Typically, WebSnap scripts are written in JavaScript, an object-based language common for Internet programming because it is the only scripting language generally available in browsers (on the client side). JavaScript (technically indicated as ECMAScript) borrows the core syntax of the C language and has almost nothing to do with Java. WebSnap uses Microsoft's ActiveScripting engine, which supports both JScript (a variation of JavaScript) and VBScript.

Inside the single cell of this table (which, oddly enough, has no rows), the script outputs a string with the `Response.Write` command. This string is built with a `for` loop over an enumerator of the application's pages, stored in the `Pages` global entity. The title of each page is added to the string only if the page is published. Each title uses a hyperlink with the exclusion of the current page. Having this code in a script, instead of hard-coded into a Delphi component, allows you to pass it to a good web designer, who can turn it into something a more visually appealing.

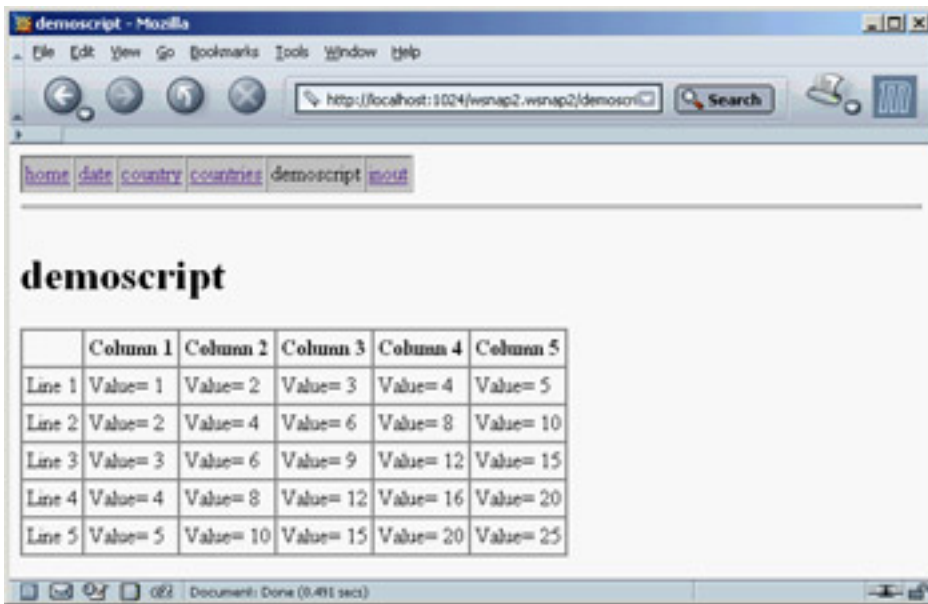

**Tip** To publish or unpublish a page, don't look for a property in the web page module. This status is controlled by a flag of the `AddWebModuleFactory` method called in the web page module initialization code. You can comment or uncomment this flag to obtain the desired effect.

As a sample of what you can do with scripting, I added to the WSnap2 example (an extension of the WSnap1 example) a *demoscript* page. The page's script can generate a full table of multiplied values with the following scripting code (see [Figure 20.8](#) for its output):

```

<table border=1 cellspacing=0>
<tr>
  <th>&nbsp;</th>
  <% for (j=1;j<=5;j++) { %>
  <th>Column <%=j %></th>
  <% } %>
</tr>
<% for (i=1;i<=5;i++) { %>
<tr>
  <td>Line <%=i %></td>
  <% for (j=1;j<=5;j++) { %>
  <td>Value= <%=i*j %></td>
  <% } %>
</tr>
<% } %>
</table>

```

**Figure 20.8:** The WSnap2 example features a plain script and a custom menu stored in an include file.

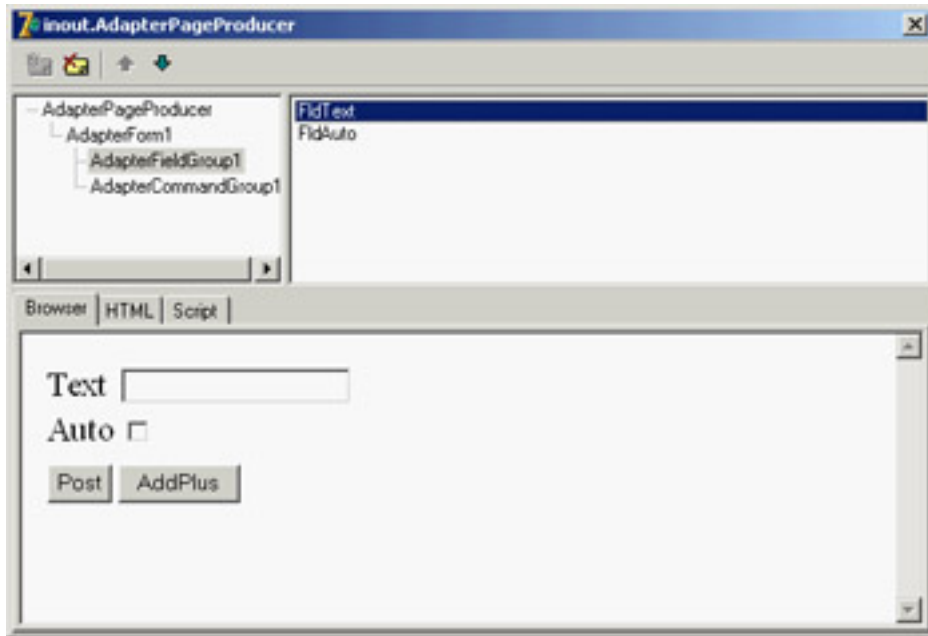

In this script, the `<%=` symbol replaces the longer `Response.Write` command. Another important feature of server-side scripting is the inclusion of pages within other pages. For example, if you plan to modify the menu, you can include the related HTML and script in a single file, instead of changing it and maintaining it in multiple pages. File inclusion is generally done with a statement like this:

```
<!-- #include file="menu.html" -->
```

In [Listing 20.1](#), you can find the complete source code of the include file for the menu, which is referenced by all of the project's other HTML files. [Figure 20.9](#) shows an example of this menu, which is displayed across the top of the page using the table-generation script mentioned earlier.

### Listing 20.1: The `menu.html` File Included in Each Page of the WSnap2 Example

```
<html>
<head>
<title><%= Page.Title %></title>
</head>
<body>
<h2><%= Application.Title %></h2>
<table cellspacing="0" cellpadding="2" border="1" bgcolor="#c0c0c0">
<tr>
<% e = new Enumerator(Pages)
for (; !e.atEnd(); e.MoveNext())
{
if (e.item().Published)
{
if (Page.Name != e.item().Name)
Response.Write ('<td><a href="' + e.item().HREF + '"' +
e.item().Title + '</a></td>')
else
Response.Write ('<td>' + e.item().Title + '</td>')
}
}
%>
</tr>
</table>
<hr>
<h1><%= Page.Title %></h1>
```

**Figure 20.9:** The Web Surface Designer for the inout page of the WSnap2 example, at design time

This script for the menu uses the `Pages` list and the `Page` and `Application` global scripting objects. WebSnap makes available a few other global objects, including `EndUser` and `Session` objects (in case you add the corresponding adapters to the application), the `Modules` object, and the `Producer` object, which allows access to the `Producer` component of the web page module. The script also has available the `Response` and `Request` objects of the web module.

## Adapters

In addition to these global objects, within a script you can access all the adapters available in the corresponding web page module. (Adapters in other modules, including shared web data modules, must be referenced by prefixing their name with the `Modules` object and the corresponding module.) Adapters allow you to pass information from your compiled Delphi code to the interpreted script, providing a scriptable interface to your Delphi application. Adapters contain fields that represent data and host actions that represent commands. The server-side scripts can access these values and issue these commands, passing specific parameters to them.

## Adapter Fields

For simple customizations, you can add new fields to specific adapters. For instance, in the WSnap2 example, I added a custom field to the application adapter. After selecting this component, you can either open its Fields editor (accessible via its shortcut menu) or work in the Object TreeView. After adding a new field (called `AppHitCount` in the example), you can assign a value to it in its `OnGetValue` event. Because you want to count the hits (or requests) on any page of the web application, you can also handle the `OnBeforePageDispatch` event of the *global* `PageDispatcher` component to increase the value of a local field, `HitCount`. Here is the code for the two methods:

```
procedure Thome.PageDispatcherBeforeDispatchPage(Sender: TObject;
  const PageName: String; var Handled: Boolean);
begin
  Inc (HitCount);
end;
```

```
procedure Thome.AppHitCountGetValue(Sender: TObject; var Value: Variant);
begin
```

```
Value := HitCount;  
end;
```

Of course, you could use the page name to also count hits on each page (and you could add support for persistency, because the count is reset every time you run a new instance of the application). Now that you've added a custom field to an existing adapter (corresponding to the `Application` script object), you can access it from within any script, like this:

```
<p>Application hits since last activation:  
<%= Application.AppHitCount.Value %></p>
```

## Adapter Components

In the same way, you can add custom adapters to specific pages. If you need to pass along a few fields, use the generic Adapter component. Other custom adapters (besides the global `ApplicationAdapter` you've already used) include these:

- The `PagedAdapter` component has built-in support for showing its content over multiple pages.
- The `DataSetAdapter` component is used to access a Delphi dataset from a script and is covered in the section "[WebSnap and Databases](#)."
- The `StringValuesList` holds a list of name/value pairs, such as a string list, and can be used directly or to provide a list of values to an adapter field. The inherited `DataSetValuesList` adapter has the same role but grabs the list of name/value pairs from a dataset, providing support for lookups and other selections.
- User-related adapters, such as the `EndUser`, `EndUserSession`, and `LoginForm` adapters, are used to access user and session information and to build a login form for the application that is automatically tied to the users list. I'll discuss these adapters in the section "[Sessions, Users, and Permissions](#)" later in this chapter.

## Using the AdapterPageProducer

Most of these components are used in conjunction with an `AdapterPageProducer` component. The `AdapterPageProducer` can generate portions of script after you visually design the desired result. As an example, I've added to the `WSnap2` application the `inout` page, which has an adapter with two fields, one standard and one Boolean:

```
object Adapter1: TAdapter  
  OnBeforeExecuteAction = Adapter1BeforeExecuteAction  
  object TAdapterActions  
    object AddPlus: TAdapterAction  
      OnExecute = AddPlusExecute  
    end  
    object Post: TAdapterAction  
      OnExecute = PostExecute  
    end  
  end  
end  
object TAdapterFields  
  object Text: TAdapterField  
    OnGetValue = TextGetValue  
  end  
  object Auto: TAdapterBooleanField  
    OnGetValue = AutoGetValue  
  end  
end  
end
```

The adapter also has a couple of actions that post the current user input and add a plus sign (+) to the text. The same plus sign is added when the `Auto` field is enabled. Developing the user interface for this form and the related scripting

would take some time using plain HTML. But the AdapterPageProducer component (used in this page) has an integrated HTML designer, which Borland calls Web Surface Designer. Using this tool, you can visually add a form to the HTML page and add an AdapterFieldGroup to it. Connect this field group to the adapter to automatically display editors for the two fields. Then you can add an AdapterCommandGroup and connect it to the AdapterFieldGroup, to provide buttons for all of the adapter's actions. You can see an example of this designer in [Figure 20.9](#).

To be more precise, the fields and buttons are automatically displayed if the `AddDefaultFields` and `AddDefaultCommands` properties of the field group and command group are set. The effect of these visual operations to build this form are summarized in the following DFM snippet:

```
object AdapterPageProducer: TAdapterPageProducer
  object AdapterForm1: TAdapterForm
    object AdapterFieldGroup1: TAdapterFieldGroup
      Adapter = Adapter1
      object FldText: TAdapterDisplayField
        FieldName = 'Text'
      end
      object FldAuto: TAdapterDisplayField
        FieldName = 'Auto'
      end
    end
  object AdapterCommandGroup1: TAdapterCommandGroup
    DisplayComponent = AdapterFieldGroup1
    object CmdPost: TAdapterActionButton
      ActionName = 'Post'
    end
    object CmdAddPlus: TAdapterActionButton
      ActionName = 'AddPlus'
    end
  end
end
```

Now that you have an HTML page with some scripts to move data back and forth and issue commands, let's look at the source code required to make this example work. First, you must add to the class two local fields to store the adapter fields and manipulate them, and you need to implement the `OnGetValue` event for both, returning the field values. When each button is clicked, you must retrieve the text passed by the user, which is not automatically copied into the corresponding adapter field. You can obtain this effect by looking at the `ActionValue` property of these fields, which is set only if something was entered (for this reason, when nothing is entered you set the Boolean field to `False`). To avoid repeating this code for both actions, place it in the `OnBeforeExecuteAction` event of the web page module:

```
procedure Tinout.Adapter1BeforeExecuteAction(Sender, Action: TObject;
  Params: TStrings; var Handled: Boolean);
begin
  if Assigned (Text.ActionValue) then
    fText := Text.ActionValue.Values [0];
    fAuto := Assigned (Auto.ActionValue);
  end;
```

Notice that each action can have multiple values (in case components allow multiple selections); but this is not the case, so you can grab the first element. Finally, here is the code for the `OnExecute` events of the two actions:

```
procedure Tinout.AddPlusExecute(Sender: TObject; Params: TStrings);
begin
  fText := fText + '+';
end;
```

```

procedure TInout.PostExecute(Sender: TObject; Params: TStrings);
begin
    if fAuto then
        AddPlusExecute (Self, nil);
end;

```

As an alternative, adapter fields have a public `EchoActionFieldValue` property you can set to get the value entered by the user and place it in the resulting form. This technique is typically used in case of errors, to let the user change the input starting with the values already entered.

**Note** The `AdapterPageProducer` component has specific support for Cascading Style Sheets (CSS). You can define the CSS for a page using either the `StylesFile` property or the `Styles` string list. Any element of the editor of the producer's items can define a specific style or choose a style from the attached CSS. You accomplish this last operation (which is the suggested approach) using the `StyleRule` property.

## Scripts Rather Than Code?

Even this example of the combined use of an adapter and an adapter page producer, with its visual designer, shows the power of this architecture. However, this approach also has a drawback: By letting the components generate the script (in the HTML, you have only the `<#SERVERSCRIPT>` tag), you save a lot of development time; but you end up mixing the script with the code, so changes to the user interface will require updating the program. The division of responsibilities between the Delphi application developer and the HTML/script designer is lost. And, ironically, you end up having to run a script to accomplish something the Delphi program could have done right away, possibly much faster.

In my opinion, `WebSnap` is a powerful architecture and a huge step forward from `WebBroker`, but it must be used with care to avoid misusing some of these technologies just because they are simple and powerful. For example, it might be worth using the `AdapterPageProducer` designer to generate the first version of a page, and then grabbing the generated script and copying it to a plain Page-Producer's HTML, so that a web designer can modify the script with a specific tool.

For nontrivial applications, I prefer the possibilities offered by XML and XSL, which are available within this architecture even if they don't have a central role. You'll find more on this topic in [Chapter 22](#).

## Locating Files

When you have written an application like the one just described, you must deploy it as a CGI or dynamic library. Instead of placing the templates and include files in the same folder as the executable file, you can devote a subfolder or custom folder to host all the files. The `LocateFileService` component handles this task.

The component is not intuitive to use. Instead of having you specify a target folder as a property, the system fires one of this component's events any time it has to locate a file. (This approach is much more powerful.) There are three events: `OnFindIncludeFile`, `OnFindStream`, and `OnFindTemplateFile`. The first and last events return the name of the file to use in a `var` parameter. The `OnFindStream` event allows you to provide a stream directly, using one you already have in memory or that you've created on the fly, extracted from a database, obtained via an HTTP connection, or gotten any other way you can think of. In the simplest case of the `OnFindIncludeFile` event, you can write code like the following:

```

procedure TPageProducerPage2.LocateFileService1FindIncludeFile(
    ASender: TObject; AComponent: TComponent; const AFileName: String;
    var AFoundFile: String; var AHandled: Boolean);
begin
    AFoundFile := DefaultFolder + AFileName;
    AHandled := True;
end;

```

## WebSnap and Databases

Delphi has always shone in the area of database programming. For this reason, it is not surprising to see a lot of support for handling datasets within the WebSnap framework. Specifically, you can use the `DataSetAdapter` component to connect to a dataset and display its values in a form or a table using the `AdapterPageProducer` component's visual editor.

### A WebSnap Data Module

As an example, I built a new WebSnap application (called `WSnapTable`) with an `AdapterPage-Producer` as its main page to display a table in a grid and another `AdapterPageProducer` in a secondary page to show a form with a single record. I also added to the application a `WebSnap Data Module`, as a container for the dataset components. The data module has a `ClientDataSet` that's wired to a `dbExpress` dataset through a provider and based on an `InterBase` connection, as shown here:

```
object ClientDataSet1: TClientDataSet
  Active = True
  ProviderName = 'DataSetProvider1'
end
object SQLConnection1: TSQLConnection
  Connected = True
  ConnectionName = 'IBLocal'
  LoginPrompt = False
end
object SQLDataSet1: TSQLDataSet
  SQLConnection = SQLConnection1
  CommandText =
    'select CUST_NO, CUSTOMER, ADDRESS_LINE1, CITY, STATE_PROVINCE, ' +
    ' COUNTRY from CUSTOMER'
end
object DataSetProvider1: TDataSetProvider
  DataSet = SQLDataSet1
end
```

### The DataSetAdapter

Now that you have a dataset available, you can add a `DataSetAdapter` to the first page and connect it to the web module's `ClientDataSet`. The adapter automatically makes available all of the dataset's fields and several predefined actions for operating on the dataset (such as `Delete`, `Edit`, and `Apply`). You can add them explicitly to the `Actions` and `Fields` collections to exclude some of them and customize their behavior, but this step is not always required.

Like the `PagedAdapter`, the `DataSetAdapter` has a `PageSize` property you can use to indicate the number of elements to display in each page. The component also has commands you can use to navigate among pages. This approach is particularly suitable when you want to display a large dataset in a grid. These are the adapter settings for the main page of the `WSnapTable` example:

```
object DataSetAdapter1: TDataSetAdapter
  DataSet = WebDataModule1.ClientDataSet1
  PageSize = 6
end
```

The corresponding page producer has a form containing two command groups and a grid. The first command group (displayed above the grid) has the predefined commands for handling pages: `CmdPrevPage`, `CmdNextPage`, and `CmdGotoPage`. The last command generates a list of numbers for the pages, so that a user can jump to each of them directly. The `AdapterGrid` component has the default columns plus an extra column hosting `Edit` and `Delete`

commands. The bottom command group provides a button used to create a new record. You can see an example of the table's output in [Figure 20.10](#) and the complete settings of the AdapterPageProducer in [Listing 20.2](#).

The screenshot shows a web browser window with the URL `http://localhost:1024/wsnaptable-unsnaptable/`. The page title is "WSnapTable" and the content is labeled "table". Below the title, there are navigation links: "Previous Page", "1", "2", "3", and "Next Page". The main content is a table with the following data:

CUST_NO	CUSTOMER	ADDRESS_LINE1	CITY	STATE_PROVINCE	COUNTRY	COMMANDS
1001	Signature Design	15500 Pacific Heights Blvd.	San Diego	CA	USA	<a href="#">Edit</a> <a href="#">Delete</a>
1002	Dallas Technologies	P. O. Box 47000	Dallas	TX	USA	<a href="#">Edit</a> <a href="#">Delete</a>
1003	Furde, Griffith and Co.	2300 Newbury Street	Boston	MA	USA	<a href="#">Edit</a> <a href="#">Delete</a>
1004	Central Bank	66 Lloyd Street	Manchester		England	<a href="#">Edit</a> <a href="#">Delete</a>
1005	IT Systems, LTD	400 Connaught Road	Central Hong Kong		Hong Kong	<a href="#">Edit</a> <a href="#">Delete</a>
1005	DataServe International	2000 Carling Avenue	Ottawa	ON	Canada	<a href="#">Edit</a> <a href="#">Delete</a>

Below the table, there is a "New" button.

**Figure 20.10:** The page shown by the WSnapTable example at startup includes the initial portion of a paged table.

### **Listing 20.2: AdapterPageProducer Settings for the WSnapTable Main Page**

```

object AdapterPageProducer: TAdapterPageProducer
object AdapterForm1: TAdapterForm
object AdapterCommandGroup1: TAdapterCommandGroup
    DisplayComponent = AdapterGrid1
object CmdPrevPage: TAdapterActionButton
    ActionName = 'PrevPage'
    Caption = 'Previous Page'
end
object CmdGotoPage: TAdapterActionButton...
object CmdNextPage: TAdapterActionButton
    ActionName = 'NextPage'
    Caption = 'Next Page'
end
end
object AdapterGrid1: TAdapterGrid
    TableAttributes.CellSpacing = 0
    TableAttributes.CellPadding = 3
    Adapter = DataSetAdapter1
    AdapterMode = 'Browse'
object ColCUST_NO: TAdapterDisplayColumn
    ...
object AdapterCommandColumn1: TAdapterCommandColumn
    Caption = 'COMMANDS'
object CmdEditRow: TAdapterActionButton
    ActionName = 'EditRow'
    Caption = 'Edit'
    PageName = 'formview'
    DisplayType = ctAnchor
end

```

```

    object CmdDeleteRow: TAdapterActionButton
        ActionName = 'DeleteRow'
        Caption = 'Delete'
        DisplayType = ctAnchor
    end
end
end
object AdapterCommandGroup2: TAdapterCommandGroup
    DisplayComponent = AdapterGrid1
    object CmdNewRow: TAdapterActionButton
        ActionName = 'NewRow'
        Caption = 'New'
        PageName = 'formview'
    end
end
end
end
end
end

```

---

There are a couple of things to notice in this listing. First, the grid's `AdapterMode` property is set to `Browse` (other possibilities are `Edit`, `Insert`, and `Query`). This dataset display mode for adapters determines the type of user interface (text or edit boxes and other input controls) and the visibility of other buttons (for example, `Apply` and `Cancel` buttons are only present in the edit view; the opposite is true for the `Edit` command).

**Note** You can also modify the adapter mode by using server-side script and accessing `Adapter.Mode`.

Second, I modified the display of the commands in the grid using the `ctAnchor` value for the `DisplayType` property instead of the default button style. Similar properties are available for most components of this architecture to tweak the HTML code they produce.

## Editing the Data in a Form

Some of the commands are connected to a different page, which will be displayed after the commands are invoked. For example, the `edit` command's `PageName` property is set to `formview`. This second page of the application has an `AdapterPageProducer` with components hooked to the same `DataSetAdapter` as of the other table, so that all the requests will be automatically synchronized. If you click the `Edit` command, the program will open the secondary page that displays the data of the record corresponding to the command.

[Listing 20.3](#) shows the details of the page producer for the program's second page. Again, building the HTML form visually using the Delphi-specific designer (see [Figure 20.11](#)) was a very fast operation.

### Listing 20.3: AdapterPageProducer Settings for the formview Page

---

```

object AdapterPageProducer: TAdapterPageProducer
    object AdapterForm1: TAdapterForm
        object AdapterErrorList1: TAdapterErrorList
            Adapter = table.DataSetAdapter1
        end
        object AdapterCommandGroup1: TAdapterCommandGroup
            DisplayComponent = AdapterFieldGroup1
            object CmdApply: TAdapterActionButton
                ActionName = 'Apply'
                PageName = 'table'
            end
            object CmdCancel: TAdapterActionButton

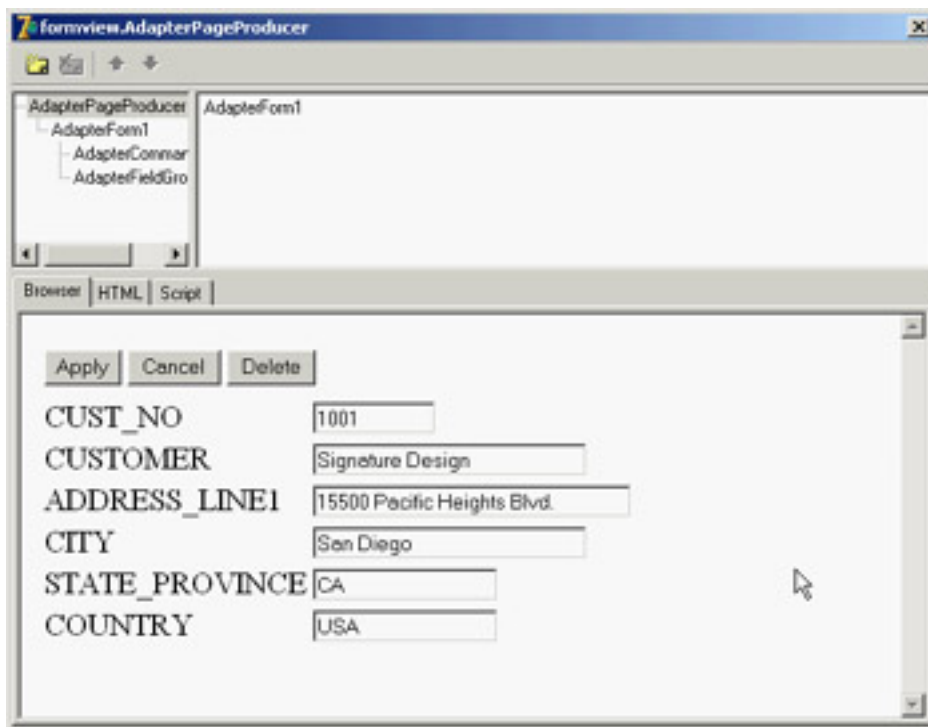

```

```

    ActionName = 'Cancel'
    PageName = 'table'
end
object CmdDeleteRow: TAdapterActionButton
    ActionName = 'DeleteRow'
    Caption = 'Delete'
    PageName = 'table'
end
end
object AdapterFieldGroup1: TAdapterFieldGroup
    Adapter = table.DataSetAdapter1
    AdapterMode = 'Edit'
    object FldCUST_NO: TAdapterDisplayField
        DisplayWidth = 10
        FieldName = 'CUST_NO'
    end
    object FldCUSTOMER: TAdapterDisplayField
        ...
    end
end
end
end
end

```

---

**Figure 20.11:** The formview page shown by the WSnapTable example at design time, in the Web Surface Designer (or AdapterPageProducer editor)

In the listing, you can see that all the operations send the user back to the main page and that the `AdapterMode` is set to `Edit`, unless there are update errors or conflicts. In this case, the same page is displayed again, with a description of the errors obtained by adding an `AdapterErrorList` component at the top of the form.

The second page is not published, because selecting it without referring to a specific record would make little sense. To unpublish the page, you comment the corresponding flag in the initialization code. Finally, to make the changes to the database persistent, you can call the `ApplyUpdates` method in the `OnAfterPost` and `OnAfterDelete` events of the `ClientDataSet` component hosted by the data module.

Another problem (which I haven't fixed) relates to the fact that the SQL server assigns the ID of each customer, so that when you enter a new record, the data in the ClientDataSet and in the database are no longer aligned. This situation can cause Record Not Found errors.

## Master/Detail in WebSnap

The DataSetAdapter component has specific support for master/detail relationships between datasets. After you've created the relationship among the datasets, as usual, define an adapter for each dataset and then connect the `MasterAdapter` property of the detail dataset's adapter. Setting up the master/detail relationship between the adapters makes them work in a more seamless way. For example, when you change the work mode of the master or enter new records, the detail automatically enters into Edit mode or is refreshed.

The WSnapMD example uses a data module to define such a relationship. It includes two ClientDataSet components, each connected to a SQLDataSet through a provider. The data access components each refer to a table, and the ClientDataSet components define a master/detail relationship. The same data module hosts two dataset adapters that refer to the two datasets and again define the master/detail relationship:

```
object dsaDepartment: TDataSetAdapter
  DataSet = cdsDepartment
end
object dsaEmployee: TDataSetAdapter
  DataSet = cdsEmployee
  MasterAdapter = dsaDepartment
end
```

**Warning** I originally tried to use a SimpleDataSet component to avoid cluttering the data module, but this approach didn't work. The master/detail portion of the program was correct, but moving from a page to the next or a previous page with the related buttons kept failing. The reason is that if you use a SimpleDataSet, a bug closes the dataset at each interaction, losing the status information.

This WebSnap application's only page has an AdapterPageProducer component hooked to both dataset adapters. The page's form has a field group hooked to the master and a grid connected with the detail. Unlike other examples, I tried to improve the user interface by adding custom attributes for the various elements. I used a gray background, displayed some of the grid borders (HTML grids are often used by Web Surface Designer), centered most of the elements, and added spacing. Notice that I added extra spaces to the button captions to prevent them from being too small. You can see the related code in the following detailed excerpt and the effect in [Figure 20.12](#):

**Figure 20.12:** The WSnapMD example shows a master/detail structure and has some customized output.

```

object AdapterPageProducer: TAdapterPageProducer
object AdapterForm1: TAdapterForm
    Custom = 'Border="1" CellSpacing="0" CellPadding="10" ' +
        'BgColor="Silver" align="center"'
object AdapterCommandGroup1: TAdapterCommandGroup
    DisplayComponent = AdapterFieldGroup1
    Custom = 'Align="Center"'
object CmdFirstRow: TAdapterActionButton...
object CmdPrevRow: TAdapterActionButton...
object CmdNextRow: TAdapterActionButton...
object CmdLastRow: TAdapterActionButton...
end
object AdapterFieldGroup1: TAdapterFieldGroup
    Custom = 'BgColor="Silver"'
    Adapter = WDataMod.dsaDepartment
    AdapterMode = 'Browse'
end
object AdapterGrid1: TAdapterGrid
    TableAttributes.BgColor = 'Silver'
    TableAttributes.CellSpacing = 0
    TableAttributes.CellPadding = 3
    HeadingAttributes.BgColor = 'Gray'
    Adapter = WDataMod.dsaEmployee
    AdapterMode = 'Browse'
object ColEMP_NO: TAdapterDisplayColumn...
object ColFIRST_NAME: TAdapterDisplayColumn...
object ColLAST_NAME: TAdapterDisplayColumn...
object ColDEPT_NO: TAdapterDisplayColumn...
object ColJOB_CODE: TAdapterDisplayColumn...
object ColJOB_COUNTRY: TAdapterDisplayColumn...
object ColSALARY: TAdapterDisplayColumn...
end
end
end

```

## Sessions, Users, and Permissions

Another interesting feature of the WebSnap architecture is its support for sessions and users. Sessions are supported using a classic approach: temporary cookies. These cookies are sent to the browser so that following requests from the same user can be acknowledged by the system. By adding data to a session instead of an application adapter, you can have data that depends on the specific session or user (although a user can run multiple sessions by opening multiple browser windows on the same computer). For supporting sessions, the application keeps data in memory, so this feature is not available in CGI programs.

### Using Sessions

To underline the importance of this type of support, I built a WebSnap application with a single page showing both the total number of hits and the total number of hits for each session. The program has a `SessionService` component with default values for its `MaxSessions` and `DefaultTimeout` properties. For every new request, the program increases both an `nHits` private field of the page module and the `SessionHits` value of the current session:

```
procedure TSessionDemo.WebAppPageModuleBeforeDispatchPage(Sender: TObject;
  const PageName: String; var Handled: Boolean);
begin
  // increase application and session hits
  Inc (nHits);
  WebContext.Session.Values ['SessionHits'] :=
    Integer (WebContext.Session.Values ['SessionHits']) + 1;
end;
```

**Note** The `WebContext` object (of type `TWebContext`) is a thread variable created by WebSnap for each request. It provides thread-safe access to other global variables used by the program.

The associated HTML displays status information by using both custom tags evaluated by the `OnTag` event of the page producer and script evaluated by the engine. Here is the core portion of the HTML file:

```
<h3>Plain Tags</h3>
<p>Session id: <#SessionID>
<br>Session hits: <#SessionHits></p>
<h3>Script</h3>
<p>Session hits (via application): <%=Application.SessionHits.Value%>
<br>Application hits: <%=Application.Hits.Value%></p>
```

The parameters of the output are provided by the `OnTag` event handler and the fields' `OnGetValue` events:

```
procedure TSessionDemo.PageProducerHTMLTag(Sender: TObject; Tag: TTag;
  const TagString: String; TagParams: TStrings; var ReplaceText: String);
begin
  if TagString = 'SessionID' then
    ReplaceText := WebContext.Session.SessionID
  else if TagString = 'SessionHits' then
    ReplaceText := WebContext.Session.Values ['SessionHits']
end;
```

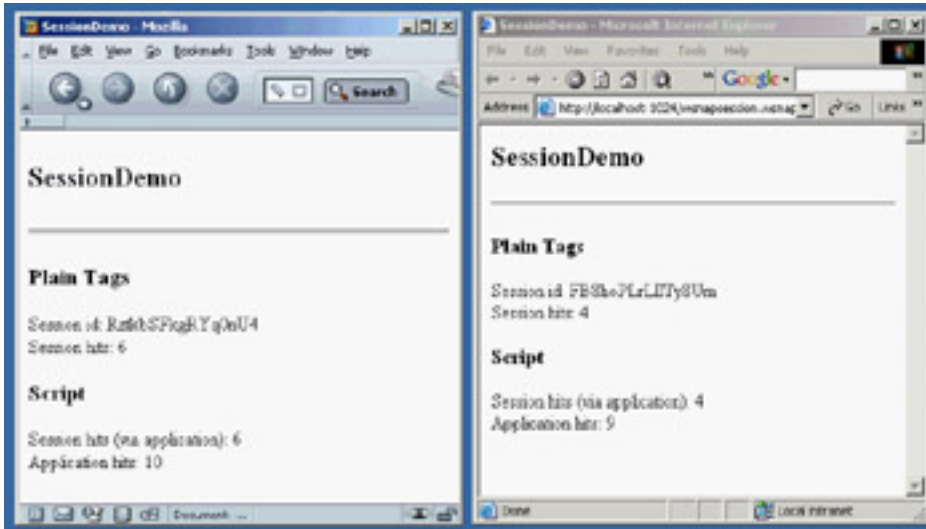

```
procedure TSessionDemo.HitsGetValue(Sender: TObject; var Value: Variant);
begin
  Value := nHits;
end;
```

```
procedure TSessionDemo.SessionHitsGetValue(Sender: TObject; var Value: Variant);
begin
```

```
Value := Integer (WebContext.Session.Values ['SessionHits']);  
end;
```

The effect of this program is visible in [Figure 20.13](#), where I've activated two sessions in two different browsers.

**Figure 20.13:** Two instances of the browser operate on two different sessions of the same WebSnap application.

**Tip** In this example, I used both the traditional WebBroker tag replacement and the newer WebSnap adapter fields and scripting, so that you can compare the two approaches. Keep in mind that they are both available in a WebSnap application.

## Requesting Login

In addition to generic sessions, WebSnap also has specific support for users and login-based authorized sessions. You can add to an application a list of users (with the WebUserList component), each with a name and a password. This component is rudimentary in the data it can store. However, instead of filling it with your list of users, you can keep the list in a database table (or in another proprietary format) and use the WebUserList component's events to retrieve your custom user data and check the user passwords.

You'll generally also add to the application the SessionService and EndUserSessionAdapter components. At this point, you can ask the users to log in, indicating for each page whether it can be viewed by everyone or only by logged-in users. This is accomplished by setting the wpLoginRequired flag in the constructor of the TWebPageModuleFactory and TWebAppPageModuleFactory classes in the web page unit's initialization code.

**Note** Rights and publication information is included in the factory rather than in the WebPageModule because the program can check the access rights and list the pages even without loading the module.

When a user tries to see a page that requires user identification, the login page indicated in the EndUserSessionAdapter component is displayed. You can create such a page easily by creating a new web page module based on an AdapterPageProducer and adding to it the LoginFormAdapter. In the page's editor, add a field group within a form, connect the field group to the LoginFormAdapter, and add a command group with the default Login button. The resulting login form will have fields for the username and its password, and also for the requested page. This last value is automatically filled with the requested page, in case this page required authorization and the user wasn't already logged in. This way, a user can immediately reach the requested page without being bounced back to a generic menu.

The login form is typically not published, because the corresponding Login command is already available when the user isn't logged in to the system; when the user logs in, it is replaced by a Logout command. This command is obtained by the standard script of the web page module, particularly the following:

```
<% if (EndUser.Logout != null) { %>
```

```
<% if (EndUser.DisplayName != '') { %>
  <h1>Welcome <%=EndUser.DisplayName %></h1>
<% } %>
<% if (EndUser.Logout.Enabled) { %>
  <a href="<%=EndUser.Logout.AsHREF%>">Logout</a>
<% } %>
<% if (EndUser.LoginForm.Enabled) { %>
  <a href="<%=EndUser.LoginForm.AsHREF%>">Login</a>
<% } %>
<% } %>
```

There isn't much else to say about the WSnapUsers application, because it has almost no custom code and settings. This script for the standard template demonstrates the access to the user data.

## Single Page Access Rights

In addition to making pages require a login for access, you can give specific users the right to see more pages than others. Any user has a set of rights separated by semicolons or commas. The user must have all the rights defined for the requested page. These rights, which are generally listed in the `ViewAccess` and `ModifyAccess` properties of the adapters, indicate respectively whether the user can see the given elements while browsing or can edit them. These settings are granular and can be applied to entire adapters or specific adapter fields (notice I'm referring to the adapter fields, not the user interface components within the designer). For example, you can hide some of a table's columns from given users by hiding the corresponding fields (and also in other cases, as specified by the `HideOptions` property).

The global `PageDispatcher` component also has `OnCanViewPage` and `OnPageAccessDenied` events, which you can use to control access to various pages of a program within the program code, allowing for even greater control.

## What's Next?

In this chapter, I've covered web server applications, using multiple server-side techniques and two different frameworks of the Delphi class library: WebBroker and WebSnap. This wasn't an in-depth presentation, because I could write an entire book on this topic alone. It was intended as a starting point, and (as usual) I've tried to make the core concepts clear rather than building complex examples.

If you want to learn more about the WebSnap framework and see examples in actions, refer to the extensive Delphi demos in the `\Demos\WebSnap` folder. Some other options, relating to XML, XSL, and client-side scripts, will be examined in the [Chapter 22](#).

[Chapter 21](#) is devoted to another alternative framework for developing web server applications in Delphi: IntraWeb. This third-party tool has been around for a few years, but it has now become more relevant because Borland included it in Delphi 7. As you'll see, IntraWeb can be integrated in a WebBroker or WebSnap program, or it can be used as a separate architecture.

## Chapter 21: Web Programming with IntraWeb

### Overview

Since Delphi 2 days, Chad Z. Hower has been building a Delphi architecture for simplifying the development of web applications, with the idea of making web programming as simple and as visual as standard Delphi form programming. Some programmers are fully acquainted with dynamic HTML, JavaScript, Cascading Style Sheets, and the latest Internet technologies. Other programmers just want to build web applications in Delphi the way they build VCL or CLX applications.

IntraWeb is intended for this second category of developers, although it is so powerful that even expert web programmers can benefit from its use. In Chad's words, IntraWeb is for building web applications, not websites. Moreover, IntraWeb components can be used in a specific application, or they can be used in a WebBroker or WebSnap program.

In this chapter I cannot cover every detail of IntraWeb—with 50 components installed on Delphi's palette and several module designers, it's a very large library. My plan is to cover its foundations, so that you can choose whether to use it for your forthcoming projects or for portions of those projects, as it fits best.

**Tip** For documentation on IntraWeb, refer to the PDF manuals on the Delphi 7 Companion CD. If you cannot find them, these manuals are also available on Atozed Software's website for download. For support on IntraWeb, refer to the Borland newsgroups.

**Note** This chapter has had a special review by Chad Z. Hower, a.k.a. "Kudzu," the original author and project coordinator for Internet Direct (Indy; see [Chapter 19](#), "Internet Programming: Sockets and Indy") and author of IntraWeb. Chad's areas of specialty include TCP/IP networking and programming, interprocess communication, distributed computing, Internet protocols, and object-oriented programming. When not programming, he likes to cycle, kayak, hike, downhill ski, drive, and do just about anything outdoors. Chad also posts free articles, programs, utilities, and other oddities at Kudzu World at <http://www.Hower.org/Kudzu/>. Chad is an American expatriate who currently spends his summers in St. Petersburg, Russia, and his winters in Limassol, Cyprus. Chad can be reached at [cpub@Hower.org](mailto:cpub@Hower.org).

## Introducing IntraWeb

IntraWeb is a component library currently produced by Atozed Software ([www.atozedsoftware.com](http://www.atozedsoftware.com)). In Delphi 7 Professional and Enterprise, you can find the corresponding version of IntraWeb. The professional version can be used only in *Page mode*, as you'll see later in this chapter. Although Delphi 7 is the first version of the Borland IDE to include this set of components, IntraWeb has been around for several years; it has received appraisal and support, including the availability of several third-party components.

**Tip** IntraWeb third-party components include IWChart by Steema (the makers of TeeChart), IWBold by Centillex (for integration with Bold), IWOpenSource, IWTranslator, IWDialogs, IWDataModulePool by Arcana, IW Component Pack by TMS, and IWGranPrimo by GranPrimo. You'll find an updated list of third parties on [www.atozedsoftware.com](http://www.atozedsoftware.com).

Although you don't have the source code for the core library (available on request and upon a specific payment), the IntraWeb architecture is fairly open, and the full source code of the components is readily available. IntraWeb is part of the Delphi standard installation now, but it is also available for Kylix. Written with care, IntraWeb applications can be fully cross-platform.

**Note** In addition to the Delphi and Linux versions, C++ Builder and Java versions of IntraWeb are available. A .NET version is in the works and will probably become available along with a future Delphi for .NET version.

As an owner of Delphi 7, you're entitled to receive the first significant update release (version 5.1) and can upgrade your license to a full IntraWeb Enterprise edition including upgrades and support from Atozed Software (see their website for details). More serious documentation (help and PDF files) will be available in this 5.1 upgrade.

## From Websites to Web Applications

As I mentioned earlier, the idea behind IntraWeb is to build web applications rather than websites. When you work with WebBroker or WebSnap (covered in [Chapter 20](#), "Web Programming with WebBroker and WebSnap"), you think in terms of web pages and page producers, and work closely at the HTML generation level. When you work with IntraWeb, you think in terms of components, their properties, and their event handlers, as you do in Delphi visual development.

For example, create a new IntraWeb application by selecting File → New → Other, moving to the IntraWeb page of the New Items dialog box, and choosing Stand Alone Application. In the following dialog box (which is part of Delphi, not of the IntraWeb wizard) you can choose an existing folder or enter a new one that will be created for you (I'm mentioning this because it is far from clear in the dialog). The resulting program has a project file and two different units (I'll cover this structure later).

For the moment, let's create an example (called IWSimpleApp in the book's source code). To build it, follow these steps:

1. Move to the main form of the program and add to it a button, an edit box, and a list box from the IW Standard page of the Components palette. That is, don't add the VCL components from the Standard page of the palette—instead, use the corresponding IntraWeb components: IWButton, IWEdit, and IWListBox.
2. Slightly modify their properties as follows:

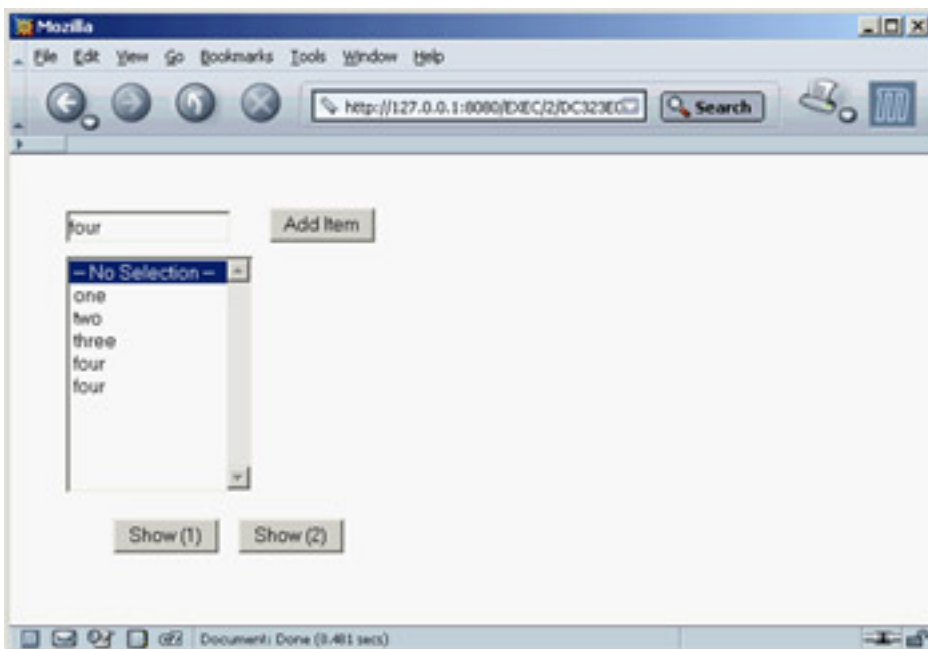

```
object IWButton1: TIWButton
  Caption = 'Add Item'
end
object IWEdit1: TIWEdit
  Text = 'four'
end
object IWListBox1: TIWListBox
  Items.Strings = (
    'one'
```

```
    'two'  
    'three' )  
end
```

3. Handle the `OnClick` event of the button by double-clicking on the component at design time as usual and writing this familiar code:

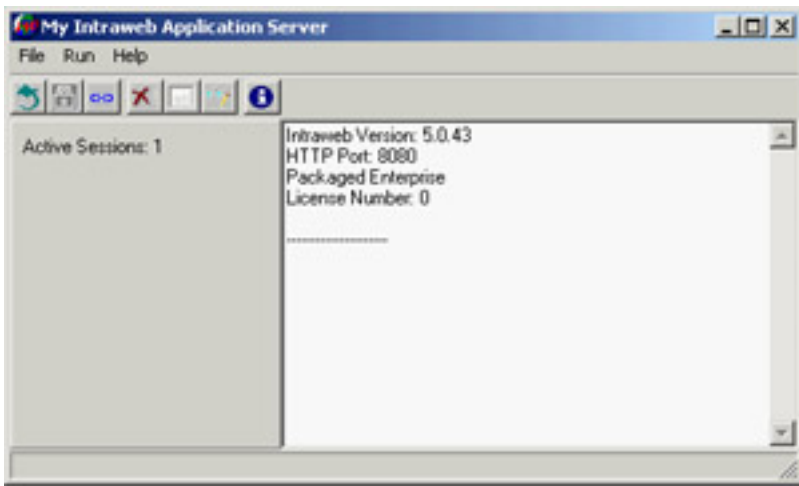

```
procedure TFormMain.IWButton1Click(Sender: TObject);  
begin  
    IWListBox1.Items.Add (IWEdit1.Text);  
end;
```

That's all it takes to create a web-based application capable of adding text to a list box, as you can see in [Figure 21.1](#) (which shows the final version of the program, with a couple more buttons). The important thing to notice when you run this program is that every time you click the button, the browser sends a new request to the application, which runs the Delphi event handler and produces a new HTML page based on the new status of the components on the form.

**Figure 21.1:** The IWSimpleApp program in a browser

As you execute the application, you won't see the program output in the browser, but rather IntraWeb's controller form, shown in [Figure 21.2](#). A stand-alone IntraWeb application, is a full-blown HTTP server, as you'll see in more detail in the [next section](#). The form you see is managed by the `IWRun` call in the project file created by default in each stand-alone IntraWeb application. The debug form allows you to select a browser and run the application through it or copy the URL of the application to the Clipboard, so you can paste it within your browser. It's important to know that the application will by default use a random port number, which is different for each execution; so, you'll have to use a different URL every time. You can modify this behavior by selecting the server controller's designer (similar to a data module) and setting the `port` property. In the example I've used 8080 (one of the common HTTP ports), but any other value will do.

**Figure 21.2:** The controller form of a stand-alone IntraWeb application

IntraWeb code is mainly server side, but IntraWeb also generates JavaScript to control some application features; you can also execute extra code on the client side. You do so by using specific client-side IntraWeb components or by writing your own custom JavaScript code. As a comparison, the two buttons at the bottom of the form in the IWSimpleApp example show a message box using two different approaches.

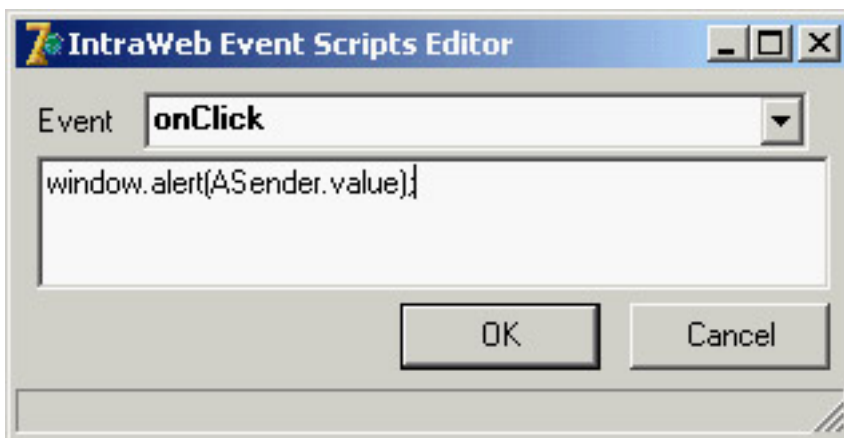

The first of these two buttons (IWButton2) shows a message using a server-side event, with this Delphi code:

```

procedure TFormMain.IWButton2Click(Sender: TObject);
var
    nItem: Integer;
begin
    nItem := IWListbox1.ItemIndex;
    if nItem >= 0 then
        WebApplication.ShowMessage (IWListBox1.Items [nItem])
    else
        WebApplication.ShowMessage ('No item selected');
end;

```

The second of these two buttons (IWButton3) uses JavaScript, which is inserted in the Delphi program by setting the proper JavaScript event handler in the special property editor for the ScriptEvents property:

## A First Look Behind the Scenes

You have seen that creating an IntraWeb application is as simple as creating a Delphi form-based program: You place components on a form and handle their events. Of course, the effect is rather different, because the application runs in a browser. To give you a feel for what's going on, let's briefly look behind the scenes of this simple program. Doing so should help you understand the effect of setting the component properties and of working with them in general.

This is a browser-based program, so there is no better way to understand it than by looking at the HTML it sends to the browser. Open the source of the IWSimpleApp program's page (not listed here, because it would waste too much book space), and you'll notice it is divided into three main sections. The first is a list of styles (based on the HTTP `style` tag) with lines like the following:

```
.IWEDIT1CSS {position:absolute;left:40;top:40;z-index:100;
font-style:normal;font-size:10pt;text-decoration:none;}
```

IntraWeb uses styles to determine not only the visual appearance of each component, such as its font and color, but also the component's position, using default absolute positioning. Each style is affected by a number of the IntraWeb component's properties, so you can easily experiment if you have some knowledge of style sheets. If you aren't familiar with style sheets, just use the properties and trust that IntraWeb will do its best to render the components in the web page.

The second block consists of JavaScript scripting. The main script block contains initialization code and the code of client-side event handlers for the components, like the following:

```
function IWBUTTON1_OnClick(ASender) {
    return SubmitClickConfirm('IWBUTTON1','', true, '');
}
```

This handler invokes the corresponding server-side code. If you've provided the JavaScript code directly in the IntraWeb application, as discussed earlier, you'll see this code:

```
function IWBUTTON3_onClick(ASender) {
    window.alert(ASender.value);
}
```

The scripting section of the page has also references to other files required by the browser and made available by IntraWeb. Some of these files are generic; others are tied to the specific browser: IntraWeb detects the browser being used and returns different JavaScript code and base JavaScript files.

**Note** Because JavaScript is not identical on all browsers, IntraWeb supports only some of them, including all recent versions of Microsoft Internet Explorer, Netscape Navigator, and the open-source Mozilla (which I've used while writing this chapter). Opera has more limited JavaScript support, so by default if it is recognized IntraWeb will issue an error (depending on the *SupportedBrowsers* property of the controller). Opera can be used with the free Arcana components and will officially be supported in IW 5.1. Keep in mind that a browser can fake its identity: For example, Opera is often set to identify itself as Internet Explorer, preventing a proper identification to make it possible to use sites restricted to other browsers, but possibly leading to run time errors or inconsistencies.

The third part of the generated HTML is the definition of the page structure. Inside the `body` tag is a `form` tag (on the same line) with the next action to be executed:

```
<form onsubmit="return FormDefaultSubmit();" name="SubmitForm"
action="/EXEC/3/DC323E01B09C83224E57E240" method="POST">
```

The `form` tag hosts the specific user interface components, such as buttons and edit boxes:

```
<input type="TEXT" name="IWEDIT1" size="17" value="four"
id="IWEDIT1" class="IWEDIT1CSS">
<input value="Add Item" name="IWBUTTON1" type="button"
onclick="return IWBUTTON1_OnClick(this);"
id="IWBUTTON1" class="IWBUTTON1CSS">
```

The form has also a few hidden components that IntraWeb uses to pass information back and forth. However, the URL is the most important way to pass information in IntraWeb; in the program it looks like this:

```
http://127.0.0.1:8080/EXEC/2/DC323E01B09C83224E57E240
```

The first part is the IP address and port used by the stand-alone IntraWeb application (it changes when you use a

different architecture to deploy the program), followed by the `EXEC` command, a progressive request number, and a session ID. We'll get back to session later on, but suffice to say that IntraWeb uses a URL token instead of cookies to make its applications available regardless of browser settings. If you prefer, you can use cookies instead of URLs by changing the `TrackMode` property in the server controller.

**Warning** The version of IntraWeb that shipped with Delphi 7 had a bug involving cookies and some time zone settings. It has been fixed, and the patch is available as a free update on the Atozed software website.

## IntraWeb Architectures

Before I write more examples to demonstrate the use of other IntraWeb components available in Delphi 7, let's discuss another key element of IntraWeb: the different architectures you can use to create and deploy applications based on this library. You can create IntraWeb projects in Application mode (which accounts for all of the features of IntraWeb) or Page mode (which is a simplified version you can plug into existing Delphi WebBroker or WebSnap applications). Application mode applications can be deployed as ISAPI libraries, Apache modules, or by using IntraWeb Standalone mode (a variation of the Application mode architecture). Page mode programs can be deployed as any other WebBroker application (ISAPI, Apache module, CGI, etc.). IntraWeb features three different but partially overlapping architectures:

**Standalone Mode** Provides you with a custom web server, as in the first example you built. This is handy for debugging the application (because you can run it from the Delphi IDE and place breakpoints anywhere in the code). You can also use Standalone mode to deploy applications on internal networks (intranets) and to let users work in offline mode on their own computers, with a web interface. If you run a stand-alone IntraWeb program with the `-install` flag, it will run as a service, and the dialog box won't appear. Standalone mode gives you a way to deploy an Application mode IntraWeb program using IntraWeb itself as web server.

**Application Mode** Allows you to deploy an IntraWeb application on a commercial server, building an Apache module or an IIS library. Application mode includes session management and all the IntraWeb features and is the preferred way to deploy a scalable application for use on the Web. To be precise, Application mode IntraWeb programs can be deployed as stand-alone programs, ISAPI libraries, or Apache modules.

**Page Mode** Opens a way to integrate IntraWeb pages in WebBroker and WebSnap applications. You can add features to existing programs or rely on other technologies for portions of a dynamic site based on HTML pages, while providing the interactive portions with IntraWeb. Page mode is the only choice for using IntraWeb in CGI applications, but it lacks session-management features. Stand-alone IntraWeb servers do not support Page mode.

In the examples in the rest of the chapter, I'll use Standalone mode for simplicity and easier debugging, but I'll also cover Page mode support.

## Building IntraWeb Applications

When you build an IntraWeb application, a number of components are available. For example, if you look at the IW Standard page of Delphi's Component Palette, you'll see an impressive list of core components, from the obvious button, check box, radio button, edit box, list box, memo, and so on to the intriguing tree view, menu, timer, grid, and link components. I won't list each component and describe its use with an example—I'd rather use some of the components in a few demos and underline the architecture of IntraWeb rather than specific details.

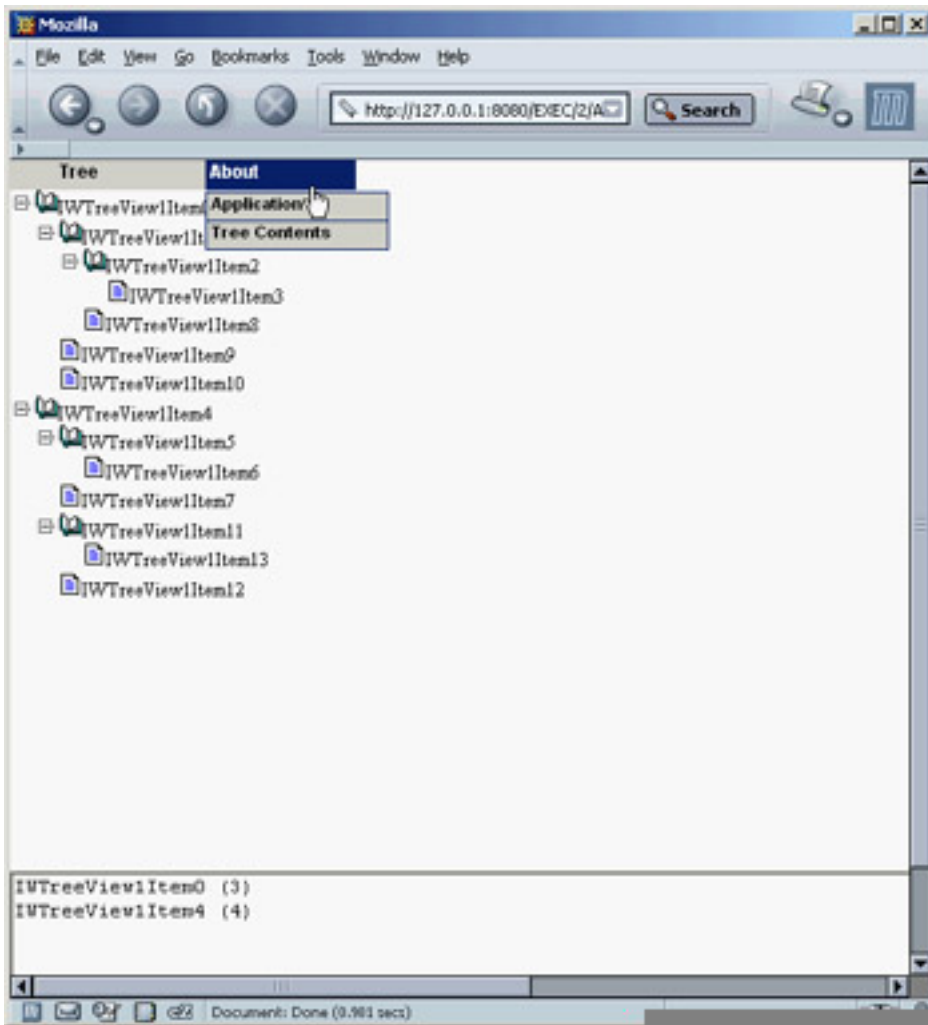

I've built an example (called IWTree) showcasing the menu and tree view components of IntraWeb but also featuring the creation of a component at run time. This handy component makes available in a dynamic menu the content of a standard Delphi menu, by referring its `AttachedMenu` property to a `TMenu` component:

```
object MainMenu1: TMainMenu
  object Tree1: TMenuItem
    object ExpandAll1: TMenuItem
    object CollapseAll1: TMenuItem
    object N1: TMenuItem
    object EnlargeFont1: TMenuItem
    object ReduceFont1: TMenuItem
  end
  object About1: TMenuItem
    object Application1: TMenuItem
    object TreeContents1: TMenuItem
  end
end
object IWMenu1: TIWMenu
  AttachedMenu = MainMenu1
  Orientation = iwOHorizontal
end
```

If the menu items handle the `OnClick` event in the code, they become links at run time. You can see an example of a menu in a browser in [Figure 21.3](#). The example's second component is a tree view with a set of predefined nodes. This component has a lot of JavaScript code to let you expand and collapse nodes directly in the browser (with no need to call back the server). At the same time, the menu items allow the program to operate on the menu by expanding or collapsing nodes and changing the font. Here is the code for a couple of event handlers:

```
procedure TFormTree.ExpandAll1Click(Sender: TObject);
var
  i: Integer;
begin
  for i := 0 to IWTreeView1.Items.Count - 1 do
    IWTreeView1.Items [i].Expanded := True;
  end;

procedure TFormTree.EnlargeFont1Click(Sender: TObject);
begin
  IWTreeView1.Font.Size := IWTreeView1.Font.Size + 2;
end;
```

**Figure 21.3:** The IWTree example features a menu, a tree view, and the dynamic creation of a memo component.

Thanks to the similarity of IntraWeb components to standard Delphi VCL components, the code is easy to read and understand.

The menu has two submenus, which are slightly more complex. The first displays the application ID, which is an application execution/session ID. This identifier is available in the `AppID` property of the `WebApplication` global object. The second submenu, Tree Contents, shows a list of the first tree nodes of the main level along with the number of direct subnodes. What's interesting, though, is that the information is displayed in a memo component created at run time (see again [Figure 21.3](#)), exactly as you'll do in a VCL application:

```

procedure TFormTree.TreeContents1Click(Sender: TObject);
var
    i: Integer;
begin
    with TIWMemo.Create(Self) do
    begin
        Parent := Self;
        Align := alBottom;
        for i := 0 to IWTreeView1.Items.Count - 1 do
            Lines.Add (IWTreeView1.Items [i].Caption + ' (' +
                IntToStr (IWTreeView1.Items [i].SubItems.Count) + ')');
    end;
end;

```

**Tip** Notice that alignment in IntraWeb works similarly to its VCL counterpart. For example, this program's menu with alTop alignment, the tree view has alClient alignment, and the dynamic memo is created with alBottom alignment. As an alternative, you can use anchors (again working as in the VCL): You can create bottom-right buttons, or components in the middle of the page, with all four anchors set. See the following demos for examples of this technique.

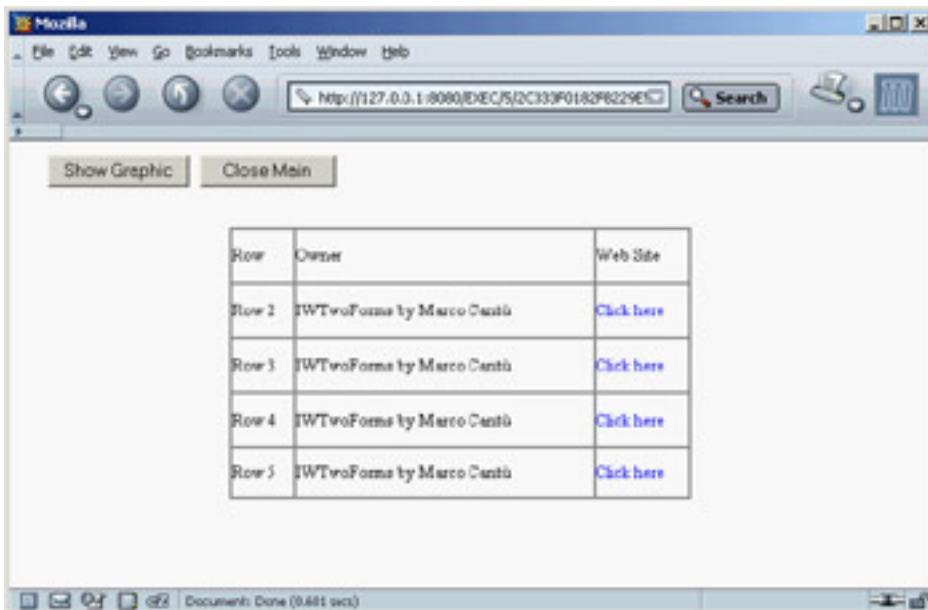

## Writing Multipage Applications

All the programs you have built so far have had a single page. Now let's create an IntraWeb application with a second page. As you'll see, even in this case, IntraWeb development resembles standard Delphi (or Kylix) development, and is different than most other Internet development libraries. This example will also serve as an excuse to delve into some of the source code automatically generated by the IntraWeb application wizard.

Let's start from the beginning. The main form of the IWTwoForms example features an IntraWeb grid. This powerful component allows you to place within an HTML grid both text and other components. In the example, the grid content is determined at startup (in the OnCreate event handler of the main form):

```
procedure TFormMain.IWAppFormCreate(Sender: TObject);  
var  
    i: Integer;  
    link: TIWURL;  
begin  
    // set grid titles  
    IWGrid1.Cell[0, 0].Text := 'Row';  
    IWGrid1.Cell[0, 1].Text := 'Owner';  
    IWGrid1.Cell[0, 2].Text := 'Web Site';  
    // set grid contents  
    for i := 1 to IWGrid1.RowCount - 1 do  
    begin  
        IWGrid1.Cell [i,0].Text := 'Row ' + IntToStr (i+1);  
        IWGrid1.Cell [i,1].Text := 'IWTwoForms by Marco Cantù';  
        link := TIWURL.Create(Self);  
        link.Text := 'Click here';  
        link.URL := 'http://www.marcocantu.com';  
        IWGrid1.Cell [i,2].Control := link;  
    end;  
end;
```

The effect of this code is shown in [Figure 21.4](#). In addition to the output, there are a few interesting things to notice. First, the grid component uses Delphi anchors (all set to False) to generate code that keeps it centered in the page, even if a user resizes the browser window. Second, I've added an IWURL component to the third column, but you could add any other component (including buttons and edit boxes) to the grid.

**Figure 21.4:** The IWTwoForms example uses an IWGrid component, embedded text, and IWURL components.

The third and most important consideration is that an IWGrid is translated into an HTML grid, with or without a frame around it. Here is a snippet of the HTML generated for one of the grid rows:

```
<tr>
  <td valign="middle" align="left" NOWRAP>
    <font style="font-size:10pt;">Row 2</font>
  </td>
  <td valign="middle" align="left" NOWRAP>
    <font style="font-size:10pt;">IWTwoForms by Marco Cantù</font>
  </td>
  <td valign="middle" align="left" NOWRAP>
    <font style="font-size:10pt;"></font>
    <a href="#" onclick="parent.LoadURL('http://www.marcocantu.com')"
      id="TIWURL1" name="TIWURL1"
      style="z-index:100;font-style:normal;font-size:10pt;text-decoration:none;">
      Click here</a>
  </td>
</tr>
```

**Tip** In the previous listing, notice that the linked URL is activated via JavaScript, not with a direct link. This happens because all actions in IntraWeb allow for extra client-side operations, such as validations, checks, and submits. For example, if you set the *Required* property for a component, if the field is empty the data won't be submitted, and you'll see a JavaScript error message (customizable by setting the descriptive *FriendlyName* property).

The core feature of the program is its ability to show a second page. To accomplish this, you first need to add a new IntraWeb page to the application, using the Application Form option on the IntraWeb page of Delphi's New Items dialog box (File → New → Other). Add to this page a few IntraWeb components, as usual, and then add to the main form a button or other control you'll use to show the secondary form (with the reference *anotherform* stored in a field of the main form):

```
procedure TFormMain.btnShowGraphicClick(Sender: TObject);
begin
  anotherform := TAnotherForm.Create(WebApplication);
  anotherform.Show;
end;
```

Even if the program calls the *Show* method, it can be considered like a *ShowModal* call, because IntraWeb considers visible pages as a stack. The last page displayed is on the top of the stack and is displayed in the browser. By closing

this page (hiding or destroying it), you re-display the previous page. In the program, the secondary pages closes itself by calling the `Release` method, which as in the VCL is the proper way to dispose of a currently executing form. You can also hide the secondary form and then display it again, to avoid re-creating it each time (particularly if doing so implies losing the user's editing operations).

**Warning** In the program I added a Close button to the main form. It should not call `Release`, but rather should invoke the `WebApplication` object's `Terminate` method, passing the output message, as in `WebApplication .Terminate('Goodbye!')`. The demo uses an alternative call: `TerminateAndRedirect`.

Now that you have seen how to create an IntraWeb application with two forms, let's briefly examine how IntraWeb creates the main form. The relevant code, generated by the IntraWeb wizard as you create a new program, is in the project file:

```
begin
  IWRun(TFormMain, TIWServerController);
```

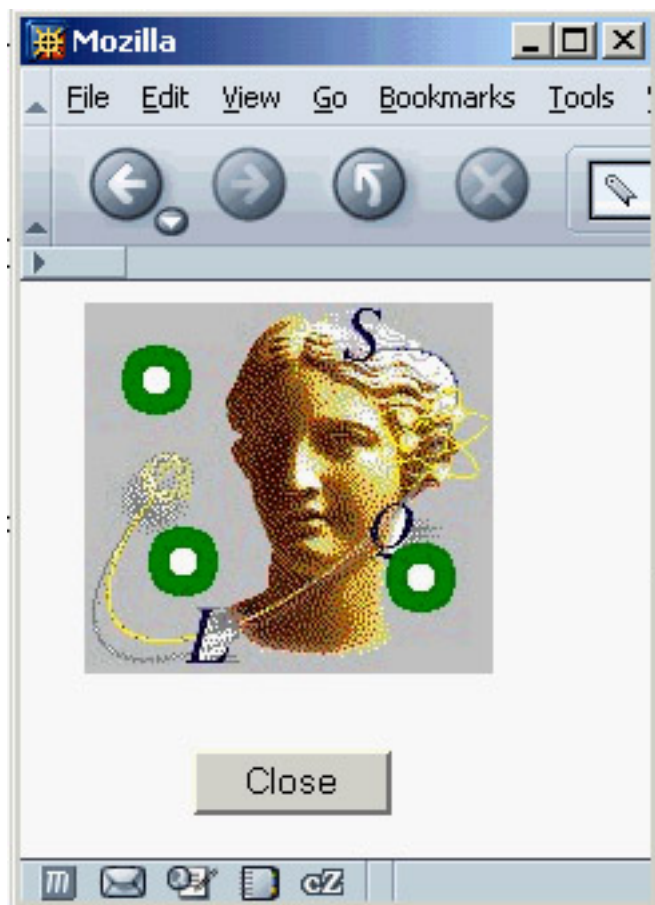

This is different from Delphi's standard project file, because it calls a global function instead of applying a method to a global object representing the application. The effect, though, is quite similar. The two parameters are the classes of the main form and of the IntraWeb controller, which handle sessions and other features as you'll see in a while.

The secondary form of the IWTwoForms example shows another interesting feature of IntraWeb: its extensive graphics support. The form has a graphical component with the classic Delphi Athena image. This is accomplished by loading a bitmap into the an `IWImage` component: IntraWeb converts the bitmap into a JPEG, stores it in a cache folder created under the application folder, and returns a reference to it, with the following HTML:

```

```

The extra feature provided by IntraWeb and exploited by the program is that a user can click on the image with the mouse to modify the image by launching server-side code. In this program, the effect is to draw small green circles.

This effect is obtained with the following code:

```

procedure Tanotherform.IWImageMouseDown(ASender: TObject;
  const AX, AY: Integer);
var
  aCanvas: TCanvas;
begin
  aCanvas := IWImage1.Picture.Bitmap.Canvas;
  aCanvas.Pen.Width := 8;
  aCanvas.Pen.Color := clGreen;
  aCanvas.Ellipse(AX - 10, AY - 10, AX + 10, AY + 10);
end;

```

**Warning** The painting operation takes place on the bitmap canvas. Do not try to use the Image canvas (as you can do with the VCL's TImage component), and do not try to use a JPEG in the first place, or you'll see either no effect or a run-time error.

## Sessions Management

If you've done any web programming, you know that session management is a complex issue. IntraWeb provides predefined session management and simplifies the way you work with sessions. If you need session data for a specific form, all you have to do is add a field to that form. The IntraWeb forms and their components have an instance for each user session. For example, in the IWSession example, I've added to the form a field called `FormCount`. As a contrast, I've also declared a global unit variable called `GlobalCount`, which is shared by all the instances (or sessions) of the application.

To increase your control over session data and let multiple forms share it, you can customize the `TUserSession` class that the IntraWeb Application Wizard places in the `ServerController` unit. In the IWSession example, I've customized the class as follows:

```

type
  TUserSession = class
  public
    UserCount: Integer;
  end;

```

IntraWeb creates an instance of this object for each new session, as you can see in the `IWServerControllerBaseNewSession` method of the `TIWServerController` class in the default `ServerController` unit:

```

procedure TIWServerController.IWServerControllerBaseNewSession(
  ASession: TIWApplication; var VMainForm: TIWAppForm);
begin
  ASession.Data := TUserSession.Create;
end;

```

In an application's code, the session object can be referenced by accessing the `Data` field of the `RWebApplication` global variable, used to access the current user's session.

**Note** `RWebApplication` is a *threadvar* variable, defined in the `IWInit` unit. It gives you access to the session data in a thread-safe way: you need to take special care to access it even in a multi-threading environment. This variable can be used outside of a form or control (which are natively session-based), which is why it is primarily used inside data modules, global routines, and non-IntraWeb classes.

Again, the default `ServerController` unit provides a helper function you can use:

```

function UserSession: TUserSession;
begin
  Result := TUserSession(RWebApplication.Data);
end;

```

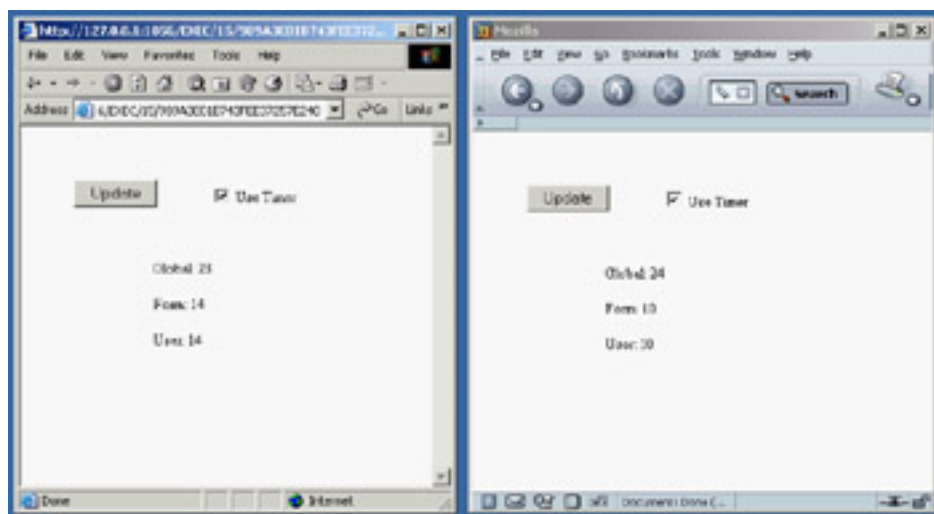

Because most of this code is generated for you, after adding data to the `TUserSession` class you simply use it through the `UserSession` function, as in the following code extracted from the `IWSession` example. When you click a button, the program increases several counters (one global and two session-specific) and shows their values in labels:

```
procedure TFormMain.IWButton1Click(Sender: TObject);  
begin  
  InterlockedIncrement (GlobalCount);  
  Inc (FormCount);  
  
  Inc (UserSession.UserCount);  
  
  IWLabel1.Text := 'Global: ' + IntToStr (GlobalCount);  
  IWLabel2.Text := 'Form: ' + IntToStr (FormCount);  
  IWLabel3.Text := 'User: ' + IntToStr (UserSession.UserCount);  
end;
```

Notice that the program uses Windows' `InterlockedIncrement` call to avoid concurrent access to the global shared variable by multiple threads. Alternative approaches include using a critical section or Indy's `TidThreadSafeInteger` (found in the `IdThreadsafe` unit).

[Figure 21.5](#) shows the output of the program (with two sessions running in two different browsers). The program has also a check box that activates a timer. Odd as it sounds, in an IntraWeb application, timers work almost the same as in Windows. When the timer interval expires, code is executed. Over the Web, this means refreshing the page by triggering a refresh in the JavaScript code:

**Figure 21.5:** The `IWSession` application has both session-specific and global counters, as you can see by running two sessions in two different browsers (or even in the same browser).

```
IWTIMER1=setTimeout('SubmitClick("IWTIMER1","", false)',5000);
```

## Integrating with WebBroker (and WebSnap)

Up to now, you have built stand-alone IntraWeb applications. When you create an IntraWeb application in a library to be deployed on IIS or Apache, you are basically in the same situation. Things change considerably, however, if you want to use IntraWeb Page mode, which is integrated in an IntraWeb page in a WebBroker (or WebSnap) Delphi application.

The bridge between the two worlds is the `IWPageProducer` component. This component hooks to a WebBroker action like any other page producer component and has a special event you can use to create and return an IntraWeb form:

```
procedure TWebModule1.IWPageProducer1GetForm(ASender: TIWPageProducer;  
  AWebApplication: TIWApplication; var VForm: TIWPageForm);
```

```

begin
  VForm := TFormMain.Create(AWebApplication);
end;

```

With this single line of code (plus the addition of an `IWebModuleController` component in the web module), the WebBroker application can embed an IntraWeb page, as the `Cgilntra` program does. The `IWebModuleController` component provides *core services* for IntraWeb support. A component of this type must exist in every project for IntraWeb to work properly.

**Warning** The release that comes with Delphi 7 has a problem with Delphi's Web App Debugger and the `IWebModuleController` component. This issue has been fixed and is a free update.

Here is a summary of the DFM of the example program's web module:

```

object WebModule1: TWebModule1
  Actions = <
    item
      Default = True
      Name = 'WebActionItem1'
      PathInfo = '/show'
      OnAction = WebModule1WebActionItem1Action
    end
    item
      Name = 'WebActionItem2'
      PathInfo = '/iwdemo'
      Producer = IWPageProducer1
    end>
  object IWebModuleController1: TIWebModuleController
  object IWPageProducer1: TIWPageProducer
    OnGetForm = IWPageProducer1GetForm
  end
end
end

```

Because this is a Page mode CGI application, it has no session management. Moreover, the status of the components in a page is not automatically updated by writing event handlers, as in a standard IntraWeb program. To accomplish the same effect you need to write specific code to handle further parameters of the HTTP request. It should be clear even from this simple example that Page mode does less for you than Application mode, but it's more flexible. In particular, IntraWeb Page mode allows you to add visual RAD design capabilities to your WebBroker and WebSnap applications.

## Controlling the Layout

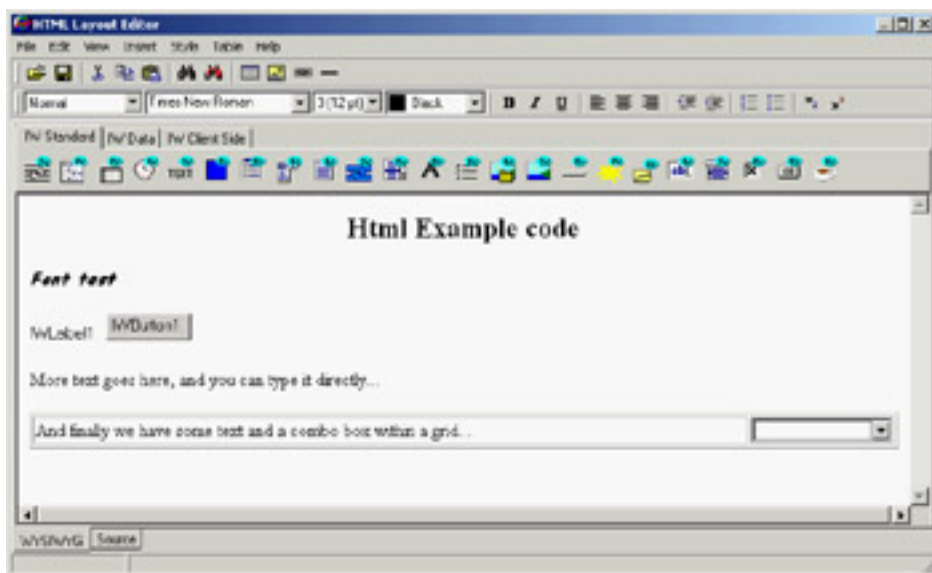

The `Cgilntra` program features another interesting technology available in IntraWeb: the definition of a custom layout based on HTML. (That topic isn't really related, because HTML layouts work also in Application mode—but I've happened to use these two techniques in a single example.) In the programs built so far, the resulting page is the mapping of a series of components placed at design time on a form, in which you can use properties to modify the resulting HTML. But what if you want to embed a data-entry form within a complex HTML page? Building the entire page contents with IntraWeb components is awkward, even if you can use the `IWText` component to embed a custom piece of HTML within an IntraWeb page.

The alternative approach is represented by the use of IntraWeb's layout managers. In IntraWeb you invariably use a layout manager; the default is the `IWLayoutMgrForm` component. The other two alternatives are `IWTemplateProcessorHTML` for working with an external HTML template file and `IWLayoutMgrHTML` for working with internal HTML.

This second component includes a powerful HTML editor you can use to prepare the generic HTML as well as embed the required IntraWeb components (something you'll have to do manually with an external HTML editor). Moreover, as you select an IntraWeb component from this editor (which is activated by double-clicking on an `IWLayoutMgrHTML`

component), you'll be able to use Delphi's Object Inspector to customize the component's properties. As you can see in [Figure 21.6](#), the HTML Layout Editor available in IntraWeb is a powerful visual HTML editor; the HTML text it generates is available in a separate page. (The HTML editor will be improved in a coming upgrade, and a few quirks will be fixed.)

**Figure 21.6:** IntraWeb's HTML Layout Editor is a full-blown visual HTML editor.

In the generated HTML, the HTML defines the structure of the page. The components are marked only with a special tag based on curly braces, as in the following of the example:

```
<P> { %IWLabel1% } { %IWButton1% } </P>
```

**Tip** Notice that when you're using HTML the components don't use absolute positioning but flow along with the HTML. Thus the form becomes only a component holder, because the size and position of the form's components are ignored.

Needless to say, the HTML you see in the visual designer of the HTML Layout Editor corresponds almost perfectly to the HTML you'll see when running the program in a browser.

## Web Database Applications

As in Delphi's libraries, a significant portion of IntraWeb's available controls relates to the development of database applications. The IntraWeb Application Wizard has a version that allows you to create an application with a data module—a good starting point for the development of a database application. In such a case, the application's predefined code creates an instance of the data module for each session, saving it in the session's data.

Here is the predefined `TUserSession` class (and its constructor) for an IntraWeb application with a data module:

```

type
  TUserSession = class(TComponent)
  public
    DataModule1: TDataModule1;
    constructor Create(AOwner: TComponent); override;
  end;

constructor TUserSession.Create(AOwner: TComponent);
begin
  inherited;
  DataModule1 := TDataModule1.Create(AOwner);
end;

```

The unit of the data module doesn't have a global variable for it; if it did, all the data would be shared among all sessions, with severe risks of trouble in case of concurrent requests in multiple threads. However, the data module already exposes a global function having the same name as the global variable Delphi would use, accessing the current session's data module:

```

function DataModule1: TDataModule1;
begin
  Result := TUserSession(RWebApplication.Data).DataModule1;
end;

```

This means you can write code like the following:

```
DataModule1.SimpleDataSet1
```

But instead of accessing a global data module, you are using the current session's data module.

In the first sample program featuring database data, called `IWScrollData`, I've added to the data module a `SimpleDataSet` component and to the main form an `IWDBGrid` component with the following configuration:

```

object IWDBGrid1: TIWDBGrid
  Anchors = [akLeft, akTop, akRight, akBottom]
  BorderSize = 1
  CellPadding = 0
  CellSpacing = 0
  Lines = tlRows
  UseFrame = False
  DataSource = DataSource1
  FromStart = False
  Options = [dgShowTitles]
  RowAlternateColor = clSilver
  RowLimit = 10
  RowCurrentColor = clTeal
end

```

The most important settings are the removal of a frame hosting the control with its own scroll bars (the `UseFrame` property), the fact that the data is displayed from the current data set position (the `FromStart` property), and the number of rows to be displayed in the browser (the `RowLimit` property). In the user interface, I've removed vertical

lines and colored alternate rows. I also had to set up a color for the current row (the `RowCurrentColor` property); otherwise the alternate colors won't appear to work properly, since the current row is the same color as the background rows, regardless of its position (set the `RowCurrentColor` property to `clNone` to see what I mean). These settings produce the effect you can see in [Figure 21.7](#) or by running the `IWScrollData` example.

EMP_ID	FIRST_NAME	LAST_NAME	PHONE_NUMBER	HIRE_DATE	DEPT_ID	JOB_CODE	JOB_TITLE	SALARY
24	Ford	Ford	917	11/09/90	60	Analyst	3	USA
25	Rogers	De Silva	288	11/09/90	60	Analyst	3	USA
26	Jones	Bell	3	08/09/90	110	Sales	3	USA
27	Rogers	Brown	4	02/09/90	120	Sales	3	England
28	Wales	Shaw	7	02/09/90	120	Analyst	4	England
41	Levy	Fung	219	09/09/91	60	Analyst	4	USA
42	Abel	Perkins	209	01/09/91	60	Analyst	3	USA
43	Walker	Shelton	210	08/09/91	90	CPA	1	USA
50	Grant	Hollman	430	08/09/90	130	Prod	4	USA

**Figure 21.7:** The data-aware grid of the `IWScrollData` example

The program opens the data set when the form is created, using the data set hooked to the current data source:

```

procedure TFormMain.IWAppFormCreate(Sender: TObject);
begin
    DataSource1.DataSet.Open;
end;

```

The example's relevant code is in the button code, which can be used to move through the data showing the following page or returning to the previous one. Here is the code for one of the two methods (the other is omitted, because it's very similar):

```

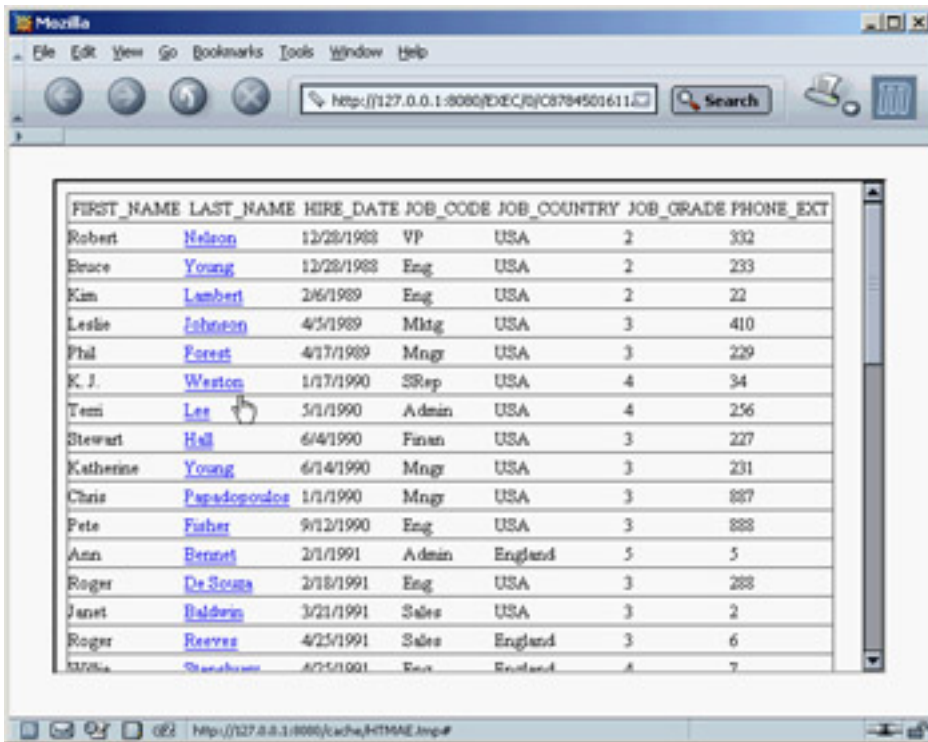

procedure TFormMain.btnNextClick(Sender: TObject);
var
    i: Integer;
begin
    nPos := nPos + 10;
    if nPos > DataSource1.DataSet.RecordCount - 10 then
        nPos := DataSource1.DataSet.RecordCount - 10;
    DataSource1.DataSet.First;
    for i := 0 to nPos do
        DataSource1.DataSet.Next;
end;

```

## Linking to Details

The grid of the `IWScrollData` example shows a single page of a table's data; buttons let you scroll up and down the pages. An alternative grid style in IntraWeb is offered by framed grids, which can move larger amounts of data to the web browser within a screen area of a fixed size using a frame and an internal scroll bar, as a Delphi `ScrollBox` control does. This is demonstrated by the `IWGridDemo` example.

The example customizes the grid in a second powerful way: It sets the `Columns` collection property of the grid. This setting allows you to fine-tune the output and behavior of specific columns, for example by showing hyperlinks or handling clicks on items or title cells. In the `IWGridDemo` example, one of the columns (the last name) is turned into a hyperlink; the employee number is passed as a parameter to the follow-up command, as you can see in [Figure 21.8](#).

**Figure 21.8:** The main form of the IWGridDemo example uses a framed grid with hyperlinks to the secondary form.

[Listing 21.1](#) shows a summary of the grid's key properties. Notice in particular the last name column, which as mentioned has a linked field (which turns the cell's text into a hyperlink) and an event handler responding to its selection. In this method, the program creates a secondary form in which a user can edit the data:

```

procedure TGridForm.IWDBGrid1Columns1Click(ASender: TObject;
  const AValue: String);
begin
  with TRecordForm.Create (WebApplication) do
    begin
      StartID := AValue;
      Show;
    end;
end;

```

### **Listing 21.1: Properties of the IWDBGrid in the IWGridDemo Example**

```

object IWDBGrid1: TIWDBGrid
  Anchors = [akLeft, akTop, akRight, akBottom]
  UseFrame = True
  UseWidth = True
  Columns = <
    item
      Alignment = taLeftJustify
      BGColor = clNone
      DoSubmitValidation = True
      Font.Color = clNone
      Font.Enabled = True
      Font.Size = 10
      Font.Style = []
      Header = False
      Height = '0'
      VAlign = vaMiddle
      Visible = True
      Width = '0'

```

```

Wrap = False
BlobCharLimit = 0
CompareHighlight = hcNone
DataField = 'FIRST_NAME'
Title.Alignment = taCenter
Title.BGColor = clNone
Title.DoSubmitValidation = True
Title.Font.Color = clNone
Title.Font.Enabled = True
Title.Font.Size = 10
Title.Font.Style = []
Title.Header = False
Title.Height = '0'
Title.Text = 'FIRST_NAME'
Title.VAlign = vaMiddle
Title.Visible = True
Title.Width = '0'
Title.Wrap = False
end
item
  DataField = 'LAST_NAME'
  LinkField = 'EMP_NO'
  OnClick = IWDBGrid1Columns1Click
end
item
  DataField = 'HIRE_DATE'
end
item
  DataField = 'JOB_CODE'
end
item
  DataField = 'JOB_COUNTRY'
end
item
  DataField = 'JOB_GRADE'
end
item
  DataField = 'PHONE_EXT'
end>
DataSource = DataSource1
Options = [dgShowTitles]
end

```

---

By setting the second form's `StartID` property, you can locate the proper record:

```

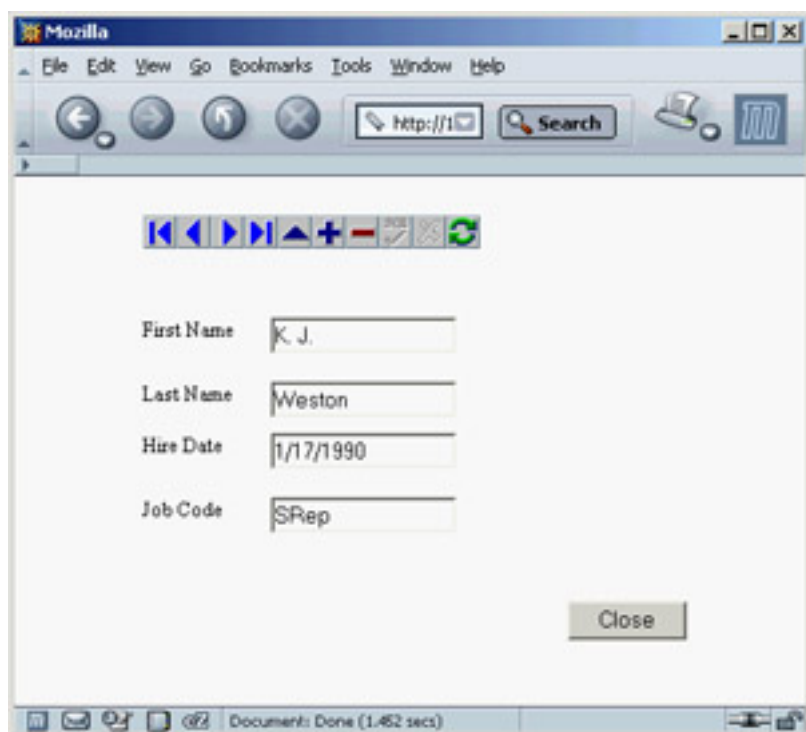

procedure TRecordForm.SetStartID(const Value: string);
begin
  FStartID := Value;
  DataSource1.DataSet.Locate('EMP_NO', Value, []);
end;

```

**Tip** The IWDBGrid columns have also an `OnTitleClick` event you can handle to sort the data or perform other operations on the column.

The secondary form is hooked to the same data module as the main form. So, after the database data is updated, you

can see it in the grid (but the updates are kept only in memory, because the program doesn't have an `ApplyUpdates` call). The secondary form uses a few edit controls and a navigator, provided by IntraWeb. You can see this form at run time in [Figure 21.9](#).

**Figure 21.9:** The secondary form of the IWGridDemo example allows a user to edit the data and navigate through records.

## Moving Data to the Client Side

Regardless of how you use it, the IWDBGrid component produces HTML with the database data embedded in the cells, but it cannot work on the data on the client side. A different component (or a set of IntraWeb components) allows you to follow a different model. The data is sent to the browser in a custom format, and the JavaScript code on the browser populates a grid and operates on the data, moving from record to record without asking more data to the server.

**Note** This architecture is similar to Delphi's native Internet Express architecture, which I'll cover in [Chapter 22](#) ("Using XML Technologies").

You can use several IntraWeb components for a client-side application, but these are the most important ones:

**IWClientSideDataSet** An in-memory dataset you define by setting the `ColumnNames` and `Data` properties within your program's code. In future updates, you will be able to edit client-side data, sort it, filter it, define master-detail structures, and more.

**IWClientSideDataSetDBLink** A data provider you can connect to any Delphi dataset, connecting it with the `DataSource` property.

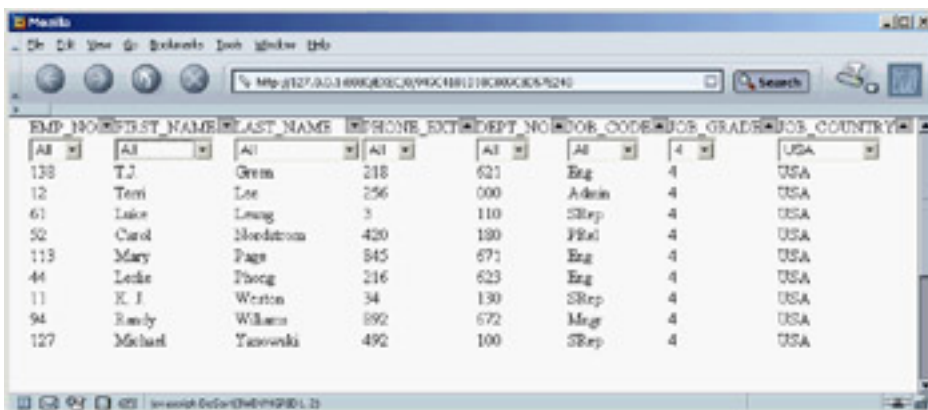

**IWDynGrid** A dynamic grid component connected to one of the two previous components using the `Data` property. This component moves all the data to the browser and can operate on it on the client via JavaScript.

There are other client-side components in IntraWeb, such as IWCSLabel, IWCSNavigator, and IWDynamicChart (which works only with Internet Explorer). As an example of using this approach, I've built the IWClientGrid example. The program has little code, because there is a lot available in the components being used. Here are the core

elements of its main form:

```
object formMain: TFormMain
  SupportedBrowsers = [brIE, brNetscape6]
  OnCreate = IWebAppFormCreate
  object IWDynGrid1: TIWDynGrid
    Align = alClient
    Data = IWClientSideDatasetDBLink1
  end
  object DataSource1: TDataSource
    Left = 72
    Top = 88
  end
  object IWClientSideDatasetDBLink1: TIWClientSideDatasetDBLink
    DataSource = DataSource1
  end
end
```

The dataset from the data module is hooked to the DataSource when the form is created. The resulting grid, shown in [Figure 21.10](#), allows you to sort the data on any cell (using the small arrow *after* the column title) and filter the data displayed on one of the field's possible values. In the figure, for example, you can sort the employee data by last name and filter it by country and job grade.

EMP_NO	FIRST_NAME	LAST_NAME	PHONE_EXT	DEPT_NO	JOB_CODE	JOB_GRADE	JOB_COUNTRY
138	TJ	Green	218	621	Eng	4	USA
12	Toni	Lee	256	000	Admin	4	USA
61	Luise	Leung	3	110	SRep	4	USA
52	Carol	Nordstrom	420	190	Fin	4	USA
113	Mary	Page	345	671	Eng	4	USA
44	Lodie	Thong	216	623	Eng	4	USA
11	K. J.	Watson	34	130	SRep	4	USA
94	Randy	Williams	892	672	Mgr	4	USA
127	Michael	Yasvski	492	100	SRep	4	USA

**Figure 21.10:** The grid of the IWClientGrid example supports custom sorting and filtering without re-fetching the data on the web server.

This functionality is possible because the data is moved to the browser within the JavaScript code. Here is a snippet of one of the scripts embedded in the page's HTML:

```
<script language="Javascript1.2">
var IWDYNGRID1_TitleCaptions =
  [ "EMP_NO", "FIRST_NAME", "LAST_NAME", "PHONE_EXT",
    "DEPT_NO", "JOB_CODE", "JOB_GRADE", "JOB_COUNTRY" ];
var IWDYNGRID1_CellValues = new Array();
IWDYNGRID1_CellValues[0] = [ 2, 'Robert', 'Nelson', '332', '600', 'VP', 2, 'USA' ];
IWDYNGRID1_CellValues[1] = [ 4, 'Bruce', 'Young', '233', '621', 'Eng', 2, 'USA' ];
IWDYNGRID1_CellValues[2] = [ 5, 'Kim', 'Lambert', '22', '130', 'Eng', 2, 'USA' ];
IWDYNGRID1_CellValues[3] = [ 8, 'Leslie', 'Johnson', '410', '180', 'Mktg', 3, 'USA' ];
IWDYNGRID1_CellValues[4] = [ 9, 'Phil', 'Forest', '229', '622', 'Mgr', 3, 'USA' ];
```

**Note** The reason to use this JavaScript-based approach, instead of an XML-based approach featured by other similar technologies, is that only Internet Explorer has support for *XML data islands*. Mozilla and Netscape lack this feature and have limited XML support in general. Mimicking it in JavaScript, as Internet Explorer does, is very expensive at run time.

## What's Next?

This chapter's description of IntraWeb's features has been far from complete, but my aim was mainly to let you evaluate this technology so you can choose whether to use it in your forthcoming Delphi projects. IntraWeb is so powerful that you now have a good reason to build web applications in Delphi, instead of resorting to other development tools.

You can read much more about IntraWeb in the documentation, found on the Delphi Companion CD (not on the main CD). Delphi's default installation includes the IntraWeb demos, including the extensive Features example that shows at once most of the features of this component library. Also refer to the IntraWeb website ([www.atozedsoftware.com](http://www.atozedsoftware.com)) for updates and further documentation and examples.

In this book, we have another alternative web development approach to cover, based on XML and XSLT. [Chapter 22](#) is devoted to a complete roundup of XML-related technologies from the Delphi perspective. So, we'll have another chance to cover web development in Delphi, using one of the techniques I like best—but that's also one of the most complex.

## Chapter 22: Using XML Technologies

### Overview

Building applications for the Internet means using protocols and creating browser-based user interfaces, as you've done in the preceding two chapters, but also opens an opportunity for exchanging business documents electronically. The emerging standards for this type of activity center around the XML document format and include the SOAP transmission protocol, XML schemas for the validation of documents, and XSL for rendering documents as HTML.

In this chapter, I'll discuss the core XML technologies and the extensive support Delphi has offered for them since version 6. Because XML knowledge is far from widespread, I'll provide a little introduction about each technology, but you should refer to books specifically devoted to them to learn more. In [Chapter 23](#), I'll focus specifically on web services and SOAP.

## Introducing XML

Extensible Markup Language (XML) is a simplified version of SGML and is getting a lot of attention in the IT world. XML is a *markup language*, meaning it uses symbols to describe its own content—in this case, *tags* consisting of specially defined text enclosed in angle brackets. It is *extensible* because it allows for free markers (in contrast, for example, to HTML, which has predefined markers). The XML language is a standard promoted by the World Wide Web Consortium (W3C). The XML Recommendation is at [www.w3.org/TR/REC-xml](http://www.w3.org/TR/REC-xml).

XML has been touted as the ASCII of the year 2000, to indicate a simple and widespread technology and also to indicate that an XML document is a plain-text file (optionally with Unicode characters instead of plain ASCII text). The important characteristic of XML is that it is descriptive, because every tag has an almost human-readable name. Here is an example, in case you've never seen an XML document:

```
<book>
  <title>Mastering Delphi 7</title>
  <author>Cantu</author>
  <publisher>Sybex</publisher>
</book>
```

XML has a few disadvantages I want to underline from the beginning. The biggest is that without a formal description, a document is worth little. If you want to exchange documents with another company, you must agree on what each tag means and also on the semantic meaning of the content. (For example, when you have a quantity, you have to agree on the measurement system or include it in the document.) Another disadvantage is that XML documents are much larger than other formats; using strings for numbers, for example, is far from efficient, and the repeated opening and closing tags eat up a lot of space. The good news is that XML compresses well, for the same reason.

## Core XML Syntax

A few technical elements of XML are worth knowing before we discuss its usage in Delphi. Here is a short summary of the key elements of the XML syntax:

- White space (including the space character, carriage return, line feed, and tabs) is generally ignored (as in an HTML document). It is important to format an XML document to make it readable by a human being, but your programs won't care much.
- You can add comments within `<!--` and `-->` markers, which are basically ignored by XML processors. There are also directives and processing instructions, enclosed within `<?>` and `?>` markers.
- There are a few special or reserved characters you cannot use in the text. The only two symbols you can *never* use are the less-than character (or left angle bracket, `<`, used to delimit a marker), which is replaced by `&lt;`, and the ampersand character (`&`), which is replaced by `&amp;`. Other optional special characters are `&gt;` for the greater-than symbol (right angle bracket, `>`), `&apos;` for the single quote (`'`), and `&quot;` for the double quote (`"`).
- To add non-XML content (for example, binary information or a script), you can use a CDATA section, enclosed within `<![CDATA[` and `]]>`.
- All markers are enclosed by angle brackets, `<` and `>`. Markers are case sensitive (in contrast to HTML).
- For each opening marker, you must have a matching closing marker, denoted by an initial slash character:  
`<node>value</node>`
- Markers must not overlap—they must be *properly nested*, as in the first line here (the second line is not correct):  
`<node>xx <nested> yy</nested> </node> // OK`  
`<node>xx <nested> yy</node> </nested> // WRONG`

- If a marker has no content (but its presence is important), you can replace the opening and closing markers with a single marker that includes a final (*trailing*) slash: `<node/>`.

- Markers can have attributes, using multiple attribute names followed by a value enclosed within quotes:

```
<node attrib1="aaa">
```

- Any XML node can have multiple attributes, multiple embedded tags, and only one block of text, representing the value of the node. It is common practice for XML nodes to have either a textual value or embedded tags, and not both. Here is an example of the full syntax of a node:

```
<node attrib1="aaa" attrib2="bbb">
  value1
  <child1>
    value2
  </child1>
</node>
```

- A node can have multiple child nodes with the same tag (tags need not be unique). Attribute names are unique for each node.

## Well-Formed XML

The elements discussed in the [previous section](#) define the syntax of an XML document, but they are not enough. An XML document is considered syntactically correct, or *well formed*, if it follows a few extra rules. Notice that this type of check doesn't guarantee that the content of the document is meaningful—only that the tags are properly laid out.

Each document should have a prologue indicating that it is indeed an XML document, which version of XML it complies with, and possibly the type of character encoding. Here is an example:

```
<?xml version="1.0" encoding="UTF-8"?>
```

Possible encodings include Unicode character sets (such as UTF-8, UTF-16, and UTF-32) and some ISO encodings (such as ISO-10646-xxx or ISO-8859-xxx). The prologue can also include external declarations, the schema used to validate the document, namespace declarations, an associated XSL file, and some internal entity declarations. Refer to XML documentation or books for more information about these topics.

An XML document is well formed if it has a prologue, has a proper syntax (see the rules in the [previous section](#)), and has a tree of nodes with a single root. Most tools (including Internet Explorer) check whether a document is well formed when loading it.

**Note** XML is more formal and precise than HTML. The W3C is working on an XHTML standard that will make HTML documents XML compliant, for better processing with XML tools. This implies many changes in a typical HTML document, such as avoiding attributes with no values, adding all the closing markers (as in `</p>` and `</li>`), adding the slash to stand-alone markers (as `<hr/>` and `<br/>`), proper nesting, and more. An HTML-to-XHTML converter called HTML Tidy is hosted by the W3C website at [www.w3.org/People/Raggett/tidy/](http://www.w3.org/People/Raggett/tidy/).

## Working with XML

To get acquainted with the format of XML, you can use one of the existing XML editors available on the market (including Delphi itself and Context, a programmer's editor written in Delphi). When you load an XML document into Internet Explorer, you'll see whether it is correct and, in this case, you'll see it within the browser in a tree-like structure. (At the time I'm writing this, other browsers have more limited XML support.)

To speed up this type of operation, I've built the simplest XML editor I could come up with—basically a memo with XML syntax-checking and a browser attached to it. The XmlEditOne example has a PageControl with three pages. The first page, Settings, hosts a couple of components in which you can insert the path and the name of the file you want to

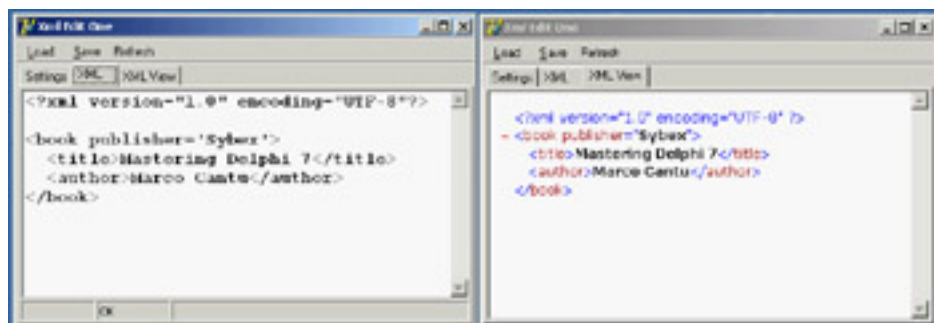

work with. (The reason for not using a standard dialog will become clear when I show you an extension of the program.) The edit box hosting the complete filename is automatically updated with the path and filename, provided the AutoUpdate check box is selected.

The second page hosts a Memo control; the text of the XML file is loaded and saved by clicking the two toolbar buttons. As soon as you load the file, or each time you modify its text, its content is loaded into a DOM to let a parser check for its correctness (something that would be complex to do with your own code). To parse the code, I've used the XMLDocument component available in Delphi, which is basically a wrapper around a DOM available on the computer and indicated by its `DOMVendor` property. I'll discuss the use of this component in more detail in the [next section](#). For the moment, suffice to say you can assign a string list to its `XML` property and activate it to let it parse the XML text and eventually report an error with an exception.

For this example, this behavior is far from good, because while typing the XML code you'll have temporarily incorrect XML. Still, I prefer not to ask the user to click a button to do the validation, but rather to let it run continuously. Because it is not possible to disable the parse exception raised by the XMLDocument component, I had to work at a lower level, extracting the `DOMPersist` property (referring to the persistency interface of the DOM) after extracting the `IXMLDocumentAccess` interface from the XMLDocument component (called `XmlDoc` in this code). You can also extract the `IDOMParseError` interface from the document component, to display any error message in the status bar:

```
procedure TFormXmlEdit.MemoXmlChange(Sender: TObject);  
var  
    eParse: IDOMParseError;  
begin  
    XmlDoc.Active := True;  
    xmlBar.Panels[1].Text := 'OK';  
    xmlBar.Panels[2].Text := '';  
    (XmlDoc as IXMLDocumentAccess).DOMPersist.loadxml(MemoXml.Text);  
    eParse := (XmlDoc.DOMDocument as IDOMParseError);  
    if eParse.errorCode <> 0 then  
        with eParse do  
            begin  
                xmlBar.Panels[1].Text := 'Error in: ' + IntToStr(Line) + '.' +  
                    IntToStr(LinePos);  
                xmlBar.Panels[2].Text := SrcText + ': ' + Reason;  
            end;  
    end;  
end;
```

You can see an example of the output of the program in [Figure 22.1](#), alongside the XML tree view provided by the third page (for a correct document). The third page of the program is built using the WebBrowser component, which embeds Internet Explorer's ActiveX control. Unfortunately, there is no direct way to assign a string with the XML text to this control, so you'll have to save the file first and then move to its page to trigger the loading of the XML in the browser (after manually clicking the Refresh button at least once).

**Figure 22.1:** The XmlEditOne example allows you to enter XML text in a memo, indicating errors as you type, and shows the result in the embedded browser.

**Note** I've used this code as a starting point to build a full-fledged XML editor called XmiTypist for a company I work with. It includes syntax highlighting, XSLT support, and a number of extra features. Refer to [Appendix A](#), "Extra Delphi Tools by the Author" for the availability of this free XML editor.

## Managing XML Documents in Delphi

Now that you know the core elements of XML, we can begin discussing how to manage XML documents in Delphi programs (or in programs in general; some of the techniques discussed here go beyond the language used). There are two typical techniques for manipulating XML documents: using a Document Object Model (DOM) interface or using the Simple API for XML (SAX). The two approaches are quite different:

- The DOM loads the entire document into a hierarchical tree of nodes, allowing you to read them and manipulate them to change the document. For this reason, the DOM is suitable when you want to navigate the XML structure in memory and edit it, or for creating new documents from scratch.
- The SAX parses the document, firing an event for each element of the document without building a structure in memory. Once parsed by the SAX, the document is lost, but this operation is generally much faster than the construction of the DOM tree. Using the SAX is good for reading a document once—for example, if you're looking for a portion of its data.

There is a third classic way to manipulate (and specifically create) XML documents: string management. Creating a document by adding strings is the fastest operation, particularly if you can do a single pass (and don't need to modify nodes already generated). Even reading documents by means of string functions is very fast, but this process can become difficult for complex structures.

Besides these classic XML processing approaches, which are also available for other programming languages, Delphi provides two more techniques you should consider. The first is the definition of interfaces that map the document structure and are used to access the document instead of the generic DOM interface. As you'll see, this approach makes for faster coding and more robust applications. The second technique is the development of transformations that allow you to read a generic XML document into a ClientDataSet component or save the dataset into an XML file of a given structure (not the specific XML structure natively supported by the ClientDataSet or MyBase).

I won't try to fully assess which option is better suited for each type of document and manipulation, but I will highlight some of the advantages and disadvantages while discussing examples of each approach in the following sections. At the end of the chapter, I'll discuss the relative speed of techniques for processing large files.

## Programming with the DOM

Because an XML document has a tree-like structure, loading an XML document into a tree in memory is a natural fit. This is what the DOM does. The DOM is a standard interface, so when you have written code that uses a DOM, you can switch DOM implementations without changing your source code (at least, if you haven't used any non-custom extensions).

In Delphi, you can install several DOM implementations, available as COM servers, and use their interfaces. One of the most commonly used DOM engines on Windows is the one provided by Microsoft as part of the MSXML SDK but also installed by Internet Explorer (and for this reason in all recent versions of Windows) and many other Microsoft applications. (With the full MSXML SDK also containing documentation and examples you don't get in other embedded installations of the same library.) Other DOM engines directly available in Delphi 7 include Apache Foundation's Xerces and the open-source OpenXML.

**Tip** OpenXML is a native Object Pascal DOM available at [www.philo.de/xml](http://www.philo.de/xml). Another native Delphi DOM is offered by TurboPower. These solutions offer two advantages: They don't require an external library for the program to execute, because the DOM component is compiled into your application; and they are cross-platform.

Delphi embeds the DOM implementations into a wrapper component called XMLDocument. I used this component in the preceding example, but here I will examine its role in a more general way. The idea behind using this component instead of the DOM interface is that you remain more independent from the implementations and can work with some simplified methods, or helpers.

The DOM interface is complex to use. A *document* is a collection of nodes, each having a name, a text element, a collection of attributes, and a collection of child nodes. Each collection of nodes lets you access elements by position or search for them by name. Notice that the text within the tags of a node, if any, is rendered as a child of the node and listed in its collection of child nodes. The root node has some extra methods for creating new nodes, values, or attributes.

With Delphi's XMLDocument, you can work at two levels:

- At a lower level, you can use the `DOMDocument` property (of the `IDOMDocument` interface type) to access a standard W3C Document Object Model interface. The official DOM is defined in the `xmlDom` unit and includes interfaces like `IDOMNode`, `IDOMNodeList`, `IDOMAttr`, `IDOMElement`, and `IDOMText`. With the official DOM interfaces, Delphi supports a lower-level but standard programming model. The DOM implementation is indicated by the XMLDocument component in the `DOMVendor` property.
- As a higher-level alternative, the XMLDocument component also implements the `IXMLDocument` interface. This is a custom DOM-like API defined by Borland in the `XMLIntf` unit and comprising interfaces like `IXMLNode`, `IXMLNodeList`, and `IXMLNodeCollection`. This Borland interface simplifies some of the DOM operations by replacing multiple method calls, which are repeated often in sequence, with a single property or method.

In the following examples (particularly the `DomCreate` demo), I'll use both approaches to give you a better idea of the practical differences between the two approaches.

### An XML Document in a TreeView

The starting point generally consists of loading a document from a file or creating it from a string, but you can also start with a new document. As a first example of using the DOM, I've built a program that can load an XML document into a DOM and show its structure in a TreeView control. I've also added to the `XmlDomTree` program a few buttons with sample code used to access to the elements of a sample file, as an example of accessing the DOM data. Loading the document is simple, but showing it in a tree requires a recursive function that navigates the nodes and subnodes. Here is the code for the two methods:

```
procedure TFormXmlTree.btnLoadClick(Sender: TObject);
```

```

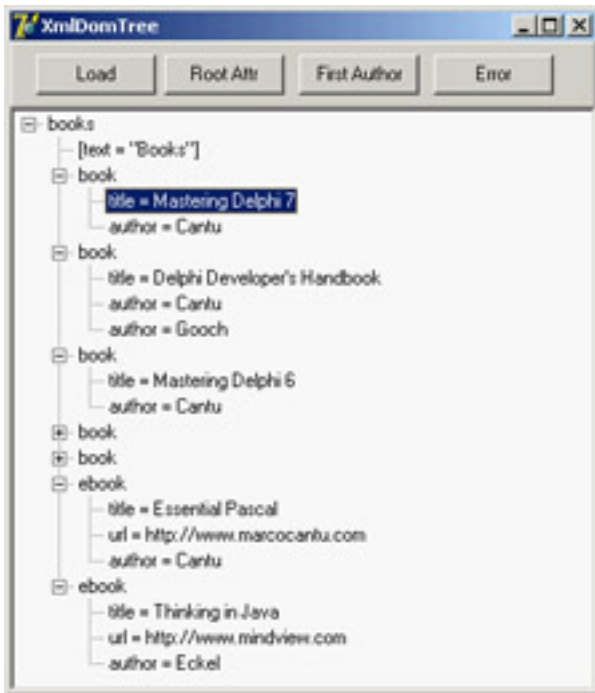

begin
  OpenFileDialog1.InitialDir := ExtractFilePath (Application.ExeName);
  if OpenFileDialog1.Execute then
    begin
      XMLDocument1.LoadFromFile(OpenDialog1.FileName);
      Treeview1.Items.Clear;
      DomToTree (XMLDocument1.DocumentElement, nil);
      TreeView1.FullExpand;
    end;
  end;

procedure TFormXmlTree.DomToTree (XmlNode: IXMLNode; TreeNode: TTreeNode);
var
  I: Integer;
  NewTreeNode: TTreeNode;
  NodeText: string;
  AttrNode: IXMLNode;
begin
  // skip text nodes and other special cases
  if XmlNode.NodeType <> ntElement then
    Exit;
  // add the node itself
  NodeText := XmlNode.NodeName;
  if XmlNode.IsTextElement then
    NodeText := NodeText + ' = ' + XmlNode.NodeValue;
  NewTreeNode := TreeView1.Items.AddChild(TreeNode, NodeText);
  // add attributes
  for I := 0 to XmlNode.AttributeNodes.Count - 1 do
    begin
      AttrNode := XmlNode.AttributeNodes.Nodes[I];
      TreeView1.Items.AddChild(NewTreeNode,
        '[' + AttrNode.NodeName + ' = "' + AttrNode.Text + '" ]');
    end;
  // add each child node
  if XmlNode.HasChildNodes then
    for I := 0 to XmlNode.ChildNodes.Count - 1 do
      DomToTree (XmlNode.ChildNodes.Nodes [I], NewTreeNode);
    end;
end;

```

This code is interesting because it highlights some of the operations you can do with a DOM. First, each node has a `NodeType` property you can use to determine whether the node is an element, attribute, text node, or special entity (such as CDATA and others). Second, you cannot access the textual representation of the node (its `NodeValue`) unless it has a text element (notice that the text node will be skipped, as per the initial test). After displaying the name of the item, and then the text value if available, the program shows the content of each attribute directly and of each subnode by calling the `DomToTree` method recursively (see [Figure 22.2](#)).

**Figure 22.2:** The XmlDomTree example can open a generic XML document and show it inside a TreeView common control.

Once you have loaded the sample document that accompanies the XmlDomTree program (shown in [Listing 22.1](#)) into the XmlDocument component, you can use the various methods to access generic nodes, as in the previous tree-building code, or fetch specific elements. For example, you can grab the value of the attribute *text* of the root node by writing:

```
XMLDocument1.DocumentElement.Attributes ['text']
```

Notice that if there is no attribute called *text*, the call will fail with a generic error message, "Invalid variant type conversion," which helps neither you nor the end user to understand what's wrong. If you need to access to the first attribute of the root without knowing its name, you can use the following code:

```
XMLDocument1.DocumentElement.AttributeNodes.Nodes[0].NodeValue
```

To access the nodes, you use a similar technique, possibly taking advantage of the *ChildValues* array. This is a Delphi extension to the DOM, which allows you to pass as parameter either the name of the element or its numeric position:

```
XMLDocument1.DocumentElement.ChildNodes.Nodes[1].ChildValues['author']
```

This code gets the (first) author of the second book. You cannot use the *ChildValues['book']* expression, because there are multiple nodes with the same name under the root node.

## Creating Documents Using the DOM

Although I mentioned earlier that you can create an XML document by chaining together strings, this technique is far from robust. Using a DOM to create a document ensures that the XML will be well formed. Also, if the DOM has a schema definition attached, you can validate the structure of the document while adding data to it.

To highlight different cases of document creation, I've built the DomCreate example. This program can create XML documents within the DOM, showing their text on a memo and optionally in a TreeView.

**Warning** The XmlDocument component uses the doAutoIndent option to improve the output of the XML text to the memo by formatting the XML in a slightly better way. You can choose the type of indentation by setting the *NodeIndentStr* property. To format generic XML text, you can also use the global *FormatXMLData* function using the default setting (two spaces) as indentation. Oddly, there doesn't seem a way to pass a different parameter to the function.

The Simple button on the form creates simple XML text using the low-level, official DOM interfaces. The program calls the document's *createElement* method for each node, adding them as children of other nodes:

```

procedure TForm1.btnSimpleClick(Sender: TObject);
var
    iXml: IDOMDocument;
    iRoot, iNode, iNode2, iChild, iAttribute: IDOMNode;
begin
    // empty the document
    XMLDoc.Active := False;
    XMLDoc.XML.Text := '';
    XMLDoc.Active := True;

    // root
    iXml := XmlDoc.DOMDocument;
    iRoot := iXml.appendChild (iXml.createElement ('xml'));
    // node "test"
    iNode := iRoot.appendChild (iXml.createElement ('test'));
    iNode.appendChild (iXml.createElement ('test2'));
    iChild := iNode.appendChild (iXml.createElement ('test3'));
    iChild.appendChild (iXml.createTextNode('simple value'));
    iNode.insertBefore (iXml.createElement ('test4'), iChild);

```

```

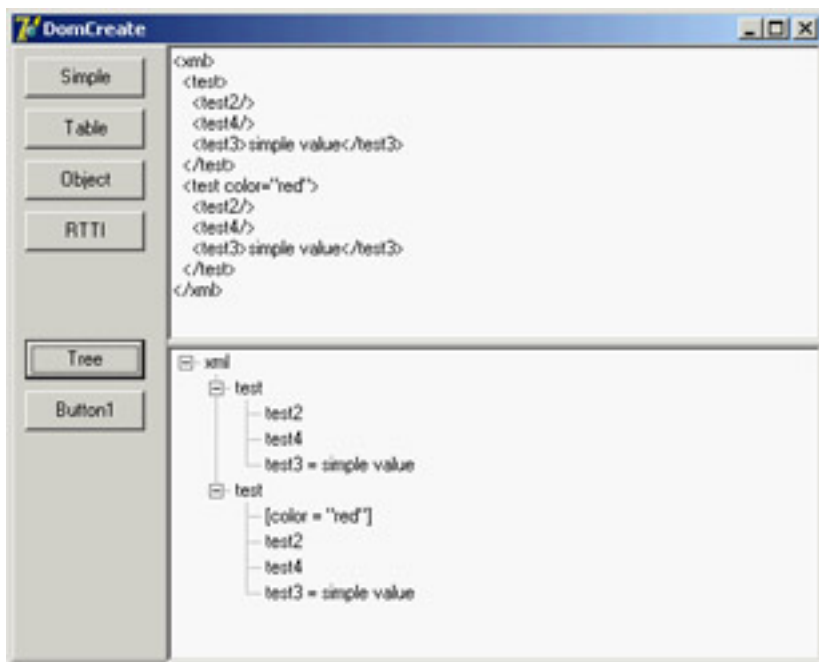

// node replication
iNode2 := iNode.cloneNode (True);
iRoot.appendChild (iNode2);

// add an attribute
iAttribute := iXml.createAttribute ('color');
iAttribute.nodeValue := 'red';
iNode2.attributes.setNamedItem (iAttribute);

// show XML in memo
Memo1.Lines.Text := FormatXMLData (XMLDoc.XML.Text);
end;

```

Notice that text nodes are added explicitly, attributes are created with a specific create call, and the code uses `cloneNode` to replicate an entire branch of the tree. Overall, the code is cumbersome to write, but after a while you may get used to this style. The effect of the program is shown (formatted in the memo and in the tree) in [Figure 22.3](#).

**Figure 22.3:** The DomCreate example can generate various types of XML documents using a DOM.

The second example of DOM creation relates to a dataset. I've added to the form a `dbExpress` dataset component (but any other dataset would do). I also added to a button the call to my custom `DataSetToDOM` procedure, like this:

```
DataSetToDOM ('customers', 'customer', XMLDoc, SQLDataSet1);
```

The `DataSetToDOM` procedure creates a root node with the text of the first parameter, grabs each record of the dataset, defines a node with the second parameter, and adds a subnode for each field of the record, all using extremely generic code:

```

procedure DataSetToDOM (RootName, RecordName: string; XMLDoc: TXMLDocument;
  DataSet: TDataSet);
var
  iNode, iChild: IXMLNode;
  i: Integer;
begin
  DataSet.Open;
  DataSet.First;
  // root

```

```

XMLDoc.DocumentElement := XMLDoc.CreateNode (RootName);

// add table data
while not DataSet.EOF do
begin
  // add a node for each record
  iNode := XMLDoc.DocumentElement.AddChild (RecordName);
  for I := 0 to DataSet.FieldCount - 1 do
  begin
    // add an element for each field
    iChild := iNode.AddChild (DataSet.Fields[i].FieldName);
    iChild.Text := DataSet.Fields[i].AsString;
  end;
  DataSet.Next;
end;
DataSet.Close;
end;

```

The preceding code uses the simplified DOM access interfaces provided by Borland, which include an `AddChild` node that creates the subnode, and the direct access to the `Text` property for defining a child node with textual content. This routine extracts an XML representation of your dataset, also opening up opportunities for web publishing, as I'll discuss later in the section on XSL.

Another interesting opportunity is the generation of XML documents describing Delphi objects. The `DomCreate` program has a button that describes a few properties of an object, again using the low-level DOM:

```

procedure AddAttr (iNode: IDOMNode; Name, Value: string);
var
  iAttr: IDOMNode;
begin
  iAttr := iNode.ownerDocument.createAttribute (name);
  iAttr.nodeValue := Value;
  iNode.attributes.setNamedItem (iAttr);
end;

procedure TForm1.btnObjectClick(Sender: TObject);
var
  iXml: IDOMDocument;
  iRoot: IDOMNode;
begin
  // empty the document
  XMLDoc.Active := False;
  XMLDoc.XML.Text := '';
  XMLDoc.Active := True;

  // root
  iXml := XmlDoc.DOMDocument;
  iRoot := iXml.appendChild (iXml.createElement ('Button1'));

  // a few properties as attributes (might also be nodes)
  AddAttr (iRoot, 'Name', Button1.Name);
  AddAttr (iRoot, 'Caption', Button1.Caption);
  AddAttr (iRoot, 'Font.Name', Button1.Font.Name);
  AddAttr (iRoot, 'Left', IntToStr (Button1.Left));
  AddAttr (iRoot, 'Hint', Button1.Hint);

  // show XML in memo

```

```

Memol.Lines := XmlDoc.XML;
end;

```

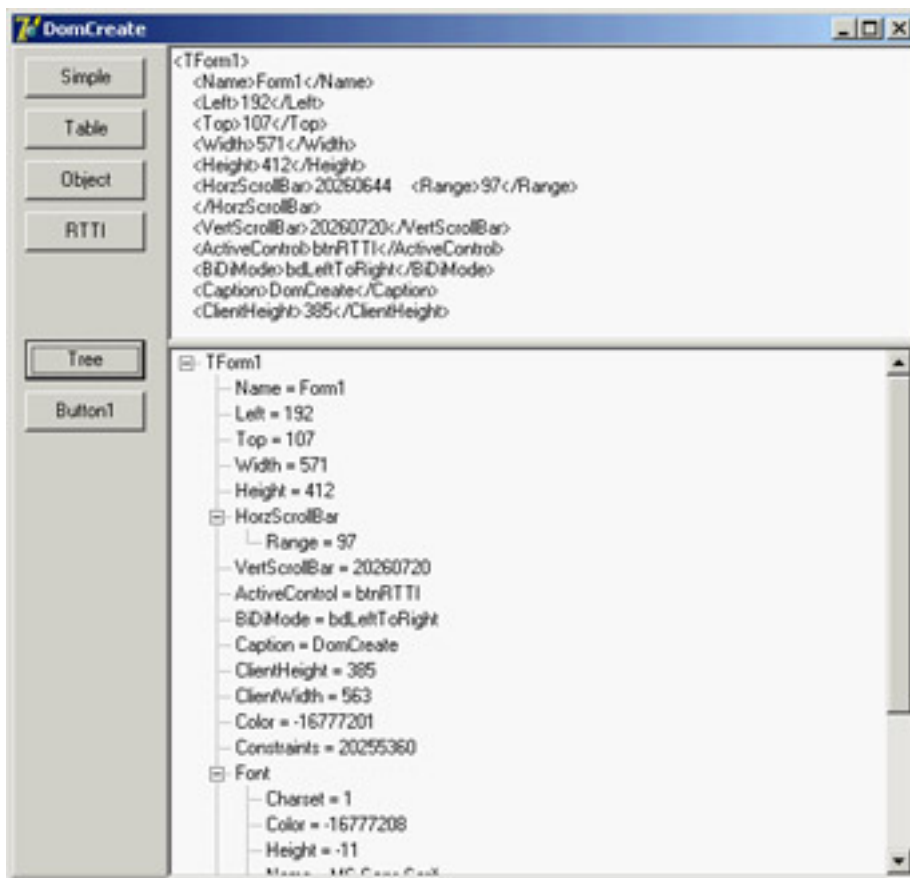

Of course, it is more interesting to have a generic technique capable of saving the properties of each Delphi component (or *persistent object*, to be more precise), recursing on persistent subobjects and indicating the names of referenced components. I've done this in the `ComponentToDOM` procedure, which uses the low-level RTTI information provided by the `TyplInfo` unit, including the extraction of the list of component properties not having a default value. Once more, the program uses the simplified Delphi XML interfaces:

```

procedure ComponentToDOM (iNode: IXmlNode; Comp: TPersistent);
var
  nProps, i: Integer;
  PropList: PPropList;
  Value: Variant;
  newNode: IXmlNode;
begin
  // get list of properties
  nProps := GetTypeData (Comp.ClassInfo)^.PropCount;
  GetMem (PropList, nProps * SizeOf(Pointer));
  try
    GetPropInfos (Comp.ClassInfo, PropList);
    for i := 0 to nProps - 1 do
      if not IsDefaultPropertyValue(Comp, PropList [i], nil) then
        begin
          Value := GetPropValue (Comp, PropList [i].Name);
          NewNode := iNode.AddChild(PropList [i].Name);
          NewNode.Text := Value;
          if (PropList [i].PropType^.Kind = tkClass) and (Value <> 0) then
            if TObject (Integer(Value)) is TComponent then
              NewNode.Text := TComponent (Integer(Value)).Name
            else
              // TPersistent but not TComponent: recurse
              ComponentToDOM (newNode, TObject (Integer(Value)) as TPersistent);
          end;
        finally
          FreeMem (PropList);
        end;
      end;
    end;
  end;

```

These two lines of code, in this case, trigger the creation of the XML document (shown in [Figure 22.4](#)):

**Figure 22.4:** The XML generated to describe the form of the DomCreate program. Notice (in the tree and in the memo text) that properties of class types are further expanded.

```
XMLDoc.DocumentElement := XMLDoc.CreateNode( Self.ClassName );
ComponentToDOM (XMLDoc.DocumentElement, Self);
```

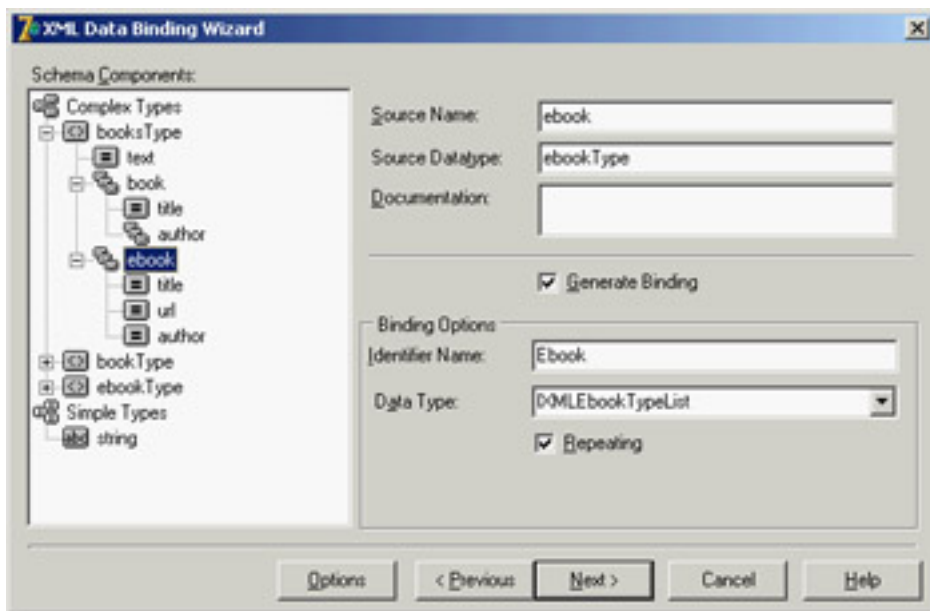

## XML Data-Binding Interfaces

You have seen that working with the DOM to access or generate a document is tedious, because you must use positional information and not logical access to the data. Also, handling series of repeated nodes of different possible types (as shown in the XML sample in [Listing 22.1](#), describing books) is far from simple. Moreover, using a DOM, you can create any well-formed document; but (unless you use a validating DOM) you can add any subnode to any node, coming up with almost useless documents, because no one else will be able to manage them.

To solve these issues, Borland added to Delphi an XML Data Binding Wizard, which can examine an XML document or a document definition (a schema, a Document Type Definition (DTD), or another type of definition) and generate a set of interfaces for manipulating the document. These interfaces are specific to the document and its structure and allow you to have more readable code, but they are certainly less generic as far as the types of documents you can handle (and this is more positive than it might sound at first).

You can activate the XML Data Binding Wizard by using the corresponding icon in the first page of the IDE's New Items dialog box or by double-clicking the XMLDocument component. (It is odd that the corresponding command is not in the shortcut menu of the component.)

After a first page in which you can select an input file, this wizard shows you the structure of the document graphically, as you can see in [Figure 22.5](#) for the sample XML file from [Listing 22.1](#). In this page, you can give a name to each entity of the generated interfaces, if you don't like the defaults suggested by the wizard. You can also change the rules used by the wizard to generate the names (an extended flexibility I'd like to have in other areas of the Delphi IDE). The final page gives you a preview of the generated interfaces and offers options for generating schemas and other definition files.

**Figure 22.5:** Delphi's XML Data Binding Wizard can examine the structure of a document or a schema (or another document definition) to create a set of interfaces for simplified and direct access to the DOM data.

For the sample XML file with the author names, the XML Data Binding Wizard generates an interface for the root node, two interfaces for the elements lists of two different types of nodes (books and e-books), and two interfaces for the elements of the two types. Here are a few excerpts of the generated code, available in the `XmlIntfDefinition` unit of the `XmlInterface` example:

```

type
  IXMLBooksType = interface(IXMLNode)
    ['{C9A9FB63-47ED-4F27-8ABA-E71F30BA7F11}']
    { Property Accessors }
    function Get_Text: WideString;
    function Get_Book: IXMLBookTypeList;
    function Get_Ebook: IXMLEbookTypeList;
    procedure Set_Text(Value: WideString);
    { Methods & Properties }
    property Text: WideString read Get_Text write Set_Text;
    property Book: IXMLBookTypeList read Get_Book;
    property Ebook: IXMLEbookTypeList read Get_Ebook;
  end;

  IXMLBookTypeList = interface(IXMLNodeCollection)
    ['{3449E8C4-3222-47B8-B2B2-38EE504790B6}']
    { Methods & Properties }
    function Add: IXMLBookType;
    function Insert(const Index: Integer): IXMLBookType;
    function Get_Item(Index: Integer): IXMLBookType;
    property Items[Index: Integer]: IXMLBookType read Get_Item; default;
  end;

  IXMLBookType = interface(IXMLNode)
    ['{26BF5C51-9247-4D1A-8584-24AE68969935}']
    { Property Accessors }
    function Get_Title: WideString;
    function Get_Author: IXMLString_List;
    procedure Set_Title(Value: WideString);
    { Methods & Properties }
    property Title: WideString read Get_Title write Set_Title;
    property Author: IXMLString_List read Get_Author;
  
```

```
end;
```

For each interface, the XML Data Binding Wizard also generates an implementation class that provides the code for the interface methods by translating the requests into DOM calls. The unit includes three initialization functions, which can return the interface of the root node from a document loaded in an `IXMLDocument` component (or a component providing a generic `IXMLDocument` interface), or return one from a file, or create a brand new DOM:

```
function Getbooks(Doc: IXMLDocument): IXMLBooksType;  
function Loadbooks(const FileName: WideString): IXMLBooksType;  
function Newbooks: IXMLBooksType;
```

After generating these interfaces using the wizard in the `XmlInterface` example, I've repeated XML document access code that's similar to the `XmlDomTree` example but is much simpler to write (and to read). For example, you can get the attribute of the root node by writing

```
procedure TForm1.btnAttrClick(Sender: TObject);  
var  
    Books: IXMLBooksType;  
begin  
    Books := Getbooks (XmlDocument1);  
    ShowMessage (Books.Text);  
end;
```

It is even simpler if you recall that while typing this code, Delphi's code insight can help by listing the available properties of each node, thanks to the fact that the parser can read in the interface definitions (although it cannot understand the format of a generic XML document). Accessing a node of one of the sublists is a matter of writing one of the following statements (possibly the second, with the default array property):

```
Books.Book.Items[1].Title // full  
Books.Book[1].Title       // further simplified
```

You can use similarly simplified code to generate new documents or add new elements, thanks to the customized `Add` method available in each list-based interface. Again, if you don't have a predefined structure for the XML document, as in the dataset-based and RTTI-based examples of the previous demonstration, you won't be able to use this approach.

## Validation and Schemas

The XML Data Binding Wizard can work from existing schemas or generate a schema for an XML document (and eventually save it in a file with the `.XDB` extension). An XML document describes some data, but to exchange this data among companies, it must stick to some agreed structure. A schema is a document definition against which a document can be checked for correctness, an operation usually indicated with the term *validation*.

The first—and still widespread—type of validation available for XML used *document type definitions (DTDs)*. These documents describe the structure of the XML but cannot define the possible content of each node. Also, DTDs are not XML document themselves, but use a different, awkward notation.

At the end of 2000, the W3C approved the first official draft of XML *schemas* (already available in an incompatible version called XML-Data within Microsoft's DOM). An XML schema is an XML document that can validate both the structure of the XML tree and the content of the node. A schema is based on the use and definition of simple and complex data types, similar to what happens in an OOP language.

A schema defines complex types, indicating for each the possible nodes, their optional sequence (*sequence*, *all*), the number of occurrences of each subnode (*minOccurs*, *maxOccurs*), and the data type of each specific element. Here is the schema defined by the XML Data Binding Wizard for the sample books file:

```
<?xml version="1.0"?>  
<xs:schema xmlns:xs="http://www.w3.org/2001/XMLSchema "  
    xmlns:xdb="http://www.borland.com/schemas/delphi/7.0/XMLDataBinding">  
    <xs:element name="books" type="booksType"/>  
    <xs:complexType name="booksType">
```

```

<xs:annotation>
  <xs:appinfo xdb:docElement="books" />
</xs:annotation>
<xs:sequence>
  <xs:element name="book" type="bookType" maxOccurs="unbounded" />
  <xs:element name="ebook" type="ebookType" maxOccurs="unbounded" />
</xs:sequence>
<xs:attribute name="text" type="xs:string" />
</xs:complexType>
<xs:complexType name="bookType">
  <xs:annotation>
    <xs:appinfo xdb:repeated="True" />
  </xs:annotation>
  <xs:sequence>
    <xs:element name="title" type="xs:string" />
    <xs:element name="author" type="xs:string" maxOccurs="unbounded" />
  </xs:sequence>
</xs:complexType>
<xs:complexType name="ebookType">
  <xs:annotation>
    <xs:appinfo xdb:repeated="True" />
  </xs:annotation>
  <xs:sequence>
    <xs:element name="title" type="xs:string" />
    <xs:element name="url" type="xs:string" />
    <xs:element name="author" type="xs:string" />
  </xs:sequence>
</xs:complexType>
</xs:schema>

```

Microsoft and Apache DOM engines have good support for schemas. Another tool I've used for validation is XML Schema Validator (XSV), an open-source attempt at a conformant schema-aware processor, which can be used either directly via the Web or after downloading a command-line executable (see the links to the current website of this tool in the W3C's XML Schema pages).

**Note** The Delphi editor supports code completion for XML files via DTDs. Dropping a DTD file in Delphi's *bin* directory and referring to it with a *DOCTYPE* tag should enable this feature, which is not officially supported by Borland.

## Using the SAX API

The Simple API for XML (SAX) doesn't create a tree for the XML nodes, but parses the node—firing events for each node, attribute, value, and so on. Because it doesn't keep the document in memory, using the SAX allows you to manage much larger documents. Its approach is also useful for one-time examination of a document or retrieval of specific information. This is a list of the most important events fired by the SAX:

- `StartDocument` and `EndDocument` for the entire document
- `StartElement` and `EndElement` for each node
- `Characters` for the text within the nodes

It is common to use a stack to handle the current path within the nodes tree, and push and pop elements to and from the stack for every `StartElement` and `EndElement` event.

Delphi does not include specific support for the SAX interface, but you can import Microsoft's XML support (the MSXML library). In particular, for the `SaxDemo1` example I've used version 2 of MSXML, because this version is widely

available. I've generated a Pascal type library import unit from the type library, and the import unit is available within the source code of the program, but you must have that specific COM library registered on your computer to run the program successfully.

**Note** Another example at the end of this chapter (LargeXml) demonstrates, among other things, the use of the SAX API, including the OpenXml engine.

To use the SAX, you must install a SAX event handler within a SAX reader, and then load a file and parse it. I've used the SAX reader interface provided by MSXML for VB programmers. The official (C++) interface had a few errors in its type library that prevented Delphi from importing it properly. The main form of the SaxDemo1 example declares

```
sax: IVBSAXXMLReader;
```

In the `FormCreate` method, the `sax` variable is initialized with the COM object:

```
sax := CoSAXXMLReader.Create;  
sax.ErrorHandler := TMySaxErrorHandler.Create;
```

The code also sets an error handler, which is a class implementing a specific interface (`IVBSAXErrorHandler`) with three methods that are called depending on the severity of the problem: `error`, `fatalError`, and `ignorableWarning`.

Simplifying the code a little, the SAX parser is activated by calling the `parseURL` method after assigning a content handler to it:

```
sax.ContentHandler := TMySaxHandler.Create;  
sax.parseURL (filename)
```

So, the code ultimately resides in the `TMySaxHandler` class, which has the SAX events. Because I have multiple SAX content handlers in this example, I've written a base class with the core code and a few specialized versions for specific processing. Following is the code of the base class, which implements both the `IVBSAXContentHandler` interface and the `IDispatch` interface the `IVBSAXContentHandler` interface is based on:

```
type  
TMySaxHandler = class (TInterfacedObject, IVBSAXContentHandler)  
protected  
    stack: TStringList;  
public  
    constructor Create;  
    destructor Destroy; override;  
    // IDispatch  
    function GetTypeInfoCount(out Count: Integer): HRESULT; stdcall;  
    function GetTypeInfo(Index, LocaleID: Integer; out TypeInfo):  
        HRESULT; stdcall;  
    function GetIDsOfNames(const IID: TGUID; Names: Pointer;  
        NameCount, LocaleID: Integer; DispIDs: Pointer): HRESULT; stdcall;  
    function Invoke(DispID: Integer; const IID: TGUID; LocaleID: Integer;  
        Flags: Word; var Params; var Result, ExcepInfo, ArgErr: Pointer):  
        HRESULT; stdcall;  
    // IVBSAXContentHandler  
    procedure Set_documentLocator(const Param1: IVBSAXLocator);  
        virtual; safecall;  
    procedure startDocument; virtual; safecall;  
    procedure endDocument; virtual; safecall;  
    procedure startPrefixMapping(var strPrefix: WideString;  
        var strURI: WideString); virtual; safecall;  
    procedure endPrefixMapping(var strPrefix: WideString); virtual; safecall;  
    procedure startElement(var strNamespaceURI: WideString;  
        var strLocalName: WideString; var strQName: WideString;
```

```

    const oAttributes: IVBSAXAttributes); virtual; safecall;
procedure endElement(var strNamespaceURI: WideString;
    var strLocalName: WideString; var strQName: WideString);
    virtual; safecall;
procedure characters(var strChars: WideString); virtual; safecall;
procedure ignorableWhitespace(var strChars: WideString);
    virtual; safecall;
procedure processingInstruction(var strTarget: WideString;
    var strData: WideString); virtual; safecall;
procedure skippedEntity(var strName: WideString); virtual; safecall;
end;

```

The most interesting portion, of course, is the final list of SAX events. All this base class does is emit information to a log when the parser starts (`startDocument`) and finishes (`endDocument`) and keep track of the current node and its parent nodes with a stack:

```

// TMySaxHandler.startElement
stack.Add (strLocalName);
// TMySaxHandler.endElement
stack.Delete (stack.Count - 1);

```

An implementation is provided by the `TMySimpleSaxHandler` class, which overrides the `startElement` event triggered for any new node to output the current position in the tree with the following statement:

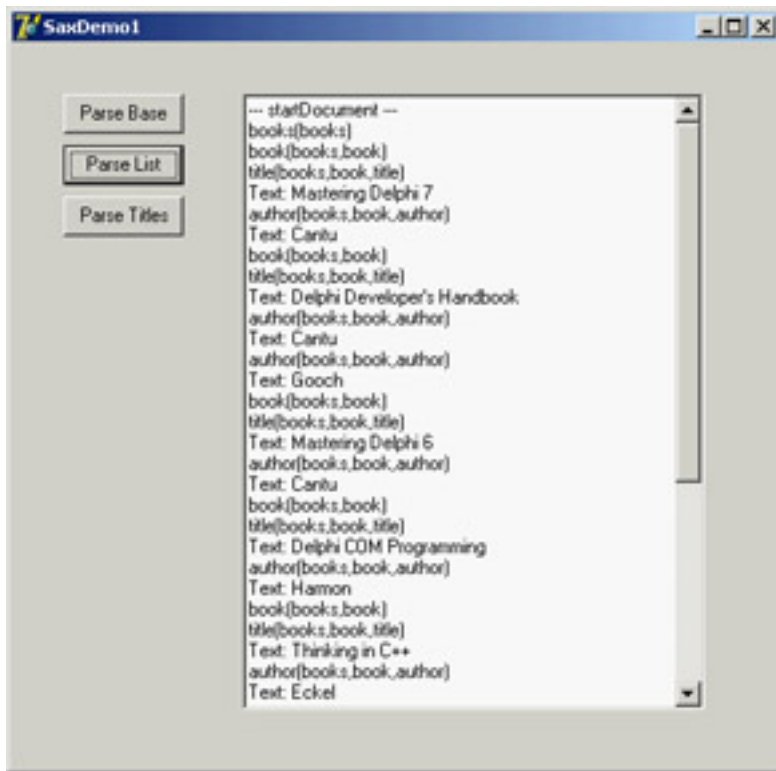

```
Log.Add (strLocalName + '(' + stack.CommaText + ')');
```

The second method of the class is the `characters` event, which is triggered when a node value (or a text node) is encountered and outputs its content (as you can see in [Figure 22.6](#)):

```

procedure TMySimpleSaxHandler.characters(var strChars: WideString);
var
    str: WideString;
begin
    inherited;
    str := RemoveWhites (strChars);
    if (str <> '') then
        Log.Add ('Text: ' + str);
end;

```

**Figure 22.6:** The log produced by reading an XML document with the SAX in the Sax-Demo1 example

This is a generic parsing operation affecting the entire XML file. The second derived SAX content handler class refers to the specific structure of the XML document, extracting only nodes of a given type. In particular, the program looks for nodes of the *title* type. When a node has this type (in `startElement`), the class sets the `isbook` Boolean variable. The text value of the node is considered only immediately after a node of this type is encountered:

```
procedure TMyBooksListSaxHandler.startElement(var strNamespaceURI,
    strLocalName, strQName: WideString; const oAttributes: IVBSAXAttributes);
begin
    inherited;
    isbook := (strLocalName = 'title');
end;

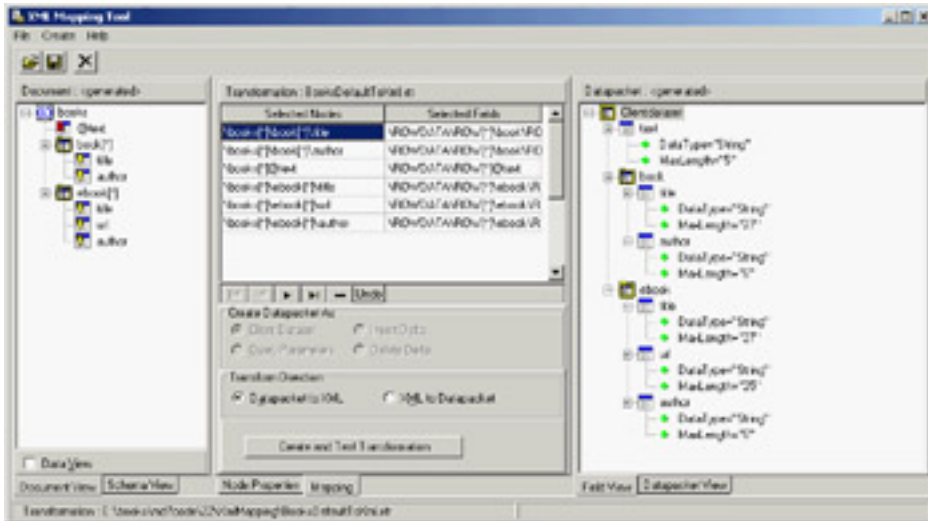

procedure TMyBooksListSaxHandler.characters(var strChars: WideString);
var
    str: string;
begin
    inherited;
    if isbook then
        begin
            str := RemoveWhites (strChars);
            if (str <> '') then
                Log.Add (stack.CommaText + ': ' + str);
        end;
end;
end;
```

## Mapping XML with Transformations

You can use one more technique in Delphi to handle some XML documents: You can create a *transformation* to translate the XML of a generic document into the format used natively by the ClientDataSet component when saving data to a MyBase XML file. In the reverse direction, another transformation can turn a dataset available within a ClientDataSet (through a DataSetProvider component) into an XML file of a required format (or schema).

Delphi includes a wizard to generate such transformations. Called the XML Mapping Tool, or XML Mapper for short, it

can be invoked from the IDE's Tools menu or executed as a stand-alone application. The XML Mapper, shown in [Figure 22.7](#), is a design-time helper that assists you in defining transformation rules between the nodes of a generic XML document and fields of the ClientDataSet data packet.

**Figure 22.7:** The XML Mapper shows the two sides of a transformation to define a mapping between them (with the rules indicated in the central portion).

The XML Mapper window has three areas:

- On the left is the XML document section, which displays information about the structure of the XML document (and eventually its data, if the related check box is active) in the Document View or an XML schema in the Schema View, depending on the selected tab.
- On the right is the data packet section, which displays information about the metadata in the data packet, either in the Field View (indicating the dataset structure) or in the Datapacket View (reporting the XML structure). The XML Mapper can also open files in the native ClientDataSet format.
- The central portion is used by the mapping section. It contains two pages: Mapping, where you can see the correspondence between selected elements of the two sides that will be part of the mapping; and Node Properties, where you can modify the data types and other details of each possible mapping.

The Mapping page of the central pane also hosts the shortcut menu used to generate the transformation. The other panes and views have specific shortcut menus you can use to perform the various actions (besides the few commands in the main menu).

You can use XML Mapper to map an existing schema (or extract it from a document) to a new data packet, an existing data packet to a new schema or document, or an existing data packet into an existing XML document (if a match is reasonable). In addition to converting the data of an XML file into a data packet, you can also convert to a delta packet of the ClientDataSet. This technique is useful for merging a document to an existing table, as if a user had inserted the modified table records. In particular, you can transform an XML document into a delta packet for records to be modified, deleted, or inserted.

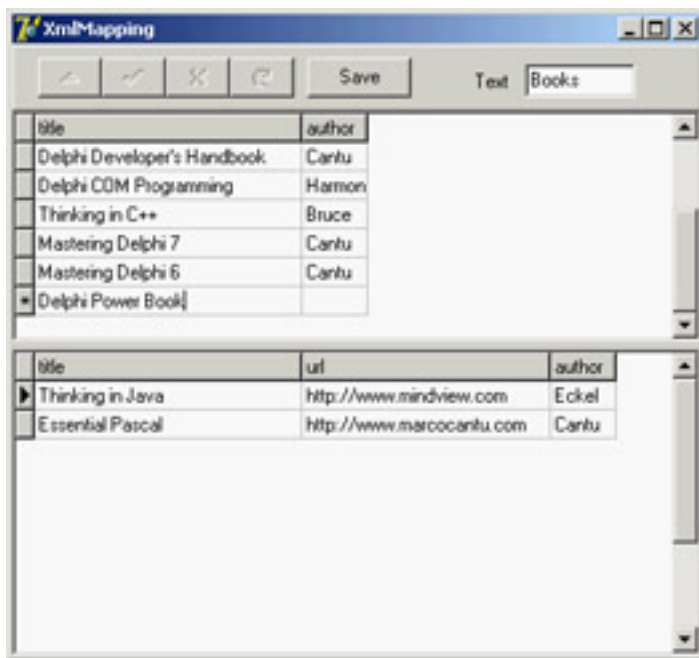

The result of using the XML Mapper is one or more transformation files, each representing a one-way conversion (so you need at least two transformation files to convert data back and forth). These transformation files are then used at design time and at run time by the XMLTransform, XMLTransformProvider, and XMLTransformClient components.

As an example, I opened the books XML document, which has a structure that doesn't easily match a table, because it includes two lists of values of different types (I've skipped easier examples in which the XML has a plain rectangular structure). After opening the `Sample.XML` file in the XML Document section, I used its shortcut menu to select all of its elements (Select All) and to create the data packet (Create Datapacket From XML). This command automatically fills the right pane with the data packet and the central portion with the proposed transformation. You can also view its effect in a sample program by clicking the Create And Test Transformation button. Doing so opens a generic

application that can load a document into the dataset using the transformation you've just created.

In this case, the XML Mapper generates a table with two dataset fields: one for each possible list of subelements. This was the only possible standard solution, because the two sublists have different structures, and it is the only solution that allows you to edit the data in a DBGrid attached to the ClientDataSet and save it back to a complete XML file, as demonstrated by the XmlMapping example. This program is basically a Windows-based editor for a complex XML document.

The example uses a TransformProvider component with two transformation files attached to read in an XML document and make it available to a ClientDataSet. As the name suggests, this component is a dataset provider. To build the user interface, I didn't connect the ClientDataSet directly to a grid, because it has a single record with a text field plus two detailed datasets. For this reason, I added to the program two more ClientDataSet components attached to the dataset fields and connected to two DBGrid controls. This explanation is easier to understand by looking at the definition of the non-visual components from DFM source code in the following excerpt and at its output in [Figure 22.8](#).

**Figure 22.8:** The XmlMapping example uses a TransformProvider component to make a complex XML document available for editing within multiple ClientDataSet components.

```
object XMLTransformProvider1: TXMLTransformProvider
  TransformRead.TransformationFile = 'BooksDefault.xtr'
  TransformWrite.TransformationFile = 'BooksDefaultToXml.xtr'
  XMLDataFile = 'Sample.xml'
end
object ClientDataSet1: TClientDataSet
  ProviderName = 'XMLTransformProvider1'
  object ClientDataSet1text: TStringField
  object ClientDataSet1book: TDataSetField
  object ClientDataSet1lebook: TDataSetField
end
object ClientDataSet2: TClientDataSet
  DataSetField = ClientDataSet1book
end
object ClientDataSet3: TClientDataSet
  DataSetField = ClientDataSet1lebook
end
```

This program allows you to edit the data of the various sublists of nodes within the grids, modifying them and also

adding or deleting records. As you apply the changes to the dataset (clicking the Save button, which calls `ApplyUpdates`), the transform provider saves an updated version of the file to disk.

As an alternative approach, you can also create transformations that map only portions of the XML document into a dataset. As an example, see the `BooksOnly.xtr` file in the folder of the `XmlMapping` example. The modified XML document you'll generate will have a different structure and content from the original, including only the portion you've selected. So, it can be useful for viewing the data, but not for editing it.

**Note** It is not surprising that the transformation files are themselves XML documents, as you can see by opening one in the editor. This XML document uses a custom format.

At the opposite side, you can see how a transformation can be used to take a database table or the result of a query and produce an XML file with a more readable format than that provided by default by the `ClientDataSet` persistence mechanism. To build the `MapTable` example, I placed a `dbExpress SimpleDataSet` component on a form and attached a `DataSetProvider` to it and a `ClientDataSet` to the provider. After opening the table and the client dataset, I saved its content to an XML file.

At that point, I opened the XML Mapper, loaded the data packet file into it, selected all the data packet nodes (with the `Select All` command from the shortcut menu) and invoked the `Create XML From Datapacket` command. In the following dialog box, I accepted the default name mappings for fields and only changed the suggested name for record nodes (`ROW`) into something more readable (`Customer`). If you now test the transformation, the XML Mapper will display the contents of the resulting XML document in a custom tree view.

After saving the transformation file, I was ready to resume developing the program, removing the `ClientDataSet` and adding a `DataSource` and a `DBGrid` (as a user might edit in on an attached `DBGrid` before transforming it), and an `XMLTransformClient` component. This component has the transformation file connected to it, but not an XML file. Instead, it refers to the data through the provider. Clicking the button shows the XML document within a memo (after formatting it) instead of saving it to a file, something you can do by calling the `GetDataAsXml` method (even if the Help file is far from clear about the use of this method):

```
procedure TForm1.btnMapClick(Sender: TObject);  
begin  
    Mem1.Lines.Text := FormatXmlData(XMLTransformClient1.GetDataAsXml(''));  
end;
```

This is the only code for the program visible at run time in [Figure 22.9](#); you can see the original dataset in the `DBGrid` and the resulting XML document in the memo control below the grid. The application has much simpler code than the `DomCreate` example I used to generate a similar XML document, but it requires the design-time definition of the transformation. The `DomCreate` example could work on any dataset at run time without any connection to a specific table, because it has rather generic code. In theory, it is possible to produce similar dynamic mappings by using the events of the generic `XMLTransform` component, but I find it easier to use the DOM-based approach discussed earlier. Notice also that the `FormatXmlData` call produces nicer output but slows down the program, because it involves loading the XML into a DOM.

The screenshot shows a window titled "MapTable" with a table of customer data and an XML output area below it.

**Figure 22.9:** The MapTable example generates an XML document from a database table using a custom transformation file.

## XML and Internet Express

Once you have defined the structure of an XML document, you might want to let users see and edit the data in a Windows application or over the Web. This second case is interesting because Delphi provides specific support for it. Delphi 5 introduced an architecture called Internet Express, which is now available as part of the WebSnap platform. WebSnap also offers support for XSL, which I'll discuss later in this chapter.

In [Chapter 16](#), "Multitier DataSnap Applications," I discussed the development of DataSnap applications. Internet Express provides a client component called XMLBroker for this architecture, which can be used in place of a client dataset to retrieve data from a middle-tier DataSnap program and make it available to a specific type of page producer called InetXPageProducer. You can use these components in a standard WebBroker application or in a WebSnap program. The idea behind Internet Express is that you write a web server extension (as discussed in [Chapter 20](#), "Web Programming with WebBroker and WebSnap"), which in turn produces web pages hooked to your DataSnap server. Your custom application acts as a DataSnap client and produces pages for a browser client. Internet Express offers the services required to build this custom application easily.

I know this sounds confusing, but Internet Express is a four-tier architecture: SQL server, application server (the DataSnap server), web server with a custom application, and web browser. Of course, you can place the database access components within the same application handling the HTTP request and generating the resulting HTML, as in a client/ server solution. You can even access a local database or an XML file, in a two-tier structure (the server program and the browser).

In other words, Internet Express is a technology for building clients based on a browser, which lets you send the entire dataset to the client computer along with the HTML and some JavaScript for manipulating the XML and showing it into the user interface defined by the HTML. The JavaScript enables the browser to show the data and manipulate it.

### The XMLBroker Component

Internet Express uses multiple technologies to accomplish this result. The DataSnap data packets are converted into the XML format to let the program embed this data into the HTML page for web client-side manipulation. The delta data packet is also represented in XML. These operations are performed by the XMLBroker component, which can handle XML and provide data to the new JavaScript components. Like the ClientDataSet, the XMLBroker has the following:

- A `MaxRecords` property indicating the number of records to add to a single page
- A `Params` property hosting the parameters that components will forward to the remote query through the provider
- A `WebDispatch` property indicating the update request the broker responds to

The InetXPageProducer allows you to generate HTML forms from datasets in a visual way similar to the development of an AdapterPageProducer user interface. The Internet Express architecture, the interfaces it uses internally, and some of its IDE editor can together be considered the parent of the WebSnap architecture. With the notable difference of generating scripts to be executed on the server side and on the client side, they both provide an editor for placing visual components and generating such scripts. Personally, I'm not terribly happy that the older Internet Express is more XML-oriented than the newer WebSnap.

**Tip** Another common feature of the InetXPageProducer and the AdapterPageProducer is the support for Cascading Style Sheets (CSS). These components have the `Style` and `StylesFile` properties for defining the CSS, and each visual element has a `StyleRule` property you can use to select the style name.

### JavaScript Support

To make the editing operations on the client side powerful, the InetXPageProducer uses special JavaScript components and code. Delphi embeds a large JavaScript library, which the browser must download. This process might seem a nuisance, but it is the only way the browser interface (which is based on dynamic HTML) can be rich

enough to support field constraints and other business rules with the browser. This functionality is impossible with plain HTML. The JavaScript files provided by Borland, which you should make available on the website hosting the application, are the following:

File	Description
XmlDom.js	DOM-compatible XML parser (for browsers lacking native XML DOM support)
XmlDb.js	JavaScript classes for the HTML controls
XmlDisp.js	JavaScript classes for binding XML data with the HTML controls
XmlErrDisp.js	Classes for reconciling errors
XmlShow.js	JavaScript functions to display data and delta packets (for debugging purposes)

HTML pages generated by Internet Express usually include references to these JavaScript files, such as:

```
<script language=Javascript type="text/javascript"
  src="IncludePathURL/xmlDb.js"></script>
```

You can customize the JavaScript by adding code directly to the HTML pages or by creating new Delphi components written to fit with the Internet Express architecture that emits JavaScript code (possibly along with HTML). As an example, the sample `TPromptQueryButton` class of `INetXCustom` generates the following HTML and JavaScript code:

```
<script language=javascript type="text/javascript">
  function PromptSetField(input, msg) {
    var v = prompt(msg);
    if (v == null || v == "")
      return false;
    input.value = v
    return true;
  }
  var QueryForm3 = document.forms['QueryForm3'];
</script>
<input type=button value="Prompt..."
  onclick="if (PromptSetField(PromptResult, 'Enter some text\n'))
  QueryForm3.submit();">
```

**Tip** If you plan to use Internet Express, look at the `INetXCustom` extra demo components, available in the `\Demos\Midas\InternetExpress\INetXCustom` folder. Follow the detailed instructions in the `readme.txt` file to install these components, which are provided by Borland with no support but allow you to add many more features to your Internet Express applications with little extra effort.

To deploy this architecture you don't need anything special on the client side, because any browser up to the HTML 4 standard can be used, on any operating system. The web server, however, must be a Win32 server (this technology is not available in Kylix), and you must deploy the `DataSnap` libraries on it.

## Building an Example

To better understand what I'm talking about, and as a way to cover more technical details, let's try a demo called `leFirst`. To avoid configuration issues, this is a CGI application accessing a dataset directly—in this case, a local table retrieved via a `ClientDataSet` component. Later, I'll show you how to turn an existing `DataSnap` Windows client into a browser-based interface. To build `leFirst`, I created a new CGI application and added to its data module a `ClientDataSet` component hooked to a local `.CDS` file and a `DataSetProvider` component connected with the dataset. The next step is to add an `XMLBroker` component and connect it to the provider:

```
object ClientDataSet1: TClientDataSet
  FileName = 'C:\Program Files\Common Files\Borland
```

```

    Shared\Data\employee.cds'
end
object DataSetProvider1: TDataSetProvider
    DataSet = ClientDataSet1
end
object XMLBroker1: TXMLBroker
    ProviderName = 'DataSetProvider1'
    WebDispatch.MethodType = mtAny
    WebDispatch.PathInfo = 'XMLBroker1'
    ReconcileProducer = PageProducer1
    OnGetResponse = XMLBroker1GetResponse
end

```

The `ReconcileProducer` property is required to show a proper error message in case of an update conflict. As you'll see later, one of the Delphi demos includes some custom code, but in this example I've connected a traditional `PageProducer` component with a generic HTML error message. After setting up the XML broker, you can add an `InetXPageProducer` to the web data module. This component has a standard HTML skeleton; I've customized it to add a title, without touching the special tags:

```

<HTML><HEAD>
    <title>IeFirst</title>
</HEAD><BODY>
    <h1>Internet Express First Demo (IeFirst.exe)</h1>
    <#INCLUDES><#STYLES><#WARNINGS><#FORMS><#SCRIPT>
</BODY>

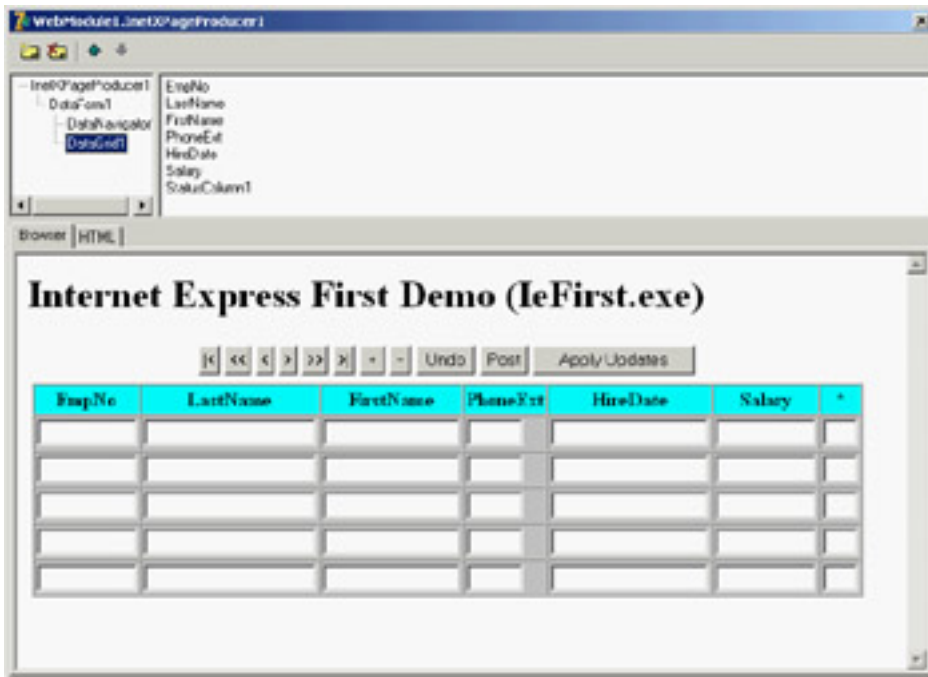

```

The special tags are automatically expanded using the JavaScript files of the directory specified by the `IncludePathURL` property. You *must* set this property to refer to the web server directory where these files reside. You can find them in the `\Delphi7\Source\WebMidas` directory. The five tags have the following effect:

Tag	Effect
<#INCLUDES>	Generates the instructions to include the JavaScript libraries
<#STYLES>	Adds the embedded style sheet definition
<#WARNINGS>	Used at design time to show errors in the <code>InetXPageProducer</code> editor
<#FORMS>	Generates the HTML code produced by the components of the web page
<#SCRIPT>	Adds a JavaScript block used to start the client-side script

**Note** The `InetXPageProducer` component also handles a few more internal tags. `<#BODYELEMENTS>` corresponds to all five tags of the predefined template. `<#COMPONENT Name=WebComponentName>` is part of the generated HTML code used to declare the components generated visually. `<#DATA PACKET XMLBroker=BrokerName>` is replaced with the XML of the data packet.

To customize the resulting HTML of the `InetXPageProducer`, you can use its editor, which again is similar to the one for `WebSnap` server-side scripting. Double-click the `InetXPageProducer` component, and Delphi opens a window like the one shown in [Figure 22.10](#) (with the example's final settings). In this editor, you can create complex structures starting with a query form, data form, or generic layout group. In the example data form, I added a `DataGrid` and a `DataNavigator` component without customizing them any further (an operation you do by adding child buttons, columns, and other objects, which fully replace the defaults).

**Figure 22.10:** The InetXPage-Producer editor allows you to build complex HTML forms visually, similarly to the AdapterPageProducer.

The DFM code for the InetXPageProducer and its internal components in my example is as follows. You can see the core settings plus some limited graphical customizations:

```

object InetXPageProducer1: TInetXPageProducer
  IncludePathURL = '/jssource/'
  HTMLDoc.Strings = (...)
object DataForm1: TDataForm
  object DataNavigator1: TDataNavigator
    XMLComponent = DataGrid1
    Custom = 'align="center"'
  end
object DataGrid1: TDataGrid
  XMLBroker = XMLBroker1
  DisplayRows = 5
  TableAttributes.BgColor = 'Silver'
  TableAttributes.CellSpacing = 0
  TableAttributes.CellPadding = 2
  HeadingAttributes.BgColor = 'Aqua'
  object EmpNo: TTextColumn...
  object LastName: TTextColumn...
  object FirstName: TTextColumn...
  object PhoneExt: TTextColumn...
  object HireDate: TTextColumn...
  object Salary: TTextColumn...
  object StatusColumn1: TStatusColumn...
end
end
end

```

The value of these components is in the HTML (and JavaScript) code they generate, which you can preview by selecting the HTML tab of the InetXPageProducer editor. Here are a few pieces of the definitions in the HTML, for the buttons, the data grid heading, and one of the grid's cells:

```

// buttons
<table align="center">
  <tr><td colspan="2">

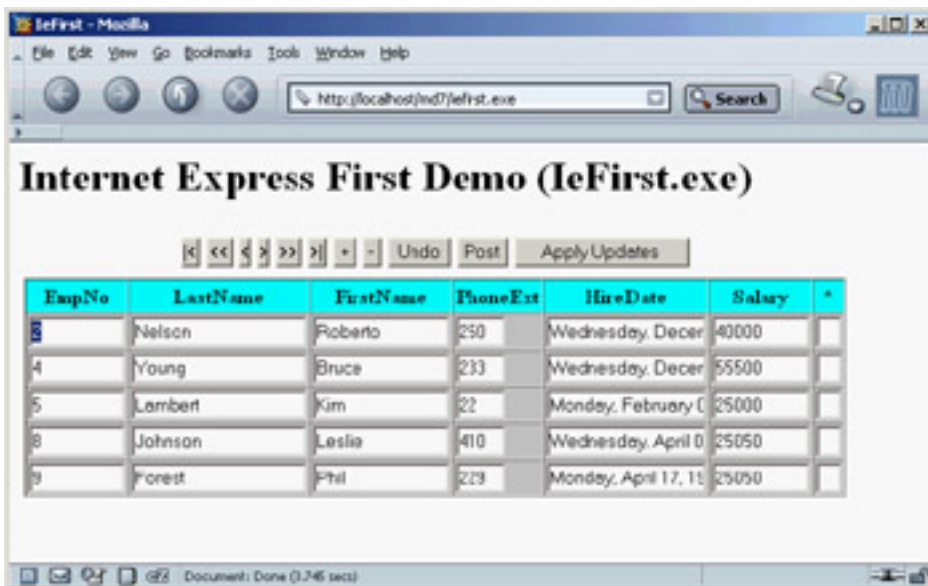

```

```

<input type="button" value="|<"
  onclick='if (xml_ready) DataGrid1_Dispatch.first();'>
<input type="button" value="<<"
  onclick='if (xml_ready) DataGrid1_Dispatch.pgup();'>
...
// data grid heading
<table cellspacing="0" cellpadding="2" border="1" bgcolor="silver">
  <tr bgcolor="aqua">
    <th>EmpNo</th>
    <th>LastName</th>
    ...
  </tr>
  <tr>
    // a data cell
    <td><div>
      <input type="text" name="EmpNo" size="10"
        onfocus='if(xml_ready)DataGrid1_Dispatch.xfocus(this);'
        onkeydown='if(xml_ready)DataGrid1_Dispatch.keys(this);'>
    </div></td>...

```

When the HTML generator is set up, you can go back to the web data module, add an action to it, and connect the action with the InetXPageProducer via the `Producer` property. This should be enough to make the program work through a browser, as you can see in [Figure 22.11](#).

**Figure 22.11:** The IeFirst application sends the browser some HTML components, an XML document, and the JavaScript code to show the data in the visual components.

If you look at the HTML file received by the browser, you'll find the table mentioned in the preceding definition, some JavaScript code, and the database data in the data packet XML format. This data is assembled by the XML broker and passed to the producer component to be embedded in the HTML file. The number of records sent to the client depends on the XMLBroker, not on the number of lines in the grid. Once the XML data is sent to the browser, you can use the navigator component's buttons to move around in the data without requiring further access to the server to fetch more. This is different from the paging behavior of WebSnap. One is not necessarily better than the other; it depends on the specific application you are building.

At the same time, the JavaScript classes in the system allow the user to type in new data, following the rules imposed by the JavaScript code hooked to dynamic HTML events. By default, the grid has an extra asterisk column indicating which records have been modified. The update data is collected in an XML data packet in the browser and sent back to the server when the user clicks the Apply Updates button. At this point, the browser activates the action specified by

the `WebDispatch.PathInfo` property of the `XMLBroker`. There is no need to export this action from the web data module, because this operation is automatic (although you can disable it by setting `WebDispatch.Enable` to `False`).

The `XMLBroker` applies the changes to the server, returning the content of the provider connected to the `ReconcileProvider` property (or raising an exception if this property is not defined). When everything works fine, the `XMLBroker` redirects the control to the main page that contains the data. However, I've experienced some problems with this technique, so the `leFirst` example handles the `OnGetResponse`, indicating this is an update view:

```
procedure TWebModule1.XMLBroker1GetResponse(Sender: TObject;  
    Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);  
begin  
    Response.Content := '<h1>Updated</h1><p>' + InetXPageProducer1.Content;  
    Handled := True;  
end;
```

## Using XSLT

Another approach for generating HTML starting from an XML document is the use of the Extensible Stylesheet Language (XSL) or, to be more precise, its XSL Transformations (XSLT) subset. The aim of XSLT is to transform an XML document into another document, generally an XML document. One of the most frequent uses of the technology is to turn an XML document into an XHTML document to be sent to a browser from a web server. Another interesting related technology is XSL-FO (XSL Formatting Objects), which can be used to turn an XML document into a PDF or another formatted document.

An XSLT document is a well-formed XML document. The structure of an XSLT file requires a root node like the following:

```
<xsl:stylesheet version="1.0" xmlns:xsl="...">
```

The content of the XSLT file is based on one or more templates (or rules or functions), which will be processed by the engine. Their node is `xsl:template`, usually with a `match` attribute. In the simplest case, a template operates on nodes with a given name; you invoke the template by passing to it one or more nodes with an XPath expression:

```
xsl:apply-templates select="node_name"
```

The starting point for this operation is a template that processes the root node, which can be the only template of the XSLT file. Within templates, you can find any of the other commands, such as the extraction of a value from an XML document (`xsl:value-of select`), looping statements (`xsl:for-each`), conditional expressions (`xsl:if`, `xsl:choose`), sorting requests (`xsl:sort`), and numbering requests (`xsl:number`), just to mention a few common XSLT commands.

## Using XPath

XSLT uses other XML technologies, notably XPath to identify portions of documents. XPath defines a set of rules to locate one or more nodes within a document. The rules are based on a path-line structure of the node within the XML tree, so that `/books/book` identifies any *book* node under the *books* document root. XPath uses special symbols to identify nodes:

- A star (\*) stands for any node; for example, `book/*` indicates any subnode under a *book* node.
- A dot (.) stands for the current node.
- The pipe symbol (|) indicates alternatives, as in `book|ebook`.
- A double slash (//) stands for any path, so that `//title` indicates all the title nodes, whatever their parent nodes, and `books//author` indicates any *author* node under a *books* node regardless of the nodes in between.
- The at sign (@) indicates an attribute instead of a node, as in the hypothetical `author/@lastname`.
- Square brackets can be used to choose only nodes or attributes having a given value. For example, to select all authors with a given first name attribute, you can use `author[@name="marco"]`.

There are many other cases, but this short introduction to the rules of XPath should get you started and help you understand the following examples. An XSLT document is an XML document that works on the structure of a source XML document and generates in output another XML document, such as an XHTML document you can view in a web browser.

**Note** Commonly used XSLT processors include MS-XML, Xalan from the Apache XML project ([xml.apache.org](http://xml.apache.org)), and the Java-based Xt from James Clarke. From Delphi, you can also use the XSLT engine, included in TurboPower's XML Partner Pro ([www.turbopower.com](http://www.turbopower.com)).

## XSLT in Practice

Let's discuss a couple of examples. As a starting point, you should study XSL by itself, and then focus on its activation from within a Delphi application.

For your initial tests, you can connect an XSL file directly to an XML file. As you load the XML file in Internet Explorer, you will see the resulting XHTML transformation. The connection is indicated in the heading of the XML document with a command like this:

```
<?xml-stylesheet type="text/xsl" href="sampleembedded.xsl"?>
```

This is what I've done in the `sampleembedded.xml` file available in the `XslEmbed` folder. The related XSL embeds various XSL snippets that I don't have space to discuss in detail. For example, it grabs the entire list of authors or filters a specific group of them with this code:

```
<h2>All Authors</h2>
<ul>
  <xsl:for-each select="books//author">
    <li><xsl:value-of select="."/></li>
  </xsl:for-each>
</ul>
<h3>E-Authors</h3>
<ul>
  <xsl:for-each select="books/ebook/author">
    <li><xsl:value-of select="."/></li>
  </xsl:for-each>
</ul>
```

More complex code is used to extract nodes only when a specific value is present in a subnode or attribute, regardless of the higher-level nodes. The following XSL snippet also has an `if` statement and produces an attribute in the resulting node, as a way to build an `href` hyperlink in the HTML:

```
<h3>Marco's works (books + ebooks)</h3>
<ul>
  <xsl:for-each select="books/*[author = 'Cantu']">
    <li> <xsl:value-of select="title"/>
      <xsl:if test="url">
        (<a><xsl:attribute name="href"><xsl:value-of select="url"/>
          </xsl:attribute>Jump to document</a>)
      </xsl:if>
    </li>
  </xsl:for-each>
</ul>
```

## XSLT with WebSnap

Within the code of a program, you can execute the `TransformNode` method of a DOM node, passing to it another DOM hosting the XSL document. Instead of using this low-level approach, however, you can let WebSnap help you to create an XSL-based example. You can create a new WebSnap application (I've built a CGI program called `XslCust` in this case) and choose an `XSLPageProducer` component for its main page, to let Delphi help you begin the application code. Delphi also includes a skeleton XSL file for manipulating a `ClientDataSet` data packet and adds many new views to the editor. The XSL text replaces the HTML file; the XML Tree page shows the data, if any; the XSL Tree page shows the XSL within the Internet Explorer ActiveX; the HTML Result page shows the code produced by the transformation; and the Preview page shows what a user will see in a browser.

**Tip** In Delphi 7, the editor provides full-blown code completion for XSLT, which makes editing this code in the editor as powerful as it is in some sophisticated and specific XML editors.

To make this example work, you must provide data to the XSLPageProducer component via its `XMLData` property. This property can be hooked up to an `XMLDocument` or directly to an `XMLBroker` component, as I've done in this case. The broker takes its data from a provider connected to a local table attached to the classic `Customer.cds` component table of the classic `DBDEMOS`. The effect is that, with the following Delphi-generated XSL, you get (even at design time) the output of shown in [Figure 22.12](#):

```
<?xml version="1.0"?>
<xsl:stylesheet
  version="1.0"
  xmlns:xsl="http://www.w3.org/1999/XSL/Transform">

  <xsl:template match="/">
    <html>
      <body>
        <xsl:apply-templates/>
      </body>
    </html>
  </xsl:template>

  <xsl:template match="DATAPACKET">
    <table border="1">
      <xsl:apply-templates select="METADATA/FIELDS"/>
      <xsl:apply-templates select="ROWDATA/ROW"/>
    </table>
  </xsl:template>

  <xsl:template match="FIELDS">
    <tr>
      <xsl:apply-templates/>
    </tr>
  </xsl:template>

  <xsl:template match="FIELD">
    <th>
      <xsl:value-of select="@attrname"/>
    </th>
  </xsl:template>

  <xsl:template match="ROWDATA/ROW">
    <xsl:variable name="fieldDefs" select="//METADATA/FIELDS"/>
    <xsl:variable name="currentRow" select="current()"/>
    <tr>
      <xsl:for-each select="$fieldDefs/FIELD">
        <td>
          <xsl:value-of select="$currentRow/@*[name()=current()/@attrname]"/><br/>
        </td>
      </xsl:for-each>
    </tr>
  </xsl:template>

</xsl:stylesheet>
```

**Figure 22.12:** The result of an XSLT transformation generated (even at design time) by the XSLPageProducer component in the XslCust example

**Note** The standard XSL template has been extended since Delphi 6, because the original versions didn't account for null fields omitted from the XML data packet. I presented several extensions to the original XSL code at the 2002 Borland Conference, and some of my suggestions have been incorporated in the template.

This code generates an HTML table consisting of the expansion of field metadata and row data. The fields are used to generate the table heading, with a <th> cell for each entry in a single row. The row data is used to fill in the other rows of the table. Taking the value of each attribute (`select="@"`) wouldn't be enough, because an attribute might be missing. For this reason, the list of fields and the current row are saved in two variables; then, for each field, the XSL code extracts the value of a row item having an attribute name (`@*[name()=...]`) corresponding to the name of the current field stored in its *attrname* attribute (`@attrname`). This code is far from simple, but it is a compact and portable way to examine different portions of an XML document at the same time.

## Direct XSL Transformations with the DOM

Using the XSLPageProducer can be handy, but generating multiple pages based on the same data just to handle different possible XSL styles with WebSnap isn't the best approach. I've built a plain CGI application called CdsXslt that can transform a ClientDataSet data packet into different types of HTML, depending on the name of the XSL file passed as a parameter. The advantage is that I can modify the existing XSL files and add new XSL files to the system without having to recompile the program.

To obtain the XSL transformation, the program loads both the XML and the XSL files into two XMLDocument components called `xmlDom` and `XslDom`. Then it invokes the `transformNode` method of the XML document, passing the XSL document as a parameter and filling in a third XMLDocument component called `HtmlDom`:

```

procedure TWebModule1.WebModule1WebActionItem1Action(Sender: TObject;
  Request: TWebRequest; Response: TWebResponse; var Handled: Boolean);
var
  xslfile, xslfolder: string;
  attr: IDOMAttr;
begin
  // open the client dataset and load its XML in a DOM
  ClientDataSet1.Open;
  XmlDom.Xml.Text := ClientDataSet1.XMLData;
  XmlDom.Active := True;
  // load the requested xsl file
  xslfile := Request.QueryFields.Values ['style'];
  if xslfile = '' then
    xslfile := 'customer.xsl';

```

```

xslfolder := ExtractFilePath (ParamStr (0)) + 'xsl\';
if FileExists (xslfolder + xslfile) then
  xslDom.LoadFromFile (xslfolder + xslfile)
else
  raise Exception.Create('Missing file: ' + xslfolder + xslfile);
XSLDom.Active := True;
if xslfile = 'single.xsl' then
begin
  attr := xslDom.DOMDocument.createAttribute('select');
  attr.value := '//ROW[@CustNo="' + Request.QueryFields.Values ['id'] + '"']';
  xslDom.DOMDocument.getElementsByTagName ('xsl:apply-templates').
    item[0].attributes.setNamedItem(attr);
end;
// do the transformation
HTMLDom.Active := True;
xmlDom.DocumentElement.transformNode (xslDom.DocumentElement, HTMLDom);
Response.Content := HTMLDom.XML.Text;
end;

```

The code uses the DOM to modify the XSL document for displaying a single record, adding the XPath statement for selecting the record indicated by the `id` query field. This `id` is added to the hyperlink by the XSL with the list of records, but I'll skip listing more XSL files. They are available for study in the XSL subfolder of this example's folder.

**Warning** To run this program, deploy the XSL files in a folder called XSL under the one where the script is located. You can find the demo files in the XSL subfolder of the scripts folder of this chapter. To deploy these files in a different location, change the code above that extracts the XSL folder name from the program name available in the first common line parameter (as the global *Application* object defined in the Forms unit is not accessible in a CGI application).

## Processing Large XML Documents

As you have seen, there are often many different techniques to accomplish the same task with XML. In many cases you can choose any solution with the goal of writing less and more maintainable code; but when you need to process a large number of XML documents or very large XML documents, you must consider efficiency.

Discussing theory by itself is not terribly useful, so I've built an example you can use (and modify) to test different solutions. The example is called LargeXml, and it covers a specific area: moving data from a database to an XML file and back. The example can open a dataset (using dbExpress) and then replicate the data many times in a ClientDataSet in memory. The structure of the in-memory ClientDataSet is cloned from that of the data access component:

```
SimpleDataSet1.Open;
ClientDataSet1.FieldDefs := SimpleDataSet1.FieldDefs;
ClientDataSet1.CreateDataSet;
```

After using a radio group to determine the amount of data you want to process (some options require minutes on a slow computer), the data is cloned with this code:

```
while ClientDataSet1.RecordCount < nCount do
begin
    SimpleDataSet1.RecNo := Random (SimpleDataSet1.RecordCount) + 1;
    ClientDataSet1.Insert;
    ClientDataSet1.Fields [0].AsInteger := Random (10000);
    for I := 1 to SimpleDataSet1.FieldCount - 1 do
        ClientDataSet1.Fields [i].AsString := SimpleDataSet1.Fields [i].AsString;
    ClientDataSet1.Post;
end;
```

## From a ClientDataSet to an XML Document

Now that the program has a (large) dataset in memory, it provides three different ways to save the dataset to a file. The first is to save the XMLData of the ClientDataSet directly to a file, obtaining an attribute-based document. This is probably not the format you want, so the second solution is to apply an XmlMapper transformation with an XMLTransformClient component. The third solution involves processing the dataset directly and writing out each record to a file:

```
procedure TForm1.btnSaveCustomClick(Sender: TObject);
var
    str: TFileStream;
    s: string;
    i: Integer;
begin
    str := TFileStream.Create ('data3.xml', fmCreate);
    try
        ClientDataSet1.First;
        s := '<?xml version="1.0" standalone="yes" ?><employee>';
        str.Write(s[1], Length (s));

        while not ClientDataSet1.EOF do
            begin
                s := '';
                for i := 0 to ClientDataSet1.FieldCount - 1 do
                    s := s + MakeXmlstr (ClientDataSet1.Fields[i].FieldName,
                        ClientDataSet1.Fields[i].AsString);
                s := MakeXmlStr ('employeeData', s);
                str.Write(s[1], length (s));
            end;
    finally
        str.Free;
    end;
end;
```

```

ClientDataSet1.Next
end;
s := '</employee>';
str.Write(s[1], length (s));
finally
str.Free;
end;
end;

```

This code uses a simple (but effective) support function to create XML nodes:

```

function MakeXmlstr (node, value: string): string;
begin
Result := '<' + node + '>' + value + '</' + node + '>';
end;

```

If you run the program, you can see the time taken by each operation, as shown in [Figure 22.13](#). Saving the ClientDataSet data is the fastest approach, but you probably don't get the result you want. Custom streaming is only slightly slower; but you should consider that this code doesn't require you to first move the data to a ClientDataSet, because you can apply it directly even to a unidirectional dbExpress dataset. You should forget using the code based on the XmlMapper for a large dataset, because it is hundreds of times slower, even for a small dataset (I haven't been able to try a large dataset, because the process takes too long). For example, the 50 milliseconds required by custom streaming for a small dataset become more than 10 seconds when I use the mapping, and the result is very similar.

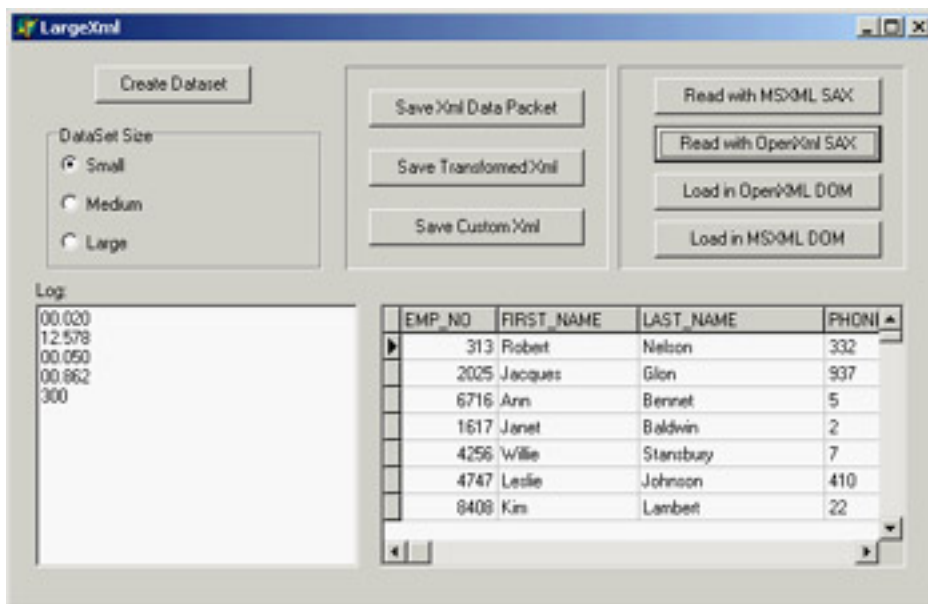

Figure 22.13: The LargeXml example in action

## From an XML Document to a ClientDataSet

Once you have a large XML document, obtained by a program (as in this case) or from an external source, you need to process it. As you have seen, XmlMapper support is far too slow, so you are left with three alternatives: an XSL transformation, a SAX, or a DOM. XSL transformations will probably be fast enough, but in this example I've opened the document with a SAX; it's the fastest approach and doesn't require much code. The program can also load a document in a DOM, but I haven't written the code to navigate the DOM and save the data back to a ClientDataSet.

In both cases, I've tested the OpenXml engine versus the MSXML DOM. This allows you to see the two SAX solutions compared, because (unluckily) the code is slightly different. I can summarize the results here: Using the MSXML SAX is slightly faster than using the OpenXml SAX (the difference is about 20 percent), whereas loading in the DOM marks a large advantage in favor of MSXML.

The MSXML SAX code uses the same architecture discussed in the SaxDemo1 example, so here I've listed only the code of the handlers you use. As you can see, at the beginning of an employeeData element you insert a new record, which is posted when the same node is closed. Lower-level nodes are added as fields of the current record. Here is the code:

```

procedure TMyDataSaxHandler.startElement(var strNamespaceURI, strLocalName,
    strQName: WideString; const oAttributes: IVBSAXAttributes);
begin
    inherited;
    if strLocalName = 'employeeData' then
        Form1.clientdataset2.Insert;
    strCurrent := '';
end;

procedure TMyDataSaxHandler.characters(var strChars: WideString);
begin
    inherited;
    strCurrent := strCurrent + RemoveWhites(strChars);
end;

procedure TMyDataSaxHandler.endElement(var strNamespaceURI, strLocalName,
    strQName: WideString);
begin
    if strLocalName = 'employeeData' then
        Form1.clientdataset2.Post;
    if stack.Count > 2 then
        Form1.ClientDataSet2.FieldByName (strLocalName).AsString := strCurrent;
    inherited;
end;

```

The code for the event handlers in the OpenXml version is similar. All that changes are the interface of the methods and the names of the parameters:

```

type
    TDataSaxHandler = class (TXmlStandardHandler)
    protected
        stack: TStringList;
        strCurrent: string;
    public
        constructor Create(aowner: TComponent); override;
        function endElement(const sender: TXmlCustomProcessorAgent;
            const locator: TdomStandardLocator;
            namespaceURI, tagName: WideString): TXmlParserError; override;
        function PCDATA(const sender: TXmlCustomProcessorAgent;
            const locator: TdomStandardLocator; data: WideString):
            TXmlParserError; override;
        function startElement(const sender: TXmlCustomProcessorAgent;
            const locator: TdomStandardLocator; namespaceURI, tagName: WideString;
            attributes: TdomNameValueList): TXmlParserError; override;
        destructor Destroy; override;
    end;

```

It is also more difficult to invoke the SAX engine, as shown in the following code (from which I've removed the code for the creation of the dataset, the timing, and the logging):

```

procedure TForm1.btnReadSaxOpenClick(Sender: TObject);
var
    agent: TXmlStandardProcessorAgent;
    reader: TXmlStandardDocReader;

```

```
filename: string;
begin
  Log := memoLog.Lines;
  filename := ExtractFilePath (Application.Exename) + 'data3.xml';
  agent := TXmlStandardProcessorAgent.Create(nil);
  reader:= TXmlStandardDocReader.Create (nil);
  try
    reader.NextHandler := TDataSaxHandler.Create (nil); // our custom class
    agent.reader := reader;
    agent.processFile(filename, filename);
  finally
    agent.free;
    reader.free;
  end;
end;
```

## What's Next?

In this chapter I've covered XML and related technologies, including DOM, SAX, XSLT, XML schemas, XPath, and a few more. You've seen how Delphi simplifies DOM programming with XML access using interfaces and XML transformations. I've also discussed the use of XSL for web programming, introducing the XSLT support of WebSnap and the Internet Express architecture.

[Chapter 23](#) will continue the discussion of XML with one of the most interesting and promising technologies of the last few years: web services. I'll cover SOAP and WSDL, and also introduce UDDI and other related technologies. If you are interested in the topics discussed here from the Delphi perspective, you should refer to books specifically devoted to XML, XML schemas, and XSLT.

## Chapter 23: Web Services and SOAP

### Overview

Of all the recent features of Delphi, one stands out clearly: the support for web services built into the product. The fact that I'm discussing it near the end of the book has nothing to do with its importance, but only with the logical flow of the text, and with the fact that this is not the starting point from which to learn Delphi programming.

The topic of web services is broad and involves many technologies and business-related standards. As usual, I'll focus on the underlying Delphi implementation and the technical side of web services, rather than discuss the larger picture and business implications.

This chapter is also relevant because Delphi 7 adds a lot of power to the implementation of web services provided by Delphi 6, including support for attachments, custom headers, and much more. You'll see how to create a web service client and a web service server, and also how to move database data over SOAP using the DataSnap technology.

## Web Services

The rapidly emerging web services technology has the potential to change the way the Internet works for businesses. Browsing web pages to enter orders is fine for individuals (business-to-consumer [B2C] applications) but not for companies (business-to-business [B2B] applications). If you want to buy a few books, going to a book vendor website and punching in your requests is probably fine. But if you run a bookstore and want to place hundreds of orders a day, this is far from a good approach, particularly if you have a program that helps you track your sales and determine reorders. Grabbing the output of this program and reentering it into another application is ridiculous.

Web services are meant to solve this issue: The program used to track sales can automatically create a request and send it to a web service, which can immediately return information about the order. The next step might be to ask for a tracking number for the shipment. At this point, your program can use another web service to track the shipment until it is at its destination, so you can tell your customers how long they have to wait. As the shipment arrives, your program can send a reminder via SMS or pager to the people with pending orders, issue a payment with a bank web service, and ... I could continue but I think I've given you the idea. Web services are meant for computer interoperability, much as the Web and e-mail let people interact.

## SOAP and WSDL

Web services are made possible by the Simple Object Access Protocol (SOAP). SOAP is built over standard HTTP, so that a web server can handle the SOAP requests and the related data packets can pass through firewalls. SOAP defines an XML-based notation for requesting the execution of a method by an object on the server and passing parameters to it; another notation defines the format of a response.

**Note** SOAP was originally developed by DevelopMentor (the training company run by COM expert Don Box) and Microsoft, to overcome weaknesses involved with using DCOM in web servers. Submitted to the W3C for standardization, it is being embraced by many companies, with a particular push from IBM. It is too early to know whether there will be standardization to let software programs from Microsoft, IBM, Sun, Oracle, and many others truly interoperate, or whether some of these vendors will try to push a private version of the standard. In any case, SOAP is a cornerstone of Microsoft's .NET architecture and also of the current platforms by Sun and Oracle.

SOAP will replace COM invocation, at least between different computers. Similarly, the definition of a SOAP service in the Web Services Description Language (WSDL) format will replace the IDL and type libraries used by COM and COM+. WSDL documents are another type of XML document that provides the metadata definition of a SOAP request. As you get a file in this format (generally published to define a service), you'll be able to create a program to call it.

Specifically, Delphi provides a bi-directional mapping between WSDL and interfaces. This means you can grab a WSDL file and generate an interface for it. You can then create a client program, embedding SOAP requests via these interfaces, and use a special Delphi component that lets you convert your local interface requests into SOAP calls (I doubt you want to manually generate the XML required for a SOAP request).

The other way around, you can define an interface (or use an existing one) and let a Delphi component generate a WSDL description for it. Another component provides you with a SOAP-to-Pascal mapping, so that by embedding this component and an object implementing the interface within a server-side program, you can have your web service up and running in a matter of minutes.

## BabelFish Translations

As a first example of the use of web service, I've built a client for the BabelFish translation service offered by AltaVista. You can find this and many other services for experimentation on the XMethods website ([www.xmethods.com](http://www.xmethods.com)).

After downloading the WSDL description of this service from XMethods (also available among the source code files for this chapter), I invoked Delphi's Web Services Importer in the Web Services page of the New Items dialog box and selected the file. The wizard lets you preview the structure of the service (see [Figure 23.1](#)) and generate the proper Delphi-language interfaces in a unit like the following (with many of the comments removed):

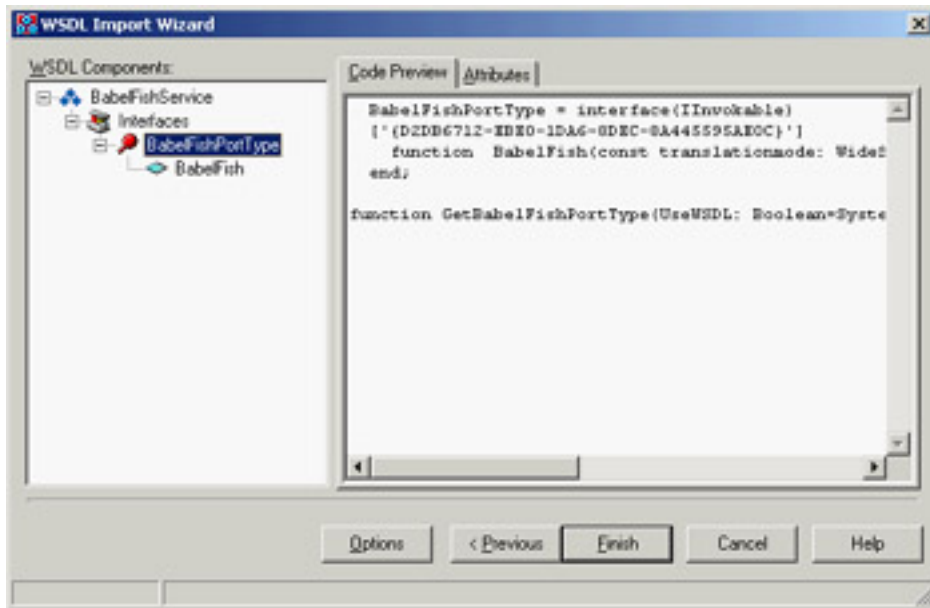

Figure 23.1: The WSDL Import Wizard in action

```
unit BabelFishService;
```

```
interface
```

```
uses InvokeRegistry, SOAPHTTPClient, Types, XSBuiltIns;
```

```
type
```

```
  BabelFishPortType = interface(IInvokable)
  ['{D2DB6712-EBE0-1DA6-8DEC-8A445595AEOC}']
    function BabelFish(const translationmode: WideString;
      const sourcedata: WideString): WideString; stdcall;
  end;
```

```
function GetBabelFishPortType(UseWSDL: Boolean=System.False;
  Addr: string=''; HTTPRIO: THTTPRIO = nil): BabelFishPortType;
```

```
implementation
```

```
// omitted
```

```
initialization
```

```
  InvRegistry.RegisterInterface(TypeInfo(BabelFishPortType),
    'urn:xmethodsBabelFish', '');
  InvRegistry.RegisterDefaultSOAPAction(TypeInfo(BabelFishPortType),
    'urn:xmethodsBabelFish#BabelFish');
```

```
end.
```

Notice that the interface inherits from the `IInvokable` interface. This interface doesn't add anything in terms of methods to Delphi's `IInterface` base interface, but it is compiled with the flag used to enable RTTI generation, `{ $M+ }`, like the `TPersistent` class. In the `initialization` section, you notice that the interface is registered in the global invocation registry (or `InvRegistry`), passing the type information reference of the interface type.

**Note** Having RTTI information for interfaces is the most important technological advance underlying SOAP invocation. Not that SOAP-to-Pascal mapping isn't important—it is crucial to simplify the process—but having RTTI for an interface makes the entire architecture powerful and robust.

The third element of the unit generated by the WSDL Import Wizard is a global function named after the service, introduced in Delphi 7. This function helps simplify the code used to call the web service. The `GetBabelFishPortType` function returns an interface of the proper type, which you can use to issue a call directly. For instance, the following code translates a short sentence from English into Italian (as indicated by the value of the first parameter, `en_it`) and shows it on screen:

```
ShowMessage (GetBabelFishPortType.BabelFish('en_it', 'Hello, world!'));
```

If you look at the code for the `GetBabelFishPortType` function, you'll see that it creates an internal invocation component of the class `THTTTPRIO` to process the call. You can also place this component manually on the client form (as I've done in the example program) to gain better control over its various settings (and handle its events).

This component can be configured in two basic ways: You can refer to the WSDL file or URL, import it, and extract from it the URL of the SOAP call; or, you can provide a direct URL to call. The example has two components that provide the alternative approaches (with exactly the same effect):

```
object HTTPRIO1: THTTTPRIO
  WSDLLocation = 'BabelFishService.xml'
  Service = 'BabelFish'
  Port = 'BabelFishPort'
end
object HTTPRIO2: THTTTPRIO
  URL = 'http://services.xmethods.net:80/perl/soaplite.cgi'
end
```

At this point, there is little left to do. You have information about the service that can be used for its invocation, and you know the types of the parameters required by the only available method as they are listed in the interface. The two elements are merged by extracting the interface you want to call directly from the `HTTTPRIO` component, with an expression like `HTTPRIO1 as BabelFishPortType`. It might seem astonishing at first, but it is also outrageously simple.

This is the web service call done by the example:

```
EditTarget.Text := (HTTPRIO1 as BabelFishPortType).
  BabelFish(ComboBoxType.Text, EditSource.Text);
```

The program output, shown in [Figure 23.2](#), allows you to learn foreign languages (although the teacher has its shortcomings!). I haven't replicated the same example with stock options, currencies, weather forecasts, and the many other services available, because they would look much the same.

**Figure 23.2:** An example of a translation from English to German obtained by Alta-Vista's BabelFish via a web service

**Warning**

Although the web service interface provides you with the types of the parameters, in many cases you need to refer to some actual documentation of the service to know what the values of the parameters really mean and how they are interpreted by the service. The BabelFish web service is an example of this issue, as I had to look at some textual documentation to find out the list of translation types, available in the demo in a combo box.

[Team LiB](#)[◀ PREVIOUS](#)[NEXT ▶](#)

## Building Web Services

If calling a web service in Delphi is straightforward, the same can be said of developing a service. If you go into the Web Services page of the New Items dialog box, you can see the SOAP Server Application option. Select it, and Delphi presents you with a list that's quite similar to what you see if you select a WebBroker application. A web service is typically hosted by a web server using one of the available web server extension technologies (CGI, ISAPI, Apache modules, and so on) or the Web App Debugger for your initial tests.

After completing this step, Delphi adds three components to the resulting web module, which is just a plain web module with no special additions:

- The HTTPSoapDispatcher component receives the web request, as any other HTTP dispatcher does.
- The HTTPSoapPascalInvoker component does the reverse operation of the HTTPRIO component; it can translate SOAP requests into calls of Pascal interfaces (instead of shifting interface method calls into SOAP requests).
- The WSDLHTMLPublish component can be used to extract the WSDL definition of the service from the interfaces it support, and performs the opposite role of the Web Services Importer Wizard. Technically, this is another HTTP dispatcher.

## A Currency Conversion Web Service

Once this framework is in place—something you can also do by adding the three components listed in the [previous section](#) to an existing web module—you can begin writing a service. As an example, I've taken the euro conversion example from [Chapter 3](#), "The Run-Time Library," and transformed it into a web service called ConvertService. First, I've added to the program a unit defining the interface of the service, as follows:

```
type
  IConvert = interface(IInvokable)
    ['{FF1EAA45-0B94-4630-9A18-E768A91A78E2}']
    function ConvertCurrency (Source, Dest: string; Amount: Double): Double;
      stdcall;
    function ToEuro (Source: string; Amount: Double): Double; stdcall;
    function FromEuro (Dest: string; Amount: Double): Double; stdcall;
    function TypesList: string; stdcall;
  end;
```

Defining an interface directly in code, without having to use a tool such as the Type Library Editor, provides a great advantage, as you can easily build an interface for an existing class and don't have to learn using a specific tool for this purpose. Notice that I've given a GUID to the interface, as usual, and used the `stdcall` calling convention, because the SOAP converter does not support the default `register` calling convention.

In the same unit that defines the interface of the service, you should also register it. This operation will be necessary on both the client and server sides of the program, because you will be able to include this interface definition unit in both:

```
uses InvokeRegistry;
```

### initialization

```
InvRegistry.RegisterInterface(TypeInfo(IConvert));
```

Now that you have an interface you can expose to the public, you have to provide an implementation for it, again by means of the standard Delphi code (and with the help of the predefined `TInvokableClass` class:

```
type
  TConvert = class (TInvokableClass, IConvert)
  protected
    function ConvertCurrency (Source, Dest: string; Amount: Double): Double;
```

```

    stdcall;
function ToEuro (Source: string; Amount: Double): Double; stdcall;
function FromEuro (Dest: string; Amount: Double): Double; stdcall;
function TypesList: string; stdcall;
end;

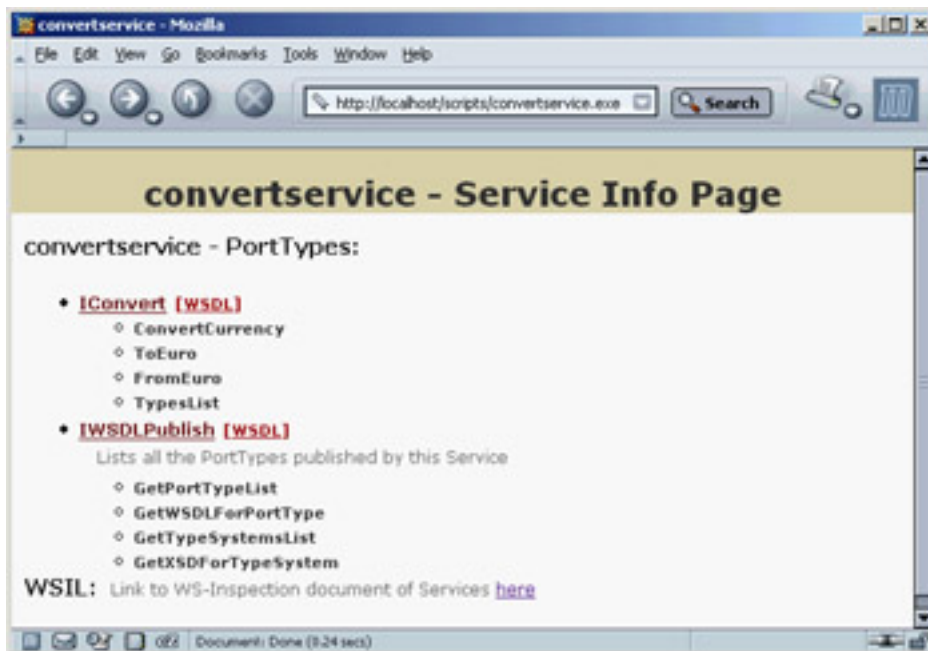

```

The implementation of these functions, which call the code of the euro conversion system from [Chapter 3](#), is not discussed here because it has little to do with the development of the service. However, it is important to notice that this implementation unit also has a registration call in its initialization section:

```
InvRegistry.RegisterInvokableClass (TConvert);
```

## Publishing the WSDL

By registering the interface, you make it possible for the program to generate a WSDL description. The web service application (since the Delphi 6.02 update) is capable of displaying a first page describing its interfaces and the detail of each interface, and returning the WSDL file. By connecting to the web service via a browser, you'll see something similar to [Figure 23.3](#).

**Figure 23.3:** The description of the Convert-Service web service provided by Delphi components

**Note** Although other web service architectures automatically provide you with a way to execute the web service from the browser, this technique is mostly meaningless, because using web services makes sense in an architecture where different applications interoperate. If all you need to do is show data on a browser, you should build a website!

This auto-descriptive feature was not available in web services produced in Delphi 6 (which provided only the lower-level WSDL listing), but it is quite easy to add (or customize). If you look at the Delphi 7 SOAP web module you'll notice a default action with an `OnAction` event handler invoking the following default behavior:

```
WSDLHTMLPublish1.ServiceInfo(Sender, Request, Response, Handled);
```

This is all you have to do to retrofit this feature into an existing Delphi web service that lacks it. To provide similar functionality manually, you must call into the invocation registry (the `InvRegistry` global object), with calls like `GetInterfaceExternalName` and `GetMethExternalName`.

What's important is the web service application's ability to document itself to any other programmer or programming tool, by exposing the WSDL.

## Creating a Custom Client

Let's move to the client application that calls the service. I don't need to start from the WSDL file, because I already have the Delphi interface. This time the form doesn't even have the HTTPRIO component, which is created in code:

```
private
    Invoker: THTTPrIo;

procedure TForm1.FormCreate(Sender: TObject);
begin
    Invoker := THTTPrIo.Create(nil);
    Invoker.URL := 'http://localhost/scripts/ConvertService.exe/soap/iconvert';
    ConvIntf := Invoker as IConvert;
end;
```

As an alternative to using a WSDL file, the SOAP invoker component can be associated with an URL. Once this association has been done and the required interface has been extracted from the component, you can begin writing straight Pascal code to invoke the service, as you saw earlier.

A user fills the two combo boxes, calling the `TypesList` method, which returns a list of available currencies within a string (separated by semicolons). You extract this list by replacing each semicolon with a line break and then assigning the multiline string directly to the combo items:

```
procedure TForm1.Button2Click(Sender: TObject);
var
    TypeNames: string;
begin
    TypeNames := ConvIntf.TypesList;
    ComboBoxFrom.Items.Text := StringReplace (TypeNames, ';', sLineBreak,
        [rfReplaceAll]);
    ComboBoxTo.Items := ComboBoxFrom.Items;
end;
```

After selecting two currencies, you can perform the conversion with this code ([Figure 23.4](#) shows the result):

```
procedure TForm1.Button1Click(Sender: TObject);
begin
    LabelResult.Caption := Format ('%n', [(ConvIntf.ConvertCurrency(
        ComboBoxFrom.Text, ComboBoxTo.Text, StrToFloat(EditAmount.Text))]);
end;
```

**Figure 23.4:** The ConvertCaller client of the Convert-Service web service shows how few German marks you used to get for so many Italian liras, before the euro changed everything.

## Asking for Database Data

For this example, I built a web service (based on the Web App Debugger) capable of exposing data about employees of a company. This data is mapped to the EMPLOYEE table of sample InterBase database we've used so often throughout the book. The Delphi interface of the web service is defined in the SoapEmployeeIntf unit as follows:

```

type
  ISoapEmployee = interface (IInvokable)
    ['{77D0D940-23EC-49A5-9630-ADE0751E3DB3}']
    function GetEmployeeNames: string; stdcall;
    function GetEmployeeData (EmpID: string): string; stdcall;
  end;

```

The first method returns a list of the names of all the employees in the company, and the second returns the details of a given employee. The implementation of this interface is provided in the Soap-EmployeeImpl unit with the following class:

```

type
  TSoapEmployee = class(TInvokableClass, ISoapEmployee)
  public
    function GetEmployeeNames: string; stdcall;
    function GetEmployeeData (EmpID: string): string; stdcall;
  end;

```

The implementation of the web service lies in the two previous methods and some helper functions to manage the XML data being returned. But before we get to the XML portion of the example, let me briefly discuss the database access section.

## Accessing the Data

All the connectivity and SQL code in this example are hosted in a separate data module. Of course, I could have created some connection and dataset components dynamically in the methods, but doing so is contrary to the approach of a visual development tool like Delphi. The data module has the following structure:

```

object DataModule3: TDataModule3
  object SQLConnection: TSQLConnection
    ConnectionName = 'IBConnection'
    DriverName = 'Interbase'
    LoginPrompt = False
    Params.Strings = // omitted
  end
  object dsEmplList: TSQLDataSet
    CommandText = 'select EMP_NO, LAST_NAME, FIRST_NAME from EMPLOYEE'
    SQLConnection = SQLConnection
    object dsEmplListEMP_NO: TStringField
    object dsEmplListLAST_NAME: TStringField
    object dsEmplListFIRST_NAME: TStringField
  end
  object dsEmpData: TSQLDataSet
    CommandText = 'select * from EMPLOYEE where Emp_No = :id'
    Params = <
      item
        DataType = ftFixedChar
        Name = 'id'
        ParamType = ptInput
      end>
    SQLConnection = SQLConnection
  end
end

```

As you can see, the data module has two SQL queries hosted by SQLDataSet components. The first is used to retrieve the name and ID of each employee, and the second returns the entire set of data for a given employee.

## Passing XML Documents

The problem is how to return this data to a remote client program. In this example, I've used the approach I like best: I've returned XML documents, instead of working with complex SOAP data structures. (I don't get how XML can be seen as a messaging mechanism for SOAP invocation—along with the transport mechanism provided by HTTP—but then, it is not used for the data being transferred. Still, very few web services return XML documents, so I'm beginning to wonder if it's me or many other programmers who can't see the full picture.)

In this example, the `GetEmployeeNames` method creates an XML document containing a list of employees, with their first and last names as values and the related database ID as an attribute, using two helper functions `MakeXmlStr` (already described in the [last chapter](#)) and `MakeXmlAttribute` (listed here):

```

function TSoapEmployee.GetEmployeeNames: string;
var
  dm: TDataModule3;
begin
  dm := TDataModule3.Create (nil);
  try
    dm.dsEmplList.Open;
    Result := '<employeeList>' + sLineBreak;
    while not dm.dsEmplList.EOF do
      begin
        Result := Result + ' ' + MakeXmlStr ('employee',
          dm.dsEmplListLASTNAME.AsString + ' ' +
          dm.dsEmplListFIRSTNAME.AsString,
          MakeXmlAttribute ('id', dm.dsEmplListEMPNO.AsString)) + sLineBreak;
        dm.dsEmplList.Next;
      end;
  end;

```

```

    Result := Result + '</employeeList>';
finally
    dm.Free;
end;
end;

function MakeXmlAttribute (attrName, attrValue: string): string;
begin
    Result := attrName + '=' + attrValue + '';
end;

```

Instead of the manual XML generation, I could have used the XML Mapper or some other technology; but as you should know from [Chapter 22](#) ("Using XML Technologies"), I rather prefer creating XML directly in strings. I'll use the XML Mapper to process the data received on the client side.

**Note** You may wonder why the program creates a new instance of the data module each time. The negative side of this approach is that each time, the program establishes a new connection to the database (a rather slow operation); but the plus side is that you have no risk related to the use of a multithreaded application. If two web service requests are executed concurrently, you can use a shared connection to the database, but you must use different dataset components for the data access. You could move the datasets in the function code and keep only the connection on the data module, or have a global shared data module for the connection (used by multiple threads) and a specific instance of a second data module hosting the datasets for each method call.

Let's now look at the second method, `GetEmployeeData`. It uses a parametric query and formats the resulting fields in separate XML nodes (using another helper function, `FieldsToXml`):

```

function TSoapEmployee.GetEmployeeData(EmpID: string): string;
var
    dm: TDataModule3;
begin
    dm := TDataModule3.Create (nil);
    try
        dm.dsEmpData.ParamByName('ID').AsString := EmpID;
        dm.dsEmpData.Open;
        Result := FieldsToXml ('employee', dm.dsEmpData);
    finally
        dm.Free;
    end;
end;

function FieldsToXml (rootName: string; data: TDataSet): string;
var
    i: Integer;
begin
    Result := '<' + rootName + '>' + sLineBreak;;
    for i := 0 to data.FieldCount - 1 do
        Result := Result + ' ' + MakeXmlStr (
            LowerCase (data.Fields[i].FieldName),
            data.Fields[i].AsString) + sLineBreak;
    Result := Result + '</' + rootName + '>' + sLineBreak;;
end;

```

## The Client Program (with XML Mapping)

The final step for this example is to write a test client program. You can do so as usual by importing the WSDL file defining the web service. In this case, you also have to convert the XML data you receive into something more

manageable—particularly the list of employees returned by the `GetEmployeeNames` method. As mentioned earlier, I've used Delphi's XML Mapper to convert the list of employees received from the web service into a dataset I can visualize using a DBGrid.

To accomplish this, I first wrote the code to receive the XML with the list of employees and copied it into a memo component and from there to a file. Then, I opened the XML Mapper, loaded the file, and generated from it the structure of the data packet and the transformation file. (You can find the transformation file among the source code files of the SoapEmployee example.) To show the XML data within a DBGrid, the program uses an XMLTransformProvider component, referring to the transformation file:

```
object XMLTransformProvider1: TXMLTransformProvider
  TransformRead.TransformationFile = 'EmplListToDataPacket.xtr'
end
```

The ClientDataSet component is not hooked to the provider, because it would try to open the XML data file specified by the transformation. In this case, the XML data doesn't reside in a file, but is passed to the component after calling the web service. For this reason the program moves the data to the ClientDataSet directly in code:

```
procedure TForm1.btnGetListClick(Sender: TObject);
var
  strXml: string;
begin
  strXml := GetISoapEmployee.GetEmployeeNames;
  strXML := XMLTransformProvider1.TransformRead.TransformXML(strXml);
  ClientDataSet1.XmlData := strXml;
  ClientDataSet1.Open;
end;
```

With this code, the program can display the list of employees in a DbGrid, as you can see in [Figure 23.5](#). When you retrieve the data for the specific employee, the program extracts the ID of the active record from the ClientDataSet and then shows the resulting XML in a memo:

```
procedure TForm1.btnGetDetailsClick(Sender: TObject);
begin
  Memo2.Lines.Text := GetISoapEmployee.GetEmployeeData(
    ClientDataSet1.FieldName ('id').AsString);
end;
```

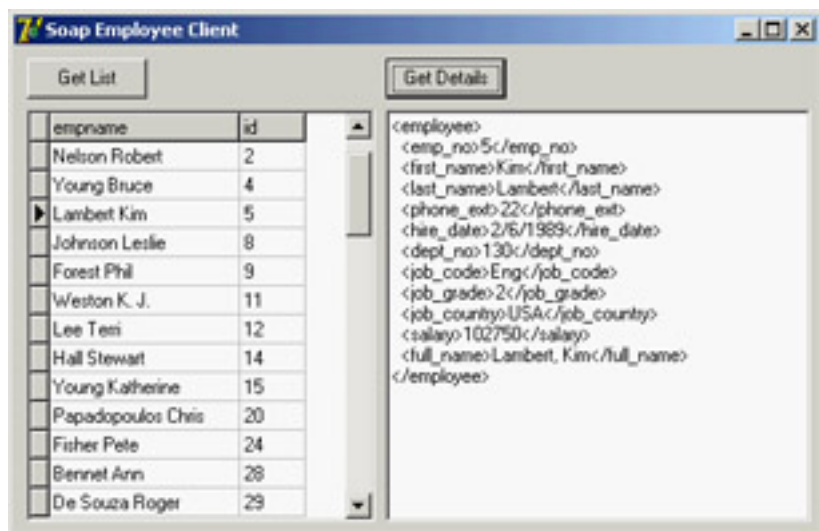

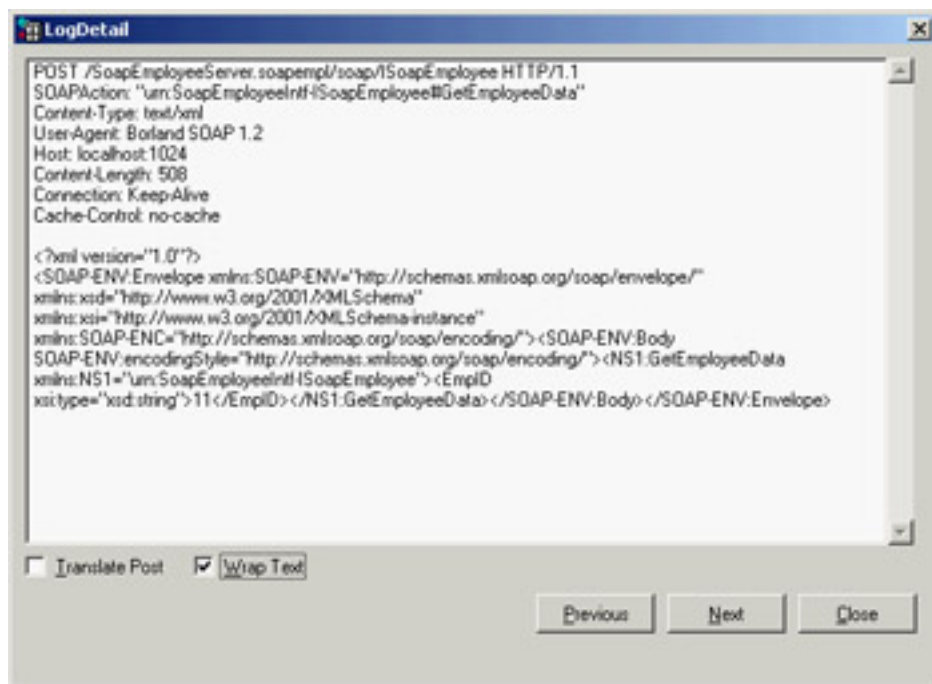

Figure 23.5: The client program of the SoapEmployee web service example

## Debugging the SOAP Headers

One final note for this example relates to the use of the Web App Debugger for testing SOAP applications. Of course, you can run the server program from the Delphi IDE and debug it easily, but you can also monitor the SOAP headers passed on the HTTP connection. Although looking at SOAP from this low-level perspective can be far from simple, it is the ultimate way to check if something is wrong with either a server or a client SOAP application. As an example, in [Figure 23.6](#) you can see the HTTP log of a SOAP request from the last example.

**Figure 23.6:** The HTTP log of the Web App Debugger includes the low-level SOAP request.

The Web App Debugger might not always be available, so another common technique is to handle the events of the HTTPRIO component, as the BabelFishDebug example does. The program's form has two memo components in which you can see the SOAP request and the SOAP response:

```
procedure TForm1.HTTPRIO1BeforeExecute(const MethodName: String;
var SOAPRequest: WideString);
begin
    MemoRequest.Text := SoapRequest;
end;
```

```
procedure TForm1.HTTPRIO1AfterExecute(const MethodName: String;
    SOAPResponse: TStream);
begin
    SOAPResponse.Position := 0;
    MemoResponse.Lines.LoadFromStream(SOAPResponse);
end;
```

## Exposing an Existing Class as a Web Service

Although you might want to begin developing a web service from scratch, in some cases you may have existing code to make available. This process is not too complex, given Delphi's open architecture in this area. To try it, follow these steps:

1. Create a web service application or add the related components to an existing WebBroker project.
2. Define an interface inheriting from `IInvokable` and add to it the methods you want to make available in the web service (using the `stdcall` calling convention). The methods will be similar to those of the class you want to make available.

3. Define a new class that inherits from the class you want to expose and implements your interface. The methods will be implemented by calling the corresponding methods of the base class.
4. Write a factory method to create an object of your implementation class any time a SOAP request needs it.

This last step is the most complex. You could define a factory and register it as follows:

```
procedure MyObjFactory (out Obj: TObject);  
begin  
    Obj := TMyImplClass.Create;  
end;
```

#### **initialization**

```
InvRegistry.RegisterInvokableClass(TMyImplClass, MyObjFactory);
```

However, this code creates a new object for every call. Using a single global object would be equally bad: Many different users might try to use it, and if the object has state or its methods are not concurrent, you might be in for big problems. You're left with the need to implement some form of session management, which is a variation on the problem we had with the earlier web service connecting to the database.

## DataSnap over SOAP

Now that you have a reasonably good idea how to build a SOAP server and a SOAP client, let's look at how to use this technology in building a multitier DataSnap application. You'll use a Soap Server Data Module to create the new web service and the SoapConnection component to connect a client application to it.

### Building the DataSnap SOAP Server

Let's look at the server side first. Go to the Web Services page of the New Items dialog box and use the Soap Server Application icon to create a new web service, and then use the Soap Server Data Module icon to add a DataSnap server-side data module to the SOAP server. I did this in the SoapDataServer7 example (which uses the Web App Debugger architecture for testing purposes). From this point on, all you do is write a normal DataSnap server (or a middle-tier DataSnap application), as discussed in [Chapter 16](#) ("Multitier DataSnap Applications"). In this case, I added InterBase access to the program by means of dbExpress, resulting in the following structure:

```
object SoapTestDm: TSoapTestDm
  object SQLConnection1: TSQLConnection
    ConnectionName = 'IBLocal'
  end
  object SQLDataSet1: TSQLDataSet
    SQLConnection = SQLConnection1
    CommandText = 'select * from EMPLOYEE'
  end
  object DataSetProvider1: TDataSetProvider
    DataSet = SQLDataSet1
  end
end
```

The data module built for a SOAP-based DataSnap server defines a custom interface (so you can add methods to it) inheriting from `IAppServerSOAP`, which is defined as a published interface (even though it doesn't inherit from `IInvokable`).

**Tip** Delphi 6 used DataSnap's standard `IAppServer` interface for exposing data via SOAP. Delphi 7 has replaced the default with the inherited `IAppServerSOAP` interface, which is functionally identical but allows the system to discriminate the type of call depending on the interface name. You'll see shortly how to call an older application from a client built in Delphi 7, because this process is not automatic.

The implementation class, `TSoapTestDm`, is the data module, as in other DataSnap servers. Here is the code Delphi generated, with the addition of the custom method:

```
type
  ISampleDataModule = interface(IAppServerSOAP)
    ['{D47A293F-4024-4690-9915-8A68CB273D39}']
    function GetRecordCount: Integer; stdcall;
  end;

  TSampleDataModule = class(TSoapDataModule, ISampleDataModule,
    IAppServerSOAP, IAppServer)
    DataSetProvider1: TDataSetProvider;
    SQLConnection1: TSQLConnection;
    SQLDataSet1: TSQLDataSet;
  public
    function GetRecordCount: Integer; stdcall;
  end;
```

The base `TSoapDataModule` doesn't inherit from `TInvokableClass`. This is not a problem as long as you provide

an extra factory procedure to create the object (which is what `TInvokableClass` does for you) and add it to the registration code (as discussed earlier, in the section "[Exposing an Existing Class as a Web Service](#)):

```
procedure TSampleDataModuleCreateInstance(out obj: TObject);  
begin  
    obj := TSampleDataModule.Create(nil);  
end;  
  
initialization  
    InvRegistry.RegisterInvokableClass(  
        TSampleDataModule, TSampleDataModuleCreateInstance);  
    InvRegistry.RegisterInterface(TypeInfo(ISampleDataModule));
```

The server application also publishes the `IAppServerSOAP` and `IAppServer` interfaces, thanks to the (little) code in the `SOAPMidas` unit. As a comparison, you can find a SOAP `DataSnap` server built with Delphi 6 in the `SoapDataServer` folder. The example can still be compiled in Delphi 7 and works fine, but you should write new programs using the structure of the newer; an example is in the `SoapDataServer7` folder.

**Tip** Web service applications in Delphi 7 can include more than one SOAP data module. To identify a specific SOAP data module, use the `SOAPServerIID` property of the `SoapConnection` component or add the data module interface name to the end of the URL.

The server has a custom method (the Delphi 6 version of the program also had one, but it never worked) that uses a query with the `select count(*) from EMPLOYEE` SQL statement:

```
function TSampleDataModule.GetRecordCount: Integer;  
begin  
    // read in the record count by running a query  
    SQLDataSet2.Open;  
    Result := SQLDataSet2.Fields[0].AsInteger;  
    SQLDataSet2.Close;  
end;
```

## Building the DataSnap SOAP Client

To build the client application, called `SoapDataClient7`, I began with a plain program and added a `SoapConnection` component to it (from the Web Services page of the palette), hooking it to the URL of the `DataSnap` web service and referring to the specific interface I'm looking for:

```
object SoapConnection1: TSoapConnection  
    URL = 'http://localhost:1024/SoapDataServer7.soapdataserver/' +  
        'soap/Isampledatabodule'  
    SOAPServerIID = 'IAppServerSOAP - {C99F4735-D6D2-495C-8CA2-E53E5A439E61}'  
    UseSOAPAdapter = False  
end
```

Notice the last property, `UseSOAPAdapter`, which indicates you are working against a server built with Delphi 7. As a comparison, the `SoapDataClient` (again, no 7) example, which uses a server created with Delphi 6 and recompiled with Delphi 7, must have this property set to `True`. This value forces the program to use the plain `IAppServer` interface instead of the new `IAppServerSOAP` interface.

From this point on, you proceed as usual, adding a `ClientDataSet` component, a `DataSource`, and a `DBGrid` to the program; choosing the only available provider for the client dataset; and hooking the rest. Not surprisingly, for this simple example, the client application has little custom code: a single call to open the connection when a button is clicked (to avoid startup errors) and an `ApplyUpdates` call to send changes back to the database.

## SOAP versus Other DataSnap Connections

Regardless of the apparent similarity of this program to all the other DataSnap client and server programs built in [Chapter 16](#), there is a very important difference worth underlining: The SoapDataServer and SoapDataClient programs do not use COM to expose or call the `IAppServerSOAP` interface. Quite the opposite—the socket- and HTTP-based connections of DataSnap still rely on local COM objects and a registration of the server in the Windows Registry. The native SOAP-based support, however, allows for a totally custom solution that's independent of COM and that offers many more chances to be ported to other operating systems. (You can recompile this server in Kylix, but not the programs built in [Chapter 16](#).)

The client program can also call the custom method I've added to the server to return the record count. This method could be used in a real-world application to show only a limited number of records but inform the user how many haven't yet been downloaded from the server. The client code to call the method relies on an extra HTTPRIO component:

```
procedure TFormSDC.Button3Click(Sender: TObject);  
var  
    SoapData: ISampleDataModule;  
begin  
    SoapData := HttpRio1 as ISampleDataModule;  
    ShowMessage (IntToStr (SoapData.GetRecordCount));  
end;
```

## Handling Attachments

One of the most important features Borland added to Delphi 7 is full support for SOAP attachments. Attachments in SOAP allow you to send data other than XML text, such as binary files or images. In Delphi, attachments are managed through streams. You can read or indicate the type of attachment encoding, but the transformation of a raw stream of bytes into and from a given encoding is up to your code. This process isn't too complex, though, if you consider that Indy includes a number of encoding components.

As an example of how to use attachments, I've written a program that forwards the binary content of a ClientDataSet (also hosts images) or one of the images alone. The server has the following interface:

```
type
  ISoapFish = interface(IInvokable)
  [ '{4E4C57BF-4AC9-41C2-BB2A-64BCE470D450}' ]
    function GetCds: TSoapAttachment; stdcall;
    function GetImage(fishName: string): TSoapAttachment; stdcall;
end;
```

The implementation of the GetCds method uses a ClientDataSet that refers to the classic BIOLIFE table, creates a memory stream, copies the data to it, and then attaches the stream to the TSoapAttachment result:

```
function TSoapFish.GetCds: TSoapAttachment; stdcall;
var
  memStr: TMemoryStream;
begin
  Result := TSoapAttachment.Create;
  memStr := TMemoryStream.Create;
  WebModule2.cdsFish.SaveToStream(memStr); // binary
  Result.SetSourceStream(memStr, soReference);
end;
```

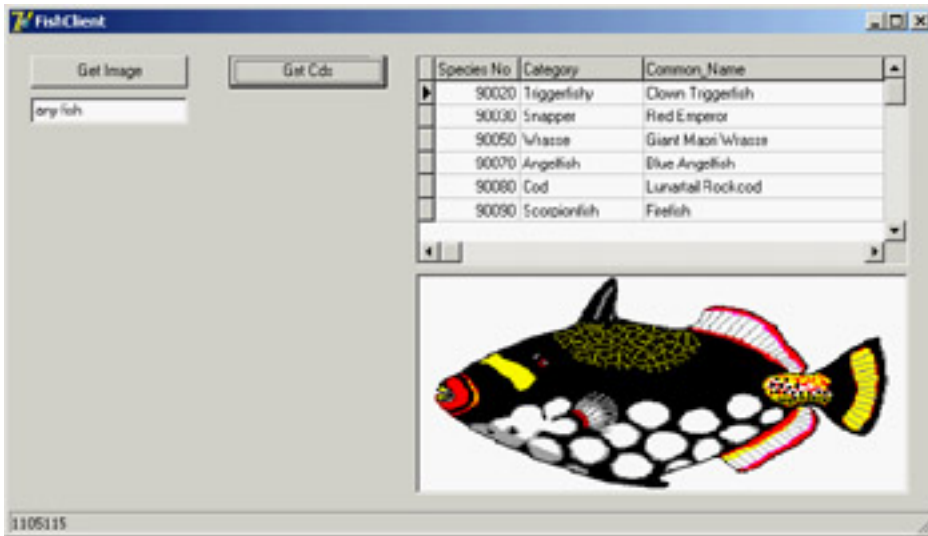

On the client side, I prepared a form with a ClientDataSet component connected to a DBGrid and a DBImage. All you have to do is grab the SOAP attachment, save it to a temporarily in-memory stream, and then copy the data from the memory stream to the local ClientDataSet:

```
procedure TForm1.btnGetCdsClick(Sender: TObject);
var
  sAtt: TSoapAttachment;
  memStr: TMemoryStream;
begin
  nRead := 0;
  sAtt := (HttpRiol as ISoapFish).GetCds;
  try
    memStr := TMemoryStream.Create;
    try
      sAtt.SaveToStream(memStr);
      memStr.Position := 0;
      ClientDataSet1.LoadFromStream(memStr);
    finally
      memStr.Free;
    end;
  finally
    DeleteFile(sAtt.CacheFile);
    sAtt.Free;
  end;
end;
```

**Warning** By default, SOAP attachments received by a client are saved to a temporary file, referenced by the *CacheFile* property of the *TSOAPAttachment* object. If you don't delete this file it will remain in a folder that hosts temporary files.

This code produces the same visual effect as a client application loading a local file into a *ClientDataSet*, as you can see in [Figure 23.7](#). In this SOAP client I used an *HTTPRIO* component explicitly to be able to monitor the incoming data (which will possibly be very large and slow); for this reason, I set a global *nRead* variable to zero before invoking the remote method. In the *OnReceivingData* event of the *HTTPRIO* object's *HTTPWebNode* property, you add the data received to the *nRead* variable. The *Read* and *Total* parameters passed to the event refer to the specific block of data sent over a socket, so they are almost useless by themselves to monitor progress:

```
procedure TForm1.HTTPRIO1HTTPWebNode1ReceivingData(  
    Read, Total: Integer);  
begin  
    Inc (nRead, Read);  
    StatusBar1.SimpleText := IntToStr (nRead);  
    Application.ProcessMessages;  
end;
```

**Figure 23.7:** The FishClient example receives a binary *ClientDataSet* within a SOAP attachment.

## Supporting UDDI

The increasing popularity of XML and SOAP opens the way for business-to-business communication applications to interoperate. XML and SOAP provide a foundation, but they are not enough—standardization in the XML formats, in the communication process, and in the availability of information about a business are all key elements of a real-world solution.

Among the standards proposed to overcome this situation, the most notable are Universal Description, Discovery, and Integration (UDDI, [www.uddi.org](http://www.uddi.org)) and Electronic Business using eXtensible Markup Language (ebXML, [www.ebxml.org](http://www.ebxml.org)). These two solutions partially overlap and partially diverge and are now being further worked on by the OASIS consortium (Organization for the Advancement of Structured Information Standards, [www.oasis-open.org](http://www.oasis-open.org)). I won't get into the problems with business processes; instead I'll only discuss some of the technical elements of UDDI, because it is specifically supported by Delphi 7.

### What Is UDDI?

The Universal Description, Discovery, and Integration (UDDI) specification is an effort to create a catalog of web services offered by companies throughout the world. The goal of this initiative is to build an open, global, platform-independent framework to let business entities find each other, define how they interact with the Internet network, and share a global business registry. Of course, the idea is to speed up the adoption of e-commerce, in the form of B2B applications.

UDDI is basically a global business registry. Companies can register themselves on the system, describing their organization and the web services they offer (in UDDI the term *web services* is used in a very wide sense, including e-mail addresses and websites). The information in the UDDI registry for each company is divided into three areas:

**White Pages** Include contact information, addresses, and the like.

**Yellow Pages** Register the company in one or more taxonomies, including industrial categories, products sold by the company, geographical information, and other (possibly customizable) taxonomies.

**Green Pages** List the web services offered by the company. Each service is listed under a service type (called a *tModel*), which can be predefined or a type specifically described by the company (for example, in terms of WSDL).

Technically, the UDDI registry should be perceived like today's DNS, and should have a similar distributed nature: multiple servers, mirrored and caching data. Clients can cache data following given rules.

UDDI defines specific data models for a business entity, a business service, and a binding template. The *BusinessEntity* type includes core information about the business, such as its name, the category it belongs to, and contact information. It supports the taxonomies of the yellow pages, with industry information, product types, and geographic details.

The *BusinessService* type includes descriptions of web services (used for the green pages). The main type is only a container for the related services. The services can be bound to a taxonomy (geographical area, product, and so on). Every *BusinessService* structure includes one or more *BindingTemplates* (the reference to the service).

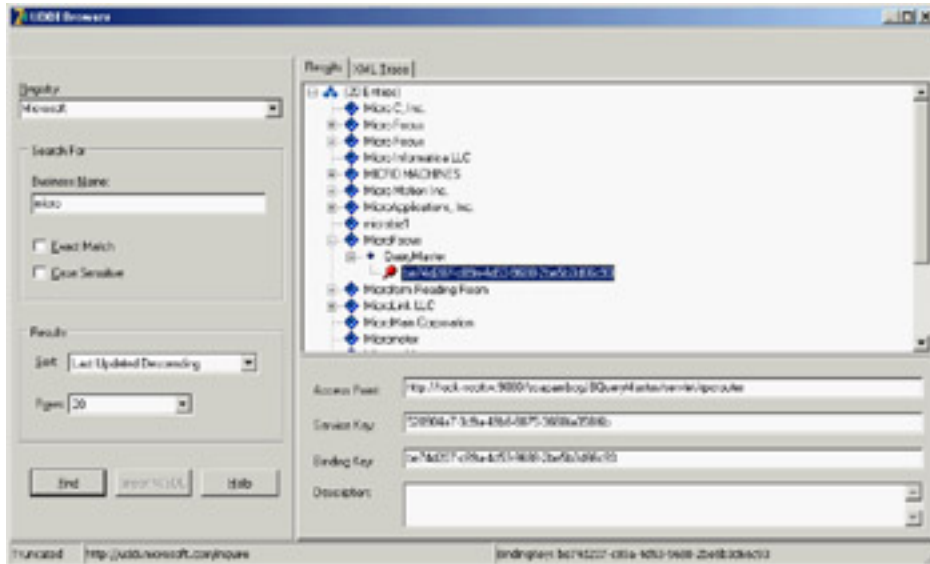

The *BindingTemplate* has a *tModel*. The *tModel* includes information about formats, protocols, and security, and references to technical specifications (possibly using the WSDL format). If multiple companies share a *tModel*, a program can interact with all of them with the same code. A given business program, for example, can offer a *tModel* for other software programs to interact with it, regardless of the company that has adopted the software.

The UDDI API is based on SOAP. Using SOAP, you can both register data and query a registry. Microsoft also offers a COM-based SDK, and IBM has a Java Open Source toolkit for UDDI. UDDI APIs include inquiry (*find\_xx* and

get\_xx) and publishing (save\_xx and delete\_xx) on each of the four core data structures (businessEntity, businessService, bindingTemplate, and tModel).

## UDDI in Delphi 7

Delphi 7 includes a UDDI browser you can use to find a web service while importing a WSDL file. The UDDI browser, shown in [Figure 23.8](#), is activated by the WSDL Import Wizard. This browser uses only UDDI version 1 servers (a newer interface is available, but it isn't supported) and has a few predefined UDDI registries. You can add predefined settings in the UDDIBrow.ini file in the Delphi bin folder.

**Figure 23.8:** The UDDI Browser embedded in the Delphi IDE

This is a handy way to access web services information, but it is not all that Delphi provides. Although the UDDI Browser is not available as a stand-alone application, the UDDI interface units are available (and they are not trivial to import). So, you can write your own UDDI browser.

I'll sketch a simple solution, which is a starting point for a full-blown UDDI browser. The UddiInquiry example, shown in action in [Figure 23.9](#), has a number of features, but not all of them work smoothly (particularly the category search features). The reason lies in the fact that using UDDI implies navigating complex data structures, which are not always mapped in the most obvious way by the WSDL importer. This makes the example code fairly involved; so, I'll show you only the code for a plain search, and not even all of it (another reason is that some readers may not be particularly interested in UDDI).

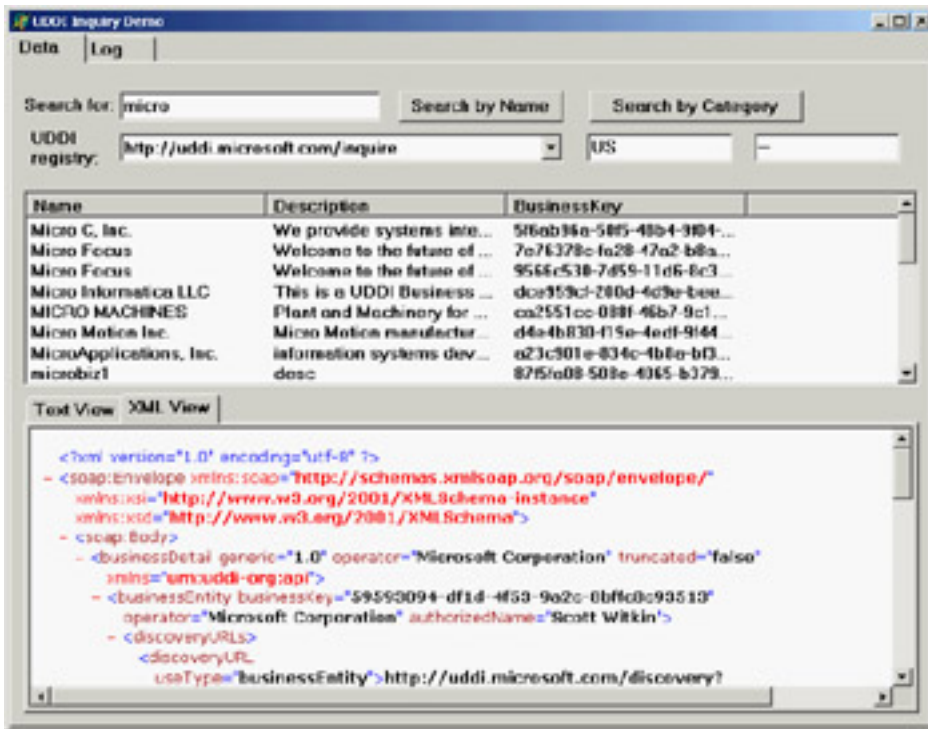

Figure 23.9: The UddiInquiry example features a limited UDDI browser.

As the program starts, it binds the HTTPRIO component it hosts with the InquireSoap UDDI interface, defined in the inquire\_v1 unit provided with Delphi 7:

```

procedure TForm1.FormCreate(Sender: TObject);
begin
    httprio1.Url := comboRegistry.Text;
    inftInquire := httprio1 as InquireSoap;
end;

```

Clicking the Search button makes the program call the find\_business UDDI API. Because most UDDI functions require many parameters, it has been imported using a single record-based parameter of type FindBusiness; it returns a businessList2 object:

```

procedure TForm1.btnSearchClick(Sender: TObject);
var
    findBusinessData: Findbusiness;
    businessListData: businessList2;
begin
    httprio1.Url := comboRegistry.Text;

    findBusinessData := FindBusiness.Create;
    findBusinessData.name := edSearch.Text;
    findBusinessData.generic := '1.0';
    findBusinessData.maxRows := 20;

    businessListData := inftInquire.find_business(findBusinessData);
    BusinessListToListView (businessListData);
    findBusinessData.Free;
end;

```

The businessList2 object is a list that is processed by the businessListToListView method of the program's main form, showing the most relevant details in a list view component:

```

procedure TForm1.businessListToListView(businessList: businessList2);
var
    i: Integer;

```

```
begin
  ListView1.Clear;
  for i := 0 to businessList.businessInfos.Len do
  begin
    with ListView1.Items.Add do
    begin
      Caption := businessList.businessInfos [i].name;
      SubItems.Add (businessList.businessInfos [i].description);
      SubItems.Add (businessList.businessInfos [i].businessKey);
    end;
  end;
end;
```

By double-clicking on a list view item you can further explore its details, although the program shows the resulting XML information in a plain textual format (or a `TWebBrowser`-based XML view) and doesn't further process it. As mentioned, I don't want to get into technical details; if you're interested, you can find them by looking at the source code.

## What's Next?

In this chapter, I've focused on web services, covering SOAP, WSDL, and UDDI. Refer to the W3C website and to the UDDI ([www.uddi.org](http://www.uddi.org)) and ebXML ([www.ebxml.org](http://www.ebxml.org)) sites for more information in the area of business-oriented web services. I didn't delve much into these non-technical issues, but they were worth mentioning.

You should have noticed in this chapter that Delphi is strong player in the area of web services, with a powerful, open architecture. You can use web services to interact with applications written for the Microsoft .NET platform; Delphi has much to offer for this architecture, because it includes a Delphi for .NET preview (covered in the two final chapters of the book).

[Chapter 24](#), "The Microsoft .NET Architecture from the Delphi Perspective," is focused on the .NET platform; [Chapter 25](#), "Delphi for .NET Preview: The Language and the RTL," covers the new Delphi compiler.

## Chapter 24: The Microsoft .NET Architecture from the Delphi Perspective

### Overview

Every few years a new technology comes along that turns our industry upside down. Some of these technologies thrive, some mutate into something else, and many are revealed to be half-baked marketing fluff. Almost in military fashion, the arrival of a new technology is invariably preceded by an artillery barrage of hype. Experienced programmers know to keep their heads down until the hype barrage subsides. After all, the proof will be in the technical pudding, so to speak.

Your reaction to Microsoft's .NET initiative will depend somewhat on your background. If you have previous experience with Java or Delphi, you might wonder what all the fuss is about. But, if you have been slogging it out in the trenches writing applications for Windows in C++ (or, heaven forbid, in C), you might be overwhelmed with joy.

The purpose of this chapter is to explain some of the technologies that make up the .NET initiative and to show how they fit into the world of Windows programming in general and Delphi programming in particular. We will begin by installing and configuring the Delphi for .NET Preview compiler. Then we will broadly cover some of the .NET technologies. Finally, we will discuss these technologies in greater detail, weaving in some Delphi code for illustration.

**Note** This chapter and the following one were by Marco with extensive help from John Bushakra, who works for Borland's RAD tools documentation department.

## Installing the Delphi for .NET Preview

The Delphi for .NET Preview requires but does not install .NET Framework Runtime, which is freely downloadable from Microsoft's MSDN website. As a developer, you'll probably want to take an extra step and install the more complete .NET Framework SDK, which includes documentation and tools for developers (but is also much larger). You should install the .NET Framework Runtime or SDK before you install the Delphi for .NET Preview.

The Preview compiler is compatible with the .NET Framework SDK and service pack 1. If you have applied service pack 2 or later, then you will have to perform the extra step of rebuilding the precompiled units (the `dcuil` files) installed with the Preview. This requirement might go away in subsequent updates to the Delphi for .NET Preview compiler.

**Note** A few months after Delphi 7 shipped (in November 2002), Borland released a significant update of the Delphi for .NET Preview. As a registered Delphi user, you can download updates to the Preview from the Borland website. Do this even before installing the version that comes in the Delphi box, as you'll need to uninstall it to update to a newer version.

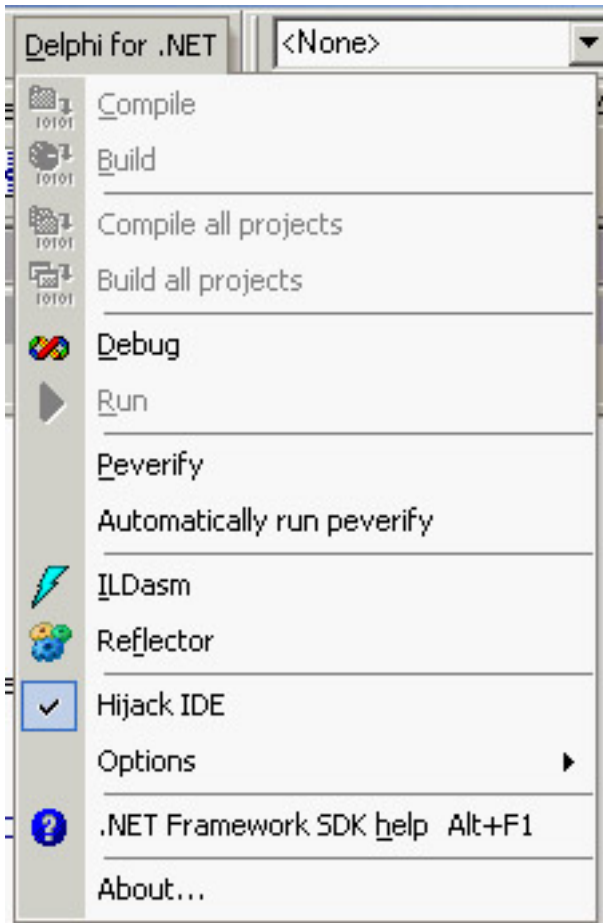

**Warning** I've used the November 2002 version of the Delphi for .NET Preview to test the examples of this and the .NET chapter, although most of them will also compile against the original version that shipped with Delphi 7. By the time you read this, a newer version might be available; check the author's website for updates of the examples.

After installing the .NET Framework SDK, insert the Delphi for .NET Preview CD and run the setup program. The Preview will install itself in a separate directory from your Delphi 7 installation, and none of your Delphi 7 settings are affected by installing the Preview.

Previously I mentioned that you would need to rebuild the precompiled units shipped with the compiler, if you have installed service pack 2 for the .NET Framework. If this applies to you, open a command window and navigate to the `source\rtl` directory under the root of the compiler installation directory. There, you will find a file called `rebuild.bat`, which you must execute to perform the rebuild. You might see some errors and warnings; these are known issues at the time of this writing, and might be cleared up in subsequent updates to the compiler. Once the batch file has completed, you will be ready to go.

The `dccil` compiler is located in the `bin` directory. Along with the compiler, in this directory is a file called `dccil.cfg` that specifies the default unit search path (the `-U` compiler switch), which is the `units` directory under the root installation directory. As packaged, the Delphi for .NET Preview compiler is strictly for use with a command window.

However, Borland has made available an unsupported plug-in to the Delphi 7 IDE on the Borland Developers Network website, referred to as Delphi for .NET common line compiler IDE integration. Using the plug-in, you can control the `dccil` compiler from within the IDE, as you can see in the menu installed by this plug-in.

Note, however, that the plug-in does not give you the full capability of designing forms and all the other things Delphi is famous for. The Delphi for .NET Preview compiler is intended to give you some advance warning about new language features and a glimpse into how the Delphi run-time library might look in the .NET context. You can download this plug-in from the Code Central area of the Borland Developer Network website, [bdn.borland.com](http://bdn.borland.com) (if you cannot find it, look under the number 18889).

Another valuable resource you might want to work with is the Reflector. This tool was written by Lutz Roeder (who happens to work at Microsoft, by the way) and is available on his own website, [www.aisto.com/roeder/dotnet](http://www.aisto.com/roeder/dotnet).

**Note** Reflector is like Microsoft's Intermediate Language Disassembler (ILDASM) tool—it allows you to inspect .NET assemblies (executables and DLLs) and their types and members.

## Testing the Installation

Now it's time to test your Delphi for .NET Preview installation by compiling a simple console program that prints a message.

You can start this project using Delphi 7, or you can type in the text with your favorite editor:

```
program HelloWorld;  
  
{ $APPTYPE CONSOLE }  
  
uses  
  Borland.Delphi.SysUtils;  
  
begin  
  WriteLn ('Hello, Delphi! - Today is ' +  
    DateToStr (Now));  
end.
```

Notice how similar the code looks to the Delphi applications you're used to. The only difference is the `uses` clause. Borland has organized the units of the Delphi library into namespaces similar to those of the Common Language Runtime (CLR). I will discuss this in more detail in the [next chapter](#).

Save the file as `HelloWorld.dpr` and open a command window. Navigate to the location of the file and type  
`dccil HelloWorld.dpr`

The result should be an executable image, `HelloWorld.exe`, which you can run from the command line to produce a single line of output. If you are using the IDE plug-in, compiling and running the program will involve pressing `Ctrl+F9` or `F9` after you've enabled IDE *hijacking* (see the Hijack IDE menu item in the screenshot above).

If this program seems boring, you can begin your exploration of .NET using the windowed version of the hello world program instead of the console version. Called `HelloWin`, this program creates and shows a window on the screen, writing into its caption. It also shows the call to `Application.Run`, used to activate the application's message processing loop:

```
program HelloWin;  
  
uses  
    System.Windows.Forms,  
    Borland.Delphi.SysUtils;  
  
var  
    aForm: Form;  
  
begin  
    aForm := Form.Create;  
    aForm.Text := 'Hello Delphi';  
    Application.Run (aForm);  
end.
```

In .NET presentations, the previous code raises the enthusiasm of programmers used to Microsoft development tools. As a Delphi programmer, you might have used almost this same code since 1995, so you might wonder where this excitement comes from. The output of these programs is far from interesting, but you can at least prove they are not classic Win32 applications by running `ILDASM` on them (directly from the plug-in's menu). You can see the output for the `HelloWorld` executable in [Figure 24.1](#). Notice that the unit's global code is wrapped in a pseudo class called `uUnit`. Unlike Delphi, the .NET runtime doesn't account for global procedures and functions, but only class methods. But I'm getting ahead of myself; let's start from the beginning and look at the NET platform.

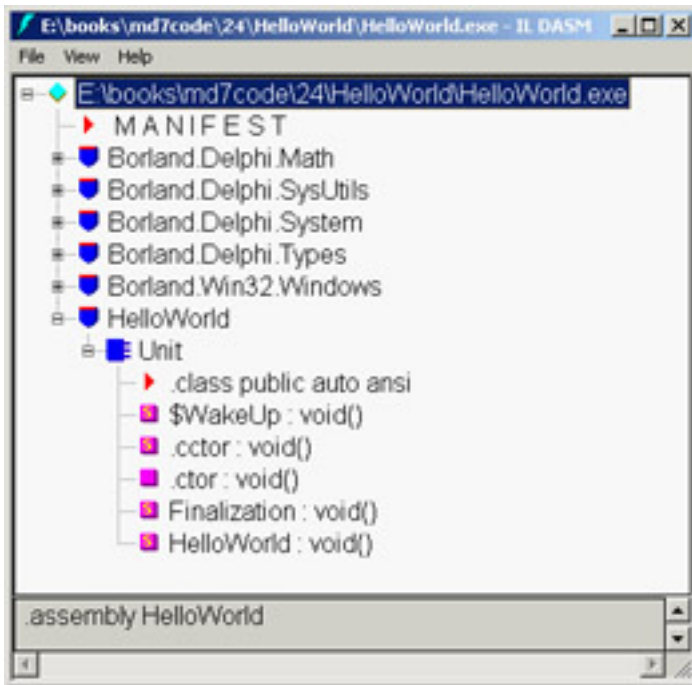

Figure 24.1: The HelloWorld demo as seen in ILDASM

## Microsoft's .NET Platform

Microsoft's .NET platform comprises many different specifications and initiatives. The core functionality of the .NET platform has been given over to the European Computer Manufacturer's Association (ECMA) and is undergoing the standardization process. At the time of this writing, the C# language specification has just passed ECMA's process and is heading for ISO standardization.

**Note** You can find the standard documents for the C# programming language and the Common Language Infrastructure (CLI) at [www.ecma.ch](http://www.ecma.ch). An interesting element of the CLI specification is the standard naming convention for variables and methods.

From the programmer's standpoint, the core feature of the .NET platform is its managed environment, which allows the execution of intermediate code compiled by many different programming languages (provided they conform to a common definition of the base data types). This environment embeds many features ranging from sophisticated memory management up to integrated security, to name just two. On top of this managed environment, Microsoft has built a large class library, covering diverse areas of development (Windows-based forms, web development, web services development, XML processing, database access, and many more).

This is only a short overview. To get more into the details we need to learn the precise terms used in the .NET Platform, most of which are indicated by three-letter acronyms, introduced in the following subsections.

### The Common Language Infrastructure (CLI)

The CLI is the main pillar of the .NET platform. It was submitted to the ECMA in December 2001. The CLI comprises many different specifications:

**Common Type System (CTS)** The CTS lays the groundwork for integrating disparate programming languages. It specifies how types are declared and used, and language compilers must conform to this specification in order to take advantage of the .NET platform's cross-language integration.

**Extensible Metadata** The CLI specifies that every unit of deployment (an *assembly*) must be a self-describing entity. Therefore, an assembly must carry with it data that fully identifies the assembly (its name, version, and optional culture and public key), data that describes the types defined within the assembly, data listing other files referenced, and any special security permissions that are required. Furthermore, the metadata system is extensible, so an assembly might also contain user-defined descriptive elements, known as custom attributes.

**Note** The term culture is used by Microsoft as an extension of the term's language (the language used for the user messages of a library) and locale (the dates and number formatting settings for a country). The idea is to cover anything peculiar to a country, or portions of a country.

**Common Intermediate Language (CIL)** CIL is the programming language of a virtual execution environment with an abstract microprocessor. Compilers targeting the .NET platform do not generate native CPU instructions, but instead generate instructions in the intermediate language of the abstract processor. In this respect, the CLI is similar to Java byte code.

**P/Invoke** Programs that execute in the .NET runtime each play in their own private sandbox. Unlike the traditional Win32 programming model, a large and complicated layer of software exists between them and the operating system. But the .NET runtime does not completely replace the Win32 API, so there must be a way to bridge between the two worlds. This bridge is called Platform Invocation Service (in short, P/Invoke or PInvoke).

**Framework Class Library (FCL)** The .NET Framework Class Library (FCL), or .NET Framework for short (or even .NET Fx), is a class hierarchy with a design similar to that of Borland's VCL. Features also available in the VCL are actually quite similar, although the .NET Framework has a much larger

set of classes (covering many more areas of programming). The architectural difference between the .NET Framework and the VCL is that the .NET Framework is not only callable from other languages, it can be directly extended by other languages. This means that, as a Delphi programmer, you have the ability to directly inherit from classes in the .NET Framework, just as you would inherit from any other Delphi class. Moreover, the CLI gives you the ability to extend a class written in any language that has a compiler that targets the .NET runtime. The *factorable* part of the FCL means that parts of the class hierarchy can be factored out; for example, to create a stripped-down version for use on a handheld device.

**Extended Portable Executable (PE) File Format** Microsoft is using its standard Portable Executable (PE) file format (the file format used by standard Win32 executable files) to support the metadata requirements of the CLI. The advantage of using this format is that the operating system can load a .NET application the same way it loads a native Win32 application. Common loading is about where the similarity ends though, since all managed code is in a special section. The framework modifies the loader so when it finds it is dealing with a .NET entity, it passes control over to the CLR that then works out how to call the managed entry points.

## The Common Language Runtime (CLR)

The CLI is a specification, and the CLR is Microsoft's implementation of that specification. Not surprisingly, the CLR is a superset of the specification. To a programmer, the CLR is an all-encompassing run-time library that unifies the vast array of services provided by the Windows operating system and presents them to you in an object-oriented framework.

On a larger scale, the CLR is responsible for every aspect of the .NET universe: loading the executable image, verifying its identity and type safety, compiling CIL code into native CPU instructions, and managing the application during its lifetime. CIL code that is intended to be run in the CLR is called *managed code*, whereas all other code (such as Intel executable code produced by Delphi 7) is *unmanaged*.

## Common Language Specification (CLS)

Closely related to the Common Type System, the CLS is a subset of that specification that defines the rules that govern how types created in different programming languages can interoperate. Not all languages are created equal, and some languages have features that can't be found elsewhere. The CLS tries to find a happy medium, specifying those items that a large set of languages can implement. Microsoft tried to make the CLS as small as possible, yet still accommodate a large set of languages.

Some features of Delphi are not CLS compliant. This does not mean the code cannot be executed by the CLR and work on the .NET platform; it only means you are using a language feature that can't be supported by other languages, so that particular part of your code cannot be used by other .NET applications if they are written in languages other than Delphi.

**Note** If you have experience with Java, you might find some of these items familiar. The .NET platform shares many concepts with the Java platform, in particular the intermediate language and virtual execution system, although with the core difference of Java being pcode interpreted by default, whereas .NET is invariably JIT compiled. There are also relevant analogies in the class libraries. In most cases, however, don't take corresponding Java concepts for granted, because differences in the implementation details might significantly affect how you use an apparently similar feature.

The various specifications of the CLI give a glimmer of hope about cross-platform development. But, you probably won't hear the "write once, run anywhere," mantra from Microsoft. This is due to the fact that they consider the user interface to be a key part of an application, and a normal PC screen compared to, say, a mobile phone screen has inherently different capabilities. There are two major ongoing efforts to implement the CLI on other operating systems. The Rotor project (officially called Microsoft Shared Source CLI or MS SSCLI) is written by the Microsoft Research team. Rotor consists of a large donation of software, under Microsoft's Shared Source license, and the necessary tools to build it on the FreeBSD, Win2, and Mac OS X 10.2 operating systems.

The second well-known CLI implementation on another operating system is the Mono Project, which supports Win32 and Linux. Mono is building what is essentially a clean-room implementation of the CLI on Linux and is released with a

much more open license. Borland has a wait-and-see approach about Mono; there has been no word about whether Delphi will be a player in that arena.

The Rotor project seems to be aimed toward educators and people who are just curious about how the CLR is implemented, because its license is very open to academia but prohibits any commercial use. The Mono project, however, may give Microsoft some serious competition. The most serious stumbling block to true portability will probably continue to be the graphical user interface. The Rotor project does not include any GUI elements, while Mono has started developing WinForms using the WINE library. There is also a GTK# project associated with Mono, which is a binding of the GTK+ toolkit to the C# language.

Today's computing environment is a nebulous mass of diverse possibilities. Handheld devices have complex operating systems of their own, and Microsoft has a keen interest in this arena. Microsoft is working on a version of the .NET platform called the .NET Compact Framework, which is intended for handheld devices. The .NET platform could also serve as a springboard for tomorrow's technologies. Sixty-four bit processors are just around the corner, and .NET will no doubt be running there.

Does this mean you can run your managed application on Linux, 64-bit Windows, and your PDA? No. It is not reasonable to expect a user interface geared for a 1600×1200 pixel display on a 21-inch monitor to port to a handheld device. So, regarding .NET as a cross-platform tool, you will gain some advantage, but you should not expect your application to be a straight port especially if you are porting to another operating system or a handheld device.

In the following sections, we will examine some components of the CLI in more detail.

## Assemblies

Microsoft coined the term *assembly* to denote a "unit of deployment" in the .NET runtime environment. In manufacturing, an assembly is a group of separate but related parts that are put together to form a single functional unit. Sometimes an assembly consists of only one part, but it might consist of many. So it is with assemblies in .NET.

Typically, an assembly consists of only one file—either a single executable or a dynamic link library. An assembly could consist of a group of related DLLs, or a DLL and associated resources like images or strings. Going back to the manufacturing analogy, each assembly, whether it consists of one part or multiple parts, contains a packing slip called a *manifest*. A manifest describes the contents of something, and an assembly manifest contains the metadata for an assembly. The manifest is the implementation of the extensible metadata system described in the CLI.

As you look through the installation directory for the Delphi for .NET Preview compiler, you will find a `units` folder. In this folder are a number of files with the extensions `.dcua` and `.dcuil`. These are not PE files, so they cannot be examined with ILDASM.

A `.dcua` file catalogs the namespaces and types in a .NET assembly (which, keep in mind, can consist of multiple executable files). A `.dcuil` file corresponds to a namespace. The `.dcuil` file contains all the compiler symbols for a namespace, as well as references to the `.dcua` files that contribute to that namespace (an assembly can contribute types to more than one namespace).

**Note** A *namespace* is a hierarchical containment mechanism that organizes classes and other types. We will discuss namespaces in more detail in [Chapter 25](#), "Delphi for .NET Preview: The Language and the RTL."

An application is built against a certain set of assemblies; the application is said to *reference* these assemblies. When the set of assemblies changes, the compiler must rebuild any `.dcuil` files that contain references to `.dcua` files that are no longer in the set. Likewise, if a change is made to an assembly, the compiler must rebuild the corresponding `.dcua` and `.dcuil` files for that assembly. A `.dcuil` file is roughly equivalent to a Delphi `.dcu` file, but a `.dcua` file does not have a corresponding file type in the Delphi for Win32 universe.

Different project types produce different types of .NET assemblies: A Delphi `program` produces an executable assembly; a `library` project produces a DLL assembly.

## The Intermediate Language

The Common Language Runtime is an implementation of a virtual execution system, or virtual machine. Like all virtual machines, the CLR has its own abstract microprocessor. As already mentioned, the assembly language of the virtual processor is called Common Intermediate Language (CIL), although before being promoted as a standard it was called Microsoft Intermediate Language (MSIL), a terms you'll still see around often. Compilers that target the CLR do not generate code in the native instruction set of any specific, real microprocessor. Instead, .NET compilers target the abstract processor of the CLR. The hardware abstraction built into the CLR hints at some cross-platform viability. Remember, Microsoft's CLR is but one implementation of the CLI; any hardware/operating system platform that has a CLI-compliant execution environment built for it could be targeted.

Of course, there is no real microprocessor that can execute CIL directly, so it must be compiled to the instruction set of the native hardware prior to execution. This is the job of the Just in Time (JIT) compiler. Here is where the CLR differs from other virtual machine implementations (like Java). The CLR is not an interpreter, nor does it execute bytecode. On the .NET platform, CIL is always compiled to native CPU instructions, and once compiled it is cached in memory; so chances are good that it will never have to be recompiled.

**Note** In some memory-constrained environments (such as a PDA), compiled code can be discarded. In this case, the code would need to be recompiled if it was ever reloaded.

Compiling IL is not a very expensive operation (MS Research has spent years developing technology to allow the JIT compilation to be as negligible as possible) but does imply a little overhead and it must be repeated every time you run even the same program. Most applications will see a little increase in startup time (what's particularly slow is loading all the .NET framework itself with the first .NET application run in a Windows session); however, this is limited because not all code in an application is compiled at once. The JIT compiler works in conjunction with the loader, and so IL code is not compiled until it is called (on a method by method basis).

JIT compilation is the normal case on the .NET platform, but it is possible to compile a managed executable into native instructions and store the native image on disk. By doing so, you avoid the negative impact of JIT compilation on your application's startup time. The .NET Framework runtime contains a utility called the Native Image Generator (`Ngen.exe`) to accomplish this.

The native image created by Ngen is stored in the native image cache. The next time the CLR tries to load the assembly, it looks in the native image cache first. If a native image of the assembly is found, it is preferred over the IL version. Note that you must also deploy the IL version of the assembly, because the native image does not contain any metadata. In addition, the end user or administrator could remove your native image from the cache. In this case, there would be no native image to find, and the CLR would revert back to the usual JIT compilation of the IL version.

The ability to generate a native executable image can be helpful, but you should profile your application under both environments (JIT and native image) to see whether the detrimental effects of the JIT compiler are that bad. The JIT compiler is, after all, a real compiler for a specific microprocessor, and as such it can do some performance optimizations of its own. It employs good algorithms to reduce its overhead and also introduces optimizations to the compiled code (somewhat like Delphi does in its compilations).

Looking over the IL code generated by your compiler can be highly educational. Microsoft provides a utility called the IL Disassembler (`ildasm.exe`) that you can use to dissect your assemblies at the lowest level. Located in the `bin` directory of your .NET Framework SDK installation, `ildasm` can load any assembly and its metadata: the manifest, the classes, their methods and properties, and, of course, the IL code generated by the compiler. We will look more at ILDASM in this chapter and the next. The Reflector tool mentioned earlier is also useful in this regard.

## Managed and Safe Code

Simply put, *managed code* is any code that is loaded, JIT compiled, and executed under the auspice of the CLR. Like all executable and library modules on the Windows platform, managed code modules are stored in Microsoft's Portable Executable (PE) file format. A managed PE file contains additional header information and, when loaded, jumps into the runtime's execution engine (to a function in `MSCorEE.dll`).

The runtime initializes, and then it looks for the module's entry point. The IL code in the entry point is JIT compiled to native CPU instructions. Finally, execution begins at the module's entry point. The situation is similar for a library module; the PE file directs the loader to jump to a different function in `MSCorEE.dll`.

In contrast, *unmanaged code* consists not of IL, but rather of traditional, native CPU instructions. Unmanaged code executes outside of the runtime and therefore can't take advantage of the services provided by the CLR—at least not without special measures.

Unmanaged code can create .NET Framework classes using COM Interop services. The .NET Framework class is wrapped in a COM proxy and exposed to unmanaged code as if it were a COM object. The COM Interop bridge goes the other way too, allowing a COM objects in a COM server to be accessed by managed code. Finally, the Platform Invoke services of the CLR allow managed code to call the Win32 API directly.

**Note** The Delphi for .NET Preview compiler produces fully managed code. There is currently no support for mixing managed and unmanaged (native) code within the same module, as you can with Microsoft's Visual C++ .NET (which uses a mechanism called IJW: It Just Works).

A module is completely self-describing, because it contains both IL code and metadata that describes the data elements used by the code. Taking the IL code and the metadata together, the CLR can perform another level of verification beyond the static checking done by the compiler. This process, which is always performed unless a system administrator turns it off, verifies that code is type safe. Verifiably type-safe code is known as *safe code*. Safe code passes the following type-safety checks:

- Only valid operations are invoked on objects. This includes parameter validation, return type verification, and visibility checks.
- Objects are always assigned to compatible types.
- The code uses no explicit pointers, as they might refer to invalid memory locations.

As you'd expect, *unsafe code* fails to pass these checks. But, just because code is not verifiably type safe does not mean it is unsafe; it simply means the code could not be verified, either due to a limitation in the verification process, or perhaps in the compiler itself. When it will be released as a finished product, the Delphi for .NET compiler is expected to generate verifiably type-safe code.

Some Delphi language constructs are not CLS compliant, but this is different than not being verifiably type safe. Non-CLS-compliant language constructs will be covered more in [Chapter 25](#).

The .NET Framework SDK contains a PEVerify utility that exhaustively analyzes a managed PE for type safety (`peverify.exe`). The Delphi 7 IDE plug-in mentioned previously lets you automatically run PEVerify on your code after every build.

## The Common Type System

The Common Type System (CTS) is the bulldozer that levels the playing field for programming languages in the .NET framework. The CTS fully specifies the primitive types and object types known to the CLR. These types are used to define an object model that is shared among all languages that target the CLR.

The Component Object Model (COM) has been the usual way to achieve binary compatibility and language interoperability on the Windows platform. The CTS goes beyond that, allowing languages as different as Eiffel, C#, and Delphi to integrate with each other. Components written in these disparate languages can pass objects among themselves and directly extend their capabilities through inheritance. This level of integration of programming languages is unprecedented.

All types defined by the CTS fall into two categories: value types and reference types. Value types, as their name implies, have pass-by-value semantics. For example, say you have a variable that is a value type. If you pass this variable as a parameter to a function and modify the parameter within the function, the original variable will be

unaffected. Examples of value types include scalar types, enumerations, and records. Aggregate types such as Delphi records (or C# structures) are known as value classes within the CTS.

On the other hand, reference types have alias, or pass-by-reference, semantics. If you have a variable that is a reference type (for example, an instance of a class) and you pass that variable as a parameter to a function, any changes you make to the parameter will also affect the variable. Examples of reference types include class types and interfaces. Pointer types are also reference types, as are delegates, which will be discussed shortly.

## Objects and Properties

Like Delphi, the CTS implements a single-inheritance model. A class must inherit from one and only one ancestor and may declare itself to be an implementer of zero or more interfaces. Other familiar object-oriented attributes of the CTS are private, public, and protected visibility of classes and class members (with other visibility specifiers available, as discussed in the [next chapter](#)). These CTS visibility specifiers have meanings similar to those in Delphi; however, they are more restricted, in line with C++ semantics. (In [Chapter 25](#) we'll look at how Delphi's visibility specifiers map to the CTS versions, and examine the specific changes made to the language thus far to accommodate additional features of the CTS.)

As you peruse the .NET literature, you will notice similarities between the capabilities of CTS class types and Delphi classes. The traditional object-oriented features of fields and methods are supported, of course. In addition, the CTS implements properties in a way that is conceptually similar to the familiar Delphi notion. Properties in CTS can have read and write access methods that restrict or compute values on the fly, or they can simply mask private fields. However there are also many differences, including the fact that property get/set methods must have the same visibility as the property itself to ensure languages that don't support property syntax can still access the property. Although Delphi doesn't enforce this in the source code, it modifies compiled code behind the scenes if necessary.

## Events and Delegates

One reason the Win32 API has survived so long is that at its lowest levels it is based on fundamental concepts, such as using the address of a function as a callback mechanism. The entire Windows user interface event system is based on callback functions (and some of events in the VCL framework are built on top of even that system). The callback mechanism is so powerful that it surely must make its way into the CTS. Using callbacks in a type-safe, language-neutral way relies on a reference type called a *delegate*.

CTS delegates are different from ordinary function pointers, in that they can reference both static and instance methods of a class. The declaration of a delegate must match the signature of the methods the delegate will reference. In Delphi for .NET, usage of delegates is similar to that of familiar procedural types:

```
type
  TMyClass = class
  public
    procedure myMethod;
  end;

var
  threadDelegate: System.Threading.ThreadStart;
  tmc: TMyClass;
  aThread: System.Threading.Thread;

begin
  tmc := TMyClass.Create;
  threadDelegate := @tmc.myMethod;
  aThread := Thread.Create (threadDelegate);
  aThread.Start;
```

The `threadDelegate` variable is of type `System.Threading.ThreadStart`, which is a CLR delegate class. Methods you assign to a delegate have a signature matching the delegate's, which in this case is a procedure taking no parameters. (You can find this code snippet in the `Delegate` sample folder.)

The compiler is hiding a lot of complexity here. Behind the scenes, the compiler must create an instance of the class `System.MulticastDelegate`. The delegate—the function being encapsulated (`myMethod` in this case)—is invoked using methods on the `MulticastDelegate` class. This class supports the simultaneous encapsulation of multiple functions in a single delegate. In a user interface event model, this translates to having multiple listeners for an event.

**Note** Incidentally, the fact that delegates are classes tells you why you can declare a delegate outside the scope of a class. Because delegates are instances of `System.MulticastDelegate` (or a compiler-generated descendant class), you can declare them anywhere you can declare a class.

Each specific language compiler implements some form of semantic sugar to make the creation of events and the addition and removal of event listeners less painful. For example, in C#, Microsoft used the `+=` and `-=` operators to add and remove functions from the underlying delegate. Delphi for .NET uses set semantics for the same purpose. In [Chapter 25](#) we'll explore this topic, showing how the functions `Include` and `Exclude` are used to assign event handlers. We'll also look at how Delphi's `:=` assignment operator works, with regard to assigning event handlers in the .NET universe.

## Garbage Collection

The garbage collector is that part of the CLR that performs automatic management of memory allocation and deallocation. All Delphi 7 offers in this respect is reference counting for interface-based variables (see [Chapter 2](#) for details). When there are no more references to an object, the memory for it is reclaimed. This is also the basic idea of the CLR garbage collector, but the similarities stop there. The CLR's garbage collector can detect that two objects are still referring one to the other, but there is no other reference to them, so they can be discarded, something a reference counting system (like the one in Delphi) fails to handle.

Using a GC means you can create objects, reference one from another as you need, and simply forget about the hassles of deleting those objects. The system will do all that's needed for you. That's all you really need to know. Note that this implies that you don't need to *balance* object creation and destruction in your code architecture, nor do you need to use `try/finally` blocks to make sure objects are destroyed; these are just a couple of specific circumstances in which you'll benefit from a GC.

Only when you need to write low-level classes will you have to remember to free unmanaged resources, such as window or file handles. The CLR class `System.Object` contains a protected `Finalize` method that you can override to free up unmanaged resources. You must be aware of some important things before you begin overriding `Finalize`. (If you want some in-depth information on this topic, see the sidebar "[Issues with Overriding Finalize.](#)")

---

### Issues with Overriding Finalize

Overriding the `Finalize` method is inefficient because it requires your object to make at least two trips through the garbage collector. The job of the garbage collector is to reclaim memory, and it can't do this until it runs your object's `Finalize` method. So, the garbage collector must give special treatment to all objects with `Finalize` methods. It puts them on a special list, which has the side effect of keeping them alive through this round of garbage collection (because there is now another reference to the object). Eventually, a thread walks through the special list, runs each object's `Finalize` method, and removes the object from the list. Removing the object from the list takes away the last reference to it, so next time the garbage collector runs, the object's memory can be reclaimed.

But inefficiency is not the only problem with finalizers. You also can never be sure when your object's finalizer will run. If you are relying on the `Finalize` method to give back unmanaged resources, the object might hold onto these resources longer than you expect.

When `Finalize` runs, it does not run in the same thread of execution as your object. This means all thread synchronization and blocking must be avoided, because it's not your thread you are blocking, it's the CLR's finalizer thread. On a related note, if an exception is thrown from `Finalize` the CLR catches it, not you, and the exception will be swallowed.

---

The recommended approach for freeing up unmanaged resources is to implement the dispose pattern. This is a strategy for providing an object both an automatic way to dispose the external resources it refers to when it is garbage collected and also a way to free the same resources upon the direct invocation of a method. In real terms, coding this pattern equates to implementing an interface called `IDisposable`. `IDisposable` consists of one method: `Dispose`. The `IDisposable` interface gives you deterministic control over freeing up resources used in your objects. Unlike `Finalize`, the `Dispose` method is public and is meant to be called by you (or users of your class), not by the garbage collector.

You may have read .NET literature explaining how the C# language implements destructor semantics by having the compiler create a `Finalize` method on your class behind the scenes. To implement the `IDisposable` interface in C#, you must do so directly and wire everything so that the `Dispose` method can be called directly or from the automatically generated `Finalize` method. This is not the way things work in Delphi for .NET.

Creating a destructor for your class does not cause the compiler to implement a finalizer behind the scenes. Instead, it causes the compiler to implement the `IDisposable` interface. But nothing is stopping you from implementing `IDisposable` directly, so if you want to rely on the compiler's behind-the-scenes magic, you must follow a strict pattern. Your class destructor must be declared exactly as shown here:

```
destructor Destroy; override;
```

When the compiler sees this declaration, it generates code to mark your class as an implementor of `IDisposable`. Then, using a feature of CIL, your destructor is marked as the implementation of the `Dispose` method (this can be done even though the name of the method is `Destroy`, not `Dispose`).

The usual way to dispose of objects in Delphi is to call the `Free` method on the object. In Delphi for .NET, the `Free` method is implemented so that it tests to see whether the object implements the `IDisposable` interface. If you follow the previous destructor signature, the compiler implements it for you; `Free` then calls `Dispose`, which winds up in your `Destroy` method.

Let's create a project and declare a class with a destructor that follows the pattern. Then you'll use ILDASM to inspect the generated code. The code is available in [Listings 24.1](#) and [24.2](#).

### **Listing 24.1: The Project of the DestructorTest Example**

---

```
program DestructorTest;  
  
{ $APPTYPE CONSOLE }  
  
uses  
  MyClass in 'MyClass.pas';  
  
var  
  test : TMyClass;  
  
begin  
  WriteLn ('DestructorTest starts');  
  test := TMyClass.Create;  
  test.Free;  
  WriteLn ('DestructorTest ends');  
end.
```

---

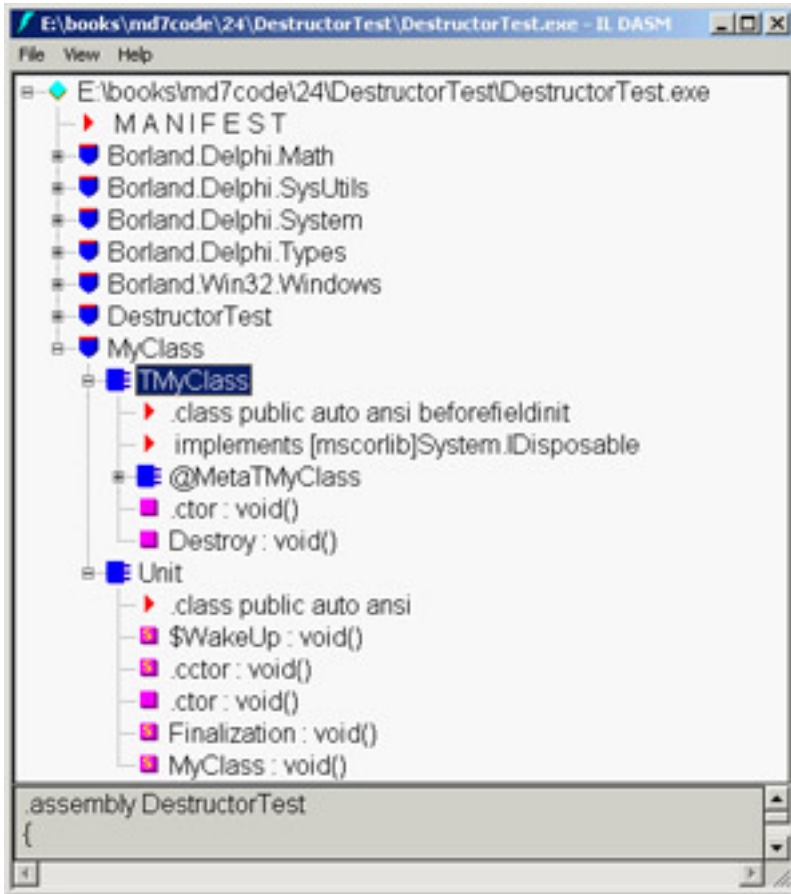

### **Listing 24.2: The Unit of the DestructorTest Example**

---

```
unit MyClass;  
  
interface  
  
type  
  TMyClass = class  
    public  
      destructor Destroy; override;  
    end;  
  
implementation  
  
destructor TMyClass.Destroy;  
begin  
  WriteLn ('In destructor (which is actually the IDisposable.Dispose method)');  
end;
```

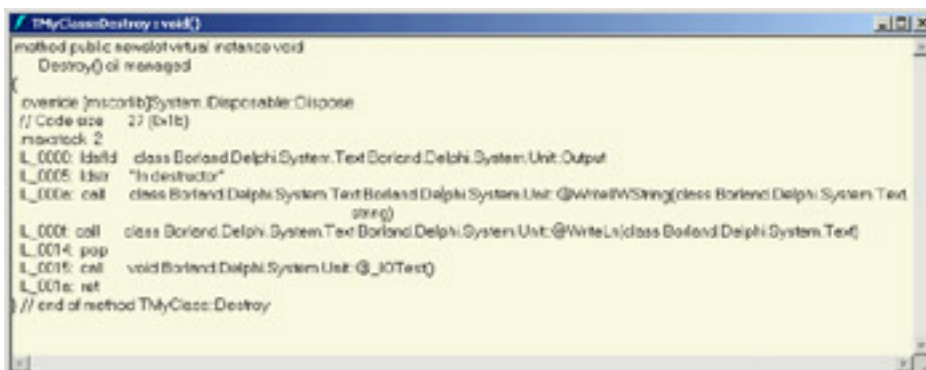

end.

After compiling this program you can run it; but we are not so much interested in running the program as in inspecting it with ILDASM. Start ILDASM and select File | Open. Navigate to the directory where `DestructorTest.exe` is located, and open it. You will see a window similar to that shown in [Figure 24.2](#).

**Figure 24.2:** The ILDASM output for the DestructorTest example

The tree entry labeled `MyClass` represents the namespace created to hold all the symbols in the unit. Expand the `MyClass` node and notice the entries for `TMyClass` and `Unit`. Delphi for .NET creates a CLR class for each unit to implement initialization and finalization and also to let you still write global routines; they become methods of that `Unit` class. Expand the node for `TMyClass` and notice the `Destroy` node, which has a pink block. This node represents the `Destroy` method in `TMyClass`. Double-click the `Destroy` node to open a window displaying the full IL code for this method, as shown in [Figure 24.3](#).

**Figure 24.3:** The ILDASM IL window for the `Destroy` destructor

The line you're looking for uses the `.override` directive:

```
.override [mscorlib]System.IDisposable::Dispose
```

This is an explicit override, and it says that the `Destroy` method is the implementation of `Dispose` in the `IDisposable` interface. The `.override` directive is how the thread of execution winds up in your destructor when `Dispose` is called from `Free`.

**Note** The way `IDisposable` was dealt with illustrates a familiar pattern in the ongoing work on the Delphi for .NET compiler. Unlike C#, Delphi is an old language with a large and loyal following and a sizable existing code base. Borland could not sweep everything aside and mandate a new way of doing things that would break all existing code. The implementation of `IDisposable` was done in a way that should allow Delphi programmers to continue using familiar paradigms and minimize the impact of porting their existing code to the .NET platform.

## Garbage Collection and Efficiency

Among programmers, the use of a garbage collector (GC) is the topic of many debates. Most programmers like the fact that a GC helps them reduce the chance of memory management errors. Some programmers, though, fear that a GC might not be efficient enough, a fear that often prevented the widespread use of this technology. The inefficient GC of the early Java virtual machines didn't really help in this respect. Even Microsoft has a hard time convincing all programmers to use its GC, up to the point that they overrate their solution depicting it as perfect. Even in Microsoft technical documentation about the GC, you'll find lots of hype and little facts.

**Note** This is not to say that the GC doesn't do an adequate job; quite the contrary. But it works differently than it is presented. At present, your only way to know how the GC works is to write test case programs and study their effect.

As a starting point for your exploration, you can use the `GarbageTest` example. Use a Windows memory analysis tool to see how the memory is affected by program execution. The `GarbageTest` example declares the following class of large objects (about 10 KB):

```
type
  TMyClass = class
  private
    data: Integer;
    list: array [1..10240] of Char;
    s: string;
  public
    constructor Create;
  end;
```

The simplest test code is the following:

```
for i := 1 to 10000 do
begin
  mc := TMyClass.Create;
  WriteLn (mc.s);
end;
```

Writing this simple program in Delphi will flood the memory, because there is no call to `Free`. In .NET, however, the GC reuses the single memory block, so memory consumption is flat. If you save each object in an array declared as `objlist: array [1..10000] of TMyClass;`

the memory consumption will increase at each cycle of the loop, causing problems! Keeping the object references in memory and then releasing them regularly or randomly can provide more complex tests. You'll find a few snippets in

the program code, but you'll have to exercise your knowledge and imagination to build other significant test cases.

## Deployment and Versioning

Most Windows software developers have at some point felt the pain caused by deploying shared libraries. The .NET Framework can adapt to a number of different deployment scenarios. In the simplest scenario, the end user can copy files to a directory and go. When it's time to remove the application from the machine, the end user can remove the files, or the entire directory, if it doesn't contain any data. In this scenario there is no installer, no uninstaller, and no registry to deal with.

**Tip** You can package your application for the Microsoft Installer if you want to and still deploy to a single directory, with no Registry impact.

Outside of the easy scenario, the deployment options become complex and a bit bewildering, because the problem itself is complicated. How do you enable developers to deploy new versions of shared components, while at the same time ensuring that the new version won't break an application that depends on behavior provided by a prior version? The only answer is to develop a system that allows differing versions of the same component to be deployed *side-by-side*.

The first thing you need to learn about deployment in the .NET Framework is that the days of deploying shared components to `C:\Windows\System32` are gone. Instead, the .NET Framework includes two kinds of assemblies, well-defined rules governing how the system searches for them, and an infrastructure that supports the deployment of multiple versions of the same assembly on the same machine.

Before talking about the two kinds of assemblies, I will explain the two kinds of deployment:

**Public, or Global** A publicly deployed assembly is one you intend to share either among your own applications or with applications written by other people. The .NET Framework specifies a well-known location in which you are to deploy such assemblies.

**Private** A privately deployed assembly is one you do not intend to share. It is typically deployed to your application's base installation directory.

The type of assembly you create depends on how you intend to deploy it. The two types of assemblies are as follows:

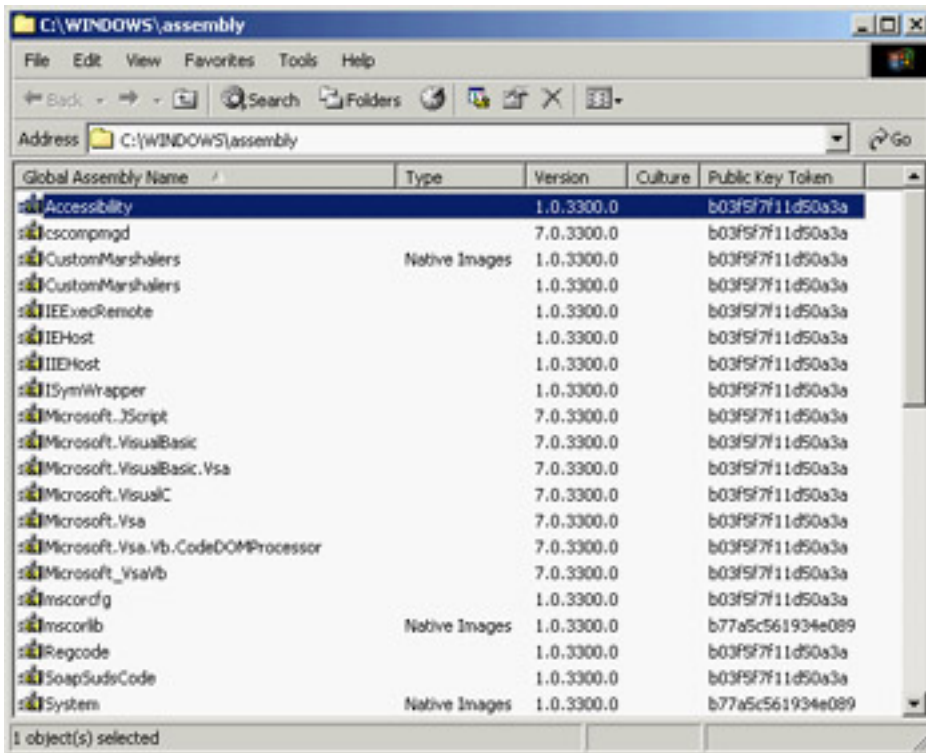

**Strong Name Assemblies** A strong name assembly is digitally signed. The signature consists of the assembly's identity (name, version, and optional culture plus a key pair with public and private components). All global assemblies must be strong name assemblies. The name, version, and culture are attributes of the assembly, stored in its metadata. How you create and update these attributes depends largely on your development tools.

**Everything Else** There is no official name for an assembly that does not have a strong name. An assembly that does not have a strong name can only be deployed privately, and it cannot take advantage of the side-by-side versioning features of the CLR.

The key pair that completes the signing of a strong name assembly is generated by a tool provided by the .NET Framework SDK, called SN (`sn.exe`). SN creates a key file, which is referenced by the assembly in an attribute. The signing of an assembly can only take place when it is created, or *built*. However, in the form of signing called *delayed signing*, developers work only with the public part of the key. Later, when the final build of the assembly is prepared, the private key is added to the signature. Currently the Delphi for .NET compiler is weak on custom attributes. Because attributes are required to express the identity and reference the key file, support for strong name assemblies isn't quite complete at the time of writing.

Strong name assemblies are usually intended to be shared, so you deploy them in the Global Assembly Cache (GAC) (but they can be deployed privately as well). Because the GAC is a system folder with a specialized structure, you can't just copy the assembly there. Instead, you must use another tool contained in the .NET Framework runtime, called GACUTIL (`gacutil.exe`). GACUTIL installs files into and removes files from the GAC.

The GAC is a special system folder with a hierarchy that supports side-by-side deployment of assemblies, as you can see in [Figure 24.4](#). The intent is to hide the structure of the GAC so you don't have to worry about the complexities involved. GACUTIL reads the assembly's identity from its metadata and uses that information to construct a folder within the GAC to hold the assembly.

**Figure 24.4:** .NET's Global Assembly Cache as seen in Windows Explorer

**Note** You can see the true folder hierarchy by opening a command window and navigating to the `C:\Windows\assembly` directory. This hierarchy is hidden from you if you use Windows Explorer to view it.

When you create a reference to a strong name assembly in the GAC, you are creating a reference to a specific version of that assembly. If a later version of that same assembly is deployed on the machine, it will be put into a separate location in the GAC, leaving the original intact. Because your assembly referenced a specific version, that's the version it always gets.

## What's Next?

Your reaction to the .NET initiative will depend on your programming background. If you come from the Java environment, from a traditional Windows tool (even if object-oriented), or from Delphi, you may find many new features or many concepts you are already familiar with. The .NET platform is a technical achievement that offers a staggering array of options and possibilities. Compared with the earlier Microsoft system interfacing technologies (the Windows API and COM), the progress is significant. The best part is that you can take advantage of the platform using the tools and languages you feel are best for the job, soon including Delphi.

In [Chapter 25](#) we will examine specific changes to the Delphi language. We will look at deprecated features and types, new features that have already been added to the language, and examples demonstrating the use of .NET Framework classes from Delphi for .NET.

## Chapter 25: Delphi for .NET Preview: The Language and the RTL

### Overview

The [last chapter](#) introduced Microsoft's .NET architecture. Now it is time to focus on the Delphi for .NET Preview that ships with Delphi 7. This chapter will cover specific changes that were made to the Delphi language to make it compatible with the Common Language Runtime. There have been some important additions to the language, such as namespaces and new visibility specifiers. Other long-standing features of the language had to be dropped because they are not supported in a type-safe environment.

This chapter discusses areas of the new compiler including the use of some of Microsoft's own class libraries for .NET and ASP support.

Bear in mind that the Delphi for .NET compiler is still being crafted as I write this. Borland's plan was to release the Preview compiler with Delphi 7 and to provide periodic updates to registered Delphi customers throughout the remainder of 2002 and in the early 2003 (before the Galileo project is completed). Some of the language features discussed here may not be implemented, or may be in varying states of completeness, depending on which version of the compiler you are working with. At the end of this chapter I list web resources you can monitor to keep abreast of the changes and latest news regarding Borland's Delphi for .NET compiler.

**Note** As was true in [Chapter 24](#), most of this material comes from John Bushakra.

## Deprecated Delphi Language Features

We will begin by looking at some of the Delphi features that had to be dropped (deprecated) in order to be compatible with the Common Language Runtime (CLR). Then we'll look at new features added (or planned) in Delphi for .NET, which will shape the Delphi language in the near future, possibly also on the Win32 and Linux platforms.

### Deprecated Types

Some of Delphi's types will not survive the transition to a managed, virtual execution system. So far, the following types are either known to be deprecated or have uncertain fates:

**Pointers** Pointers are considered unsafe types by the CLR, and all forms of pointer arithmetic are forbidden. *Unsafe* means the code cannot be verified for type safety. The final version of the Delphi for .NET compiler may support unsafe, unmanaged pointers, but in the meantime you can use dynamic arrays to get back some of the functionality of the (also deprecated) `GetMem`, `FreeMem`, and `ReallocMem` functions.

**Types Based on *file of <type>*** File types based on the old Pascal *file of <type>* syntax cannot be supported because the compiler has no way to determine the size of a given type on the target platform.

**Pre-Delphi *Object Syntax*** The pre-Delphi *object* syntax has been deprecated and will not be supported in the final release of the compiler. This syntax was introduced back in the Turbo Pascal era and allowed you to declare a new class with the syntax `type MyClass = object;`. Variables of this type were stack-based, contrary to the heap-based class type objects.

**Real48 and Comp** These types won't be supported. Real48 type is a 6-byte floating-point type. The Comp type will be replaced by Int64 in the future, as noted in the Delphi 7 Language Reference.

### Strings and Other Types

The following types, although not candidates for deprecation, will have changes made to their underlying implementation. These changes are almost transparent, but you can expect slightly different behavior in some circumstances:

**Strings** In Delphi for .NET, strings map to the CLR type `System.String` and are wide by default. This means they use 16 bits per character, like the `WideString` type in Delphi 7. In addition, all characters are wide by default.

**Records** Records are mapped to value types. [Chapter 24](#), "The Microsoft .NET Architecture from the Delphi Perspective," talked about the two main categories of types specified by the Common Type System (CTS): reference types and value types. A record will be a value type on the .NET platform. The CLR demands that value types cannot have inheritance, but you can define methods on them (which, of course, is completely new to the Delphi language). Methods defined on value types must be declared as `final`. (The new `final` keyword is discussed in "[New Delphi Language Features](#)" section.)

**TDateTime** In Delphi, this type is based on the same implementation as Microsoft's DATE type (see [Chapter 2](#), "The Delphi Language," for more details). The .NET platform uses a different implementation. The `System.DateTime` structure (a descendant of `System.ValueType`) measures time from midnight, January 1, 0001 C.E. (Common Era) to 11:59:59 p.m., December 31, 9999 C.E. On this clock, one tick equals 100 nanoseconds. Going forward, Delphi for .NET will transition to the .NET platform standard for measuring time. Date calculations that depend on the floating-point implementation will require your attention when porting to the .NET platform. In particular, if you are

using Delphi's `Trunc` and `Frac` functions to separate the date and time portions of the floating-point value, then you could be in for some interesting bugs in the future.

**Currency** Currency will be mapped to the CLR type `System.Decimal`.

## Deprecated Code Features

As is the case with the types listed in the [previous section](#), some Delphi features that have been part of the language a long time cannot be ported to the .NET platform:

**Variant Records** Variant records with overlapping fields are not supported by the CLR. In general, you can't make any assumptions regarding the layout of fields in a record declaration, because the Just In-Time (JIT) compiler reserves the right to optimize things to suit the underlying platform.

*ExitProc* Things don't always happen when you'd like them to, or in the order you'd like them to. Such problems with unit initialization and finalization have been overcome (although there are still issues to be aware of, as I discuss later in this chapter), but `ExitProc` is not supported.

**Dynamic Aggregation of Interfaces** The CLR doesn't support dynamic aggregation of interfaces using the `implements` keyword, because it cannot be verified for type safety. A class must declare all interfaces it will implement.

**ASM Statements** ASM statements and inline assembly language are not supported by the Delphi for .NET Preview compiler. The future of `asm` in the final version is doubtful. The compiler would have to be able to mix managed IL (Intermediate Language) and unmanaged native CPU instructions, like Microsoft's Visual C++ compiler.

*automated* **Keyword** The `automated` keyword was created to support OLE Automation. It is not needed in the .NET environment. The same is true for the `dispid` keyword, which is used to dispatch COM Automation methods by number instead of by name. Notice that although they're no longer explicitly required, GUIDs are supported on the .NET platform; they appear as custom attributes on a type.

**Direct Memory Access Functions** Direct memory access functions like `BlockRead`, `BlockWrite`, `GetMem`, `FreeMem`, and `ReallocMem`, as well as `Absolute`, and `Addr`, all deal with unmanaged pointers, and so cannot be used with managed, safe code. The `@` operator is available in the current Preview version of the compiler (but is not expected to remain in the final version), although you cannot type cast pointers or do any pointer arithmetic.

**Note** As discussed in [Chapter 2](#), Delphi 7 provides a new set of compiler warnings to help you get ready to port your code. These warnings flag certain features and language constructs that are known to be unsafe on the .NET platform and therefore should be avoided. The warnings are turned off by default for a new Delphi 7 project but are active when you recompile an existing project. You can also turn them on with the `{ $WARN UNSAFE_CODE ON }` compiler directive and similar directives. Refer to [Chapter 2](#) for more details.

## New Delphi Language Features

The first release of the dccil compiler included new features required by the CLR, and more have been added in subsequent updates.

### Unit Namespaces

Namespaces play an important role in the .NET Framework. They allow the class hierarchy to be extended by multiple third parties without fear of conflicting symbol names. Windows and COM use a 16-byte GUID to uniquely identify components, and this magic number must be recorded in the system registry. On the .NET platform, the concept of namespaces—plus metadata and the hard-and-fast rules about locating assemblies—makes GUIDs obsolete.

Ironically, the idea of a Delphi unit is similar to the CLR's namespaces. It's not too far a leap, if you think of a unit as a container of symbols, and a namespace as a container of units. In Delphi for .NET, the namespace to which a unit belongs is declared in the `unit` clause:

```
unit NamespaceA.NamespaceB.UnitA;
```

The dots indicate the containment of one namespace within another, and ultimately of the unit within the namespace. The dots separate the declaration into components, and each component—up to but not including the rightmost one—is a namespace. The entire declaration taken as a whole, dots and all, is the unit name. The dots simply serve as separators; no new symbols are introduced by the declaration. In this example, `NamespaceA.NamespaceB` is the namespace, and `NamespaceA.NamespaceB.UnitA` is the name of the unit. `NamespaceA.NamespaceB.UnitA.pas` would be the name of the source file, and the compiler would produce an output file called `NamespaceA.NamespaceB.UnitA.dcuil`.

The `program` statement (and eventually the `package` and `library` statements) optionally declares the default namespace for the entire project. Otherwise, the project is called a *generic project*, and the default namespace is that specified by the `-ns` compiler option. If no default project namespace is specified with compiler options, then behavior reverts to not using namespaces, like in Delphi 7 (and prior releases).

The `unit` clause does not have to declare membership in any explicit namespace. It might look like a traditional Delphi statement:

```
unit UnitA;
```

A unit that does not declare membership in a namespace is called a *generic unit*. Generic units automatically become members of the project namespace. Note, however, that this does not affect the source filename.

**Warning** At the time of this writing, namespace support is very limited; this section describes how it should work in the future, rather than how it works now.

In the project file, you can specify a `namespaces` clause to list a set of namespaces for the compiler to search when it is trying to resolve references to generic units. The `namespaces` clause must appear immediately after the `program` (or `package` or `library`) statement and before any other clause or block type. The namespaces are separated by commas, and the list is terminated with a semicolon. For example:

```
program NamespaceA.MyProgram
  namespaces Foo.Bar, Foo.Frob, Foo.Nitz;
```

This example adds the namespaces `Foo.Bar`, `Foo.Frob`, and `Foo.Nitz` to the generic unit search space.

This discussion leads up to showing you how the compiler searches for generic units when you build your program. When you use a unit and fully qualify its name with the full namespace declaration, there is no problem:

```
uses Foo.Frob.Gizmos;
```

The compiler knows the name of the `dcuil` file (or the `.pas` file) in this case. But suppose you only said the following:

```
uses Gizmos;
```

This is called a *generic unit reference*, and the compiler must have a way to find its `dcuil` file.

The compiler searches namespaces in the following order:

1. The current unit namespace (if any)
2. The default project namespace (if any)
3. The namespaces listed in the project's `namespaces` clause (if any)
4. The namespaces specified by compiler options

For the first item, if the current unit specifies a namespace, then subsequent generic unit references in the current unit's `uses` clause are looked for first in the current unit's namespace. Consider this example:

```
unit Foo.Frob.Gizmos;  
uses doodads;
```

The first search location for the unit `doodads` would be in the namespace `Foo.Frob`. So, the compiler would try to open `Foo.Frob.Doodads.dcuil`. Failing this, the compiler would move on and prefix the unit name `doodads` with the default project namespace, and so on down the list.

The same symbol name can appear in different namespaces. When such ambiguity occurs, you must refer to the symbol by its full namespace and unit name. If you have a symbol named `Hoozitz` in unit `Foo.Frob.Gizmos`, you can refer to the symbol with either

```
Hoozitz; // if the name is unambiguous  
Foo.Frob.Gizmos.Hoozitz;
```

but not with

```
Gizmos.Hoozitz; // error!  
Frob.Gizmos.Hoozitz; // error!
```

Unit and namespace names can become quite long and unwieldy. You can create an alias for the fully qualified name with the `as` keyword in the `uses` clause:

```
uses Foo.Frob.DepartmentOfRedundancyDepartment.UIToys as ToyUnit;
```

Unit aliases introduce new identifiers, so their names cannot conflict with any other identifiers in the same unit (aliases are local to their unit). Even if you declare an alias, you can still use the original, longer name to refer to the unit.

**Note** The case of a namespace declaration is preserved and emitted into assembly metadata as is. However, as far as Delphi is concerned, two namespaces that differ only in case are equivalent.

## Extended Identifiers

The cross-language integration of the CTS and CLR brings up some interesting situations for compiler developers. For example, what if the name of an identifier in an assembly is the same as one of your language keywords? Consider the Delphi language keyword `type`. `Type` is also the name of a CLR class. Because `type` is a language keyword, it cannot be used as the name of an identifier. You can avoid this problem two ways in Delphi for .NET (these techniques were not implemented in Delphi 7 and previous versions).

First, you can use the fully qualified name of the identifier:

```
var  
  T: System.Type;
```

The second, shorter way is to use the new ampersand operator (&) to prefix the identifier. The following has the same effect as the previous example:

```
var
  T: &Type;
```

In this statement the ampersand tells the compiler to look for a symbol with the name `Type` and to not consider it as a keyword. The compiler will look for the `Type` symbol in the available units, finding it in `System` (the same mechanism works regardless of the unit defining the symbol).

## The *final* and *sealed* Keywords

Two more concepts specified by the Common Language Infrastructure (CLI) have been added to the Delphi for .NET compiler: the class attribute `sealed` and the method attribute `final`. Putting the `sealed` attribute on a class effectively ends the class's ability to be used as a base class. Here is a sample code snippet:

```
type
  TDeriv1 = class (TBase)
    procedure A; override;
  end sealed;
```

A class cannot derive from a class that has been sealed. Similarly, a virtual method marked with the `final` attribute cannot be overridden in any descendant class, as in the following sample code.

```
type
  TDeriv1 = class (TBase)
    procedure A; override; final;
  end;

  TDeriv2 = class (TDeriv1)
    procedure A; override; // error: "cannot override a final method"
  end;
```

Borland added the `sealed` and `final` keywords to map an existing feature of .NET, but why did Microsoft introduce these attributes? The `final` and `sealed` attributes give users of your code important insights into how you intend your classes to be used. Moreover, these attributes give the compiler hints that allow it to generate more efficient Common Intermediate Language (CIL).

## New Visibility and Access Specifiers

Delphi's notion of visibility—public, protected, and private—is a bit different from that of the CLI. In languages like C++ and Java, when you specify a visibility of private or protected on a class member, that class member is only visible to descendants of the class in which it is defined. As you saw in [Chapter 2](#), however, Delphi enforces the idea of private and protected only for classes in different units, because everything is visible within a single unit. To be CTS compliant, the language required new visibility specifiers:

*class private* A member declared with class private visibility follows the C++ and Java rules. That is, class private members can be accessed only in methods or properties of the declaring class. Procedures and functions declared at the unit level and methods of other classes do not have access.

*class protected* Similarly, class protected members are visible only within the declaring class, and to descendants of the declaring class. Other classes in the same unit have access only if they inherit from this class.

See the `ProtectedPrivate` example in the `LanguageTest` folder of the chapter's source code for a trivial test case.

## Class Static Members

Delphi has long supported class methods—methods you can apply to a class as a whole and also as a specific instance, even if the methods' code cannot refer to the current object (the `Self` parameter of a class methods references the current class, not the current object). Delphi for .NET extends this idea by adding the `class static` specifier, class properties, class static fields, and class constructors:

**Class Static Methods** Like Delphi 7 class methods, class static members can be called without an object instance, and no `Self` parameter refers to an object. Unlike in Delphi 7, however, you cannot refer to the class itself. For example, calling the `ClassName` method will fail. Also unlike in Delphi 7, you cannot use the `virtual` keyword with class static methods.

**Class Static Properties** Like class methods, class static properties can be accessed without an object instance. The access methods or backing fields for class static properties must be declared class static themselves. Class static properties cannot be published, nor can they have stored or default value definitions.

**Class Static Fields** A class static field can be accessed without an object instance. Class static fields and properties are typically used as design tools; they allow you to declare variables and constants within the meaningful context of a class declaration.

**Class Constructor** A class constructor is a private constructor (it must be declared with class private visibility) that runs prior to the first use of the declaring class. The CLR offers no guarantee of when this will happen, except to say it will happen before the first use of the class. In CLR terms, this can get a bit tricky, because code is not considered "used" unless (and until) it is executed. A class can declare only one class constructor. Descendants can declare their own class constructors, but only one can be declared in any class.

You can't call a class constructor from source code; it is called automatically as a way to initialize class static fields and properties. Even the `inherited` keyword is prohibited, because the compiler takes care of this for you.

The following example class declaration illustrates the syntax for these new specifiers:

```
TMyClass = class
class private // can only be accessed within TMyClass
    // Class constructor must have class private visibility
    class constructor Create;
class protected // can be accessed in TMyClass and in descendants
    // Class static accessors for class static property P1, below
    class static function getP1 : Integer;
    class static procedure setP1(val : Integer);
public
    // fx can be called without an object instance
    class static function fx(p : Integer) : Integer;
    // Class static property P1 must have class static accessors
    class static property P1 : Integer read getP1 write setP1;
end;
```

## Nested Types

Nested types are similar to class fields, in that they can be accessed through a class reference; an object instance is not needed. Declared within the scope of a class, nested types give you a way to use the enclosing class as a kind of namespace for the type.

## Multicast Events

Delphi has always had the ability to set an event listener—a function that is called when an event is fired. The CLR supports the use of multiple event listeners so that more than one function can respond when an event is fired. These are called *multicast events*. Delphi for .NET introduces two new property access methods, `add` and `remove`, to support multicast events. The `add` and `remove` methods can be used only on properties that are events.

To support multicast events, you must have a way to store all the functions that register themselves as listeners. As stated in [Chapter 24](#), multicast events are implemented using the CLR `MulticastDelegate` class. And, as discussed there, the compiler hides a lot of complexity behind the scenes. The `add` and `remove` keywords handle the storage and removal of event listeners, but the containment mechanism is an implementation detail you aren't expected to deal with. The compiler automatically generates `add` and `remove` methods for you, and these methods implement storage of event listeners in an efficient way.

In the final release of Delphi for .NET, the `add` and `remove` methods should work hand in hand with an overloaded version of the standard functions `Include` and `Exclude`. In your source code, when you'd want to register a method as an event listener, you call `Include`. To remove a method, call `Exclude`. For example:

```
Include(EventProp, eventHandler);  
Exclude(EventProp, eventHandler);
```

Behind the scenes, `Include` and `Exclude` will call the methods assigned to the `add` and `remove` access functions, respectively. At the time of this writing, this technology wasn't working, so the book examples don't use it.

To support legacy code, the Delphi assignment operator (`:=`) still works as a way to assign a single event handler. The compiler generates code to go back and replace the last event handler (and only that event handler) that was set with the assignment operator. The assignment operator works separately and independently from the `add/remove` (or `Include/Exclude`) mechanism. In other words, the use of the assignment operator does not affect the list of event handlers that have been added to the `MulticastDelegate`.

As an example, you can refer to the `XmlDemo` program. The following code snippet (the working code at the time of this writing) creates a button at run time and installs two event handlers for its `Click` event:

```
MyButton := Button.Create;  
MyButton.Location := Point.Create (  
    Width div 2 - MyButton.Width div 2, 2);  
MyButton.Text := 'Load';  
MyButton.add_Click (OnButtonClick);  
MyButton.add_click (OnButtonClick2);  
Controls.Add (MyButton);
```

## Custom Attributes

Recall from [Chapter 24](#) that one of the requirements of the CLI is an extensible metadata system. All .NET language compilers are required to emit metadata for the types defined within an assembly. The *extensible* part of extensible metadata means that programmers can define their own attributes and apply them to just about anything: assemblies, classes, methods, and more. The compiler emits these into the assembly's metadata. At run time, you can query for the attributes that were applied to an entity (assembly, class, method, and so on) using the methods of the CLR class `System.Type`.

Custom attributes are reference types derived from the CLR class `System.Attribute`. Declaring a custom attribute class is just like declaring any other class (this code snippet is extracted from the trivial `NetAttributes` project part of the `LanguageTest` folder):

```
type  
    TMyCustomAttribute = class(TCustomAttribute)  
    private
```

```

    FAttr : Integer;
public
    constructor Create(val: Integer);
    property customAttribute : Integer read FAttr write FAttr;
end;
...
constructor TMyCustomAttribute.Create(val: Integer)
begin
    inherited Create;
    customAttribute := val;
end;

```

The syntax for applying the custom attribute is similar to that of C#:

```

type
    [TMyCustomAttribute(17)]
    TFoo = class
public
    function Pl(X : Integer) : Integer;
end;

```

The custom attribute is applied to the construct immediately following it. In the example, it is applied to the class `TFoo`. No doubt you noticed that the custom attribute syntax is nearly identical to that of Delphi's GUID syntax. Here we have a problem: GUIDs are applied to interfaces; they must immediately *follow* the interface declaration. Custom attributes, on the other hand, must immediately *precede* the declaration to which they apply. How can the compiler determine whether the thing in the square brackets is a traditional Delphi-style GUID (which should be applied to the preceding interface declaration) or a .NET-style custom attribute (which should be applied to the first member of the interface)?

There is no way to tell, so you have to punt—make a special case for custom attributes and interfaces. If you apply a GUID to an interface, it must immediately follow the declaration of the interface, and it must follow the established Delphi syntax:

```

type
    interface IMyInterface
    ['(12345678-1234-1234-1234-1234567890ab)']

```

CLR's `GuidAttribute` custom attribute is used to apply GUIDs; it is part of the `System.Runtime.InteropServices` namespace. If you use this custom attribute to apply a GUID, then you must follow the CLR standard and put the attribute declaration before the interface.

## Class Helpers

Class helpers are an intriguing new language feature added to Delphi for .NET. The main reason for supporting class helpers is the way Borland maps .NET core classes with its own RTL classes, as covered later in the section "[Class Helpers for the RTL](#)." Here I will focus on this feature from a language perspective.

A class helper gives you a way to extend a class without using derivation, by adding new methods (but not new data). The odd fact, compared to inheritance, is that you can create objects of the original class, which is extended maintaining the same name. This means you can *plug-in* methods to an existing object of an existing class. A simple example will help clarify the idea.

Suppose you have a class (probably one you haven't written yourself—otherwise you could have extended it right away) like this:

```

type
    TMyObject = class
private
    Value: Integer;

```

```
Text: string;  
public  
  procedure Increase;  
end;
```

Now you can add a `Show` method to objects of this class by writing a class helper to extend it:

```
type  
  TMyObjectHelper = class helper for TMyObject  
  public  
    procedure Show;  
  end;  
  
procedure TMyObjectHelper.Show;  
begin  
  WriteLn (Text + ' ' + IntToStr (Value) + ' -- ' +  
    Self.ClassType.ClassName + ' -- ' + ToString);  
end;
```

Notice that `Self` in the class helper method is the object of the class that the helper is for. You can use it like this:

```
Obj := TMyObject.Create;  
...  
Obj.Show;
```

You'll end up seeing the name of the `TMyObject` class in the output. If you inherit from the class, however, the class helper will also be usable on the derived class (so you end up adding a method to an entire hierarchy), and everything will work properly. For your experiments, refer to the `ClassHelperDemo` example in the `LanguageTest` folder.

## The Run-time Library and VCL

Located in the `source\rtl` directory of the Delphi for .NET Preview installation, you will find the source files for the run-time library (RTL). You can already see the migration of units into CLR namespaces, as reflected in the source filenames.

Borland is taking the approach (for the most part) of preserving the original unit name and prefixing it with the namespace name `Borland.Delphi`. Operating system–specific things (such as registry and `ini` file utilities) go in the `Borland.Win32` namespace, because these classes, procedures, and functions are Borland-specific wrappers of Windows-specific features. The naming trend should continue, although not all units will make the transition, and some will have their contents reorganized into an appropriate namespace.

Perusing the RTL source files is both highly educational and highly recommended; however, remember that you are looking at a preview release of a product, not the final version. The contents of the RTL source files are still subject to change—you should not make any assumptions, and you should definitely not introduce dependencies into your own code based on what you see there.

### Class Helpers for the RTL

With the warnings out of the way, let's see what has been done to the RTL so far. The most interesting change is perhaps the introduction of class helpers.

`Borland.Delphi.System.pas` includes the following declaration:

```
type
  TObject = System.Object;
```

It tells you that Delphi's `TObject` class is an alias for the CLR class `System.Object`. This is important: `TObject` is not a descendant of `System.Object`—it is semantically equivalent. What happened to the methods that used to be defined in `TObject`, such as `ClassName` and `ClassParent`? That's where the class helper comes in.

The methods that used to be directly declared and implemented in `TObject` are now declared and implemented in a class called `TObjectHelper`. `TObjectHelper` is then declared to be a class helper for `TObject`. In `Borland.Delphi.System.pas` is the following:

```
type
  TObjectHelper = class helper for TObject
    procedure Free;
    function ClassType: TClass;
    class function ClassName: string;
    class function ClassNameIs(const Name: string): Boolean;
    class function ClassParent: TClass;
    class function ClassInfo: TObject;
    class function InheritsFrom(AClass: TClass): Boolean;
    class function MethodAddress(const Name: string): TObject;
    class function SystemType: System.Type;
    function FieldAddress(const Name: string): TObject;
    procedure Dispatch(var Message);
  end;
```

A class helper gives you a way to extend a class without using derivation.

You might want to extend a CLR class but not derive from it in order to use the CLR class with existing Delphi code. No doubt you've noticed that Delphi's class framework and the .NET Framework share a fair amount of functionality. In some cases there are name clashes between the two—for example, Borland's `Exception` class and the CLR's `System.Exception` class. On one hand, the two classes do basically the same thing, but they expose that

functionality in different ways. On the other hand, large amounts of existing Delphi code have been using Borland's `Exception` class for a long time.

The only workable solution was to create a mechanism that would allow developers (including Borland) to leverage the CLR classes, and that would also allow the CLR classes to be extended to include long-standing behaviors expected by existing Delphi code.

## The VCL

The .NET Framework classes in the `System.Windows.Forms` namespace are not a replacement for the GUI portion of the Win32 API. The same happens with most other portions of the .NET Framework: its role is to make the underlying API easier to use by providing an easier object-oriented interface compatible with the core services of the .NET environment. The GUI subset of Win32 is still there, occupying the same place it always has. `System.Windows.Forms` organizes this GUI subset of the Win32 API, presents it in an object-oriented way, and layers an event model on top of it; but classes in `System.Windows.Forms` call the unmanaged code in Win32. When you use `System.Windows.Forms`, you are still calling the Win32 APIs, but now you have a large layer of software called the CLR sitting between your code and Win32.

This entire preamble is important to acknowledge why the VCL takes this same approach. `TObject` is rooted (if you will) from `System.Object` through the use of a class helper. `TPersistent` and `TComponent` still descend from there. Thus the VCL class `TForm`, for example, is not a descendant of the class `System.Windows.Forms.Form`. Instead, the entire VCL hierarchy remains much as it is today. `TForm` will ultimately descend from `TWinControl`, which itself is a descendant of `TControl` and then `TComponent`.

If you consider the entire `System.Windows.Forms` namespace as a single entity, the VCL then becomes a kind of sibling to it, rather than a child of it. Both frameworks ultimately rely on the native, unmanaged Win32 API for the underlying implementation of the user interface controls.

## Looking into the VCL.NET Source

The update of the Delphi .NET Preview compiler made available by Borland in November 2002, although still preliminary, provides details about the architecture the company is planning. If you open the `Borland.Vcl.Controls` unit, you'll be surprised by its similarity to the Win32 version. The source code is almost identical; the differences exist behind the scenes at the `TObject` and `TComponent` level. I've already covered the former, so let's focus on the core component class, which is defined in three steps:

### type

```
TComponent = System.ComponentModel.Component;  
TComponentHelper = class helper (TPersistentHelper) for TComponent  
TComponentSite = class(TObject, ISite, IServiceProvider)
```

The `TComponent` class corresponds to the .NET Framework class, with a helper providing extra methods and properties and a further class offering the extra data required by the helper class. The situation is complex, and I don't want to get into the details because the `TComponent` class is marked as experimental and may change in further updates.

Getting back to the VCL, a large set of components is already available, so you can begin porting code. The only trouble you'll face with the November 2002 update is that streaming is not supported; so, you must add the component-creation code in the form constructor (an action that will not be required by the final version of Delphi for .NET).

As an interesting example to help you figure out the architecture of the VCL classes, I've ported to .NET the `ClassInfo` example from [Chapter 3](#), "The Run-Time Library." The `NetClassInfo` example uses this modified code in the project source (again, something you won't have to do in the future):

```
Application.Initialize;  
Form1 := TForm1.Create (Application);  
Application.MainForm := Form1;
```

The code for the form, as I've mentioned, has an extra method called by the constructor and used to initialize the controls. This method is quite long, so I'll provide only a few excerpts here:

```
procedure TForm1.InitializeControls;  
begin
```

```

// creating all controls...
Label3:= TLabel.Create(Self);
Panell:= TPanel.Create(Self);
Label1:= TLabel.Create(Self);
Label2:= TLabel.Create(Self);
...

// setting form properties and events
Left:= 217;
Top:= 109;
Caption:= 'Class Info';
OnCreate:= FormCreate;

// initializing controls (only one is listed here)
with Label3 do
begin
    Parent:= Self;
    Left:= 8;
    Top:= 8;
    Width:= 56;
    Height:= 13;
    Caption:= 'Class Name';
end;

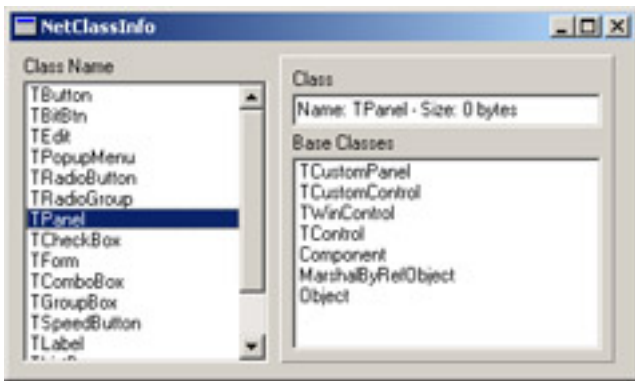

```

The rest of the application's code remains almost identical, which is surprising considering that this is a low-level example. I had to remove the call to `InstanceSize`, because the compiler cannot resolve the size of an object given the architecture of .NET, and I had to test for the base class against `Object` instead of `TObject`. Here is the code snippet that produces the output shown in [Figure 25.1](#):

```

procedure TForm1.ListClassesClick(Sender: TObject);
var
    MyClass: TClass;
begin
    MyClass := ClassArray [ListClasses.ItemIndex];
    EditInfo.Text := Format ('Name: %s - Size: %d bytes',
        [MyClass.ClassName, 0 {MyClass.InstanceSize}]);
    with ListParent.Items do
    begin
        Clear;
        while MyClass.ClassName <> 'Object' do
        begin
            MyClass := MyClass.ClassParent;
            Add (MyClass.ClassName);
        end;
    end;
end;

```

**Figure 25.1:** The NetClassInfo example shows the base classes of a given component.

## Further VCL Examples

To provide starting points for your own experiments with the VCL under .NET, I've built two more examples. NetEuroConv is a port of the EuroConv example from [Chapter 3](#) based on the RTL's conversion engine. NetLibSpeed is a port of the LibSpeed example used in [Chapter 5](#) ("Visual Controls") to compare the VCL and VisualCLX libraries' speed in creating visual components. The number you'll see makes little sense in such a preliminary version of a library, although the fact that VCL.NET takes four to five times as long for the same purpose may worry you.

As I mentioned, these examples are meant to be only starting points for your experiments. They may not work with further updates of the Delphi for .NET Preview.

**Note** Stay tuned to my website for updates of this section of the book and the related examples.

## Using Microsoft Libraries

The VCL is not quite ready, but you can use the .NET Framework class library as a basis for experimentation with the Delphi for .NET Preview compiler. It can be educational to build programs with the compiler and then inspect them with Intermediate Language Disassembler (ILDASM), for instance. This will be the aim of this section. If you want to look at a simpler example using XML support, refer to the `XmlDemo` mentioned earlier in the chapter.

The `CLRReflection` program opens an assembly and then uses reflection to inspect the modules and types defined within that assembly. This program demonstrates using a common dialog box (the `OpenFileDialog`), constructing menus, handling events, using Delphi's dynamic arrays, and, of course, reflection. Let's look at the project file first:

```
program CLRReflection;

uses
  System.Windows.Forms,
  ReflectionUnit;

var
  reflectForm : ReflectionForm;
begin
  reflectForm := ReflectionForm.Create;
  System.Windows.Forms.Application.Run(reflectForm);
end.
```

The code looks almost like a good old VCL application. You define a variable for your main form, and then you create the form. Then you use the `Run` method of the .NET Framework class `System.Windows.Forms.Application`. Here the code is analogous (at least in concept) to the way it is done in the VCL.

Note that throughout this example I have given the fully qualified name for .NET Framework classes. I did so to make sure you know where these classes are located. Because the `uses` clause includes `System.Windows.Forms`, you could shorten the expression

```
System.Windows.Forms.Application.Run(reflectForm);
```

to

```
Application.Run(reflectForm);
```

Now, look at [Listing 25.1](#), which shows the unit where the main form is defined. Note that this code compiles with the November 2002 update of the Delphi for .NET Preview, but not with the version originally shipping with Delphi 7.

### Listing 25.1: The `ReflectionUnit` Unit of the `CLRReflection` Example

    module: System.Reflection.Module;
    types: array of System.Type;
    t: System.Type;
    members: array of System.Reflection.MemberInfo;
    m: System.Reflection.MemberInfo;
    i,j,k: Integer;
    s: String;
begin
    try
        { Clear the listbox }
        typesListBox.BeginUpdate;
        typesListBox.Items.Clear;

        { Load the assembly and get its modules }
        assy := System.Reflection.Assembly.LoadFrom(fileName);
        modules := assy.GetModules;

        {For every module, get all types }
        for i := 0 to High(modules) do
            begin
                module := modules[i];
                types := module.GetTypes;

                { For every type, get all of its members }
                for j := 0 to High(types) do
                    begin
                        t := types[j];
                        members := t.GetMembers;

                        { for every member, get type information and add to list box }
                        for k := 0 to High(members) do
                            begin
                                m := members[k];
                                s := module.Name + ':' + t.Name + ':' + m.Name +
                                    ' (' + m.MemberType.ToString + ')';
                                typesListBox.Items.Add(s);
                            end;
                        end;
                    end;
                end;
            end;
        typesListBox.EndUpdate;
    except
    end;

```

```
except
    System.Windows.Forms.MessageBox.Show('Could not load the assembly.');
```

---

```
end;
end;

end.
```

The unit begins by declaring its dependency on .NET Framework `dcuil` files and on the `Borland.Delphi.SysUtils` unit. From there it goes straight into declaring the class for the main form, which is a descendent of the .NET Framework class, `System.Windows.Forms.Form`. The form class layout looks familiar: You have member variables for all the controls, and these are declared to be of types found in the .NET Framework class library.

The functions `exitItemClick` and `openItemClick` are event handler declarations. The signature of event handler methods is specified by the CLR. All event handlers are procedures that take two parameters: the object that fired the event (a derivative of `System.Object`) and the event arguments, which are wrapped in the `System.EventArgs` (or a derived) class. (You will see how to hook up these event handlers in a moment.)

Let's move on to the class constructor. I must call attention to the first statement in the constructor, which calls `inherited Create`.

**Warning** Here you see a major departure from the .NET Framework way of life, compared to what you are used to with the VCL and with Delphi in general. In Delphi, the constructor initializes member variables, putting the object instance into a known-good state; it does not do any memory allocation. So, it is not uncommon to see a constructor make assignments and then call the inherited constructor. Indeed, you might not call the inherited constructor at all. In Delphi for .NET, you can't get away with this approach. In your constructor, you must call `inherited Create`, and it must be the method's first executable statement. Currently, if you fail to do so, you will get a compiler error saying that `Self` is uninitialized and that the inherited constructor must be called prior to accessing any ancestor fields.

After calling the inherited constructor, you are back in familiar territory. Although this code uses a different class hierarchy, it should be clear to any Delphi programmer. You make an instance of `System.Windows.Forms.OpenFileDialog` by calling the `Create` constructor—this is how you create an instance of any .NET Framework class.

The next few lines demonstrate setting properties, both of the `OpenFileDialog` object instance and of the form itself. Finally, you add two controls (a label for the filename and the `ListBox` that will hold the assembly) to the form's `Controls` collection, which is a property of type `Control.ControlCollection`.

The `InitializeMenu` procedure demonstrates allocation and layout of a `System.Windows.Forms.MainMenu` object instance. Where the File menu is initialized, a dynamic array holds each menu item. The dynamic array is then passed to the `AddRange` method. This code could have been accomplished by calling the `Add` method separately for each menu item.

The next interesting thing in `InitializeMenu` is the wiring of the menu item event handlers. In [Chapter 24](#) and earlier in this chapter, I mentioned the behind-the-scenes complexity involved with delegates and multicast events. Here you see some of that complexity coming to the foreground.

You can't do it yet in Delphi for .NET, but in other .NET languages such as C#, you can use the language keyword `event` to introduce an event handler delegate. The event declaration specifies a delegate to use as a callback mechanism. Because the event is a `System.MulticastDelegate` derivative (a `System.EventHandler` delegate in this case), other objects can add and remove event handlers, and these handlers are called when the event fires.

The C# language adds a bit of syntactic sugar to help this pill go down more easily. C# defines `+=` and `-=` operators for adding and removing event handlers, respectively. Eventually Delphi will get its own spoonful of sugar, with the `Include/Exclude` mechanism mentioned previously. CTS mandates that all .NET compilers targeting this event

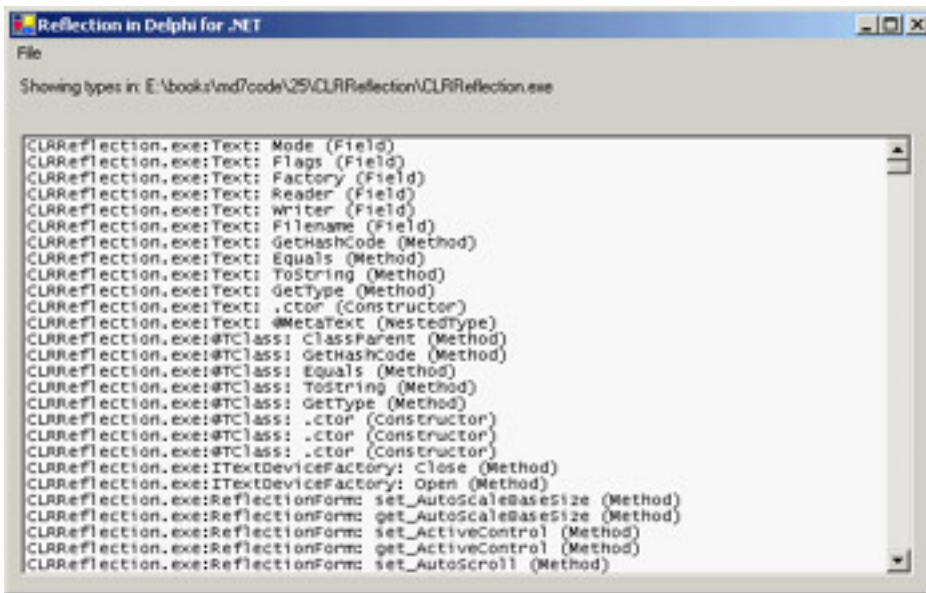

model must generate methods named `add_<Event>` and `remove_<Event>`. These `add_` and `remove_` methods wrap the `Combine` and `Remove` methods declared in `System.Delegate`.

For now, to assign an event handler, you must use these `add_` and `remove_` methods; ordinarily, you would not concern yourself with them, because the compiler would hide this complexity. In the current class declaration, you introduce two methods whose signatures match the `System.EventHandler` delegate: `openItemClick` and `exitItemClick`. You then call the `add_Click` method on the respective menu item, passing your event handler as the callback method.

Now that the setup is out of the way, let's look at the code that reflects over the types defined within an assembly. You can load any assembly (thus creating an object instance), given its filename, with the static `LoadFrom` method. Once you have an assembly object, the keys to the kingdom are yours; you can use reflection to look over the assembly from any angle.

The collection of modules contained within an assembly is available with the `GetModules` method. From there you can drill down to the types defined in the module with `GetTypes`. As you saw in the `InitializeMenu` procedure, you can use dynamic arrays for properties that expose a collection with a `System.Array`.

Finally, each individual member of the module and types arrays contains a `Name` property, which you can use to build a string to display in the `ListBox`. The final effect of the code is visible in [Figure 25.2](#).

```
CLRReflection.exe:Text: Mode (Field)
CLRReflection.exe:Text: Flags (Field)
CLRReflection.exe:Text: Factory (Field)
CLRReflection.exe:Text: Reader (Field)

```

**Figure 25.2:** The `CLRReflection` example, with an assembly loaded

## ASP.NET with the Delphi Language

You might like it or not (I'm not that fond of it), but Microsoft's ASP technology plays a significant role in the development of web applications, as least on the Windows platform. With the transition to ASP.NET, this technology has fully embraced the .NET Framework; now, with the availability of a Delphi compiler for .NET, the Delphi language can be your language of choice in the development of ASP applications.

To create a test, configure IIS to support ASP.NET (I won't cover these steps, which are beyond the scope of this book, but you can find more information on [www.asp.net](http://www.asp.net)) and then place in the target folder the `web.config` file distributed by Borland along with the Delphi for .NET Preview (and available in the `aspx` subfolder). This configuration file defines the mapping of the language to a specific library, again provided by Borland. The core of the file (which uses XML format) has the following elements:

```
<compilation debug="true">
  <assemblies>
    <add assembly="DelphiProvider" />
  </assemblies>
  <compilers>
    <compiler language="Delphi" extension=".pas"
      type="Borland.Delphi.DelphiCodeProvider,DelphiProvider" />
  </compilers>
</compilation>
```

To test that the configuration is correct, nothing is better than trying an example. Create a new file (I've called mine `asppbase.aspx`, available in the `DelphiAsp` folder of the chapter source code) and type something like the following:

```
<html>
<body>

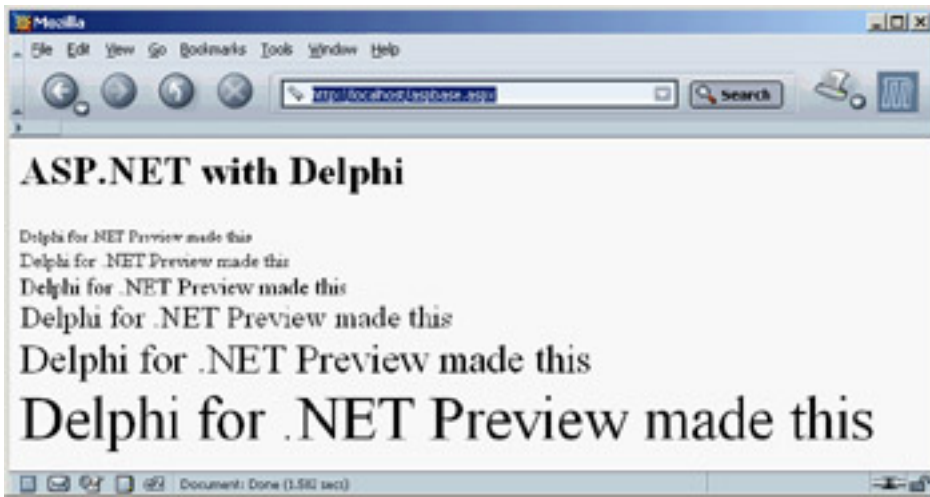

<h1>ASP.NET with Delphi</h1>

<script language="Delphi" runat="server">
procedure HelloMessage(msg: string);
var
  i: Integer;
begin
  for i := 2 to 7 do
    Response.Write ('<font size=' + inttostr (i) +
      '>' + msg + '</font> <br>')
end;
</script>

<% HelloMessage('Delphi for .NET Preview made this'); %>

</body>
</html>
```

The effect is to execute the Delphi code after transforming this file into a .NET source, compiling it with the Delphi preview compiler, and compiling the IL into assembly code (remember, even scripts in .NET are compiled before they are executed). If everything goes well, the browser should display output like that shown in [Figure 25.3](#).

**Figure 25.3:** The `aspbase.aspx` example in a browser

From this point on, you can do anything an ASP.NET application provides. The only other example I want to show you is the use of controls with event handlers, which I've covered in a different situation for .NET applications based on Windows forms.

This example, saved in the `aspui.aspx` file in the `AspDelphi` folder, uses HTML to define a form with a textbox (that is, an edit control) and a button, plus an output label. The button has a Delphi language event handler attached to it, which moves the user input to the label (the output of the program appears in [Figure 25.4](#)):

```
<html>
<body>

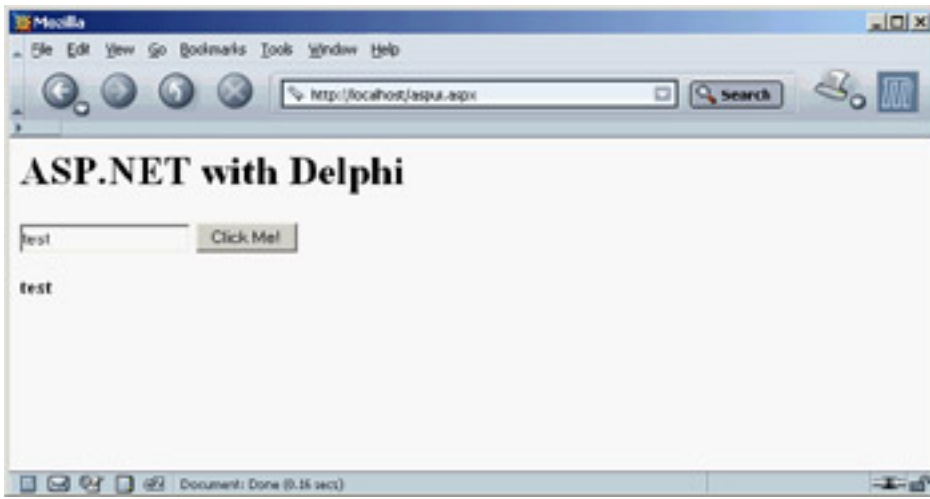

<h1>ASP.NET with Delphi</h1>

<script language="Delphi" runat="server">
  procedure ButtonClick(Sender: System.Object; E: EventArgs);
  begin
    Message.Text := Edit1.Text;
  end;
</script>

<form runat="server">
  <asp:textbox id="Edit1" runat="server"/>
  <asp:button text="Click Me!" OnClick="ButtonClick" runat="server"/>
</form>

<p><b><asp:label id="Message" runat="server" text="message"/></b></p>

</body>
</html>
```

**Figure 25.4:** The output of the `aspui.aspx` example, after typing in the edit box and clicking the button

This has been a limited introduction to ASP.NET with the Delphi language provider. However, it should give you a feeling for the possibilities opening up for Delphi programmers in this new world of .NET.

## What's Next?

While you're waiting for the Delphi for .NET product, currently code-named Galileo, you can begin experimenting with the Delphi for .NET Preview that ships with Delphi 7 (and the subsequent updates made available by Borland). Of course, you should stay tuned to Borland's Developer Network website ([bdn.borland.com](http://bdn.borland.com)) and newsgroups and to the author's site for update information about this area of Delphi, which is definitely a work in progress.

Just as Borland wants to provide the best tools to developers, I hope this book has helped you master Delphi, the most successful tool Borland has brought to the market in the last few years. Remember to check from time to time the reference, foundations, and advanced material I've collected on my website ([www.marcocantu.com](http://www.marcocantu.com)). Much of this material could not be included in this book, because of space constraints; see [Appendix C](#), "Free Companion Books on Delphi," for more information.

[Appendixes A](#) and [B](#) discuss some of the add-ins I've built, which are freely available on my site, and a few other notable free Delphi tools. Also check my site for updates and integration of the material in the book, and feel free to use the newsgroups hosted there for your questions about the book and about Delphi in general.

## Appendix A: Extra Delphi Tools by the Author

### Overview

During the last few years I have developed a number of small components and Delphi add-in tools. Some of these tools were written for books or were the result of extending examples from books. Others were written as a helper for repetitive operations. All these tools are available for free, and some include the source code. This appendix provides a list, including in particular tools mentioned in the book. Support for all these tools is available on my newsgroups (see [www.marcocantu.com](http://www.marcocantu.com) for directions).

## CanTools Wizards

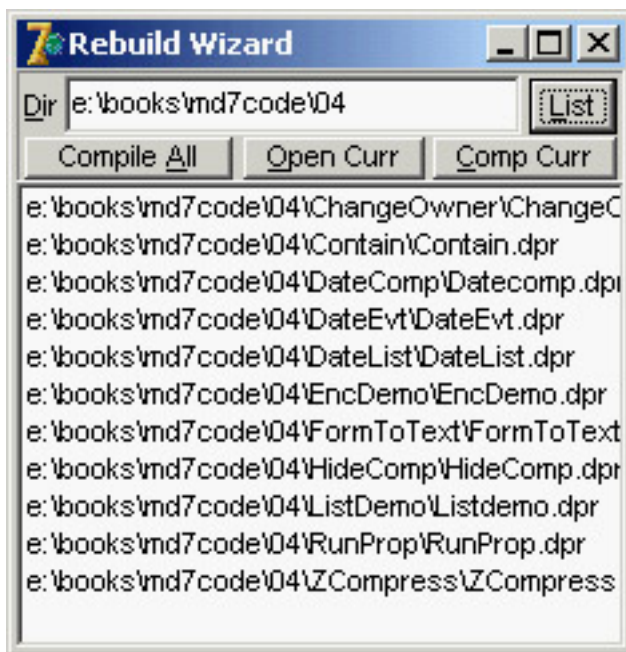

This is a set of wizards you can install in Delphi, either within an extra pull-down menu or as a submenu of the Tools menu). The wizards (freely available at [www.marcocantu.com/cantoolsw](http://www.marcocantu.com/cantoolsw)) are unrelated and offer disparate features:

**List Template Wizard** Streamlines the development of similar list-based classes, each with its own type of objects. This wizard is mentioned in [Chapter 4](#). Because it does a search-and-replace operation on a base source file, it can be used any time you need repeated code and the name of a class (or other entity) varies.

**OOP Form Wizard** (Mentioned in [Chapter 4](#).) Allows you to hide the published components of a form, making your form more object-oriented and providing a better encapsulation mechanism. Start it when a form is active, and it will fill the `OnCreate` event handler. Then you must manually move part of the code into the unit initialization section.

**Object Inspector Font Wizard** Lets you change the font of the Object Inspector (something particularly useful for presentations, because the Object Inspector's font is too small to be seen easily on a projection screen). Another option available in the settings dialog allows you to toggle an internal feature of the Object Inspector and display the font names (in the drop-down combo box for that property) using a specific font.

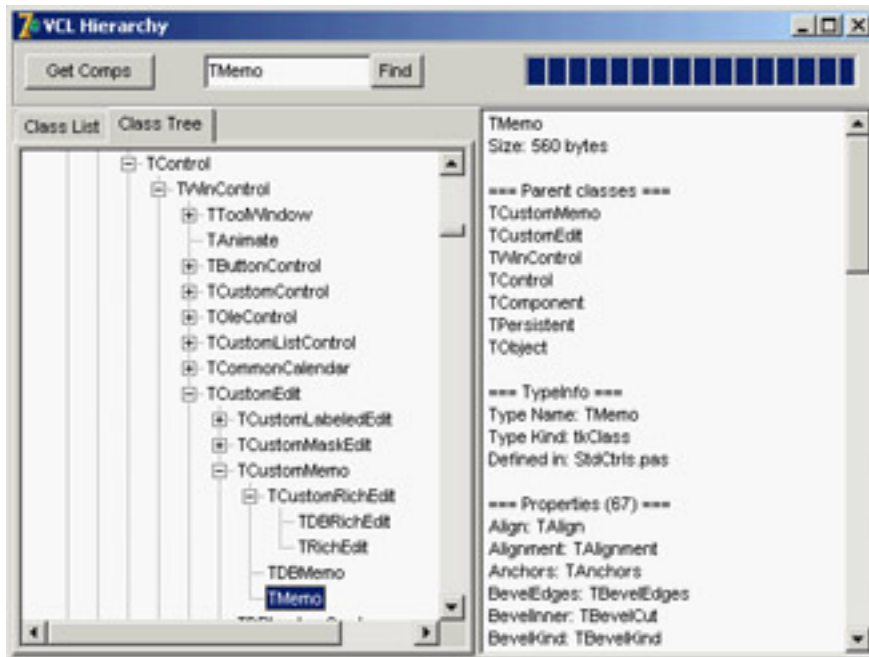

**Rebuild Wizard** Allows you to rebuild all the Delphi projects in a given subfolder after loading each of them in sequence in the IDE. You can use this wizard to grab a series of projects (like those in a book) and open the one you are interested in by clicking on the list:

You can also automatically compile a given project or start a (slow) multiproject build: In the compiler results dialog, you click a button to proceed only if the corresponding environment option is set. If this environment option is not set, you won't see the compiler errors, because the compiler messages are superseded at every compilation.

**Clip History Viewer** Keeps track of a list of text items you've copied to the Clipboard. A memo in the viewer's window shows the last 100 clipped lines. Editing the memo (and clicking Save) modifies this Clipboard history. If you keep Delphi open, the Clipboard will also get text from other programs (but only text, of course). I've seen occasional Clipboard-related error messages caused by this wizard.

**VCL Hierarchy Wizard** Shows the (almost) complete hierarchy of the VCL, including third-party components you've installed, and allows you to search one class and see many details (base and subclasses, published properties, and so on). Clicking the button regenerates both the list and the tree (in sequence—hence the progress bar runs twice):

The list of classes is generated by using predefined core classes (some are still missing; feel free to send suggestions) and then adding each component of the installed packages (Delphi's, yours, third parties'...) along with the classes of all the published properties having a class type. However, classes used only as public properties are not included.

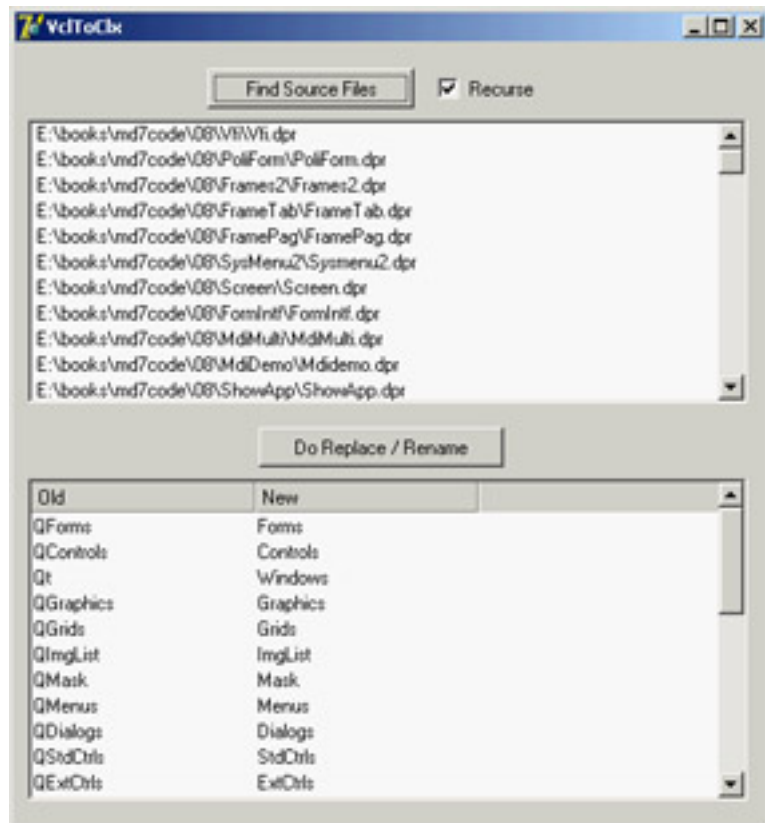

**Extended Database Forms Wizard** Does much more than the Database Forms Wizard available in the Delphi IDE, allowing you to choose the fields to place on a form and also to use a dataset other than those based on the BDE.

**Multiline Palette Manager** Allows you to turn Delphi's Component Palette into a TabControl with multiple lines of tabs:

## VclToClx Conversion Program

You can use this stand-alone tool to convert a Delphi project from VCL to CLX (and vice versa, if you configure it to do so). It can simultaneously convert all the files in a given folder and its subfolders. Here's an example of its output:

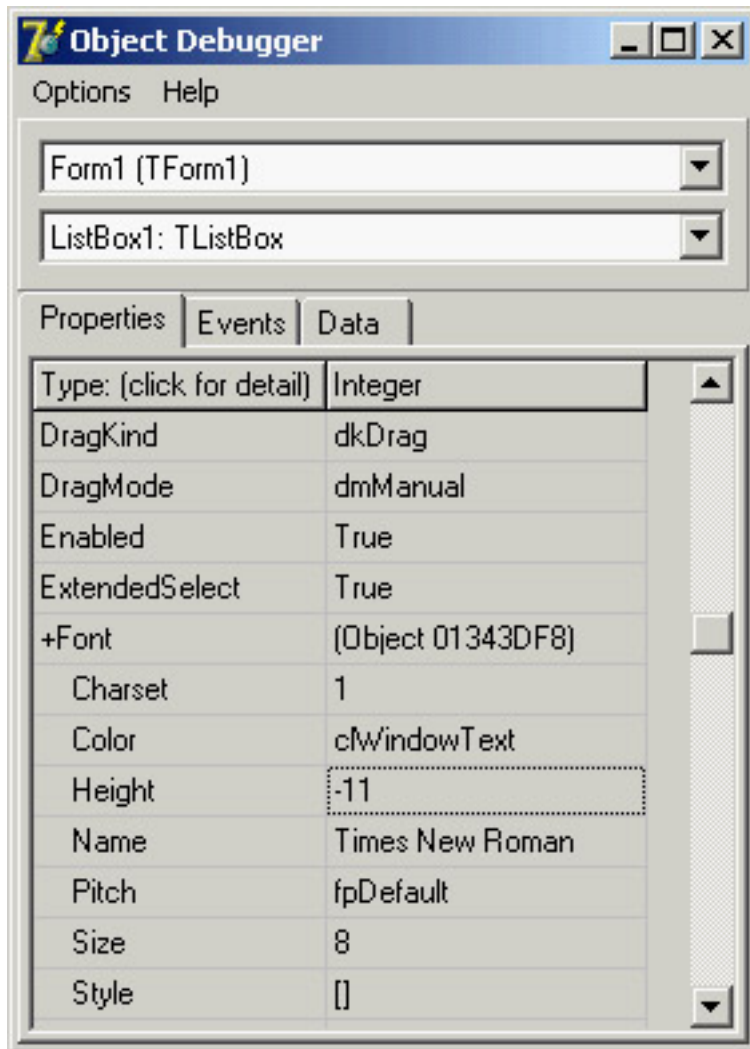

The program's source code is available in the `Tools` folder of the book's source code. The `VclToClx` program converts unit names (based on a configuration file) and handles the DFM issue by renaming the DFM files to XFM and fixing the references in the source code. The program is unsophisticated—it doesn't parse the source code but instead looks for occurrences of the unit names followed by a comma or semicolon, as happens in a `uses` statement. It also requires the unit name to be preceded by a space, but you can modify the program to look for a comma. Don't skip this extra test; otherwise the Forms unit will be converted to `QForms`, but the `QForms` unit will be re-converted to `QQForms`!

## Object Debugger

At design time, you can use the Object Inspector to set the properties of the components of your forms and other designers. In Delphi 4, Borland introduced a run-time Debug Inspector, which has a similar interface and shows similar information. Before Borland added this feature, I implemented a run-time clone of the Object Inspector meant for debugging programs:

It allows read-write access to all the published properties of a component, and has two combo boxes that let you select a form and a component within the form. Some of the property types have custom property editors (lists and so on).

You can place the Object Debugger component on a program's main form (or you can create it dynamically in code): It will appear in its own window. There is room for improvement, but even in its current form this tool is handy and has numerous users.

This component's source code is freely available in the `Tools` folder of the book's source code.

## Memory Snap

There are many tools to track the memory status of a Delphi application. During the development of a project, I had to write such a tool, and afterward I made it available.

I've written a custom memory manager that plugs into Delphi's default memory manager, keeping track of all memory allocations and de-allocations. In addition to reporting the total number (something Delphi also does now by default), it can save a detailed description of the memory status to a file.

Memory Snap keeps in memory a list of allocated blocks (up to a given total number, which can be easily varied), so that it can dump the contents of the heap to a file with a low-level perspective. This list is generated by examining each memory block and determining its nature with empirical techniques you can see in the source code (although they are not easy to understand). The output is saved in a file, because this is the only activity that doesn't require a memory allocation that would affect the results. Here is a snippet of a sample file:

```
157) 00C035CC: object: [TList - 16]
158) 00C035E0: buffer with heap pointer [00C032B0]
159) 00C03730: string: [5-1]: Edit1
160) 00C03744: object: [TEdit - 544]
161) 00C03968: object: [TFont - 36]
162) 00C03990: object: [TSizeConstraints - 32]
163) 00C039B4: object: [TBrush - 24]
164) 00C039F4: buffer with heap pointer [00C01FE4]
165) 00C03B34: buffer with heap pointer [00C01F18]
166) 00C03B48: string: [0-0]: dD
167) 00C03B58: string: [11-2]: c:\mman.log
```

The program could be extended to profile memory usage by type (strings, objects, other blocks), track unreleased blocks, and keep memory allocations under control.

Again, the source code of this component is freely available in the `Tools` folder of the book's source code.

## Licensing and Contributions

As you have seen, some of these tools are available with full source code. They are licensed under the LGPL (Lesser General Public License, [www.gnu.org/copyleft/lesser.html](http://www.gnu.org/copyleft/lesser.html)), which means you can freely use and redistribute them in any way, including making modifications, while the author retains the original copyright. The LGPL doesn't allow you to close-source your extensions, but you can use this library code within programs you sell, regardless of the source code availability. If you extend these tools by fixing bugs or adding new features, I ask you to send your updates to me so I can further distribute the enhancements and we can avoid forking the code into too many versions. The license does not require you to do so, though.

## Appendix B: Extra Delphi Tools from Other Sources

Thousands of Delphi add-on components and tools are available on the market, ranging from simple freebies to large open-source projects, from shareware programs to highly professional components. This appendix provides a list of notable open-source projects I've mentioned elsewhere in the book.

### Delphi Preinstalled Open-Source Components

Delphi 7 includes the source code for two notable open-source projects:

**Internet Direct (Indy)** This project is covered in detail in [Chapter 19](#), "Internet Programming: Sockets and Indy." The official website for Indy is [www.nevrona.com/indy](http://www.nevrona.com/indy), but you should also refer to the Indy Portal at [www.atozedsoftware.com/indy](http://www.atozedsoftware.com/indy). Support is available on Borland's newsgroups.

**Open XML** This is a Delphi-based XML DOM and SAX engine, which I covered in [Chapter 22](#) ("Using XML Technologies"). Refer to [www.philo.de/xml](http://www.philo.de/xml) for updates and more information. Support for Open XML is available on a mailing list you can sign up for on the website.

Delphi also includes a third open-source project: the ZLib compression library, covered in [Chapter 4](#) ("Core Library Classes"). It isn't listed here because it is not Delphi based.

## Other Open-Source Projects

The Delphi programmers' community has been very active since its inception and has produced numerous tools that were and are freely distributed among programmers. A subset of these tools is available with complete source code, as is often true for commercial Delphi components as well.

### Project JEDI

The Joint Endeavor of Delphi Innovators, better known as Project JEDI ([www.delphi-jedi.org](http://www.delphi-jedi.org)), is not a single project but rather is the largest community of open-source Delphi developers. The site hosts its own projects, plus others contributed and maintained by members on separate websites.

Project JEDI started as an effort to translate APIs for specific Windows libraries distributed by Microsoft or other companies. Making available the Delphi units with the declarations of those APIs allowed any Delphi developer to use them easily. More recently, the goals of Project JEDI have been extended with the definition of many subprojects and groups. In addition to an ever-growing API library, you can find projects including the JEDI Visual Component Library (JVCL), the JEDI Code Library (JCL, a set of utility functions and non-visual classes, including a nice un-handled exception stack tracer), plus many projects in the area of graphics, multimedia, and game programming. Other activities range from a JEDI Version Control System client to the DARTH header conversion kit, from a programmer's editor to online tutorials.

Other JEDI-associated projects include Indy (covered earlier), GExperts, and the Delphree site (covered next).

### GExperts

GExperts ([www.gexperts.org](http://www.gexperts.org)) is probably the most widespread add-in for the Delphi IDE, providing features ranging from a multiline Component Palette to source code navigation aids. Self-described as "a set of tools built to increase the productivity of Delphi and C++Builder programmers," it includes a large collection of wizards, including Procedure List, Clipboard History, Expert Manager, Grep Search, Grep Regular Expressions, Grep Results, Message Dialog, Backup Project, Set Tab Order, Clean Directories, Favorite Files, Class Browser, Source Export, Code Librarian, ASCII Chart, PE Information, Replace Components, Component Grid, IDE Menu Shortcuts, Project Dependencies, Perfect Layout, To Do List, Code Proofreader, Project Option Sets, and Components to Code.

### The Delphree Site

There are many other Delphi-related projects in the open-source and community development areas. Although I cannot list all the relevant ones here, I can refer you to a website that tries to track all such projects. The Delphree (Delphi Free) website is available at [delphree.clexpert.com](http://delphree.clexpert.com).

This site has a comprehensive list of Delphi open-source projects, ranging from libraries to programmers' tools to end user applications.

### DUnit

Among the many ideas promoted by extreme programming, I find unit testing particularly interesting. *Unit Testing* is the continuous development of test code even before a program is written. To do this, it is important to have a proper test framework. A group of Delphi programmers created such an architecture, called DUnit. You can find it on SourceForge at [dunit.sourceforge.net](http://dunit.sourceforge.net).

## Appendix C: Free Companion Books on Delphi

### Overview

This is the seventh edition of *Mastering Delphi*, and I've also written other books, material for classes and conference presentations, and much more; so, in addition to the thousand or so pages this book can accommodate, I have a lot of other material about Delphi programming, particularly introductory material. Over the last few years, I've turned this information into electronic books (in HTML or PDF format) available for free on my website. This appendix outlines the titles and their contents, and provides references to the download pages (all hosted on [www.marcocantu.com](http://www.marcocantu.com)).

## Essential Pascal

*Essential Pascal* is an introduction to the foundations of the language invented by Professor Nicklaus Wirth and spread by Borland with its world-famous Turbo Pascal compilers during the 1980s. The 100-page book doesn't cover the OOP extensions, but details many features Borland added to the core language over the years. The following is a list of this e-book's chapters, available at [www.marcocantu.com/epascal](http://www.marcocantu.com/epascal):

Chapter 1: "Pascal History"

Chapter 2: "Coding in Pascal"

Chapter 3: "Types, Variables, and Constants"

Chapter 4: "User-Defined Data Types"

Chapter 5: "Statements"

Chapter 6: "Procedures and Functions"

Chapter 7: "Handling Strings"

Chapter 8: "Memory (and Dynamic Arrays)"

Chapter 9: "Windows Programming"

Chapter 10: "Variants"

Chapter 11: "Programs and Units"

Chapter 12: "Files in the Pascal Language"

Appendix A: "Glossary of Terms"

Appendix B: "Examples"

As you can see on the website, the book has been translated by volunteers into quite a few languages.

## Essential Delphi

*Mastering Delphi* has changed from an introductory text to an intermediate one as I've tried to cover most of the features Borland has added to Delphi over the years. In the process, I had to cut some of the material aimed at programmers who've never used Delphi or a visual tool. This material is now contained in the *Essential Delphi* e-book, freely available in PDF format on my site at [www.marcocantu.com/edelphi](http://www.marcocantu.com/edelphi). Here is the table of contents (which is still under development):

Chapter 1: "A Form Is a Window"

Chapter 2: "Highlights of the Delphi Environment"

Chapter 3: "The Object Repository and the Delphi Wizards"

Chapter 4: "A Tour of the Basic Components"

Chapter 5: "Creating and Handling Menus"

Chapter 6: "Multimedia Fun"

Chapter 7: "Saving Settings: From INI Files to the Registry"

Chapter 8: "More on Forms"

Chapter 9: "Delphi Database 101 (with Paradox)"

Chapter 10: "Printing"

Appendix A: "Essential SQL"

Appendix B: "Common VCL Properties"

# Index

**Note to the Reader:** Throughout this index **boldfaced** page numbers indicate primary discussions of a topic. *Italicized* page numbers indicate illustrations.

## C

C# programming language, [10](#)

C++ programming language, [401–402](#)

CAB files, [34](#), [493](#)

cached updates, [638–642](#)

CacheFile property, [893](#)

caches and buffers

with ClientDataSet, [584](#)

for dataset records, [698–703](#)

in TDataSet, [687](#)

CacheSize property, [630–631](#)

caFree value, [279](#)

caHide value, [279](#)

Calc example, [531–533](#), [533](#)

CalcController component, [733](#)

CalcOp component, [733–734](#)

CalcText component, [729–730](#)

CalcTotal component, [733](#)

CalcType property, [730](#)

calculated fields

adding, [530–533](#), [531](#), [533](#)

internally calculated, [513](#)

calculations in Rave, [733–734](#)

callback functions, [308](#)

callback interfaces, [497–498](#)

callback mechanisms, [910](#)

CallFirst example, [406](#), [407](#)

calling

DLLs, [406](#), [407](#), [408–410](#)

procedures, [409–410](#)

caMinimize value, [279](#)

CancelBatch method, [638](#)

CancelUpdates method, [638](#)

caNone value, [279](#)

CanTools wizards, [945–947](#)

Canvas property, [262](#)

CaptionPlus method, [57](#)

captions and Caption property  
for actions, [222](#)  
inputting, [260](#)  
for menu items, [174](#)  
for property pages, [490](#)  
removing, [258](#)  
in TabSheet, [203](#)  
toolbar, [236](#)

Capture property, [264–265](#)

Cascade method, [312](#)

Cascading Style Sheets (CSS), [764–765](#), [797](#), [859](#)

case-insensitive searches, [602–603](#)

case toggling, shortcut keys for, [16](#)

casting

RTTI for, [67–69](#)

type-safe down-casting, [67–69](#)

categories, property

in Object Inspector, [21–22](#)

registering, [366–367](#), [367](#)

Category property, [222](#), [224](#)

CCLibDir entry, [26](#)

CDATA section, [834](#)

CDK (Component Development Kit), [340](#)

CDS formats, [511](#), [512](#)

cdsCalcFields method, [531–532](#)

CdsCalcs example, [549–553](#), [550](#)

CdsDelta example, [586–588](#), [586](#)

CdsXstl example, [868–869](#)

CFG files, [34](#)

CGI programs, [768–769](#), [769](#)

CgiDate example, [768–769](#), [769](#)

CgiIntra example, [823–824](#)

ChangeAlignment method, [230](#)

ChangeColor method, [476](#)

Changed method, [344](#), [383](#)

ChangedAllowed property, [244](#)

ChangeFamily method, [97](#)

ChangeFormFont property, [344](#), [348](#)

ChangeOwner example, [119–120](#), [120](#)

ChangesToClone property, [712](#)

- character sets in XML, [835](#)
- characters event, [850](#), [852](#)
- characters method, [872](#)
- CheckBiDirectional function, [572](#)
- CheckBox component, [165–166](#)
- CheckBoxList component, [169](#)
- CheckCapsLock method, [218](#)
- Checked property
  - for actions, [222](#), [230](#)
  - in CheckBoxList, [169](#)
- child components, messages for, [374](#)
- child forms in MDI applications, [315–316](#), [315](#)
- child windows in MDI applications, [311–315](#), [313](#)
- CIL (Common Intermediate Language), [904](#), [907–908](#)
  - CTS in, [909–911](#)
  - managed and safe code in, [908–909](#)
- class completion
  - in editor, [13–14](#)
  - for methods, [45](#)
- Class\_DColorPropPage constant, [489](#)
- Class\_DFontPropPage constant, [489](#)
- Class\_DPImagePropPage constant, [489](#)
- Class\_DStringPropPage constant, [489](#)
- class factories, [460](#)
- class helpers, [929–931](#)
- class interfaces, [48](#)

grouping in, [549](#), [550](#)

packets and caches in, [584](#)

transactions in, [589–591](#), [591](#)

updates in, [584–589](#), [585–586](#), [588](#)

database design for, [557–561](#)

with dbExpress library, [566](#)

components, [569–574](#), [571](#), [573](#)

metadata in, [578–579](#), [579](#)

parametric queries in, [579–581](#), [580–581](#)

platforms and databases, [567–569](#)

printing in, [581–584](#)

single and multiple components with, [575–578](#), [577](#)

unidirectional cursors, [566–567](#)

with InterBase, [561–566](#), [563–564](#)

unidirectional cursors in, [560–561](#)

client socket connections, [740](#)

client windows, subclassing, [317–318](#)

ClientDataSet component, [508–509](#), [567](#), [575](#)

client/server programming with

aggregates in, [550–552](#), [550](#)

grouping in, [549](#), [550](#)

packets and caches in, [584](#)

transactions in, [589–591](#), [591](#)

updates in, [584–589](#), [585–586](#), [588](#)

for DataSnap, [649](#), [655–656](#), [656](#)

filtering for, [513](#)

formats in, [511](#)

indexing for, [512–513](#)

local tables for

connections for, [509–510](#), [510](#)

defining, [511–512](#), [512](#)

locating records in, [514–515](#)  
master/detail structures in, [552–553](#), [553](#)  
Midas library for, [510–511](#)  
for updates, [576](#)  
in WebSearch program, [785](#)  
in WebSnap, [799](#), [803](#)  
in XML, [838](#), [854–856](#), [870–873](#)

ClientHandle property, [312](#)

ClientHeight property, [269](#)

ClientRefresh example, [661](#), [661](#)

clients

Automation, [474–475](#)  
for DataSnap, [652–653](#)  
MDI, [310–311](#)  
thin, [649](#)  
in Web database applications, [831–832](#), [832](#)

ClientToScreen method, [175](#), [183](#)

ClientWidth property, [269](#)

Clip History Viewer, [946](#)

Clipboard

for actions, [229–230](#)  
for components, [24–25](#)  
for DDE, [456](#)  
with TabControl, [208–209](#)  
for toolbar operations, [214–215](#)

ClipBrd unit, [208](#)

ClipCursor function, [263](#)

clocks

digital, [349–352](#)  
XClock, [492–493](#), [493](#)

Clone method, [633](#)

cloneNode, [843](#)

clones

in ADO, [633](#), [633](#)  
property, [187](#)  
recordset, [633](#)

Close method, [279–280](#)

closing

datasets, [694–695](#)  
forms, [279–280](#)

closing markers in XML, [834–835](#)

CLR (Common Language Runtime), [905–906](#)

CLRReflection example, [934–940](#), [940](#)

CLS (Common Language Specification), [905–906](#)

CLX (Component Library for Cross-Platform), [5](#), [110–112](#)

structure of, [111–112](#)

styles for, [219–220](#), [220](#)

cm\_ prefix, [373–378](#)

cm\_DialogChar message, [377](#)

cm\_DialogKey message, [260](#), [377](#)

cm\_FocusChanged message, [378](#)

cm\_MouseEnter message, [372](#)

cm\_MouseExit message, [372](#)

CmdGotoPage command, [799](#)

CmdLine global variable, [84](#)

CmdNextPage command, [799](#)

CmdPrevPage command, [799](#)

CmExit method, [677](#)

CMNTest example, [377–378](#)

cn\_ prefix, [373](#), [377](#)

CNHScroll method, [676](#)

CNVScroll method, [676–677](#)

CoCreateGuid function, [459](#)

code completion, [14–15](#)

Code Explorer window, [11–12](#), [12](#)

code generation vs. streaming, [113–114](#)

code in Delphi for .NET Preview, [921–922](#)

code insight technology, [14](#)

code parameters, [15](#)

Code Template Parameters dialog box, [450](#), [450](#)

code templates, [15](#)

CoFirstServer class, [475](#)

ColHeights property, [683](#)

collaboration diagrams, [434](#)

collections

classes in, [131](#)

for properties, [381–385](#), [383](#)

colons (:) in to-do items, [9](#)

color

for controls, [160–161](#)

converting to strings, [187–188](#)

in DLLs, [404](#), [410–411](#)

list box of, [186–188](#)  
messages for, [377](#)  
in Object Inspector, [20](#)  
transparent, [267](#), [267](#)

Color property  
in Splitter, [180](#)  
in TControl, [159–160](#)

ColorBox component, [169](#)

ColorDialog component, [288](#)

ColorDrawItem method, [185–186](#)

ColorKeyHole example, [267–268](#), [267](#)

ColorRef type, [404](#)

Colors toolbar in Rave, [718](#)

ColorToString function, [187–188](#)

Column property, [763](#)

ColumnLayout property, [167](#)

columns and Columns property  
in DataSetTableProducer, [763](#)  
in DBGrid, [382](#), [516](#)  
editing, [539–540](#)  
in ListBox, [167](#)  
in RadioGroup, [166](#)  
totals of, [537](#), [537](#)

Columns property editor, [533](#)

COM (Component Object Model), [455–456](#)

and ADO.NET, [645–646](#)

class factories in, [460](#)

data types in, [478](#)

in Delphi, [500–502](#), [502](#)

GUIDs in, [458–460](#), [459](#)

history of, [456–457](#)

instanting and threading methods in, [463](#)

Interop services in, [908](#)

IUnknown for, [457–458](#)

server for, [460–461](#)

interface properties for, [465–466](#)

interfaces and objects for, [461–463](#), [462](#)

object initialization for, [464](#)

testing, [464–466](#)

virtual methods in, [466–467](#)

COM+, [456](#), [494](#), [650](#)

components for, [494–496](#), [495–496](#)

events for, [497–500](#), [499](#)

transactional data modules for, [497](#)

COM Component Install Wizard, [498](#)

- COM+ Event Object wizard, [498](#)
- COM Object Wizard, [461–462](#), [462](#), [498](#)
- combo boxes, [216–217](#), [341–348](#), [345–346](#)
- ComboBox component, [168](#)
- ComboBoxEx component, [169](#)
- ComConts unit, [96](#)
- ComDlg32.DLL file, [287](#)
- CommandHandlers class, [741](#)
- commands, [173](#)
  - and actions, [173](#)
  - Menu Designer for, [174](#), [174](#)
  - pop-up menus, [174–176](#)
- CommandText Editor, [573](#), [573](#)
- CommandText property
  - in SQLDataSet, [573](#)
  - in TADODataset, [626](#)
- CommandType property
  - in SQLDataSet, [573](#)
  - in TADODataset, [626](#)
- CommDlg example, [287–288](#), [288](#)
- comments
  - in ModelMaker, [444–445](#), [444](#)
  - TODO, [7–9](#)
  - in XML, [834](#)
- Commit action, [596](#)
- Commit method, [589](#)
- CommitRetaining command, [596–597](#)
- CommitTrans method, [634](#)
- common dialog boxes, [287–288](#), [288](#)
- Common Intermediate Language (CIL), [904](#), [907–908](#)
  - CTS in, [909–911](#)
  - managed and safe code in, [908–909](#)
- Common Language Infrastructure (CLI), [903–904](#)
- Common Language Runtime (CLR), [905–906](#)
- Common Language Specification (CLS), [905–906](#)
- Common Object Request Broker Architecture (CORBA), [651](#)
- Common Type System (CTS), [903–904](#), [909](#)
  - events and delegates in, [910–911](#)
  - objects and properties in, [909–910](#)
- ComObj unit, [96](#), [457](#)
- Comp type, [920](#)

CompareValue function, [89](#)

comparisons

for ClientDataSet, [513](#)

with floating-point numbers, [89](#)

with strings, [91–92](#)

compatibility

in DLLs, [404–405](#)

with Linux, [88](#)

type, in inheritance, [62–63](#)

compilation

conditional, [156](#)

for libraries, [156](#)

.NET Preview, [900](#)

for projects, [30–32](#)

compiler messages, [9–10](#), [31](#), [31](#)

Compiler Messages page, [31](#), [31](#)

Compiler page, [28](#)

complex numbers, [95](#)

Component Development Kit (CDK), [340](#)

component diagrams, [434](#)

Component Library for Cross-Platform (CLX), [5](#), [110–112](#)

structure of, [111–112](#)

styles for, [219–220](#), [220](#)

Component Object Model. See [COM \(Component Object Model\)](#)

Component Palette, [23–24](#)

bitmaps for, [348](#), [349](#)

for copying and pasting components, [24–25](#)

for databases, [507](#)

submenus on, [5](#)

templates and frames in, [25–26](#), [26](#)

Component property, [395](#)

component streaming system, [52](#)

Component Template Information dialog box, [25](#)

component templates, [25–26](#)

Component Wizard, [341–342](#)

ComponentCount property, [119](#)

ComponentIndex property, [118](#)

components, [109](#), [162](#). See also [classes](#); controls

vs. ActiveX controls, [484–485](#)

for adapters, [794–795](#)

Automation servers in, [477–478](#), [477](#)

base classes for, [340](#)

class references for, [76–78](#), [78](#)

- collection properties, [381–385](#), [383](#)
- for COM+, [494–496](#), [495–496](#)
- commands, [173–176](#)
- compound, [349](#)
  - external components in, [352–354](#), [353](#)
  - frames for, [357–358](#)
  - graphical. See [Arrow component](#)
  - interfaces for, [354–356](#)
  - internal components in, [349–350](#)
  - publishing subcomponents of, [350–352](#), [352](#)
- copying and pasting, [24–25](#)
- dynamic creation of, [47–48](#), [47](#)
- editors for, [392–395](#), [394](#)
- extending libraries for, [337–340](#)
- Fonts combo box, [341–348](#), [341](#), [345–346](#)
- hiding, [159](#)
- input focus, [176–178](#), [176–177](#)
- lists, [167–172](#), [170](#)
- messages for, [376](#)
- without names, [122](#)
- nonvisual dialog, [378–381](#), [381](#)
- for options, [165–166](#)
- packages for, [337–339](#)
- property editors, [388–392](#), [390–391](#)
- ranges, [172–173](#)
- text-input, [162–165](#), [165](#)
- windows controls. See [windows](#)
- writing, [339–340](#)

Components property, [118–120](#)

ComponentState property, [300](#)

ComponentStyle property, [351](#)

ComponentToDOM method, [845](#)

- compound components, [349](#)
  - external components in, [352–354](#), [353](#)
  - frames for, [357–358](#)
  - graphical. See [Arrow component](#)
  - interfaces for, [354–356](#)
  - internal components in, [349–350](#)
  - publishing subcomponents of, [350–352](#), [352](#)

compound documents, [456](#), [479–483](#), [482](#)

compressed CAB files, [493](#)

compressing streams, [145–146](#), [145](#)

CompressStream function, [146](#)

ComputePoints method, [360–361](#), [365](#)

ComputerName property, [652](#), [655](#)

ComServ unit, [96](#)

concurrency

access in, [557](#)

in COM+, [496](#)

InterBase for, [561](#)

conditional compilation, [156](#)

conflicts in ADO, [641–642](#)

Connected property, [655](#)

Connection component, [575](#)

connection protocols for DataSnap, [650–651](#)

connection string editor, [618–619](#), [619–620](#)

connection strings, [618–619](#)

ConnectionBroker component, [652–653](#), [666](#)

ConnectionString property, [571](#)

connections

ClientDataSet, [509–510](#), [510](#)

dbExpress, [576–577](#), [577](#)

pooling, [643–644](#)

socket, [740](#), [744–747](#)

connections.ini file, [570](#), [572](#)

ConnectionString property, [618–619](#), [621](#), [629](#)

ConnectKind property, [478](#)

constant strings, [85](#)

ConstraintErrorMessage property, [657](#)

constraints and Constraints property, [179](#), [657](#)

in DataSnap example, [657–658](#)

for forms, [270](#)

in Splitter, [180](#)

constructor keyword, [54](#)

constructors, [54–55](#), [926](#)

container classes, [131–132](#)

containers, type-safe, [133–135](#)

contains keyword, [346](#)

contains lists, [345–346](#)

Contains section, [348](#)

Content method

in DataSetTableProducer, [762](#)

in PageProducer, [760](#)

in QueryTableProducer, [778](#)

Content property, [772](#)

ContentFields property, [778](#)

- ContentStream property, [784](#)
- ContentType property, [784](#)
- Contrrs unit, [131](#)
- Contrib.INI file, [692–693](#)
- ControlBar component, [231–234](#), [232](#)
  - docking toolbars in, [235–239](#), [236](#)
  - menus ins, [234](#)
- ControlBarLowerDockOver method, [247–248](#)
- ControllerBand property, [727](#), [731](#)
- controllers in Automation, [467](#)
- controls, [111](#), [149](#). See also [components](#)
  - activation and visibility of, [159](#)
  - ActiveX. See [ActiveX controls](#)
  - anchors for, [179–180](#), [179](#)
  - colors for, [160–161](#)
  - converting, [156–158](#)
  - data-aware. See [data-aware controls](#)
  - dual libraries support for, [151–155](#), [152](#)
  - fonts, [159–160](#)
  - forms. See [forms](#)
  - ListView, [188–193](#), [191](#)
  - menus. See [menus](#)
  - owner-draw, [184–185](#)
    - list box of colors, [186–188](#)
    - menu items, [185–186](#), [186](#)
  - parents of, [158–159](#)
  - size and position of, [159](#)
  - status bars, [217–219](#), [218](#)
  - TControl for, [158–162](#)
  - ToolBar, [213–219](#), [214](#)
  - TreeView, [193–197](#), [194](#), [199](#)
  - TWidgetControl, [161–162](#)
  - TWinControl, [161](#)
  - VCL vs. VisualCLX, [149–158](#), [152](#)
  - windows. See [windows](#)
- Controls property, [159](#)
- ConvDemo example, [97](#), [98](#)
- conversions, [96–99](#), [98](#)
  - Booleans, [86](#)
  - colors, [187–188](#)
  - controls, [156–158](#)
  - currency, [99–102](#), [101](#), [880–882](#), [881](#), [883](#)
  - DFM files, [33](#), [153](#)

  - members, [447](#)

- stream data, [140–142](#)
- strings, [86–87](#), [187–188](#)
- temperatures, [96](#)
- types, [67–69](#)
- to uppercase names, [602–603](#)

CONVERT.EXE utility, [33](#), [140](#)

Convert function, [96](#)

Convert Project to Model option, [437](#)

Convert to Model option, [437](#)

Convert tool, [33](#), [140](#)

ConvertAndShow method, [141](#)

ConvertIt demo, [100](#)

ConvertService service, [880–882](#), [881](#), [883](#)

ConvUtils unit, [91](#), [96](#)

CoolBar component, [230–231](#)

coordinates

- for controls, [159](#)
- in dragging, [544](#)
- for mouse-related keys, [262](#)
- in Rave, [719](#)
- in scrolling, [273–274](#), [273](#)

Copy1Click method, [209](#)

CopyFile method, [138–139](#)

copying

- components, [24–25](#)
- files, [138–139](#)

CORBA (Common Object Request Broker Architecture), [651](#)

core library classes, [109](#), [148](#)

- Classes unit, [147–148](#)
- collections, [131](#)
- containers, [131–135](#)
- events, [124–128](#)
- lists, [128–131](#), [130](#), [133–135](#)
- RTL package, [110–112](#), [110](#)
- streaming, [135–148](#), [141](#)
- TComponent, [117–124](#), [120](#)
- TPersistent, [112–117](#), [117](#)

core syntax of XML, [834–835](#)

Count command, [316](#)

Count property, [128](#)

count(\*) wildcard, [561](#)

CountBlanks property, [730](#)

- counters
  - hit, [782–785](#)
  - in Interbase 6, [565](#)
- CountSubstr function, [93](#)
- CountSubstrEx function, [93](#)
- CppDll example, [401–402](#), [402](#)
- cracks in datasets, [697](#)
- Create constructors, [54](#)
  - for file streams, [138](#)
  - overloaded, [54–55](#)
  - in TMDClock, [351](#)
  - in TObject, [54](#)
- Create XML From Datapacket command, [856–857](#)
- CreateComObject function, [460](#), [465](#), [475](#)
- CreateComps example, [47–48](#), [47](#)
- CreateDataSet method, [511](#)
- createElement method, [842](#)
- CreateFileMapping function, [413–414](#)
- CreateForm method, [77](#), [277](#)
- CreateGUID function, [87](#)
- CreateHandle method, [161](#)
- CreateInstance method
  - in IClassFactory, [460](#)
  - in IObjectContext, [497](#)
- CreateMutex method, [308](#)
- CreateOleObject function, [475](#)
- CreateParams method, [161](#), [258](#)
- CreatePolygonalRgn method, [365](#)
- CreateTable method, [695](#)
- CreateWindowEx function, [258](#)
- CreateWindowHandle method, [161](#)
- CreateWnd method, [161](#), [327](#), [342–343](#)

- Method Implementation Code Editor, [441–442](#), [442](#)
- for packages, [345](#), [345](#), [347–348](#), [417](#), [417](#)
- for properties, [388–392](#), [390–391](#), [533](#)
- type-library, [470–472](#), [471](#)
- for unit code, [439–441](#)

EDivByZero exception, [73](#)

Electronic Business using Extensible Markup Language (ebXML), [894](#)

ellipsis (...) on menus, [173](#)

embedded units, [568–569](#)

embedding, [480–481](#)

EMDataSetError class, [687–688](#)

Empty Project template, [40–41](#)

empty values with field events, [535](#)

Enable property, [863](#)

EnableCommit method, [497](#)

EnableControls method, [538–539](#)

Enabled property

- for actions, [222](#), [227](#)
- in TControl, [159](#)
- in Timer, [350](#)

encapsulation, [48](#)

- access specifiers for, [48–50](#), [60–62](#)
- and forms, [52–54](#), [53](#)
- with properties, [50–52](#), [51](#)

end-of-file cracks, [697](#)

endDocument event, [850](#), [852](#)

endElement event, [850](#), [872](#)

EndThread function, [84](#)

EndUser object, [793](#), [795](#)

EndUserSession adapter, [795](#)

EndUserSessionAdapter component, [807–808](#)

EnlargeFont1Click method, [816](#)

EnsureRange function, [89](#)

Enterprise Studio edition, [4](#)

entities in database design, [557–558](#)

enumerated properties, [358–360](#)

EnumModules function, [84](#), [425–426](#)

EnumWindows functions, [308](#)

EnumWndProc method, [308–309](#)

Environment Options dialog box, [6–7](#)

- for AutoSave feature, [11](#)
- for Code Explorer, [11–12](#)
- for compiler, [30](#)
- for DFM file saving, [19](#)
- for HTML editing, [788](#)
- for Project Explorer, [32](#)
- for secondary forms, [280](#)
- for type libraries, [471](#)

environment variables in CGI programs, [769](#)

Environment Variables page, [7](#)

Eof tests, [536](#)

EofCracks, [697](#)

EqualsValue constant, [89](#)

equi-joins, [636](#)

error method, [851](#)

ErrorLog example, [75–76](#), [76](#)

errors. See also [exceptions](#)

- in ADO, [641](#)
- database, [553–554](#)
- logging, [75–76](#), [76](#)

Essential Delphi, [954](#)

Essential Pascal, [953–954](#)

etm60.exe tool, [33](#)

EuroConv example, [100–102](#), [101](#)

EuroRound function, [102](#)

euros, converting, [100–102](#), [101](#)

event-driven programming, [302–303](#)

Event Editor in Rave, [717](#), [731–732](#)

Event Types view, [443](#)

EventHandler method, [162](#)

events, [124](#)

- for ActiveX controls, [484](#)
- for applications, [296](#)
- for Arrow component, [364–366](#)

- for COM+, [497–500](#), [499](#)
- in CTS, [909–910](#)
- in DataSnap example, [658–659](#)
- defining, [364–365](#)
- in Delphi for .NET Preview, [926–927](#)
- in Interbase [6](#), [565–566](#)
- method pointers for, [125–126](#)
- null values with, [535–536](#), [536](#)
- as properties, [126–128](#)
- in Qt, [162](#)

EvtSubscriber library, [498](#)

Excel

- with Automation, [479](#)
- Jet engine for, [625–626](#), [626](#)

Excel IISAM, [626](#)

except blocks, [71–73](#)

Exception class, [75](#)

Exception1 example, [73–75](#)

exceptions, [71](#)

- in calculated fields, [532](#)
- classes for, [73–75](#)
- for components, [339](#)
- and debugging, [74](#)
- error logging, [75–76](#), [76](#)
- program flow and finally block in, [72–73](#)

Exclude method, [927](#)

EXE files, [36](#)

ExecSQL method, [572](#)

executable files, [30](#), [82–83](#)

executable viewer tool, [33](#)

Execute method

- in TFindWebThread, [753](#)
- in TMdListBoxDialog, [380](#)
- in TMdListCompEditor, [395](#)
- in TPrimeAdder, [305–306](#)

ExecuteTarget method, [385–387](#)

ExecuteVerb method

- in IComponentEditor, [393](#)
- in TMdListCompEditor, [394](#)

exitItemClick method, [937](#), [939–940](#)

ExitProc function, [921](#)

ExpandAll1lick method, [816](#)

ExpandFileName function, [87](#)

- expanding component references in-place, [20](#)
- explicit transactions, [589](#)
- Explorer page, [32](#)
- exploring projects, [32](#), [32](#)
- exporting
  - Jet engine for, [628–629](#)
  - strings from DLLs, [404–406](#)
- exports clause
  - in Apache, [782](#)
  - for DLLs, [399](#), [404](#)
- expression evaluation, tooltip, [16](#)
- ExtCtrls unit, [163](#)
- Extended Database Form Wizard, [947](#)
- extended identifiers, [924](#)
- extended ListBox selections, [167](#)
- Extended Properties property, [624](#), [626](#), [629](#)
- ExtendedSelect property, [167](#)
- extending libraries, [337–340](#)
- Extensible Stylesheet Language (XSLT), [864](#)
  - examples, [865–866](#)
  - with WebSnap, [866–868](#), [866](#)
  - XPath in, [864–865](#)
- external components
  - in compound components, [352–354](#), [353](#)
  - interfaces for, [354–356](#)
- external declarations, [398](#), [406](#)
- external definitions for DLLs, [400](#)
- external keys, [559](#)
- external symbols, [15](#)
- External Translation Manager tool, [33](#)
- \$EXTERNALSYM directive, [400](#)
- ExtraCode property, [197](#)
- ExtractStrings method, [147](#)
- Extras key for hot-track activation, [24](#)

file management, [102–104](#), [103–104](#)

File Transfer Protocol (FTP)

API for, [754–755](#)

ports for, [739](#)

FileCreate function, [87](#)

FileName property, [244](#)

files

actions for, [224](#)

copying, [138–139](#)

locating, [798](#)

produced by system, [34–38](#)

source code, [38–39](#)

streaming, [138–139](#)

FilesList example, [102–104](#), [103–104](#)

Filled property, [359](#), [366–367](#), [489](#)

FillFormList method, [299–300](#)

FillFormsList method, [300](#)

Fills toolbar in Rave, [718](#)

Filter property, [513](#)

FilterGroup property, [638](#), [641](#)

filtering for ClientDataSet, [513](#)

final keyword, [924–925](#)

Finalize method, [911–912](#)

finally blocks, [71–73](#)

Find and Replace dialog boxes, [288](#)

find\_business API, [897](#)

Find method, [132](#)

FindClose function, [102](#)

FindComponent method, [121](#), [286–287](#), [765](#)

FindFirst function, [102](#)

FindGlobalComponent function, [121](#)

FindNearest method, [777](#)

FindNext function, [102](#)

FindNextPage function, [205–206](#)

FindWindow function, [307](#)

FirstDll example, [405–406](#)

FishClient example, [893](#), [894](#)

Flat property, [213](#)

- floating-point numbers
  - comparisons with, [89](#)
  - conversions with, [87](#)

FloatingDockSiteClass property, [234](#)

FloatToCurr function, [87](#)

FloatToDateTime function, [87](#)

fly-by-hints, [182–184](#), [184](#), [218](#), [218](#)

fm flags, [138](#)

FocusControl property, [177](#)

Font dialog box, [288](#), [288](#)

Font property, [21](#), [159](#)

FontDialog component, [288](#)

FontMaster component in Rave, [724](#)

FontMirror property, [724](#)

FontNamePropertyDisplayFontNames variable, [21](#)

fonts

- in Automation, [478](#)
- for controls, [159–160](#)
- for dialog boxes, [288](#), [288](#)
- listing, [299](#)
- for menu items, [216](#)
- in Object Inspector, [21](#)
- size of, [276–277](#)
- with toolbars, [215](#)

Fonts combo box, [341–344](#)

- package for, [344–347](#), [345–346](#)
- using, [347–348](#)

Fonts toolbar in Rave, [718](#)

ForEach method, [133](#)

ForEachFactory method, [462](#)

ForEachModule function, [425–426](#)

Form component, [119](#)

Form Designer, [18–19](#)

Format function, [85](#), [582](#)

FormatDateTime function, [60](#)

formats for Rave, [720–721](#), [720](#)

FormatXMLData method, [842](#), [857](#)

FormCount property, [821](#)

FormCreate method, [127](#)

- for pages, [204](#)
- in TDateForm, [127](#)

in TForm1, [196–197](#)

in TFormUserIntf, [423](#)

FormDestroy method, [131](#)

FormDLL example, [411](#)

FormIntf demo, [330–331](#)

FormMouseDown method, [263–264](#)

FormMouseMove method, [263–264](#)

FormMouseUp method, [263](#), [265](#)

FormProp example, [53](#), [53](#)

forms, [251](#)

About boxes and splash screens for, [289–292](#), [290](#)

activating, [298](#), [298](#)

border icons for, [256–257](#), [257](#)

borders for, [254–256](#), [254](#)

client area in, [269](#)

closing, [279–280](#)

constraints in, [270](#)

creating, [277–279](#), [278](#)

dialog boxes

creating, [282–287](#), [284–285](#)

predefined, [287–289](#), [288](#)

direct input

keyboard, [259–261](#), [260](#)

mouse, [261–265](#)

displaying, [267–268](#), [267](#)

in DLLs, [410–411](#)

and encapsulation, [52–54](#), [53](#)

fields in

hiding, [122–123](#)

removing, [121–122](#)

inheritance in

from base forms, [319–321](#), [319–320](#)

polymorphic, [321–324](#), [322](#)

multiple-page, [202](#)

image viewer in, [207–210](#), [207](#)

PageControl and TabSheet for, [202–207](#), [204–205](#)

for user interface wizard, [210–213](#), [211](#)

in packages, [417–419](#), [417](#)

painting in, [265–267](#)

plain, [252–253](#), [253](#)

position of, [268–269](#)

properties for, [53–54](#), [53](#)

scaling, [274–277](#)

scrolling, [270–271](#)

automatic, [272–273](#)

coordinates in, [273–274](#), [273](#)

example, [271–272](#), [272](#)

secondary, [280–281](#)  
size of, [269](#)  
snapping in, [269](#)  
splitting, [180–181](#), [180](#)  
style of, [254](#)  
TForm class, [251–259](#), [253–254](#), [257–258](#)  
tracking, [299–302](#), [300](#)  
WebBroker technology for, [777–781](#), [780](#)  
windows for, [257–259](#), [258](#)

HandleNeeded method, [161](#)

HandleReconcileError function, [588](#)

HandlesPackages lists, [422](#)

HandlesTarget method, [385](#)

hashed associative lists, [132–133](#)

header files, [401–402](#)

headers in CGI programs, [769](#)

Height property

for components, [18](#)

for forms, [268–269](#)

in TControl, [159](#)

in TMdArrow, [359](#)

HelloWorld example, [901–902](#), [903](#)

Help actions, [224](#)

Help files, [33](#), [340](#)

HelpContext property, [222](#), [256](#)

Hide method, [159](#)

HideComp example, [122–123](#)

HideOptions property, [808](#)

HideUnused property, [246](#)

hiding

components, [159](#)

form fields, [122–123](#)

forms, [279](#)

high-level protocols in socket programming, [740](#)

high-low technique, [600](#)

hint directives, [44](#)

Hint property

for actions, [222](#)

in Application, [217](#)

for toolbars, [236](#)

HintColor property, [182](#)

HintHidePause property, [182](#)

HintPause property, [182](#)

hints in ToolBar, [182–184](#), [184](#), [218](#), [218](#), [236](#)

HintShortPause property, [182](#)

hit counters, [782–785](#)

HitsGetValue method, [806](#)

HookEvents method, [162](#)

horizontal splitting of forms, [181](#)

HorzScrollBar property, [270](#), [273](#)

hosts file in IP addresses, [739](#)

hosts in socket programming, [741](#)

HOSTS.SAM file, [739](#)

hot-track activation, [24](#)

HotImages property, [213](#)

Hower, Chad Z., [809](#)

HTM files, [36](#)

HTML (Hypertext Markup Language), [758–759](#)

- for data, [761–762](#), [762](#)
- for dynamic pages, [764–765](#)
- for pages, [759–761](#), [760](#)
- producer components for, [759](#)
- style sheets for, [764–765](#)
- for tables, [762–764](#), [763](#)
- templates for, [788](#)

HTML editor, [788](#)

HTML Import, [629](#)

HTML tab, [862](#)

HTMLDoc property, [788](#)

HtmlDom component, [868](#)

HtmlEdit example, [165](#), [165](#)

HTMLFile property, [788](#)

HtmlProd example, [759–764](#), [760](#), [762](#)

HtmlStringToCds method, [785](#)

HtmlToList method, [752–754](#)

HTTP (Hypertext Transfer Protocol), [651](#), [750–751](#)

- API for, [754](#)
- for browsers, [756–757](#), [757](#)
- grabbing content in, [751–754](#), [755](#)
- ports for, [739](#)
- server, [757–758](#), [758](#)

WinInet API for, [754–756](#)

HttpDecode function, [743](#)

HttpEncode function, [743](#)

HTTPRIO component, [879](#)

HttpServ example, [757–758](#), [758](#)

HTTPSoapDispatcher component, [879](#)

HTTPSoapPascalInvoker component, [879](#)

httpssvr.dll file, [651](#)

HTTPWebNode property, [893](#)

HttpWork method, [754](#)

Hypertext Markup Language. See [HTML \(Hypertext Markup Language\)](#)

OnAdvancedDrawItem event, [186](#)

OnArrowDbClick event, [364–365](#)

OnBeforeDispatchPage event, [790](#)

OnBeforeExecuteAction event, [797](#)

OnBeforePageDispatch event, [794](#)

OnCalcFields event, [531](#), [585](#)

OnCanResize event, [270](#)

OnCanViewPage event, [808](#)

OnChange event

in TabControl, [208](#)

in TDate, [126](#)

in TMdArrow, [363](#)

OnClick event, [125](#), [261](#)

OnClose event, [278–279](#), [300](#)

OnCloseQuery event, [278–279](#)

OnCloseUp event, [168](#)

OnColumnClick event, [191](#)

OnCommand event, [742](#)

OnCommandGet event, [757](#), [765](#)

OnConstrainedResize event, [270](#)

OnContextMenu event, [175](#)

OnContextPopup event, [176](#)

OnCreate event, [277–279](#), [299](#)

OnCreateNodesClass event, [197](#)

OnDataChange event, [546](#)

OnDeactivate event, [296](#), [298](#)

OnDeleteError event, [553](#)

OnDestroy event, [279](#), [301](#)

OnDockDrop event, [236](#)

OnDockOver event, [235–236](#)

OnDoubleClick event, [285](#)

OnDragDrop event, [98](#)

for docking, [234](#)

for TreeView, [195](#)

OnDragOver event, [98](#)

for docking, [234](#)

for TreeView, [195](#)

OnDrawColumnCell event, [540–541](#)

OnDrawItem event, [185](#)

OnDrawTab event, [209](#)

OnDropDown event, [168](#)

one-to-many relations, [557](#)

one-to-one relations, [557](#)

OneCopy example, [308–310](#)

OnEditButtonClick event, [533](#)

OnEditError event, [553](#)

OnEndDock event, [234](#), [236](#)

OnEnter event, [177–178](#)

OnException event, [75](#), [296](#), [553](#)

OnExecute event

- in ActionFont, [313](#)
- in ActionLink, [223–224](#)
- for actions, [228](#), [228](#)

OnExecuteAction, [223](#)

OnExit event, [177–178](#)

OnFind event, [288](#)

OnFindIncludeFile event, [798](#)

OnFindStream event, [798](#)

OnFindTemplateFile event, [798](#)

OnFormatCell event, [763](#)

OnGetData event, [668](#)

OnGetDataSetProperties event, [667](#)

OnGetItem event, [249](#)

OnGetItemCount event, [249](#)

OnGetResponse event, [864](#)

OnGetText event, [535](#), [541](#), [549](#)

OnGetValue event, [794](#), [797](#)

OnHelp event, [257](#), [296](#)

OnHint event, [217](#), [296](#)

OnHTMLTag event, [760](#)

OnIdle event, [215](#), [296](#), [304](#)

OnItemSelected event, [250](#)

OnKeyPress event, [163](#), [259](#)

Online Analytical Processing (OLAP), [617](#)

OnLogTrace event, [576](#)

OnMeasureItem event, [185](#), [187](#)

OnMessage event, [296](#)

OnMinimize event, [296](#)

OnMouseDown event, [261](#)

OnMouseMove event, [261–262](#)

OnMouseUp event, [261](#)

OnMouseWheel event, [261](#)

OnMouseWheelDown event, [261](#)

OnMouseWheelUp event, [261](#)

OnMove event, [181](#)

OnNewRecord event, [547](#)

OnPageAccessDenied event, [808](#)

OnPaint event, [265–266](#), [274](#)

OnPostError event, [553](#)

OnReceivingData event, [893](#)

OnReconcileError event, [587](#), [651](#), [659–660](#)

OnRecordChangeComplete event, [641](#)

OnRecordSetCreate event, [622](#)

OnReplace event, [288](#)

OnResize event, [269–271](#)

OnRestore event, [296](#)

OnScroll event, [271](#)

OnSetText event, [535](#), [541](#)

OnShortCut event, [296](#)

OnShow event, [278](#)

OnShowHint event, [183](#), [296](#)

OnStartDock event, [234](#)

OnStateChange event, [525](#), [546](#)

OnStatusTextChange event, [486](#)

OnTag event, [760](#)  
    in PageProducer, [779](#)  
    in WebSnap, [791](#)

OnTimer event, [492](#)

OnTitleChange event, [486](#)

OnTitleClick event, [830](#)

OnTrace event, [576](#)

OnUpdate event  
    in ActionCount, [227](#)  
    in ActionFont, [313](#)  
    and actions, [224](#), [229](#)

- in MDI applications, [314](#)
- OnUpdateData event, [660](#)
- OnUpdateError event, [553](#), [641](#), [660](#)
- OnValidate event, [535](#)
- OnWillChangeRecord event, [641](#)

- PageNumInit component in Rave, [724](#)
- PageProducer component, [759–761](#), [774](#), [779](#), [788](#)

pages

frames with, [326–328](#), [327](#)

frames without, [328–330](#), [329](#)

Web, ActiveX controls in, [492–493](#), [493](#)

Pages example, [202–207](#), [204–205](#)

Pages list, [793](#)

PageScroller component, [172–173](#)

PageSize property, [799](#)

PageTail component, [774–775](#)

Paint method, [358](#), [361–363](#), [362](#)

painting

DBGrids, [540–542](#), [542](#)

in windows, [265–267](#)

Panel component, [119](#)

Panels property, [382](#)

Paradox, Jet engine for, [624–625](#), [625](#)

ParamByName method, [581](#)

ParamCount global variable, [84](#)

parameters

code, [15](#)

for DLLs, [399](#)

for mouse events, [262](#)

in overloaded methods, [46](#)

in stored procedures, [565](#)

parametric queries

in DataSnap, [663](#), [663](#)

in dbExpress, [579–581](#), [580–581](#)

Params property

in queries, [663](#)

in SQLConnection, [572](#)

in SQLDataSet, [580–581](#)

in XMLBroker, [858](#)

ParamStr global variable, [84](#)

Parent property, [158–159](#)

ParentColor property, [160](#)

ParentFont property, [160](#)

ParentXxx properties, [374](#)

ParQuery example, [580–581](#), [581](#)

parsers, MSXML, [644](#)

parseURL method, [851](#)

PAS files, [36](#)

Pascal language, [38](#), [44](#)

passing XML documents, [884–886](#)

PasswordChar property, [163](#)

Paste Link operation, [480](#)

PasteSpecialClick event, [481](#)

PasteSpecialDialog method, [481](#)

pasting components, [24–25](#)

patch files, [415](#)

path delimiter functions, [87](#)

PathInfo property, [863](#)

patterns in ModelMaker, [447–450](#)

PCE.exe tool, [33](#)

PChar type, [405–406](#)

PE (Portable Executable) format, [904](#), [908](#)

Peek method, [131](#)

people in InterBase example, [603–605](#)

performance in InterBase, [561](#)

Performance Monitor for connections, [644](#)

permissions in WebSnap, [808](#)

Persisted Recordset provider, [618](#)

persistence

- in ADO recordsets, [644–645](#)
- in Arrow component properties, [362–364](#), [364](#)
- class for, [113](#)
- in streaming, [140–142](#), [141](#)

Personal edition, [4](#)

pessimistic locking in ADO, [635–636](#)

PEVerify utility, [909](#)

physical keys, [558–559](#)

PickList property, [516](#)

PixelsPerInch property, [275–276](#)

plain component packages, [338](#)

plain forms, [252–253](#), [253](#)

Platform Invocation Service (P/Invoke), [904](#)

platform-specific symbols, [156](#)

platforms for databases, [567–569](#)

playing compound objects, [480](#)

PlaySound function, [64](#), [372](#), [391](#)

PMdReclInfo pointer type, [696](#)

po options, [666–667](#)

pointers

for bookmarks, [696](#)

in Delphi for .NET Preview, [920](#)

in object reference model, [55](#), [55](#)

for procedures, [409–410](#)

PoliForm example, [322–324](#), [322](#)

PolyAnimals example, [64](#), [64](#)

polymorphic forms, [321–324](#), [322](#)

polymorphism, [63–66](#), [64](#)

abstract methods in, [66–67](#)

in interfaces, [70](#)

pooling

connection, [643–644](#)

object, [667](#)

Pop method, [131](#)

pop-up menus, [173–176](#)

POP3 (Post Office Protocol, version 3), [740](#)

PopulateTypes method, [937–938](#)

Popup method, [175](#)

PopupMenuActionBarEx component, [242](#)

PopupMenu property, [174–175](#)

portability

of database engines, [506](#)

in library selection, [155](#)

of text DFM files, [19](#)

Portable Executable (PE) format, [904](#), [908](#)

PortableDragTree example, [196–197](#)

porting programs, [247–248](#)

ports in socket programming, [739–740](#)

Pos function, [93](#)

PosEx function, [93](#)

position and Position property

of controls, [159](#), [163](#)

of Form Designer components, [18](#)

of forms, [255](#), [268–269](#)

of mouse, [262](#)

of scroll bars, [271](#)

in TStream, [136](#)

Post command, [520](#)

POST method, [778](#)

Post Office Protocol, version 3 (POP3), [740](#)

PostMessage method, [66](#), [303–304](#), [310](#)

predefined items

actions, [224–225](#)

dialog boxes, [287–289](#), [288](#)

preemptive multitasking, [302](#)

Preferences page

for AutoSave feature, [11](#)

for compiler, [30](#)

for docking, [6](#)

prefixes

for functions, [360](#)

for names, [121](#)

pressed-down state, [173](#)

Preview compiler, [900](#)

Preview pages, HTML, [788](#)

previewing in Rave, [719](#), [719](#)

primary keys, [558–560](#)

printing in dbExpress, [581–584](#)

PrintOutDataSet method, [582–583](#)

PrioritySchedule property, [246](#)

private specifier, [48–50](#), [925](#)

ProcessMessages function, [303–304](#)

Producer object, [793](#)

Producer property, [772](#), [776](#), [863](#)

ProducerContent property, [772](#)

Professional Studio edition, [4](#)

program flow in exceptions, [72–73](#)

program statement, [922](#)

programmability, client/server programming for, [557](#)

ProgressBar component, [172](#), [671–673](#), [673](#)

Project JEDI, [952](#)

Project Manager, [26–28](#), [27](#), [723](#)

Project Options dialog box, [28](#)

for applications, [296](#)

for Automation, [477](#)

for forms, [277](#), [278](#), [280](#)

for messages, [31](#), [31](#)

for ModelMaker documentation, [445](#)

for packages, [346](#), [346](#)

Project toolbar in Rave, [718](#)

Project Tree panel, [717](#)

project-wide to-do items, [9](#)

ProjectFile property, [719](#)

projects, [26–28](#), [27](#)

  compiling and building, [30–32](#)

  exploring, [32](#), [32](#)

  names for, [407–408](#)

  options for, [28–30](#)

prologues in XML, [835](#)

PropCom example, [466](#)

properties

  accessing by name, [115–117](#), [117](#)

  for ActiveX controls, [489–491](#), [490](#)

  categories

    in Object Inspector, [21–22](#)

    registering, [366–367](#), [367](#)

  code completion for, [14–15](#)

  collections for, [381–385](#), [383](#)

  in CTS, [909–910](#)

  in Delphi for .NET Preview, [925–926](#)

  editors

    installing, [391–392](#)

    for sound, [388–391](#), [390–391](#)

    writing, [388](#)

  encapsulation with, [50–52](#), [51](#)

  events as, [126–128](#)

  for forms, [53–54](#), [53](#)

  names for, [360](#)

  in Object Inspector, [20–21](#)

Properties dialog box, [20](#)

Property Editor dialog box, [438–439](#), [439](#)

property keyword, [53](#)

Property panel, [717](#)

protected specifier, [48–50](#), [60–62](#), [925](#)

protection, client/server programming for, [557](#)

Protection example, [61–62](#)

protocols

  for DataSnap, [650–651](#)

  in socket programming, [740](#)

provider options in DataSnap, [666–667](#)

ProviderFlags property, [658](#)

ProviderName property, [655](#)

proxy forms, [114](#)

PtInRegion function, [365](#)

public deployment, [916](#)

public specifier, [48–50](#), [52](#)

published keyword, [52](#), [114–115](#)

Publisher example, [499–500](#)

publishing

subcomponents, [350–352](#), [352](#)

WSDL, [881–883](#), [881](#)

pull-down menus, [173](#)

purely abstract classes, [69](#)

Push method, [131](#)

PWideChar type, [460](#)

## R

radio items on menus, [173](#)

RadioButton component, [165–166](#)

RadioGroup component, [166](#)

RadioButton property, [173](#), [230](#)

raise keyword, [71](#)

raising exceptions, [71](#)

RandomFrom function, [89](#)

RandomRange function, [89](#)

Range property, [270](#), [272–273](#)

ranges, components for, [172–173](#)

Rave, [715–716](#)

calculations in, [733–734](#)

components of, [722–723](#)

basic, [723–725](#)

data access, [725–726](#), [725](#)

data-aware, [728–730](#), [729](#)

regions and bands, [726–728](#), [727](#)

data connections in, [721–722](#), [722](#)

design environment in, [716–719](#), [716](#)

master/detail reports in, [730–731](#), [731](#)

mirroring in, [732–733](#)

rendering formats for, [720–721](#), [720](#)

RVProject component in, [719–720](#), [719](#)

scripts for, [731–732](#), [732](#)

RaveDatabase component, [726](#)

RaveDetails example, [730–732](#), [731–732](#)

RaveDirectDataView component, [726](#)

RaveDriverDataView component, [726](#)

RaveLookupSecurity component, [726](#)

RaveProject component, [723](#)

RaveSimpleSecurity component, [726](#)

RaveSingle example, [721–722](#), [722](#)

RC files, [37](#)

RDSConnection component, [508](#), [619](#)

re-raising exceptions, [71](#)

read clauses, [50](#), [52](#), [465](#)

Read method, [143](#)

read-only ProgressBars, [671–673](#), [673](#)

read-only properties  
in Object Inspector, [20](#)  
setting, [52](#)

read-write TrackBar, [674–677](#), [677](#)

ReadBool method, [332](#)

ReadBuffer method, [137](#)

ReadComponent method, [136](#)

ReadComponentRes method, [140](#)

ReadInteger method, [332](#)

ReadString method, [332](#)

Real48 type, [920](#)

ReallocMem function, [921](#)

rebuild.bat file, [900](#)

Rebuild Wizard, [946](#)

RecNo property, [537](#)

Reconc unit, [588](#)

Reconcile Error Dialog unit, [588](#), [588](#)

ReconcileProducer property, [860](#)

ReconcileProvider property, [863](#)

record buffers, [698–703](#)

record viewer component, [678–683](#), [682](#)

RecordChanged method, [679](#)

RecordCount property, [537](#), [560](#), [631–632](#)

recording macros, shortcut keys for, [16](#)

records

in Delphi for .NET Preview, [920–921](#)

editing, [520](#)

locating, [514–515](#)

locking, [587](#)

in ADO, [635–636](#), [639–641](#)

in client/server programming, [557](#)

recursive, [86](#)

status of, [585](#), [585](#)

recordsets in ADO

clone, [633](#)

disconnected, [642–643](#)

persistent, [644–645](#)

recursive locks, [86](#)

redefining methods, [64–65](#)

refactoring ModelMaker code, [446–447](#)

reference-counting techniques, [476](#)

references, class, [76–78](#), [78](#)

referential integrity, [559](#)

ReflectionForm class, [935](#)

Reflector tool, [901](#)

RefList example, [189–193](#), [191](#)

RefList2 example, [283–285](#), [284](#)

Refresh in Model option, [438](#)

Refresh method, [266](#), [660](#)

refreshing

data, [660–662](#), [661](#)

screen, [266–267](#), [660](#)

RefreshRecords method, [660–661](#)

regasm (Framework Assembly Registration Utility), [501](#)

region components, [726–728](#), [727](#)

Register ActiveX Server command, [488](#)

Register method

for component editors, [395](#)

for components, [342](#), [357](#)

for packages, [345](#)

for property categories, [366–367](#)

for property editors, [391](#)

RegisterActions method, [387](#)

RegisterClass method, [330](#)

RegisterColorSelect method, [421](#)

registering

ActiveX libraries, [34](#), [488](#)

Automation servers, [473–474](#)

component editors, [395](#)

components, [342](#)

conversion rates, [99–101](#)

property categories, [366–367](#), [367](#)

RegisterPooled method, [667](#)

RegisterPropertyInCategory function, [366–367](#)

Registry

for automation servers, [473–474](#)

cleaning up, [33](#)

for COM servers, [464](#)

for connection pooling, [644](#)

for GUIDs, [458–459](#)

for hot-track activation, [24](#)

and INI files, [331–332](#)

for shared component templates, [26](#)

## Chapter 1: Delphi 7 and Its IDE

[Figure 1.1:](#) A form and a data module in the Delphi 7 IDE

[Figure 1.2:](#) The Preferences page of the Environment Options dialog box

[Figure 1.3:](#) The Edit To-Do Item window can be used to modify a to-do item, an operation you can also do directly in the source code.

[Figure 1.4:](#) The multiple languages supported by the Delphi IDE can be associated with various file extensions in the Source Options page of the Editor Properties dialog box.

[Figure 1.5:](#) You can configure the Code Explorer in the Environment Options dialog box.

[Figure 1.6:](#) The Diagram view shows relationships among components (and even allows you to set them up).

[Figure 1.7:](#) The Print Options for the Diagram view

[Figure 1.8:](#) The Frames1 example demon-strates the use of frames. The frame (on the left) and its instance inside a form (on the right) are kept in synch.

[Figure 1.9:](#) Delphi's multitarget Project Manager

[Figure 1.10:](#) The new Compiler Messages page of the Project Options dialog box

[Figure 1.11:](#) The Project Browser

[Figure 1.12:](#) The first page of the New Items dialog box, generally known as the Object Repository

## Chapter 2: The Delphi Programming Language

[Figure 2.1:](#) The output of the CreateComps example, which creates Button components at run time

[Figure 2.2:](#) The DateProp example's form

[Figure 2.3:](#) Two forms of the FormProp example at run time

[Figure 2.4:](#) A representation of the structure of an object in memory, with a variable referring to it

[Figure 2.5:](#) A representation of the operation of assigning an object reference to another object. This is different from copying the actual content of an object to another.

[Figure 2.6:](#) The output of the NewDate program, with the name of the month and of the day depending on Windows regional settings

[Figure 2.7:](#) The output of the PolyAnimals example

[Figure 2.8:](#) The ErrorLog example and the log it produces

[Figure 2.9:](#) An example of the output of the ClassRef example

## Chapter 3: The Run-Time Library

[Figure 3.1:](#) The Rounding example, demonstrating banker's rounding and arithmetic rounding

[Figure 3.2:](#) The form of the VariantComp example at design time

[Figure 3.3:](#) The ConvDemo example at run time

[Figure 3.4:](#) The output of the EuroConv unit, showing the use of Delphi's conversion engine with a custom measurement unit

[Figure 3.5:](#) An example of the output of the FilesList application

[Figure 3.6:](#) The dialog box of the SelectDirectory procedure, displayed by the FilesList application

[Figure 3.7:](#) The output of the IfSender example

[Figure 3.8:](#) The output of the ClassInfo example

## Chapter 4: Core Library Classes

[Figure 4.1:](#) A graphical representation of the main groups of VCL components

[Figure 4.2:](#) The output of the RunProp example, which accesses properties by name at run time

[Figure 4.3:](#) In the ChangeOwner example, clicking the Change button moves the `Button1` component to the second form.

[Figure 4.4:](#) The list of dates shown by the ListDemo example

[Figure 4.5:](#) The textual description of a form component, displayed inside itself by the FormToText example

[Figure 4.6:](#) The ZCompress example can compress a file using the ZLib library.

## Chapter 5: Visual Controls

[Figure 5.1:](#) A comparison of the first three pages of the Component Palette for a CXL-based application (above) and a VCL-based application (below)

[Figure 5.2:](#) An application written with CLX can be directly recompiled under Linux with Kylix (displayed in the background).

[Figure 5.3:](#) The HtmlEdit example at run time: When you add new HTML text to the memo, you get an immediate preview.

[Figure 5.4:](#) The NameValues example uses the ValueListEditor component, which shows the name/value or key/value pairs of a string list, also visible in a plain memo.

[Figure 5.5:](#) Delphi's Menu Designer in action

[Figure 5.6:](#) The Edit Tab Order dialog box

[Figure 5.7:](#) The InFocus example at run time

[Figure 5.8](#): The controls of the Anchors example move and stretch automatically as the user changes the size of the form. No code is needed to move the controls, only proper use of the `Anchors` property.

[Figure 5.9](#): The Split1 example's splitter component determines the minimum size for each control on the form, even those not adjacent to the splitter.

[Figure 5.10](#): The ListBox control of the CustHint example shows a different hint, depending on which list item the mouse is over.

[Figure 5.11](#): The owner-draw menu of the ODMenu example

[Figure 5.12](#): Different examples of the output of a ListView component in the RefList program, obtained by changing the `ViewStyle` property and adding the check boxes

[Figure 5.13](#): The DragTree example after loading the data and expanding the branches

[Figure 5.14](#): The CustomNodes example has a tree view with node objects based on different custom classes, thanks to the `OnCreateNodes-Class` event.

## **Chapter 6: Building the User Interface**

[Figure 6.1](#): The first sheet of the PageControl of the Pages example, with its shortcut menu

[Figure 6.2](#): The second page of the example can be used to size and position the tabs. Here you can see the tabs on the left of the page control.

[Figure 6.3](#): The interface of the bitmap viewer in the BmpViewer example. Notice the owner-draw tabs.

[Figure 6.4](#): The first page of the WizardUI example at design time

[Figure 6.5](#): The RichBar example's toolbar. Notice the drop-down menu.

[Figure 6.6](#): The StatusBar of the RichBar example displays a more detailed description than the fly-by hint.

[Figure 6.7](#): The StylesDemo program, a Windows application that currently has an unusual Motif layout

[Figure 6.8](#): The Pages example uses the current Windows XP theme, as it includes a manifest file (compare the figure with 6.1)

[Figure 6.9](#): The ActionList component editor, with a list of predefined actions you can use

[Figure 6.10](#): The ActionList editor of the Actions example

[Figure 6.11](#): The Actions example, with a detailed description of the `Sender` of an Action object's `OnExecute` event

[Figure 6.12](#): The MdEdit2 example at run time, while a user is rearranging the toolbars in the control bar

[Figure 6.13](#): The MdEdit2 example allows you to dock the toolbars (but not the menu) at the top or bottom of the form or to leave them floating.

[Figure 6.14](#): The DockTest example with three controls docked in the main form

[Figure 6.15](#): The main form of the DockPage example after a form has been docked to the page control on the left.

[Figure 6.16](#): The three pages of the ActionManager editor dialog box

[Figure 6.17:](#) Using the `CustomizeDlg` component, you can let a user customize the toolbars and the menu of an application by dragging items from the dialog box or moving them around in the action bars.

[Figure 6.18:](#) The `ActionManager` disables least-recently used menu items that you can still see by selecting the menu extension command.

[Figure 6.19:](#) The `ListActions` application has a toolbar hosting a static list and a virtual list.

## **Chapter 7: Working with Forms**

[Figure 7.1:](#) The dynamic form generated by the `DynaForm` example is completely created at run time, with no design-time support.

[Figure 7.2:](#) Sample forms with the various border styles, created by the `Borders` example

[Figure 7.3:](#) The `BIcons` example. By selecting the Help border icon and clicking the button, you get the help displayed in the figure.

[Figure 7.4:](#) The `NoTitle` example has no real caption but a fake one made with a label.

[Figure 7.5:](#) The `KPreview` program at design time

[Figure 7.6:](#) During a dragging operation, the `MouseOne` example uses a dotted line to indicate the final area of a rectangle.

[Figure 7.7:](#) The output of the `ColorKeyHole`, showing the effect of the new `TransparentColor` and `AlphaBlend` properties and the `Animate-Window` API

[Figure 7.8:](#) The output of the `Scroll1` example

[Figure 7.9:](#) The lines to draw on the virtual surface of the form

[Figure 7.10:](#) The Forms page of the Delphi Project Options dialog box

[Figure 7.11:](#) The dialog box of the `RefList2` example used in edit mode. Notice the `ComboBoxEx` graphical component in use.

[Figure 7.12:](#) The three forms (a main form and two dialog boxes) of the `DlgApply` example at run time

[Figure 7.13:](#) The Font selection dialog box with an Apply button

[Figure 7.14:](#) The main form of the `Splash` example, with the splash screen (this is the `Splash2` version)

## **Chapter 8: The Architecture of Delphi Applications**

[Figure 8.1:](#) The `ActivApp` example shows whether the application is active and which of the application's forms is active.

[Figure 8.2:](#) The output of the `Screen` example with some secondary forms

[Figure 8.3:](#) The `MdiDemo` program uses a series of predefined Delphi actions connected to a menu and a toolbar.

[Figure 8.4:](#) The output of the `MdiMulti` example, with a child window that displays circles

[Figure 8.5](#): The menu bar of the MdiMulti application changes automatically to reflect the currently selected child window, as you can see by comparing the menu bar with that of Figure 8.4.

[Figure 8.6](#): The New Items dialog box allows you to create an inherited form.

[Figure 8.7](#): The two forms of the VFI example at run time

[Figure 8.8](#): The base-class form and the two inherited forms of the PoliForm example at design time

[Figure 8.9](#): A frame and two instances of it at design time, in the Frames2 example

[Figure 8.10](#): Each page of the FramePag example contains a frame, thus separating the code of this complex form into more manageable chunks.

[Figure 8.11](#): The first page of the FrameTab example at run time. The frame inside the tab is created at run time.

## **Chapter 9: Writing Delphi Components**

[Figure 9.1](#): The Package Editor

[Figure 9.2](#): The Project Options for packages

[Figure 9.3](#): The Contains section of the Package Editor shows both the units that are included in the package and the component resource files.

[Figure 9.4](#): The Object Inspector can automatically expand sub-components, showing their properties, as in the case of the `Timer` property of the `TMdClock` component.

[Figure 9.5](#): A component referencing an external label at design time

[Figure 9.6](#): The output of the Arrow component

[Figure 9.7](#): The output of the Arrow component with a thick pen and a special hatch brush

[Figure 9.8](#): The Arrow component defines a custom property category, `Arrow`, as you can see in the Object Inspector. Notice that properties can be visible in multiple section, such as the `Filled` property in this case.

[Figure 9.9](#): An example of the use of the `ActiveButton` component

[Figure 9.10](#): The `ListDialDemo` example shows the dialog box encapsulated in the `ListDial` component.

[Figure 9.11](#): The collection editor, with the Object `TreeView` and the Object Inspector for the collection item

[Figure 9.12](#): The list of sounds provides a hint for the user, who can also type in the property value or double-click to activate the editor (shown later, in Figure 9.13).

[Figure 9.13](#): The Sound Property Editor's form displays a list of available sounds and lets you load a file and hear the selected sound.

[Figure 9.14](#): The custom menu items added by the component editor of the `ListDialog` component

## **Chapter 10: Libraries and Packages**

[Figure 10.1](#): The output of the `CallCpp` example when you have clicked each of the buttons

[Figure 10.2](#): The output of the CallFrst example, which calls the DLL you've built in Delphi

[Figure 10.3](#): The Application page of the Project Options dialog box now has a Library Name section.

[Figure 10.4](#): If you run two copies of the UseMem program, you'll see that the global data in its DLL is not shared.

[Figure 10.5](#): The structure of the package hosting a form in Delphi's Package Editor

[Figure 10.6](#): The output of the PackInfo example, with details of the packages it uses

## **Chapter 11: Modeling and OOP Programming (with ModelMaker)**

[Figure 11.1](#): A class diagram in ModelMaker

[Figure 11.2](#): A class diagram with interfaces, classes, and interface delegation

[Figure 11.3](#): ModelMaker's Interface Wizard

[Figure 11.4](#): A sequence diagram for an event handler of the NewDate example

[Figure 11.5](#): The organizational possibilities of the Diagrams view

[Figure 11.6](#): The Property Editor dialog

[Figure 11.7](#): ModelMaker with the Implementation tab active

[Figure 11.8](#): ModelMaker's Difference view

[Figure 11.9](#): The Documentation tab of a Class Symbol

[Figure 11.10](#): ModelMaker's Code Template Parameters dialog box

## **Chapter 12: From COM to COM+**

[Figure 12.1](#): An example of the GUIDs generated by the NewGuid example. Values depend on my computer and the time I run this program.

[Figure 12.2](#): The COM Object Wizard

[Figure 12.3](#): The Word document is being created and composed by the WordTest Delphi application.

[Figure 12.4](#): The type-library editor, showing the details of an interface

[Figure 12.5](#): Delphi's Type Library Import dialog box.

[Figure 12.6](#): The second toolbar of the OleCont example (above) is replaced by the server's toolbar (below).

[Figure 12.7](#): The WordCont example shows how to use Automation with an embedded object.

[Figure 12.8](#): The WebDemo program after choosing a page that's well known by Delphi developers

[Figure 12.9](#): The XArrow ActiveX control and its property page, hosted by the Delphi environment

[Figure 12.10](#): The XClock control in the sample HTML page

[Figure 12.11](#): The New Trans-ational Object dialog box, used to create a COM+ object

[Figure 12.12](#): The newly installed COM+ component in a custom COM+ application (as shown by Microsoft's Component Services tool)

[Figure 12.13](#): A COM+ event with two subscriptions in the Component Services management console

[Figure 12.14](#): The NetImport program uses a .NET object to sum numbers.

## **Chapter 13: Delphi's Database Architecture**

[Figure 13.1](#): A sample local table active at design time in the Delphi IDE

[Figure 13.2](#): The XML display of a CDS file in the MyBase2 example. The table structure is defined by the program, which creates a file for the dataset on its first execution.

[Figure 13.3](#): The data-aware controls of the DbAware example at design time in Delphi

[Figure 13.4](#): The output of the CustLookup example, with the DBLookupCombo-Box showing multiple fields in its drop-down list

[Figure 13.5](#): The Fields Editor with the Add Fields dialog box

[Figure 13.6](#): The output of the FieldAcc example after the Center and Format buttons have been clicked

[Figure 13.7](#): The definition of a calculated field in the Calc example

[Figure 13.8](#): The output of the Calc example. Notice the Population Density calculated column and the ellipsis button displayed when you edit it.

[Figure 13.9](#): The output of the FieldLookup example, with the drop-down list inside the grid displaying values taken from another database table

[Figure 13.10](#): By handling the *OnGetText* and *OnSetText* events of a date field, the NullDates example displays specific output for null values.

[Figure 13.11](#): The output of the Total program, showing the total salaries of the employees

[Figure 13.12](#): The DrawData program displays a grid that includes the text of a memo field and the ubiquitous Borland fish.

[Figure 13.13](#): The MltGrid example has a DBGrid control that allows the selection of multiple rows.

[Figure 13.14](#): The output of the NonAware example in Browse mode. The program manually fetches the data every time the current record changes.

[Figure 13.15](#): In the SendToDb example, you can use a combo box to select the record you want to see.

[Figure 13.16](#): The CdsCalcs example demonstrates that by writing a little code, you can have the DBGrid control visually show the grouping defined in the ClientDataSet.

[Figure 13.17](#): The bottom portion of a ClientDataSet's Fields Editor displays aggregate fields.

[Figure 13.18](#): The MastDet example at run time

## **Chapter 14: Client/Server with dbExpress**

[Figure 14.1:](#) IBConsole lets you manage, from a single computer, InterBase databases hosted by multiple servers.

[Figure 14.2:](#) IBConsole can open separate windows to show you the details of each entity—in this case, a table.

[Figure 14.3:](#) IBConsole's Interactive SQL window lets you try in advance the queries you plan to include in your Delphi programs.

[Figure 14.4:](#) The dbExpress Connection Editor with the dbExpress Drivers Settings dialog box

[Figure 14.5:](#) The CommandText Editor used by the SQLDataSet component for queries

[Figure 14.6:](#) A sample log obtained by the SQLMonitor in the DbxSingle example

[Figure 14.7:](#) The SchemaTest example allows you to see a database's tables and the columns of a given table.

[Figure 14.8:](#) Editing a query component's collection of parameters

[Figure 14.9:](#) The ParQuery example at run time

[Figure 14.10:](#) The CdsDelta program displays the status of each record of a ClientDataSet.

[Figure 14.11:](#) The CdsDelta example allows you to see the temporary update requests stored in the `Delta` property of the ClientDataSet.

[Figure 14.12:](#) The Reconcile Error dialog provided by Delphi in the Object Repository and used by the CdsDelta example

[Figure 14.13:](#) The form of the TranSample application at design time. The radio buttons let you set different transaction isolation levels.

[Figure 14.14:](#) The output of the IbxUpdSql example

[Figure 14.15:](#) The output of the IbxMon example, based on the IBMonitor component

[Figure 14.16:](#) The server information displayed by the IbxMon application

[Figure 14.17:](#) The editor for the `GeneratorField` property of the IBX datasets

[Figure 14.18:](#) A form showing companies, office locations, and people (part of the RWBlocks example)

[Figure 14.19:](#) The RWBlocks example form for class registrations

[Figure 14.20:](#) The free query form of the RWBlocks example is intended for power users.

## **Chapter 15: Working with ADO**

[Figure 15.1:](#) Delphi's connection string editor

[Figure 15.2:](#) The first page of Microsoft's connection string editor

[Figure 15.3:](#) The OpenSchema example retrieves the primary keys of the database tables.

[Figure 15.4:](#) Setting extended properties

[Figure 15.5:](#) ABCCompany.xls in Delphi—a small tribute to Douglas Adams

[Figure 15.6:](#) The form of the DataClone example, with two copies of a dataset (the original and a clone)

## **Chapter 16: Multitier DataSnap Applications**

[Figure 16.1:](#) The Remote Data Module Wizard

[Figure 16.2:](#) When you activate a ClientDataSet component connected to a remote data module at design time, the data from the server becomes visible as usual.

[Figure 16.3:](#) The error message displayed by the ThinCli2 example when the employee ID is too large

[Figure 16.4:](#) The form of the ClientRefresh example, which automatically refreshes the active record and allows more extensive updates by clicking the buttons

[Figure 16.5:](#) The secondary form of the ThinPlus example, showing the data of a parametric query

[Figure 16.6:](#) The ThinPlus example shows how a dataset field can either be displayed in a grid in a floating window or extracted by a ClientDataSet and displayed in a second form. You'll generally do one of the two things, not both!

## **Chapter 17: Writing Database Components**

[Figure 17.1:](#) The data-aware ProgressBar in action in the DbProgr example

[Figure 17.2:](#) The DbTrack example's track bars let you enter data in a database table. The check box and buttons test the enabled status of the components.

[Figure 17.3:](#) The ViewGrid example demonstrates the output of the RecordView component, using Borland's sample BioLife database table.

[Figure 17.4:](#) An example of the MdDbGrid component at design time. Notice the output of the graphics and memo fields.

[Figure 17.5:](#) The structure of each buffer of the custom dataset, along with the various local fields referring to its subportions

[Figure 17.6:](#) The form of the StreamDSDemo example. The custom dataset has been activated, so you can already see the data at design time.

[Figure 17.7:](#) The output of the DirDemo example, which uses an unusual dataset that shows directory data

[Figure 17.8:](#) The ObjDataSet-Demo example showcases a dataset mapped to objects using RTTI.

## **Chapter 18: Reporting with Rave**

[Figure 18.1:](#) The Rave Designer with a simple report

[Figure 18.2:](#) The Rave Report Preview window for a report

[Figure 18.3:](#) After executing a Rave project, a user can choose the output format or rendering engine.

[Figure 18.4:](#) The RaveSingle report (generated with the help of a wizard) at design time

[Figure 18.5:](#) The Rave Designer's Data Text Editor

[Figure 18.6:](#) The master/detail report. The Band Style Editor appears in front of it.

[Figure 18.7:](#) The bold text in the report is determined at run time by a script.

## **Chapter 19: Internet Programming: Sockets and Indy**

[Figure 19.1:](#) The client program of the IndySock1 example

[Figure 19.2:](#) The client and server programs of the data-base socket example (IndyDbSock)

[Figure 19.3:](#) The SendList program at design time

[Figure 19.4:](#) The WebFind application can be used to search for a list of sites on the Google search engine.

[Figure 19.5:](#) The output of the BrowseFast text-only browser

[Figure 19.6:](#) The page displayed by connecting a browser to the custom HttpServ program

[Figure 19.7:](#) The output of the HtmlProd example, a simple demonstration of the Page-Producer component, when the user clicks the Demo Page button

[Figure 19.8:](#) The output of the HtmlProd example for the Print Line button

[Figure 19.9:](#) The editor of the DataSetTable-Producer component's `Columns` property provides you with a preview of the final HTML table (if the data-base table is active).

## **Chapter 20: Web Programming with WebBroker and WebSnap**

[Figure 20.1:](#) The output of the CgiDate application, as seen in a browser

[Figure 20.2:](#) A list of applications registered with the Web App Debugger is displayed when you hook to its home page.

[Figure 20.3:](#) The output corresponding to the table path of the BrokDemo example, which produces an HTML table with internal hyperlinks

[Figure 20.4:](#) The form action of the CustQueP example produces an HTML form with a selection component dynamically updated to reflect the current status of the database.

[Figure 20.5:](#) The WebSearch program shows the result of multiple searches done on Google.

[Figure 20.6:](#) The options offered by the New Web-Snap Application dialog box include the type of server and a button that lets you select the core application components.

[Figure 20.7:](#) The New WebSnap Page Module dialog box

[Figure 20.8:](#) The WSnap2 example features a plain script and a custom menu stored in an include file.

[Figure 20.9:](#) The Web Surface Designer for the inout page of the WSnap2 example, at design time

[Figure 20.10:](#) The page shown by the WSnapTable example at startup includes the initial portion of a paged table.

[Figure 20.11](#): The formview page shown by the WSnapTable example at design time, in the Web Surface Designer (or AdapterPageProducer editor)

[Figure 20.12](#): The WSnapMD example shows a master/detail structure and has some customized output.

[Figure 20.13](#): Two instances of the browser operate on two different sessions of the same WebSnap application.

## **Chapter 21: Web Programming with IntraWeb**

[Figure 21.1](#): The IWSimpleApp program in a browser

[Figure 21.2](#): The controller form of a stand-alone IntraWeb application

[Figure 21.3](#): The IWTree example features a menu, a tree view, and the dynamic creation of a memo component.

[Figure 21.4](#): The IWTwoForms example uses an IWGrid component, embedded text, and IWURL components.

[Figure 21.5](#): The IWSession application has both session-specific and global counters, as you can see by running two sessions in two different browsers (or even in the same browser).

[Figure 21.6](#): IntraWeb's HTML Layout Editor is a full-blown visual HTML editor.

[Figure 21.7](#): The data-aware grid of the IWScrollData example

[Figure 21.8](#): The main form of the IWGridDemo example uses a framed grid with hyperlinks to the secondary form.

[Figure 21.9](#): The secondary form of the IWGridDemo example allows a user to edit the data and navigate through records.

[Figure 21.10](#): The grid of the IWClientGrid example supports custom sorting and filtering without re-fetching the data on the web server.

## **Chapter 22: Using XML Technologies**

[Figure 22.1](#): The XmlEditOne example allows you to enter XML text in a memo, indicating errors as you type, and shows the result in the embedded browser.

[Figure 22.2](#): The XmlDomTree example can open a generic XML document and show it inside a TreeView common control.

[Figure 22.3](#): The DomCreate example can generate various types of XML documents using a DOM.

[Figure 22.4](#): The XML generated to describe the form of the DomCreate program. Notice (in the tree and in the memo text) that properties of class types are further expanded.

[Figure 22.5](#): Delphi's XML Data Binding Wizard can examine the structure of a document or a schema (or another document definition) to create a set of interfaces for simplified and direct access to the DOM data.

[Figure 22.6](#): The log produced by reading an XML document with the SAX in the Sax-Demo1 example

[Figure 22.7](#): The XML Mapper shows the two sides of a transformation to define a mapping between them (with the rules indicated in the central portion).

[Figure 22.8](#): The XmlMapping example uses a TransformProvider component to make a complex XML document available for editing within multiple ClientData-Set components.

[Figure 22.9:](#) The MapTable example generates an XML document from a database table using a custom transformation file.

[Figure 22.10:](#) The InetXPage-Producer editor allows you to build complex HTML forms visually, similarly to the AdapterPageProducer.

[Figure 22.11:](#) The leFirst application sends the browser some HTML components, an XML document, and the JavaScript code to show the data in the visual components.

# **Introduction**

## **ABOUT OPENGL**

### **What it Is and Is Not**

OpenGL is an Open Graphics Library. Although Silicon Graphics originally developed it for one of their own graphics workstations, it is not a proprietary system for a single platform. OpenGL is now an industry standardized library of graphics commands that enable programs to produce anything from simple lines to 3-D animation. The OpenGL Architecture Review Board works to insure that each implementation complies with the library's defined standard.

OpenGL is strictly about graphics. Unlike Direct X (for Windows) it has nothing to do with sound, joysticks, etc. It does one thing, graphics, and it does that one thing very well. It is not a resource hog; its two Windows libraries consume less than one megabyte of disk space. Although OpenGL gives the graphics programmer a rich and powerful set of commands, it provides a clean and simple Application Programming Interface (API). Just the little bit of programming work introduced in Chapter 1 is sufficient to produce some graphics effects. Most of that work is simply getting Windows to work with OpenGL. Very little effort with OpenGL commands themselves is required to produce some basic graphics.

### **The Windows Implementation**

In Windows, OpenGL is implemented in `opengl32.dll` for the main graphics commands, and `glu32.dll` for the utility library. As those file names imply, OpenGL is only available for 32-bit versions of Windows, such as NT and 95 or later. Windows NT, Windows 98, and OEM versions of Windows 95 (pre-installed by the computer manufacturer) include the OpenGL libraries, but a separately purchased copy of Windows 95 may require downloading the two DLL's from the Internet. Alternatively, you may obtain modules from the appropriate vendors, that take advantage of hardware support in newer video cards. Such hardware-supporting libraries may have names slightly different from the ones provided by

Microsoft.

The two Dynamic Link Libraries (DLL's) contain a powerful set of routines by which one can produce truly impressive three-dimensional graphics scenes and animations, especially with 16-bit palettes or better. The Windows implementation can work with 8-bit palettes, but that requires extra coding the book presents later. For now set the system to work with High Color (16-bit) or True Color (24-bit or 32-bit).

## ABOUT THE READER

The intended audience for this book is the Delphi developer interested in graphics programming. While the reader does not require expert level knowledge to benefit from this book, he or she should be familiar with Delphi's event-driven model, with Object Pascal's Unit structure, and with object-oriented programming. The reader should also be comfortable with Windows programming in general.

Not only should the reader be experienced using the above programming concepts, but should also be familiar enough with Delphi's IDE (Integrated Development Environment) to implement those concepts. The book asks, without detailed explanation, the reader to perform such tasks as generate specific event handlers or save a project to a new location with a different name.

The reader also needs to know enough about the user interface for a suitable 32-bit version of Windows to be able set the color depth to 16 or 24 bits. Of course, the reader must have direct access to Windows NT or 95 or later, as well as to a 32 bit version of Delphi.

Finally, the reader needs to have an interest in graphics programming. That's it! The reader does not need to start out with much graphics knowledge, just an interest.

If you have read this far without cringing, this book must be for you. No longer are you (the reader) treated as if you were off in another room being discussed behind your back. Congratulations! Welcome to the wonderful world of graphics programming with Delphi and OpenGL.

## ABOUT DELPHI

OpenGL produces various graphic images in a window, which in Delphi is a form. The place to perform the OpenGL commands is Delphi event handlers. Since the Windows version of OpenGL is a 32-bit DLL, use at least Delphi 2. Finally, Delphi 3 and 4 bring a required feature. They come with an interface unit for OpenGL and its utility library. Using OpenGL with Delphi requires a 32-bit version of Delphi, an OpenGL interface unit, and a working knowledge of developing Delphi applications.

### The Interface Unit

If your version of Delphi does not have an OpenGL interface unit, you can download one from the Internet. Wherever you obtain the interface unit, simply reference it in the **uses** clause of any unit that invokes OpenGL commands. Be sure to place the .DCU (Delphi Compiled Unit) file in Delphi's library path, otherwise give a full path to it in the .DPR (Delphi PProject) file. For example, in Delphi 3, the interface file is in the LIB directory under the DELPHI 3 directory. To see or modify the library path, go to the Library tab of the Environment Options window.

## Roll Your Own Interface

Actually, this book provides enough information about the OpenGL commands by which to construct an interface unit. A sample format of an interface unit follows. Notice the call in the initialization section that disables floating point exceptions. Keep in mind that Silicon Graphics, Inc., holds the copyright to the OpenGL libraries, and the required unit is an interface to their libraries.

```
unit OpenGL;  
  
interface  
  
uses  
    Windows;  
  
const  
    GL_COLOR_BUFFER_BIT = $4000;  
Type  
    HGLRC = THandle;  
    GLenum = cardinal;  
    GLbitfield = cardinal;  
    GLfloat = single;  
    GLclampf = single;  
  
{regular commands}  
procedure glClear(mask:GLbitfield); stdcall;  
procedure glClearColor(red,green,blue,alpha:GLclampf); stdcall  
function glGetError: GLenum; stdcall;  
  
{utility commands}  
  
implementation  
  
{regular commands}  
procedure glClear; external opengl32;  
procedure glClearColor; external opengl32;  
function glGetError; external opengl32;  
  
{utility commands}  
  
initialization  
    Set8087CW($133F);  
end.
```

## ABOUT THIS BOOK

### Style Convention

The type style used in this book is simple and straightforward. **Bold** type, **larger** font sizes, and **CAPITALIZATION** indicate levels of organization of the topics, in a fairly obvious way. *Italics* introduce new terms whose explanations soon follow. Code examples and

listings use a monospaced font, with certain key words, such as **procedure**, in bold face in a manner similar to the syntax highlighting used in the Delphi editor. The interface example above illustrates these techniques.

## Content

This is a hands-on, learn-by-doing book. For greatest benefit from the book place it near the computer, turn on the computer, and launch Delphi. Create a separate directory or folder in a suitable location for placing various OpenGL projects. Naming the directory “OPENGL” is a good choice.

Some people may prefer to develop a thorough background before they write their first line of code. I am not one of those people. While I do like to have a good understanding of the tools I am using and the tasks I am (hopefully) accomplishing, I also like to dive in and start doing something! I wrote this book the way someone like me would like to see books written.

Code writing begins as soon as possible, and explanation and theory appear as needed, building the concepts a little at a time. Each step has just enough explanation to use the program code under development, without a dumping of the whole load at once. Appendix A is the reference section for each OpenGL command.

This book generally takes each concept from the simple to the complex, making the basic steps obvious before obscuring them with a lot of detail. Do not be alarmed when some portions of code do not work very well. Sometimes the best way to show the reason for doing something a certain way is to take the direct approach first and, by the results, demonstrate why it must be a little different.

In short, this is a learning adventure, so fasten your seat belts, launch Delphi, and start!

[Previous](#) [Table of Contents](#) [Next](#)

# **Chapter 1**

## **The First Steps**

In an ideal world only a few lines of code would produce graphics right now. Alas, in the real world, some preliminary housekeeping is necessary. In this chapter you will learn how to make the necessary connection between Windows and OpenGL. The plan is to produce some graphics as soon as possible, so be patient with the necessary set up. In the spirit of getting to the interesting code as soon as possible, this chapter is fairly short and ends with actual graphics output. Although it is just a simple colored background, it shows that the code setting it up successfully did its job. Though trivial, this simple scene is not just a token reward for enduring a necessary evil. The code for producing it forms the basis for more advanced output.

## **DIRECTORY STRUCTURE**

To use this book effectively you will be writing code along the way and will create and save a number of projects, so pick a drive for keeping these OpenGL projects. Create a directory and name it OpenGL. Under that directory create subdirectories named Chapter.1, Chapter.2, etc. Some chapters may produce several projects, and these each have their own subdirectories under the chapter directory. You can, of course, organize in some other way, but the book proceeds as if you use the recommended directory structure and names for your projects, so you must translate as you go.

## **PRELIMINARY CODE**

### **Getting Ready to Start to Begin**

OpenGL is intended to be fairly platform-independent, rather than just for Windows. Therefore OpenGL needs a link to Windows, using some special structures and API extensions in Windows to provide this link. In Delphi a good place for the connection is within a form's OnCreate event handler.

Create a new project and save it in a new directory under the OpenGL directory created earlier. Name the new directory "Chapter.1," name the project "First.Dpr," and name the main unit "First1.Pas". Double-click the main form to set up the form's OnCreate event handler. Define a

variable of type `TPixelFormatDescriptor` and fill it in. Defining the pixel format with this structure permits describing some properties that the Windows GDI (graphics device interface) needs in order to work with OpenGL.

```
procedure TForm1.FormCreate(Sender: TObject);  
var  
    pfd: TPixelFormatDescriptor;  
    FormatIndex: integer;  
begin  
    fillchar(pfd, SizeOf(pfd), 0);  
    with pfd do  
        begin  
            nSize      := SizeOf(pfd);  
            nVersion   := 1; {The current version of the descriptor is 1}  
            dwFlags    := PFD_DRAW_TO_WINDOW or PFD_SUPPORT_OPENGL;  
            iPixelFormat := PFD_TYPE_RGBA;  
            cColorBits := 24; {support 24-bit color}  
            cDepthBits := 32; {depth of z-axis}  
            iLayerType := PFD_MAIN_PLANE;  
        end; {with}  
        FormatIndex := ChoosePixelFormat(Canvas.Handle, @pfd);  
end; {FormCreate}
```

Inform the system of the desired properties by calling `ChoosePixelFormat`, passing it form's device context and a pointer to the descriptor. Depending on what the device context can support, the contents of the descriptor may be altered to reflect the best approximation of the request. Windows uses Device Contexts, and OpenGL uses Rendering Contexts. This code attempts to map them to each other.

**DEVICE CONTEXT** The use of a device context is not obvious in this code. In Delphi, the `Canvas` property is a wrapper for a window's device context, and `Canvas.Handle` is the handle to the device context. This code uses native Delphi where possible, leaving out error checking and other details for clarity. Be patient for a while; the code improves later.

**DESCRIPTOR FIELDS** This descriptor has a number of fields that can remain zero or the equivalent, so explicit assignment statements were unnecessary. Here is a quick look at the rest of the contents of the descriptor to meet the current needs:

- 1.nSize.** Windows structures often require the size of the structure as part of the structure itself. This field follows that tradition.
- 2.nVersion.** The version number of the descriptor structure is 1, so a 1 must be stored here.
- 3.dwFlags.** The bits are set by or-ing together some pre-defined constants. `PFD_DRAW_TO_WINDOW` has an obvious meaning; you could be drawing to a bitmap in memory instead. `PFD_SUPPORT_OPENGL` is certainly a desired feature. Keep in mind that this code does not yet do anything with OpenGL; it just gets Windows ready for OpenGL. These are Windows structures and Windows API calls. Windows does not assume the code will work with OpenGL unless the code tells it. `ChoosePixelFormat` attempts to find a pixel format with the same flags set as those passed to it in the descriptor.
- 4.iPixelFormat.** Use RGBA (red, green, blue, alpha) pixels. Explanation of Alpha comes later.
- 5.cColorBits.** Support 24-bit color.
- 6.cDepthBits.** Set the depth of the z-axis to 32. Explanation of depth comes later.
- 7.iLayerType.** The current version only supports the main plane.

`ChoosePixelFormat` is a function that returns an integer, stored in `FormatIndex`. It returns zero to indicate an error, or a positive number as an index to the appropriate pixel format. `SetPixelFormat`

sets the pixel format of the device context, using that index. Now the bottom of the OnCreate event handler looks like this:

```
FormatIndex := ChoosePixelFormat(Canvas.Handle,@pfd);
SetPixelFormat(Canvas.Handle,FormatIndex,@pfd);
end; {FormCreate}
```

The functions receive the handle to the window's device context and change the pixel format of the window. So far none of the code produces visible results other than a standard blank form, but keep coding. OpenGL will shine forth soon.

## Starting to Begin

**RENDERING CONTEXT** Now that the code takes care of the pixel format, proceed to the rendering context. Add GLContext to the private section of the form:

```
type
  TForm1 = class (TForm)
    procedure FormCreate(Sender: TObject);
  private
    GLContext : HGLRC;
  public
    { Public declarations }
  end;
```

The HGLRC type is a handle to an OpenGL Rendering Context type. Here is its declaration for the interface unit:

```
type
  HGLRC = THandle;
```

<a href="#">Previous</a>	<a href="#">Table of Contents</a>	<a href="#">Next</a>
--------------------------	-----------------------------------	----------------------

## Delphi Developer's Guide to OpenGL

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

The new variable receives the result of `wglCreateContext`. This is one of several `wgl` (Windows-GL) functions for managing rendering contexts. Place this call at the bottom of the event handler:

```
FormatIndex := ChoosePixelFormat(Canvas.Handle, @pfd);
SetPixelFormat(Canvas.Handle, FormatIndex, @pfd);
GLContext := wglCreateContext(Canvas.Handle);
end; {FormCreate}
```

As the name implies, this function creates the OpenGL rendering context needed by the window. Now make it current:

```
FormatIndex := ChoosePixelFormat(Canvas.Handle, @pfd);
SetPixelFormat(Canvas.Handle, FormatIndex, @pfd);
GLContext := wglCreateContext(Canvas.Handle);
wglMakeCurrent(Canvas.Handle, GLContext);
end; {FormCreate}
```

**CLEAN UP** You should always put away your tools when finished with them, and you should always put away windows resources when finished with them. Go to the events page of the object inspector for the form. Double-click the `OnDestroy` event. Fill in the event handler as follows:

```
procedure TForm1.FormDestroy(Sender: TObject);
begin
    wglMakeCurrent(Canvas.Handle, 0);
    wglDeleteContext(GLContext);
end;
```

Passing a zero to `wglMakeCurrent` makes the previously current context no longer current. Now that `GLContext` is no longer current, delete it with `wglDeleteContext`.

## Begin

**USES CLAUSE** So far the code is nothing but Windows and Delphi code. The time has arrived for some OpenGL code. Add OpenGL to a **uses** clause. Put it in the interface section in order to use an OpenGL type in the interface.

**uses**

Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs, OpenGL, Menus;

**PAINT** Again go to the events page of the form's object inspector. This time double-click the OnPaint event. This event fires every time the window (form) needs repainting, such as when the form has been partially (or fully) covered and then exposed again. It also fires when the form first shows. Make this event handler like the following:

```
procedure TForm1.FormPaint(Sender: TObject);
begin
    {background}
    glClearColor(0.0,0.4,0.0,0.0);
    glClear(GL_COLOR_BUFFER_BIT);

    {error checking}
    errorCode := glGetError;
    if errorCode<>GL_NO_ERROR then
        raise Exception.Create('Error in Paint'#13+
            gluErrorString(errorCode));
end;
```

The given OpenGL commands have the following declaration:

```
procedure glClear(mask:GLbitfield); stdcall;
procedure glClearColor(red,green,blue,alpha:GLclampf); stdcall;
```

Their implementations are simply references to the DLL which contains the code and look like this:

```
procedure glClear; external opengl32;
procedure glClearColor; external opengl32;
```

**ERROR CHECKING** Notice this code introduces a little bit of error checking. This method is small enough (so far) that including the error checking code at this point does not obscure the main activity.

Use glClearColor to set the background color. Each color component ranges in floating point value from zero to one. In this case the color has no red, 0.4 units of green, and no blue. Set alpha to zero for now. The background color is a dark green (a little less than half the maximum intensity of green, which would be 1.0).

This is a good time to introduce an OpenGL type. Much of this graphics library, including color specifications, uses floating point numbers. To keep itself portable, OpenGL defines a type called GLfloat. Under Windows on Intel processors and compatibles, GLfloat is the same as a Delphi single, which is an IEEE (Institute for Electrical and Electronics Engineers) 32 bit floating point value. In the interface unit is a type declaration like this:

```
GLfloat = single;
```

Next call glClear and pass it a bit mask that tells it what to clear. This clears the buffers enabled for writing colors. For error checking this segment of code introduces the function glGetError, which appears often. It returns a number of type GLenum, which is an alias for Cardinal. The following type declaration appear in the interface unit:

```
GLenum = Cardinal;
```

Store the result in `errorCode`, which you should add to the private section of the form declaration.

```
ErrorCode: GLenum;
```

Compare the result to `GL_NO_ERROR`, a pre-defined constant of obvious meaning. If there is an error, raise an exception. The application handles this exception simply by displaying the message. The message includes another new function, `gluErrorString`, from the OpenGL utility library. It returns a pointer to some text (`PChar`). The text represents the meaning of the error number passed to the function. Delphi's string concatenation knows how to handle that `PChar`.

The constant has this declaration:

```
GL_NO_ERROR = 0;
```

Here is the declaration for the function:

```
function gluErrorString(errCode:GLenum):PChar; stdcall;
```

Since this function name begins with “glu,” its code is found in the other DLL:

```
function gluErrorString; external glu32;
```

Now, save the program (you have been warned!) and compile it. Do not run it from the Delphi IDE (Integrated Development Environment). OpenGL programs sometimes crash if launched from the IDE even though they work fine when run independently. That is why it was so important to save your work before starting, just in case you got stubborn and ran it from the IDE anyway. You might be lucky, but you might not. Use the Windows Run command, giving it the appropriate path. Behold! A dark green form!

**MORE DEVICE CONTEXT** Some of the code just written needs improving. The time has arrived to demonstrate why. Drag the form by its title bar left and right and up and down, so that parts are obscured and re-exposed repeatedly. Partially cover it with some other window, then uncover it. Do this a number of times until something strange happens. Eventually some part of the form fails to show green after exposure.

[Previous](#) [Table of Contents](#) [Next](#)

While `Canvas.Handle` is the handle to the device context, it is not reliable for these purposes, because it is generated on the fly, when referenced, then released. So the device context matched up with the rendering context at one point may not even exist at another point. The rendering context would not then have a valid association. The application needs a handle it can control. In the private section of the form define `glDC`:

**type**

```
TForm1 = class (TForm)
    procedure FormCreate(Sender: TObject);
    procedure FormDestroy(Sender: TObject);
    procedure FormPaint(Sender: TObject);
private
    GLContext: HGLRC;
    glDC: HDC;
    errorCode: GLenum;
public
    { Public declarations }
end ;
```

In the `FormCreate` method (OnCreate handler), call `getDC` and replace all references to `Canvas.Handle` with `glDC`:

```
glDC := getDC(handle);
FormatIndex := ChoosePixelFormat(glDC, @pfd);
SetPixelFormat(glDC, FormatIndex, @pfd);
GLContext := wglCreateContext(glDC);
wglMakeCurrent(glDC, GLContext);
end; {FormCreate}
```

Save the code again, compile it, then run it (independently). Now it works much

more reliably.

**MORE ERROR HANDLING** In the FormCreate method is the basic setup required to use OpenGL under Windows. Now that the code has appeared in its simplicity, it is time to complicate it with error checking. It is not exciting, but all good software requires some kind of error handling or reporting. With these learning programs, if something fails, at least some kind of clue should appear. Add a boolean to the form's private declaration. As a field of a TObject descendant it is initialized to false. If you are not familiar with this initialization, see Delphi's online help for the InitInstance method under TObject.

**private**

```
    GLContext: HGLRC;  
    glDC: HDC;  
    errorCode: GLenum;  
    openGLReady: boolean;
```

In FormPaint test openGLReady because there is no point in calling OpenGL commands if they were not even set up.

```
procedure TForm1.FormPaint(Sender: TObject);  
begin  
    if not openGLReady then  
        exit;  
    {background}  
    glClearColor(0.0,0.4,0.0,0.0);  
    glClear(GL_COLOR_BUFFER_BIT);  
  
    {error checking}  
    error := glGetError;  
    if error<>GL_NO_ERROR then  
        raise Exception.Create('Error in Paint'#13+  
            gluErrorString(errorCode));  
end;
```

FormCreate also needs to test some function results. On failure call GetLastError which returns a Windows error code. If execution make it all the way to the end of the method, the reward is setting OpenGLReady to true.

```
    glDC := getDC(handle);  
    FormatIndex := ChoosePixelFormat(glDC,@pfd);  
    if FormatIndex=0 then  
        raise Exception.Create('ChoosePixelFormat failed '+  
            IntToStr(GetLastError));  
  
    if not SetPixelFormat(glDC,FormatIndex,@pfd) then  
        raise Exception.Create('SetPixelFormat failed '+  
            IntToStr(GetLastError));  
  
    GLContext := wglCreateContext(glDC);  
    if GLContext=0 then
```

```
raise Exception.Create('wglCreateContext failed '+
    IntToStr(GetLastError)');

if not wglMakeCurrent(glDC, GLContext) then
    raise Exception.Create('wglMakeCurrent failed '+
        IntToStr(GetLastError)');
OpenGLReady := true;
end; {FormCreate}
```

Be sure to save your work. The next chapter starts with this code as the foundation.

## **DEFINITIONS**

### **Term**

24-bit color

### **Meaning**

On typical PC video hardware colors have three components: red, green, and blue. Each color component can range in integer value from 0 (none) to 255 (maximum intensity), allowing an 8-bit (1-byte) integer to specify each intensity. You can specify 256\*256\*256 color combinations. These 16,777,216 possible colors are more than the human eye can distinguish. In a True Color or 24-bit color mode you can specify the color components directly, using at least a 24-bit number, but with a lesser "color depth" (number of bits to specify a color), the number you use to describe a color is just an index into a "palette" or pre-defined array of colors.

Background color

The color that shows through in a window when nothing else is drawn at a particular location. When a window is cleared, it is filled with the appropriate background color.

Current context

The active (currently being used) rendering context.

Device Context

A set of information about Windows drawing modes and

commands.

GDI	Graphics Device Interface. A standardized way of specifying graphics operations under Windows independently of the hardware.
Pixel	Picture element. The smallest unit of drawing. A dot.
Pixel format	Those characteristics of a device context needed for setting up a rendering context.
Rendering Context	A set of information about OpenGL states and commands under Windows.
RGBA	Red, Green, Blue, Alpha. OpenGL's method of specifying color. Each of the three color components are floating point values that range from 0.0 (none) to 1.0 (maximum intensity). The combination of the three "pure" colors produces the color intended for the viewer. The alpha component is reserved for a later chapter.

## IDENTIFIER REFERENCE

Identifier	Description
ChoosePixelFormat	A Windows function that receives a handle to a device context and a pointer to a pixel format descriptor. It returns an integer index to Windows' best attempt at a pixel format matching the specifications in the descriptor.
getDC	A Windows function that receives a handle to a window and returns a handle to that window's device context.
GetLastError	A Windows function that returns an integer representing the most recent error.
glClear	An OpenGL command that erases a buffer, filling it with the most recently specified background color. If the buffer is the color buffer, then the window is filled with the background color.
glClearColor	An OpenGL command that receives red, blue, green, and alpha floating point values sets the background color to be used by glClear.
GLenum	An OpenGL numeric type that maps to Delphi cardinal;
GLfloat	An OpenGL numeric type that maps to Delphi single.

glGetError	An OpenGL function that returns an integer value representing an error flag set by an OpenGL command, and clears that flag. If no error flags are set when called, the function returns the value of GL_NO_ERROR.
gluErrorString	An OpenGL utility function that receives an error number (such as returned by glGetError) and returns a pointer to a human-readable string (null-terminated) describing the associated OpenGL error flag.
GL_NO_ERROR	An OpenGL constant to represent a successful command.
HDC	A Windows type. Handle to a device context.
HGLRC	A Windows/OpenGL type. Handle to a rendering context.
SetPixelFormat	A Windows function that specifies the pixel format to use with the given device context. While ChoosePixelFormat merely obtains an index to a pixel format, this function sets that pixel format as the one to use. The function receives a handle to the device context, an index to the desired pixel format (such as the one returned by ChoosePixelFormat) and a pointer to the pixel format descriptor (as modified by ChoosePixelFormat). It returns true on success or false on failure. Call GetLastError to learn more about the failure.
TPixelFormatDescriptor	A Windows type. A structure of this type contains the fields needed to select and set a pixel format.
wglCreateContext	A Windows function that creates a rendering context for the specified device context. It receives a handle to the device context and returns a handle to the rendering context.
wglDeleteContext	A Windows function that deletes the specified rendering context. It receives the handle to the rendering context and returns true on success and false on failure.
wglMakeCurrent	A Windows function that makes the specified rendering context current (the one available for use) with the specified device context. It receives the handle to the device context and the handle to the rendering context and returns true on success and false on failure.

## SUMMARY

Chapter 1 showed how to:

1. Link the Windows graphics device context with the OpenGL rendering context.
2. Use actual OpenGL commands to fill a window with a color.

### 3. Perform some basic error checking with OpenGL commands.

## Chapter 2 Basics

OpenGL majors in three-dimensional graphics, but computer monitors operate with essentially flat, two-dimensional screens. Representing a three-dimensional space on a two-dimensional surface requires *projection*. Each point in the space projects mathematically to an appropriate point on the surface. This chapter introduces OpenGL commands to identify the part of the window to receive the projection, to set up the projection, and to draw an object. Included with the projection is a *clipping* volume, outside of which no drawing happens. These foundational concepts and commands permit drawing something besides a mere background. This chapter also brings another Delphi event handler into use.

Use the first chapter's final code as the starting point in this chapter. If you have not already done so, create a new directory under the "OPENGL" directory and name it "Chapter.2." In Delphi load the First.Dpr project and do a File|Save Project As in the new directory, naming it "Rect.Dpr." Do File|Save As for the "First1.Pas" unit. Name it "Rect1.Pas" in the new directory.

### VIEW PORT

#### Event Handler

Drawing a green background is a wonderful accomplishment, but by itself, a green background is not very exciting. Drawing a shape ON the background is much more interesting. For now, drawing a rectangle is the next great advance in OpenGL knowledge. The place for drawing is the form's OnPaint event handler, but setting up the drawing area also needs the OnResize handler. Go to the events page of the form's object inspector and double-click OnResize. In the event handler place a call to glViewport and a call to glOrtho, and a modicum of error checking:

```
procedure TForm1.FormResize(Sender: TObject);  
begin  
    if not openGLReady then  
        exit;  
    glViewport(0,0,ClientWidth,ClientHeight);  
    glOrtho(-1.0,1.0,-1.0,1.0,-1.0,1.0);  
    errorCode := glGetError;  
    if errorCode<>GL_NO_ERROR then  
        raise Exception.Create('FormResize:'+gluErrorString(errorCode));  
end
```

## Declaration

Remember that OpenGL is fairly platform independent, so it does not inherently know anything about the coordinate system of the operating environment. Use `glViewport` to make a connection between the coordinates used by the windowing system (Microsoft Windows) and the coordinates used by OpenGL. Its declaration looks like this:

```
procedure glViewport(x,y:GLint; width,height:GLsizei); stdcall;
```

`GLint` and `GLsizei` both map to integer. The meaning of `width` and `height` are as expected, but `x` and `y` need more attention. Windows measures from the upper left corner of a region, but OpenGL measures from the lower left, as if it were relating to the first quadrant of a set of Cartesian coordinates. The main thing to note is that the `y`-direction runs opposite to the familiar Windows coordinates, but fits more naturally with coordinates commonly used in mathematics.

If you are building your own interface unit, the Listing 2-1 encompasses the declarations used thus far, plus a few more that are just waiting in the wings. Add other declarations when they appear.

**Listing 2-1.** Beginning of an Interface Unit.

```
unit OpenGL;  
  
interface  
  
uses  
    Windows;  
  
const  
    GL_COLOR_BUFFER_BIT = $4000;  
    GL_NO_ERROR = 0;  
Type  
    HGLRC = THandle;  
    GLenum = cardinal;  
    GLbitfield = cardinal;  
    GLfloat = single;  
    GLclampf = single;  
    GLint = integer;  
    GLsizei = integer;  
  
    {regular commands}  
procedure glClear(mask:GLbitfield); stdcall;  
procedure glClearColor(red,green,blue,alpha:GLclampf); stdcall;  
function glGetError: GLenum; stdcall;  
procedure glViewport(x,y:GLint; width,height: GLsizei); stdcall;  
  
    {utility commands}  
function gluErrorString(errCode:GLenum):PChar; stdcall;  
  
implementation  
  
    {regular commands}  
procedure glClear; external opengl32;  
procedure glClearColor; external opengl32;  
function glGetError; external opengl32;  
procedure glViewport; external opengl32;  
  
    {utility commands}
```

```
function gluErrorString; external glu32;
```

### **initialization**

```
    Set8087CW($133F);  
end.
```

## **Analogy**

Think of the form as a wall. With `glViewport` cut a hole in the wall through which to view a scene. In this case, cut a hole the size of the entire client area of the form, so all that is left is the frame. A smaller “opening” is possible:

```
glViewport(50,30,80,70);
```

The above example starts at 50 pixels from the left side of the form and 30 pixels up from the bottom of the form. It is 80 pixels wide and 70 pixels tall (going up from the bottom).

It may not be a good idea to specify such absolute coordinates without specifying a non-resizable border or limiting the minimum window size.

One side note: `glViewport` limits the portion of the window in which the scene is *rendered*, but does not restrict the area in which the background is cleared. In the wall analogy think of the background color as something sprayed onto the stage for the scene. Not only does the spray go through the hole in the wall, but the spray also covers the entire wall! There are remedies for this problem, but that subject comes later.

In simplest terms rendering is drawing with OpenGL. To render a scene is to use OpenGL constructs and commands to cause pixels to illuminate in a pattern that represents the scene envisioned by the programmer.

## **ORTHOGRAPHIC PROJECTION**

### **Meaning**

The call to `glOrtho` defines a clipping volume, which is a region in space in which objects can be seen. Any part of a scene that lies outside of the region is not visible (clipped). Of course, though the rendered scenes may be conceptually three-dimensional, they must be projected onto a two-dimensional screen. The available projections are orthographic projection and perspective projection. You get one guess as to which kind `glOrtho` uses. In orthographic projection, also known as parallel projection, an object appears the same size whether it is near or far from the viewer. Showing a simple, flat rectangle certainly does not need anything more complicated. Here is the declaration:

```
procedure glOrtho(left,right,bottom,top,zNear,zFar: GLdouble); stdcall;
```

`GLdouble` is the same thing as a Delphi double, an IEEE 64 bit floating point value.

```
GLdouble = double;
```

## Delphi Developer's Guide to OpenGL

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

Left, right, bottom, and top describe the same area as the `glViewport`, but with programmer-defined values for the edges. The rendering commands use values relative to these. In the above `FormResize` method, `-1.0` is the new value given to the left side of the view port, and `1.0` is the value for the right side. The bottom of the view port is now `-1.0`, and the top is `1.0`. The `z`-values represent directions perpendicular to the screen. The `zNear` value represents the `z`-axis coordinate of the clipping region face nearest the viewer, while `zFar` designates the face farthest from the viewer, deepest into the screen. Those values represent in 3-dimensional space whatever the programmer wants them to mean.

### Flexibility

Here is another example of `glOrtho` with `glViewport`:

```
glViewport(0,0,ClientWidth,ClientHeight);  
glOrtho(3.204,17.2,-11.0,1.45,5.025,41.0);
```

The call to `glViewport` remains the same to isolate the effect, in this example, of changing the values given to `glOrtho`. For example, the clipping region now has a value of `17.2` for its right side. It is still located at the same place as before, which is the right side of the view port, at `ClientWidth`. The value of `17.2` was just convenient. Delphi's Object Pascal language has a similar concept for arrays:

```
var  
  first: array[0..9] of integer;  
  second: array[1..10] of integer;  
  third: array[100..109] of integer;
```

All three of the above variables are equivalent arrays of ten integers, but with different starting points. Why not just use zero-based arrays? After all, that is

all that is available in some programming languages. The answer is that they are declared in a manner convenient for the programmer. An alternate form may allow less typing in the coding of an algorithm, or may more obviously represent some real world concept.

Similarly the programmer has the freedom to assign arbitrary values to the orthographic clipping region. He may choose values for computational convenience or for better conceptual representation of the scene. There is a little bit of order imposed on the glOrtho universe, however. Negative z-values are in front of the view port in the window, and positive z-values are behind the view port. Placing the clipping region entirely in front of the view port strains the hole-in-the-wall analogy, but the comparison has already served its purpose.

## DRAWING

### Command Placement

At last the time has arrived to draw something: a rectangle. As expected, the place to draw the rectangle is in the OnPaint event handler. The drawing commands need to appear between glBegin and glEnd; The latter requires no parameters; the former takes a parameter to set the drawing mode:

```
procedure glBegin(mode:GLenum); stdcall;  
procedure glEnd; stdcall;
```

Between glBegin and glEnd goes a list of vertices, and possibly a few commands related to the vertices. Each vertex is simply a point in space specified by the glVertex command. This command takes many forms, but only a few of them are appropriate here:

```
procedure glVertex2f (x,y: GLfloat); stdcall;  
procedure glVertex3f (x,y,z: GLfloat); stdcall;  
procedure glVertex4f (x,y,z,w: GLfloat); stdcall;
```

### State Variables

In the FormPaint method (Listing 2-2), not only does glClearColor set the clear color (background), but glColor sets the foreground color for drawing. These calls set state variables which remain the same until similar calls explicitly change them. If the command says to draw in blue, all drawing is done in blue until another call changes the state. OpenGL's state variables are in DLLs, not directly accessible to the programmer. You read and write OpenGL's state variables via function and procedure calls. The glColor command is before glBegin in the current event handler method, but it is one of the limited set of commands that can appear between glBegin and glEnd, since color changes are often necessary in the midst of a drawing sequence.

**Listing 2-2.** Setting State Variables in FormPaint.

```
procedure TForm1.FormPaint(Sender: TObject);
```

```

begin
  if not openGLReady then
    exit;
    {green background}
    glClearColor(0.0,0.4,0.0,0.0);
    glClear(GL_COLOR_BUFFER_BIT);

    {red rectangle}
    glColor3f(0.5,0.0,0.0);
    glBegin(GL_POLYGON);
      glVertex2f(0.25,0.25);
      glVertex2f(0.75,0.25);
      glVertex2f(0.75,0.75);
      glVertex2f(0.25,0.75);
    glEnd;
    glFlush;

    errorCode := glGetError;
    if errorCode<>GL_NO_ERROR then
      raise Exception.Create('Error in Paint'#13+
        gluErrorString(errorCode));
end;

```

Here is the declaration of the glColor command used in the FormPaint method:

```
procedure glColor3f(red,green,blue:GLfloat); stdcall;
```

The new constant has this declaration:

```
GL_POLYGON = 9;
```

Since glColor3f has arguments of 0.5, 0.0, and 0.0, OpenGL is drawing in half-intensity red. Alpha is not specified, so it gets 0.0 also. In the calls to glVertex2f, no z-value is passed, so all of the rectangle lies in the z = 0.0 plane. That means the rectangle lies in the same plane as the view port, neither in front nor behind. Recall that glOrtho received arguments of -1.0 for left and 1.0 for right. Since the x-values in glVertex are all positive, the rectangle is entirely on the right side of the viewing area. The same is true of the y-values, so the rectangle lies entirely in the upper half of the viewing area. Remember that all the drawing coordinates are relative to the values defining the clipping region, so changing the arguments to glOrtho could affect the size, shape, and position of the drawing.

## Drawing Mode

```
procedure glBegin(mode:GLenum); stdcall;
```

Note the argument passed to glBegin. GL\_POLYGON informs OpenGL that the subsequent vertex list establishes the corners of a polygon. The number of vertices between glEnd and glBegin are the number of vertices in the polygon,

which in this case is a quadrilateral. The first side of the polygon is a line from the first vertex to the second. The second side of the polygon is a line from the second vertex to the third, and so on until the polygon closes with a line from the last vertex to the first. OpenGL knows to do all that simply by being given `GL_POLYGON`. It further knows to fill in the interior of the polygon with the color previously specified in `glColor`. What if a complete scene needs more than one type of figure? Make multiple `glBegin`, `glEnd` pairs, passing the appropriate mode arguments.

## Delphi Developer's Guide to OpenGL

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

Another new command introduced here is `glFlush`. For the sake of efficiency, the graphics engine does not necessarily start drawing as soon as it receives its first command. It may continue to accumulate information in a buffer until given a little kick. The call to `glFlush` forces it to start drawing.

```
procedure glFlush; stdcall;
```

To illustrate another drawing mode, `GL_LINES`, Listing 2-3 is the code for the `OnPaint` event handler that produced Figure 2-1, including a couple of new commands needed for that purpose.

**Figure 2-1.** `glViewport` and `glOrtho`

**Listing 2-3.** Using `GL_LINES`.

```
{white background}
glClearColor(1.0,1.0,1.0,0.0);
glClear(GL_COLOR_BUFFER_BIT);

{top of the form}
glColor3f(0.0,0.0,1.0);
glRectf(-300.0,300.0,300.0,345.0);

glLineWidth(2.0);
glColor3f(0.0,0.0,0.0);
glBegin(GL_LINES);
    {left side}
```

```

    glVertex2f(-300.0,-300.0);
    glVertex2f(-300.0,300.0);

    {bottom}
    glVertex2f(-300.0,-300.0);
    glVertex2f(300.0,-300.0);

    {right side}

    glVertex2f(-275.0,300.0); {arrow}
    glVertex2f(-282.0,285.0);

    glVertex2f(-275.0,300.0); {arrow}
    glVertex2f(-268.0,285.0);
glEnd;

```

When the drawing mode is `GL_LINES`, each pair of calls to `glVertex` defines a line segment. The declaration for the new mode is:

```
GL_LINES = 1;
```

Rectangles are so common that OpenGL has a special command just for drawing them. The first two parameters define one vertex, and the next two define the opposite vertex. The rectangle assumes  $z = 0$ . The float version just introduced is one of many variations. Also introduced is a command for setting the width of the lines in pixels. The default width is 1.0.

```
procedure glRectf(x1,y1,x2,y2:GLfloat); stdcall;  
procedure glLineWidth(width:GLfloat); stdcall;
```

## ADDITIONAL CONSIDERATIONS

### Naming Convention

You may have noticed by now that all the OpenGL command names begin with “gl.” The graphics library has a well-defined naming convention, which this book mentions from time to time. So far the “gl” prefix has dominated, which does apply to all OpenGL commands. A “glu” prefix has also made a cameo appearance. It is the standard for all commands of the utility library. Chapter 1 presented the “wgl” prefix for the extensions to Microsoft Windows that support OpenGL rendering. Similarly the X Window System (for Unix) extensions use a “glx” prefix, and OS/2 Presentation Manager extensions use “pgl.”

The naming convention does not stop with prefixes. The glVertex commands, for example, have a number suffix, such as 2, 3, or 4, indicating the number of parameters the command requires. A later chapter explains the fourth (w) parameter, but for now, if it receives no explicit value, it receives a value of 1.0. In the two-parameter version, even the z-value goes without assignment, so it gets a 0.0 value by default. The “f” suffix indicates these versions of glVertex take GLfloat parameters. Other parameter types are possible, so as many as 24 different versions of the glVertex command are available.

The FormPaint method used the glColor3f command. The “3” indicates that this version of the command takes three parameters, but there is another version of the command that takes four parameters. The “f” indicates that the parameters are of type GLfloat.

### Error Handling in Depth

Chapter 1 introduced `glGetError`, but gave it only superficial treatment. Checking it every time a command could possibly produce an error would have a performance penalty. Notice that `FormPaint` performs a single call to `glGetError` at the end of the method. Fortunately the graphics library is capable of storing multiple error codes. If several error codes have accumulated, multiple calls to `glGetError` are required to clear them all. Accordingly this application replaces its default exception handler. Place this at the end of the private section of the form's type declaration:

```
procedure ExceptionGL(Sender:TObject;E:Exception);
```

The application's `OnException` event handler activates whenever an exception climbs all the way up the stack without being handled along the way. The default handler simply displays the corresponding error message. To replace the default one with one more suitable for OpenGL, place this at the beginning of the `FormCreate` method:

```
Application.OnException := ExceptionGL;
```

Finally, here is the body of the new exception handler. By calling `ShowException` it does what the old exception handler would have done, then in the loop it calls `glGetError` and shows all the pending OpenGL errors until they have all been cleared:

```
procedure TForm1.ExceptionGL(Sender:TObject;E:Exception);  
begin  
  ShowException(Sender,E);  
  repeat  
    errorCode := glGetError;  
    if errorCode<>GL_NO_ERROR then
```

```
        showMessage(gluErrorString(errorCode));  
    until errorCode=GL_NO_ERROR;  
end
```

## Order of Events

Now, compile the program and launch it with the Windows “Run” command. Resize it several ways. Watch the shape of the rectangle as you do the resizing. Careful observation reveals that if the form only shrinks, the shape of the rectangle does not change. If the form enlarges either horizontally or vertically or both, the shape of the rectangle changes appropriately. An expected event is not firing. This calls for further investigation.

In the variable declaration section add:

```
    EventFile: TextFile;
```

So that an “Event.Log” text file opens for writing at program start, and closes at program end, make the end of the unit look like this:

```
initialization  
    assignFile(EventFile, 'Event.Log');  
    rewrite(EventFile);  
finalization  
    closeFile(EventFile);  
end.
```

To record each firing of the OnPaint event, at the beginning of FormPaint add the following:

```
    writeln(EventFile, 'Paint  '+IntToStr(TimeGetTime));
```

TimeGetTime is a Windows API call that returns the number of milliseconds since Windows last loaded. To access it the unit needs MMSystem in the uses clause. Now, to log each firing of the OnResize event, at the beginning of FormResize add this line:

```
    writeln(EventFile, 'Resize '+IntToStr(TimeGetTime));
```

Now compile and run as before. Wait about one second. Shrink the form from the right side. Wait another second. Shrink the form from the bottom. Wait another second. Enlarge the form a little at the bottom. Now close the form. Examine the contents of the Event.Log file in the current (project) directory. At the top of the file are “Resize” and “Paint” with nearly identical time stamps, only 10 or 20 milliseconds apart. They fired at program start. About 1000 milliseconds later (depending on the accuracy of the “one second” wait) is another “Resize” line. That fired when the form shrank from the right side. Another 1000 milliseconds later is another “Resize” entry, which fired when the form shrank from the bottom. Still 1000 milliseconds later is another “Resize” followed shortly by a “Paint.”

After careful consideration, this makes sense. When the form shrinks, Windows only sends a Resize message. Why should Windows send a Paint message just for the

covering of some already painted territory? Only form enlargement in one or both directions exposes new area that needs painting. Windows does not know about the special need to adjust the interior of the form. Since the Windows Resize and Paint messages are what trigger the Delphi OnResize and OnPaint events, a form shrinkage does not trigger the necessary adjustment of the rectangle.

The way to remedy this little problem is to call FormPaint on those occasions when it would otherwise be neglected. FormResize is called for every OnResize event, so that is a good place to check whether either dimension enlarged. If not, then no OnPaint event happens, so you must call FormPaint directly. After cleaning out the text file code, add these fields to the private section of the form type declaration:

```
    oldw,  
    oldh: integer;
```

The fields preserve the previous width and height for comparison with new values. Initialize them at the end of the FormCreate method:

```
    yldw := ClientWidth;  
    oldh := ClientHeight;
```

Finally, this code at the end of FormResize insures the FormPaint method always fires when needed:

```
    if (ClientWidth<=oldw) and (ClientHeight<=oldh) then  
        FormPaint(Sender);  
    oldh := ClientHeight;  
    oldw := ClientWidth;
```

Save, compile and run (from Windows). Resize to your heart's content.

## Matrices and Command Placement

At this point the program is ready for a little experimentation with glOrtho. Change left from -1.0 to 0.0, then save, compile and run as before.

```
    glOrtho(0.0,1.0,-1.0,1.0,-1.0,1.0);
```

Remember that the values given to the vertices of the rectangle are relative to the clipping volume. Since the range of horizontal numbers in the call to glOrtho is half the former range, the rectangle should be twice as wide as before. Program execution shows that to be the case. Now, resize the form exactly one time. Something is wrong! The rectangle jumps to the left side. Resize the form again. The rectangle is gone, never to be seen again!

This experience exposes another important concept. OpenGL relies heavily on *matrices*. A matrix is a two-dimensional array of numbers for which a special set of mathematical operations apply. For every call to glOrtho, OpenGL creates a matrix from the parameters and multiplies it by the projection matrix. Each successive call changes the projection matrix. The symmetrical numbers passed to glOrtho just masked the potential strange behavior, but the unbalanced numbers for this version exposed the problem. One solution is to move the call to glOrtho to the last line of

the FormCreate method. Save, compile and run. Resize the form a few times. Now the expected behavior manifests itself.

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

Go ahead and experiment some more with passing different values to `glOrtho`, leaving everything else the same. These variations should give a sense of the relationship between the values in the projection matrix and the values of the vertices.

### View Port Manipulation

The view port is the next experimental subject. The orthographic projection can change some of its boundary numbers, but still have the same boundary (the view port). Just the arbitrary meaning of the numbers change. The view port boundary numbers have a real meaning, which is window coordinates. Changing these numbers changes the actual boundary of the view port.

Restore the call to `glOrtho` to its symmetrical arrangement, but leave it at the bottom of `FormCreate`.

```
glOrtho(-1.0,1.0,-1.0,1.0,-1.0,1.0);  
end; {FormCreate}
```

In `FormResize` change the vertical extent in the call to `glViewport`.

```
glViewport(0,0,ClientWidth,ClientHeight div 2);
```

Compile and run as before. From this point on using the Windows Run command rather than running from the IDE is taken for granted and needs no further mention. Now the view port only covers the lower half of the window. Remember that OpenGL coordinates normally start from the bottom of the window, even when using “window coordinates.” The red rectangle is still in the upper right quadrant of the view port, but since the view port itself is confined to the lower half of the window, the rectangle is now in the lower half of the window. Since the view port is only half as tall, the rectangle is half as tall as it was.

Now, try it the other way.

```
glViewport(0,0,ClientWidth div 2,ClientHeight);
```

Compile and run. This time everything lies on the left side of the screen. The rectangle is still in the right side of the view port, but it lies in the left side of the window. Notice that with these restrictions on the size of the view port, the background color still covers the whole window. This experiment should be enough to give a good feel for glViewport, so take out the **div** operators to restore the original appearance.

## Mixing Windows Components

One of the really neat features of OpenGL is that it does not prevent using regular Windows components. This opens many possibilities for user interaction with your graphics constructs. The coming chapters will explore a number of different ways users can give information to your applications. Since these are illustrations and exercises, they are not the ultimate in slick, state-of-the-art front ends; they are just enough to demonstrate a technique. For the first such demonstration, drop a MainMenu component on the form. Right-Click the component and select the Menu Designer. Give it one menu item with a caption of “&Z-Value.” Close the Menu Designer, click the menu item, and edit the event handler as follows:

```
procedure TForm1.Zvalue1Click(Sender: TObject);  
var  
    zString: string[7];  
begin  
    zString := InputBox('Z-Value', 'float:', '0.0');  
end;
```

The first argument gives the title of the input box. The second is the prompt. “float:” serves as a reminder to enter a floating point value. The third argument provides a default value to return.

Position the form near the center of the screen or set the form’s Position property to poScreenCenter. Save, compile and run. Click the menu item. Close the input box. The menu showed properly. The input box showed properly. Since the form shows at or near the center of the screen, and the input box shows near the center of the screen, the input box has to obscure part of the form. Since there was no hole left in the form when the input box closed, then the OnPaint event must have fired. The only adverse effect is the fact that the view port is a little shorter, since the presence of the menu reduced the ClientHeight.

## Pushing the (X,Y,Z) Limits

Add zvalue as a new field to the private section of the form declaration.

```
private  
    GLContext: HGLRC;  
    glDC: HDC;  
    errorCode: GLenum;
```

```

    openGLReady: boolean;
    oldw,
    oldh: integer;
    zvalue: GLfloat;
    procedure ExceptionGL(Sender:TObject;E:Exception);

```

Edit the Zvalue1Click event handler.

```

procedure TForm1.Zvalue1Click(Sender: TObject);
var
    zString: string[7];
begin
    zString := InputBox('Z-Value','float:','0.0');
    zvalue := StrToFloat(zString);
end;

```

Change the calls to glVertex from the two-parameter version to the three-parameter version inside FormPaint, using the freshly-minted zvalue as the third argument.

```

    glBegin(GL_POLYGON);
        glVertex3f(0.25,0.25,zvalue);
        glVertex3f(0.75,0.25,zvalue);
        glVertex3f(0.75,0.75,zvalue);
        glVertex3f(0.25,0.75,zvalue);
    glEnd;

```

Save, compile and run. Select the menu item and enter 0.5 in the input box (and press the Ok button, of course). Do it again, but enter 1.0 as the value. Again, but use 1.01. Something different happened! The rectangle disappeared! Every time the input box covers part of form and closes, the form must re-paint. The results of each new zvalue appear as soon as the box closes. As long as zvalue is between the z-axis limits of the clipping volume (the glOrtho projection), the rectangle is visible. The side of the clipping volume toward the viewer is at  $z = 1.0$ . The side of the clipping volume away from the viewer, into the screen is at  $z = -1.0$ . As long as the rectangle lies between  $-1.0$  and  $1.0$  on the z-axis, it is visible. Values of 0.5, 1.0, -0.5, and -1.0 kept the figure in sight, but 1.01 and  $-1.01$  made it vanish.

Use the Menu Designer to add two more main menu items. The captions are &Y-Value and &X-Value. Add the following event handlers:

```

procedure TForm1.Yvalue1Click(Sender: TObject);
var
    yString: string[7];
begin
    yString := InputBox('Y-Value','float:','0.0');
    yvalue := StrToFloat(yString);
end;
procedure TForm1.Xvalue1Click(Sender: TObject);
var

```

```
xString: string[7];  
begin  
  xString := InputBox('X-Value', 'float:', '0.0');  
  xvalue := StrToFloat(xString);  
end;
```

Add xvalue and yvalue to private section of the form declaration:

```
private  
  GLContext: HGLRC;  
  glDC: HDC;  
  errorCode: GLenum;  
  openGLReady: boolean;  
  oldw,  
  oldh: integer;  
  xvalue,  
  yvalue,  
  zvalue: GLfloat;  
procedure ExceptionGL(Sender:TObject;E:Exception);
```

<a href="#">Previous</a>	<a href="#">Table of Contents</a>	<a href="#">Next</a>

## Delphi Developer's Guide to OpenGL

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

Use the new fields in the drawing:

```
glBegin(GL_POLYGON) ;
    glVertex3f(xvalue+0.25,yvalue+0.25,zvalue) ;
    glVertex3f(xvalue+0.75,yvalue+0.25,zvalue) ;
    glVertex3f(xvalue+0.75,yvalue+0.75,zvalue) ;
    glVertex3f(xvalue+0.25,yvalue+0.75,zvalue) ;
glEnd;
```

Save, compile and run. Try 0.5 and  $-1.5$  for `yvalue`, then go back to 0.0. Try the same numbers for `xvalue`. Now the meaning of a clipping volume should be quite clear. If any part of the figure goes outside the boundaries of the clipping volume, that part is clipped off, but the rest remains visible.

**Figure 2-2.** Clipping with `yvalue = 0.5`

Naturally, good code uses a more reliable method of insuring a re-paint than just having an input box go away, but for this little clipping demonstration, it was sufficient.

## DEFINITIONS

Clipping	The act of not drawing the part of a scene that lies beyond a specified plane.
Clipping volume	A volume enclosed by clipping planes. The parts of a scene lying outside the volume are not drawn.
Foreground color	The current drawing color.

Matrix	A two-dimensional array of numbers for which special mathematical operations have been defined.
Orthographic projection	Parallel projection.
Parallel projection	A projection that does not make size correction for distance.
Polygon	A closed two-dimensional figure consisting of three or more vertices with sides connecting one vertex to the next, and finally a side connecting the last vertex to the first.
Projection	The mathematical transformation of points in a three-dimensional scene onto a flat surface, such as the computer screen.
Quadrilateral	A four-sided polygon.
Render	To convert drawing elements into an image. To draw with OpenGL.
State variables	Much OpenGL information is contained in variables whose values remain the same until deliberately changed. This kind of information is a state. The variables that hold such information are state variables.
Vertex	A point in three-dimensional space, usually representing an endpoint of a line segment or a corner of a polygon.
View port	The portion of a window's client area in which to draw the clipping area.

## IDENTIFIER REFERENCE

glBegin	An OpenGL command designating the start of a list of vertices. It receives a mode parameter that tells OpenGL what to do with those vertices.
GLbitfield	An OpenGL type that maps to Delphi cardinal.
GLclampf	An OpenGL type equivalent to Delphi single.
glColor	An OpenGL command that sets the foreground color.
GLdouble	An OpenGL type equivalent to Delphi double.
glEnd	An OpenGL command that terminates a list of vertices started with glBegin.
GLenum	An OpenGL type that maps to Delphi cardinal.
GLfloat	An OpenGL type that maps to Delphi single.
glFlush	An OpenGL command that forces drawing to the screen.
GLint	An OpenGL type that maps to Delphi integer.
glLineWidth	An OpenGL command that specifies the width, in pixels, of all subsequent lines drawn.

glOrtho	An OpenGL command that specifies an orthographic projection and clipping volume.
glRect	An OpenGL command for drawing a rectangle.
GLsizei	An OpenGL type that maps to Delphi integer.
glVertex	An OpenGL command for specifying the coordinates of a vertex.
glViewport	An OpenGL command that specifies the viewport in window coordinates.
GL_COLOR_BUFFER_BIT	An OpenGL constant that identifies the color buffer.
GL_LINES	An OpenGL constant to pass to glBegin. Each pair of vertices then specifies a line segment, separate from any of the other line segments.
GL_POLYGON	An OpenGL constant to pass to glBegin. All the vertices listed before glEnd are connected to form a polygon.
TimeGetTime	A Windows function that returns the number of milliseconds since Windows was started.

## SUMMARY

Chapter 2 presented the following concepts:

1. Perform drawing in the window's OnPaint event handler.
2. Drawing occurs within the bounds of the view port.
3. The view port definition uses the operating system's window coordinates, but counts in the y-direction from the bottom up.
4. Use glColor to set the foreground drawing color, changing as needed. The color is one of many state variables that remain the same until the programmer directly changes them via function or procedure call.
5. Presenting a 3-D scene on a 2-D screen requires projection.
6. Orthographic projection does not change the apparent size of an object to correct for distance. It is also called parallel projection.
7. The projection is a volume in space bounded by the view port.
8. The programmer may assign the numbers defining the projection volume for clarity or convenience.
9. The projection region is a clipping volume. Any part of a scene that lies outside the volume simply does not appear.
10. Adjust the view port in the window's OnResize event handler.
11. Projection involves matrix multiplication. Repeated invocation is repeated multiplication which probably gives unintended results. The solution in this chapter was to invoke projection only once in the FormCreate method.
12. OpenGL does not hinder the use of Windows features such as menus and dialog boxes.
13. The glGetError function returns the error code number for recent

operations. It returns a number equal to GL\_NO\_ERROR if no errors have accumulated. OpenGL stores accumulated errors, so the program must call glGetError repeatedly until GL\_NO\_ERROR comes back.

# Chapter 3 Introducing 3-D

Chapter 2 introduced drawing a two-dimensional figure and projecting it onto the screen. However, OpenGL is rather under-utilized in 2-D. OpenGL shines in three-dimensional operations. This chapter explores the third (z) dimension and shows a way to draw a cube in three-dimensional space. The cube has six square faces with different colors for each. This chapter shows how to rotate, move, and stretch the cube, as well as cut it open to show what is inside.

The Rect program from chapter 2 makes a good starting point for the next program. Create a new directory as before and name it “Chapter.3.” Under that directory create a directory called “Cube.” In Delphi load the Rect.Dpr project and do a File|Save Project As in the new directory, naming it “Cube.Dpr.” Do File|Save As for the “Rect1.Pas” unit. Name it “Cube1.Pas” in the new directory.

## DEPTH

The introduction of a third dimension calls for an understanding of the direction in which that dimension runs. Construct a new FormPaint method as shown in Listing 3-1.

**Listing 3-1.** FormPaint Method with Depth.

```
procedure TForm1.FormPaint(Sender: TObject);  
begin  
    if not openGLReady then  
        exit;  
  
    {green background}
```

```

glClearColor(0.0,0.4,0.0,0.0);
glClear(GL_COLOR_BUFFER_BIT or GL_DEPTH_BUFFER_BIT);

glBegin(GL_POLYGON); {near face}
    glColor3f(0.5,0.0,0.0);
    glVertex3f(-0.4,-0.4,-0.4);
    glVertex3f(+0.4,-0.4,-0.4);
    glVertex3f(+0.4,+0.4,-0.4);
    glVertex3f(-0.4,+0.4,-0.4);
glEnd;

glBegin(GL_POLYGON); {back face}
    glColor3f(0.0,0.0,0.5);
    glVertex3f(-0.2,-0.2,+0.4);
    glVertex3f(+0.6,-0.2,+0.4);
    glVertex3f(+0.6,+0.6,+0.4);
    glVertex3f(-0.2,+0.6,+0.4);
glEnd;

glFlush;

errorCode := glGetError;
if errorCode<>GL_NO_ERROR then
    raise Exception.Create('Error in Paint'#13+
        gluErrorString(errorCode));
end; {FormPaint}

```

The z value of the original (red) rectangle is  $-0.4$ . The second rectangle is  $0.8$  units farther along the positive z direction with a z value of  $+0.4$ . The second (blue) rectangle also lies  $0.2$  units farther in the positive x direction and  $0.2$  units farther in the positive y direction, so that one rectangle does not completely obscure the other.

Without a *depth test* an object drawn later may appear on top of an object drawn earlier, no matter how near or far the respective objects actually were. The explanation for the depth test appears just a few paragraphs later, but for now, add some lines to the bottom of the FormCreate method:

```

glOrtho(-1.0,1.0,-1.0,1.0,-1.0,1.0);
glEnable(GL_DEPTH_TEST);
glMatrixMode(GL_MODELVIEW);
glLoadIdentity;
end; {FormCreate}

```

Save, compile, and run to see the result. As Figure 3-1 shows, the red rectangle is in front and the blue rectangle is in back. The conclusion is that with an orthographic projection, the farther an object lies in the positive z direction, (or at least less negative), the farther the object is from the viewer.

**Figure 3-1.** Depth

## CUBE

Now you are ready for another illustration. For the sake of this illustration, comment out the `glEnable(GL_DEPTH_TEST)` statement you just put in.

### Square View Port

The new project name certainly suggests the next shape under discussion. A cube provides a fairly simple figure for introducing 3-D. In geometry a cube has identical height, width, and depth. Unfortunately the projection of such a figure onto the computer screen may not look like a cube unless the view port is square. Since the current view port matches the form's client height and client width, those properties should be set equal to each other. Select the form and go to the object inspector. Set `ClientHeight` to 340, and set `ClientWidth` to 340.

### Distinguish Faces

A cube has six square faces. In `FormPaint` draw six colored squares, using different colors for each face for easy distinction. If all the faces of the cube were the same color, they would blend into each other and obscure the shape. The application of lighting effects solves such problems, but that subject comes later. Modify the `FormPaint` method as in listing 3-2.

**Listing 3-2.** Six Colored Faces.

```
procedure TForm1.FormPaint(Sender: TObject);  
begin  
    if not openGLReady then  
        exit;  
  
    {green background}  
    glClearColor(0.0,0.4,0.0,0.0);  
    glClear(GL_COLOR_BUFFER_BIT or GL_DEPTH_BUFFER_BIT);  
  
    glBegin(GL_POLYGON); {near face}  
        glColor3f(0.5,0.0,0.0);  
        glVertex3f(-0.4,-0.4,-0.4);  
        glVertex3f(+0.4,-0.4,-0.4);  
        glVertex3f(+0.4,+0.4,-0.4);  
        glVertex3f(-0.4,+0.4,-0.4);  
    glEnd;  
  
    glBegin(GL_POLYGON); {right face}  
        glColor3f(0.3,0.3,0.8);
```

```

        glVertex3f(+0.4,-0.4,-0.4);
        glVertex3f(+0.4,-0.4,+0.4);
        glVertex3f(+0.4,+0.4,+0.4);
        glVertex3f(+0.4,+0.4,-0.4);
    glEnd;

    glBegin(GL_POLYGON); {left face}
        glColor3f(0.5,0.0,0.5);
        glVertex3f(-0.4,-0.4,+0.4);
        glVertex3f(-0.4,-0.4,-0.4);
        glVertex3f(-0.4,+0.4,-0.4);
        glVertex3f(-0.4,+0.4,+0.4);
    glEnd;

    glBegin(GL_POLYGON); {back face}
        glColor3f(0.0,0.0,0.5);
        glVertex3f(+0.4,-0.4,+0.4);
        glVertex3f(-0.4,-0.4,+0.4);
        glVertex3f(-0.4,+0.4,+0.4);
        glVertex3f(+0.4,+0.4,+0.4);
    glEnd;

    glBegin(GL_POLYGON); {bottom face}
        glColor3f(0.5,0.5,0.0);
        glVertex3f(-0.4,-0.4,-0.4);
        glVertex3f(-0.4,-0.4,+0.4);
        glVertex3f(+0.4,-0.4,+0.4);
        glVertex3f(+0.4,-0.4,-0.4);
    glEnd;

    glBegin(GL_POLYGON); {top face}
        glColor3f(0.3,0.0,0.1);
        glVertex3f(-0.4,+0.4,-0.4);
        glVertex3f(+0.4,+0.4,-0.4);
        glVertex3f(+0.4,+0.4,+0.4);
        glVertex3f(-0.4,+0.4,+0.4);
    glEnd;

    glFlush;

    errorCode := glGetError;
    if errorCode<>GL_NO_ERROR then
        raise Exception.Create('Error in Paint'#13+
            gluErrorString(errorCode));
    end; {FormPaint}

```

### Depth Test

Save, compile, and run and admire the beautiful cube! Well, at least tolerate the colored rectangle. Why is there no evidence of a third dimension? Actually the straight-on view guarantees that only the front face shows. Or does it? Notice the color. The front face is red. The back face is blue. The blue back face shows on the screen! Why? OpenGL drew all six faces. The four edge-on faces have no effect, but the back face was drawn after the front face, so it is the one that shows. Fortunately there is a way to tell OpenGL to test depth and not draw pixels that should be hidden. This ability, as well as others, becomes effective by means of the `glEnable` command:

```
procedure glEnable(cap:GLenum); stdcall;
```

Turn on each capability by passing the appropriate constant. Here is the declaration for the depth-testing constant:

```
GL_DEPTH_TEST = $0B71;
```

Enabling depth testing sets up a depth buffer that contains depth information on each pixel within the clipping volume. Of the pixels that map to the same spot on the screen, OpenGL draws only the one nearest the viewer. This process is OpenGL's method of hidden surface removal. The bottom of the `FormCreate` method with depth testing added follows:

```
openGLReady := true;  
oldw := ClientWidth;  
oldh := ClientHeight;  
glOrtho(-1.0,1.0,-1.0,1.0,-1.0,1.0);  
glEnable(GL_DEPTH_TEST);  
end; {FormCreate}
```

## Matrices Revisited

Save, compile, and run. Observe that no change is evident. This means that more must be done to make the depth test work. Therefore it is time to give more consideration to matrices. OpenGL is full of them. Matrices describe the very scene itself, and there are matrices for texture, for projection, etc. There are commands to select among those matrices. There are even matrix stacks. Some commands, such as `glLoadIdentity`, directly manipulate the active matrix, and other commands use their parameters to construct a matrix, then multiply the appropriate matrix by the constructed matrix.

### The ModelView Matrix

Consider a 4x4 matrix that represents the coordinate system of the scene. Call it the Model matrix. Apply this matrix to every vertex in the scene as part of the process of illuminating the appropriate dots on the screen. Now consider a 4x4 matrix that represents the coordinates of the viewer. Call it the View matrix. Finally consider Einstein's Theory of Relativity. What?! Well, anyway, think of two automobiles side by side. The observer is in the first car and sees the second car sliding backwards. Or is the first car with the observer actually moving forward? Or does it matter? In a universe that contains only those two cars, either description is equally valid. Similarly the Model matrix and the View matrix are equally useful. In fact they are the same matrix. Its true name is the ModelView matrix.

Here is the OpenGL command that identifies which matrix other commands will affect:

```
procedure glMatrixMode(mode:GLenum); stdcall;
```

These are the constants to pass for the mode parameter:

```
GL_MODELVIEW    = $1700;  
GL_PROJECTION   = $1701;  
GL_TEXTURE      = $1702;
```

Here is the declaration of the command that sets the current matrix to be the *identity matrix*, which is a matrix that, when multiplied with another matrix, leaves a product the same as the other matrix.

```
procedure glLoadIdentity; stdcall;
```

For the three-dimensional rendering program to work, make the bottom of `FormCreate` look like this:

```
glEnable(GL_DEPTH_TEST);  
glMatrixMode(GL_MODELVIEW);  
glLoadIdentity;  
end; {FormCreate}
```

So save, compile, and run. Ah! The correct face shows. But it still does not

look like a cube.

## ROTATION

### Three Faces

Looking at a cube straight on just does not reveal its third dimension. The cube must have an orientation that shows more than one face. Indeed, a cube showing two faces is not much better, because it still just looks like two rectangles side by side. The obvious answer is to draw the cube skewed at some angle. Not only that, but the rotation must not be about a single coordinate axis, or about any line parallel to a single axis, otherwise no more than two faces can show.

### glRotate

Drawing the cube rotated calls for some ugly math to apply to each vertex. Actually the math involved looks fairly simple when expressed as matrices, but it is ugly because the programmer has to carry out the details. There is a better way! Draw the cube simply, as before, then let OpenGL rotate it. Here is the needed command in two versions:

```
procedure glRotated(angle,x,y,z:GLdouble); stdcall;  
procedure glRotatef(angle,x,y,z:GLfloat); stdcall;
```

**PURPOSE** The purpose of this command is to define an axis of rotation and an amount of rotation. The command then causes the scene to rotate about the axis. Or it causes the coordinate system of the scene, and therefore the viewing angle of the observer, to rotate about the axis. Take your choice; it is relative! What really happens is that OpenGL creates a rotation matrix from the parameters and multiplies it with the active matrix, in this case, the ModelView matrix.

**PARAMETERS** This simple program certainly does not need double precision to accomplish its purpose, so the float version is the proper choice for the command.

Either version uses four parameters. The angle parameter defines the amount of rotation. Interestingly it takes its value in degrees rather than radians, which is fortunate for mere mortals who do not spend their days immersed in trigonometry. The x, y, and z parameters define a point in three-dimensional space with respect to the coordinates of the clipping (projection) volume.

The given point helps define the *vector* that serves as the axis of rotation. Two points can define a line; the other point is (0.0,0.0,0.0), the origin for the projection coordinate system. Think of a vector as a line with direction, from the origin toward the other point, and then continuing on forever.

**DIRECTION** To understand the direction of rotation, imagine an observer located at the origin looking toward the point defined by the x, y, and z parameters. The object turns counter-clockwise with respect to that vantage point.

### Action

In the Menu Designer add a fourth main menu item. Give it a caption of &Angle and exit from the Menu Designer. Click the menu item to produce the event handler and fill it in as follows:

```
procedure TForm1.Angle1Click(Sender: TObject);  
var  
    astring: string[7];  
begin  
    astring := InputBox('Angle of Rotation', 'float:', '0.0');  
    angle := StrToFloat(astring);  
    glMatrixMode(GL_MODELVIEW);  
    glLoadIdentity;  
  
    glRotatef(angle, xvalue, yvalue, zvalue);  
end;
```

The other three menu choices, left over from the Rect program, set the coordinates for the point (other than the origin) that defines the axis of rotation. The new menu choice defines the angle of rotation and performs the rotation. Notice that `glMatrixMode` makes the `ModelView` matrix active every time, since that is the matrix on which to perform the action. This action is one of several *transformations*. OpenGL enables the programmer to perform three basic `ModelView` transformations or combinations thereof on the `ModelView` matrix, rotation, *translation* (movement in a straight line through space), and *scale* (changing the size of an object in each of the three dimensions independently). The call to `glLoadIdentity` is present to insure that the rotation transformation acts from a known and understood condition. Some situations may naturally call for allowing the transformations to accumulate, but not this simple interactive angle entry.

Save, compile and run. Enter coordinates to define the axis (vector) of rotation. Enter various angles and see the results. Notice that any multiple of 360.0 returns the cube to its original orientation and that negative angles rotate the cube clockwise. All the different colors for the faces help identify which faces come into view.

## TWO-FACED POLYGONS

### Open the Cube

There is no way to avoid it. Polygons are two-faced. That is not a character assassination but a geometric statement. When a polygon facing the viewer rotates 180 degrees, it does not disappear; it has a back face that the viewer can see. To illustrate, expose the inside of the cube by commenting out the right side as in Listing 3-3.

**Listing 3-3.** Right Side Missing.

```
procedure TForm1.FormPaint(Sender: TObject);  
begin  
    if not openGLReady then  
        exit;  
  
    {green background}  
    glClearColor(0.0,0.4,0.0,0.0);  
    glClear(GL_COLOR_BUFFER_BIT or GL_DEPTH_BUFFER_BIT);  
  
    glBegin(GL_POLYGON); {near face}  
        glColor3f(0.5,0.0,0.0);  
        glVertex3f(-0.4,-0.4,-0.4);  
        glVertex3f(+0.4,-0.4,-0.4);  
        glVertex3f(+0.4,+0.4,-0.4);  
        glVertex3f(-0.4,+0.4,-0.4);  
    glEnd;  
    (*  
    glBegin(GL_POLYGON); {right face}  
        glColor3f(0.3,0.3,0.8);  
        glVertex3f(+0.4,-0.4,-0.4);  
        glVertex3f(+0.4,-0.4,+0.4);  
        glVertex3f(+0.4,+0.4,+0.4);  
        glVertex3f(+0.4,+0.4,-0.4);  
    glEnd;  
    *)  
    glBegin(GL_POLYGON); {left face}  
        glColor3f(0.5,0.0,0.5);  
        glVertex3f(-0.4,-0.4,+0.4);  
        glVertex3f(-0.4,-0.4,-0.4);  
        glVertex3f(-0.4,+0.4,-0.4);  
        glVertex3f(-0.4,+0.4,+0.4);  
    glEnd;  
  
    glBegin(GL_POLYGON); {back face}
```

```

        glColor3f(0.0,0.0,0.5);
        glVertex3f(+0.4,-0.4,+0.4);
        glVertex3f(-0.4,-0.4,+0.4);
        glVertex3f(-0.4,+0.4,+0.4);
        glVertex3f(+0.4,+0.4,+0.4);
    glEnd;

    glBegin(GL_POLYGON); {bottom face}
        glColor3f(0.5,0.5,0.0);
        glVertex3f(-0.4,-0.4,-0.4);
        glVertex3f(-0.4,-0.4,+0.4);
        glVertex3f(+0.4,-0.4,+0.4);
        glVertex3f(+0.4,-0.4,-0.4);
    glEnd;

    glBegin(GL_POLYGON); {top face}
        glColor3f(0.3,0.0,0.1);
        glVertex3f(-0.4,+0.4,-0.4);
        glVertex3f(+0.4,+0.4,-0.4);
        glVertex3f(+0.4,+0.4,+0.4);
        glVertex3f(-0.4,+0.4,+0.4);
    glEnd;

    glFlush;

    errorCode := glGetError;
    if errorCode<>GL_NO_ERROR then
        raise Exception.Create('Error in Paint'#13+
            gluErrorString(errorCode));
end; {FormPaint}

```

Save, compile, and run. With the menus make xvalue and yvalue each equal to 1.0, but leave zvalue alone. For the angle enter 30.0 (degrees). Note the inside face for the back square and the top square. Experiment with various combinations of positive and negative values for all four parameters until all interior faces have presented themselves.

## Culling

There it is! Those polygons have a back side! What if the cube was not open? The shocking truth is that even if there is no possible way to see the back side of the polygons, OpenGL draws them! Fortunately *depth testing* (hidden surface removal) keeps them from bleeding though. Better yet, an OpenGL command can tell it not even to draw them.

```
procedure glCullFace(mode:GLenum); stdcall;
```

The possible values for mode (with obvious meanings) are:

```

GL_FRONT          = $0404;
GL_BACK           = $0405;

```

```
GL_FRONT_AND_BACK= $0408;
```

To *cull* faces means to remove them from the list of things to draw. Like many other OpenGL options, the programmer must first enable this option before using it. The value to give glEnable is:

```
GL_CULL_FACE= $0B44;
```

Add some code so the bottom of FormCreate looks like this:

```
glEnable(GL_DEPTH_TEST);  
glMatrixMode(GL_MODELVIEW);  
glLoadIdentity;  
  
glEnable(GL_CULL_FACE);  
glCullFace(GL_BACK);  
end; {FormCreate}
```

Save, compile, and run yet again. As before, experiment with various combinations of positive and negative values for all four parameters and see what the inside of the cube looks like when the inner faces simply are not drawn.

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

## VERTEX DIRECTION

How does OpenGL know which face of a polygon the programmer intended to be front and which to be back? The answer lies in the order of the vertices.

Consider the front square of this chapter's cube.

```
glBegin(GL_POLYGON); {near face}
  glColor3f(0.5,0.0,0.0);
  glVertex3f(-0.4,-0.4,-0.4);
  glVertex3f(+0.4,-0.4,-0.4);
  glVertex3f(+0.4,+0.4,-0.4);
  glVertex3f(-0.4,+0.4,-0.4);
glEnd;
```

Mentally number the vertices from one to four. Vertex one is the lower left corner. Vertex two is the lower right corner. Vertex three is the upper right corner. Vertex four is the upper left corner. Imagine movement from one to two to three to four and back to one. The direction or *winding* is counter-clockwise, which is the default direction for OpenGL to identify the front face of a polygon. Those same vertices, if viewed from the other side, would present a clockwise winding. Figure 3-2 shows the counter-clockwise winding of the front view.

**Figure 3-2.** Counter-Clockwise Winding.

Consider the back square of the cube. Its vertex order was designed to present a clockwise winding from the viewer's position, making the face inside the cube the back face and the face outside the cube the front face. That is the usual arrangement. If the cube were rotated 180 degrees around the z-axis, the front face of that square would be toward the viewer. The next experiment reverses the back square's winding. Here is the original code for the back square:

```
glBegin(GL_POLYGON); {back face}
  glColor3f(0.0,0.0,0.5);
  glVertex3f(+0.4,-0.4,+0.4);
  glVertex3f(-0.4,-0.4,+0.4);
  glVertex3f(-0.4,+0.4,+0.4);
  glVertex3f(+0.4,+0.4,+0.4);
glEnd;
```

Rearrange the vertices to reverse the winding:

```
glBegin(GL_POLYGON); {back face}
  glColor3f(0.0,0.0,0.5);
  glVertex3f(+0.4,+0.4,+0.4);
  glVertex3f(-0.4,+0.4,+0.4);
  glVertex3f(-0.4,-0.4,+0.4);
  glVertex3f(+0.4,-0.4,+0.4);
glEnd;
```

Save, compile, and run. Give the xvalue 0.3, the yvalue 1.0, and the angle 50.0. While the other interior faces have been culled, the interior face of the back square has been drawn. With a large enough angle, the back square is toward the viewer, but since its exterior face is a "back" face, it does not appear. Indeed, only the bottom of the cube shows at all.

## TRANSLATION

Restore the original winding of the back square and uncomment the right square. While rotation may be the most interesting transformation, it is certainly not the only one of importance. Translation may be the most common transformation.

### Menu

Use the Menu Designer to add &Translate as another main menu item. Click on it and fill in the event handler thusly:

```
procedure TForm1.Translate1Click(Sender: TObject);
begin
  glMatrixMode(GL_MODELVIEW);
  glTranslatef(xvalue,yvalue,zvalue);
  Invalidate;
end;
```

The `glTranslate` command takes three parameters that specify the relative amount of movement in each direction. The translation command has two forms:

```
procedure glTranslated(x,y,z:GLdouble); stdcall;  
procedure glTranslatef x,y,z:GLfloat); stdcall;
```

## Accumulation

Notice the absence of `glLoadIdentity`. Transformations will accumulate and demonstrate the effects of combining different kinds. Comment out the `glLoadIdentity` in the `Angle1Click` method as well. Notice also the presence of the `Invalidate Windows` API call. This causes Windows to send a `WM_PAINT` message, which triggers the `OnPaint` event. This is certainly superior to the (temporary) reliance on covering and uncovering the window by another window.

## More Clipping

As usual, save, compile, run, and play with the various menu choices and values. The transformations accumulate, and may allow the cube to disappear altogether. Certainly the translation transformation provides more opportunity to experiment with clipping. Enough translation in the positive `z` direction provides some interesting effects. The far side of the cube disappears as if cut off by an invisible wall.

Did you see that flicker each time you selected `Translate`? Ugh! Do not despair; the chapter on animation shows how to redraw images without flicker.

Even more interesting is the effect of translation in the negative `z` direction. With just the right `z` values, a face or a corner nearest the viewer disappears, allowing a peek inside the cube without having to neglect drawing a square. What does the viewer see inside? He sees a mysterious green nothing because of the culling, as in Figure 3-3, where clipping in both the negative `y` direction and the negative `z` direction is evident.

**Figure 3-3.** Clipping and Culling.

## SCALE

### Menu

With the `Menu Designer` add still another main menu item, `&Scale`. Produce the following event handler in the same manner as before:

```
procedure TForm1.Scale1Click(Sender: TObject);  
begin  
    glMatrixMode(GL_MODELVIEW);  
    glScalef(xvalue,yvalue,zvalue);  
    Invalidate;  
end;
```

The only new command has the following declarations:

```
procedure glScaled(x,y,z:GLdouble); stdcall;  
procedure glScalef(x,y,z:GLfloat); stdcall;
```

[Previous](#) [Table of Contents](#) [Next](#)

### Description

The scale command multiplies the size of the objects in the scene. The value given for the x parameter multiplies the x-dimension, the y value passed to the command multiplies the y-dimension, and the z parameter's value multiplies the z-dimension. A call to `glScale(2.0,2.0,2.0)` makes the cube twice as wide, twice as tall, and twice as deep as the original specifications. So why are there three parameters? Each dimension's multiplier has a separate specification so each dimension can be scaled differently. A call to `glScale(0.5,3.0,0.8)` makes the cube (or whatever drawing follows) only half as wide, three times as tall, and 80 percent of the original depth. The programmer can draw something and then distort it freely. Of course a cube so mutilated is no longer a cube. Save, compile, run, and experiment. Figure 3-4 shows a distorted (former) cube.

**Figure 3-4.** The Cube After `glScale`.

## ORDER OF TRANSFORMATIONS

### A New Interface

The admittedly clumsy interface used thus far has exhausted its usefulness. It was kept simple in order to minimize distraction from the OpenGL coding, but further development calls for a better user interface. The new interface is nothing elegant, but is a great improvement.

Create a new directory under “Chapter.3” named “Multi.” Do a File|Save Project As of Cube.Dpr into the new directory, calling it Mult.Dpr. Save Cube1.Pas as Multi.Pas. Empty all the menu item event handlers by deleting the lines of code within and save again so Delphi can remove the newly empty event handlers. In the Menu Designer delete the existing menu items and put in &Parameters, &Transformation, &Identity, and &Cull Disable. Create and fill in their event handlers as in Listing 3-4.

**Listing 3-4.** Menu Item Event Handlers.

```

procedure TForm1.Parameters1Click(Sender: TObject);
begin
    FormTransform.ShowModal;
end;

procedure TForm1.Transformation1Click(Sender: TObject);
var
    list: TStringList;
    lno: integer;
begin
    list := TStringList.Create;
    list.sorted := true;
    with list,transData do
    begin
        if translate then
            Add(OrT+'T');
        if scale then
            Add(OrS+'S');
        if rotate then
            Add(OrR+'R');
        if count=0 then
            exit;

        glMatrixMode(GL_MODELVIEW);
        for lno := 0 to count-1 do
        begin
            case strings[lno][2] of
                'R': begin
                    glRotatef(ra,rx,ry,rz);
                end;
                'S': begin
                    glScalef(sx,sy,sz);
                end;
                'T': begin
                    glTranslatef(tx,ty,tz);
                end;
            end; {case}
        end; {for}
    end; {with}
    List.Free;

```

```
        Invalidate;
    end;
procedure TForm1.Identity1Click(Sender: TObject);
begin
    glMatrixMode(GL_MODELVIEW);
    glLoadIdentity;
    Invalidate;
end;

procedure TForm1.Cull1Click(Sender: TObject);
begin
    glDisable(GL_CULL_FACE);
    Invalidate;
end;
```

Create a new form and name it FormTransform, then save the unit as Trans1. To the form add three check boxes, four labels, ten edit controls, three radio groups, and two bit buttons to look like Figure 3-5. An efficient way to describe the component names and properties is to show the form as text as in Listing 3-5.

```

The scope of this book is to teach OpenGL with Delphi, with the assumption that the reader is at

least somewhat experienced in programming with Delphi. Therefore the ordinary Delphi code is presented with little comment.

## Simultaneous Commands

This program still draws the same old cube, but provides for specifying two or three transformations (with independent parameters) to apply to the cube at the same time. The check boxes allow the user to specify which transformations to apply, and the radio groups allow the user to specify the order in which to apply them. The edit controls allow the user to specify the floating point values for the various parameters.

The event handler for the &Transformation menu item performs the transformations specified on the secondary form. TForm1.Transformation1Click creates a sorted string list that identifies the order in which to perform the transformation. The handler sets the matrix mode to GL\_MODELVIEW and performs the transformations in the appropriate order, using the arguments stored in the transData record. The call to Invalidate insures that FormPaint fires after the transformation calls.

## **Delphi Developer's Guide to OpenGL**

*(Publisher: Wordware Publishing, Inc.)*

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

Save, compile, run, and experiment, not only with the values to give to each transformation, but also with the order of the transformation. Admittedly the difference is subtle for just one “object” in the scene, but many combinations will show a difference according to the sequence of the transformations. Order does matter; try it and see.

## **DEFINITIONS**

Culling	Removing faces from the list of things to draw based on front or back designation.
Depth buffer	A list of information about the distance of pixels from the viewer.
Depth test	Determination of whether to draw pixels by comparing their distance from the viewer with that of other pixels at the same screen position.
Hidden surface removal	Not drawing surface that would otherwise be obscured from the viewer anyway.
Identity matrix	A matrix whose product with a second matrix is identical to the second matrix.
ModelView matrix	The matrix representing the coordinate system.
Origin	The point located at (0.0,0.0,0.0).
Scale	Each dimension of an object is adjusted independently by specified factors.
Transformation	Adjusting the coordinate system.
Translation	Moving an object through space.

Vector A line with direction from a starting point toward a second point, then continuing on forever. Vectors are specified as if the first point were the origin and the second point simply sets the direction. With the first point understood to be the origin, the second point alone identifies the vector.

## IDENTIFIER REFERENCE

<code>glCullFace</code>	An OpenGL command that specifies culling of front or back faces or both.
<code>glEnable</code>	An OpenGL command that allows certain features.
<code>glLoadIdentity</code>	An OpenGL command that sets the specified matrix equal to the identity matrix.
<code>glMatrixMode</code>	An OpenGL command that makes the specified matrix the currently active matrix.
<code>glRotate</code>	An OpenGL command that performs the rotation transformation.
<code>glScale</code>	An OpenGL command that performs the scale transformation.
<code>glTranslate</code>	An OpenGL command that performs the translation transformation.
<code>GL_BACK</code>	An OpenGL constant for <code>glCullFace</code> .
<code>GL_CULL_FACE</code>	An OpenGL constant for <code>glEnable</code> .
<code>GL_DEPTH_BUFFER_BIT</code>	An OpenGL constant for <code>glClear</code> .
<code>GL_DEPTH_TEST</code>	An OpenGL constant for <code>glEnable</code> .
<code>GL_FRONT</code>	An OpenGL constant for <code>glCullFace</code> .
<code>GL_FRONT_AND_BACK</code>	An OpenGL constant for <code>glCullFace</code> .
<code>GL_MODELVIEW</code>	An OpenGL constant for <code>glMatrixMode</code> .
<code>GL_PROJECTION</code>	An OpenGL constant for <code>glMatrixMode</code> .
<code>GL_TEXTURE</code>	An OpenGL constant for <code>glMatrixMode</code> .
<code>Invalidate</code>	A Windows function that causes Windows to send <code>WM_PAINT</code> and returns true on success, false on failure.

## SUMMARY

Chapter 3 introduced three-dimensional rendering with these concepts:

1. Left to itself, OpenGL draws all surfaces whether they should show or not.
2. Turn on Depth Testing with `glEnable` to allow hidden surface removal.
3. The `ModelView` matrix represents the coordinate system of the scene or the coordinates of the viewer, whichever is convenient.

4. The ModelView transformations are rotation, transformation, and scale.
5. Use `glRotate` to rotate the scene counter-clockwise by a certain angle about a given axis.
6. Polygons have two faces. Cull back or front faces with `glCullFace`. Pass it `GL_FRONT`, `GL_BACK`, or `GL_FRONT_AND_BACK`.
7. Determine clockwise or counter-clockwise winding of a polygon by the order of specifying the vertices. By default the front face of a polygon has counter-clockwise winding.
8. Successive transformations before painting accumulate, and changing the order of the transformations can produce different results.
9. Use the Invalidate Windows API call to insure that a window redraws.

## Chapter 4 Perspective

Orthographic, or parallel, projection is fine for many purposes, but when the goal is realism in the graphics, *perspective* projection may be more appropriate. In the real world the fact that objects appear smaller when more distant is universally familiar. Artists recognize that elements of a scene appear to come together to a vanishing point at some great distance. This chapter shows how to produce this realistic effect and to position vertices in such an environment.

### ILLUSTRATION

With OpenGL the programmer can construct a (you guessed it!) matrix to project a scene onto the computer screen in a manner that simulates perspective. This process is called (appropriately) perspective projection. Consider two parallel lines as in the following code.

```
glBegin(GL_LINES);  
    glVertex3f(-0.5,0.1,-2.2);  
    glVertex3f(-0.5,15.0,-32.2);  
    glVertex3f(+0.5,0.1,-2.2);  
    glVertex3f(+0.5,15.0,-32.2);  
glEnd;
```

The two line segments run side by side off into the z distance, rising in the y direction. Figure 4-1 shows how they appear with perspective projection. Although reproducing this effect requires more code than given here, this is enough to show that the two lines are indeed parallel. The apparent convergence of the lines is due entirely to the perspective projection.

**Figure 4-1.** Parallel Lines in Perspective Projection

## COMMAND

To set up the perspective projection matrix, use this command:

```
procedure glFrustum(left, right, bottom, top, zNear, zFar:GLdouble); stdcall;
```

### Clipping Volume

What in the world is a frustum? Basically a frustum is a pyramid with the top chopped off. Since the clipping volume looks like a frustum with a rectangular base, lying horizontally, the command name makes sense. Figure 4-2 shows the shape of the clipping volume.

**Figure 4-2.** Clipping Volume from glFrustum.

### Parameters

Notice that the parameters for glFrustum are the same as the parameters for glOrtho. In general these parameters have a similar usage, but there are enough differences between them to warrant caution. Just as in glOrtho, left, right, bottom, and top define a rectangle. In glOrtho, however, the front rectangle and the rear rectangle are identical except for their z value, so only one rectangle specification is sufficient. In glFrustum, the near and the far rectangles are very different sizes, but the command only takes the values for the near rectangle.

How in the world does this command define the far rectangle? The answer lies in the usage of the znear and zfar parameters. The znear value is the distance from the viewer to the near face of the frustum, which is the “cut” across the pyramid. The znear distance must be expressed as a positive number. The zfar value is the distance to the farther face of the frustum (base of the pyramid), which must be a positive number larger than znear. In effect the viewer is at the apex of the pyramid, so znear and zfar are enough to define the base of the frustum from its front face, as Figure 4-2 suggests.

## DEPTH

### Previous Cube

Create a directory (under the OpenGL directory, of course) and name it Chapter.4. Under that directory create a directory named Multi. Copy the files from OpenGL\Chapter.3\Multi to OpenGL\Chapter.4\Multi. Open this project in Delphi and edit the FormCreate method in Multi.Pas. Replace

```
glOrtho(-1.0, 1.0, -1.0, 1.0, -1.0, 1.0);
```

with

```
glMatrixMode(GL_PROJECTION);  
glFrustum(-1.0, 1.0, -1.0, 1.0, 2.0, 37.0);
```

This command change maps the same near face rectangle, but specifies the z range differently, as well as providing a different projection. The clipping volume starts at 2.0 units from the viewer and extends to 37.0 units from the viewer. In glOrtho znear and zfar just provided a range of values whose meaning was entirely up to the programmer. With parallel projection apparent sizes are not affected by distance from the viewer, so that distance is not a consideration. With perspective projection, distance from the viewer is a primary ingredient.

Compile and Run. Nothing but the green background shows because under the new coordinate system the cube was constructed entirely in front of the front clipping face. Use transformations to bring the cube

into view. Fill out the parameters as in Figure 4-3, click Ok, and select Transformation from the menu.

**Figure 4-3.** Parameters to Bring the Cube into View

Now the cube shows, but it looks a little strange. It is like the back is larger than the front. Test this theory with a rotation transformation. Set it up as in Figure 4-4.

**Figure 4-4.** Parameters to Rotate the Cube

Sure enough, the back of the cube appears larger than the front. Since this is the opposite of what perspective projection should produce, something must be wrong. This is a good time to test the coordinates.

## Test

Like the depth test in Chapter 3 draw two rectangles in the FormPaint method, replacing the current contents. The reason for the choice of z coordinates will soon become evident. Save the project as Depth.Dpr in OpenGL\Chapter.4\Depth and save the main unit as Depth1.Pas in the Depth directory also. Remove the Trans1 unit from the project, remove the uses Trans1 statement from the main unit, remove the Main Menu control and empty the contents of the menu item event handlers. Adjust the form's ClientHeight back to 340. Here is what FormPaint should look like:

```
procedure TForm1.FormPaint(Sender: TObject);
begin
    if not openGLReady then
        exit;

    {green background}
    glClearColor(0.0,0.4,0.0,0.0);
    glClear(GL_COLOR_BUFFER_BIT or GL_DEPTH_BUFFER_BIT);

    glBegin(GL_POLYGON); {near face}
        glColor3f(0.5,0.0,0.0);
        glVertex3f(-0.4,-0.4,-2.4);
        glVertex3f(+0.4,-0.4,-2.4);
        glVertex3f(+0.4,+0.4,-2.4);
        glVertex3f(-0.4,+0.4,-2.4);
    glEnd;

    glBegin(GL_POLYGON); {back face}
        glColor3f(0.0,0.0,0.5);
        glVertex3f(-0.2,-0.2,-2.8);
        glVertex3f(+0.6,-0.2,-2.8);
        glVertex3f(+0.6,+0.6,-2.8);
        glVertex3f(-0.2,+0.6,-2.8);
    glEnd;

    glFlush;

    errorCode := glGetError;
    if errorCode<>GL_NO_ERROR then
        raise Exception.Create('Error in Paint'#13+
```

```
        gluErrorString(errorCode));  
end; {FormPaint}
```

## Delphi Developer's Guide to OpenGL

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

Save, Compile, and Run. Again the red rectangle is in front of the blue rectangle. But look again at the z coordinates of the two rectangles. The farther (blue) rectangle is more negative in the z direction than the near rectangle. In the orthographic projection clipping volume a more distant point is more positive (or less negative) than a nearer point, and the specifications of the cube vertices took that fact into account. So when the same vertices appeared in a perspective projection clipping volume whose z coordinates run in the opposite direction, naturally the cube was distorted.

### Better Cube

In Delphi load the previous project under Chapter.4, Multi.Dpr. Adapt the coordinates of the cube vertices to the new z direction reality. Remember that moving away from the viewer is to travel in the negative z direction, even though the znear and zfar parameters are positive and more positive respectively. Make the FormPaint method look like this:

```
procedure TForm1.FormPaint(Sender: TObject);  
begin  
    if not openGLReady then  
        exit;  
  
    {green background}  
    glClearColor(0.0,0.4,0.0,0.0);  
    glClear(GL_COLOR_BUFFER_BIT or GL_DEPTH_BUFFER_BIT);  
  
    glBegin(GL_POLYGON); {near face}  
        glColor3f(0.5,0.0,0.0);  
        glVertex3f(-0.4,-0.4,+0.4);  
        glVertex3f(+0.4,-0.4,+0.4);  
        glVertex3f(+0.4,+0.4,+0.4);
```

```

        glVertex3f(-0.4,+0.4,+0.4);
    glEnd;

    glBegin(GL_POLYGON); {right face}
        glColor3f(0.3,0.3,0.8);
        glVertex3f(+0.4,-0.4,+0.4);
        glVertex3f(+0.4,-0.4,-0.4);
        glVertex3f(+0.4,+0.4,-0.4);
        glVertex3f(+0.4,+0.4,+0.4);
    glEnd;

    glBegin(GL_POLYGON); {left face}
        glColor3f(0.5,0.0,0.5);
        glVertex3f(-0.4,-0.4,-0.4);
        glVertex3f(-0.4,-0.4,+0.4);
        glVertex3f(-0.4,+0.4,+0.4);
        glVertex3f(-0.4,+0.4,-0.4);
    glEnd;

    glBegin(GL_POLYGON); {back face}
        glColor3f(0.0,0.0,0.5);
        glVertex3f(+0.4,-0.4,-0.4);
        glVertex3f(-0.4,-0.4,-0.4);
        glVertex3f(-0.4,+0.4,-0.4);
        glVertex3f(+0.4,+0.4,-0.4);
    glEnd;

    glBegin(GL_POLYGON); {bottom face}
        glColor3f(0.5,0.5,0.0);
        glVertex3f(-0.4,-0.4,+0.4);
        glVertex3f(-0.4,-0.4,-0.4);
        glVertex3f(+0.4,-0.4,-0.4);
        glVertex3f(+0.4,-0.4,+0.4);
    glEnd;

    glBegin(GL_POLYGON); {top face}
        glColor3f(0.3,0.0,0.1);
        glVertex3f(-0.4,+0.4,+0.4);
        glVertex3f(+0.4,+0.4,+0.4);
        glVertex3f(+0.4,+0.4,-0.4);
        glVertex3f(-0.4,+0.4,-0.4);
    glEnd;

    glFlush;

    errorCode := glGetError;
    if errorCode<>GL_NO_ERROR then
        raise Exception.Create('Error in      Paint'#13+
            gluErrorString(errorCode));
    end; {FormPaint}

```

For convenience, move the cube inside the clipping volume with a call to `glTranslatef` near the bottom of the `FormCreate` method. Place it there so it will only happen once.

```
glLoadIdentity();
glTranslatef(0.0,0.0,-2.4);

glEnable(GL_CULL_FACE);
glCullFace(GL_BACK);
end; {FormCreate}
```

## MOVEMENT

### Rotation

Set up a transformation using the parameters of Figure 4-4, then perform the rotation. Notice that since the cube is so close to the front clipping face, the rotation sends a corner right outside the clipping volume. Now it is apparent that clipping works just like in the orthographic projection clipping volume. Notice too that back face culling also works as expected. The exposed interior of the cube reveals a green nothing. Select Cull Disable from the menu and behold the interior faces of the cube.

### Translation

In the parameter screen uncheck rotation and check translation. Set  $z$  to  $-0.1$  and the rest to  $0.0$ . Click Ok, and select Transformation from the menu repeatedly until the entire cube is inside the clipping volume. Now the image, shown in Figure 4-5, demonstrates clearly that the far side of the cube appears smaller than the near side.

**Figure 4-5.** Near and Far Sides of a Cube in Perspective

Next hold down `Alt+T` so that the keyboard starts repeating. Watch the cube retreat into the distance. Now that's perspective!

## MULTIPLE OBJECTS

### Matrix Stack

Most scenes built with OpenGL consist of more than just a single object on a plain background. Building various objects in the right places is an obvious way to build more complex scenes, but it can get tedious. Suppose the scene has a number of objects that are similar to each other and the programmer has to

describe them over and over. Isn't computer software supposed to relieve people of certain tiresome repetitive tasks? OpenGL provides a way!

Put a commonly used object in its own procedure or method. Build it around the origin (0.0,0.0,0.0) for ease of coding. Rotate it, translate it, even scale it, to put it in the right place, with the right orientation, and in the right shape. Then (this is important!) restore the ModelView matrix to its former condition and build and place another object.

What programming structure useful for saving and restoring something comes to mind? A stack would be nice. Indeed, as mentioned previously, OpenGL even provides a matrix stack. The commands for storing the current matrix on the stack, and retrieving it back, are:

```
procedure glPopMatrix; stdcall;  
procedure glPushMatrix; stdcall;
```

## Reuse an Object

Save the Mult project as Obj.Dpr in a new directory named Objects under Chapter.4. Remove Trans1.Pas from the project and save Multi.Pas as Objct.Pas in the new directory. Delete the menu object from the form, and empty all the menu item event handlers, and adjust the ClientHeight of the form back to 340.

## Delphi Developer's Guide to OpenGL

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

The object of choice these days is a cube. To make it available for reuse, collect the code to draw the cube and put it in a separate method.

```
procedure TForm1.Cube;  
begin  
    glBegin(GL_POLYGON); {near face}  
        glColor3f(0.5,0.0,0.0);  
        glVertex3f(-0.4,-0.4,+0.4);  
        glVertex3f(+0.4,-0.4,+0.4);  
        glVertex3f(+0.4,+0.4,+0.4);  
        glVertex3f(-0.4,+0.4,+0.4);  
    glEnd;  
  
    glBegin(GL_POLYGON); {right face}  
        glColor3f(0.3,0.3,0.8);  
        glVertex3f(+0.4,-0.4,+0.4);  
        glVertex3f(+0.4,-0.4,-0.4);  
        glVertex3f(+0.4,+0.4,-0.4);  
        glVertex3f(+0.4,+0.4,+0.4);  
    glEnd;  
  
    glBegin(GL_POLYGON); {left face}  
        glColor3f(0.5,0.0,0.5);  
        glVertex3f(-0.4,-0.4,-0.4);  
        glVertex3f(-0.4,-0.4,+0.4);  
        glVertex3f(-0.4,+0.4,+0.4);  
        glVertex3f(-0.4,+0.4,-0.4);  
    glEnd;  
  
    glBegin(GL_POLYGON); {back face}  
        glColor3f(0.0,0.0,0.5);  
        glVertex3f(+0.4,-0.4,-0.4);
```

```

        glVertex3f(-0.4,-0.4,-0.4);
        glVertex3f(-0.4,+0.4,-0.4);
        glVertex3f(+0.4,+0.4,-0.4);
    glEnd;

    glBegin(GL_POLYGON); {bottom face}
        glColor3f(0.5,0.5,0.0);
        glVertex3f(-0.4,-0.4,+0.4);
        glVertex3f(-0.4,-0.4,-0.4);
        glVertex3f(+0.4,-0.4,-0.4);
        glVertex3f(+0.4,-0.4,+0.4);
    glEnd;

    glBegin(GL_POLYGON); {top face}
        glColor3f(0.3,0.0,0.1);
        glVertex3f(-0.4,+0.4,+0.4);
        glVertex3f(+0.4,+0.4,+0.4);
        glVertex3f(+0.4,+0.4,-0.4);
        glVertex3f(-0.4,+0.4,-0.4);
    glEnd;
end;

```

Declare the method at the end of the private section of the form:

```

private
    GLContext: HGLRC;
    glDC: HDC;
    errorCode: GLenum;
    openGLReady: boolean;
    oldw,
    oldh: integer;
    procedure ExceptionGL(Sender:TObject;E:Exception);
    procedure Cube;
public

```

## Make a Scene

This is enough information to build a scene with multiple copies of the cube. Make the FormPaint method look like this:

```

procedure TForm1.FormPaint(Sender: TObject);
begin
    if not openGLReady then
        exit;

    {background}
    glClearColor(0.6,0.8,0.8,0.0);
    glClear(GL_COLOR_BUFFER_BIT or GL_DEPTH_BUFFER_BIT);

    glPushMatrix;
    glTranslatef(-0.7,0.7,-2.8);

```

```

Cube;
glPopMatrix;

glPushMatrix;
glTranslatef(1.9, -1.6, -5.4);
Cube;
glPopMatrix;

glFlush;

errorCode := glGetError;
if errorCode <> GL_NO_ERROR then
    raise Exception.Create('Error in Paint'#13+
        gluErrorString(errorCode));
end; {FormPaint}

```

Notice the sequence: push the ModelView matrix, translate to the desired location, call the routine that builds the object about the origin, and pop the matrix. Do this for each object in the scene; even if a given object is not repeated, it is usually simpler to construct at the origin, especially if it has symmetry. In this simple example only a translation appears before each cube, but any combination the three transformations could take its place.

Save, Compile, and Run. Behold a 3-D, two-object scene! Notice the marvelous new background color. Perhaps its name should be “Clear Blue Sky with Light Smog.” Figure 4-6 shows how it looks. The new color, though far from pretty, provides better contrast for the cubes.

**Figure 4-6.** Two Cubes in Perspective

## INDEPENDENT MOVEMENT

The techniques for creating multiple copies of an object and placing them in different places also lend themselves to moving the objects separately. To demonstrate, add some fields to the private section of the form type declaration:

```

x1, y1, z1, x2, y2, z2, xr1, yr1, zr1,
xr2, yr2, zr2, angle1, angle2, sign: GLfloat;

```

Initialize sign at the very bottom of the FormCreate method:

```

sign := 0.1;

```

### Translate

In the FormPaint method replace

```
glTranslatef(-0.7,0.7,-2.8);
```

with

```
glTranslatef(x1,y1,z1);
```

Also replace

```
glTranslatef(1.9,-1.6,-5.4);
```

with

```
glTranslatef(x2,y2,z2);
```

Now that the arguments in the `glTranslatef` calls are variables, code to manipulate the variables is appropriate. Using the Object Inspector set the form's `KeyPreview` property to true. On the Events page double click the `OnKeyPress` event and fill in the following event handler:

```
procedure TForm1.FormKeyPress(Sender: TObject; var Key: Char);  
var  
    ok: boolean;  
begin  
    ok := true;  
    case Key of  
        '+': sign := 0.1;  
        '-': sign := -0.1;  
        'X': x1 := x1+sign;  
        'x': x2 := x2+sign;  
        'Y': y1 := y1+sign;  
        'y': y2 := y2+sign;  
        'Z': z1 := z1+sign;  
        'z': z2 := z2+sign;  
    else  
        ok := false;  
    end; {case}  
    if ok then  
        Invalidate;  
end;
```

Whenever the user executes a keystroke the `FormKeyPress` method tests the character in the case statement and adjusts the variables accordingly. Pressing “+” or “-” sets the sign variable accordingly. The letters “x”, “y”, and “z” set the corresponding variables, with the capital letters setting x1, etc., and the lowercase letters setting x2, etc. If a desired letter came through, then a call to `Invalidate` causes the `FormPaint` method to fire again.

The sign variable starts with a positive value of one tenth. Pressing “-” changes it to negative one tenth and pressing “+” changes it back. This value adds to the other variables in response to the appropriate letter. Save, Compile, and Run. Start by pressing the minus key, then pressing and holding a capital “Z” until a cube comes into view. Since the variables are fields of the form, they start as 0.0 unless explicitly changed. That means both cubes remain

out of site at the origin until the user gives them a lot of negative z. Capital letters affect one cube and lower case letters affect the other cube. Experiment with pressing the desired keys and enjoy the power of moving the two cubes independently.

## Rotate

Being able to move two cubes independently represents a definite advance in the available OpenGL power, but rotating the cubes separately is an even greater advance. Better yet is the power to combine rotation and translation for each cube (independently). The variables have already been declared. After each `glTranslatef` goes a `glRotatef`:

```
glTranslatef(x1,y1,z1);  
glRotatef(angle1,xr1,yr1,zr1);
```

```
glTranslatef(x2,y2,z2);  
glRotatef(angle2,xr2,yr2,zr2);
```

<a href="#">Previous</a>	<a href="#">Table of Contents</a>	<a href="#">Next</a>

## Delphi Developer's Guide to OpenGL

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

The case statement in the FormKeyPress method needs an addition so that it can manipulate the rotation variables. The letters to check are upper and lower case “r,” “s,” and “t.”

```
'a': angle2 := angle2+10.0*sign;  
'r': xr2 := xr2+sign;  
's': yr2 := yr2+sign;  
't': zr2 := zr2+sign;  
'A': angle1 := angle1+10.0*sign;  
'R': xr1 := xr1+sign;  
'S': yr1 := yr1+sign;  
'T': zr1 := zr1+sign;
```

The letters “r,” “s,” and “t” set up the axis of rotation for each cube. Each axis is a *vector* (line segment with direction) from (0.0,0.0,0.0) toward the vertex constructed from (xr1,yr1,zr1) or (xr2,yr2,zr2). The letter “a” adjusts the amount of rotation (angle1 or angle2) about the appropriate vector. It would be nice to have a little help visualizing the axes of rotation. Add the following method to draw a representation of the coordinate axes along with the two rotation vectors:

```
procedure TForm1.Axes;  
begin  
    glLineWidth(3.0);  
    glBegin(GL_LINES);  
    glColor3f(0.0,0.0,0.0);  
  
    glVertex3f(+0.0,+0.0,+0.4);  
    glVertex3f(+0.0,+0.0,-0.4);  
  
    glVertex3f(+0.4,+0.0,+0.0);  
    glVertex3f(-0.4,+0.0,+0.0);  
end
```

```

        glVertex3f(+0.0,+0.4,+0.0);
        glVertex3f(+0.0,-0.4,+0.0);
    glEnd;

    glLineWidth(1.0);
    glBegin(GL_LINES);
        glColor3f(1.0,1.0,0.0);
        glVertex3f(0.0,0.0,0.0);
        glVertex3f(xr1,yr1,zr1);

        glColor3f(0.0,1.0,1.0);
        glVertex3f(0.0,0.0,0.0);
        glVertex3f(xr2,yr2,zr2);
    glEnd;
end;

```

Declare the new method at the bottom of the form's private section:

```

        procedure ExceptionGL(Sender:TObject;E:Exception);
        procedure Cube;
        procedure Axes;
public
    { Public declarations }
end;

```

Call the Axes method inside the FormPaint method, just before the call to glFlush. Translate it along the z axis to bring it inside the clipping volume. Translate it a little along the x and y axes so that the viewer will see it slightly from above and from the side, to make its three-dimensional nature more evident.

```

    glPushMatrix;
    glTranslatef(-0.6,-0.6,-2.8);
    Axes;
    glPopMatrix;

    glFlush;

```

Save, Compile, and Run. In addition to all the previous abilities of the program, it can now use the three new letters to rotate the cubes. Whew!

## Transformation Order Revisited

About the only thing left for this structure is to add scaling as well, but that would not add much to the OpenGL knowledge because the results are easy to predict. There is something else that can contribute significantly to the level of OpenGL understanding. The ability to switch back and forth between rotating before translation and rotating after translation reveals a dramatic difference between the two. Add the following to the case statement:

```

    'B': before := true;

```

```
'b': before := false;
```

The form declaration needs to include the before field:

```
errorCode: GLenum;  
before,  
openGLReady: boolean;  
oldw,  
oldh: integer;  
x1,y1,z1,x2,y2,z2,xr1,yr1,zr1,  
xr2,yr2,zr2,angle1,angle2,sign: GLfloat;  
procedure ExceptionGL(Sender:TObject;E:Exception);  
procedure Cube;  
procedure Axes;
```

FormPaint needs an enhancement using the value of the before field to control whether the call to glRotatef happens before or after the call to glTranslatef:

```
glPushMatrix;  
if before then  
    glRotatef(angle1,xr1,yr1,zr1);  
glTranslatef(x1,y1,z1);  
if not before then  
    glRotatef(angle1,xr1,yr1,zr1);  
Cube;  
glPopMatrix;  
  
glPushMatrix;  
if before then  
    glRotatef(angle2,xr2,yr2,zr2);  
glTranslatef(x2,y2,z2);  
if not before then  
    glRotatef(angle2,xr2,yr2,zr2);  
Cube;  
glPopMatrix;
```

Again Save, Compile, and Run. Bring the cubes into view and position and orient them as you please, but be sure to include some rotation for each of them. Now press “B” and “b” to show the difference between rotation before translation and rotation after translation. The experiment with order of transformations at the end of Chapter 3 gave small distinctions, but this time the difference is exceedingly obvious. For example, a small rotation about the y axis changes the direction of the cube’s own personal z axis, so a subsequent translation along the z axis sends it off in a different direction than if the translation happens first. Try it and see.

## Another View

Frankly, transformations in OpenGL can be very confusing, so any aid to comprehension is welcome. For this purpose think of the translations as applying to the objects rather than the coordinate system. Then think of the transformations as happening in reverse order. When you push and pop the ModelView matrix several

times, treat this reverse order concept separately between each push and pop.

Different people may need to consider OpenGL transformations in different ways to understand them. Possibly this alternate view will be the best one for many readers of this book.

## DEFINITIONS

Frustum	A geometric figure formed when the top of a cone or pyramid is cut off by a plane parallel to the base.
Perspective projection	A projection in which the apparent size of each object is adjusted for distance from the viewer.

## **IDENTIFIER REFERENCE**

glFrustum	An OpenGL command that sets up perspective projection and the clipping volume.
glPopMatrix	An OpenGL command that saves the current OpenGL matrix on the matrix stack.
glPushMatrix	An OpenGL command that retrieves a matrix from the matrix stack and makes it the current OpenGL matrix.

## **SUMMARY**

Here are the high points of Chapter 4:

1. The shape of the clipping region for perspective projection is a frustum, which is a pyramid with the top chopped off.
2. The command is glFrustum; the parameters are the same as for glOrtho, but the znear and zfar parameters have different effects and must be positive.
3. To move away from the viewer, deeper into the screen, is to move in the negative z direction.
4. The effects of clipping and back face culling are the same as with glOrtho.
5. When viewed in perspective, parallel lines appear to converge in the distance, and objects appear smaller as they retreat into the distance.
6. Use glPushMatrix to save the ModelView matrix and glPopMatrix to restore it. Placing transformations between those calls allows for

independent positioning and movement of objects in a scene.

**7.** Rotation changes the orientation of the axes so that a subsequent translation may go off in a different direction. When planning a positioning or movement within a scene, be careful about the order of the transformations.

**8.** OpenGL transformations seem to take effect in the reverse order of their specification in program code.

# **Chapter 5 Lighting**

In the real world things are visible because of light. All light comes from various sources, usually identifiable, but even when the source is unknown, the light was actually emitted from somewhere. Not only does the visibility of everything (except those objects that emit their own light) depend on light emitted from somewhere and reflected to the viewer, but the detailed appearance of each object depends on properties of the material composing the illuminated surface. A realistic graphics system should incorporate these facts. This chapter explores lighting and material properties.

Building on the work of Chapter 4, Save Obj.Dpr as ALight.Dpr in OpenGL\Chapter.5\Ambient. Save the main unit as ALight1.Pas.

## **ENABLE LIGHTING**

One of the great features of OpenGL is the ability to produce realistic effects through simulation of lighting. In the code in the first four chapters, OpenGL provided the equivalent of lighting so that the objects were visible. Now is the time to provide lighting specifications directly. Here is a necessary OpenGL constant:

```
GL_LIGHTING = $0B50;
```

At the bottom of the FormCreate method enable lighting:

```
glEnable(GL_LIGHTING);
```

Save, Compile and Run. Maneuver one of the cubes into the viewing volume (clipping region). Ugh! The red square is black! Rotate the cube so that two more faces show at least a little. They are black, too! It is difficult to distinguish one face from another because they have exactly the same color. Now that the program is taking responsibility for making the objects in the scene visible, OpenGL is taking no responsibility at all. Obviously the program needs to do more than just enable lighting.

Basically three kinds of lighting are available through OpenGL, *Ambient*, *Diffuse*, and *Specular*. This chapter will examine each of them in turn.

## AMBIENT LIGHT

### Definition

Ambient light has no apparent source, but seems to come from all directions. In the real world, all light has a source, but some light may be reflected and scattered from several surfaces before finally reaching the viewer. The source of such light may be difficult or impossible to trace. This kind of light is called ambient light. OpenGL simulates this effect by providing illumination equally from all directions. It can be associated with a particular light or it can have no specific source, just magically appearing (at the programmer's command).

### Commands and Constants

The command for defining a light is a variation of `glLight`. Use the “f” suffix to use `GLfloat` parameters. Many commands, including ones already discussed, have a vector version, indicated by a “v” suffix. The vector version substitutes a pointer to an array in place of several scalar parameters. The `glLight` command only takes three parameters in any version, so only the vector version meets the current need. The `glLightModel` command takes three parameters and also has a vector version suitable for the occasion. Then there is the `glColorMaterial` command, which introduces the idea of material properties. The relevant declarations follow. First a necessary type:

```
PGLfloat = ^GLfloat;
```

Here are some useful constants:

```
GL_LIGHT_MODEL_AMBIENT = $0B53;
GL_COLOR_MATERIAL      = $0B57;
GL_AMBIENT              = $1200;
GL_LIGHT0               = $4000;
GL_LIGHT1               = $4001;
GL_LIGHT2               = $4002;
GL_LIGHT3               = $4003;
GL_LIGHT4               = $4004;
GL_LIGHT5               = $4005;
GL_LIGHT6               = $4006;
GL_LIGHT7               = $4007;
```

Finally, the commands:

```
procedure glColorMaterial(face,mode:GLenum); stdcall;
procedure glLightModelfv(pname:GLenum;params:PGLfloat); stdcall;
procedure glLightfv(light,pname:GLenum;params:PGLfloat); stdcall;
```

Consider the parameters in the commands. The `face` parameter can be `GL_FRONT`, `GL_BACK`, or `GL_FRONT_AND_BACK`. Right now `GL_FRONT` is sufficient. The `mode` parameter specifies the kind of lighting to which the material property relates. The example under development uses `GL_AMBIENT`. The `params` pointer could be pointing to a single `GLfloat`, or the first element of an array of them. While this is very C-like, Delphi can handle it nicely. The `pname` parameter identifies the purpose for two of the commands. The command for the simplest method of implementing ambient light is `glLightModel`. Pass it

GL\_LIGHT\_MODEL\_AMBIENT for the first parameter.

## THE EASY WAY

Lighting introduces a new level of complexity to the specification of an object's appearance. A simple color specification does not tell the whole story about how a surface responds to light. *Material* properties allow a more complete way to describe responses to light. The present example avoids some of the complexity by having the material color track the current color by means of the glColorMaterial command. This is one of the options that requires enabling before use.

At the bottom of the FormCreate method, after the enabling of lighting , initialize the array and place some of the new commands with the appropriate arguments.

```
AmbientDef[0] := 1.0; {red}
AmbientDef[1] := 1.0; {green}
AmbientDef[2] := 1.0; {blue}
AmbientDef[4] := 1.0; {alpha}
glEnable(GL_COLOR_MATERIAL);
glColorMaterial(GL_FRONT, GL_AMBIENT);
glLightModelfv(GL_LIGHT_MODEL_AMBIENT, @AmbientDef);
```

In this version of the glLightModel command, using GL\_LIGHT\_MODEL\_AMBIENT, means the array contains the color specification of the ambient light. Here, giving maximum intensity (1.0) to the red, green, and blue components specifies a white ambient light. A later chapter covers alpha; just set it to 1.0 for now. Declare the array in the private section of the form.

```
AmbientDef: array[0..3] of GLfloat;
```

Save, Compile, and Run. Now the cubes look like they did before. So what did the new commands accomplish? One benefit is control. Experiment with decreasing the red, green, and blue components of AmbientDef (positions 0, 1, and 2 in the array). Reducing the overall intensity of the ambient light or giving it a color bias produces effects that may be desirable in some applications.

## THE HARD WAY

A more flexible approach uses the `glLight` command. Make a new directory named `OpenGL\Chapter.5\Ambient0`. In that directory save the program as `Amb0.Dpr` and the main unit as `Ambient0.Pas`. Change the bottom of the `FormCreate` method to this:

```
glEnable(GL_LIGHTING);
AmbientDef[0] := 1.0; {red}
AmbientDef[1] := 1.0; {green}
AmbientDef[2] := 1.0; {blue}
AmbientDef[3] := 1.0; {alpha}

glLightfv(GL_LIGHT0, GL_AMBIENT, @AmbientDef);
glEnable(GL_LIGHT0);
```

This approach defines a particular light (`LIGHT0`) instead of just setting up a light model. At least eight lights are available; some implementations of OpenGL may allow more. Notice that you must turn on any light you want to use. This example switches on `LIGHT0` with `glEnable(GL_LIGHT0)`. To use a light, the simple color tracking of `glColorMaterial` is not adequate. So instead of `glColor` commands inside the `Cube` method, use `glMaterial` commands. A vector version is most convenient, so define an array at the top of `Cube`. For this example there is no attempt to produce the same colors as before.

```
procedure TForm1.Cube;
var
    ambient: array[0..3] of GLfloat;
begin
    fillchar(ambient, sizeof(ambient), 0);
    ambient[3] := 1.0; {alpha}
```

```

glBegin(GL_POLYGON); {near face}
    ambient[0] := 0.5; {red}
    glMaterialfv(GL_FRONT, GL_AMBIENT, @ambient);
    glVertex3f(-0.4, -0.4, +0.4);
    glVertex3f(+0.4, -0.4, +0.4);
    glVertex3f(+0.4, +0.4, +0.4);
    glVertex3f(-0.4, +0.4, +0.4);
glEnd;

glBegin(GL_POLYGON); {right face}
    ambient[1] := 0.5; {green} {total=yellow}
    glMaterialfv(GL_FRONT, GL_AMBIENT, @ambient);
    glVertex3f(+0.4, -0.4, +0.4);
    glVertex3f(+0.4, -0.4, -0.4);
    glVertex3f(+0.4, +0.4, -0.4);
    glVertex3f(+0.4, +0.4, +0.4);
glEnd;

glBegin(GL_POLYGON); {left face}
    ambient[0] := 0.0; {red} {total=green}
    glMaterialfv(GL_FRONT, GL_AMBIENT, @ambient);
    glVertex3f(-0.4, -0.4, -0.4);
    glVertex3f(-0.4, -0.4, +0.4);
    glVertex3f(-0.4, +0.4, +0.4);
    glVertex3f(-0.4, +0.4, -0.4);
glEnd;

glBegin(GL_POLYGON); {back face}
    ambient[2] := 0.5; {blue} {total=turquoise}
    glMaterialfv(GL_FRONT, GL_AMBIENT, @ambient);
    glVertex3f(+0.4, -0.4, -0.4);
    glVertex3f(-0.4, -0.4, -0.4);
    glVertex3f(-0.4, +0.4, -0.4);
    glVertex3f(+0.4, +0.4, -0.4);
glEnd;

glBegin(GL_POLYGON); {bottom face}
    ambient[1] := 0.0; {green} {total=blue}
    glMaterialfv(GL_FRONT, GL_AMBIENT, @ambient);
    glVertex3f(-0.4, -0.4, +0.4);
    glVertex3f(-0.4, -0.4, -0.4);
    glVertex3f(+0.4, -0.4, -0.4);
    glVertex3f(+0.4, -0.4, +0.4);
glEnd;

glBegin(GL_POLYGON); {top face}
    ambient[0] := 0.5; {red} {total=magenta/magenta}
    glMaterialfv(GL_FRONT, GL_AMBIENT, @ambient);
    glVertex3f(-0.4, +0.4, +0.4);
    glVertex3f(+0.4, +0.4, +0.4);

```

```

        glVertex3f(+0.4,+0.4,-0.4);
        glVertex3f(-0.4,+0.4,-0.4);
    glEnd;
end;

```

Save, Compile, and Run. Bring the cubes into view and move them around. Notice something rather strange. A side of the cube facing directly toward the viewer is brighter than the same side with a significantly different angle to the viewer.

That is not the behavior of ambient light. Perhaps it has been set too bright. Ambient light is often a minor part of the total light in a scene. In the FormCreate method cut it down as follows:

```

AmbientDef[0] := 0.3; {red}
AmbientDef[1] := 0.3; {green}
AmbientDef[2] := 0.3; {blue}
AmbientDef[3] := 1.0; {alpha}

```

Save, Compile, and Run. Manipulate the scene as before. Alas, there is little noticeable difference between ambient light at 30% and ambient light at 100%. Something is very wrong.

Actually, LIGHT0 has a special characteristic different from LIGHT1, LIGHT2 or any of the others. LIGHT0 by default has a white light diffuse component and a white light specular component. The default ambient component is black, but the present code replaced the default value. To see the effect of ambient light alone requires replacing the diffuse and specular parts (with black). Make these changes to the FormCreate method:

```

glEnable(GL_LIGHTING);
fillchar(AmbientDef,SizeOf(AmbientDef),0);
glLightfv(GL_LIGHT0,GL_DIFFUSE,@AmbientDef);
glLightfv(GL_LIGHT0,GL_SPECULAR,@AmbientDef);

AmbientDef[0] := 0.3; {red}
AmbientDef[1] := 0.3; {green}
AmbientDef[2] := 0.3; {blue}
AmbientDef[3] := 1.0; {alpha}

glLightfv(GL_LIGHT0,GL_AMBIENT,@AmbientDef);
glEnable(GL_LIGHT0);

```

The new constants are:

```

GL_DIFFUSE = $1201;
GL_SPECULAR = $1202;

```

Now Save, Compile, and Run. Bring the cubes into view. What a difference! The cubes are rather dim, which is natural for only 30% ambient illumination, but most importantly, they are uniformly dim. This is how ambient light should appear!

Can OpenGL handle bright white ambient light, or did the earlier supposition that the ambient light was set out of natural range have merit? Find out by replacing all the 0.3 values in AmbientDef with 1.0. Save, Compile, Run, and move cubes around. Now uniform illumination abounds. Though it is quite bright, the ambient light appears evenly distributed regardless of angle, which is the right behavior for ambient light.

## **DIFFUSE LIGHT**

### **Definition**

Imagine a lamp lighting a large room. Much of the light bounces off many surfaces before reaching a viewer. While the light actually came from the lamp, it seems simply to be everywhere. This is the ambient portion of the light. Obviously, however, some of the light proceeds directly from the source to the surface of some object in the room and reflects directly to the viewer. However, unless the surface is a mirror, the light tends to scatter rather than bounce off at a predictable angle. In the real world nothing is perfectly smooth, but some things have been polished enough that the surface irregularities are too small to matter. Such surfaces are “shiny.” Most surfaces have irregularities large enough to scatter most light as in Figure 5-1. These surfaces are “flat.” Unless the surface is white, it will absorb some colors from the light and reflect the rest, thus defining its color in terms of the portion of the light it reflects. This scattering effect determines the diffuse portion of the light. Not only does OpenGL allow the definition of at least eight light sources, but it also allows independent specification of the ambient portion and diffuse portion of each light.

**Figure 5-1.** Diffuse Reflection from a Flat Surface

### **Positional Lamps**

Save the project as Difu.Dpr in a new directory called OpenGL\Chapter.5\Dif1 and save the main unit as Diffus.Pas. For the lamp under development, most

light shines directly on an object from the lamp (the diffuse portion), and a lesser contribution comes from multiple reflections (the ambient portion). Prepare to change the AmbientDef assignments in the FormCreate method as follows, but do not type it in just yet:

```
glEnable(GL_LIGHTING);
AmbientDef[0] := 0.3; {red}
AmbientDef[1] := 0.3; {green}
AmbientDef[2] := 0.3; {blue}
AmbientDef[3] := 1.0; {alpha}
```

While bland, homogenized arrays like this provide a simple, fairly language-independent way of passing data to the OpenGL DLL's, Delphi allows more meaningful structures that use memory exactly the same way. The following type declaration of a record structure is more intuitive and does not require the programmer to memorize the order of the colors:

```
TLightDesc=record
    red,
    green,
    blue,
    alpha: GLfloat;
end;
```

Wait! Don't type that in either! Arrays use contiguous memory, but record structures may have "holes" in the data due to memory alignment by the compiler. This particular record structure is safe (for the moment) because each of the elements is four bytes in size, but to guarantee that the record memory layout is exactly the same as the array memory layout, use the **packed** reserved word and place the declaration just above the form's class declaration:

```
type
    TLightDesc=packed record
        red,
        green,
        blue,
        alpha: GLfloat;
    end;
TForm1 = class(TForm)
```

Of course the type for the AmbientDef field within the form declaration should become:

```
AmbientDef: TLightDesc;
```

Now the new assignments to AmbientDef in the FormCreate method can proceed:

```
glEnable(GL_LIGHTING);
```

```

with AmbientDef do
begin
    red := 0.3;
    green := 0.3;
    blue := 0.3;
    alpha := 1.0;
end;

```

The key distinction between diffuse light and ambient light is that the source of diffuse light has a position. Therefore a demonstration of diffuse light requires the ability to set the position of the lamp. Accordingly add these lines to the case statement in the FormKeyPress method:

```

    'l': x1 := x1+sign;
    'm': y1 := y1+sign;
    'n': z1 := z1+sign;

```

In the form's class declaration add these "L" variable declarations to describe the lamp position:

```

    x1,y1,z1,
    x1,y1,z1,x2,y2,z2,xr1,yr1,zr1,
    xr2,yr2,zr2,angle1,angle2,sign: GLfloat;
    AmbientDef: TLightDesc;
    LightPlace: TLightPlace;

```

LightPlace is also new and needs a type declaration.

```

type
    TLightDesc=packed record
        red,
        green,
        blue,
        alpha: GLfloat;
    end;
    TLightPlace=packed record
        x,
        y,
        z,
        w: GLfloat;
    end;
TForm1 = class(TForm)

```

In the FormPaint method, place some code to manipulate the light position:

```

    glPushMatrix;
    if before then
        glRotatef(angle2,xr2,yr2,zr2);
        glTranslatef(x2,y2,z2);
    if not before then
        glRotatef(angle2,xr2,yr2,zr2);

```

```

Cube;
glPopMatrix;
glPushMatrix;
glTranslatef(x1,y1,z1);
glLightfv(GL_LIGHT0, GL_POSITION, @LightPlace);
glPopMatrix;

```

Save, Compile, Run, and bring a cube barely into view, then go two keystrokes more down the negative z-axis. Move the cube near the upper left corner of the form. The cube appears very bright, but that will change as the lamp moves.

Press the minus key, then press the lowercase “n” repeatedly. After about five such presses, a slight difference is noticeable. As you continue to advance the lamp down the negative z-axis, watch the shading develop on the cube!

Now it should be possible to have a uniformly colored cube that still shows its three-dimensional nature by its shading in a diffuse light source. In the Cube method change the type of the ambient local variable:

```

procedure TForm1.Cube;
var
    ambient: TLightDesc;
begin

```

Remove all assignments to ambient inside the Cube method and replace them with one set of assignments as follows:

```

procedure TForm1.Cube;
var
    ambient: TLightDesc;
begin
    ambient.red := 0.2;
    ambient.green := 0.5;
    ambient.blue := 0.8;
    ambient.alpha := 1.0;
    glMaterialfv(GL_FRONT, GL_AMBIENT, @ambient);
    glBegin(GL_POLYGON); {near face}

```

Save, Compile, Run, and perform movements as before. Around the 22<sup>nd</sup> “n” press the shading of the cube is more than sufficient to distinguish the faces. Enjoy! This is tremendous progress from the first step of making a colored background.

[Previous](#) [Table of Contents](#) [Next](#)

### Different Material Colors

Various material properties can be set independently, including colors for ambient reflectivity, specular reflectivity, and diffuse reflectivity. Allowing the surface to reflect ambient light differently from diffuse light provides for some interesting effects. Adjust the top of the Cube method as follows:

```
procedure TForm1.Cube;  
var  
    diffuse,  
    ambient: TLightDesc;  
begin  
    ambient.red := 0.2;  
    ambient.green := 0.5;  
    ambient.blue := 0.8;  
    ambient.alpha := 1.0;  
    diffuse.red := 0.8;  
    diffuse.green := 0.5;  
    diffuse.blue := 0.2;  
    diffuse.alpha := 1.0;  
    glMaterialfv(GL_FRONT, GL_DIFFUSE, @diffuse);  
    glMaterialfv(GL_FRONT, GL_AMBIENT, @ambient);  
    glBegin(GL_POLYGON); {near face}
```

Save, etc. as before. This version more clearly demonstrates the ambient contribution and the diffuse contribution from the light source. At first the diffuse light reflection color clearly dominates. As the light advances down the negative z-axis until it is almost past the near face of the cube, ambient reflection clearly shows one color, and diffuse reflection another color. When the light moves a little more, the ambient reflection color will completely dominate. Why does the diffuse contribution wane before the light is past the

cube? Another behavior of real light reflecting off real surfaces is the fact that as the angle from the light source to the surface flattens, less of the diffuse light reflects to the viewer. Figure 5-2 illustrates light shining on a surface from an acute angle (left) and from a more obtuse angle (right). The right side of the illustration shows less of the scattered (diffuse) light reaching the viewer. OpenGL reproduces this behavior nicely.

**Figure 5-2.** Diffuse Light at Different Angles.

So far the exercises have depended on the fact that LIGHT0 has a white diffuse component by default. The next exercise illustrates colored light on surfaces of different color. Accordingly, at the bottom of the FormCreate method, make the light pure red and explicitly define the diffuse component.

```

glEnable(GL_LIGHTING);
with AmbientDef do
begin
    red := 0.6;
    green := 0.0;
    blue := 0.0;
    alpha := 1.0;
end;
LightPlace.w := 1.0;

glLightfv(GL_LIGHT0, GL_AMBIENT, @AmbientDef);
glLightfv(GL_LIGHT0, GL_DIFFUSE, @AmbientDef);
glEnable(GL_LIGHT0);
end; {FormCreate}

```

Save ... well, you know the drill. Now, since the only light is red, that is the only light reflected, so the cube looks pure red. What will happen if the material property has no red component? Find out by removing the red at the top of the Cube method. At the same time return the cube to having only one color response to the light.

```

procedure TForm1.Cube;
var
    ambient: TLightDesc;
begin
    ambient.red := 0.0;
    ambient.green := 0.5;
    ambient.blue := 0.8;
    ambient.alpha := 1.0;
    glMaterialfv(GL_FRONT, GL_DIFFUSE, @ambient);
    glMaterialfv(GL_FRONT, GL_AMBIENT, @ambient);
    glBegin(GL_POLYGON); {near face}

```

Repeat the steps and see the result. The cube is black. Only red light is

available. The cube reflects no red light. Therefore the cube reflects no virtually light.

## Spotlights

The light source discussed so far can be a spotlight. First, this naked light needs some clothes. For this stage of the learning adventure, dress it in a ... cube. Save the project as Spot.Dpr in OpenGL\Chapter.5\Spot, and save the main unit as Spot1.pas in that directory. Give the Cube method the ability to set its material color from a passed parameter. Adjust its declaration inside the form class declaration and add a few fields.

```
CubeColor,  
SpotColor,  
DiffDef,  
AmbientDef: TLightDesc;  
LightPlace: TLightPlace;  
procedure ExceptionGL(Sender:TObject;E:Exception);  
procedure Cube(matColor:TLightDesc);  
procedure Axes;
```

Now change its implementation code to handle the parameter.

```
procedure TForm1.Cube(matColor:TLightDesc);  
begin  
    glMaterialfv(GL_FRONT,GL_AMBIENT,@matColor);  
    glMaterialfv(GL_FRONT,GL_DIFFUSE,@matColor);  
    glBegin(GL_POLYGON); {near face}
```

Set the color records in the FormCreate method.

```
glEnable(GL_LIGHTING);  
with AmbientDef do  
begin  
    red := 0.3;  
    green := 0.3;  
    blue := 0.3;  
    alpha := 1.0;  
end;  
with DiffDef do  
begin  
    red := 1.0;  
    green := 1.0;  
    blue := 1.0;  
    alpha := 1.0;  
end;  
with CubeColor do  
begin  
    red := 0.5;  
    green := 0.0;
```

```
    blue := 0.8;
    alpha := 1.0;
end;
with SpotColor do
begin
    red := 0.0;
    green := 0.5;
    blue := 0.5;
    alpha := 1.0;
end;
```

```
LightPlace.w := 1.0;
```

```
glLightfv(GL_LIGHT0, GL_AMBIENT, @AmbientDef);
glLightfv(GL_LIGHT0, GL_DIFFUSE, @DiffDef);
```

Make the two calls to Cube in the FormPaint method use the parameter.

```
Cube(CubeColor);
```

Also adjust the code that positions the light Be sure to make this cube smaller with glScalef.

```
glPushMatrix;
glScalef(0.33, 0.33, 0.33);
glTranslatef(x1, y1, z1);
glLightfv(GL_LIGHT0, GL_POSITION, @LightPlace);
Cube(SpotColor);
glPopMatrix;
```

## Delphi Developer's Guide to OpenGL

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

Now, go back to the bottom of the `FormCreate` method and initialize some positions so you will not have to do so much work to position the objects. Note that the “l” in the variable names is an ell not a one.

```
z2 := -2.7;  
x2 := -0.7;  
y2 := 0.7;  
z1 := -6.7;  
x1 := -1.8;  
y1 := -2.1;  
end; {FormCreate}
```

Since the `glScale` command affects translation (and rotation), as well as the object size, adjust the case statement in the `FormKeyPress` method.

```
'l': x1 := x1+3.0*sign;  
'm': y1 := y1+3.0*sign;  
'n': z1 := z1+3.0*sign;
```

Save, Compile, and Run. (You are remembering not to run from the IDE, aren't you?) The magenta (or purple) cube and the cyan (blue-green, turquoise, whatever) “spotlight” are visible from the start. Use the “l,” “m,” and “n” keys to move the spotlight around. The center of the small cyan cube tracks the position of the light source so that the cube appears to BE the light source. Notice the effect different light positions have on illumination of the magenta cube.

A really interesting effect is the illumination of the small cube from the inside, so that the sides of the cube appear to be translucent. This brings up an important fact. OpenGL knows nothing about shadows. When you “shine” an OpenGL light source on an OpenGL object, you see a very good representation of real illumination. However, if you interpose another seemingly solid OpenGL

object between the light source and the first object, the more distant object receives illumination just as if there were nothing in the way. The consequence of this fact is that if you want shadows, you will have to program them yourself. Do not despair; it can be done. More about that comes later.

Notice that only half of the cyan cube lights up. By default an OpenGL diffuse light source has a 180 degree spread as shown in figure 5-3, which includes the cyan cube that represented the spotlight. A real spotlight is more focused, and OpenGL permits this effect with an appropriate constant in a familiar command.

```
glLightf(GL_LIGHT0, GL_SPOT_CUTOFF, cutoff);
```

**Figure 5-3.** Default Spread of a Diffuse Light Source.

The new constant has this value:

```
GL_SPOT_CUTOFF = $1206;
```

Express the value of the cutoff variable in degrees. Think of the light spreading from a spotlight as a cone of light. The angle from the center of the cone to the edge of the cone is the cutoff angle, as shown in figure 5-4.

**Figure 5-4.** The Spotlight Cutoff Angle.

Add the cutoff field to the “ell” line in the form’s class declaration.

```
x1,y1,z1,xr1,yr1,zr1,cutoff,
x1,y1,z1,x2,y2,z2,xr1,yr1,zr1,
xr2,yr2,zr2,angle1,angle2,sign: GLfloat;
```

Use the cutoff field in the FormCreate method.

```
glLightfv(GL_LIGHT0, GL_AMBIENT, @AmbientDef);
glLightfv(GL_LIGHT0, GL_DIFFUSE, @DiffDef);
cutoff := 55.0;
glLightf(GL_LIGHT0, GL_SPOT_CUTOFF, cutoff);
glEnable(GL_LIGHT0);
```

Save, Compile, Run. Move the spotlight around with “l,” “m,” and “n.” Notice that you must move the spotlight closer to the magenta cube in the x and y

directions or farther in the positive z direction in order to illuminate the magenta cube.

## Directional Spotlights

A feature still missing from the spotlight illustrated thus far in the chapter is the ability to aim it. What kind of spotlight is it that you can't ... spot? One thing needed for that purpose is to add some more "ell" fields in the form class declaration.

```
x1,y1,z1,xr1,yr1,zr1,angle1,cutoff,  
x1,y1,z1,x2,y2,z2,xr1,yr1,zr1,  
xr2,yr2,zr2,angle1,angle2,sign: GLfloat;
```

The `xr1`, `yr1`, and `zr1` fields set up the axis of rotation for the cyan cube and the aiming direction of the spotlight. Similarly the `angle1` field is the number of degrees of rotation about the axis for both the cube and the aiming of the spotlight. The default aim of a spotlight is a vector from the origin (0.0,0.0,0.0) to (0.0,0.0,-1.0) down the negative z-axis, which points toward the far face of the cube at its starting position. Therefore aiming the far face of the cube effectively aims the spotlight.

To manipulate those fields, add to the case statement in the `FormKeyPress` method.

```
'k': angle1 := angle1+30.0*sign;  
'o': xr1 := xr1+3.0*sign;  
'p': yr1 := yr1+3.0*sign;  
'q': zr1 := zr1+3.0*sign;
```

Add a new type:

```
TLightDesc=packed record  
  red,  
  green,  
  blue,  
  alpha: GLfloat;  
end;  
TLightPlace=packed record  
  x,  
  y,  
  z,  
  w: GLfloat;  
end;  
TPosition=packed record  
  x,  
  y,  
  z: GLfloat;  
end;
```

Add a new field of that type in the form's class declaration:

```
AmbientDef: TLightDesc;  
LightPlace: TLightPlace;  
SpotDirect: TPosition;
```

Initialize SpotDirect in the FormCreate method to match the default value of a spotlight direction. Except for the z field, the zeros that come automatically from creating an instance of the form are sufficient.

```
with SpotColor do  
begin  
    red := 0.0;  
    green := 0.5;  
    blue := 0.5;  
    alpha := 1.0;  
end;  
SpotDirect.z := -1.0;  
LightPlace.w := 1.0;
```

Finally, to the FormPaint method add the use of SpotDirect and the rotational “ell” fields.

```
glPushMatrix;  
glScalef(0.33,0.33,0.33);  
if before then  
    glRotatef(angle1,xr1,yr1,zr1);  
glTranslatef(xl,yl,zl);  
if not before then  
    glRotatef(angle1,xr1,yr1,zr1);  
glLightfv(GL_LIGHT0,GL_POSITION,@LightPlace);  
glLightfv(GL_LIGHT0,GL_SPOT_DIRECTION,@SpotDirect);  
Cube(SourceColor);
```

Save, Compile, Run, and press the plus key. Press the lower-case “o” to set the axis of rotation for the spotlight in the positive x direction. Press and hold the lower-case “k” to produce rotation of the spotlight about the x-axis. Watch the change in lighting on the magenta cube as the spotlight direction changes. That is not a bad effect for just a little code. There is certainly a lot of power in simple OpenGL commands! Notice the brilliance the face of the cyan cube from which the light seems to emanate.

## EMISSION

### Definition

Here is a profound revelation. Light sources emit light. They glow. A surface that glows looks different from a surface that merely reflects light. OpenGL provides a way to produce this effect. Notice that the subject is the appearance of surfaces. Therefore the appropriate command is `glMaterialfv` rather than `glLightfv`. The new constant is:

```
GL_EMISSION = $1600;
```

The purpose of the use of `GL_EMISSION` is to intensify the surface color so that it seems to glow. It does not add to the light shed on other surfaces.

### Implementation

Save the spot project as `Emission.Dpr` in `OpenGL\Chapter.5\Emit`. Save the main unit as `Emit1.Pas` in the same directory. Since the use of `GL_EMISSION` applies to the material properties of a face in the spotlight cube, some special purpose code is necessary for this illustration. In the `Cube` method surround the `{back face}` part with material commands. The `if` statement tests for a red component so the magenta cubes will not be affected, but the cyan cube will be affected. Remember this is just special code for a brief illustration.

```
if matColor.red=0.0 then
    glMaterialfv(GL_FRONT, GL_EMISSION, @matColor);
glBegin(GL_POLYGON); {back face}
    glVertex3f(+0.4, -0.4, -0.4);
    glVertex3f(-0.4, -0.4, -0.4);
    glVertex3f(-0.4, +0.4, -0.4);
```

```

        glVertex3f(+0.4,+0.4,-0.4);
    glEnd();
    glMaterialfv(GL_FRONT, GL_EMISSION, @black);

```

The black emission statement confines the effect of the previous emission statement to the one face, otherwise everything would eventually end up with GL\_EMISSION. Of course the black field requires declaration within the form's class declaration. Happily it will automatically be initialized to all zeros.

```

        black: TLightDesc;
        LightPlace: TLightPlace;
        SpotDirect: TPosition;

```

Frankly, since the back face of the cyan cube already almost seems to glow, using matColor with GL\_EMISSION will have no noticeable effect. Replace it with the emit field.

```

if matColor.red=0.0 then
    glMaterialfv(GL_FRONT, GL_EMISSION, @emit);

```

Declare emit in the form's class declaration:

```

        emit: TLightDesc;
        black: TLightDesc;
        LightPlace: TLightPlace;
        SpotDirect: TPosition;

```

Initialize emit in the FormCreate method:

```

with emit do
begin
    red := 0.6;
    green := 1.0;
    blue := 1.0;
    alpha := 1.0;
end;
end; {FormCreate}

```

Save, Compile, Run, press plus, and press little "o." Hold down little "k" until the back side partially faces the viewer. Notice the intensity of the back face. This illustrates a feature that is seldom used, but you may find handy on special occasions.

To see why you needed glMaterialfv(GL\_FRONT, GL\_EMISSION, @black), comment it out, re-compile, and re-run. GL\_EMISSION affected everything. Ugh! The effect of a glMaterial command remains until explicitly changed.

Remember that emission is just a surface effect in OpenGL; it is not one of the three kinds of light that come from a light source. The next topic deals with such a type of light.

# SPECULAR LIGHT

## Definition

The third component of light from a light source is *specular* light. Ambient light has been scattered from many surfaces and seems to come from all directions. Diffuse light comes from a specific direction (the source, of course), but scatters from surfaces, giving a soft, “flat” appearance to surfaces. Ambient and Diffuse components of a light source commonly share the same color. Specular light is also directional, but much “tighter” in reflection than diffuse light, often with a different color. Specular light more closely follows the classical rule of reflection wherein the angle of reflection equals the angle of incidence, as in Figure 5-5.

**Figure 5-5.** Specular Reflection Angles.

As you might expect, the result of reflection of specular light depends greatly on the material properties of the surface. You may have noticed that in the real world surfaces that are smooth and “shiny” often show a small bright spot in bright, direct light. The bright spot is known as the specular highlight. With OpenGL you can give a surface the appearance of being smooth and shiny by producing such a bright spot. While the color of the surface with respect to ambient and diffuse light may vary, the color of the specular highlight tends toward white.

## Implementation

To demonstrate the specular component of a light source, load the Spot.Dpr project from OpenGL\Chapter.5\Spot. Create a new directory called OpenGL\Chapter.5\Spec and save the project as Specular.Dpr into the new directory. Save its main unit as Spec1.Pas in the same directory. At the bottom of the FormCreate method add a new glLightfv command.

```
glLightfv(GL_LIGHT0, GL_SPECULAR, @SpecDef);  
end; {FormCreate}
```

Actually, LIGHT0 by default has a pure white specular component, but this illustration needs something a little less intense. Assign a medium gray to it.

```
with SpecDef do  
begin  
  red := 0.5;  
  green := 0.5;  
  blue := 0.5;  
  alpha := 1.0;  
end;  
glLightfv(GL_LIGHT0, GL_SPECULAR, @SpecDef);
```

```
end; {FormCreate}
```

Oh yes! Be sure to declare SpecDef in the form's class declaration.

```
    CubeColor ,  
    SpotColor ,  
    DiffDef ,  
    SpecDef ,  
    AmbientDef: TLightDesc;  
    LightPlace: TLightPlace;  
    SpotDirect: TPosition;
```

For convenience, change the initial value of z2 from -2.7 to -3.7, moving the larger cube farther back, so that the spotlight cube will not bury itself in the larger cube in the coming illustration.

```
    z2 := -3.7;  
    x2 := -0.7;  
    y2 := 0.7;  
    z1 := -6.7;  
    x1 := -1.8;  
    y1 := -2.1;
```

To the specular light component add the surface color response to that light.

```
    glLightfv(GL_LIGHT0, GL_SPECULAR, @SpecDef);  
    glMaterialfv(GL_FRONT, GL_SPECULAR, @SpecDef);  
end; {FormCreate}
```

Notice that the new glMaterialfv command is in the FormCreate method. Remember that such a command remains in effect until another command changes it. By placing it here, with no contradictory command elsewhere, you give all surfaces the same response to specular light for all time. Well, it lasts for as long as the program runs, anyway.

<a href="#">Previous</a>	<a href="#">Table of Contents</a>	<a href="#">Next</a>

## Delphi Developer's Guide to OpenGL

(Publisher: Wordware Publishing, Inc.)

Author(s): Jon Jacobs

ISBN: 1556226578

Publication Date: 08/01/99

[Previous](#) [Table of Contents](#) [Next](#)

The specular effect needs one more specification. Remember that specular highlights appear on shiny surfaces. Naturally OpenGL defines a constant for setting shininess in a command.

```
GL_SHININESS = $1601;
```

The shininess property is an integer that can range in value from 0 to 128. Therefore the property needs an integer form of the `glMaterial` command. Give it maximum shininess for this illustration.

```
glLightfv(GL_LIGHT0, GL_SPECULAR, @SpecDef);  
glMaterialfv(GL_FRONT, GL_SPECULAR, @SpecDef);  
glMateriali(GL_FRONT, GL_SHININESS, 128);  
end; {FormCreate}
```

Save, Compile, Run, and press plus. Press little “m” four times to raise the spotlight toward the magenta cube. Do you see the faint light streak running from the lower left corner to the upper right corner of the near face? It is not much, but that is as good as it gets with a face of a cube. To see a better specular highlight, you need a surface with some curvature. A later chapter introduces curved surfaces.

## HOW MUCH LIGHT

So far you have seen three light source components: Ambient, Diffuse, and Specular. Each of these has three color components: red, green, and blue. There is also an alpha component, which still must be put off until later. Never fear! You will see alpha when the time is right. You have also seen material properties which specify the response to light. Material properties also have Ambient, Diffuse, and Specular parts. Each of these also has the three color components.

So what determines how much light of each color reaches the viewer? Would you believe a simple multiplication? Figure 5-6 illustrates.

**Figure 5-6.** Multiplying a Light Component.

## DEFINITIONS

<b>Term</b>	<b>Meaning</b>
Ambient light	Light that has reflected from various surfaces and seems to come from all directions with no readily identifiable source. The component of an OpenGL light source used to simulate that effect.
Diffuse light	Light that comes from an identifiable source and scatters when reflected. The component of an OpenGL light source used to simulate that effect.
Flat surface	A surface with enough roughness to scatter most light it reflects, producing a dull, non-glossy appearance. A surface that is not shiny.
Material properties	Characteristics of a surface that affect its appearance.
Shiny surface	A mirror-like surface. A surface that is smooth enough that much of the light it reflects is not scattered, giving a glossy appearance. Such a surface may be characterized by a specular highlight under a suitable light source.
Specular highlight	A bright spot that appears on a smooth, shiny surface under a strong light source.
Specular light	The component of an OpenGL light source used to determine the color and intensity of a specular highlight.
Spotlight	A light source with both position and direction. The space illuminated by the source is shaped like a cone. The cone is defined by an angle from the “aim” direction of the light.

## **IDENTIFIER REFERENCE**

### **Identifier**

glColorMaterial

### **Description**

An OpenGL command that causes material properties to track the current color set by glColor. It takes two parameters. The first tells which face or faces will be affected. The second tells which properties will track the current color. You must enable color tracking for this to work.

glLight

An OpenGL command that defines characteristics of an OpenGL light source. You must enable lighting and enable the specific light.

glLightModel

An OpenGL command that provides a simplified method of setting up a lighting environment instead of defining specific lights.

glMaterial

An OpenGL command for defining material properties.

GL\_AMBIENT

An OpenGL constant specifying the ambient portion of light or material properties in various OpenGL commands.

GL\_BACK

An OpenGL constant specifying the back face of polygons to be affected in various OpenGL commands.

GL\_COLOR\_MATERIAL

The OpenGL constant to pass to enable or disable color tracking.

GL_DIFFUSE	An OpenGL constant specifying the diffuse portion of light or material properties in various OpenGL commands.
GL_EMISSION	An OpenGL constant to pass to the glMaterial command, so that the affected surfaces appear to be glowing.
GL_FRONT	An OpenGL constant specifying the front face of polygons to be affected in various OpenGL commands.
GL_FRONT_AND_BACK	An OpenGL constant specifying both the front and back faces of polygons to be affected in various OpenGL commands.
GL_LIGHT0 .. GL_LIGHT7	OpenGL constants for specifying specific OpenGL light sources.
GL_LIGHTING	An OpenGL constant to pass to glEnable or glDisable to turn on or turn off lighting calculations.
GL_LIGHT_MODEL_AMBIENT	An OpenGL constant to pass to glLightModel to specify global ambient light.
GL_SPECULAR	An OpenGL constant specifying the specular portion of light or material properties in various OpenGL commands.
GL_SPOT_CUTOFF	An OpenGL constant to pass to glLight to specify the angle that defines the cone of illumination from a spotlight.
Packed	An Object Pascal reserved word used to make a data structure take the minimum amount of memory. The elements of the structure fit together with no unused memory between them because the compiler does not attempt to align the data elements on word or double-word boundaries.
PGLfloat	A data type which is a pointer to a GLfloat.

## SUMMARY

Chapter 5 presented new levels of realism with lighting. Here are the high points:

1. Use glEnable(GL\_LIGHTING) to inform OpenGL that you will take responsibility for lighting specification.
2. OpenGL allows at least eight separate light sources.
3. All light has a source. Each light source has three components whose color compositions can be separately identified:
  - a. Ambient light seems to come from all directions.
  - b. Diffuse light comes from a specific direction and scatters upon

reflection, giving a soft, flat appearance to surfaces.

c. Specular light reflects sharply and appears as a specular highlight on smooth surfaces.

4. Specify the color response of a surface to each light component with the `glMaterial` commands.

5. Emission is also a material property for OpenGL.

6. In addition to the color response to specular light, you must also specify the smoothness or shininess of the surface with the `GL_SHININESS` constant in the `glMateriali` command.

# Database Application Developer's Guide

## Delphi for Windows

### Chapter 1 Introduction

#### Copyright Agreement

Delphi enables you to create robust database applications quickly and easily. Delphi database applications can work directly with desktop databases like Paradox, dBASE, the Local InterBase Server, and ODBC data sources. The Delphi Client/Server edition also works with remote database servers such as Oracle, Sybase, Microsoft SQL Server, Informix, InterBase, and ODBC data sources. Delphi client applications can be scaled easily between mission critical network-based client/server databases, and local databases on a single machine.

This chapter introduces Delphi's database tools, including the Data Access and Data Controls component pages, the Fields Editor, the Database Desktop, and the Database Forms Expert.

### What you should know first

Building a database application is similar to building any other Delphi application. This book assumes you understand the basic application development techniques covered in the *Delphi User's Guide*, including:

- Creating and managing *projects*
- Creating *forms* and managing *units*
- Working with *components, properties, and events*
- Writing simple Object Pascal source code

You also need to have a working knowledge of the Database Management System (DBMS) your Delphi database applications access, whether it is a desktop database such as dBASE or Paradox, or an SQL server. For information specific to building client/server applications with Delphi, see Chapter 6, "Building a client/server application."

This book assumes you have a basic understanding of relational databases, database design, and data management. There are many third-party books covering these topics if you need to learn more about them.

# Overview of Delphi's database features and capabilities

A Delphi database application is built using Delphi database development tools, Delphi data-access components, and data-aware GUI components. A database application uses Delphi components to communicate with the Borland Database Engine (BDE), which in turn communicates with databases. The following figure illustrates the relationship of Delphi tools and Delphi database applications to the BDE and data sources:

**Figure 1.1** Delphi database architecture

The following table summarizes Delphi's database features.

**Table 1.1** Database features summary

Tool	Purpose
Data Access components	Access databases, tables, stored procedures, and custom component editors.
Data Control components	Provide user interface to database tables.
Database Desktop (DBD)	Create, index, and query Paradox and dBASE tables, and SQL databases. Access and edit data from all sources.

**Table 1.1** Database features summary (continued)

Tool	Purpose
ReportSmith	Create, view, and print reports.
Borland Database Engine (BDE)	Access data from file-based Paradox and dBASE tables, and from local InterBase server databases.
BDE Configuration Utility	Create and manage database connection Aliases used by the BDE.
Local InterBase Server	Provides a single-user, multi-instance desktop SQL server for building and testing Delphi applications, before scaling them up to a production database, such as Oracle, Sybase, Informix, or InterBase on a remote server.
InterBase SQL Link	Native driver that connect Delphi applications to the Local InterBase Server.

These features enable you to build database applications with live connections to Paradox and dBASE tables, and the Local InterBase Server through the BDE. In many cases, you can create simple data access applications with these components and their properties without writing a line of code.

The BDE is built into Delphi components so you can create database applications without needing to know anything about the BDE. The Delphi installation program installs drivers and sets up configuration for Paradox, dBASE, and the Local InterBase Server, so you can begin working with tables native to these systems immediately. The BDE Configuration Utility enables you to tailor database connections and manage database aliases.

Advanced BDE features are available to programmers who need more functionality. These features include local SQL, which is a subset of the industry-standard SQL that enables you to issue SQL statements against Paradox and dBASE tables; low-level API function calls for direct engine access; and ODBC support for communication with other ODBC-compliant databases, such as Access and Btrieve.

Delphi includes Borland ReportSmith, so you can embed database report creation, viewing, and printing capabilities in Delphi database applications. Delphi also includes the Database Desktop (DBD), a tool that enables you to create, index, and query desktop and SQL databases, and to copy data from one source to another. For more information about ReportSmith, see *Creating Reports*. For more information about the DBD, see Appendix A, "Using Database Desktop."

The Local InterBase Server is a single-user, multi-instance, 16-bit, ANSI SQL-compliant, Windows-based version of Borland's 32-bit InterBase SQL server that is available for Novell NetWare, Windows NT, and Unix. For more information, see the *Local InterBase Server User's Guide*.

The following table lists the additional database features available in the Client/server edition of Delphi. These features extend Delphi's database capabilities to access remote

SQL database servers such as Sybase, Microsoft SQL Server, Oracle, Informix, and InterBase.

**Table 1.2** Additional Delphi Client/Server database features

Tool	Purpose
SQL Drivers	Both SQL Links and ReportSmith provide native drivers that connect Delphi database applications to remote SQL database servers, such as Oracle, Sybase, Microsoft SQL Server, Informix, and InterBase.
Visual Query Builder	Creates SQL statements by visually manipulating tables and columns.

SQL Links provide Delphi applications with SQL access to data residing on remote servers, including Sybase, Microsoft SQL Server, Oracle, and Informix. When an SQL Link driver is installed, SQL statements are passed directly to the server for parsing and execution. For more information about using passthrough SQL, see Chapter 5, "Using SQL in applications."

## What is a database?

Delphi programmers should understand some basic concepts about databases, data, and data access, before building database applications. A database consists of one or more tables, where each table contains a series of columns into which records (also called "rows") are stored. Each record is identical in structure. For example, a database of addresses consists of a table with name, street address, city, state, and zipcode columns. The intersection of a single column and row is referred to as a field. Fields contain values. The following figure illustrates these concepts:

**Figure 1.2** Structure of a table

The current *field* is one field in a single record. The current *record* is a single record in a multi-record set that is the focus of attention. For example, some Delphi database applications display multiple columns and records in a grid format for editing. As far as Delphi controls are concerned, only one field in a single record is "current," meaning that editing tasks affect only the data in that field.

Different databases vary widely in structure. A database in Paradox consists of one or more files, each of which contains a single table or index, but an SQL relational database on a remote server generally consists of a single file that contains all tables, indices, and

other database structures. Delphi's Data Access and Data Control components encapsulate the underlying structure of the databases your application uses, so that your application can present the same interface to an end user whether it accesses a local Paradox file or a database on a remote SQL server.

The information in most databases is constantly changing. When you access a networked database from a Delphi application, many users may be accessing and updating the database at the same time. When any database application accesses a database, whether to process a query or generate a report, the application receives a snapshot of the database as it was at the time the application accessed the database. An application's view of data may differ from the data currently in the database, so database applications should always be robust enough to react to such data changes. For more information about building client/server applications that access remote data, see Chapter 6, "Building a client/server application."

## What is data?

---

In this book, "data" refers to information stored in a database. Data may be a single item in a field, a record that consists of a series of fields, or a set of records. Delphi applications can retrieve, add, modify, or delete data in a database.

## What is data access?

---

Delphi applications can access data from desktop database tables on a file server or local disk drive and from remote database servers. To access a data source, a Delphi application uses Data Access components to establish a connection through the BDE. The installation program for Delphi installs drivers and sets up configurations for Paradox, dBASE, and the Local InterBase Server so you can begin working with tables native to these systems immediately.

To connect to another data source requires the installation of a driver for that specific database and subsequent configuration of the BDE to recognize the driver. Connecting to remote database servers requires the Client/Server edition of Delphi that includes SQL Links to access to Sybase, Microsoft SQL Server, Oracle, Informix, and InterBase on NT, NetWare, and Unix servers. For more information about installing and configuring the SQL Link drivers, see the *SQL Links User's Guide*.

The BDE uses *aliases* as convenient shorthand names for often-used data sources, whether local or remote. The BDE Configuration Utility enables you to define and modify aliases that Delphi applications can use immediately. For more information about defining aliases, see Appendix B, "Using the BDE configuration utility."

Once drivers are installed and network connections established, Delphi applications can access data from any authorized server. The examples in Chapter 2 demonstrate techniques for accessing data from a database—specifically, sample data tables that are shipped and installed as part of the Delphi package. Although the example project in the next chapter deals with local desktop data, the techniques for accessing remote data are essentially the same, as subsequent chapters demonstrate.

**Note** An SQL version of the example project is provided in the DEMOS directory.

## Data sources

---

Delphi database applications get their data through the BDE. The different data sources (not to be confused with the *TDataSource* component) that the BDE can use are shown in Table 1.3.

**Table 1.3** Delphi data sources

Data source	Description	File extension
Paradox	Tables created with Paradox or Database Desktop. Each table is in a separate file.	.DB
dBASE	Tables created with dBASE or Database Desktop. Each table is in a separate file.	.DBF
ASCII files	Tables created with Database Desktop. Each table is in a separate file.	.TXT
Local InterBase Server	Database created with InterBase Windows ISQL. Multiple tables in a single database file.	.GDB
SQL Database Server: Oracle, Sybase, Microsoft SQL Server, Informix, InterBase	Database created with server-specific tools, or the DBD, accessed across network with SQL Links. Delphi Client/Server Edition only.	Depends on server
ODBC data sources	Databases such as Microsoft Access, Btrieve, FoxPro, etc.	Depends on data source

---

## Understanding Delphi database architecture

---

Delphi uses object-oriented components to create database applications, just as it does with non-database applications. Like standard components, database components have attributes, or *properties*, that are set by the programmer at design time. These properties can also be set programmatically at run time.

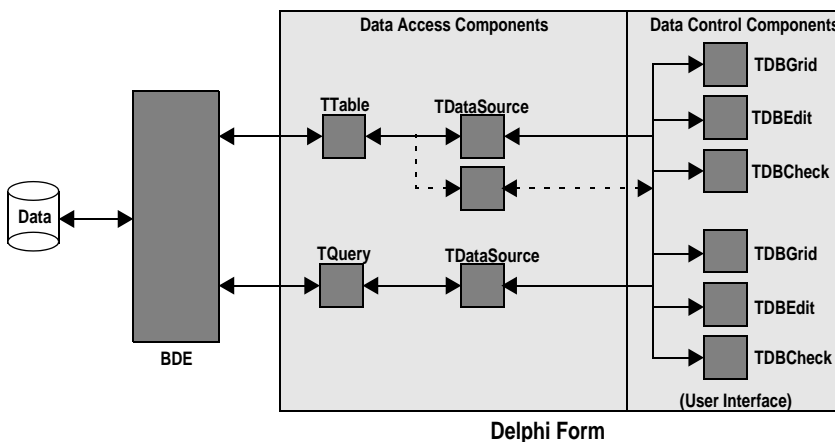

Database components have default behavior that enables them to perform useful functions with little or no programming. The Delphi Component palette provides two database component pages:

- The *Data Access page* contains Delphi objects that simplify database access by encapsulating database source information, such as the database to connect to, the tables in that database to access, and specific field references within those tables. Examples of the most frequently used data access objects include *TTable*, *TQuery*, *TDataSource*, and *TReport*.
- The *Data Controls page* contains data-aware user interface components for displaying database information in forms. Data Control components are like standard user interface components, except that their contents can be derived from or passed to database tables. Examples of the most frequently used data control components include *TDBEdit*, *TDBNavigator*, and *TDBGrid*.

Datasets, such as *TTable*, *TQuery*, and *TStoredProc* components, are not visible at run time, but provide applications their connection to data through the BDE. Data Control components are attached to dataset components by a *TDataSource* component, to provide a visual interface to data.

The following figure illustrates how Data Access and Data Control components relate to data, to one another, and to the user interface in a Delphi database application:

**Figure 1.3** Database components architecture

As this figure illustrates, a form usually contains at least three database components: a dataset component (*TTable* and *TQuery* in the figure) that communicates with the BDE; a *TDataSource* component that acts as a conduit between a dataset component and the user interface; and one or more data control components, such as *TDBEdit* or *TDBGrid*, that enable a user to browse, edit, or enter data.

## Overview of the Data Access page

The Data Access page of the Delphi Component palette provides a set of database encapsulation objects that simplify database access.

**Figure 1.4** Data Access page of the Component palette

When building a database application, you place data access components on a form, then assign them properties that specify the database, table, and records to access. They provide the connection between a data source and Data Control components.

At run time, after an application is built and compiled, data access objects are not visible, but are “under the hood,” where they manage data access.

The following table lists the data access objects on the Data Access page, and briefly describes how they are used:

**Table 1.4** Data Access components

Component	Purpose
TDataSource	Acts as a conduit between a TTable, TQuery, TStoredProc component and data-aware components, such as TDBGrid.
TTable	Retrieves data from a database table via the BDE and supplies it to one or more data-aware components through a TDataSource component. Sends data received from a component to a database via the BDE.
TQuery	Uses SQL statements to retrieve data from a database table via the BDE and supplies it to one or more data-aware components through a TDataSource component, or uses SQL statements to send data from a component to a database via the BDE.
TStoredProc	Enables an application to access server stored procedures. Sends data received from a component to a database via the BDE.
TDatabase	Sets up a persistent connection to a database, especially a remote database requiring a user login and password.
TBatchMove	Copies a table structure or its data. Can be used to move entire tables from one database format to another.
TReport	Enables printing and viewing of database reports through ReportSmith.

Four data access components deserve special mention. Most forms provide a link to a database with a TTable or TQuery component (or through a user-defined component based on the normally hidden abstract class, TDataSet, of which TTable and TQuery are descendents). Other forms provide a link to a database with TStoredProc, also a descendent of TDataSet. In turn, all forms must provide a TDataSource component to link a TTable, TQuery, or TStoredProc component to data control components that provide the visible user interface to the data.

TTable, TQuery, (and TStoredProc, when it returns a result set) contain a collection of TField components. Each TField corresponds to a column or field in the table or query. TFields are created

- Automatically, when TTable, TQuery, or TStoredProc are activated.
- At design time, using the Fields editor.

For more information about TFields and the Fields editor, see Chapter 3, “Using data access components and tools.” For more information about TStoredProc, see Chapter 6, “Building a client/server application.”

## Understanding TTable

The TTable component is the easiest way for a programmer to specify a database table for access. To put a TTable component on a form:

- 1 Select the Data Access page from the Component palette.
- 2 Click the Table icon.
- 3 Click on the form to drop the TTable component.
- 4 Enter the directory where the database resides in the DatabaseName property of the Object Inspector window. For SQL databases, enter an alias name.

**Note** An alias can also be used for local Paradox and dBASE tables. You can choose an alias from a drop-down list in the Object Inspector.

- 5 Enter the name of the table to use in the *TableName* property of the Object Inspector window, or you can also choose a table from the drop-down list instead of entering the name.

By default, a *TTable* component accesses every column in a table when you activate it. When a visual component, such as *TDBEdit*, is associated with a *TTable* object, it can display any field in the table. Multi-column visual components, such as *TDBGrid*, access and display columns in the table using the table's *TField* list.

If you double-click a *TTable* component on a form, you invoke the Fields Editor. The Fields Editor enables you to control the way Data Control components display data. It can

- Create a static model of a table's columns, column order, and column type that does not change even if changes are made to the underlying physical table in the database.
- Provide convenient, readable, and efficient component names for programmatic access.
- Specify the order in which fields are displayed and which fields to include.
- Specify all display characteristics of fields.
- Add custom validation code.
- Create new fields for display, including calculated fields.

For complete information about the Fields Editor, see Chapter 3, "Using data access components and tools."

## Understanding TQuery

The *TQuery* component provides a tool for data access using SQL statements, such as a SELECT statement, to specify a set of records and a subset of columns from a table. *TQuery* is useful for building local SQL queries against Paradox and dBASE data, and for building client/server applications that run against SQL servers.

To put a *TQuery* component on a form:

- 1 Select the Data Access page from the Component palette.
- 2 Choose the Query icon.
- 3 Click on the form to drop the *TQuery* component.
- 4 Enter the directory where the database resides (or select an alias for SQL databases) in the *DatabaseName* property of the Object Inspector window.
- 5 Enter the SQL statement to use for data access in the SQL property of the Object Inspector window by clicking the list button to open the String Editor.

The Object Inspector window for *TQuery* does not contain a separate property for specifying a table name. Instead, a table name must always be specified as part of the SQL statement in the SQL property.

With Delphi Client/Server, you can right-click a *TQuery* component on a form, then select the Visual Query Builder from the pop-up menu. The Visual Query Builder enables you to connect to a database and build an SQL statement interactively. For complete information about the Visual Query Builder, see the online Help.

If you double-click a *TQuery* component, you invoke the Fields Editor. The Fields Editor enables you to control the way Data Control components display data. For complete information on *TQuery* and the Fields Editor, see Chapter 3, “Using data access components and tools.”

## Understanding TDataSource

Every dataset that supplies a data control component must have at least one *TDataSource* component. *TDataSource* acts as a bridge between one *TTable*, *TQuery*, or *TStoredProc* component and one or more data control components that provide a visible user interface to data.

*TTable* and *TQuery* can establish connections to a database through the BDE, but they cannot display database information on a form. Data Control components provide the visible user interface to data, but are unaware of the structure of the table from which they receive (and to which they send) data. A *TDataSource* component bridges the gap.

To put a *TDataSource* component on a form:

- 1 Select the Data Access page from the Component palette.
- 2 Choose the DataSource icon.
- 3 Click on the form to create the *TDataSource* component.
- 4 Enter the name of the *TTable* or *TQuery* component to use as a database connection source in the DataSet property of the Object Inspector. If the form contains any *TTable* or *TQuery* components, you can choose a component from the drop-down list instead.

**Note** *TDataSource* is also used to link tables or queries in a master/detail form. For more information about master/detail forms, see Chapter 2, “Building a sample database application: MASTAPP.”

## Overview of the Data Controls page

---

The Data Controls page provides a set of data-aware user-interface components that you can use to create forms-based database applications.

**Figure 1.5** The Data Controls page of the Component palette

Many data controls are data-aware versions of component classes available on the Standard page of the Component palette. In addition to standard component functionality, data controls can display data from a field in a database table, or send new or modified data from a form to a database table.

The following table lists the data controls on the Data Control page.

**Table 1.5** Data Controls components

Component	Purpose
TDBNavigator	Data-aware navigation buttons that move a table's current record pointer forward or backward; start Insert or Edit mode; post new or modified records; cancel Edit mode; and refresh display to retrieve updated data.
TDBText	Data-aware label that can display a field from a currently active record.
TDBEdit	Data-aware edit box that can display or edit a field from a currently active record.
TDBCheckBox	Data-aware check box that can display or edit a Boolean data field from a currently active record.
TDBListBox	Data-aware list box that can display values from a column in a table.
TDBComboBox	Data-aware combo box that can display or edit values from a column in a table.
TDBRadioGroup	Data-aware radio group populated with radio buttons that can display or set column values.
TDBGrid	Data-aware custom grid that enables viewing and editing data in a tabular form similar to a spreadsheet; makes extensive use of <i>TField</i> properties (set in the Fields Editor) to determine a column's visibility, display format, ordering, etc.
TDBMemo	Data-aware memo box that can display or edit text BLOB data from a currently active record.
TDBImage	Data-aware image box that can display, cut, or paste bitmapped BLOB images to and from a currently active record.
TDBLookupList	Data-aware list box that displays values mapped through another table at run time.
TDBLookupCombo	Data-aware combo box that displays values mapped through another table at run time.

Data control components make up a consistent visual user interface for Delphi database applications, whether the application accesses a local database file, or a remote database server. To see how data control components are used in an application, see the subsequent chapters of this book. For a complete description of each data control component and its properties, see the online VCL Reference.

## Overview of the Database Forms Expert

The Database Forms Expert automates many of the tasks necessary for creating data-entry or tabular forms from an existing database table. It can generate simple or master/detail forms using *TTable* or *TQuery* components. The Database Forms Expert automates such form building tasks as:

- Placing database components on a form.
- Connecting *TDataSet* components (e.g., *TTable* and *TQuery*) to a database.
- Connecting *TDataSource* components to interactive data control components and *TTable* or *TQuery* data access objects.
- Writing SQL statements for *TQuery* objects.
- Defining a tab order for components.

Inexperienced database applications programmers can use the Database Forms Expert to learn how to build database forms. Experienced database applications programmers can use it to speed application development. To learn how to use the Database Forms Expert when building an application, see Chapter 2, “Building a sample database application: MASTAPP.”

## Overview of the Database Desktop

---

The Database Desktop (DBD) is a database maintenance and data definition tool. It enables programmers to query, create, restructure, index, modify, and copy database tables, including Paradox and dBASE files, and SQL tables. You do not have to own Paradox or dBASE to use the DBD with desktop files in these formats.

The DBD can copy data and data dictionary information from one format to another. For example, you can copy a Paradox table to an existing database on a remote SQL server. For a complete description of the DBD, see Appendix A, “Using Database Desktop.”

## Developing applications for desktop and remote servers

---

Delphi Client/Server enables programmers to develop and deploy database client applications for both desktop and remote servers. One of Delphi’s strengths is the ease with which an application developed for the desktop can be adapted to access data on a remote SQL server. The user interface need not change even if the source of the data changes. To an end user, a Delphi database application looks the same whether it accesses a local database file or a remote SQL database.

For simple applications that use *TQuery* components to access desktop data, the transition to a remote server may be as simple as changing the data source. For other applications, more significant changes may be in order. Some of these changes are the result of differing conventions and concurrency issues between desktop and SQL databases.

For example, desktop databases like Paradox and dBASE are record-oriented. They always display records in ascending or descending alphabetic or numeric order. They lock and access a single record at a time. Each time a user changes a record, the changes are immediately written to the database. Desktop database users can see a range of records, and can efficiently navigate forward and backward through that range.

In contrast, data in SQL databases is set-oriented, and designed for simultaneous multiuser access. Record ordering must be specified as part of an SQL query. To accommodate multiuser access to data, SQL relies on transactions to govern access. For more information about working with transactions, see Chapter 6, “Building a client/server application.”

# Database application development methodology

---

Developing database applications with Delphi is similar to developing other types of software, but there are important distinctions and challenges that must be addressed. The methodology presented in this section should be used as a guideline that you can adapt to meet your specific business needs.

## Development scenarios

---

Since an application's design usually depends on the structure of the database it will access, the database must be defined before the application can be developed.

**Note** Database development (also called *data definition*) is a part of the overall development process, but is beyond the scope of this manual. For more information, refer to the numerous books about relational database design.

There are four possible scenarios for Delphi database application development:

- The database does not yet exist or must be re-defined.
  - Use the Database Desktop utility to define Paradox and dBASE tables. For more information, see Appendix A, "Using Database Desktop."
  - For SQL servers, use the tools provided with the server or the Database Desktop. For example, for the Local InterBase Server or an InterBase Workgroup Server, use Windows ISQL. For more information, see the *Local InterBase Server User's Guide* and the *InterBase Data Definition Guide*.
- The database exists on a desktop or LAN data source (Paradox or dBASE) and the database will access it there. If the BDE and the data source are on the same machine as the application, then the application is a standalone (not client/server) application.
- The database exists on a desktop data source, and is being upsized to an SQL server. This scenario is discussed in Appendix C, "Using local SQL."
- The database exists on an SQL server and the application will access it there. This is a standard client/server application. For information specific to developing a client/server application, Chapter 6, "Building a client/server application."

## Database application development cycle

---

The goal of database application development is to build a product which meets end users' long-term needs. While this goal may seem obvious, it is important not to lose sight of it throughout the complexities and often conflicting demands of the development process. To create a successful application it is critical to define the end users' needs in detail early in the development process.

The three primary stages of database application development are

- Design and prototyping
- Implementation
- Deployment and maintenance

There are database and application tasks in each of these phases. Depending on the size and scope of the development project, the database and application tasks may be performed by different individuals or by the same individual. Often, one team or individual will be responsible for the database tasks of the project, and another team or individual will be responsible for the application tasks.

**Figure 1.6** Development cycle

For client/server applications, the database and application tasks become more distinct, since they run on different platforms, often with different operating systems (for example, a Unix server and Windows 3.1 client).

When development responsibilities are thus divided it is important to clearly delineate in the design phase which functions will be performed by the database server and which will be performed by the client application. Usually, the functional lines are clear cut. But database processes such as stored procedures can sometimes perform functions that can also be performed by the client application. Depending on the expected deployment configuration, application requirements, and other considerations, the design can allocate such functions to either client or server.

It is also important to realize that database application development is by its nature an iterative process. Users may not fully understand their own needs, or may define additional needs as development proceeds. User interface elements are always refined as they are used. Also, changing business needs will change requirements over time. Generally, a number of iterations through the development cycle will be required before an application can meet a significant portion of its requirements.

## Design phase

The design phase begins with requirements definition. In consultation with knowledgeable end users, define the functional specifications for the database and applications. Determine which aspects of the functional requirements will be implemented in the database design, and which aspects will be implemented in the applications.

For client/server applications, often certain functions can be performed either by the server or by the application; for example, a complex mathematical transform function could be performed either by the client application or by a stored procedure on the server. The hardware deployment configuration will generally determine whether such

functions are best performed on the server or client. For example, if the client platforms are expected to be low-end desktop PCs, and the server platform is expected to be a high-end workstation, then it will probably be best to run computation-intensive functions on the server. If the hardware configuration changes, then it is possible to move the function between client and server in a later iteration.

## Implementation phase

In the implementation phase, you use Delphi to build and test the application conceived in the design phase. During the implementation phase, you should use a duplicate data source, that is, a data source that has the same essential structure as the production database, but with a small subset of representative data. It is not recommended to develop an application against a production database, since the untested application may corrupt the data or otherwise interfere with normal database activities.

If your application will ultimately be deployed to use a desktop data source, make copies of the required tables with the Database Desktop, and populate them with representative “dummy” data.

If the application will ultimately be deployed to use a remote data source (an SQL server), then you can take two approaches during the implementation phase:

- Develop and test the application against a non-production database on the Local InterBase Server.
- Develop and test the application against a non-production database on the server.

The first approach has the advantage that is isolated on the development platform(s), and so will not interfere with other server activities. It will not consume server resources or increase network traffic. Its primary disadvantage is that only standard SQL server features can be used and tested during this phase, if you are using a server other than InterBase for the deployed application.

The second approach enables you to surface all server-specific features, but will consume network and server resources during testing. This approach can be dangerous, since it is conceivable that a programmer error could cause a server to crash during testing.

## Deployment phase

In the deployment phase, the client/server application is put to the acid test: it is handed over to end users. To ensure that the application’s basic functionality is error-free, deploy a prototype application before attempting to deploy a production application.

Since the ultimate judges of an application’s efficacy are its users, developers must be prepared to incorporate changes to applications arising from their suggestions, changing business needs, and for general enhancement (for example, for usability). Sometimes application changes may require changes to the database, and conversely, changes to the database may require application changes. For this reason, application developers and database developers should work together closely during this phase. As features and enhancements are incorporated into the application, the application moves iteratively closer to completion.

Deploying a client/server application requires addressing a number of special issues, including connectivity and multiuser access. These issues are discussed in Chapter 6, “Building a client/server application.”

## Deploying an application

---

Deploying an application means giving it to the end users, and providing the necessary software they need to use the application in a production environment. Non-database applications require only an .EXE file to run—Delphi applications do not require a run time interpreter or DLL.

Typically, when deploying a database application, you will create a package that includes all the files that end users need to run the application and access data sources. These files include

- The application .EXE file and .DLL files (if any)
- Required ancillary files (for example, a README file or .HLP files for online help)
- BDE support for database access (desktop or server)
- ReportSmith Runtime for running and printing reports
- If the application uses VBX controls, include each VBX along with BIVBX11.DLL

If you are distributing the files on disks, you will generally want to compress them with a standard file compression utility, and provide the utility on the disk. You may also want to build a simple installation application to install the files for your users. For complex applications, you may want to use one of the many commercially-available installation programs.

**Important** Before distributing any files, ensure that you have the proper redistribution rights. As described in the Delphi license agreement, Delphi provides distribution rights for the BDE (including Paradox and dBASE support). Delphi Client/Server includes distribution rights for Borland SQL Links for Windows. Licenses for distribution of the Local InterBase Server are available from Borland.

For information on deploying support for remote server access, see Chapter 6, “Building a client/server application.” For client/server applications, you also must ensure that the necessary communications software (for example, TCP/IP interface) is installed on the client platforms. This software is provided with databases servers. For more information, see your server documentation.

## Deploying BDE support

---

When you deploy a database application, you must ensure that the client platform has the correct version of the BDE installed. Delphi includes Redistributable BDE, with its own installation utility, that can you can redistribute with your applications. When you deploy an application, simply include a copy of the Redistributable BDE disk.

The Delphi license agreement requires you to make *all* the files in Redistributable BDE available to your application users. This requirement enables users to install the new version of the BDE for Delphi without interfering with existing Paradox and dBASE applications. You can advise your users to save disk space and install only the drivers

required to run your application, but you must still distribute all the files in the Redistributable BDE.

For example, if your application needs access only to Paradox files, you can advise your users not to deploy the dBASE driver. The minimum BDE configuration for accessing a Paradox database requires about 500 Kbytes.

**Note** For more information on deployment, refer to the file DEPLOY.TXT installed to the DELPHI\DOC directory by default.

**Table 1.6** Redistributable Borland Database Engine files

File name	Description
IDAPI01.DLL	BDE API DLL
IDBAT01.DLL	BDE Batch Utilities DLL
IDQRY01.DLL	BDE Query DLL
IDASCI01.DLL	BDE ASCII Driver DLL
IDPDX01.DLL	BDE Paradox Driver DLL
IDDBAS01.DLL	BDE dBASE Driver DLL
IDR10009.DLL	BDE Resources DLL
ILD01.DLL	Language Driver DLL
IDODBC01.DLL	BDE ODBC Socket DLL
ODBC.NEW	Microsoft ODBC Driver Manager DLL, version 2.0
ODBCINST.NEW	Microsoft ODBC Driver installation DLL, version 2.0
TUTILITY.DLL	BDE Tutility DLL
BDECFG.EXE	BDE Configuration Utility
BDECFG.HLP	BDE Configuration Utility Help
IDAPI.CFG	BDE (IDAPI) Configuration File

## Language drivers

The BDE provides the ability to localize applications with language drivers. The language driver DLL loads the drivers specified by Paradox or dBASE tables or in IDAPI.CFG for server databases. The language drivers are files with extension .LD installed to the LANGDRV sub-directory of the BDE directory.

**Important** For language drivers to load correctly, the WIN.INI file must have the following entry, assuming the default installation directory:

```
[Borland Language Drivers]
LDPath = C:\DELPHI\IDAPI\LANGDRV
```

## ODBC Socket

The BDE comes with an ODBC Socket. It has been certified with Microsoft's 2.0 ODBC Driver Manager. If you have a different version of the ODBC Driver Manager:

- Back up your existing ODBC.DLL and ODBCINST.DLL
- Copy the version 2.0 files, ODBC.NEW and ODBCINST.NEW, from your BDE directory to your WINDOWS\SYSTEM directory.
- Rename these files to ODBC.DLL and ODBCINST.DLL.

**Note** The ODBC 2.0 Driver Manager does work with ODBC 1.x ODBC drivers.

# Building a sample database application: MASTAPP

This chapter is a tutorial and introduction to building Delphi database applications. Examples show how to perform database tasks using Delphi interactively and by programming in Object Pascal. In each example you build a single form, self-contained and independent of the others. You can save yourself some work by doing the examples in sequence. Several examples use the same basic form as a starting point.

**Note** This material assumes you know how to use Delphi; it tells you *what* to do to perform certain tasks. For more details (that is, to find out *why*), follow the cross-references in the “For more information” section that follows each example. In particular, see Chapter 3, “Using data access components and tools.”

The tutorial consists of the following sections:

- “Building forms” describes how to use the Database Form Expert to create database forms, including single-table and master-detail forms. It also describes how to enhance forms by adding components and code by hand.
- “Working with fields” describes how to read and write field values, how to search for values and do table lookups, and how to format data displayed to the user. It also describes how to work with calculated fields.
- “Using queries and ranges” describes how to use SQL queries and set ranges to select a subset of the data in one or more tables.
- “Printing reports and forms” describes how to print ReportSmith reports and Delphi forms.

## Building forms

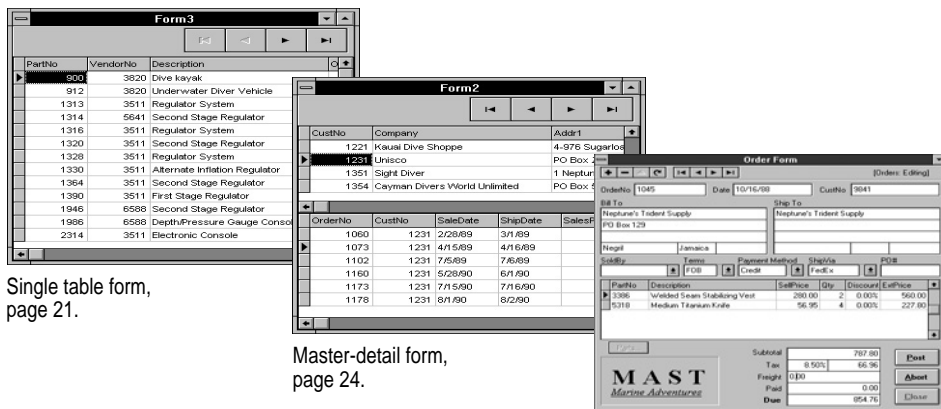

---

The material in this section focuses on database issues. To learn about general application building with Delphi, see the *User’s Guide*. The forms described here are the

basis for a database application called MASTAPP, designed to meet the record-keeping needs of the fictitious Marine Adventures & Sunken Treasures company (MAST). MAST sells diving equipment and arranges diving expeditions. MASTAPP tracks information about customers, orders, inventory, and vendors.

The tutorial starts with a simple “codeless” form for viewing and editing table data, and works up to a full-featured invoice form containing several tables, data-aware components, and other advanced Delphi features. All the forms, tables, and related files are installed by default in C:\DELPHI\DEMOS\DB\MASTAPP. During a default installation of Delphi, an alias, DBDEMOS, that points to the MASTAPP directory is created for you, or you can create your own alias using the BDE configuration utility (see Appendix B). The following figure shows the forms and tells where they are described in this chapter:

**Figure 2.1** Database forms described in the tutorial

Single table form,  
page 21.

Master-detail form,  
page 24.

One-many-many form,  
page 27.

**Note** For general information about building Delphi forms, see the *User's Guide*.

## MASTAPP aliases

All *TTable* and *TQuery* components used in example code in this chapter set their *DatabaseName* property to DBDEMOS. In contrast, the complete demo in the MASTAPP directory does the following to facilitate porting:

- 1 The main form (MAIN.PAS) has a *TDatabase* component with its *AliasName* property set to DBDEMOS and *DatabaseName* property set to MAST.
- 2 All datasets on all forms have their *Database* properties set to MAST. Now all forms can use a different BDE alias simply by changing the main form's *TDatabase* component's *AliasName* property.

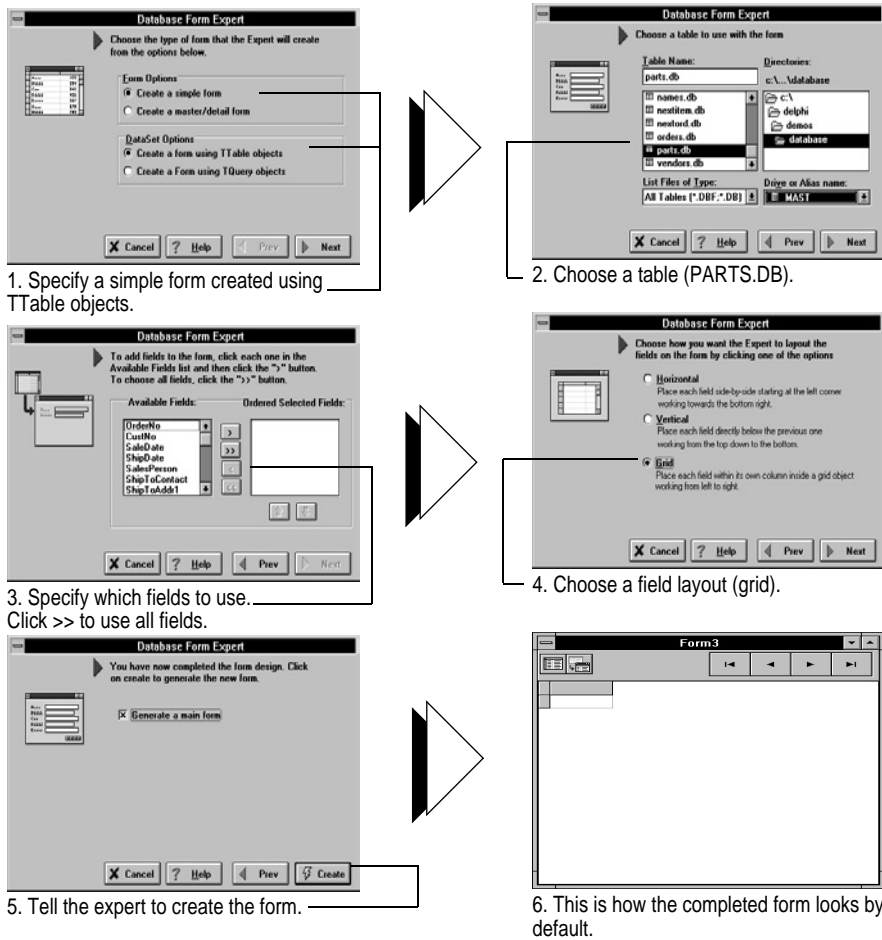

# Building a single-table form

The steps in this section show how to use the Database Form Expert to build a single-table form. Of course, anything the expert does, you can do by hand, but the expert saves a lot of time.

## What to do

- 1 Choose Help | Database Form Expert to open the Form Expert.
- 2 Specify a table, fields, and field layout as shown in the following figure. The Form Expert creates the form.
- 3 Press *F9* to run the form. Click the navigator control buttons to move through the records in the table.

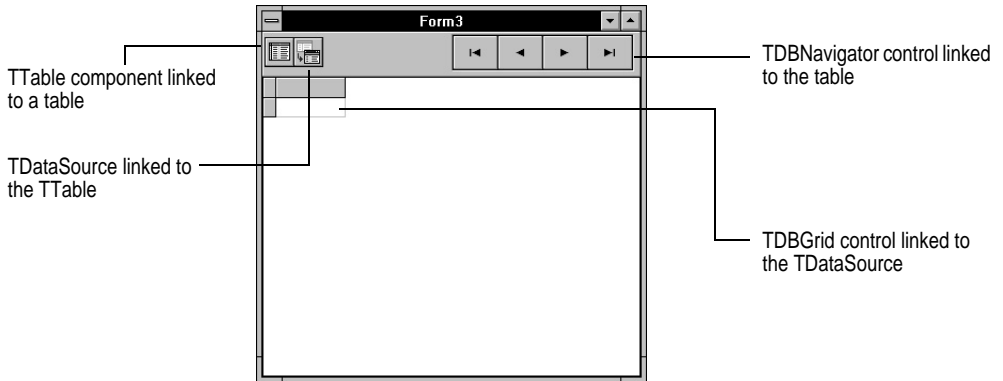

**Figure 2.2** Building a single-table form using the Database Form Expert

## How it works

The Database Form Expert builds a single-table form to match your specifications, and adds a tool bar of navigation controls. The form shown in the following figure is the basis for the full-featured BRPARTS.DFM form in the MASTAPP application. The important relationships in a data-aware form like this one are the links between the underlying data, the nonvisual components, and the data controls that display data to the user.

**Figure 2.3** A single-table form

The form contains one *TTable* component. The expert links it to the *Parts* table by setting the properties listed in the following table. A *TTable* component establishes a connection to a table in a database.

**Table 2.1** Important *TTable* properties for a single-table form

Property	Value	Remarks
<i>Active</i>	False	When <i>Active</i> is False, data-aware controls do not display data at design time. To make controls display data at design time, set <i>Active</i> to True.
<i>DataBaseName</i>	MAST	MAST is an alias that points to where the table resides. Use aliases, not hard-coded paths, to make applications portable and easy to upsize.
<i>Name</i>	Form1	Use the Object Inspector to change names.
<i>TableName</i>	PARTS.DB	Tells the component which table to link to.

The form contains one *TDataSource* component. The expert links it to the *TTable* component by setting the properties listed in the following table. A *TDataSource* component acts as a bridge between one dataset component (*TTable* in this case) and one or more data-aware controls that provide a visible interface to data.

**Table 2.2** Important *TDataSource* properties for a single-table form

Property	Value	Remarks
<i>AutoEdit</i>	True (default)	When <i>AutoEdit</i> is True, Delphi puts the <i>TDataSource</i> into Edit state automatically when the user changes a value in a linked control. To make a <i>TDataSource</i> read-only, or to control when to enter Edit state, set <i>AutoEdit</i> to False.

**Table 2.2** Important TDataSource properties for a single-table form (continued)

Property	Value	Remarks
<i>DataSet</i>	Table1	Specifies which <i>TTable</i> (or <i>TQuery</i> ) is supplying the data.
<i>Name</i>	DataSource1	Use the Object Inspector to change names.

The form contains one *TDBGrid* control. The expert links it to a *TDataSource* component by setting the properties listed in the following table. By default, a *TDBGrid* includes all the fields (columns) in a table. To limit the columns displayed by a *TDBGrid*, double-click on its associated *TTable* component to invoke the Fields Editor (see page 30).

**Table 2.3** Important TDBGrid properties for a single-table form

Property	Value	Remarks
<i>DataSource</i>	DataSource1	Links the <i>DBGrid</i> control to a <i>TDataSource</i> component, which supplies the data.

The form contains one *TDBNavigator* control. This control moves a table's current record pointer forward or backward, starts Insert or Edit state, posts new or modified records, etc. The expert links this control to the *Parts* table by setting the properties listed in the following table.

**Table 2.4** Important TDBNavigator properties for a single-table form

Property	Value	Remarks
<i>DataSource</i>	DataSource1	Links the control to a <i>TDataSource</i> component.
<i>VisibleButtons</i>	A list of button identifiers and a corresponding Boolean value that specifies whether that button is visible. Example: <i>nbFirst</i> True.	For example, by default <i>nbNext</i> is True, so the Next Record button is visible; <i>nbDelete</i> is False, so the Delete button is invisible.

The expert does more than create a form and components. It also generates a line of code to open the table at run time in case you do not activate the table at design time. For example, the expert creates *TTable* components with the *Active* property set to False. That's why the various *TDBEdit* controls aren't displaying data. You could set *Active* to True, and the controls would display data from the first record. Instead, the Form Expert generates the following code to open the table at run time.

```

procedure TEditPartsForm.FormCreate(Sender: TObject);
begin
    Table1.Open;
end;

```

This code is hooked to the form's *OnCreate* event, so Delphi executes it before creating the form. As a result, the table is opened before the form is displayed.

**Note** Code created by the Form Expert is like code you type yourself. If you rename components created by the expert, be sure to update your source file everywhere the renamed component occurs. Name changes to components that Delphi originates (for example, in the **type** declaration) are changed automatically for you by Delphi.

## For more information

For more information about

- Building Delphi forms, see the *User's Guide*.

- The Delphi database architecture, see Chapter 1, "Introduction."
- *TTable* components, see page 8.
- The Fields Editor, see page 30.
- *TDataSource* components, see page 10.

## Building a master-detail form

---

The steps in this section show how to use the Database Form Expert to build a form containing two tables: a master table and a detail table, linked one-to-many. This form is the basis for the CUSTORD.DFM form in MASTAPP. The master table is CUSTOMER.DB and the detail table is ORDERS.DB. You can access both tables using the MAST alias. The expert links these tables and creates components to display data for one customer at a time, and for each customer, to display many orders.

### What to do

When you use the Database Form Expert, building a master-detail form is much like building a single-table form (for details, see page 21).

- 1 Choose Help | Database Form Expert to open the Form Expert.
- 2 In the first panel, specify a master-detail form that uses *TTable* objects.
- 3 In subsequent panels, specify the master table (CUSTOMER.DB), fields (use them all), and field layout (grid).
- 4 Specify the detail table (ORDERS.DB), fields (all), and field layout (grid).
- 5 Specify fields to link the master and detail tables as shown in the following figure, then tell the expert to create the form.

- 6 Press *F9* to run the form. Click the navigator control buttons to move through the records in the table.

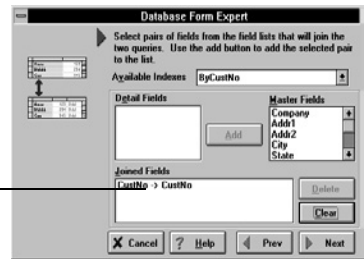

**Figure 2.4** Linking fields in a master-detail form

1. Choose an index. All Paradox tables have a primary index by default. ORDERS.DB was also created to have a secondary index named ByCustNo that orders records by customer number. Choose ByCustNo from the combo box.

2. When you choose an index, Delphi updates the lists of possible linking fields. In each list, choose CustNo, then click Add.

3. When you click Add, Delphi shows how the fields are linked. Click Next to continue.

## How it works

The expert builds a master-detail form much as it builds a single-table form (for details, see page 22). It creates *TTable* components and *TDataSource* components for the master table and the detail table and links them to the underlying data by setting properties. The expert creates controls to display the data from each table, and sets properties to link them to the corresponding *TDataSource* component. The expert also creates a *TDBNavigator* control linked to the master table.

**Figure 2.5** A master-detail form

What distinguishes a master-detail form is the link between the tables. For each record in the master table, the form displays all corresponding records in the detail table. Such a link is called a *one-to-many relationship* (see page 76 for more information). Delphi creates this relationship by setting properties of the *TTable* component linked to the detail table.

**Table 2.5** Important detail table properties

Property	Remarks
<i>IndexFieldNames</i>	Specifies the columns used to order the records in the table. You can also specify an index by name using the <i>IndexFields</i> property. For more information, see page 74.
<i>MasterFields</i>	Specifies which fields in the master table to link to. Use a semicolon to separate multiple field names. For more information, see page 76.
<i>MasterSource</i>	Specifies the <i>TDataSource</i> component linked to the master table. This data source provides a restricted view of the data in the detail table based on the values of the fields specified in <i>MasterFields</i> . For more information, see page 76.

The following table lists important properties for each component and control.

**Table 2.6** Important component properties for a master-detail form

Component	Property	Value	Remarks
<b>TTable (master)</b>	<i>Active</i>	False	When <i>Active</i> is False, data from this table is not displayed.
	<i>DataBaseName</i>	MAST	An alias that specifies where to find the table. Use aliases, not hard-coded paths, to make applications portable and easy to upsize.
	<i>Name</i>	Table1 (by default).	Use the Object Inspector to rename it (for example, Cust).
	<i>TableName</i>	CUSTOMER.DB	Specifies the master table.
<b>TDataSource (master)</b>	<i>DataSet</i>	Table1 (by default)	Specifies which <i>TTable</i> is supplying the data to this component.
	<i>Name</i>	DataSource1 (by default)	Use the Object Inspector to rename it (for example, CustSource).
<b>TTable (detail)</b>	<i>Active</i>	False	Data from this table is not displayed at design time.

**Table 2.6** Important component properties for a master-detail form (continued)

Component	Property	Value	Remarks
	<i>DataBaseName</i>	MAST	An alias that specifies where to find the table. Use aliases, not hard-coded paths, to make applications portable and easy to upsize.
	<i>IndexFieldNames</i>	CustNo	Specifies a column to use to order records in the table. <i>ByCustNo</i> is a secondary index based on <i>CustNo</i> . You can also set the <i>IndexFields</i> property to <i>ByCustNo</i> .
	<i>MasterFields</i>	CustNo	A list of one or more master table fields to link to. Use a semicolon to separate field names in the list.
	<i>MasterSourceName</i>	DataSource1 (by default) Table2 (by default)	Identifies a <i>TDataSource</i> linked to the master table. Use the Object Inspector to rename it (for example, Orders).
	<i>TableName</i>	ORDERS.DB	Specifies the detail table.
<b>TDataSource (detail)</b>	<i>DataSet</i>	Table2 (by default)	Specifies which <i>TTable</i> is supplying the data to this component.
	<i>Name</i>	DataSource2 (by default)	Use the Object Inspector to rename it (for example, OrdersSource).
<b>TDBGrid (master)</b>	<i>DataSource</i>	DataSource1 (by default)	Links the grid control to a <i>TDataSource</i> control.
<b>TDBGrid (detail)</b>	<i>DataSource</i>	DataSource2 (by default)	This data source provides a restricted view of the data in the <i>Orders</i> (detail) table, based on the values of the fields linked to the <i>Customer</i> (detail) table.
<b>TDBNavigator</b>	<i>DataSource</i>	DataSource1 (by default)	The expert links the <i>TDBNavigator</i> control to the master table.

### For more information

For more information about

- Linking tables, see step 6 on page 25.
- One to many relationships, see “Creating a master-detail form,” on page 76.
- Using the Database Form Expert, see page 21.

## Building a one-many-many form

This section describes how to build a form that displays data from three tables linked one-many-many. For example, one customer may place many orders, and each order may have many items. Use the Database Form Expert to create a master-detail form linking the *Customer* table to the *Orders* table as described on page 24. Then, to display and link the *Items* table, place components and set properties by hand. You can also use the techniques described here to build a master-detail form from scratch.

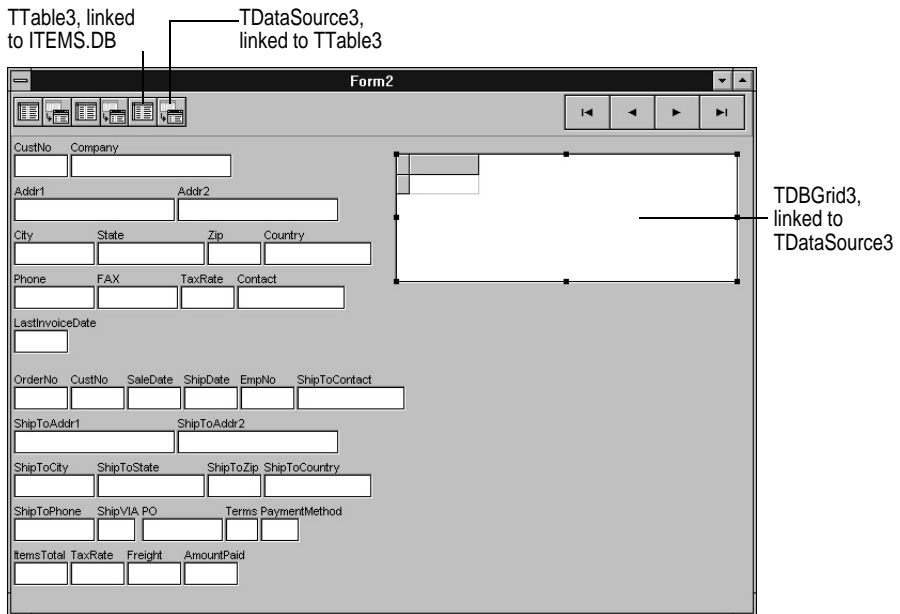

### What to do

- 1 Choose Help | Database Form Expert to open the Form Expert.
- 2 In the first panel, specify a master-detail form that uses *TTable* objects.

- 3 In subsequent panels, specify the master table (CUSTOMER.DB), fields (use them all), and field layout (horizontal).
- 4 Specify the detail table (ORDERS.DB), fields (all), and field layout (horizontal).
- 5 Specify fields to link the master and detail tables: choose CustNo for the *IndexFieldName* property and link the CustNo fields in each table. For details, see step 6 on page 25.
- 6 Tell the expert to create the form.
- 7 Move components around to make room at the bottom of the form. You may have to change the *Align* property of some controls from *alClient* to *alNone*.
- 8 Place a *TTable* component, a *TDataSource* component, and a *TDBGrid* component as shown in the following figure. (The *TTable* and *TDataSource* are on the Data Access components page; the *TDBGrid* is on the Data Controls page.) These components represent the third table in the one-many-many link. In this example its the *Items* table.

- 9 To create the link, set properties of these new components as shown in the following table.

**Figure 2.6** One-many-many form

**Table 2.7** Important component properties for a one-many-many form

Component	Property	Value	Remarks
<b>TTable</b> (third table)	<i>Active</i>	True	False by default. Set <i>Active</i> to True after setting all other properties to display data in linked controls.
	<i>DataBaseName</i>	MAST	An alias that specifies where to find the table. Use aliases, not hard-coded paths, to make an application portable and easier to upsize.
	<i>IndexFieldNames</i>	OrderNo	Specifies a column to use to order records in the table. <i>ByOrderNo</i> is a secondary index based on <i>OrderNo</i> . You can also set the <i>IndexFields</i> property to <i>ByOrderNo</i> .
	<i>MasterFields</i>	OrderNo	A list of one or more master table fields to link to. Use a semicolon to separate field names in the list.
	<i>MasterSource</i>	DataSource2 (by default)	Identifies a <i>TDataSource</i> component linked to the master table.
	<i>Name</i>	Table3 (by default).	Use the Object Inspector to rename it (for example, Items).
	<i>TableName</i>	ITEMS.DB	The name of the third table in the link.
<b>TDataSource</b> (third table)	<i>DataSet</i>	Table3 (by default)	Specifies which <i>TTable</i> is supplying the data to this component.
	<i>Name</i>	DataSource3 (by default)	Use the Object Inspector to rename it (for example, ItemsSource).
<b>TDBGrid</b> (third table)	<i>DataSource</i>	DataSource3 (by default)	This data source provides a restricted view of the data in the <i>Items</i> table, based on the values of the fields linked to the <i>Orders</i> table.

## How it works

A one-many-many form links data from three tables. The first table in the link (the *Customer* table) is the master table. The second table (*Orders*) does double duty: it's the detail table for the first table and the master table for the third table. The third table (*Items*) is a detail table for the second table. In this example, you can link these tables quickly and easily by setting properties because secondary indexes were specified for the tables when they were created.

## For more information

For more information about

- Using the Database Form Expert, see page 21.
- Creating tables and adding secondary indexes, see Appendix A, "Using Database Desktop."
- Linking tables, see step 6 on page 25.

# Working with fields

---

Examples in this section show how use code to control field values and display attributes. Delphi's data-aware controls enable end users to view and edit table data, but to access the underlying data or control how it is displayed, you want to create field components. Use the Fields Editor to define a list of fields and work with invisible components of type *TField*.

## Creating Tfield components

---

This example explains how to use the Fields Editor to define a list of some or all of the fields (columns) in a table. For each field, Delphi creates a corresponding *TField* component. *TField* components are invisible components that provide access to field values and display attributes. The following example shows how to use the Fields Editor to make a grid display four fields selected from the *Customer* table. It also shows how to specify the field order.

### What to do

- 1 Use the Database Form Expert to build a single-table form that displays all the fields of CUSTOMER.DB in a grid. For detailed instructions, see page 21.
- 2 To make the grid display data at design time, use the Object Inspector to change the *TTable* component's *Active* property to True.

- 3 Open the Fields Editor by double-clicking the *TTable* component. By default, the list of fields is empty, as shown in the following figure:

**Figure 2.7** The Fields Editor

- 4 Click Add to open a dialog box listing the fields in the *Customer* table. By default, all fields are selected. Click CustNo to select it, then control-click to select the Company, Phone, and LastInvoiceDate fields, then click OK to confirm your choices and close the dialog box. In the form, the grid changes: instead of displaying all fields, it displays the only the fields you selected.

**Figure 2.8** Adding fields to a data set

- 5 Use the Fields Editor to change the field order as follows: Click LastInvoiceDate in the list of fields, then drag it to the third place in the list, between Company and Phone. In the form, the grid changes to display columns in their new order.
- 6 Close the Fields Editor by choosing Close from the Control menu.
- 7 Press *F9* to run the form. The grid displays the four fields in the order you specified.

## How it works

This form is the basis for the full-featured CUSTORD.DFM form in the MASTAPP application. By choosing fields in the Fields Editor, you can tell a *TTable* component which fields to make available to the components that are linked to it. In effect, the Fields Editor changes the logical structure of the table. The Fields Editor also adds *TField* objects to the unit's **type** section (for example, `CustCustNo: TFloatField;`). More accurately, it adds a descendant of the *TField* type appropriate for the data type of the field. For example, when you add the CustNo field to the data set, Delphi adds a *TFloatField* object; when you add the Company field, Delphi adds a *TStringField*, and so on. This tutorial uses the general term *TField* when the specific data type is unimportant.

**Note** Specifying a list of fields in the Database Form Expert is not the same as using the Fields Editor to define a dataset. The expert places components and controls in a form to create an initial layout, but you must use the Fields Editor to specify the fields in a data set. Use *TField* components, not visual controls, to access fields programmatically. Understanding the relationship between a *TTable* component, *TField* components, and data-aware controls is crucial to building database applications with Delphi.

### For more information

For more information about

- Data sets, the Fields Editor, and *TField* components, see “Using TFields and the Fields Editor” on page 79.
- Using the Database Form Expert, see page 21.

## Setting Tfield properties at design time

---

Because they are invisible, the only way to set the properties of *TField* components at design time is by using the Fields Editor. The following example shows how to set the properties of a *TField* component at design time.

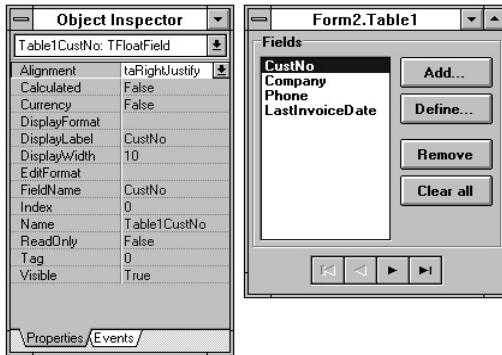

### What to do

- 1 Use the Database Form Expert to build a single-table form that displays all the fields of CUSTOMER.DB in a grid. For detailed instructions, see page 21. (If you’re working through these examples in sequence, you can use the form from the previous example and skip to step 5.)
- 2 To make the grid display data at design time, use the Object Inspector to change the *TTable* component’s *Active* property to True. This step is optional: it lets you see what happens to the form as you use the Fields Editor.
- 3 Open the Fields Editor by double-clicking the *TTable* component. By default, the list of fields is empty.
- 4 Click Add to open a dialog box listing the fields in the *Customer* table. By default, all fields are selected. Control-click to select only the CustNo, Company, Phone, and LastInvoiceDate fields, then click OK to confirm your choices and close the dialog box. In the form, the grid changes: instead of displaying all fields, it displays the only the fields you selected.
- 5 Click the CustNo field in the Fields Editor’s field list and view the properties and values displayed in the Object Inspector. (To open the Object Inspector, choose View | Object Inspector.) Notice that the component’s *Name* property is Table1CustNo. Delphi generates this name automatically by appending the field name to the name of the associated *TTable* component. Use this name to refer to the *TField* component in code.

- 6 Change the *Align* property from *taRightJustify* (the default) to *taCenter*. In the form, the grid changes: values in the *CustNo* column are centered.

**Figure 2.9** TField component properties

To display a TField component's properties in the Object Inspector, choose a field name from the list in the Fields Editor.

Delphi generates a TField component's name by appending the field name to the name of the associated TTable component. Use this name to refer to the TField in code.

### How it works

When you select a field listed in the Fields Editor, you can use the Object Inspector to set an invisible *TField* component's properties, just as you would a visible control. Note that a field's display attributes are properties of the *TField* component, not of the control that displays the value! You only have to set a property once for the *TField* component. Linked *Cust* controls use the settings automatically. This is a guiding principle of Delphi database applications: use *TField* components to work with database fields.

The following table lists important *TField* design-time properties.

**Table 2.8** Important TField design-time properties

Property	Remarks
<i>Alignment</i>	Specifies how to display the field value: left-justified, right-justified, or centered.
<i>Calculated</i>	When True, this field isn't stored in the table but instead is calculated, record by record, by Object Pascal code. Write this code in the table's <i>OnCalcFields</i> event handler.
<i>DisplayLabel</i>	The string used by grids as the column header for the corresponding field.
<i>DisplayWidth</i>	The number of characters that a grid column uses to display this field in a grid.
<i>DisplayFormat</i> and <i>EditMask</i>	Provides control over input characters for some fields types as they are displayed and edited, for example, in working with commonly formatted values such as dates and telephone numbers.
<i>FieldName</i>	The name of the field in the underlying table. Example: <i>CustNo</i> .
<i>Index</i>	The field's logical position in the data set (first position = 0).
<i>Name</i>	Formed by appending the field name to the name of the <i>TTable</i> component. Example: Given a <i>TTable</i> name of <i>Customer</i> and a field name of <i>CustNo</i> , the <i>TField</i> 's name is <i>CustomerCustNo</i> . This name is used for programmatic access to field's properties (for example: <i>CustomerCustNo.Value</i> ).
<i>ReadOnly</i>	When <i>ReadOnly</i> is True, data in the corresponding field cannot be modified.
<i>Visible</i>	When True, the corresponding field appears in grids linked to this <i>TField</i> .

### For more information

For more information about

- Setting a *TField* component's properties, see page 79.
- Using the Fields Editor, see page 30.
- Using the Database Form Expert, see page 21.

## Reading field values

---

Every line in the Fields Editor's list of fields represents a Delphi component type *TField*. When you add a field to the list in the Fields Editor, you add a new component to the form (the code appears in the unit's **type** section). Delphi provides *TField* descendents for every available field type. For example, in the *Customer* table, *CustNo* is of type *TFloatField*, and *Company* is of type *TStringField*. This example shows how to build a form so you can read field values at run time. You get a field value by reading the *Value* property of the corresponding *TField* component.

### What to do

- 1 Use the Database Form Expert to build a single-table form that displays all the fields of *CUSTOMER.DB* in a grid. For detailed instructions, see page 21.
- 2 Use the Object Inspector to change the form's *Name* property to *TutorialForm*.
- 3 Open the Fields Editor by double-clicking the *TTable* component. By default, the list of fields is empty.
- 4 Click **Add** to open a dialog box listing the fields in the *Customer* table. By default, all fields are selected. Control-click to select only the *CustNo*, *Company*, *Phone*, and *LastInvoiceDate* fields, then click **OK** to confirm your choices and close the dialog box. The Fields Editor remains open.
- 5 Place a button control and a standard edit box anywhere in the panel that contains the *TDBNavigator* control (you may need to resize the panel), then set the edit box *Name* property to *OutputField*.
- 6 Attach the following code to the button's *OnClick* event:

```
procedure TTutorialForm.Button1Click(Sender: TObject);
begin
    OutputField.Text := Table1Company.Value;
end;
```

- 7 Press **F9** to run the form. Click a field in the grid, then click the button. The text in the edit control displays the value of the *Company* field for the current record.

### How it works

The code in step 7 does a simple assignment: the edit control's *Text* property gets the value of the *TField* component named *Table1Company*, where the *TField*'s value is the value of the corresponding field in the current record of the table.

**Note** In code, refer to a *TField* by its component name, don't use the name of the field in the table. For example, use *Table1Company*, not *Company*.

You can assign the *TField* component's value directly to the *Text* property because *Table1Company* is of type *TStringField*. An edit box's *Text* property and a *TStringField*'s

*Value* property are of compatible types, so you don't need to do a conversion. However, the following code generates a type mismatch error at compile time, because `Table1CustNo` is of type *TFloatField*.

```
OutputField.Text := Table1CustNo.Value; {Causes a type mismatch error.}
```

To display a numeric field's value in an edit box, convert the value as follows.

```
OutputField.Text := Table1CustNo.AsString;
```

This code uses the *TField* property *AsString* to read the field value and convert it to a string before assigning it to the edit box's *Text* property. *TField* components have the following properties for converting values: *AsBoolean*, *AsDateTime*, *AsFloat*, *AsInteger*, and *AsString*.

The following code shows examples of how to read field values, display them in edit boxes, and assign them to variables.

```
var
    CustNoDouble: Double;
    CustNoInt: Integer;
    CustNoString: String;
begin
    {Display field value in edit control.}
    OutputField.Text := Table1Company.Value; {Compatible types, no conversion.}
    OutputField.Text := Table1CustNo.AsString; {Convert field value to compatible type.}

    {Assign field value to variables.}
    CustNoDouble := Table1CustNo.Value; {Compatible types, no conversion.}
    CustNoInt := Table1CustNo.AsInteger; {Convert field value to compatible type.}
    CustNoString := Table1CustNo.AsString; {Convert field value to compatible type.}
end;
```

## For more information

For more information about

- Using the Fields Editor, see page 30.
- Using the Database Form Expert, see page 21.
- Setting a *TField* component's properties, see page 79.

## Assigning values to fields

---

This example shows how to build a form so you can assign field values at run time. You write to a field by assigning a value to the corresponding *TField* component.

### What to do

- 1 Use the Database Form Expert to build a single-table form that displays all the fields of `CUSTOMER.DB` in a grid. For detailed instructions, see page 21. (If you're working through these examples in sequence, you can use the form from the previous example and skip to step 5.)
- 2 Use the Object Inspector to change the form's *Name* property to `TutorialForm`.

- 3 Open the Fields Editor by double-clicking the *TTable* component. By default, the list of fields is empty.
- 4 Click Add to open a dialog box listing the fields in the *Customer* table. By default, all fields are selected. Control-click to select only the CustNo, Company, Phone, and LastInvoiceDate fields, then click OK to confirm your choices and close the dialog box.
- 5 Place a button control and a standard edit box anywhere in the panel that contains the *TDBNavigator* control (you may need to resize the panel).
- 6 Attach the following code to the button's *OnClick* event to change a company's name in the CUSTOMER table based on the current value in the standard edit box:

```

procedure TTutorialForm.Button1Click(Sender: TObject);
begin
    Table1.Edit;
    Table1Company.Value := Edit1.Text;
    Table1.Post;
end;

```

- 7 Press *F9* to run the form. Type a value into the edit box, then click the button and notice the value of the Company field in the current record in the grid. It should be the same as the text in the edit box.

### How it works

The code in step 6 does three things: it puts the table into Edit state, assigns a value to the Company field of the current record, and posts the modified record back to the table (which takes the table out of Edit state). As this example shows, there is a difference between editing field values interactively using controls and editing field values in code. By default, the *AutoEdit* property of a *TDataSource* component is set to True. A user can type into a data-aware control to that data source and modify the value immediately. When the user moves off that record, changes are posted automatically. But, to modify *TField* component values based on values entered in a standard edit control, or to perform table modifications in code, you need to explicitly switch to Edit state, set the value, and post changes.

**Note** You can safely call *Edit* even if you're already in Edit or Insert state. In such cases, calls to *Edit* have no effect.

The *TField* component and the value you assign must be compatible. In the example, the edit control's *Text* property is compatible with *Table1Company*, a *TStringField*. However, the following code generates a type mismatch error at compile time, because *Table1CustNo* is a *TFloatField*.

```

Table1CustNo.Value := OutputField.Text; {Causes a type mismatch error.}

```

To assign the text of an edit control to a numeric field, convert the text as follows.

```

Table1CustNo.AsString := OutputField.Text;

```

This code uses the *TField* property *AsString* to convert the text before assigning it to *Table1CustNo*. *TField* components have the following properties for converting values: *AsBoolean*, *AsDateTime*, *AsFloat*, *AsInteger*, and *AsString*.

The following code shows examples of how to assign field values, converting them if necessary.

```
Table1CustNo.Value := 12340;  
Table1CustNo.AsInteger := 4321;  
Table1CustNo.AsString := '5678';  
  
Table2CustNo.Value := Table1CustNo.Value; {Assign value of one TField to another.}  
Table2.Fields[0] := Table1.Fields[0]; {Also assign value of one TField to another.}
```

### For more information

For more information about

- Using the Fields Editor, see page 30.
- Using the Database Form Expert, see page 21.
- Setting a *TField* component's properties, see page 79.

## Defining a calculated field

---

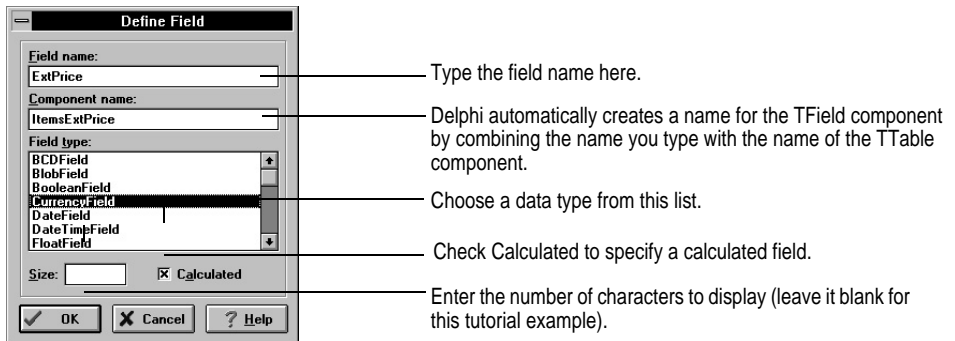

This example shows how to use the Fields Editor and *TField* components to define a calculated field. It calculates the extended price of an item, based on the unit price, quantity ordered, and discount values in the *Items* table. For more information about defining calculated fields, see page 82.

### What to do

- 1 Use the Database Form Expert to build a single-table form that displays all the fields of *ITEMS.DB* in a grid. For detailed instructions, see page 21.
- 2 Use the Object Inspector to change the form's *Name* property to *OrderForm*, change the *TTable* component's *Name* property to *Items*, and change the *TTable* component's *Active* property to *True*.
- 3 In this form's *CreateForm* procedure, change *Table1* to *Items*.
- 4 Open the Fields Editor by double-clicking the *TTable* component. By default, the list of fields is empty.
- 5 Click *Add* to open a dialog box listing the fields in the *Items* table. By default, all fields are selected. Click *OK* to add all the fields to the data set and close the dialog box. In the form, the grid displays a column for each field in the data set.

- Click Define to open the Define Field dialog box, then enter specifications for a calculated field named ExtPrice as shown in the following figure:

**Figure 2.10** Defining a calculated field

- Click OK to accept values and close the dialog box. In the form, an empty ExtPrice column appears in the grid. You may have to scroll the grid to the right to see it.
- Click Define again, then enter specifications for a second calculated field named ItemsSellPrice. It, too, should be given a CurrencyField data type. Click OK.
- Double click the *OnCalcFields* event of the *TTable* component to open the code window, then enter the following code.

```

procedure TOrderForm.ItemsCalcFields(DataSet: TDataSet);
begin
    if Parts.FindKey([ItemsPartNo]) then
    begin
        ItemsDescription.Value := PartsDescription.Value;
        ItemsSellPrice.Value := PartsListPrice.Value;
    end;
    ItemsExtPrice.Value := ItemsQty.Value *
        ItemsSellPrice.Value * (100 - ItemsDiscount.Value) / 100;
end;

```

- Type *F9* to run the form. The ExtPrice column fills with calculated values. A calculated field does not display values at design time.

### How it works

This form is the basis for the full-featured EDORDERS.DFM form in MASTAPP. It demonstrates the two key aspects of creating a calculated field in Delphi: adding the calculated field to a *TTable* component's data set, and writing code to handle the *TTable* component's *OnCalcFields* event. Delphi sends an *OnCalcFields* event each time the cursor for that table changes. The calculation accesses data through the *TField* components created in the Fields Editor, not the controls placed in the form.

The example attaches code to the *OnCalcFields* event to update the value of the calculated field. You can use the *OnCalcFields* event for other purposes; for example, to do a lookup into another table, perform a complex calculation, or do real-time data

acquisition. However, in an *OnCalcFields* event, you can only assign values to calculated fields.

### For more information

For more information about

- Programming calculated fields, see page 82.
- Using the Fields Editor, see page 30.
- Using the Database Form Expert, see page 21.
- Setting a *TField* component's properties, see page 79.

## Formatting field values at design time

---

This example shows how to format a field value by setting the *DisplayFormat* property at design time.

### What to do

- 1 Use the Database Form Expert to build a single-table form that displays all the fields of CUSTOMER.DB. Specify a vertical layout and labels aligned left. For detailed instructions, see page 21.
- 2 Use the Object Inspector to change the form's *Name* property to *EdCustForm*, change the *TTable* component's *Name* property to *Cust*, and change the *TTable* component's *Active* property to *True*. In the form, notice the Tax Rate field's display format (example: 8.5).
- 3 In this form's *CreateForm* procedure, change *Table1* to *Cust*.
- 4 Open the Fields Editor by double-clicking the *TTable* component. By default, the list of fields is empty.
- 5 Click *Add* to open a dialog box listing the fields in the *Customer* table. By default, all fields are selected. Click *OK* to add all the fields to the data set and close the dialog box.
- 6 In the Field Editor's list of fields, choose *Tax Rate*, then use the Object Inspector to view the properties of the *TFloatField* named *CustTaxRate*. The *DisplayFormat* property is blank.
- 7 In the Object Inspector, enter the following value for the *DisplayFormat* property of *CustTaxRate*: *0.00%*. In the form, the Tax Rate field's display format changes (example: 8.50%).

## How it works

Delphi provides several properties that specify a field's display format. The following table lists some of the most frequently-used properties. Any data-aware control linked to a *TField* component uses the *TField*'s display properties.

**Table 2.9** Important TField design-time properties

Property	Remarks
<i>Alignment</i>	Displays field value left justified, right justified, or centered within a data-aware control.
<i>Currency</i>	True, numeric field displays monetary values. False, numeric field does not display monetary values.
<i>DisplayFormat</i>	Specifies the format of data displayed in a data-aware component. For more information about valid patterns, see the online help.
<i>DisplayWidth</i>	The number of characters that a grid column uses to display this field in a grid.
<i>DisplayFormat</i> and <i>EditMask</i>	Provides control over input characters for some fields types as they are displayed and edited; for example, in working with commonly formatted values such as dates and telephone numbers.
<i>FieldName</i>	The name of the field in the underlying table; for example, CustNo.
<i>Index</i>	The field's logical position in the data set (first position = 0).
<i>Name</i>	Formed by appending the field name to the name of the <i>TTable</i> component. Example: Given a <i>TTable</i> name of Customer and a field name of CustNo, the <i>TField</i> 's name is CustomerCustNo. This name is used for programmatic access to field's properties (for example, CustomerCustNo.Value).
<i>Visible</i>	When True, the corresponding field can appear in linked grids.

## For more information

For more information about

- Formatting field values, see page 83.
- Using the Fields Editor, see page 30.
- Using the Database Form Expert, see page 21.
- Setting a *TField* component's properties, see page 79.

## Formatting field values at run time

This example shows how to format a field value by setting the *DisplayText* property in code.

### What to do

- 1 Use the Database Form Expert to build a single-table form that displays all the fields of CUSTOMER.DB. (If you're working through these examples in sequence, you can use the form from the previous example and skip to step 6.) Specify a vertical layout and labels aligned left. For detailed instructions, see page 21.
- 2 Use the Object Inspector to change the form's *Name* property to EdCustForm, change the *TTable* component's *Name* property to Cust, and change the *TTable* component's *Active* property to True. In the form, notice the Phone field displays U.S phone numbers (example: 808-555-0269).
- 3 In this form's *CreateForm* procedure, change Table1 to Cust.

- 4 Open the Fields Editor by double-clicking the *TTable* component. By default, the list of fields is empty.
- 5 Click Add to open a dialog box listing the fields in the *Customer* table. By default, all fields are selected. Click OK to add all the fields to the data set and close the dialog box.
- 6 In the Fields Editor's list of fields, choose Phone, then use the Object Inspector to view the events of the *TStringField* named *CustPhone*.
- 7 Double-click the *OnGetText* event to open the code window, then add code to handle the event as follows.

```

procedure TEdCustForm.CustPhoneGetText (Sender: TField;
    var Text: OpenString; DisplayText: Boolean);
begin
    if DisplayText then
        begin
            Text := CustPhone.Value;
            Delete(Text, 4, 1);
            Insert('(', Text, 1);
            Insert(')', Text, 5);
        end;
    end;
end;

```

In this sample code, *DisplayText* is True, meaning you're not actually editing the field in question, but modifying the display of the field. When *DisplayText* is True, characters that would be invalid for the user to enter, such as parentheses in this case, can be inserted into the field for display purposes only.

- 8 Press *F9* to run the form. The Phone field's display format changes (example: (808)555-0269).

### How it works

Use the *OnGetText* event to format field values. Delphi calls a *TField* component's *OnGetText* method whenever it's about to display the value of a field onscreen, for example, when redrawing a data-aware component. Delphi ignores a *TField* component's *DisplayFormat* property when you add code to its *OnGetText* event.

In this example, *CustPhoneGetText* copies the phone number string to variable *Text*, then uses the *Insert* and *Delete* procedures to place parentheses around the first three digits. This gives U.S. phone numbers a more traditional format: (713) 555-1212, instead of 713-555-1212 as stored in the file. The *DisplayText* property is True when a *TField* is displaying data but is not available for editing. When a *TField* is in Edit state, *DisplayText* is *False*.

**Note** *DisplayFormat* and *EditMask* are ignored if an *OnGetText* event handler exists.

### For more information

For more information about

- Formatting fields, see page 85.
- Editing display properties, see page 83.

- Using the Fields Editor, see page 30.
- Using the Database Form Expert, see page 21.
- Setting a *TField* component's properties, see page 79.

## Searching for field values

---

This example shows how to search for values in keyed (indexed) fields in a table. To search for values in unkeyed fields, use a query. See “Using queries and ranges” on page 47 for more information.

### What to do

This example shows how to display a record in the Customer table by searching for a customer number entered by the user.

- 1 Use the Database Form Expert to build a single-table form that displays fields from CUSTOMER.DB. Specify a vertical layout and labels aligned left. For detailed instructions, see page 21.
- 2 Place a button control in the panel that contains the *TDBNavigator* control.
- 3 Double-click the button to open a code window, then add code to handle the button's *OnClick* event as follows.

```
procedure TForm2.Button1Click(Sender: TObject);
var UserCustNo: String;
begin
  UserCustNo := InputBox('Search', 'Enter a Customer Number:', ' ');
  if not Table1.FindKey([UserCustNo]) then
    MessageDlg('Not found.', mtInformation, [mbOK], 0);
end;
```

- 4 Add the *Dialogs* unit to the **uses** clause of your form unit. The *InputBox* function used in the previous step resides in the *Dialogs* unit.
- 5 Press *F9* to run the form. Click the button and enter a number in the input dialog box (try 1560). If that number is a customer number in the table, Delphi displays the corresponding record. Otherwise, it displays a dialog box.

### How it works

*FindKey* takes an array, where each array value represents a value to search for in the corresponding key field in the table. *FindKey* searches for the first array value in the first key field, the second array value in the second key field, and so on. In this example, the array contains one value, so *FindKey* searches for it in the first key field of the table, which is *CustNo*.

The following example shows how to search for the name Frank P. Borland in a table where the key fields are *LastName*, *FirstName*, and *MiddleInitial*.

```
begin
  if not Table1.FindKey(['Borland', 'Frank', 'P.']) then
    MessageDlg('Not found.', mtInformation, [mbOK], 0);
end;
```

## For more information

For more information about

- Searching for field values, see page 70.
- Using the Fields Editor, see page 30.
- Using the Database Form Expert, see page 21.

## Validating data entry

---

This section describes ways to make sure the user doesn't enter invalid data into tables. There are three different approaches to validating data: table-based, field-based, and record-based.

Most forms use a combination of validation techniques.

- **Table-based validation.** Build in validity checks when you create tables. Using the Database Desktop, you can specify a wide range of validity checks, including minimum and maximum values, formatting pictures, and referential integrity, all without writing a line of code. Table-based validation rules are enforced by the database when the data is posted. Multiple exceptions will be raised, one after another, until all fields match the validation criteria. Delphi enforces some table-based validation rules before posting (for example, whether a field is required or not).

For more information about the DBD, see Appendix A, "Using Database Desktop."

- **Field-based validation.** There are two methods:

Create an *OnValidate* event handler. The handler is called when the field's value is modified, whether by user input or when the field is assigned a value in code.

For fields that must get values from a user (for example, a password or part number) set the *TField's Required* property to True, and write an *OnValidate* event handler for the field. Before a record is posted, an exception occurs for any fields that have a **nil** value.

- **Record-based validation.** Use this approach when other fields are involved in determining if a field is valid. For example, if it is invalid to use a credit card for purchases under \$10, you want to give a user the chance to enter both a payment method and an invoice amount before performing validation on the payment method. Otherwise, since a new order starts with a zero invoice amount, you would require the entry of all line items before permitting specification of a payment method.

Record-based validation should be performed in a table's *BeforePost* event handler. Raising an exception there prevents posting from occurring. Use the *TField FocusControl* method to inform the user which field is invalid. For an example of this technique, see "Writing code to check field values" on page 46.

## Using lists and lookups

The following examples show two techniques for using lists to restrict user input. The first example presents a list of items entered by hand. The second example presents a lookup filled with items from a field (column) of a table.

**Figure 2.11** Lists and lookups

The Terms field is a *TDBComboBox* control. The list items are hard-coded. See page 44.

The SoldBy field is a *TDBLookupCombo* control. It reads list items from a field (column) of a table. See page 45.

### What to do (list)

The following steps describe how to create the drop-down list labeled Terms in the Edorders form in MASTAPP. The Terms field specifies the payment terms for an order. Allowed values are Prepaid, Net 30, and COD.

- 1 Open the MASTAPP project, then open the Edorders form.
- 2 Place a *TTable* component. Set its *DatabaseName* and *TableName* properties to link it to the *Orders* table. Change its *Name* property to *Orders*.
- 3 Place a *TDataSource* component. Set its *DataSet* property to the *Orders TTable*. Change its *Name* property to *OrdersSource*.
- 4 Place a *TDBComboBox* control. Set its properties as shown in the following table.

**Table 2.10** Important *TDBComboBox* properties

Property	Value	Remarks
<i>DataField</i>	Terms	The name of the field in the table this control is linked to.
<i>DataSource</i>	OrdersSource	The <i>TDataSource</i> component this control is linked to.
<i>Items</i>	Prepaid Net 30 COD	Each list item is on its own line. In other words, when you enter list items, press <i>Enter</i> after each item.

## How it works

A *TDBComboBox* control works like a standard combo box control, but it's linked to a field in a table. Its *Items* property stores the list items. When the user chooses an item from the list, that value is assigned to the corresponding data field in the current record. You can add list items by hand at design time or specify them in code at run time.

## For more information

For more information about

- Using lists and combo boxes, see “Using list and combo boxes” on page 109.
- Using the Fields Editor, see page 30.
- Using the Database Form Expert, see page 21.

## What to do (lookup)

The following steps describe how to create the drop-down lookup list labeled *SoldBy* in the *Edorders* form in *MASTAPP*. The combo box labeled *SoldBy* displays a list of employee names, but it stores employee numbers. When the user chooses a name from the list, Delphi looks up the corresponding employee number and writes that value to the *Orders* tables.

- 1 Open the *MASTAPP* project, then open the *Edorders* form.
- 2 Place two *TTable* components. Set the first component's *DatabaseName* and *TableName* properties to link it to the *Orders* table, and change its *Name* property to *Orders*. Set the second component's *DatabaseName* and *TableName* properties to link it to the *Employee* table, and change its *Name* property to *Emps*.
- 3 Place two *TDataSource* components. Set the first component's *DataSet* property to the *Orders TTable* and change its *Name* property to *OrdersSource*. Set the second component's *DataSet* property to the *Emps TTable* and change its *Name* property to *EmpsSource*.
- 4 Place a *TDBLookupCombo* control. Set its properties as shown in the following table.

**Table 2.11** Important *TDBComboBox* properties

Property	Value	Remarks
<i>DataSource</i>	<i>OrdersSource</i>	The <i>TDataSource</i> component this control is linked to.
<i>DataField</i>	<i>EmpNo</i>	The name of the field in the table this control is linked to.
<i>LookupSource</i>	<i>EmpsSource</i>	The <i>TDataSource</i> component used to identify the table from which to look up field values.
<i>LookupDisplay</i>	<i>FullName</i>	The field (column) this control reads from to display list values to the user. <i>FullName</i> is a calculated field in the table pointed to by <i>LookupSource</i> .
<i>LookupField</i>	<i>EmpNo</i>	The field to search for a value corresponding to the value in the <i>LookupDisplay</i> field. This value is assigned to the field specified in <i>DataField</i> .

## How it works

The *TDBLookupCombo* control dynamically accesses a column from a table (specified in *LookupDisplay*) and displays it to the user. When the user chooses an item, Delphi finds

the value in the table specified in *LookupSource*. Then it reads the value of the field specified in *LookupField*. Finally, it assigns that value to the field specified in *DataField* in the table specified in *DataSource*.

In this example, Delphi fills a drop-down box with employee names from the *FullName* field of the *Employee* table. *FullName* is a calculated field defined for the *Employee* table. To see how *FullName* is calculated, select *Employee TTable* component, then examine its *OnCalcFields* event. When the user chooses a name from the list, Delphi reads the *EmpNo* field to get the employee number for that name. Then it assigns that value to the *EmpNo* field of the *Orders* table.

### For more information

For more information about

- Using lists and combo boxes, see “Using list and combo boxes” on page 109.
- Using the Fields Editor, see page 30.
- Using the Database Form Expert, see page 21.

## Writing code to check field values

---

This example shows how to validate a field value after the user has entered it. The following steps show how to add code to the Edorders form in MASTAPP to disallow a sale date later than the current date. The example uses the standard function *Now* to get the current timestamp.

### What to do

- 1 Open the MASTAPP project, then open the Edorders form.
- 2 Double-click the *TTable* component named Orders to open the Fields Editor.
- 3 In the Fields Editor’s list of fields, click *SaleDate*, then use the Object Inspector to view the events of the *TDateTimeField* component named *OrdersSaleDate*.
- 4 Double-click the *OnValidate* event to open the code window, then add code to handle the *OnValidate* event as follows.

```
procedure TOrderForm.OrdersSaleDateValidate(Sender: TField);
begin
  if OrdersSaleDate.Value > Now then
    raise Exception.Create('Cannot enter a future date');
end;
```

### How it works

To check field values after the user enters them, write code to handle the *OnValidate* event of the appropriate *TField* component. The example code raises an exception if the date a user enters is later than today’s date. Make sure all fields are either initialized to a valid value in an *OnNewRecord* event, or have their *TField Required* properties set to *True*.

### For more information

For more information about

- Working with *TField* components, see page 34.
- Using the Fields Editor, see page 30.

## Using queries and ranges

---

The examples in this section show how to select a set of records from a table. In Delphi, you can do this by issuing SQL statements or by setting a range (filter). SQL statements can be either static or dynamic; that is, they can be fixed or include parameters where values are provided at run time. For more information, see Chapter 5, “Using SQL in applications.”

### What to do (static query)

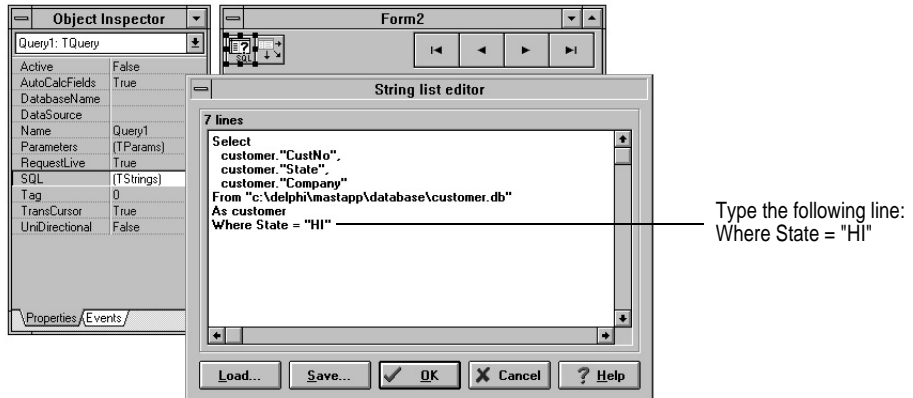

This example shows how to create and execute a static query and display the results in a form.

- 1 Use Form Expert to build a form based on a query of the *Customer* table (for detailed instructions, see page 21). Use only the *CustNo*, *Company*, and *State* fields (for simplicity). Specify a grid layout.
- 2 Use the Object Inspector to set the *TQuery* component's *Active* property to True. The grid displays the query results (by default, the query selects all records).
- 3 Set the *TQuery* component's *Active* property to False. The grid empties. (*Active* must be False to change the query.)
- 4 Use the Object Inspector to display the *TQuery* component's *SQL* property, and type the following statement after the last line in the SQL statement in the String List Editor window:  

```
where State = "HI"
```
- 5 Click OK to close the String List Editor.

- 6 Set the *TQuery* component's *Active* property to True. The grid displays only those records where the value of the *State* field is "HI." (Optional: Press *F9* to run the form.)

**Figure 2.12** Setting a *TQuery*'s SQL property

### How it works

Delphi reads the SQL statements assigned to the *TQuery* component's *SQL* property and passes them to the server without any intermediate interpretation. (Use double quotes in SQL statements, not single quotes as in Pascal code.) The server executes the query and returns the results to Delphi, and Delphi displays the result set in the grid.

**Note:** By default, a *TQuery* component's *RequestLive* property is set to False. When *RequestLive* is False, the result set returned by a query is read-only. Users cannot modify data in the form. If you want users to be able to update data returned by a query of a single table, then you can set *RequestLive* to True to request a live result set. If the query is updateable, *CanModify* returns True.

### For more information

For more information about

- Using *TQuery* components and SQL in applications, see Chapter 5.
- *RequestLive* behavior and restrictions, see Chapter 5, "Using SQL in applications."
- Using the Database Form Expert, see page 21.

### What to do (dynamic query)

This example shows how to create and execute a dynamic query and display the results in a form. A dynamic query consists of SQL statements that include parameters (variables) whose values can be assigned at design time or run time. Steps 1 through 6 show how to set parameters at design time. Steps 7 through 9 show how to do it at run time.

- 1 Use Form Expert to build a form based on a query of the *Customer* table (for detailed instructions, see page 21). Use only the *CustNo*, *Company*, and *State* fields (for simplicity). Specify a grid layout. If you're working through these examples in sequence, you can use the form from the previous example.

- 2 Use the Object Inspector to display the *TQuery* component's *SQL* property, and type the following statement after the last line in the SQL statement in the String List Editor window:

**where State = :State**

- 3 The SQL statement in the previous step contains the field name *State* and the parameter *State* (a parameter is an arbitrary string preceded by a colon). Click OK to close the String List Editor.
- 4 Right-click the *TQuery* component, then choose Define Parameters from the pop-up menu. The Define Parameters dialog box opens, ready for you to assign a field type and a value to the parameter *State*.
- 5 Choose a field type of String, and enter a value of FL, then click OK to close the dialog box.

**Figure 2.13** Defining a query parameter

To define the parameter *State*, choose a field type of String and enter a value of FL.

- 6 Set the *TQuery* component's *Active* property to True. The grid displays the query results (all records where *State* = FL).
- 7 Place a button control in the panel that contains the *TDBNavigator* control.
- 8 Double-click the button to open a code window, then write the following code to handle its *OnClick* event.

```
procedure TForm2.Button1Click(Sender: TObject);
begin
    Query1.DisableControls;
    try
        Query1.Active := False;
        Query1.Params[0].AsString := 'HI';
        Query1.Active := True;
    finally
        Query1.EnableControls;
    end;
end;
```

- 9 Press *F9* to run the form, then click the button. The grid displays the query results (all records where *State* = HI).

## How it works

In a SQL statement, a string preceded by a colon (like *:State* in the example) represents a parameter. At design time, Delphi recognizes parameters and displays them in the

Define Parameters dialog box. Then at run time, it assigns the specified values to the corresponding parameters.

You can assign values to query parameters at run time using the *Params* property. It stores parameter values in an array, where an index of 0 represents the first parameter, an index of 1 represents the second parameter, and so on. So, this statement assigns the value HI to the first parameter.

```
Query1.Params[0].AsString := 'HI';
```

You need to set the *TQuery* component's *Active* property to False before setting parameter values, then set it to True again to update the query. The calls to *DisableControls* and *EnableControls*, respectively, freeze and restore display capabilities of controls linked to the *TQuery* component. This disables data-aware control while the result set is updated.

### For more information

For more information about

- Dynamic SQL statement, see page 121.
- Using SQL in applications, see Chapter 5.
- Using TQuery components, see page 115.
- The SQL property, see page 117.
- Using the Database Form Expert, see page 21.

## Setting a range

---

This example explains how to select a set of records by setting a range (also called a filter). To set a range on a Paradox or dBASE table, work with keyed (indexed) fields. To set a range on a SQL table, you can specify the fields to be used as indexes using the *IndexFieldNames* property.

### What to do

- 1 Use the Database Form Expert to build a single-table form that displays all the fields of CUSTOMER.DB in a grid. For detailed instructions, see page 21.
- 2 Use the Object Inspector to change the form's *Name* property to CustForm, change the *TTable* component's *Name* property to Cust, and change the *TTable* component's *Active* property to True.
- 3 In this form's *CreateForm* procedure, change Table1 to Cust.
- 4 Open the Fields Editor by double-clicking the *TTable* component. By default, the list of fields is empty.
- 5 Click Add to open a list box for the fields in the *Items* table. By default, all fields are selected. Click OK to add all the fields to the data set and close the list box. Close the Fields Editor. In the form, the grid displays a column for each field in the data set.
- 6 Place a button control in the panel that contains the *TDBNavigator* control.

- 7 Double-click the button to open a code window, then add code to handle the button's *OnClick* event as follows.

```
procedure CustForm.Button1Click(Sender: TObject);
begin
    Cust.DisableControls;
try
    Cust.SetRangeStart;
    CustCustNo.Value := 3000;
    Cust.KeyExclusive := False;

    Cust.SetRangeEnd;
    CustCustNo.Value := 4000;
    Cust.KeyExclusive := True;

    Cust.ApplyRange;
finally
    Cust.EnableControls;
end;
end;
```

- 8 Press *F9* to run the form, then click the button. The grid displays records for customer numbers from 3,000 to 3,999.

### How it works

This example sets a range to include records for customer numbers from 3,000 to 3,999. Setting a range on a table affects the values displayed in data-aware components linked to that table. That's why the routine in step 7 begins by calling *Cust.DisableControls* and ends by calling *Cust.EnableControls*. *DisableControls* disables the display capabilities of controls linked to the specified table; in effect, it freezes them. *EnableControls* restores the controls to an active state.

**Important** Always use a **try...finally** statement, followed by *EnableControls*. Otherwise, after an exception occurs, data controls are inactive.

The call to *Cust.SetRangeStart* marks the beginning of a code block that sets the minimum value of the range. The next line assigns a value to the *TField* component named *CustCustNo*. (*CustNo* is the first and only key field in the *Customer* table.) Setting *Cust.KeyExclusive* to *False* indicates that the value is not to be excluded in the range. So, in this example, a customer number 3,000 would be included in the range.

The call to *Cust.SetRangeEnd* marks the beginning of a code block that sets the maximum value of the range. The next line assigns a value to *CustCustNo*. Setting *Cust.KeyExclusive* to *True* indicates that the value is to be excluded from the range. A customer number 4,000 would not be included.

The call to *Cust.ApplyRange* puts the range settings into effect. (To cancel a range, call *CancelRange*.)

# Printing reports and forms

---

This section describes how to use Delphi to print reports created using ReportSmith, and how to print a Delphi form. Designing reports with ReportSmith is described in *Creating Reports*.

**Note** To run reports, the *TReport* component needs to locate the RS\_RUN directory. You can put the RS\_RUN directory in your DOS PATH, or you can put an "EXEpath =" entry in the Delphi RS\_RUN.INI file.

## What to do: printing reports

This example show how to print a ReportSmith report that lists MAST customers.

- 1 Choose File | New Form to open the Browse Gallery, then choose Blank form and click OK to create a blank form.
- 2 Place a *TReport* component anywhere in the form. (The *TReport* component is on the Data Access components page.)
- 3 Use the Object Inspector to set the *TReport* component's properties as shown in the following table.

**Table 2.12** Important TReport properties

Property	Value	Remarks
<i>Preview</i>	True	When <i>Preview</i> is True, Delphi displays the report onscreen only; when <i>Preview</i> is False, Delphi sends the report to the printer.
<i>ReportDir</i>	C:\DELPHI\ DEMOS\DB\ MASTAPP\REPORTS	The path and directory where the report file resides.
<i>ReportName</i>	CUSTLIST.RPT	The report file name.

- 4 Place a button control anywhere in the form.
- 5 Double-click the button to open a code window, then write code to handle its *OnClick* event, as follows.

```
procedure TForm1.Button1Click(Sender: TObject);  
begin  
    Report1.Run;  
end;
```

- 6 Press *F9* to run the form.
- 7 Click the button to run the report. If the *TReport* component's *Preview* property is set to True, Delphi displays the report onscreen; if *Preview* is False, Delphi sends the report to the printer.

## How it works

The *Run* method of *TReport* opens the run-time version of ReportSmith, which prints or displays a report as specified by the *TReport* component's properties. When you're designing a form, you can double-click a *TReport* component to open the full version of ReportSmith and build a report.

## For more information

For more information about

- Using *TReport* components, see page 88.
- Using ReportSmith, see *Creating Reports*.

## What to do: printing forms

You can print a form by calling its *Print* method. Following is the code called by the Print button in the main form (MAIN.DFM) of MASTAPP. It prints whichever Delphi form is displayed “on top,” that is, in front of the others.

```
procedure TMainForm.PrintTopForm(Sender: TObject);
var TopForm: TForm;
begin
  TopForm := Screen.Forms[1]; {For a single form app, this should be Screen.Forms[0]!}
  if not TopForm.Visible then ShowMessage('Nothing to print!')
  else if MessageDlg(Format('Print "%s" form?', [TopForm.Caption]),
    mtConfirmation, mbOkCancel, 0) = mrOk then TopForm.Print;
end;
```

## How it works

The *Print* method for the *TForm* class prints a form as it appears onscreen.

## For more information

For more information about

- The *TForm* class, see the online Help.
- Designing forms, see the *User's Guide*.

# Using data access components and tools

This chapter describes how to use key Delphi features and tools when building database applications, including:

- The *TSession* component.
- Dataset components (*TTable* and *TQuery*), their properties, and their methods.
- *TDataSource* components, their properties, and their methods.
- *TField* objects, their properties, and their methods.
- The Fields Editor to instantiate and control *TField* objects.
- *TReport* and *TBatchMove* components.

This chapter provides an overview and general description of data access components in the context of application development. For in-depth reference information on database components, methods, and properties, see the online VCL reference.

## Database components hierarchy

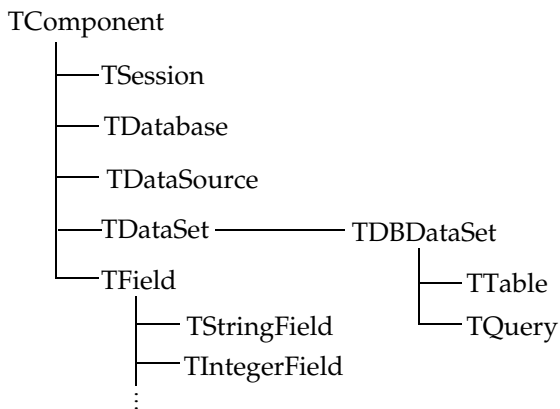

---

The Delphi database component hierarchy is important to show the properties, methods, and events inherited by components from their ancestors. The most important database components are

- *TSession*, a global component created automatically at run time. It is not visible on forms either at design time or run time.
- *TDatabase*, component that provides an additional level of control over server logins, transaction control, and other database features. It appears on the Data Access component page.
- *TDataSet* and its descendents, *TTable* and *TQuery*, collectively referred to as dataset components. *TTable* and *TQuery* components appear on the Data Access component page.

- *TDataSource*, a conduit between dataset components and data-aware components. It appears on the Data Access component page.
- *TFields*, components corresponding to database columns, created either dynamically by Delphi at run time or at design time with the Fields Editor. Data controls use them to access data from a database. In addition, you can define calculated fields whose values are calculated based on the values of one or more database columns.

**Figure 3.1** Delphi Data Access components hierarchy

This chapter describes most of these components and the tools that Delphi provides to work with them. The *TQuery* component is described in Chapter 5, “Using SQL in applications.” The *TDatabase* component is described in Chapter 6, “Building a client/server application.”

## Using the TSession component

---

The *TSession* component is rarely used, but can be useful for some specialized purposes. Delphi creates a *TSession* component named “Session” each time an application runs. You cannot see nor explicitly create a *TSession* component, but you can use its methods and properties to globally affect the application.

## Controlling database connections

---

*TSession* provides global control over database connections for an application. The *Databases* property of *TSession* is an array of all the active databases in the session. The *DatabaseCount* property is an integer specifying the number of active databases (*TDatabase* components) in the Session. For more information on *TDatabase*, see Chapter 6, “Building a client/server application.”

*KeepConnections* is a Boolean property that specifies whether to keep inactive database connections. A database connection becomes inactive when a *TDatabase* component has no active datasets. By default, *KeepConnections* is True, and an application will maintain its connection to a database even if the connection is inactive. This is generally

preferable if an application will be repeatedly opening and closing tables in the database. If *KeepConnections* is *False*, a database connection will be closed as soon as the connection is inactive. The *DropConnections* method will drop all inactive database connections.

The *NetFileDir* property specifies the directory path of the BDE network control directory. The *PrivateDir* property specifies the path of the directory in which to store temporary files (for example, files used to process local SQL statements). You should set this property if there will be only one instance of the application running at a time. Otherwise, the temporary files from multiple application instances will interfere with each other.

## Getting database information

---

*TSession* has a number of methods that enable an application to get database-related information. Each method takes a *TStrings* component as its parameter and returns into a *TStrings* the specified information:

**Table 3.1** TSession methods

Method	Returns
<i>GetAliasNames</i>	Defined BDE alias names.
<i>GetAliasParams</i>	Parameters for the specified BDE alias.
<i>GetDatabaseNames</i>	Database names and BDE aliases defined.
<i>GetDriverNames</i>	Names of BDE drivers installed.
<i>GetDriverParams</i>	Parameters for the specified BDE driver.
<i>GetTableNames</i>	All table names in the specified database.

---

For more information on these methods, see the online *VCL Reference*.

## Using datasets

---

*TTable* and *TQuery* component classes are descended from *TDataSet* through *TDBDataSet*. These component classes share a number of inherited properties, methods, and events. For this reason, it is convenient to refer to them together as datasets, when the discussion applies to both *TTable* and *TQuery*.

This section describes the features of datasets that are common to *TTable* and *TQuery*. A subsequent section discusses features unique to *TTable*. Chapter 5, “Using SQL in applications” describes features unique to *TQuery*.

**Note** *TStoredProc* is also a dataset component since it is descended from *TDBDataSet*. Therefore, much of this section also applies to *TStoredProc* if the stored procedure returns a result set rather than a singleton result. For more information on *TStoredProc*, see Chapter 6, “Building a client/server application.”

## Dataset states

---

A dataset can be in the following states, also referred to as *modes*:

**Table 3.2** Dataset states

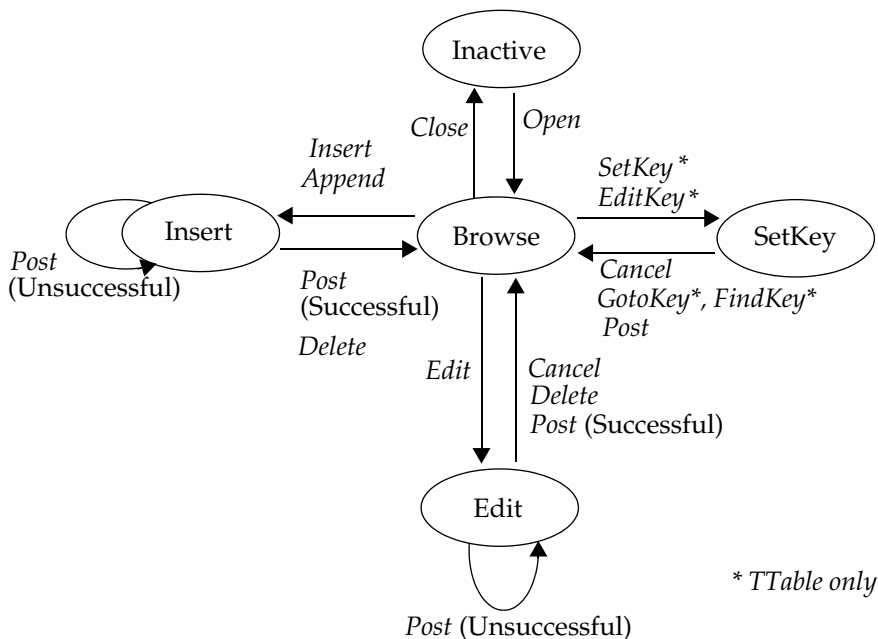

State	Description
Inactive	The dataset is closed.
Browse	The default state when a dataset is opened. Records can be viewed but not changed or inserted.
Edit	Enables the current row to be edited.
Insert	Enables a new row to be inserted. A call to <code>Post</code> inserts a new row.
SetKey	Enables <code>FindKey</code> , <code>GoToKey</code> , and <code>GoToNearest</code> to search for values in database tables. These methods only pertain to <code>TTable</code> components. For <code>TQuery</code> , searching is done with SQL syntax.
CalcFields	Mode when the <code>OnCalcFields</code> event is executed; prevents any changes to fields other than calculated fields. Rarely used explicitly.

An application can put a dataset into most states by calling the method corresponding to the state. For example, an application can put `Table1` in `Insert` state by calling `Table1.Insert` or `Edit` state by calling `Table1.Edit`. A number of methods return a dataset to `Browse` state, depending on the result of the method call. A call to `Cancel` will always return a dataset to `Browse` state.

`CalcFields` mode is a special case. An application cannot explicitly put a dataset into `CalcFields` mode. A dataset automatically goes into `CalcFields` mode when its `OnCalcFields` event is called. In `OnCalcFields`, an exception will occur if an application attempts to assign values to non-calculated fields. After the completion of `OnCalcFields`, the dataset returns to its previous mode.

The following diagram illustrates the primary dataset states and the methods that cause a dataset to change from one mode to another.

**Figure 3.2** Dataset state diagram

The *State* property specifies the current state of a dataset. The possible values correspond to the above states and are *dsInactive*, *dsBrowse*, *dsEdit*, *dsInsert*, *dsSetKey*, and *dsCalcFields*.

The *OnStateChange* event of *TDataSource* is called whenever the state of a data source's dataset changes. For more information, see "Using TDataSource events" on page 78.

## Opening and closing datasets

Before an application can access data through a dataset, the dataset must be open. There are two ways to open a dataset:

- Set the dataset's *Active* property to True, either at design time through the Object Inspector, or programmatically at run time. For example,

```
Table1.Active := True;
```

- Call the dataset's *Open* method at run time. For example,

```
Query1.Open
```

Both of these statements open the dataset and put it into Browse state.

Similarly, there are two ways to close a dataset:

- Set the dataset's *Active* property to False, either at design time through the Object Inspector, or programmatically at run time. For example,

```
Query1.Active := False;
```

- Call the dataset's *Close* method. For example,

```
Table1.Close;
```

Both of these statements return a dataset to Inactive state.

## Navigating datasets

---

There are two important concepts in understanding how Delphi handles datasets: *cursors* and *local buffers*. Each active dataset has a cursor, which is essentially a pointer to the *current row* in the dataset. A number of rows of data before and after the cursor are fetched by Delphi into the local buffer. Delphi will always fetch a number of rows into the local buffer sufficient to display the current row, plus an additional number of rows to reduce the refresh time as the user scrolls up or down in the dataset:

**Table 3.3** Navigational methods and properties

Method or property	Description
First method	Moves the cursor to the first row of a dataset.
Last method	Moves the cursor to the last row of the dataset.
Next method	Moves the cursor to the next row in the dataset.
Prior method	Moves the cursor to the prior row in the dataset.
BOF property	True when cursor is known to be at beginning of dataset, otherwise False.
EOF property	True when cursor is known to be at end of dataset, otherwise False.
MoveBy(n) method	Moves the cursor <i>n</i> rows forward in dataset, where <i>n</i> is a positive or negative integer.

Many of these methods are encapsulated in the *TDBNavigator* component. For more information on *TDBNavigator*, see Chapter 4, "Using Data Controls."

### The Next and Prior methods

The *Next* method moves the cursor down (forward) by one row in the table. For example, the following code for a button's *OnClick* event moves to the next row in Table1:

```
Table1.Next;
```

Similarly, the *Prior* method moves the cursor up (backward) by one row in the dataset. For example, to move to the previous row in the table, a button's *OnClick* text could be:

```
Table1.Prior
```

### The First and Last methods

As their names imply, the *First* and *Last* methods move to a dataset's first and last rows, respectively. For example, the following code for a button's *OnClick* event moves the cursor to the first row in Table1:

```
Table 1.First;
```

Similarly, the *Last* method moves to the last row in the dataset. To move to the last row in the table, a button's *OnClick* text could be:

```
Table1.Last
```

## The BOF and EOF properties

*BOF* is a read-only Boolean property that indicates whether a dataset is known to be at its first row. The *BOF* property returns a value of True only after:

- An application first opens a table
- A call to a Table's *First* method
- A call to a Table's *Prior* method fails

Databases are dynamic; while one application is viewing data, another may be inserting rows before or after the first application's notion of the current row. For this reason, for a non-empty table, it is unsafe to assume *BOF* is True.

For example, consider the following code:

```
Table1.Open; {BOF = True}  
Table1.Next; {BOF = False}  
Table1.Prior; {BOF = False}
```

After this code executes, *BOF* is False, even if there are no records before the current row. Once the table is open, Delphi can only determine *BOF* when an application explicitly calls *First* or a call to *Prior* fails. Similarly, Delphi can only determine *EOF* when an application explicitly calls *Last* or a call to *Next* fails.

The following code sample demonstrates a common technique for using the *BOF* property:

```
while not Table1.BOF do  
begin  
    DoSomething;  
    Table1.Prior;  
end;
```

In this code sample, the hypothetical function *DoSomething* is called on the current record and then on all the records between the current record and the beginning of the dataset. The loop will continue until a call to *Prior* fails to move the current record back. At that point, *BOF* will return a value of True and the program will break out of the loop.

To improve performance during the iteration through the table, call the *DisableControls* method before beginning the loop. This prevents data controls from displaying the iteration through the table, and speeds up the loop. After the loop completes, call the *EnableControls* method. Make sure to use a **try...finally...end** statement with the call to *EnableControls* in the **finally** clause. Otherwise, an exception will leave the application's controls inactive.

The same principles apply to the *EOF* property, which returns a value of True after:

- An application opens an empty dataset
- A call to a Table's *Last* method
- A call to a Table's *Next* fails

The following code sample provides a simple means of iterating over all the records in a dataset:

```
Table1.DisableControls;
try
    Table1.First;
while not Table1.EOF do
begin
    DoSomething;
    Table1.Next;
end;
finally
    Table1.EnableControls;
end.
```

In this case, the *Next* method and the *EOF* property are used together to reach the end of the dataset.

**Caution** A common error in using such properties in navigating a dataset is to use a **repeat. . . until** loop while forgetting to call *Table1.Next*, as in the following example:

```
Table1.First;
repeat
    DoSomething;
until Table1.EOF;
```

If code like this were executed, the application would appear to “freeze,” since the same action would be endlessly performed on the first record of the dataset, and the *EOF* property would never return a value of True.

On an empty table, opening or executing any navigational methods will return True for both *BOF* and *EOF*.

## The MoveBy function

The *MoveBy* function enables an application to move through a dataset backward or forward by a specified number of records. This function takes only one parameter, the number of records by which to move. Positive integers indicate a forward move, while negative integers indicate a backward move.

For example, to move two records forward in *Table1*, use the following:

```
Table1.MoveBy(2);
```

When using this function, keep in mind that datasets are fluid entities, and the record which was five records back a moment ago may now be only four records back, or six records, or an unknown number of records, because multiple users may be simultaneously accessing the database and modifying its data.

**Note** There is no functional difference between calling *Table1.Next* and calling *Table1.MoveBy(1)*, just as there is no functional difference between calling *Table1.Prior* or calling *Table1.MoveBy(-1)*.

## Modifying data in datasets

---

The following methods enable an application to insert, update, and delete data in datasets:

**Table 3.4** Methods to insert, update and delete data in datasets

Method	Description
Edit	Puts the dataset into Edit state. If a dataset is already in Edit or Insert state, a call to <i>Edit</i> has no effect.
Append	Posts any pending data, moves current record to the end of the dataset, and puts the dataset in Insert state.
Insert	Posts any pending data, and puts the dataset in Insert state.
Post	Attempts to post the new or altered record to the database. If successful, the dataset is put in Browse state; if unsuccessful, the dataset remains in its current state.
Cancel	Cancels the current operation and puts the dataset into Browse state.
Delete	Deletes the current record and puts the dataset in Browse state.

---

### The CanModify property

*CanModify* is a read-only property that specifies whether an application can modify the data in a dataset. When *CanModify* is False, then the dataset is read-only, and cannot be put into Edit or Insert state. When *CanModify* is True, the dataset can enter Edit or Insert state. Even if *CanModify* is True, it is not a guarantee that a user will be able to insert or update records in a table. Other factors may come in to play, for example, SQL access privileges.

*TTable* has a *ReadOnly* property that requests write privileges when set to False. When *ReadOnly* is True, *CanModify* will automatically be set to False. When *ReadOnly* is False, *CanModify* will be True if the database allows read and write privileges for the dataset and the underlying table. For more information, see “Using *TTable*.”

### Posting data to the database

The *Post* method is central to a Delphi application’s interaction with a database table. *Post* behaves differently depending on a dataset’s state.

- In Edit state, *Post* modifies the current record.
- In Insert state, *Post* inserts or appends a new record.
- In SetKey state, *Post* returns the dataset to Browse state.

Posting can be done explicitly, or implicitly as part of another procedure. When an application moves off the current record, Delphi calls *Post* implicitly. Calls to the *First*, *Next*, *Prior*, and *Last* methods perform a *Post* if the table is in Edit or Insert state. The *Append* and *Insert* methods also implicitly perform a *Post* of any pending data.

**Note** *Post* is not called implicitly by the *Close* method. Use the *BeforeClose* event to post any pending edits explicitly.

### Editing records

A dataset must be in Edit state before an application can modify records in the underlying table. The *Edit* method puts a dataset in Edit state. When in Edit state, the

*Post* method will change the current record. If a dataset is already in Edit state, a call to *Edit* has no effect.

The *Edit* and *Post* methods are often used together. For example,

```
Table1.Edit;  
Table1.FieldByName('CustNo').AsString := '1234';  
Table1.Post;
```

The first line of code in this example places the dataset in Edit mode. The next line of code assigns the string “1234” to the CustNo field. Finally, the last line posts, or writes to the database, the data just modified.

## Adding new records

To add a new record to a dataset, an application can call either the *Insert* method or the *Append* method. Both methods put a dataset into Insert state. *Insert* opens a new, empty record after the current record. *Append* moves the current record to the end of the dataset and opens a new, empty record.

When an application calls *Post*, the new record will be inserted in the dataset in a position based on its index, if defined. Thus, for indexed tables, *Append* and *Insert* perform similarly. If no index is defined on the underlying table, then the record will maintain its position—so *Append* will add the record to the end of the table, and *Insert* will insert it at the cursor position when the method was called. In either case, posting a new record in a data grid may cause all the rows before and after the new record to change as the dataset follows the new row to its indexed position and then fetches data to fill the grid around it.

## Deleting records

The *Delete* method deletes the current record from a dataset and leaves the dataset in Browse mode. The cursor moves to the following record.

## Canceling changes

An application can undo changes made to the current record at any time, if it has not yet directly or indirectly called *Post*. For example, if a Table is in Edit state, and a user has changed the data in one or more fields, the application can return the record back to its original values by calling the Table’s *Cancel* method. A call to *Cancel* always returns a dataset to Browse state.

## Working with entire records

The following methods enable an application to work with an entire record in one statement:

**Table 3.5** Methods used to work with entire records

Method	Description
<i>AppendRecord</i> ([array of values])	Appends a record with the specified column values at the end of a table; analogous to <i>Append</i> . Performs an implicit <i>Post</i> .

**Table 3.5** Methods used to work with entire records (continued)

Method	Description
<i>InsertRecord</i> ([array of values])	Inserts the specified values as a record after the current cursor position of a table; analogous to Insert. Performs an implicit Post.
<i>SetFields</i> ([array of values])	Sets the values of the corresponding fields; analogous to assigning values to TFields. Application must perform a Post.

Each method takes a comma-delimited array of values as its argument, where each value corresponds to a column in the underlying table. The values can be literals, variables, null, or **nil**. If the number of values in an argument is less than the number of columns in a dataset, then the remaining values are assumed to be null.

For un-indexed tables, *AppendRecord* adds a record to the end of the table and *InsertRecord* inserts a record after the current cursor position. For indexed tables, both methods place the record in the correct position in the table, based on the index. In both cases, the methods move the cursor to the record's position.

*SetFields* assigns the values specified in the array of parameters to fields in the dataset. The application must first perform an *Edit* to put the dataset in Edit state. To modify the current record, it must then perform a *Post*.

Since these methods depend explicitly on the structure of the underlying tables, an application should use them only if the table structure will not change.

For example, the COUNTRY table has columns for Name, Capital, Continent, Area, and Population. If Table1 were linked to the COUNTRY table, the following statement would insert a record into the COUNTRY table:

```
Table1.InsertRecord(['Japan', 'Tokyo', 'Asia']);
```

The statement does not specify values for Area and Population, so it will insert Null values for these columns. The table is indexed on Name, so the statement would insert the record based on the alphabetic collation of "Japan".

To update the record, an application could use the following code:

```
Table1.Edit;
Table1.SetRecord(nil, nil, nil, 344567, 164700000);
Table1.Post;
```

This code assumes that the cursor will be positioned on the record just entered for Japan. It assigns values to the Area and Population fields and then posts them to the database. Notice the three **nil**s that act as place holders for the first three columns, which are not changed.

## Setting the update mode

The *UpdateMode* property of a dataset determines how Delphi will find records being updated in a SQL database. This property is important in a multi-user environment when users may retrieve the same records and make conflicting changes to them.

When a user posts an update, Delphi uses the original values in the record to find the record in the database. This approach is similar to an optimistic locking scheme. *UpdateMode* specifies which columns Delphi uses to find the record. In SQL terms,

*UpdateMode* specifies which columns are included in the WHERE clause of an UPDATE statement. If Delphi cannot find a record with the original values in the columns specified (if another user has changed the values in the database), Delphi will not make the update and will generate an exception.

The *UpdateMode* property may have the following values:

- *WhereAll* (the default): Delphi uses every column to find the record being updated. This is the most restrictive mode.
- *WhereKeyOnly*: Delphi uses only the key columns to find the record being updated. This is the least restrictive mode and should be used only if other users will not be changing the records being updated.
- *WhereChanged*: Delphi uses key columns and columns that have changed to find the record being updated.

For example, consider a COUNTRY table with columns for NAME (the key), CAPITAL, and CONTINENT. Suppose you and another user simultaneously retrieve a record with the following values:

- NAME = "Philippines"
- CAPITAL = "Nairobi"
- CONTINENT = "Africa"

Both you and the other user notice that the information in this record is incorrect and should be changed. Now, suppose the other user changes CONTINENT to "Asia," CAPITAL to "Manila," and posts the change to the database. A few seconds later, you change NAME to "Kenya" and post your change to the database.

If your application has *UpdateMode* set to *WhereKey* on the dataset, Delphi compares the original value of the key column (NAME = "Philippines") to the current value in the database. Since the other user did not change NAME, your update occurs. You think the record is now ["Kenya," "Nairobi," "Africa"] and the other user thinks it is ["Philippines," "Asia," "Manila"]. Unfortunately, it is actually ["Kenya," "Asia," "Manila"], which is still incorrect, even though both you and the other user think you have corrected the mistake. This problem occurred because you had *UpdateMode* set to its least restrictive level, which does not protect against such occurrences.

If your application had *UpdateMode* set to *WhereAll*, the Delphi would check all the columns when you attempt to make your update. Since the other user changed CAPITAL and CONTINENT, Delphi would not let you make the update. When you retrieved the record again, you would see the new values entered by the other user and realize that the mistake had already been corrected.

## Bookmarking data

---

It is often useful to mark a particular location in a table so that you can quickly return to it when desired. Delphi provides this functionality through *bookmark* methods. These methods enable you to put a bookmark in the dataset, and quickly return to it later.

The three bookmarking methods are

- *GetBookmark*
- *GoToBookmark*
- *FreeBookmark*

These are used together. The *GetBookmark* function returns a variable of type *TBookmark*. A *TBookmark* contains a pointer to a particular location in a dataset. When given a bookmark, the *GoToBookmark* method will move an application's cursor to that location in the dataset.

*FreeBookmark* frees memory allocated for the specified bookmark. A call to *GetBookmark* allocates memory for the bookmark, so an application should call *FreeBookmark* before exiting, and before every use of a bookmark.

The following code illustrates a typical use of bookmarking:

```
procedure DoSomething;
var Bookmark: TBookmark;
begin
    Bookmark := Table1.GetBookmark; {allocate}
    Table1.DisableControls; {Disengage data controls}
    try
        Table1.First;
        while not Table1.EOF do
            begin
                {Do Something}
                Table1.Next;
            end;
        finally
            Table1.GotoBookmark(Bookmark);
            Table1.EnableControls;
            Table1.FreeBookmark(Bookmark); {deallocate}
        end;
    end;
```

Notice the careful positioning of statements in this code. If the call to *GetBookmark* fails, controls are not disabled. If it succeeds, the bookmark is always freed and controls are always enabled.

## Disabling, enabling, and refreshing data-aware controls

---

The *DisableControls* method disables all data-aware controls linked to a dataset. This method should be used with caution (for example, when programmatically iterating or searching through a dataset) to prevent “flickering” of the display as the cursor moves. As soon as the cursor is repositioned, an application should call the *EnableControls* method to re-enable data controls. It is important to re-enable controls with *EnableControls* as soon as the application completes its iteration or searching, to keep the form synchronized with the underlying dataset. Use a **try...finally** statement as in the example above.

The *Refresh* method flushes all local buffers and retrieves data from the specified dataset again. The dataset must be open. You can use this function to update a table if you think

the table or the data it contains might have changed. Refreshing a table can sometimes lead to unexpected results. For example, if a user is viewing a record that has been deleted, then it will seem to disappear the moment the application calls *Refresh*. Similarly, data can appear to change while a user is viewing it if another user changes or deletes a record after the data was originally fetched and before a call to *Refresh*.

## Using dataset events

---

Datasets have a number of events that enable an application to perform validation, compute totals, and perform other tasks depending on the method performed by the dataset. The events are listed in the following table.

**Table 3.6** Dataset events

Event	Description
<i>BeforeOpen, AfterOpen</i>	Called before/after a dataset is opened.
<i>BeforeClose, AfterClose</i>	Called before/after a dataset is closed.
<i>BeforeInsert, AfterInsert</i>	Called before/after a dataset enters Insert state.
<i>BeforeEdit, AfterEdit</i>	Called before/after a dataset enters Edit state.
<i>BeforePost, AfterPost</i>	Called before/after changes to a table are posted.
<i>BeforeCancel, AfterCancel</i>	Called before/after the previous state is canceled.
<i>BeforeDelete, AfterDelete</i>	Called before/after a record is deleted.
<i>OnNewRecord</i>	Called when a new record is created; used to set default values.
<i>OnCalcFields</i>	Called when calculated fields are calculated.

---

For more information on these events and methods of the *TDataSet* component, refer to the online VCL reference.

### Abort a method

To abort a method such as an *Open* or *Insert*, raise an exception or call the *Abort* procedure in any of the *Before* methods (*BeforeOpen*, *BeforeInsert*, and so on). For example, the following code confirms a delete operation:

```
procedure TForm1.TableBeforeDelete (Dataset: TDataSet);
begin
    if MessageDlg('Delete This Record?', mtConfirmation, mbYesNoCancel, 0) = mrYes then
        Abort;
end;
```

### Using OnCalcFields

The *OnCalcFields* event is used to set the values of calculated fields. The *AutoCalcFields* property determines when *OnCalcFields* is called. If *AutoCalcFields* is *True*, then *OnCalcFields* is called when:

- The dataset is opened.
- Focus moves from one visual component to another, or from one column to another in a *DBDataGrid*.

- A record is retrieved from the database.

*OnCalcFields* is also called whenever a non-calculated field's value changes, regardless of the setting of *AutoCalcFields*.

Typically, the *OnCalcFields* event will be called often, so it should be kept short. Also, if *AutoCalcFields* is *True*, *OnCalcFields* should not perform any actions that modify the dataset (or the linked dataset if it is part of a master-detail relationship), because this can lead to recursion. For example, if *OnCalcFields* performs a *Post*, and *AutoCalcFields* is *True*, then *OnCalcFields* will be called again, leading to another *Post*, and so on.

If *AutoCalcFields* is *False*, then *OnCalcFields* is called when the dataset's *Post* method is called (or any method that implicitly calls *Post*, such as *Append* or *Insert*).

While the *OnCalcFields* event is executed, a dataset will be put in *CalcFields* mode. When a dataset is in *CalcFields* mode, you cannot set the values of any fields other than calculated fields. After *OnCalcFields* is completed, the dataset will return to its previous mode.

## Using TTable

---

*TTable* is one of the most important database component classes. Along with the other dataset component class, *TQuery*, it enables an application to access a database table. This section describes the most important properties that are unique to *TTable*.

### Specifying the database table

---

*TableName* specifies the name of the database table to which the *TTable* component is linked. You can set this property at design time through the Object Inspector.

The *DatabaseName* property specifies where Delphi will look for the specified database table. It can be a BDE alias, an explicit specification, or the *DatabaseName* defined by any *TDatabase* component in the application. For Paradox and dBASE tables, an explicit specification is a directory path; for SQL tables, it is a directory path and database name.

Instead of an actual directory path or database name, *DatabaseName* can also be a BDE alias. The advantage of this is that you can change the data source for an entire application by simply changing the alias definition in the BDE Configuration Utility. For more information on using the BDE Configuration Utility, see Appendix B, "Using the BDE configuration utility." For more information on the *DatabaseName* property, see the online VCL reference.

**Note** Neither of these properties can be changed when a table is open—that is, when the table's *Active* property is set to a value of *True*.

### The TableType property

---

The *TableType* property specifies the type of the underlying database table. This property is not used for SQL tables.

If *TableType* is set to *Default*, the table's file-name extension determines the table type:

- Extension of .DB or no file-name extension: Paradox table
- Extension of .DBF : dBASE table
- Extension of .TXT : ASCII table

If the value of *TableType* is not *Default*, then the table will always be of the specified *TableType*, regardless of file-name extension.

## Searching a table

---

*TTable* has a number of functions that will search for values in a database table:

- Goto functions
- Find functions

The easiest way to search for values is with the Find functions, *FindKey* and *FindNearest*. These two functions combine the functionality of the basic Goto functions, *SetKey*, *GoToKey*, and *GoToNearest*, which are described first.

In dBASE and Paradox tables, these functions can search only on index fields. In SQL tables, they can search on any fields, if the field name is specified in the *IndexFieldNames* property of the *TTable*. For more information, see “Indexes” on page 74.

To search a dBASE or Paradox table for a value in a non-index field, use SQL SELECT syntax with a *TQuery* component. For more information on using SQL and *TQuery* components, see Chapter 5, “Using SQL in applications.”

## Using Goto functions

The *GoToKey* and *GoToNearest* methods enable an application to search a database table using a key. *SetKey* puts a table in “search mode,” more accurately referred to as SetKey state. In SetKey state, assignments indicate values for which to search for in indexed fields. *GoToKey* then moves the cursor to the first row in the table that matches those field values.

For example, the following code could be used in the *OnClick* event of a button:

```
procedure TSearchDemo.SearchExactClick(Sender: TObject);
begin
  Table1.SetKey; {First field is the key}
  Table1.Fields[0].AsString := Edit1.Text;
  Table1.GoToKey;
end;
```

The first line of code after **begin** puts *Table1* in SetKey state. This indicates that the following assignment to the table’s *Fields* property specifies a search value. The first column in the table, corresponding to *Fields[0]*, is the index. In this example, the value the application searches for is determined by the text the user types into the edit control, *Edit1*. Finally, *GoToKey* performs the search, moving the cursor to the record if it exists.

*GoToKey* is a Boolean function that moves the cursor and returns True if the search is successful. If the search is unsuccessful, it returns False and does not change the position of the cursor. For example,

```

Table1.SetKey;
Table1.Fields[0].AsString := 'Smith';
if not Table1.GotoKey
    then ShowMessage('Record Not Found');

```

If the search does not find a record with a first column matching “Smith,” the *ShowMessage* function displays a dialog box with the “Record Not Found” message.

If a table has more than one key column, and you want to search for values in a sub-set of the keys, set *KeyFieldCount* to the number of columns on which you are searching. For example, if a table has three columns in its primary key, and you want to search for values in just the first, set *KeyFieldCount* to 1. For tables with multiple-column keys, you can search only for values in contiguous columns, beginning with the first. That is, you can search for values in the first column, or the first and second, or the first, second, and third, but not just the first and third.

*GoToNearest* is similar, except it finds the nearest match to a partial field value. It can be used only for columns of string data type. For example,

```

Table1.SetKey;
Table1.Fields[0].AsString := 'Sm';
Table1.GoToNearest;

```

If a record exists with “Sm” as the first two characters, the cursor will be positioned on that record. Otherwise, the position of the cursor does not change and *GoToNearest* returns False.

If it is not searching on the primary index of a local table, then an application must specify the column names to use in the *IndexFieldNames* property or the name of the index to use in the *IndexName* property of the table. For example, if the CUSTOMER table had a secondary index named “CityIndex” on which you wanted to search for a value, you would need to set the value of the table’s *IndexName* property to “CityIndex.” You could then use the following syntax when you searching on this field:

```

Table1.IndexName := 'CityIndex';
Table1.Open;
Table1.SetKey;
Table1.FieldByName('City').AsString := Edit1.Text;
Table1.GoToNearest;

```

Because indexes often have non-intuitive names, you can use the *IndexFieldNames* property instead to specify the names of indexed fields.

Each time an application calls *SetKey*, it must set all the field values for which it will search. That is, *SetKey* clears any existing values from previous searches. To keep previous values, use *EditKey*.

For example, to extend the above search to find a record with the specified city name in a specified country, an application could use the following code:

```

Table1.EditKey;
Table1.FieldByName('Country').AsString := Edit2.Text;

```

## Using Find functions

The Find functions, *FindKey* and *FindNearest* provide easy way to search a table. They combine the functionality of *SetKey*, field assignment, and Goto functions into a single statement.

Each of these methods takes a comma-delimited array of values as its argument, where each value corresponds to a column in the underlying table. The values can be literals, variables, null, or **nil**. If the number of values in an argument is less than the number of columns in the database table, then the remaining values are assumed to be null. The functions will search for values specified in the array in the current index.

*FindKey* is similar to *GotoKey*:

- It will put a table in search mode (SetKey state).
- It will find the record in the table that matches the specified values. If a matching record is found, it moves the cursor there, and returns True.
- If a matching record is not found, it does not move the cursor, and returns False.

For example, if Table1 is indexed on its first column, then the statement:

```
Table1.FindKey([Edit1.Text]);
```

will perform the same function as the three statements:

```
Table1.SetKey; {First field is the key}  
Table1.Fields[0].AsString := Edit1.Text;  
Table1.GoToKey;
```

*FindNearest* is similar to *GotoNearest*, in that it will move the cursor to the row with the nearest matching value. This can be used for columns of string data type only.

Both of these functions work by default on the primary index column. To search the table for values in other indexes, you must specify the field name in the table's *IndexFieldNames* property or the name of the index in the *IndexName* property.

**Note** With Paradox or dBASE tables, these methods work only with indexed fields. With SQL databases, they can work with any columns specified in the *IndexFieldNames* property.

## The KeyExclusive property

The *KeyExclusive* property indicates whether a search will position the cursor on or after the specified record being searched for. If *KeyExclusive* is False (the default), then *GoToNearest* and *FindNearest* will move the cursor to the record that matches the specified values. If True, then the search functions will go the record immediately following the specified key, if found.

## Limiting records retrieved by an application

---

Tables in the real world can be huge, so applications often need to limit the number of rows they work with. The following methods of *TTable* enable an application to work with a subset of the data in a database table:

- *SetRangeStart* and *EditRangeStart*
- *SetRangeEnd* and *EditRangeEnd*
- *SetRange*([Start Values], [End Values])
- *ApplyRange*
- *CancelRange*

*SetRangeStart* indicates that subsequent assignments to field values will specify the start of the range of rows to include in the application. *SetRangeEnd* indicates that subsequent assignments will specify the end of the range of rows to include. Any column values not specified are not considered. The corresponding methods *EditRangeStart* and *EditRangeEnd* indicate to keep existing range values and update with the succeeding assignments.

*ApplyRange* applies the specified range. If *SetRangeStart* has not been called when *ApplyRange* is called, then the start range will be the beginning of the table; likewise, if *SetRangeEnd* has not been called, the end range will be the end of the table. *CancelRange* cancels the range filter and includes all rows in the table.

The *SetRange* function combines *SetRangeStart*, *SetRangeEnd*, and field assignments into a single statement that takes an array of values as its argument.

**Note** With Paradox or dBASE tables, these methods work only with indexed fields. With SQL databases, they can work with any columns specified in the *IndexFieldNames* property.

For example, suppose there is a form with a *TTable* component named *Cust*, linked to the CUSTOMER table. CUSTOMER is indexed on its first column (*CustNo*). The form also has two Edit components named *StartVal* and *EndVal*, and you have used the Fields Editor to create a *TField* component for the *CustNo* column. Then these methods could be applied (for example, in a button's *OnClick* event) as follows:

```
Cust.SetRangeStart;
CustCustNo.AsString := StartVal.Text;
Cust.SetRangeEnd;
if EndVal.Text <> '' then
    CustCustNo.AsString := EndVal.Text;
Cust.ApplyRange;
```

Notice that this code first checks that the text entered in *EndVal* is not null before assigning any values to Fields. If the text entered for *StartVal* is null, then all records from the beginning of the table will be included, since all values are greater than null. However, if the text entered for *EndVal* is null, then no records will be included, since none are less than null.

This code could be re-written using the *SetRange* function as follows:

```
if EndVal.Text <> '' then
    Cust.SetRange([StartVal.Text], [EndVal.Text]);
Cust.ApplyRange;
```

## Using partial keys

If a key is composed of one or more string fields, these methods support partial keys. For example, if an index is based on the *LastName* and *FirstName* columns, the following range specifications are valid:

```
Table1.SetRangeStart;  
Table1.FieldName('LastName').AsString := 'Smith';  
Table1.SetRangeEnd;  
Table1.ApplyRange;
```

This will include all records where LastName greater than or equal to “Smith.” The value specification could also be:

```
Table1.FieldName('LastName').AsString := 'Sm';
```

This would include records which have LastName greater than or equal to “Sm.” The following would include records with a LastName greater than or equal to “Smith” and a FirstName greater than or equal to “J”:

```
Table1.FieldName('LastName').AsString := 'Smith';  
Table1.FieldName('FirstName').AsString := 'J';
```

## The KeyExclusive property

The *KeyExclusive* property determines whether the filtered range excludes the range boundaries. The default is *False*, which means rows will be in the filtered range if they are greater than or equal to the start range specified and less than or equal to the end range specified. If *KeyExclusive* is *True*, the methods will filter strictly greater than and less than the specified values.

## Indexes

---

An *index* determines how records are sorted when a Delphi application displays data. By default, Delphi displays data in ascending order, based on the values of the primary index column(s) of a table.

Delphi supports SQL indexes, maintained indexes for Paradox tables, and maintained .MDX (production) indexes for dBASE tables. Delphi does not support:

- Non-maintained indexes on Paradox tables.
- Non-maintained or .NDX indexes of dBASE tables.
- The *IndexFieldCount* property for a dBASE table opened on an expression index.

The *GetIndexNames* method returns a list of the names of available indexes on the underlying database table. For Paradox tables, the primary index is unnamed and therefore not returned by *GetIndexNames*. To use a primary index on a Paradox table, set the corresponding *TTable's IndexName* to a null string.

*IndexFields* is an array of field names used in the index. *IndexFieldCount* is the number of fields in the index. *IndexFieldCount* and *IndexFields* are read-only properties that are available only during run-time.

Use the *IndexName* property to sort or search a table on an index other than the primary index. In other words, to use the primary index of a table, you need do nothing with the *IndexName* property. To use a secondary index, however, you must specify it in *IndexName*.

For tables in a SQL database, the *IndexFieldNames* property specifies the columns to use in the ORDER BY clause when retrieving data. The entry for this property is a

semicolon-delimited list of field names. Records are sorted by the values in the specified fields. Sorting can be only in ascending order. Case-sensitivity depends on the server being used.

For example, to sort customer records in an SQL table by zip code and then by customer number, enter the following for the *IndexFieldNames* property:

```
ZipCode;CustNo
```

For Paradox and dBASE tables, Delphi will pick an index based on the columns specified in *IndexFieldNames*. An error will occur if you specify a column or columns that cannot be mapped to an existing index.

The *IndexName* and *IndexFieldNames* properties are mutually exclusive. Setting one property clears the value of the other.

## The Exclusive property

---

The *Exclusive* property indicates whether to open the table with an exclusive lock. If True, no other user will be able to access it at the same time. You cannot open a table in Exclusive mode if another user is currently accessing the table.

If the underlying table is in a SQL database, an exclusive table-level lock may allow others to read data from the table but not modify it. Some servers may not support exclusive table-level locks, depending on the server. Refer to your server documentation for more information.

## Other properties and methods

---

In addition to dataset properties shared with *TQuery*, *TTable* has a number of unique methods and properties. For example, the unique methods include

- *EmptyTable*, which deletes all records (rows) in the table.
- *DeleteTable*, which deletes the table.
- *BatchMove*, which copies data and table structures from one table to another, similar to the operation of *TBatchMove*.

A few of the more important properties and methods are discussed in this section. For a complete list and descriptions, see the online *VCL Reference*.

## The ReadOnly and CanModify properties

Before opening a *TTable*, set *ReadOnly* False to request read and write privileges for the dataset. Set *ReadOnly* to True to request read-only privileges for the dataset. Depending on the characteristics of the underlying table, the request for read and write privileges may or may not be granted by the database.

*CanModify* is a read-only property of datasets that reflects the actual rights granted for the dataset. When *ReadOnly* is True, *CanModify* will automatically be set to False. When *ReadOnly* is False, *CanModify* will be True if the database allows read and write privileges for the dataset and the underlying table.

When *CanModify* is False, then the table is read-only, and the dataset cannot be put into Edit or Insert state. When *CanModify* is True, the dataset can enter Edit or Insert state. Even if *CanModify* is True, it is not a guarantee that a user will be able to insert or update records in a table. Other factors may come in to play, for example, SQL access privileges.

## The GoToCurrent method

*GoToCurrent* is a method that synchronizes two *TTable* components linked to the same database table and using the same index. This method takes a *TTable* component as its argument, and sets the cursor position of the *TTable* to the current cursor position of the argument. For example,

```
Table1.GotoCurrent (Table2);
```

## Creating master-detail forms

The *MasterSource* and *MasterFields* are used to define one-to-many relationships between two tables. The *MasterSource* property is used to specify a data source from which the table will get data for the master table. For instance, if you link two tables in a master-detail relationship, then the detail table can track the events occurring in the master table by specifying the master table's *TDataSource* in this property.

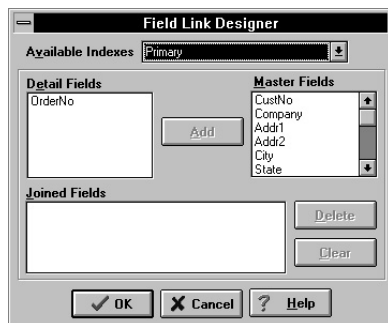

To link tables based on values in multiple column names, use a semicolon delimited list:

```
Table1.MasterFields := 'OrderNo;ItemNo';
```

## The Field Link Designer

At design time, when you double-click (or click on the ellipsis button) on the *MasterFields* property in the Object Inspector, the Field Link Designer dialog box opens.

Figure 3.3 Field Link designer

The Field Link Designer provides a visual way to link master and detail tables. The Available Indexes combo box shows the currently selected index by which to join the two tables. For Paradox tables, this will be “Primary” by default, indicating that the primary index of the detail field will be used. Any other named indices defined on the table will be shown in the drop-down list.

Select the field you want to use to link the detail table in the Detail Fields list, the field to link the master table in the Master Fields list, and then choose Add. The selected fields will be displayed in the Joined Fields list box. For example,

```
OrderNo -> OrderNo
```

For tables on a database server, the Available Indexes combo box will not appear, and you must select the detail and master fields to join manually in the Detail Fields and Master Fields list boxes.

## Using TDataSource

---

*TDataSource* acts as a conduit between datasets and data-aware controls. Often the only thing you will do with a *TDataSource* component is to set its *DataSet* property to an appropriate dataset object. Then you will set data controls' *DataSource* property to the specific *TDataSource*. You also use *TDataSource* components to link datasets to reflect master-detail relationships.

### Using TDataSource properties

---

*TDataSource* has only a few published properties in addition to the standard *Name* and *Tag* properties.

#### The DataSet property

The *DataSet* property specifies the name of the dataset from which the *TDataSource* will get its data. You can also set the *DataSet* property to a dataset on another form to synchronize the data controls on the two forms. For example,

```
procedure TForm2.FormCreate (Sender : TObject);
begin
    DataSource1.DataSet := Form1.Table1;
end;
```

#### The Enabled property

The *Enabled* property can temporarily disconnect a *TDataSource* from its *TDataSet*. When set to *False*, all data controls attached to the data source will go blank and become inactive until *Enabled* is set to *True*.

In general, it is recommended to use datasets' *DisableControls* and *EnableControls* methods to perform this function, because they affect all attached data sources.

#### The AutoEdit property

The *AutoEdit* property of *TDataSource* specifies whether datasets connected to the data source automatically enter Edit state when the user starts typing in data-aware controls linked to the dataset. If *AutoEdit* is *True* (the default), Delphi automatically puts the dataset in Edit state when a user types in a linked data-aware control. Otherwise, a dataset enters Edit state only when the application explicitly calls its *Edit* method. For more information on dataset states, see "Dataset states" on page 58.

## Using TDataSource events

---

*TDataSource* has three events associated with it:

- *OnDataChange*
- *OnStateChange*
- *OnUpdateData*

### The OnDataChange event

*OnDataChange* is called whenever the cursor moves to a new record. In other words, if an application calls *Next*, *Previous*, *Insert*, or any method that leads to a change in the cursor position, then an *OnDataChange* is triggered.

This event is useful if an application is keeping components synchronized manually.

### The OnUpdateData event

*OnUpdateData* is called whenever the data in the current record is about to be updated. For instance, an *OnUpdateData* event will occur after *Post* is called but before the data is actually posted to the database.

This event is useful if an application uses a standard (non-data aware) control and needs to keep it synchronized with a dataset.

### The OnStateChange event

*OnStateChange* is called whenever the mode (state) of a data source's dataset changes. A dataset's *State* property records its current state. This event is useful for performing actions as a *TDataSource*'s state changes, as the following examples illustrate.

During the course of a normal database session, a dataset's state will change frequently. To track these changes, you can use code in *OnStateChange* such as the following example that displays the current state in a Label component:

```
procedure TForm1.DataSource1.StateChange(Sender:TObject);
var
  S:String;
begin
  case Table1.State of
    dsInactive: S := 'Inactive';
    dsBrowse: S := 'Browse';
    dsEdit: S := 'Edit';
    dsInsert: S := 'Insert';
    dsSetKey: S := 'SetKey';
  end;
  Label1.Caption := S;
end;
```

Similarly, *OnStateChange* can be used to enable or disable buttons or menu items based on the current state. For example,

```
procedure TForm1.DataSource1.StateChange(Sender: TObject);
begin
  InsertBtn.Enabled := (Table1.State = dsBrowse);
```

```
CancelBtn.Enabled := Table1.State in [dsInsert, dsEdit, dsSetKey];
...
end;
```

## Using TFields and the Fields Editor

---

*TField* components correspond to database columns. They are created

- At run time by Delphi whenever a dataset component is active. This creates a dynamic set of *TFields* that mirrors the columns in the table at that time.
- At design time through the Fields Editor. This creates a persistent set of *TFields* that does not change, even if the structure of the underlying table changes.

There are *TField* components corresponding to all possible data types, including *TStringField*, *TSmallintField*, *TIntegerField*, *TWordField*, *TBooleanField*, *TFloatField*, *TCurrencyField*, *TBCDField*, *TDateField*, *TTimeField*, and *TDateTimeField*. This chapter discusses *TFields* in general, and the discussion applies to all the different sub-types. For information on the properties of a specific type, see the online *VCL Reference*.

### What are TField components?

---

All Delphi data-aware components rely on an underlying object class, *TField*. Although not visible on forms, *TField* components are important because they provide an application a direct link to a database column. *TFields* contain properties specifying a column's data type, current value, display format, edit format, and other characteristics. *TField* components also provide events, such as *OnValidate*, that can be used to implement field-based validation rules.

Each column retrieved from a table has a corresponding *TField* component. By default, *TField* components are dynamically generated at design time when the *Active* property of a *TTable* or *TQuery* component is set to True. At run time, these components are also dynamically generated. Dynamic generation means Delphi builds *TField* components based on the underlying physical structure of a database table each time the connection to the table is activated. Thus, dynamically generated *TFields* always correspond to the columns in the underlying database tables.

To generate a persistent list of *TField* components for an application, use the Fields Editor. Using the Fields Editor to specify a persistent list of *TField* components is smart programming. Creating *TField* components with the Fields Editor provides efficient, readable, and type-safe programmatic access to underlying data. It guarantees that each time your application runs, it uses and displays the same columns, in the same order, every time, even if the physical structure of the underlying database has changed. Creating *TField* components at design time guarantees that data-aware components and program code that rely on specific fields always work as expected. If a column on which a persistent *TField* component is based is deleted or changed, then Delphi generates an exception rather than running the application against a non-existent column or mismatched data.

## Using the Fields Editor

---

When *TTable* and *TQuery* components are connected to a database and their *Active* properties are set to True, they dynamically generate a *TField* component for each column in a table or query. Each *TField* component stores display-related information about a field. The display information is used by data control components, such as *TDBEdit* and *TDBGrid*, to format data for display in a form. You can make *TField* components persistent and edit their display characteristics by invoking the Fields Editor.

The Fields Editor enables you to:

- Generate a persistent list of *TField* components.
- Modify the display properties of persistent *TField* components.
- Remove *TField* components from the list of persistent components.
- Add new *TField* components based on existing columns in a table.
- Define calculated *TField* components that behave just like physical data columns, except that their values are computed programmatically.

### Starting the Fields Editor

To invoke the Fields Editor for a *TTable* or *TQuery* component,

- Double-click the mouse on the component, or
- Select the component, right click the mouse, and select Fields Editor from the pop-up menu.

The Fields Editor opens, with the name of the Form and Table on which it was invoked in the title bar:

**Figure 3.4** Fields Editor

The Fields list box displays the names of persistent *TField* components associated with the data access component. The first time you invoke the Fields Editor on a particular a *TTable* or *TQuery* component, the Fields list is empty because all *TFields* are dynamically created. If any *TField* objects are listed in *Fields*, then data-aware components can only display data from those fields. You can drag and drop individual *TField* objects within the *Field* list box to change the order in which fields are displayed in controls, like *TDBGrid*, that display multiple columns.

The navigator buttons at the bottom of the Fields Editor window enable you to scroll through the records one at a time, and to jump to the first or last record of the dataset if it is active.

The Add button enables you to see a list of column names in the physical dataset but not already included in the Fields list, and to create new *TField* components for them.

The Define button enables you to create calculated fields. Fields created this way are only for display purposes. The underlying physical structure of the table or data is not changed.

The Remove button deletes the selected *TFields*. The Clear All button deletes all the *TFields* shown in the Fields list.

## Adding a TField component

The Add button of the Fields Editor enables you to specify which *TField* components will be included in a dataset. To see a list of fields currently available to a *TTable* or *TQuery* component, click the Add button. The Add Fields dialog box appears.

**Figure 3.5** Fields Editor Add Fields dialog box

The *Available Fields* list box shows all database fields that do not have persistent *TFields* instantiated. Initially, all available fields are selected. Use the mouse to select specific fields and then choose OK. The selected fields move to the *Fields* list box in the main Fields Editor window.

Fields moved to the *Available Fields* list become persistent. Each time the dataset is opened, Delphi verifies that each non-calculated field exists or can be created from data in the database. If it cannot, an exception is raised, warning you that the field is not valid, and the dataset is not opened.

## Deleting a TField component

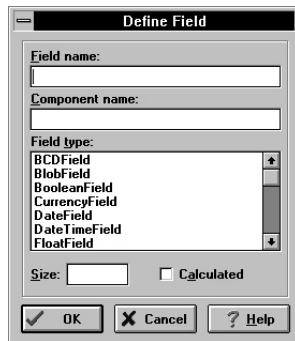

The Remove button of the Fields Editor deletes the selected *TField* components from the *Fields* list box. Fields removed from the *Field* list box are no longer in the dataset and cannot be displayed by data-aware components. Removing a *TField* component is useful to display a subset of available fields within a table, or when you want to define your own field to replace an existing field.

You can re-create deleted *TField* components with the Add button, but any changes previously made to its properties or events will be lost.

## Defining a new TField component

The Define button of the Fields Editor enables you to create new *TField* components for display. You can create a new *TField* based on a column in the underlying table (for example, to change the data type of the field), but its main purpose is to create new *TField* components whose values are calculated programmatically.

Figure 3.6 Define Field dialog box

## Defining a calculated field

A calculated field is used to display values calculated at run time in the dataset's *OnCalcFields* event handler. For example, you might create a string field that displays concatenated values from two other fields.

To create a calculated field:

- 1 Choose the Define button in the Fields Editor window.
- 2 Enter the name of the new field in the Field Name edit box, or select a field name from the drop-down list. A corresponding *TField* component name appears automatically in the Component edit box as you type. This name is the identifier you use to access the field programmatically.
- 3 Select the data type for the field from the Field Type list box.
- 4 Check the Calculated check box if it is not already checked.
- 5 Choose OK. The newly defined calculated field is automatically added to the Fields list box in the main Fields Editor window, and the component declaration is automatically added to the form's **type** declaration in the source code.

To edit the properties or events associated with the new *TField* component, select the component name in the Fields list box, then edit the properties or events via the Object Inspector.

## Programming a calculated field

Once a calculated field is defined, it has a null value unless you write code to provide values for the field. Code for a calculated field is placed in the *OnCalcFields* event for its dataset. An *OnCalcFields* event handler can only modify fields that have a *Calculated* property of True.

For example, on Form1, the *OnCalcFields* event for a *TTable* component named Table1 is

```
TForm1.Table1CalcFields
```

To program a value for a calculated field:

- 1 Select the *TTable* or *TQuery* component from the Object Inspector drop-down list.
- 2 Choose the Object Inspector Events tab.
- 3 Double-click the *OnCalcFields* property to bring up or create a *CalcFields* procedure for the *TTable* or *TQuery* component.
- 4 Write the code that sets the values and other properties of the calculated field as desired.

## Editing a TField component

---

You can customize properties and events of persistent *TField* components at design time. To do this, select the *TField* either in the Fields list box of the Fields Editor or the component list of the Object Inspector. Properties control the way a field is displayed by a data-aware component, for example, whether it can appear in a *TDBGrid*, or whether its value can be modified. Events control what happens when data in a field is fetched, changed, set, or validated.

### Editing Display properties

To edit the display properties of a selected *TField* component, click the Properties tab on the Object Inspector window. The following table summarizes display properties that can be edited. Not all properties appear for all *TField* descendants.

**Table 3.7** TField properties

Property	Purpose
<i>Alignment</i>	Displays contents of field left justified, right justified, or centered within a data-aware component.
<i>Calculated</i>	True, field value can be calculated by a <i>CalcFields</i> method at run time. False, field value is determined from the current record.
<i>Currency</i>	True, numeric field displays monetary values. False, numeric field does not display monetary values.
<i>DisplayFormat</i>	Specifies the format of data displayed in a data-aware component.
<i>DisplayLabel</i>	Specifies the column name for a field in a <i>TDBGrid</i> .
<i>DisplayWidth</i>	Specifies the width, in characters, of a grid column that display this field.
<i>EditFormat</i>	Specifies the edit format of data in a data-aware component.
<i>EditMask</i>	Limits data-entry in an editable field to specified types and ranges of characters, and specifies any special, non-editable characters that appear within the field (hyphens, parentheses, etc.).
<i>FieldName</i>	Specifies the actual name of column in the physical table from which the <i>TField</i> component derives its value and data type.
<i>Index</i>	Specifies the order of the field in a dataset.
<i>MaxValue</i>	Specifies the maximum numeric value that can be entered in an editable numeric field.

**Table 3.7** TField properties (continued)

Property	Purpose
<i>MinValue</i>	Specifies the minimum numeric value that can be entered in an editable numeric field.
<i>Name</i>	Specifies the component name of the <i>TField</i> component within Delphi.
<i>ReadOnly</i>	True: Field can be displayed in a component, but cannot be edited by a user. False: Field can be displayed and edited.
<i>Size</i>	Specifies the maximum number of characters that can be displayed or entered in a string-based field, or the size of byte and var byte fields.
<i>Tag</i>	Long integer bucket available for programmer use in every component as needed.
<i>Visible</i>	True: Field is displayed by a <i>TDBGrid</i> component. User-defined components can also make display decisions based on this property. False: Field is not displayed by a <i>TDBGrid</i> component.

Not all properties are available to all *TField* components. For example, a component of type *TStringField* does not have *Currency*, *MaxValue*, or *DisplayFormat* properties. A component of type *TFloatField* does not have a *Size* property.

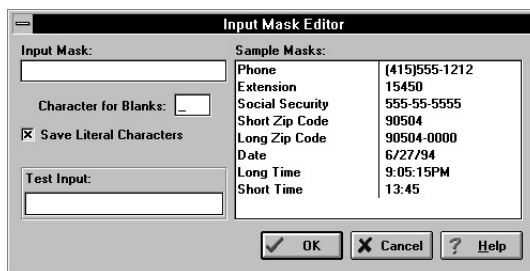

Boolean properties, those that can be toggled between True and False, can be changed by double-clicking the property in the Object Inspector. Other properties require you to enter values or pick from drop-down lists in the Object Inspector. All *TField* properties can also be manipulated programmatically.

While the purpose of most properties is straight-forward, some properties, such as *Calculated*, require additional programming steps to be useful. Others, such as *DisplayFormat*, *EditFormat*, and *EditMask*, are interrelated; their settings must be coordinated. For more information about using the *Calculated* property, see “Programming a calculated field.” For more information about using *DisplayFormat*, *EditFormat*, and *EditMask*, see “Formatting fields.”

## Using the Input Mask Editor

The *EditMask* property provides a way to limit the entries that a user can type into data aware controls tied to a *TField*. You can enter a specific edit mask by hand or use the Input Mask Editor to create a mask.

To use the Input Mask Editor, when you have selected a *TField* component, double-click on the *EditMask* field in the Object Inspector or click the ellipsis button in the Values column. The Input Mask Editor opens:

**Figure 3.7** Input Mask Editor

To use one of the sample masks, select it in the Sample Masks list box. You can then customize the mask as desired by editing it in the Input Mask text field. You can test the allowable input in the Test Input field. For more information, see the online Help.

**Note** For the *TStringField*, the *EditMask* property is also used as a display format.

## Formatting fields

Delphi provides built-in display and edit format routines and intelligent default formatting for *TField* components. These routines and formats require no action on the programmer's part. Default formatting conventions are based on settings in the Windows Control Panel. For example, using default Windows settings in the United States, a *TFloatField* column with the *Currency* property set to True sets the *DisplayFormat* property for the value 1234.56 to \$1234.56, while the *EditFormat* is 1234.56. Only format properties appropriate to the data type of a *TField* component are available for a given component.

All *TField* component formatting is performed by the following routines:

**Table 3.8** TField formatting routines

Routine	Used by . . .
FormatFloat	<i>TFloatField</i> , <i>TCurrencyField</i>
FormatDateTime	<i>TDateField</i> , <i>TTimeField</i> , <i>TDateTimeField</i>
FormatInteger	<i>TIntegerField</i> , <i>TSmallIntField</i> , <i>TWordField</i>

The format routines use the International settings specified in the Windows Control Panel for determining how to display date, time, currency, and numeric values. You can edit the *DisplayFormat* and *EditFormat* properties of a *TField* component to override the default display settings for a *TField*, or you can handle the *OnGetText* and *OnSetText* events for a *TField* to do custom programmatic formatting.

## Handling TField events

To edit the events for a selected *TField* component, click the Events tab on the Object Inspector window. The following table summarizes events that can be edited:

**Table 3.9** Published TField events

Event	Purpose
<i>OnChange</i>	Called when the value for a <i>TField</i> component changes.
<i>OnGetText</i>	Called when the value for a <i>TField</i> component is retrieved for display or editing.
<i>OnSetText</i>	Called when the value for a <i>TField</i> component is set.
<i>OnValidate</i>	Called to validate the value for a <i>TField</i> component whenever the value is changed because of an edit or insert operation.

*OnGetText* and *OnSetText* events are primarily useful to programmers who want to do custom formatting that goes beyond Delphi's built-in formatting functions, *FormatFloat*, *FormatDate*, and so on.

*TFields* have a *FocusControl* method that enables an event to set focus to the first data-aware control associated with the *TField*. This is especially important for record-oriented

validation (for example, on *BeforePost* of a *TTable*) since a *TField* may be validated whether or not its associated data control has focus.

## Using TField conversion functions

*TFields* have built-in functions for conversion among data types. Depending on the *TField* type, different conversion functions are available and do different things. The following table summarizes these functions.

**Table 3.10** TField conversion functions

TField Type	AsString	AsInteger	AsFloat	AsDateTime	AsBoolean
<b>TStringField</b>	String type by definition	Convert to Integer if possible	Convert to Float if possible	Convert to Date if possible	Convert to Boolean if possible
<b>TIntegerField</b> <b>TSmallIntField</b> <b>TWordField</b>	Convert to String	Integer type by definition	Convert to Float	Not Allowed	Not Allowed
<b>TFloatField</b> <b>TCurrencyField</b> <b>TBCDField</b>	Convert to String	Round to nearest integer value	Float type by definition	Not Allowed	Not Allowed
<b>TDateTimeField</b> <b>TDateField</b> <b>TTimeField</b>	Convert to String. Content depends on <code>DisplayFormat</code> of Field	Not Allowed	Convert Date to number of days since 01/01/0001 Convert Time to fraction of 24 hours	DateTime type by definition Zero date or time if not specified	Not Allowed
<b>TBooleanField</b>	Convert to String "True" or "False"	Not Allowed	Not Allowed	Not Allowed	Boolean type by definition
<b>TBytesField</b> <b>TVarBytesField</b> <b>TBlobField</b> <b>TMemoField</b> <b>TGraphicField</b>	Convert to String (Generally only makes sense for <code>TMemoField</code> )	Not Allowed	Not Allowed	Not Allowed	Not Allowed

The conversion functions can be used in any expression involving a *TField* component, on either side of an assignment statement. For example, the following statement converts the value of the *TField* named *MyTableMyField* to a string and assigns it to the text of the *Edit1* control:

```
Edit1.Text := MyTableMyField.AsString;
```

Conversely, this statement assigns the text of the *Edit1* control to the *TField* as a string:

```
MyTableMyField.AsString := Edit1.Text;
```

An exception occurs if an unsupported conversion is performed at run time.

## Accessing TField properties programmatically

An application can access the value of a database column through a *TField* component's *Value* property. For example, the following statement assigns the value of the *CustTableCountry* *TField* to the text in the *TEdit* component *Edit3*:

```
Edit3.Text := CustTableCountry.Value;
```

Any properties of *TField* components that are available from the Object Inspector can also be accessed and adjusted programmatically as well. For example, this statement changes field ordering by setting the *Index* property of *CustTableCountry* to 3:

```
CustTableCountry.Index := 3;
```

## Displaying data with standard controls

---

You can display database values at run time with standard components as well as data aware and *TField* components. Besides accessing *TField* components created with the Fields Editor, there are two ways to access column values at run time: the *Fields* property and the *FieldsByName* method. Each accesses the value of the current row of the specified column in the underlying database table at run time. Each requires a dataset component in the form, but not a *TDataSource* component.

In general, you should use the data-aware controls built in to Delphi in database applications. These components have properties and methods built in to them that enable them to be connected to database columns, display the current values in the columns, and make updates to the columns. If you use standard components, you must provide analogous code by hand.

### Using the Fields property

---

You can access the value of a field with the *Fields* property of a dataset component, using as a parameter the ordinal number of the column in the table (starting at 0). To access or change the field's value, convert the result with the appropriate conversion function, such as *AsString* or *AsInteger*.

This method requires you to know the order and data types of the columns in the table. Use this method if you want to iterate over a number of columns or if your application works with tables that are not available at design time.

For example, the following statement assigns the current value of the seventh column (*Country*) in the *CustTable* table to the *Edit1* component:

```
Edit1.Text := CustTable.Fields[6].AsString;
```

Conversely, you can assign a value to a column a dataset in Edit mode by assigning the appropriate *Fields* property to the value of a component. For example,

```
CustTable.Fields[6].AsString := Edit1.Text;
```

To make these assignments occur, you must enter them in an event such as a *TButton OnClick* event, or an edit control's *OnEnter* event.

### Using the FieldByName method

---

You can access the value of a field with the *FieldByName* method by specifying the dataset component name, and then passing *FieldByName* the name of the column you want to access. To access or change the field's value, convert the result with the appropriate conversion function, such as *AsString* or *AsInteger*.

This method requires you to know the name of the column you want to access or if your application works with tables that are not available at design time.

For example, the following statement assigns the value of the Country column in the CustTable table to Edit2:

```
Edit2.Text := CustTable.FieldByName('Country').AsString;
```

Conversely, you can assign a value to a column a dataset in Edit mode by assigning the appropriate *FieldByName* property to the value of a component. For example,

```
CustTable.FieldByName('Country').AsString := Edit2.Text;
```

To make these assignments occur, you must enter them in an event such as a button's *OnClick* or a Edit component's *OnExit* event.

## Incorporating reports in an application

Delphi applications can include reports created with ReportSmith with the *TReport* component. *TReport* appears on the Data Access component page. To incorporate a report in an application, simply add a *TReport* component to the desired form as you would any other component. Then specify the name of the report (created with ReportSmith) and other report parameters with properties of the component.

Designing reports with ReportSmith is described in *Creating Reports*. You can invoke ReportSmith at design time by double-clicking on a *TReport* component, or on the ReportSmith icon in the Delphi program group.

Specify the name of an existing report in the *ReportName* property and the directory in the *ReportDir* property. To load ReportSmith Runtime and print the specified report, use the *Run* method (i.e., `Report1.Run`). The report prints on the default printer defined in ReportSmith. *Preview* is a Boolean property that specifies whether to print the report or just display it: If set to True, *Run* will display the report onscreen only; if set to False, *Run* will print the report.

The *AutoUnload* property specifies whether to automatically unload the ReportSmith Runtime executable after a report is run. Generally, if an application runs one report at a time, *AutoUnload* should be True. If an application is going to run a series of reports, then *AutoUnload* should be False.

The *InitialValues* property is of type *TStrings* and specifies the report variables to use with the report. Each line specifies a report variable as follows:

```
REPORTVAR = value
```

For more information about creating and using report variables, see *Creating Reports*.

Some important methods of *TReport* are listed in the following table:

**Table 3.11** Important TReport methods

Method	Purpose
<i>Run</i>	Run a report.
<i>RunMacro</i>	Send a macro command to ReportSmith.

**Table 3.11** Important TReport methods (continued)

Method	Purpose
<i>Connect</i>	Preconnect the report to a database, so it does not prompt for login.
<i>SetVariable</i>	Change a specific report variable.
<i>ReCalcReport</i>	Run a report again. Use this when report variables have changed.

## Using TBatchMove

*TBatchMove* enables you to perform operations on groups of records or entire tables. The primary uses of this component are

- Downloading data from a server to a local data source for analysis or other operations.
- Upsizing a database from a desktop data source to a server. For more information on upsizing, see Appendix C, “Using local SQL.”

*TBatchMove* is powerful because it can create tables on the destination that correspond to the source tables, automatically mapping the column names and data types as appropriate.

Two *TBatchMove* properties specify the source and a destination for the batch move operation: *Source* specifies a dataset (a *TQuery* or *TTable* component) corresponding to an existing source table. *Destination* specifies a *TTable* component corresponding to a database table. The destination table may or may not already exist.

### Batch move modes

The *Mode* property specifies what the *TBatchMove* object will do:

**Table 3.12** Batch move modes

Property	Purpose
<i>batAppend</i>	Append records to the destination table. The destination table must already exist. This is the default mode.
<i>batUpdate</i>	Update records in the destination table with matching records from the source table. The destination table must exist and must have an index defined to match records.
<i>batAppendUpdate</i>	If a matching record exists in the destination table, update it. Otherwise, append records to the destination table. The destination table must exist and must have an index defined to match records.
<i>batCopy</i>	Create the destination table based on the structure of the source table. The destination table must not already exist—if it does, the operation will delete it.
<i>batDelete</i>	Delete records in the destination table that match records in the source table. The destination table must already exist and must have an index defined.

The *Transliterate* property specifies whether to transliterate character data to the preferred character set for the destination table.

## Data type mappings

In *Copy* mode, *TBatchMove* will create the destination table based on the column data types of the source table. In moving data between different table types, *TBatchMove* translates the data types as appropriate. The mappings from dBASE, Paradox, and InterBase data types are shown in the following tables.

**Note** To batch move data to an SQL server database, you must have that database server and Delphi Client/Server edition with the appropriate SQL Link installed. For more information, see the *SQL Links for Windows User's Guide*.

**Table 3.13** Physical data type translations from Paradox tables to tables of other driver types

From Paradox type	To dBASE type	To Oracle type	To Sybase type	To InterBase type	To Informix type
Alpha	Character	Character	VarChar	Varying	Character
Number	Float {20.4}	Number	Float	Double	Float
Money	Float {20.4}	Number	Money	Double	Money {16.2}
Date	Date	Date	DateTime	Date	Date
Short	Number {6.0}	Number	SmallInt	Short	SmallInt
Memo	Memo	Long	Text	Blob/1	Text
Binary	Memo	LongRaw	Image	Blob	Byte
Formatted memo	Memo	LongRaw	Image	Blob	Byte
OLE	OLE	LongRaw	Image	Blob	Byte
Graphic	Binary	LongRaw	Image	Blob	Byte
Long	Number {11.0}	Number	Int	Long	Integer
Time	Character {>8}	Character {>8}	Character {>8}	Character {>8}	Character {>8}
DateTime	Character {>8}	Date	DateTime	Date	DateTime
Bool	Bool	Character {1}	Bit	Character {1}	Character
AutoInc	Number{11.0}	Number	Int	Long	Integer
Bytes	Memo	LongRaw	Image	Blob	Byte
BCD	N/A	N/A	N/A	N/A	N/A

**Table 3.14** Physical data type translations from dBASE tables to tables of other driver types

From dBASE type	To Paradox type	To Oracle type	To Sybase type	To InterBase type	To Informix type
Character	Alpha	Character	VarChar	Varying	Character
Number	Short	Number	SmallInt	Short	SmallInt
others	Number	Number	Float	Double	Float
Float	Number	Number	Float	Double	Float
Date	Date	Date	DateTime	Date	Date
Memo	Memo	Long	Text	Blob/1	Text
Bool	Bool	Character {1}	Bit	Character {1}	Character
Lock	Alpha {24}	Character {24}	Character {24}	Character {24}	Character
OLE	OLE	LongRaw	Image	Blob	Byte

**Table 3.14** Physical data type translations from dBASE tables to tables of other driver types (continued)

From dBASE type	To Paradox type	To Oracle type	To Sybase type	To InterBase type	To Informix type
Binary	Binary	LongRaw	Image	Blob	Byte
Bytes	Bytes	LongRaw	Image	Blob	Byte (only for temp tables)

**Table 3.15** Physical data type translations from InterBase tables to tables of other driver types

From Interbase type	To Paradox type	To dBASE type	To Oracle type	To Sybase type	To Informix type
Short	Short	Number {6.0}	Number	Small Int	SmallInt
Long	Number	Number {11.0}	Number	Int	Integer
Float	Number	Float {20.4}	Number	Float	Float
Double	Number	Float {20.4}	Number	Float	Float
Char	Alpha	Character	Character	VarChar	Character
Varying	Alpha	Character	Character	VarChar	Character
Date	DateTime	Date	Date	DateTime	DateTime
Blob	Binary	Memo	LongRaw	Image	Byte
Blob/1	Memo	Memo	Long	Text	Text

By default *TBatchMove* matches columns based on their position in the source and destination tables. That is, the first column in the source is matched with the first column in the destination, and so on.

To override the default column mappings, use the *Mappings* property. This is a list of column mappings (one per line) in one of two forms. To map the column, *ColName*, in the source table to the column of the same name in the destination table:

```
ColName
```

Or, to map the column named *SourceColName* in the source table to the column named *DestColName* in the destination table:

```
DestColName = SourceColName
```

If source and destination column data types are not the same, *TBatchMove* will perform a “best fit”. It will trim character data types, if necessary, and attempt to perform a limited amount of conversion if possible. For example, mapping a CHAR(10) column to a CHAR(5) column will result in trimming the last five characters from the source column.

As an example of conversion, if a source column of character data type is mapped to a destination of integer type, *TBatchMove* will convert a character value of ‘5’ to the corresponding integer value. Values that cannot be converted will generate errors. See “Handling batch move errors” on page 92.

## Executing a batch move

---

Use the *Execute* method to execute the batch operation at run time. For example, if *BatchMoveAdd* is the name of a *TBatchMove* component, the following statement executes it:

```
BatchMoveAdd.Execute
```

You can also execute a batch move at design time by right clicking the mouse on a *TBatchMove* component and choosing *Execute*. The *MoveCount* property keeps track of the number of records that were moved when a batch move is executed.

## Handling batch move errors

---

There are basically two types of errors that can occur in a batch move operation: data type conversion errors and integrity violations. *TBatchMove* has a number of properties that specify how it handles errors. The *AbortOnProblem* property specifies whether to abort the operation when a data type conversion error occurs. The *AbortOnKeyViol* property indicates whether to abort the operation when an integrity (key) violation occurs.

The following properties enable a *TBatchMove* to create additional tables that document the batch move operation:

- *ChangedTableName*, if specified, creates a local (Paradox) table containing all records in the destination table that changed as a result of the batch operation.
- *KeyViolTableName*, if specified, creates a local (Paradox) table containing all records from the source table that caused an integrity violation (such as a key violation) as a result of the batch operation.
- *ProblemTableName*, if specified, creates a local (Paradox) table containing all records that could not be posted in the destination table due to data type conversion errors. For example, the table could contain records from the source table whose data had to be trimmed to fit in the destination table.

## Accessing the BDE directly

---

Delphi provides a wide range of built-in methods, properties, and functions that provide an interface to the Borland Database Engine, but applications are not limited to them. Some advanced applications may require direct access to BDE function calls, cursors, and so on. While direct BDE calls can provide additional functionality, they should be performed with caution, as they bypass Delphi's built-in functionality that keeps data-aware components synchronized with datasets.

If your application requires direct access to the BDE, you should first get the *Borland Database Engine User's Guide* from Borland. This documentation provides a complete reference and user's guide to the BDE.

The application must include the header files that reference the BDE: DBIPROCS.PAS and DBTYPES.PAS. Then the code can make direct calls to the BDE application programming interface.

BDE function calls often require parameters to specify the action to be performed. Delphi provides access to these through the following properties of dataset components:

- *DBHandle* is the handle for the database to which they are connected.
- *Handle* is the handle for the underlying cursor on the database.
- *DBLocale* and *Locale* are used for ANSI/OEM conversion for localization of applications.

After performing a BDE call directly, it is a good idea to call *Refresh* to ensure that all data-aware components are synchronized with their datasets.

## Application examples

---

This section provides some brief examples of specific database tasks, illustrating some of the material presented in the preceding sections.

### Creating a master-detail form

---

In the following example, you will create a simple form in which the user can scroll through customer records, and display all orders for the current customer. Follow these steps to create this application:

- 1 Place two *TTable*, two *TDataSource*, and two *TDBDataGrid* components on a form.
- 2 Set the properties of the first *TTable* component as follows:
  - *DatabaseName*: DBDEMO (the alias for the directory with the MAST database).
  - *TableName*: CUSTOMER (the table containing customer records).
  - *Name*: CustTable (for ease-of-use).
- 3 Name the first *TDataSource* component “CustDataSource,” and set its *Dataset* property to “CustTable.” Set the *DataSource* property of DBGrid1 to “CustDataSource.” When you activate CustTable (by setting its *Active* property to True), the grid displays the data in the CUSTOMER table.
- 4 Analogously, set the properties of the second *TTable* component as follows:
  - *DatabaseName*: DBDEMO.
  - *TableName*: ORDERS (the table containing order records).
  - *Name*: OrdTable (for ease-of-use).
- 5 Name the second *TDataSource* component “OrdDataSource,” and set its *Dataset* property to “OrdTable.” Set the *DataSource* property of DBGrid2 to “OrdDataSource.” When you activate OrdTable (by setting its *Active* property to True), the grid displays the data in the ORDERS table.

- 6 Compile and run the application now. The form displays data from each table independently and should look something like this:

**Figure 3.8** Sample form

CustNo	Company
1221	Kauai Dive Shoppe
1231	Unisco
1351	Sight Diver
1354	Cayman Divers World Unlimited

OrderNo	CustNo	SaleDate	ShipDate
1003	1351	4/12/88	
1004	1354	4/17/88	
1005	1356	4/20/88	
1006	1380	11/6/94	

- 7 The next step is to link the ORDERS table (the master table) to the CUSTOMER table (the detail table) so that the form displays only the orders placed by the current customer. To do this, exit the application, return to design mode, and set the *MasterSource* property of *OrdTable* to *CustDataSource*.
- 8 In the Object Inspector, click on the ellipsis button to the right of the *MasterFields* property of *OrdTable*. The Field Link Designer dialog box will open.
  - In the Available Indexes field, choose *ByCustNo* to link the two tables by the *CustNo* field.
  - Select *CustNo* in both the Detail Fields and Master Fields field lists.
  - Click on the Add button to add this join condition. In the Joined Fields list, "*CustNo -> CustNo*" will appear.
  - Choose OK to commit your selections and exit the Field Link Designer.

If you run the application now, you will see that the tables are linked together, and that when you move to a new record in the CUSTOMER table, you see only those records in the ORDERS table that belong to the current customer.

The *MasterSource* property specifies the *TDataSource* from which *OrdTable* will take its master column values. This limits the records it retrieves, based on the current record in *CustTable*. To do this, you must specify for *OrdTable*:

- The name of the column that links the two tables. The column must be present in each table, and must be identically named.
- The index of the column in the ORDERS table that will be linked to the CUSTOMER table.

In addition, you must ensure that the ORDERS table has an index on the *CustNo* field. Since it is a primary index, there is no need to specifically name it, and you can safely leave the *IndexName* field blank in both tables. However, if the table were linked through a secondary index, you must explicitly designate that index in the *IndexName* property.

In this example, the CUSTOMER table has a primary index on the *CustNo* column, so there is no need to specify the index name. However, the ORDERS table does not have a

primary index on *CustNo*, so you must explicitly declare it in the *IndexName* property, in this case *ByCustNo*

**Note** You can also set the *IndexFieldNames* property to *CustNo*, and the correct index will be supplied for you.

## Displaying multiple views of a table

Applications often need to display two different views of the same dataset. For instance, if you have two forms, and each displays different columns of the same row, you need to find a way to keep these forms synchronized to ensure accurate and up-to-date views of the data in each form.

There are two main concepts important to working with multiple views of a table:

- The *TDataSource* component provides access for multiple forms sharing a single dataset.
- When you want more than one different view of one table, put a *TDataSource* on each form that contains data aware components. You only need put a single *TTable* or *TQuery* component on the first form.

The simplest way to do this is to place a *TDataSource* on each form, and connect the first data source to the dataset you want to access. At run time you can then set the *DataSet* property of the second *TDataSource* to the *TTable* on the first form, for example:

```
Form2.DataSource2.DataSet := Form1.Table1;
```

Once the second *TDataSource* is assigned to a valid dataset, both forms will remain synchronized.

The *TWOFORMS.DPR* example in `\DELPHI\DEMOS\DB\TWOFORMS` demonstrates how to work with multiple forms and a single dataset. The program opens the *COUNTRY* table and shows the *Name*, *Capital*, and *Continent* fields on one form, and the *Area* and *Population* fields on a second form. A button on the first form opens the second form. Both forms have *TDBNavigator* components, so you can navigate through the table. The forms look like this:

**Figure 3.9** Two forms

- ✓ To create the program manually,
  - 1 Place a *TTable*, a *TDataSource*, a *TButton*, three *TDBEdit*, and three *TLabel* components on a form.

- 2 Give the Button the name "Detail."
- 3 Set the Table1's *DatabaseName* property to the DBDemos alias, and open the COUNTRY Table.
- 4 Connect DataSource1 to *Table1*, then connect each of the DBEdit component's *Datasource* properties to DataSource1. By performing these steps in this order, you can drop down a list in the *DataField* property of the data aware controls.
- 5 Create a second form, and place a data source, a *TBitBtn*, two *TDBLabels*, a *TDBNavigator* and two *TDBEdit* controls on the form. Don't yet connect the data source on this form to anything else.
- 6 Connect the DBEdit components to the DataSource, then enter 'Area' for the *DataField* property of DBEdit1, and 'Population' for DBEdit2.
- 7 Set the *Kind* property of the bitbutton to 'OK'.
- 8 Name this second form *DetailView*, then save the whole unit under the name DETAILS.PAS.

**Note** When you are creating the second form, you might find it helpful to temporarily create a *TTable* component and link the data source to it. This enables you to design the form using live data, and gives you access to a list of field names for each edit control. Once you have the form set up properly, you can delete the *TTable* component and at run time reconnect the data source to a table on a separate form.

- ✓ Once you have built the second form, go back to the first form and add DETAILS to the **uses** clause in the form unit's **implementation** part, and create the following event handler for the *OnClick* event of the Detail button:

```
procedure TForm1.DetailClick(Sender: TObject);
begin
    DetailView.DataSource1.DataSet := Table1;
    DetailView.Visible := True;
end;
```

This code first assigns the data source on the second form to the table in the first form. Once this connection is made, then the data source on the second form is "live." That is, it will act exactly like the data source on the first form. Then it makes the form visible.

- ✓ Now, connect the navigators on each form to the appropriate data source.

When you run the program, open the second form by clicking on the Detail button. Notice that whether you use the navigator in either form, the edit controls on the other form remain synchronized with the current record.

- ✓ Close the application and add two more lines of code to the second form's unit. This code is called in response to a click on the OK button:

```
procedure TDetailView.BitBtn1Click(Sender: TObject);
begin
    DataSource1.DataSet := nil;
    Close;
end;
```

This code sets the dataset to `null` whenever the second form is closed. While not necessary, this ensures that the hidden detail view is not responding to events.

## Using Data Controls

To display and edit data from a database, use the components on the Data Controls page of the Component palette. Data controls include components such as *TDBGrid* for displaying and editing all specified records and fields in a table, and *TDBNavigator* for navigating among records, deleting records, and posting records when they change.

**Figure 4.1** Data Controls Component palette

The following table summarizes the data controls in order from left to right as they appear on the Component palette:

**Table 4.1** Data controls

Data control	Description
TDBGrid	Displays information from a data source in a spreadsheet-like grid. Columns in the grid can be specified at design time using the Fields Editor or at run time (dynamically bound).
TDBNavigator	Provides buttons for navigating through data obtained from a data source. At design time, you can choose to include one or more buttons to navigate through records, update records, post records, and refresh the data from the data source.
TDBText	Displays data from a specific column in the current data record.
TDBEdit	Uses an edit box to display and edit data from a specific column in the current data record.
TDBMemo	Displays memo-type database data. Memo fields can contain multiple lines of text or can contain BLOB (binary large object) data.
TDBImage	Displays graphic images and BLOB data from a specific column in the current data record.
TDBListBox	Displays a list of items from which a user can update a specific column in the current data record.
TDBComboBox	Combines a TDBEdit control with an attached list. The application user can update a specific column in the current data record by typing a value or by choosing a value from the drop-down list.

**Table 4.1** Data controls (continued)

Data control	Description
TDBCheckBox	Displays a check box. If the value in the indicated column of the current record matches the text of the check box's <i>ValueChecked</i> property, the box is checked.
TDBRadioGroup	Offers a mutually exclusive set of options to enter into a specific column in the current data record in the form of radio buttons.
TDBLookupList	Displays a list of items from which a user can update a column in the current data record. The list of items is looked up in a specific column in another dataset.
TDBLookupCombo	Combines a TDBEdit control with a dropdown version of TDBLookupList. The application user can update a field in the current database by typing a value or by choosing a value from the drop-down list that is looked up in a specific column in another dataset.

Most data controls are data-aware versions of standard components. Some, such as *TDBGrid* and *TDBNavigator*, are data-aware, but differ from standard components in significant, useful ways. A *data-aware* control derives display data from a database source outside the application, and can also optionally post (or return) data changes to a data source. Data controls are data-aware at *design time*, meaning that when you connect a component to an active data source while building an application, you can immediately see live data in the controls. You can use the Fields Editor to scroll through records at design time to verify that your application is making the right database connections without requiring you to compile and run the application, but you cannot modify data at design time.

This chapter describes basic features common to all Data Control components, then describes how and when to use individual components.

## Data Control component basics

Data controls are linked to database tables through the *DataSource* property. The *DataSource* property specifies the name of the *TDataSource* component from which a control gets its data. The *TDataSource* component is linked to a dataset (for example, *TTable* or *TQuery*) that is, in turn, connected to a database table. A dataset component is a grouping of *TField* components that can be dynamically created for you at run time, or statically specified using the Fields Editor at design time. For more information about *TDataSource*, *TTable*, *TQuery*, and the Fields Editor, see Chapter 3, "Using data access components and tools."

Data controls can only access columns in tables for which there are corresponding *TField* components. If the Fields Editor is used to limit a dataset to a subset of columns in a table, then *TField* components exist only for those columns. Most data controls provide a *DataField* property where you can specify the *TField* component with which it should be associated.

When designing a form that accesses data, you must place at least one dataset component (for example, *TTable* or *TQuery*), at least one *TDataSource* component, and one or more data controls on the form.

To place a data control on a form and link it to a dataset, follow these steps:

- 1 Drop the control on the form.

- 2 Set the *DataSource* property to the name of a *TTable* or *TQuery* component already on the form. You can type the name or choose it from the drop-down list.
- 3 Set the *DataField* property to the name of a *TField* component. You can type the field name or choose it from the drop-down list.

**Note** Two data controls, *TDBGrid* and *TDBNavigator*, access all available *TField* components within a dataset, and therefore do not have *DataField* properties. For these controls, omit step 3.

When a data control is associated with a dataset, its *Enabled* property determines if its attached *TDataSource* component receives data from mouse, keyboard, or timer events. Controls are also disabled if the *Enabled* property of *TDataSource* is *False*, or if the *Active* property of the dataset is *False*.

## Updating fields

---

Most data controls can update fields by default. Update privileges depend on the status of the control's *ReadOnly* property and underlying *TField*'s and dataset's *CanModify* property. *ReadOnly* is set to *False* by default, meaning that data modifications can be made.

In addition, the data source must be in *Edit* state if updates are to be permitted. The data source *AutoEdit* property, set to *True* by default, ensures that the dataset enters *Edit* mode whenever an attached control starts to modify data in response to keyboard or mouse events.

In all data controls except *TDBGrid*, when you modify a field, the modification is copied to the underlying *TField* component when you *Tab* from the control. If you press *Esc* before you *Tab* from a field, then Delphi abandons the modifications, and the value of the field reverts to the value it held before any modifications were made. In *TDBGrid*, modifications are copied only when you move to a different record; you can press *Esc* in any record of a field before moving to another record to cancel all changes to the record.

When a record is posted, Delphi checks all data-aware components associated with the dataset for a change in status. If there is a problem updating any fields that contain modified data, Delphi raises an exception, and no modifications are made to the record.

## Displaying data as labels with TDBText

---

*TDBText* is a read-only control similar to the *TLabel* component on the Standard page of the Component palette. *TDBText* gets the text it displays from a specified field in the current record of a dataset. Because *TDBText* gets its text from a dataset, the text it displays is dynamic—the text changes as the user navigates the database table. Therefore you cannot specify the display text of *TDBText* at design time as you can with *TLabel*. When *TDBText* is linked to a data field at design time, however, you can see the current value for that field. For example, the following *TDBText* box, from the tutorial example, *MASTAPP*, displays company names.

**Figure 4.2** TDBText component

A *TDBText* control is useful when you want to provide display-only data on a form that allows user input in other controls. For example, suppose a form is created around the fields in a customer list table, and that once the user enters a street address, city, and state or province information in the form, you use a dynamic lookup to automatically determine the zipcode field from a separate table. A *TDBText* component tied to the zipcode table could be used to display the zipcode field that matches the address entered by the user.

**Note** When you create a *TDBText* component on a form, make sure its *AutoSize* property is True (the default) to ensure that the control resizes itself as necessary to display data of varying widths. If *AutoSize* is set to False, and the control is too small, data display is truncated.

## Displaying and editing fields with TDBEdit

*TDBEdit* is a data-aware version of the *TEdit* component. *TDBEdit* displays the current value of a data field to which it is linked. You can also modify values in this component.

For example, suppose *DataSource1* is a *TDataSource* component that is active and linked to an open *TTable* called *Customer*. You can then create a *TDBEdit* component (*DBEdit1*), and set its properties as follows:

- *DataSource*: *DataSource1*
- *DataField*: *CUSTNO*

The *DBEdit1* component immediately displays the value of the current row in the *CUSTNO* column of the *CUSTOMER* table, both at design time and at run time.

**Figure 4.3** TDBEdit component at design time

## Editing a field

A user can modify a database field in a *TDBEdit* component if:

- 1 The *Dataset* is in Edit state.
- 2 The *Can Modify* property of the *Dataset* is True.
- 3 The *ReadOnly* property of *TDBEdit* is False.

**Note** Edits made to a field must be posted to the database by using a navigation or *Post* button on a *TDBNavigator* component.

# Viewing and editing data with TDBGrid

*TDBGrid* enables you to view and edit all records associated with a dataset in a spreadsheet-like format:

**Figure 4.4** TDBGrid component

The diagram shows a TDBGrid component with a table of data. The table has four columns: VendorName, Address1, City, and State. The first row is highlighted, and a record indicator points to it. The table is labeled with 'Current field' and 'Column titles' above the columns, and 'Record indicator' to the left of the rows.

Current field	Column titles	VendorName	Address1	City	State
Record indicator		Cacor Corporation	161 Southfield Rd	Southfield	OH
		Underwater	50 N 3rd Street	Indianapolis	IN
		J.W. Luscher Mfg.	65 Addams Street	Berkely	MA
		Scuba Professionals	3105 East Brace	Rancho Dominguez	CA
		Divers' Supply Shop	5208 University Dr	Macon	GA
		Techniques	52 Dolphin Drive	Redwood City	CA
		Perry Scuba	3443 James Ave	Hapeville	GA

The appearance of records in *TDBGrid* depends entirely on whether the *TField* components of the dataset are dynamically created by Delphi at run time, or if you use the Fields Editor to create persistent set of *TField* components whose properties you can specify in the Object Inspector at design time.

If Delphi generates a dynamic dataset at run time, then all records are displayed using default record and field ordering, and default display and edit formats. In most cases, however, you will want to control field order and appearance. To do so, use the Fields Editor to instantiate *TField* components and set their properties at design time.

When you use the Fields Editor to instantiate *TField* components, you gain a great deal of flexibility over the appearance of records in a *TDBGrid*. For example, the order in which fields appear from left to right in *TDBGrid* is determined by the way you order *TField* components in the Fields list box of the Fields Editor. Similarly, the *DisplayFormat* and *EditFormat* properties of a *TField* component determine how that field appears in *TDBGrid* during display and editing, respectively. You can also ensure that a value is entered for a field in a new record by setting its *Required* property to True. You can even prevent a *TField* component from being displayed in a grid by setting its *Visible* property to False. For more information about using the Fields Editor to control *TField* properties, see Chapter 3, "Using data access components and tools."

To put a *TDBGrid* on a form and link it to a dataset:

- 1 Create the control on the form.
- 2 Set the *DataSource* property to the name of a *TTable* or *TQuery* component already on the form.

## Setting grid options

You can use the *TDBGrid Options* property at design time to control grid behavior and appearance at run time. When a *TDBGrid* component is first placed on a form at design time, the *Options* property in the Object Inspector is displayed with a + (plus) sign to indicate that the *Options* property can be expanded to display a series of Boolean

properties that you can set individually. To view and set these properties, double-click the *Options* property. The list of options that you can set appears in the Object Inspector below the *Options* property. The + sign changes to a – (minus) sign, indicating that you can collapse the list of properties by double-clicking the *Options* property.

The following table lists the *Options* properties that can be set, and describes how they affect the grid at run time:

**Table 4.2** Expanded TDBGrid Options properties

Option	Purpose
dgEditing	True: (Default). Enables editing, inserting, and deleting records in the grid. False: Disables editing, inserting, and deleting records in the grid.
dgAlwaysShowEditor	True: When a field is selected, it is in Edit state. False: (Default). A field is not automatically in Edit state when selected.
dgTitles	True: (Default). Displays field names across the top of the grid. False: Field name display is turned off.
dgIndicator	True: (Default). The indicator column is displayed at the left of the grid, and the current record indicator (an arrow at the left of the grid) is activated to show the current record. On insert, the arrow becomes an asterisk. On edit, the arrow becomes an I-beam. False: The indicator column is turned off.
dgColumnResize	True: (Default). Columns can be resized by dragging the column rulers in the title area. Resizing changes the corresponding width of the underlying TField component. False: Columns cannot be resized in the grid.
dgColLines	True: (Default). Displays vertical dividing lines between columns. False: Does not display dividing lines between columns.
dgRowLines	True: (Default). Displays horizontal dividing lines between records. False: Does not display dividing lines between records.
dgTabs	True: (Default). Enables tabbing between fields in records. False: Tabbing exits the grid control.
dgRowSelect	True: The selection bar spans the entire width of the grid. False: (Default). Selecting a field in a record selects only that field.
dgAlwaysShowSelection	True: (Default). The selection bar in the grid is always visible, even if another control has focus. False: The selection bar in the grid is only visible when the grid has focus.
dgConfirmDelete	True: (Default). Prompt for confirmation to delete records ( <i>Ctrl+Del</i> ). False: Delete records without confirmation.

For more information about these options, see the online Help reference.

## Editing in the grid

At run time, you can use a grid to modify existing data and enter new records, if all the following default conditions are met:

- 1 The *CanModify* property of the *Dataset* is True.
- 2 The *ReadOnly* property of *TDBGrid* is False.

In most data controls, edits to a field are posted as soon as you *Tab* to another control. By default in *TDBGrid*, edits and insertions within a field are posted only when you move to a different record in the grid. Even if you use the mouse to change focus to another control on a form, the grid does not post changes until you move off the current row. When a record is posted, Delphi checks all data-aware components associated with the dataset for a change in status. If there is a problem updating any fields that contain modified data, Delphi raises an exception, and does not modify the record.

You can cancel all edits for a record by pressing *Esc* in any field before moving to another record.

## Rearranging column order at run time

---

At run time, a user can use the mouse to drag a column to a new location in the grid if its *DragMode* property is set to *dmManual*. Dragging a column to a new position in the grid affects the order of columns in the grid and the dataset. It does not change the order of columns in the underlying physical table.

To prevent rearrangement of column order, set the *DragMode* property to *dmAutomatic*.

## Controlling grid drawing

---

You can control how individual cells in a grid are drawn. The *DefaultDrawing* property controls drawing of cells. By default, *DefaultDrawing* is set to *True*, meaning that Delphi uses the grid's default drawing method to paint cells and the data they contain. Data is drawn according to the *DisplayFormat* or *EditFormat* properties of the *TField* component associated with a given column.

If you set a grid's *DefaultDrawing* property to *False*, Delphi does not draw cells or cell contents in the grid. You must supply your own drawing routine that is keyed to the *OnDrawDataCell* event for *TDBGrid*.

## Using events to control grid behavior

---

You can modify grid behavior by writing events handlers to respond to specific actions within the grid. Because a grid typically displays many fields and records at once, you may have very specific needs to respond to changes to individual columns. For example, you might want to activate and deactivate a button elsewhere on the form every time a user enters and exits a specific column.

The following table lists *TDBGrid* events available in the Object Inspector:

**Table 4.3** TDBGrid events

Event	Purpose
<i>OnColEnter</i>	Specify action to take when a user moves into a column on the grid.
<i>OnColExit</i>	Specify action to take when a user leaves a column on the grid.
<i>OnDblClick</i>	Specify action to take when a user double clicks in the grid.
<i>OnDragDrop</i>	Specify action to take when a user drags and drops in the grid.
<i>OnDragOver</i>	Specify action to take when a user drags over the grid.

**Table 4.3** TDBGrid events (continued)

Event	Purpose
<i>OnDrawDataCell</i>	Customize drawing of grid cells.
<i>OnEndDrag</i>	Specify action to take when a user stops dragging on the grid.
<i>OnEnter</i>	Specify action to take when the grid gets focus.
<i>OnExit</i>	Specify action to take when the grid loses focus.
<i>OnKeyDown</i>	Specify action to take when a user presses any key or key combination on the keyboard when in the grid.
<i>OnKeyPress</i>	Specify action to take when a user presses a single alphanumeric key on the keyboard when in the grid.
<i>OnKeyUp</i>	Specify action to take when when a user releases a key when in the grid.

There are many uses for these events. For example, you might write a handler for the *OnDblClick* event that pops up a list from which a user can choose a value to enter in a column. Such a handler would use the *SelectedField* property to determine to current row and column. For more information about *TDBGrid* events and properties, see the online Help reference.

## Navigating and manipulating records with TDBNavigator

*TDBNavigator* provides users a simple control for navigating through records in a dataset, and for manipulating records. The navigator consists of a series of buttons that enable a user to scroll forward or backward through records one at a time, go to the first record, go to the last record, insert a new record, update an existing record, post data changes, cancel data changes, delete a record, and refresh record display.

**Figure 4.5** TDBNavigator component

The following table describes the buttons on the navigator:

**Table 4.4** TDBNavigator buttons

Button	Purpose
First	Calls the dataset's <i>First</i> method to set the current record to the first record.
Prior	Calls the dataset's <i>Prior</i> method to set the current record to the previous record.
Next	Calls the dataset's <i>Next</i> method to set the current record to the next record.
Last	Calls the dataset's <i>Last</i> method to set the current record to the last record.
Insert	Calls the dataset's <i>Insert</i> method to insert a new record before the current record, and set the dataset in Insert state.

**Table 4.4** TDBNavigator buttons (continued)

Button	Purpose
Delete	Deletes the current record. If the <i>ConfirmDelete</i> property is True it prompts for confirmation before deleting.
Edit	Puts the dataset in Edit state so that the current record can be modified.
Post	Writes changes in the current record to the database.
Cancel	Cancels edits to the current record, and returns the dataset to Browse state.
Refresh	Clears data control display buffers, then refreshes its buffers from the physical table or query. Useful if the underlying data may have been changed by another application.

## Hiding and showing navigator buttons

When you first put a *TDBNavigator* on a form, all its buttons are visible. You can use the *VisibleButtons* property to turn off buttons you do not want to use on a form. For example, on a form that is intended for browsing rather than editing, you might want to disable the *Edit*, *Insert*, *Delete*, *Post*, and *Cancel* buttons.

The *VisibleButtons* property in the Object Inspector is displayed with a + sign to indicate that it can be expanded to display a Boolean value for each button on the navigator. To view and set these values, double-click the *VisibleButtons* property. The list of buttons that can be turned on or off appears in the Object Inspector below the *VisibleButtons* property. The + sign changes to a – (minus) sign, indicating that you can collapse the list of properties by double-clicking the *VisibleButtons* property.

Button visibility is indicated by the *Boolean* state of the button value. If a value is set to True, the button appears in the *TDBNavigator*. If False, the button is removed from the navigator at design and run times.

**Note** As button values are set to False, they are removed from the *TDBNavigator* on the form, and the remaining buttons are expanded in width to fill the control. You can drag the control's handles to resize the buttons.

For more information about buttons and the methods they call, see the online Help reference.

## Displaying fly-by help

By default, the navigator displays fly-by Help Hints whenever you pass the mouse cursor over the navigator buttons. The *ShowHint* property of *TDBNavigator*, set to False by default, controls this functionality. Set *ShowHints* to True to display Help Hints.

You can provide your own hint text for a navigator by entering separate strings for each hint in the *Hints* property. The strings you enter override the default hints provided by the navigator control.

## Displaying and editing BLOB text with TDBMemo

*TDBMemo* is a data-aware component—similar to the Standard *TMemo* component—that can display binary large object (BLOB) data. *TDBMemo* displays multi-line text, and

permits a user to enter multi-line text as well. For example, you can use *TDBMemo* controls to display memo fields from dBASE and Paradox tables and text data contained in BLOB fields.

**Figure 4.6** TDBMemo component

By default, *TDBMemo* permits a user to edit memo text. To limit the number of characters users can enter into the database memo, use the *MaxLength* property. To make a *TDBMemo* component read-only, set its *ReadOnly* property to *True*.

Several properties affect how the database memo appears and how text is entered. You can supply scroll bars in the memo with the *ScrollBars* property. To prevent word wrap, set the *WordWrap* property to *False*. To permit tabs in a memo, set the *WantTabs* property to *True*. The *Alignment* property determines how the text is aligned within the control. Possible choices are *taLeftJustify* (the default), *taCenter*, and *taRightJustify*.

At run time, users can cut, copy, and paste text to and from a database memo control. You can accomplish the same task programmatically by using the *CutToClipboard*, *CopyToClipboard*, and *PasteFromClipboard* methods.

Because the *TDBMemo* can display large amounts of data, it can take time to populate the display at run time. To reduce the time it takes scroll through data records, *TDBMemo* has an *AutoDisplay* property that controls whether the accessed data should automatically be displayed. If you set *AutoDisplay* to *False*, *TDBMemo* displays the field name rather than actual data. Double-click inside the control to view the actual data.

**Note** A *TDBMemo* control raises an exception if an attempt is made to access fields that contain more than 32K of data, or if edited data exceeds 32K in length.

## Displaying BLOB graphics with TDBImage

*TDBImage* is a data-aware component that displays bitmapped graphics contained in BLOB data fields. It captures BLOB graphics images from a dataset, and stores them internally in the Windows .DIB format.

**Figure 4.7** DBImage component

By default, *TDBImage* permits a user to edit a graphics image by cutting and pasting to and from the Clipboard, or if you supply an editing method. You can accomplish the same task programmatically by using the *CutToClipboard*, *CopyToClipboard*, and

*PasteFromClipboard* methods. To make a *TDBImage* component read-only, set its *ReadOnly* property to True.

Because the *TDBImage* can display large amounts of data, it can take time to populate the display at run time. To reduce the time it takes scroll through data records, *TDBImage* has an *AutoDisplay* property that controls whether the accessed data should automatically displayed. If you set *AutoDisplay* to False, *TDBImage* displays the field name rather than actual data. Double-click inside the control to view the actual data.

## Using list and combo boxes

There are four data controls that provide data-aware versions of standard list box and combo box controls. These useful controls provide the user with a set of default data values to choose from at run time.

**Note** These components can be linked only to *TTable* components. They do not work with *TQuery* components.

The following table describes these controls:

**Table 4.5** Data-aware list box and combo box controls

Data control	Description
TDBListBox	Displays a list of items from which a user can update a specific column in the current data record.
TDBComboBox	Combines a TDBEdit control with an attached list. The application user can update a specific column in the current data record by typing a value or by choosing a value from the drop-down list.
TDBLookupList	Displays a list of items from which a user can update a column in the current data record. The list of items is looked up in a specific column in another dataset.
TDBLookupCombo	Combines a TDBEdit control with a dropdown version of TDBLookupList. The application user can update a field in the current database by typing a value or by choosing a value from the drop-down list that is looked up in a specific column in another dataset.

### TDBComboBox

The *TDBComboBox* component is similar to a *TDBEdit* component, except that at run time it has a drop-down list that enables a user to pick from a predefined set of values. Here is an example of what a *TDBComboBox* component looks like at run time:

**Figure 4.8** DBComboBox component

The *Items* property of the component specifies the items contained in the drop-down list. Use the String List Editor to specify the values for the drop-down list.

At run time, the user can choose an item from the list or (depending on the value of the *Style* property) type in a different entry. When the component is linked to a column through its *DataField* property, it displays the value in the current row, regardless of whether it appears in the *Items* list.

The following properties determine how the *Items* list is displayed at run time:

- *Style* determines the display style of the component:
  - *csDropDown* (default): Displays a drop-down list with an edit box in which the user can enter text. All items are strings and have the same height.
  - *csSimple*: Displays the *Items* list at all times instead of in a drop-down list. All items are strings and have the same height.
  - *csDropDownList*: Displays a drop-down list and edit box, but the user cannot enter or change values that are not in the drop-down list at run time.
  - *csOwnerDrawFixed* and *csOwnerDrawVariable*: Allows the items list to display values other than strings (for example, bitmaps). For more information, see the online VCL reference.
- *DropDownCount*: the maximum number of items displayed in the list. If the number of *Items* is greater than *DropDownCount*, the user can scroll the list. If the number of *Items* is less than *DropDownCount*, the list will be just large enough to display all the *Items*.
- *ItemHeight*: The height of each item when style is *csOwnerDrawFixed*.
- *Sorted*: If True, then the *Items* list will be displayed in alphabetical order.

## TDBListBox

*TDBListBox* is functionally the same as *TDBComboBox*, but instead of a drop-down list, it displays a scrollable list of available choices. When the user selects a value at run time, the component is assigned that value. Unlike *TDBComboBox*, the user cannot type in an entry that is not in the list.

Here is an example of how a *TDBListBox* component appears at run time.

**Figure 4.9** TDBListBox component

While navigating through a dataset, a *TDBListBox* component displays values in the column by highlighting the corresponding entry in its list. If the current row's value is not defined in the *Items* property, no value is highlighted in the *TDBListBox*. Changing the selection changes the underlying value in the database column and is equivalent to typing a value in a *TDBEdit* component.

The *IntegralHeight* property controls the way the list box is displayed. If *IntegralHeight* is True (the default), the bottom of the list box moves up to the bottom of the last

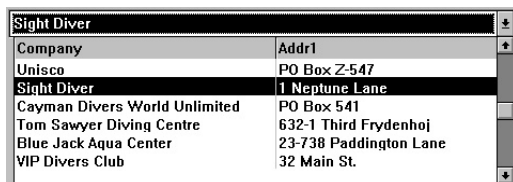

completely-displayed item in the list. If *IntegralHeight* is False, the bottom of the list box is determined by the *ItemHeight* property, and the bottom item might not be completely displayed.

## TDBLookupCombo

The *TDBLookupCombo* component is similar to *TDBComboBox*, except that it derives its list of values dynamically from a second dataset at run time, and it can display multiple columns in its drop-down list. With this control, you can ensure that users enter valid values into forms by providing an interface from which they can choose values. Here is an example of how a *TDBLookupCombo* component appears at run time:

Figure 4.10 TDBLookupCombo component

Sight Diver	
Company	Addr1
Unisco	PO Box Z-547
Sight Diver	1 Neptune Lane
Cayman Divers World Unlimited	PO Box 541
Tom Sawyer Diving Centre	632-1 Third Frydenhoj
Blue Jack Aqua Center	23-738 Paddington Lane
VIP Divers Club	32 Main St.

The lookup list for *TDBLookupCombo* must be derived from a second dataset. To display values from a column in the same table as the first dataset, drop a second data source and dataset component on the form and point them at the same data as the first data source and dataset.

Three properties establish the lookup list for *TDBLookupCombo*, and determine how it is displayed:

- *LookupSource* specifies a second data source from where the control populates its list.
- *LookupField* specifies a field in the *LookupSource* dataset which links that dataset to the primary dataset. This must be a column in the dataset pointed to by *LookupSource*, and it must contain the same values as the column pointed to by the *DataField* property (although the column names do not have to match).
- *LookupDisplay*, if set, defines the columns that *TDBLookupCombo* displays. If you do not specify values in *LookupDisplay*, *TDBLookupCombo* displays the values found in the column specified by *LookupField*. Use this property to display a column other than that specified by *LookupField*, or to display multiple columns in the drop-down list. To specify multiple columns, separate the different column names with a semicolon.

A *TDBLookupCombo* component appears similar to a *TDBComboBox* at both design time and run time, except when you want it to display multiple columns in its lookup list. How the control displays multiple columns depends on the *Options* property settings:

- *loColLines*: When True, uses lines to separate the columns displayed in the lookup list.
- *loRowLines*: When True, uses lines to separate the rows displayed in the lookup list.
- *loTitles*: When True, column names appear as titles above the columns displayed in the lookup list.

As a simple example, an order entry form could have a *TDBLookupCombo* component to specify the customer number of the customer placing the order. The user placing the order can simply click on the drop down “pick list” instead of having to remember the customer number. The value displayed could be the customer name.

To build this form,

- 1 Choose File | New Project to create a new form.
- 2 Create a *TDataSource* component onto the form, then set its *Name* property to “OrdSource.”
- 3 Drop a *TTable* component on the form, and set the *Name* property to “OrdTable,” the *DatabaseName* property to “DBDEMOS,” the *TableName* property to “ORDERS.DB,” and the *Active* property to True.
- 4 Create a second *TDataSource* component on the form, then set its *Name* property to “CustSource.”
- 5 Create a second *TTable* component on the form, and set the *Name* property to “CustTable,” the *DatabaseName* property to “DBDEMOS,” the *TableName* property to “CUSTOMER.DB,” and the *Active* property to True.
- 6 Create a *TDBGrid* component and link it to OrdSource so it displays the contents of the ORDERS table.
- 7 Create a *TDBLookupCombo* component, and set its *DataSource* property to “CustNo.” The database lookup combo box is now linked to the CustNo column of the ORDERS table.
- 8 Specify the lookup values of the *TDBLookupCombo* component:
  - Set *LookupSource* to “CustSource” (so it looks up values in the CUSTOMER table).
  - Set *LookupField* to “CustNo” (so it looks up and gets values from the CustNo column).
  - In *LookupDisplay*, type `Company;Addr1` (this displays the corresponding company name and address in the drop-down list).
- 9 Set the *loColLines* and *LoTitles* properties (under the *Option* property) of the *TDBLookupCombo* to True.

At run time, the *TDBLookupCombo* component displays a drop-down list of company names and addresses. If the user selects a new company from the list, the control is assigned the value of the corresponding customer number (CustNo). When the user scrolls off the current order in the database grid, Delphi posts the new customer number and information to the row.

## TDBLookupList

---

*TDBLookupList* is functionally the same as *TDBLookupCombo*, but instead of a drop-down list, it displays a scrollable list of the available choices. When the user selects one at run time, the component is assigned that value. Like *TDBLookupCombo*, the user cannot type in an entry that is not in the list. Here is an example of how a *TDBLookupList* component appears at run time:

**Figure 4.11** TDBLookupList component

While navigating through a dataset, a *TDBLookupList* component highlights the item in the list that corresponds to the value in the currently selected row. If the current row's value is not defined in the *Items* property, no value is highlighted in the *TDBLookupList* component. Changing the selection changes the underlying value in the database column and is equivalent to typing a value in a *TDBEdit* component.

## TDBCheckBox

*TDBCheckBox* is a data-aware version of the Standard *TCheckBox* component. It can be used to set the values of fields in a dataset. For example, a customer invoice form might have a check box control that when checked, specifies that the customer is entitled to a special discount, or when unchecked means that the customer is not entitled to a discount.

**Figure 4.12** TDBCheckBox component

Like the other data controls, *TDBCheckBox* is attached to a specific field in a dataset through its *DataSource* and *DataField* properties. Use the *Caption* property to display a label for the check box on your form.

Set the *ValueChecked* property to a value the control should post to the database if the control is checked when the user moves to another record. By default, this value is set to *True*, but you can make it any alphanumeric value appropriate to your needs. You can also enter a semicolon-delimited list of items as the value of *ValueChecked*. If any of the items matches the contents of that field in the current record, the check box is checked. For example, you can specify a *ValueChecked* string like:

```
DBCheckBox1.ValueChecked := 'True;Yes;On';
```

If the field for the current record contains values of “True,” “Yes,” or “On,” then the check box is checked. Comparison of the field to *ValueChecked* strings is case-insensitive. If a user checks a box for which there are multiple *ValueChecked* strings, the first string is the value that is posted to the database.

Set the *ValueUnchecked* property to a value the control should post to the database if the control is not checked when the user moves to another record. By default, this value is set to *False*, but you can make it any alphanumeric value appropriate to your needs. You can also enter a semicolon-delimited list of items as the value of *ValueUnchecked*. If any of the items matches the contents of that field in the current record, the check box is unchecked.

If the *DataField* of the check box is a logical field, the check box is always checked if the contents of the field is *True*, and it is unchecked if the contents of the field is *False*. In this

case, strings entered in the *ValueChecked* and *ValueUnchecked* properties have no effect on logical fields.

A *TDBCheckBox* component is grayed out and disabled whenever the field for the current record does not contain one of the values listed in the *ValueChecked* or *ValueUnchecked* properties.

## TDBRadioGroup

*TDBRadioGroup* is a data-aware version of the standard *TRadioGroup* component. It lets you set the value of a data field with a radio button control where there is a limited number of possible values for the field. The radio group consists of one button for each value a field can accept.

*TDBRadioGroup* is attached to a specific field in a dataset through its *DataSource* and *DataField* properties. A radio button for each string value entered in the *Items* property is displayed on the form, and the string itself is displayed as a label to the right of the button.

**Figure 4.13** A *TDBRadioGroup* component

For the current record, if the field associated with a radio group matches one of the strings in the *Items* or property, that radio button is selected. For example, if three strings, “Red,” “Yellow,” and “Blue,” are listed for *Items*, and the field for the current record contains the value “Blue,” then the third button in the group is selected.

**Note** If the field does not match any strings in *Items*, a radio button may still be selected if the field matches a string in the *Values* property. If the field for the current record does not match any strings in *Items* or *Values*, no radio button is selected.

The *Values* property can contain an optional list of strings that can be returned to the dataset when a user selects a radio button and posts a record. Strings are associated with buttons in numeric sequence. The first string is associated with the first button, the second string with the second button, and so on. For example, to continue the example for the three buttons labeled “Red,” “Yellow,” and “Blue,” if three strings, “Magenta,” “Yellow,” and “Cyan,” are listed for *Values*, and the user selects the first button (labeled “Red”), then Delphi posts “Magenta” to the database.

If strings for *Values* are not provided, the label from a selected radio button (from *Items*) is returned to the database when a record is posted. Users can modify the value of a data field by clicking the appropriate radio button. When the user scrolls off the current row, Delphi posts the value indicated by the radio button string to the database.

# Using SQL in applications

SQL (Structured Query Language) is an industry-standard language for database operations. Delphi enables your application to use SQL syntax directly through the *TQuery* component. Delphi applications can use SQL to access data from:

- Paradox or dBASE tables, using local SQL. The allowable syntax is a sub-set of ANSI-standard SQL and includes basic SELECT, INSERT, UPDATE, and DELETE statements. For more information on local SQL syntax, see Appendix C, “Using local SQL.”
- Databases on the Local InterBase Server. Any statement in InterBase SQL is allowed. For information on syntax and limitations, see the *InterBase Language Reference*.
- Databases on remote database servers (Delphi Client/Server only). You must have installed the appropriate SQL Link. Any standard statement in the server’s SQL is allowed. For information on SQL syntax and limitations, see your server documentation.

Delphi also supports heterogeneous queries against more than one server or table type (for example, data from an Oracle table and a Paradox table). For more information, see “Creating heterogenous queries” on page 124.

## Using TQuery

*TQuery* is a dataset component, and shares many characteristics with *TTable*, as described in Chapter 3, “Using data access components and tools.” In addition, *TQuery* enables Delphi applications to issue SQL statements to a database engine (either the BDE or a server SQL engine).

The SQL statements can be either static or dynamic, that is, they can be set at design time or include parameters that vary at run time.

## When to use TQuery

---

For simple database operations, *TTable* is often sufficient and provides portable database access through the BDE. However, *TQuery* provides additional capabilities that *TTable* does not. Use *TQuery* for:

- Multi-table queries (joins).
- Complex queries that require sub-SELECTs.
- Operations that require explicit SQL syntax.

*TTable* does not use SQL syntax; *TQuery* uses SQL, which provides powerful relational capabilities but may increase an application's overall complexity. Also, use of non-standard (server-specific) SQL syntax may decrease an application's portability among servers; for more information, see Chapter 6, "Building a client/server application."

## How to use TQuery

---

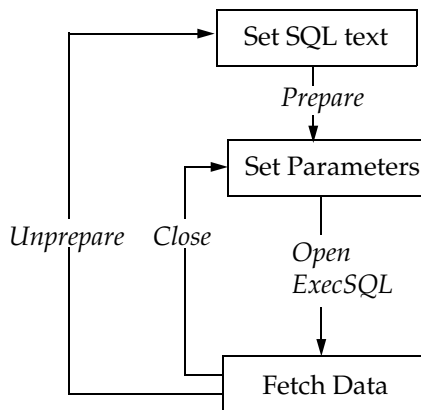

To access a database, set the *DatabaseName* property to a defined BDE alias, a directory path for desktop database files, or a file name for a server database. If the application has a *TDatabase* component, *DatabaseName* can also be set to a local alias that it defines. For more information, see "Using the *TDatabase* component" in Chapter 6, "Building a client/server application."

To issue SQL statements with a *TQuery* component:

- Assign the *TQuery* component's *SQL* property the text of the SQL statement. You can do this:
  - At design time, by editing the *TQuery*'s *SQL* property in the Object Inspector, choosing the *SQL* property, and entering the SQL statements in the String List Editor dialog box. With Delphi Client/Server, you can also use the Visual Query Builder to construct SQL syntax.
  - At run time, by closing any current query with *Close*, clearing the *SQL* property with *Clear*, and then specifying the SQL text with the *Add* method.
- Execute the statement with the *TQuery* component's *Open* or *ExecSQL* method. Use *Open* for SELECT statements. Use *ExecSQL* for all other SQL statements. The differences between *Open* and *ExecSQL* are discussed in a subsequent section.
- To use a dynamic SQL statement, use the *Prepare* method, provide parameters and then call *Open* or *ExecSQL*. *Prepare* is not required, but will improve performance for dynamic queries executed multiple times.

The following diagram illustrates the lifetime of a *TQuery* component and the methods used to work with it:

**Figure 5.1** TQuery methods and flow

**Note** *Prepare* applies only to dynamic queries. It is not required, but is recommended in most cases. For more information, see “Dynamic SQL statements” on page 121.

## The SQL property

---

The *SQL* property contains the text of the SQL statement to be executed by a Query component. This property is of type *TStrings*, which means that it is a series of strings in a list. The list acts very much as if it were an array, but it is actually a special class with unique capabilities. For more information on *TStrings*, see the online VCL reference.

A Query component can execute two kinds of SQL statements:

- Static SQL statements
- Dynamic SQL statements

A *static* SQL statement is fixed at design time and does not contain any parameters or variables. For example, this statement is a static SQL statement:

```
SELECT * FROM CUSTOMER WHERE CUST_NO = 1234
```

A *dynamic* SQL statement, also called a *parameterized* statement, includes parameters for column or table names. For example, this is a dynamic SQL statement:

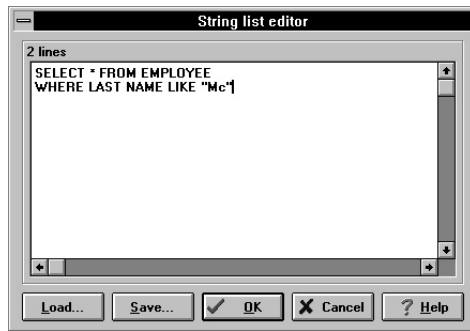

```
SELECT * FROM CUSTOMER WHERE CUST_NO = :Number
```

The variable *Number*, indicated by the leading colon, is a parameter which must be provided at run time and may vary each time the statement is executed.

## Creating the query text

You can enter the SQL text for a *TQuery* at design time by double-clicking on the *SQL* property in the Object Inspector, or choosing the ellipsis button. The String List Editor opens, enabling you to enter an SQL statement.

**Figure 5.2** Editing SQL statements in the String List Editor

Choose OK to assign the text you enter to the *SQL* property of the query. Choose Load to include text from a file or Save to save the text to a file.

To specify SQL text at run time, an application should first close the query with *Close* and clear the *SQL* property with *Clear*. For example,

```
Query1.Close; {This closes the query}
Query1.SQL.Clear; {This clears the contents of the SQL property}
```

It is always safe to call *Close*—if the query is already closed, the call will have no effect. Use the *SQL* property’s *Add* method to add the SQL statements to it. For example,

```
Query1.SQL.Add('SELECT * FROM COUNTRY');
Query1.SQL.Add('WHERE NAME = 'ARGENTINA''');
```

An application should always call *Clear* before specifying an SQL statement. Otherwise, *Add* will simply append the statements to the existing one.

**Note** The *SQL* property may contain only one complete SQL statement at a time. In general, multiple statements are not allowed. Some servers support multiple statement “batch” syntax; if the server supports this, then such statements are allowed.

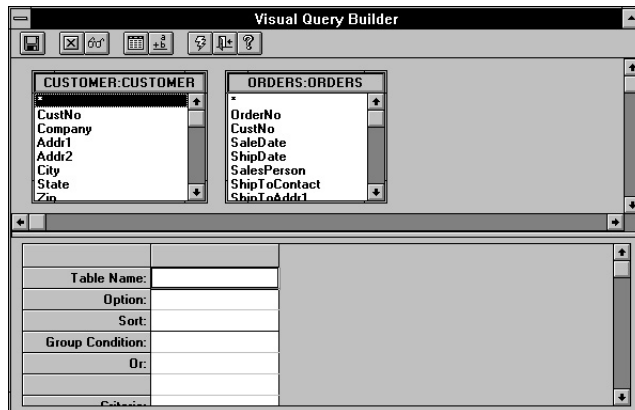

You can also use the *LoadFromFile* method to assign the text in an SQL script file to the *SQL* property. For example,

```
Query1.SQL.LoadFromFile('C:\MYQUERY.TXT');
```

## Using the Visual Query Builder

Delphi Client/Server includes a Visual Query Builder that enables you to construct SQL *SELECT* statements visually. To invoke the Visual Query Builder, right click on a *TQuery* component and select Run Visual Query Builder. A dialog box prompts you to select the database to work with; select the desired database and choose OK. Another dialog box will prompt you to enter the tables you want to query; select the desired tables, choosing Add after each, and then choose Close. The Visual Query Builder window will then become active with the select tables.

**Figure 5.3** Working in the Visual Query Builder

For information on how to use the Visual Query Builder, refer to its online Help. After you have constructed a query and exited the Visual Query Builder, the SQL statement you constructed will be entered in the *SQL* property of the selected *TQuery* component.

## Executing a query

At design time, you can execute a query by changing its *Active* property in the Object Inspector to *True*. The results of the query will be displayed in any data controls connected to the Query component (through a data source).

At run time, an application can execute a query with either the *Open* or the *ExecSQL* methods. Use *Open* for SQL statements that return a result set (SELECT statements). Use *ExecSQL* for all other SQL statements (INSERT, UPDATE, DELETE, and so on). For example,

```
Query1.Open; {Returns a result set}
```

If the SQL statement does not return a cursor and a result set from the database, use *ExecSQL* instead of *Open*. For example,

```
Query1.ExecSQL; {Does not return a result set}
```

If you don't know at design time whether a query will return a result set, use a **try...except** block with *Open* in the **try** part and *ExecSQL* in the **except** part.

## The UniDirectional property

Use the *UniDirectional* property to optimize access to a database table through a *TQuery* component. If you set *UniDirectional* to *True*, you can iterate through a table more quickly, but you will only be able to move in a forward direction. *UniDirectional* is *False* by default.

## Getting a live result set

A *TTable* component always returns a live result set to an application. That is, the user sees the data “live” from the database, and can make changes to it directly through data controls. A *TQuery* can return two kinds of result sets:

- “Live” result sets: As with *TTable* components, users can edit data in the result set with data controls. The changes are sent to the database when a *Post* occurs, or when the user tabs off a control, as described in Chapter 4, “Using Data Controls.”
- “Read only” result sets: Users cannot edit data in the result set with data controls.

By default, a query always returns a read-only result set. To get a live result set, an application must request it by setting the *RequestLive* property of *TQuery* to True. However, for the BDE to be able to return a live result set, the SELECT syntax of the query must conform to the guidelines given below. If an application requests a live result set, but the syntax does not conform to the requirements, the BDE returns a read-only result set (for local SQL) or an error return code (for passthrough SQL). If a query returns a live result set, Delphi will set the *CanModify* property to True.

**Table 5.1** Types of query result sets

<b>RequestLive</b>	<b>CanModify</b>	<b>Type of result set</b>
False	False	Read-only result set
True—SELECT syntax meets requirements	True	Live result set
True—SELECT syntax does not meet requirements	False	Read-only result set

If an application needs to update the data in a read-only result set, it must use a separate *TQuery* to construct an UPDATE statement. By setting the parameters of the update query based on the data retrieved in the first query, the application can perform the desired update operation.

### Syntax requirements for live result sets

To return a live result set, a query must have *RequestLive* set to True. The SQL syntax must conform to that of Local SQL, as described in Appendix C, “Using local SQL.” Additionally, the syntax must meet the requirements described below.

A query of a Paradox or dBASE table can return a live result set if it:

- Involves only a single table.
- Does not have an ORDER BY clause.
- Does not use aggregates such as SUM or AVG.
- Does not use calculated fields in the SELECT list.
- The WHERE clause may consist only of comparisons of column names to scalar constants. The comparison operators may be LIKE, >, <, >=, and <=. The clause may contain any number of such comparisons linked by AND or OR operators.

A query of a server table using passthrough SQL can return a live result set if it:

- Involves a single table.

- Does not have an ORDER BY clause.
- Does not use aggregates such as SUM or AVG.

In addition, if the table is on a Sybase server, it must have a unique index.

## Dynamic SQL statements

---

A dynamic SQL statement (also called a parameterized query) contains parameters that can vary at run time.

### Supplying values to parameters

---

At design time, you can supply values to parameters with the Parameters Editor. Invoke the Parameters Editor by selecting a *TQuery* component, right-clicking the mouse, and then selecting Parameters Editor. The Parameters Editor opens.

**Figure 5.4** Parameters Editor

Select the desired data type for the parameter in the Data Type combo box. Enter a value in the Value text field or select Null Value to set the parameter's value to null. When you click OK, the query will be prepared and values will be bound to the parameters. Then, when you set the query's *Active* property to True, the results of the SQL query with the specified parameter values will be shown in any data controls connected to the query.

At run time, an application can supply values to parameters with the following *TQuery* properties:

- The *Params* property, using the order that the parameters appear in the SQL statement.
- The *ParamByName* method, using the parameter names specified in the SQL statement.
- The *DataSource* property to set values from another dataset for columns that match the names of parameters that have no values.

### Preparing a query

---

The *Prepare* method sends a parameterized query to the database engine for parsing and optimization. A call to *Prepare* is not required to use a parameterized query. However, it is strongly recommended, since it will improve performance for dynamic queries that

will be executed more than once. If a query is not explicitly prepared, each time it is executed, Delphi automatically prepares it.

*Prepare* is a Boolean property of *TQuery* that indicates if a query has been prepared. The Parameters Editor automatically prepares a query when you use it to set parameter values at design time.

If a query has been executed, an application must call *Close* before calling *Prepare* again. Generally, an application should call *Prepare* once—for example, in the *OnCreate* event of the form—then set parameters using the *Params* property, and finally call *Open* or *ExecSQL* to execute the query. Each time the query is to be executed with different parameter values, an application must call *Close*, set the parameter values, and then execute the query with *Open* or *ExecSQL*.

Preparing a query consumes some database resources, so it is good practice for an application to unprepare a query once it is done using it. The *UnPrepare* method unprepares a query. When you change the text of a query at run time, Delphi automatically closes and unprepares the query.

## Using the Params property

---

When you enter a query, Delphi creates a *Params* array for the parameters of a dynamic SQL statement. *Params* is a zero-based array of *TParam* objects with an element for each parameter in the query; that is, the first parameter is *Params[0]*, the second *Params[1]*, and so on.

For example, suppose a *TQuery* component named *Query2* has the following statement for its *SQL* property:

```
INSERT
  INTO COUNTRY (NAME, CAPITAL, POPULATION)
  VALUES (:Name, :Capital, :Population)
```

An application could use *Params* to specify the values of the parameters as follows:

```
Query2.Params[0].AsString := 'Lichtenstein';
Query2.Params[1].AsString := 'Vaduz';
Query2.Params[2].AsInteger := 420000;
```

These statements would bind the value “Lichtenstein” to the *:Name* parameter, “Vaduz” to the *:Capital* parameter, and 420000 to the *:Population* parameter.

## Using the ParamByName method

---

*ParamByName* is a function that enables an application to assign values to parameters based on their names. Instead of providing the ordinal location of the parameter, you must supply its name.

For example, an application could use *ParamByName* could specify values for the parameters in the preceding example as follows:

```
Query2.ParamByName('Name').AsString := 'Lichtenstein';
Query2.ParamByName('Capital').AsString := 'Vaduz';
```

```
Query2.ParamByName('Population').AsInteger := 420000;
```

These statements would have the same effect as the three previous statements that used the *Params* array directly.

## Using the DataSource property

For parameters of a query not bound to values at design time, Delphi will check the query's *DataSource* property. This property specifies the name of a *TDataSource* component. If *DataSource* is set, and the unbound parameter names match any column names in the specified *DataSource*, Delphi binds the current values of those fields to the corresponding parameters. This capability enables applications to have linked queries.

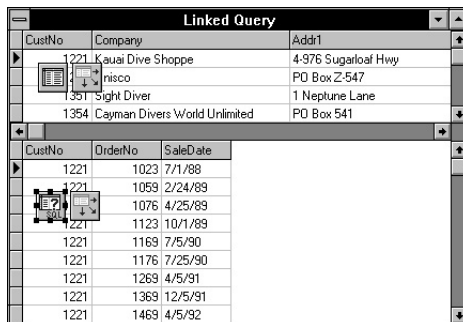

The LINKQRY sample application illustrates the use of the *DataSource* property to link a query in a master-detail form. The form contains a *TQuery* component (named *Orders*) with the following in its *SQL* property:

```
SELECT Orders.CustNo, Orders.OrderNo, Orders.SaleDate
FROM Orders
WHERE Orders.CustNo = :CustNo
```

As illustrated below, the form also contains:

- *ATDataSource* named *OrdersSource*, linked to *Orders* by its *DataSet* property.
- *ATTable* component (named *Cust*).
- *ATDataSource* named *CustSource* linked to *Cust*.
- Two data grids; one linked to *CustSource* and the other to *OrdersSource*.

**Figure 5.5** Form with linked queries

CustNo	Company	Addr1
1221	Kauai Dive Shoppe	4-976 Sugarloaf Hwy
1221	nisco	PO Box Z-547
1331	Sight Diver	1 Neptune Lane
1354	Cayman Divers World Unlimited	PO Box 541

CustNo	OrderNo	SaleDate
1221	1023	7/1/88
1221	1059	2/24/89
1221	1076	4/25/89
1221	1123	10/1/89
1221	1169	7/5/90
1221	1176	7/25/90
1221	1269	4/5/91
1221	1369	12/5/91
1221	1469	4/5/92

*Orders'* *DataSource* property is set to *CustSource*. Because the parameter *:CustNo* does not have any value assigned to it, at run time Delphi will try to match it with a column name in *CustSource*, which gets its data from the Customer table through *Cust*. Because there is a *CustNo* column in *Cust*, the current value of *CustNo* in the *Cust* table is assigned to the parameter, and the two data grids are linked in a master-detail relationship. Each time the *Cust* table moves to a different row, the *Orders* query automatically re-executes to retrieve all the orders for the current customer.

## Dynamic SQL example

---

Here's a simple form that uses a dynamic query and provides substitution parameters programmatically:

- Start a new project and place the required controls on the form. For this example, place an edit control, Edit1, a button, Button1, and a data-aware grid control, DBGrid1, on the form. Now create a *TQuery* component, Query1, and a data source, DataSource1, and set the *DataSource* property of DBGrid1 to "DataSource1" and the *Dataset* property of DataSource1 to "Query1."

Set the *DatabaseName* property of Query1 to DBDEMOS. Double-click on its SQL property in the Object Inspector and enter the following SQL statement. Remember to precede the substitution parameter with a colon:

```
SELECT * FROM country WHERE name LIKE :CountryName
```

- Prepare the query in the *OnCreate* event of the form:

```
procedure TForm1.FormCreate(Sender: TObject);
begin
    Query1.Prepare;
end;
```

- Provide parameters in response to some event. In this example, double-click on Button1 to edit the *OnClick* event and use the contents of Edit1.Text as a substitution parameter:

```
procedure TForm1.Button1Click(Sender: TObject);
begin
    Query1.Close;
    Query1.Params[0].AsString := Edit1.Text;
    Query1.Open;
end;
```

## Creating heterogenous queries

---

Some applications may require queries of tables in more than one database. Such queries are called *heterogenous queries*, and are not supported by standard SQL. A heterogenous query may join tables on different servers, and even different types of servers. For example, a heterogeneous query might involve a table in a Oracle database, a table in a Sybase database, and a local dBASE table.

Delphi supports heterogeneous queries, as long as the query syntax conforms to the requirements of local SQL, as described in Appendix C, "Using local SQL."

To perform a heterogeneous query, you must define a BDE standard alias that references a local directory, and use the alias for the *DatabaseName* of the query component. You must also define BDE aliases for each of the databases being queried. In the query text, precede each table name with the alias for its database.

You can define BDE aliases with the BDE Configuration Utility, described in Appendix B, “Using the BDE configuration utility.” For example, suppose you define an alias called *Oracle1* for an Oracle database that has a CUSTOMER table, and *Sybase1* for a Sybase database that has an ORDERS table. A simple query against these two tables would be

```
SELECT CUSTOMER.CUSTNO, ORDERS. ORDERNO  
FROM :Oracle1:CUSTOMER, :Sybase1:ORDERS
```

# Building a client/server application

Delphi Client/Server enables you to develop applications that can access remote SQL servers such as Oracle, Sybase, Informix, and InterBase, as well as local Paradox and dBASE databases. A *remote* server is one that is physically removed from the client machine on which the Delphi application runs. The server and client must be connected by a network. Delphi also includes the Local InterBase Server, a full-featured SQL server that runs on Microsoft Windows.

There are a number of issues that are particularly important when developing a client/server application:

**Portability versus optimization:** Will the application use any server-specific SQL syntax? To what degree will the database be optimized for a particular server?

**Transactions:** What kind of transaction control will the application require?

**Server features:** Will the application require the use of server features such as stored procedures? How will these be surfaced?

**Connectivity:** What communication protocol will the application use? Does the application need to be deployed to support multiple communication protocols?

**Deployment:** What executables, libraries, and other files does the application require and how are these delivered to the end user?

## Portability versus optimization

---

In a client/server system, the database running on the server and the application running on the client define the overall system, referred to as the *database/application*. While these two elements are often designed separately and considered distinct, they must be integrated to build a successful client/server application. One of the important considerations is portability versus optimization.

*Portability* refers to the ease with which an database/application can run on different servers. *Optimization* refers to the extent to which an application takes advantage of the special features of a particular system.

Client portability is not an issue with Delphi, because Delphi applications will run on any 16-bit or 32-bit Windows platform. However, server portability and communications portability can be considerations.

Because Delphi applications use the Borland Database Engine, they can be easily integrated with dBASE and Paradox applications (for desktop data sources) and other clients for server data sources.

## Server portability

---

It may be desirable to design an application so that it can be easily ported to different types of servers, either because the end-users require multiple heterogeneous server support, or because the application will be used by different groups of end-users with different types of servers. In designing a client-server application, there is an inherent trade-off between portability and optimization, because making use of server-specific features results in increased application performance but decreased portability.

A Delphi application that uses only *TTable* components for data access will be fully portable among different server types. An application may benefit from improved performance by using *TQuery* components and passthrough SQL, and as long as the SQL syntax is ANSI standard, there will be little loss of portability.

As soon as SQL syntax departs from the ANSI standard, the application will no longer be fully portable. If server portability is a consideration, you must carefully weigh whether the gain in using server-specific syntax is worth the cost in portability. Maintainability of an application may be reduced by optimization for a specific server type, because each server-specific implementation may require separate maintenance.

An application can be further optimized by using server-specific features such as stored procedures. However, this will usually require server-specific implementation in the database, and perhaps the application, depending on how the features are surfaced.

It is also important to consider that servers' transaction processing may differ in subtle yet important ways. This and other distinctions among SQL servers may complicate portability. Before attempting to create a portable database/application, you should build an application that runs reliably against one type of server database. In some cases, it may be necessary to build the application separately against each of the target server types.

## Client/server communication portability

---

Depending on the application requirements, it may be necessary to support multiple communication protocols, such as TCP/IP and Novell SPX. Providing for multiple communication protocols is simply a matter of ensuring that the client platforms have the proper communication software installed. This portability issue does not typically surface until the deployment phase, but it should be addressed in the implementation

phase to ensure that the initial test deployment packages include the proper client communication software.

## Using the Local InterBase Server

---

The Local InterBase Server (LIBS) is a version of the Borland InterBase server that runs on Windows 3.1. It provides all of the features of a SQL server for local, single-user operation. For more information on the Local Interbase Server, see the *Local InterBase Server User's Guide*. The Local Interbase Server can be used in primarily two ways for client/server development:

- As a local environment for developing a client/server application, regardless of the server to be used.
- As an intermediate step in upsizing, between the desktop and server, providing a local SQL engine for development of SQL-specific features. For more information on upsizing, see "Upsizing" on page 140.
- As a local database engine for deployment of standalone desktop SQL applications.

### Building an application to access any server

---

If you are developing a client/server application, you can use the Local InterBase Server for local development, even if the production database will run on some other server type.

If the production database already exists on a database server, you can use the Local InterBase Server as follows:

- Use your server's tools to create an SQL data definition script for the database. Remove any non-standard SQL syntax that will not work with InterBase. Generally, this means removing stored procedure definitions and other advanced features and mapping data types to InterBase data types.
- Use Windows ISQL to create a local InterBase database then execute the SQL script to define the database. For information on using Windows ISQL, see the *Local InterBase Server User's Guide*.
- Populate the database with representative data using the techniques described in "Upsizing."
- Create a Delphi database application that uses the Local InterBase Server database as a data source.
- Once the application has been sufficiently tested against the development database, change the *TDataSource* to use an alias that points to the target server. It is recommended to first test the application against a duplicate of the production database to surface server-specific features such as stored procedures.

If the production database does not already exist, you can first define a prototype database on the LIBS, and develop the application locally. Simultaneously, you can

define a congruent database on the target server. Finally, you can redirect the application to access the database on the target server.

## Building an application to access InterBase

---

To build an application that accesses a production database that already exists on an InterBase workgroup server, follow this procedure:

- Use the InterBase database backup utility to create a backup of the database, using the “Backup Metadata Only” option. This will save the structure of the database, but not the data (which may be huge). For information on how to do this, see the *Local InterBase Server User’s Guide*.
- Restore the database to the Local InterBase Server. This will be the development platform.
- Populate the database with a modest amount of representative data. Your application will access this data during the development and testing process. Because it is “dummy” data that is not connected to the production database, there is no chance that the production database will be corrupted. Your application can access any server features present in the production database, including stored procedures.
- Once the application has been sufficiently tested against the development database, change the *TDataSource* to use an alias that refers to the production server. It is recommended to first test the application against a duplicate of the production database on the server.

## Using InterBase in upsizing

---

One upsizing path is to use the Local Interbase Server (LIBS) as an intermediate data source. This enables you to address all the SQL development issues separately from connectivity and client/server issues. The steps include

- Defining the database on the Local InterBase Server, using the techniques described in “Upsizing” on page 140.
- Developing the application against the LIBS database.
- Migrating the LIBS database to the target server.
- Redirecting the application to access the target server.

## Connecting to a database server

---

Borland SQL Links for Windows enables a Delphi application to connect through the BDE to a remote database server. SQL Links drivers provide connections to Oracle, Sybase, Informix, Microsoft SQL Server, and InterBase.

Through the BDE Configuration Utility, you can set up an alias for each data source to which your application needs to connect. These aliases then become available to choose as the value of the *DatabaseName* property of *TTable* and *TQuery* components. For more

information on the BDE Configuration Utility, see Appendix B, “Using the BDE configuration utility.”

## Connectivity

---

Delphi client applications can use any network protocol (such as TCP/IP or Novell SPX/IPX) supported by the server, as long as both the server and the client machines have the proper communication software installed. You must configure the SQL Link driver for the desired protocol. For more information, see the *SQL Links for Windows User's Guide*.

Establishing an initial connection between client and server can often be problematic, especially when using TCP/IP, because there are a number of critical factors that must all be in place before a connection can be established.

### Using TCP/IP

TCP/IP is a widely-used communication protocol that enables applications to connect to many different database servers. When using TCP/IP, you must ensure:

- The TCP/IP communication software and the proper Winsock driver are installed on the client.
- The server's IP address is registered in the client's HOSTS file or that Directory Network Services (DNS) is properly configured.
- The server's port number is entered in the client's SERVICES file.
- The application is searching the proper directory paths for the DLLs it needs. Check the PATH statement in AUTOEXEC.BAT.

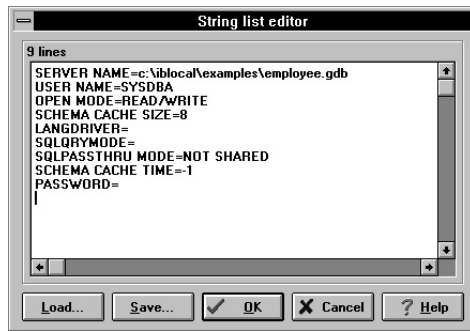

For more information, see the *SQL Links for Windows User's Guide* and your server documentation.

## Connection parameters

---

The *Params* property of a connected *TDatabase* object contains a *TString* list of all the SQL Link parameters required to connect to a server of the specified type. You can edit these parameters by clicking on the ellipsis button to the right of the *Params* property in the Object Inspector. The String List Editor opens with the parameters. For example, here are the parameters for connection to an InterBase server:

**Figure 6.1** InterBase parameters in the String List Editor

You can modify these parameters and add others as needed to customize the connection performed by the application. For more information, see the *SQL Links for Windows User's Guide*.

## Using ODBC

---

A Delphi application can access ODBC data sources such as DB2, Btrieve, or Microsoft Access through the Borland Database Engine (BDE). To do this, you must set up an ODBC driver connection using the BDE Configuration Utility. An ODBC driver connection requires:

- A vendor-supplied ODBC driver.
- The Microsoft ODBC Driver Manager.
- A BDE alias, established with the BDE Configuration Utility or with Delphi.

The BDE configuration setting AUTO ODBC (on the System page) enables an alias to automatically configure for use of ODBC. When AUTO ODBC is True, datasource and driver information will automatically be imported from the ODBC.INI file.

For more information, see the online help for the BDE Configuration Utility.

## Handling server security

---

Most database servers include security features to limit database access. Generally, the server will require a user name and password login before a user can access a database. If a server requires a login, then Delphi will prompt you at design time when you attempt to connect to a database on the server (for example, when you specify a *TableName* for a *TTable* component).

By default, a Delphi application opens the standard Login dialog box, whenever an application opens a connection to a database server. If a connection has already been established, the Login dialog box does not appear.

**Figure 6.2** Database Login dialog box

A Delphi application can handle server login several different ways:

- If the *LoginPrompt* property of a *TDatabase* component is True (the default), the standard Delphi Login dialog box will be opened when the application attempts to establish a database connection.
- By setting *LoginPrompt* to False, and including the USERNAME and PASSWORD parameters in the *Params* property of the *TDatabase* component. For example,

```
USERNAME = SYSDBA  
PASSWORD = masterkey
```

This is generally not recommended since it compromises server security.

- Use the *OnLogin* event of *TDatabase* to set login parameters. The *OnLogin* event gets a copy of the *TDatabase*'s login parameters array. Use the *Values* property to change these parameters:

```
LoginParams.Values['SERVER NAME'] := 'MYSERVERNAME';  
LoginParams.Values['USER NAME'] := 'MYUSERNAME';  
LoginParams.Values['PASSWORD'] := 'MYPASSWORD';
```

When control returns from your *DatabaseLogin* event handler, these parameters will be used to establish a connection.

## Using the TDatabase component

The *TDatabase* component is not required for database access, but it provides additional control over factors that are important for client/server applications, including the ability to:

- Create a persistent database connection.
- Customize database server logins.
- Create BDE aliases local to an application.
- Control transactions and specify transaction isolation level.

The *DataSets* property of *TDatabase* is an array of pointers to the active datasets in the *TDatabase*. The *DatasetsCount* property is an integer that specifies the number of active datasets.

## The Connected property

The *Connected* property of a *TDatabase* component specifies whether an application remains connected to a database server even when no tables are open. If an application will be opening and closing several tables in a single database, it will be more efficient to set the Database object's *Connected* property to True. That way, the application will remain connected to the database even if it does not have any tables open. It can then open and close tables repeatedly without incurring the overhead of connecting to the database each time.

A *TDatabase* object's *Connected* property can be overridden by the application-global *TSession* object. This object has a Boolean *KeepConnections* property that specifies whether to maintain database connections even if no tables are open. If *KeepConnections* is False, a *TDatabase* object's *Connected* property determines if connections are maintained when no *TTables* or *TQueries* are open. If *KeepConnections* is True (the default), database connections are always maintained. Specifically,

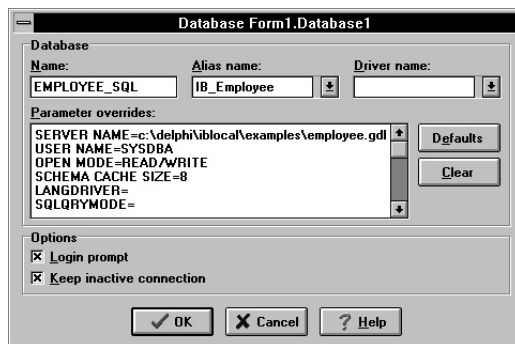

- Database connections will be maintained until the application exits or until the Session's *DropConnections* method is called .
- Setting a *TDatabase* object's *Connected* property to False will have no effect.

## Creating application-specific aliases

The *TDatabase* object enables you to create BDE aliases specific to an application. To name the alias, enter a name in the *DatabaseName* property. Any dataset components can then use the local alias by using the specified *DatabaseName*.

To customize the parameters for a local alias, double-click on the *TDatabase* component. The Database Properties Editor opens:

**Figure 6.3** Database Properties Editor

This tool enables you to customize application-specific aliases local based on existing aliases.

The three text fields at the top of the dialog box correspond to the *DatabaseName*, *AliasName*, and *DriverName* properties.

- *DatabaseName* is the name of the database connection that can be used by dataset components instead of a BDE alias, directory path, or database name. In other words, this is the name of the local alias defined by the component that will show up in the *DatabaseName* drop-down list of dataset components.
- *AliasName* is the name of an existing BDE alias configured with the BDE Configuration Utility. This is where the component gets its default parameter settings. This property will be cleared if *DriverName* is set.
- *DriverName* is the name of a BDE driver, such as STANDARD (for dBASE and Paradox), ORACLE, SYBASE, INFORMIX or INTERBASE. This property will be cleared if *AliasName* is set, because an *AliasName* specifies a driver type.

Choose the Defaults button to retrieve the default parameters for the selected alias. The values will be displayed in the Parameters list box. Any changes you make to the defaults are used instead of the default values for any database connection in the application that uses that *DatabaseName*.

The check boxes labeled “Loginprompt” and “Keep inactive connection” correspond to the *LoginPrompt* and *KeepConnections* properties of the *TDatabase* component.

## Understanding transaction control

---

SQL database servers handle requests in logical units of work called *transactions*. A transaction is a group of SQL statements that must all be performed successfully before the server will finalize (or *commit*) changes to the database. Either all the statements will succeed, or all will fail.

Transaction processing ensures database consistency even if there are hardware failures, and maintains the integrity of data while allowing concurrent multiuser access. For example, an application might update the ORDERS table to indicate that an order for a certain item was taken, and then update the INVENTORY table to reflect the reduction in inventory available. If there were a hardware failure after the first update but before the second, the database would be in an inconsistent state, since the inventory would not reflect the order entered. Under transaction control, both statements would be committed at the same time. Transaction control becomes even more important in a multiuser application.

In SQL, transactions are explicitly ended with a command to either accept or discard the actions performed. The COMMIT statement permanently commits the transaction, making changes visible to all users. The ROLLBACK statement undoes all changes made to the database in the transaction. Different database servers implement transaction processing differently. For the specifics of how your server handles transaction processing, refer to your server documentation.

## Handling transactions in applications

---

Delphi applications can control transactions:

- **Implicitly:** Delphi will automatically start and commit transactions as needed when an application calls the *Post* method (explicitly or implicitly in another method).

- **Explicitly:** depending on the level of control the application requires, either with
  - The *StartTransaction*, *Commit*, and *Rollback* methods of *TDatabase*. This is the recommended approach.
  - Passthrough SQL in a *TQuery* component. The application must use server-specific SQL transaction control statements. You must understand how your server performs transaction handling.

Transaction control statements are only meaningful when the database is on an SQL server. The *StartTrans*, *Commit*, and *Rollback* methods will raise an exception if the underlying database is Paradox or dBASE.

## Implicit transaction control

Delphi applications that use only the built-in methods can rely on implicit transaction control. Any Delphi operations on a server database that are not under explicit transaction control will be under implicit control. Delphi will commit each individual write operation (*Post*, *AppendRecord*, and so on) as a separate transaction, so it will commit database changes on a row-by-row basis. This minimizes update conflicts, but can lead to heavy network traffic.

When using implicit transaction control, keep the `SQLPASSTHRUMODE` setting at `SHARED AUTOCOMMIT`, the default. For more information, see “Setting the SQL passthrough mode.”

Implicit transaction control happens automatically, but does not provide much flexibility. If an application needs multi-row transactions or passthrough SQL, then it should use explicit transaction control.

## Explicit transaction control

The recommended approach for transaction control is to use the methods of *TDatabase*, because this will result in clearer code and a more portable application. The methods for transaction control are

- *StartTransaction*: Begins a transaction at the isolation level specified by the *TransIsolation* property of *TDatabase*. If a transaction is currently active, Delphi will raise an exception.
- *Commit*: Commits the currently active transaction on the database. If no transaction is active, Delphi will raise an exception.
- *Rollback*: Rolls back the currently active transaction. All changes to the database since the last *Commit* will be undone.

Some applications may require additional server-specific transaction control features. In this case, use a *TQuery* component with passthrough SQL statements for transaction control. Ensure that `SQLPASSTHRUMODE` is set to `NOT SHARED` so that the passthrough SQL does not affect other transactions.

## Setting the SQL passthrough mode

`SQLPASSTHRUMODE` in the BDE Configuration utility determines if passthrough SQL and standard BDE calls share the same database connection. For transactions, this

translates to whether passthrough transactions and other transactions “know” about each other. Only applications that use passthrough SQL need be concerned with `SQLPASSTHRUMODE`.

`SQLPASSTHRUMODE` can have the following settings:

- `SHARED AUTOCOMMIT` (the default)
- `SHARED NOAUTOCOMMIT`
- `NOT SHARED`

With `SHARED AUTOCOMMIT`, each operation on a single row is committed. This mode most closely approximates desktop database behavior, but is inefficient on SQL servers because it starts and commits a new transaction for each row, resulting in a heavy load of network traffic.

With `SHARED NOAUTOCOMMIT`, the application must explicitly start and commit transactions. This setting can result in conflicts in busy, multiuser environments where many users are updating the same rows.

`NOT SHARED` means that passthrough SQL and Delphi methods use separate database connections.

**Note** To control transactions with passthrough SQL, you must set `SQLPASSTHRU MODE` to `NOT SHARED`. Otherwise, passthrough SQL and Delphi’s methods may interfere with each other, leading to unpredictable results.

## Transaction isolation levels

---

A transaction’s *isolation level* determines how it interacts with other simultaneous transactions accessing the same tables. In particular, the isolation level affects what a transaction reads from the tables being accessed by other transactions.

Some servers enable you to set the transaction isolation level explicitly in passthrough SQL. If not specified, passthrough SQL operations will use a server’s default isolation level. For more information, see your server documentation.

Transactions (both explicit and implicit) using Delphi’s built-in methods will use the *TransIsolation* property of *TDatabase* to specify transaction isolation level. *TransIsolation* can have the following values:

- *tiDirtyRead*: The transaction can read uncommitted changes to the database by other transactions. This is the lowest isolation level.
- *tiReadCommitted*: The transaction can read only committed changes to the database by other transactions. This is the default isolation level.
- *tiRepeatableRead*: The transaction cannot read other transactions’ changes to previously read data. This guarantees that once a transaction reads a records, it will not change if it reads it again. This the highest isolation level.

Database servers may support these isolation levels differently or not at all. If the requested isolation level is not supported by the server, then Delphi will use the next highest isolation level. The actual isolation level used by each type of server is shown in

Table 6.1, “Server transaction isolation levels.” For a detailed description of how each isolation level is implemented, see your server documentation.

**Table 6.1** Server transaction isolation levels

<i>TransIsolation setting</i>	Oracle	Sybase and Microsoft SQL servers	Informix	InterBase
Dirty read	Read committed	Read committed	Dirty Read	Read committed
Read committed (Default)	Read committed	Read committed	Read committed	Read committed
Repeatable read	Repeatable read (READ ONLY)	Read committed	Repeatable Read	Repeatable Read

If an application is using ODBC to interface with a server, the ODBC driver must also support the isolation level. For more information, see your ODBC driver documentation.

## Using stored procedures

A stored procedure is a server-based program that can take input parameters and return output parameters to an application. Stored procedures are associated with a database, and are actually part of metadata, like tables or domains. The *TStoredProc* component enables Delphi applications to execute server stored procedures.

The *DatabaseName* property of *TStoredProc* specifies the database in which the stored procedure is defined. This property is the same as for *TTable* and *TQuery*--it can be a BDE alias or an explicit directory path and database name. The *StoredProcName* specifies the name of the stored procedure. A drop-down list will display a list of all procedures defined in the specified database.

A *TStoredProc* can return either a singleton result or a result set with a cursor, if the server supports it.

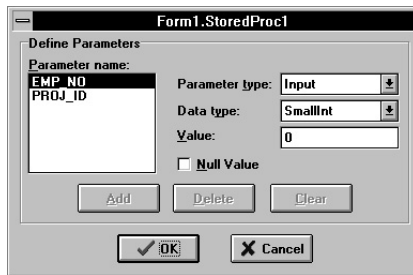

**Note** InterBase “select” procedures are called with the `SELECT` statement as if querying a table. To get output from such procedures, use a *TQuery* component with the appropriate `SELECT` syntax.

## Input and output parameters

A stored procedure has a *Params* array for its input and output parameters similar to a *TQuery* component. The order of the parameters in the *Params* array is determined by the stored procedure definition. An application can set the values of input parameters and get the values of output parameters in the array similar to *TQuery* parameters. You can also use *ParamByName* to access the parameters by name. If you are not sure of the ordering of the input and output parameters for a stored procedure, use the Parameters Editor.

To invoke the Parameters Editor, select the *TStoredProc* component and then right-click the mouse. The following dialog box opens:

**Figure 6.4** TStoredProc Parameters Editor

The Parameters Editor displays the input and output parameters for the procedure. To prepare the stored procedure with the default parameter types and field types, simply choose OK. You can set values of input parameters at design time by choosing the parameter in the Parameters list and entering a value in the Value field. To specify null input parameter values, select the Null value check box. The Parameters Editor is explained in more detail in Chapter 5, “Using SQL in applications.”

**Note** Delphi will attempt to get information on input and output parameters from the server. For some servers (such as Sybase), this information may not be accessible. In such cases, you must enter the names and data types of the input and output parameters in the Parameters Editor at design time.

## Executing a stored procedure

Before an application can execute a stored procedure, you must prepare the stored procedure, which can be done:

- At design time with the Parameters Editor.
- At run time with the *Prepare* method of *TStoredProc*.

To prepare a stored procedure at run time, use the *Prepare* method, before executing it. For example,

```
StoredProc1.Prepare;
```

To execute a prepared stored procedure, use the *ExecProc* method. Values can be assigned to and from a *TStoredProc* component just as for *TQuery* components, by using the *Params* array. For example, the following code could be in a button's *OnClick* event:

```
StoredProc1.Params[0].AsString := Edit1.Text;  
StoredProc1.ExecProc;  
Edit2.Text := StoredProc1.Params[1].AsString;
```

The first parameter, *Params*[0], is an input parameter of type String. It is assigned the text entered by the user in Edit1. Then, assuming StoredProc1 has been prepared at design time with the Parameters Editor, the stored procedure is run with *ExecProc*. Finally, the output parameter, *Params*[1], is displayed by Edit2.

On some servers, stored procedures can return a result set similar to a query. Applications can use data aware controls to display the output of such stored procedures. You do this in the same way as you display output from *TQuery*

components: create a *TDataSource* component and assign its name to a data grid's *DataSource* property.

## Oracle overloaded stored procedures

---

Oracle servers allow overloading of stored procedures; that is, different procedures with the same name. The *Overload* property enables an application to specify the procedure to execute. If *Overload* is zero (the default), there is assumed to be no overloading. If *Overload* is one (1), then Delphi will execute the first stored procedure with the overloaded name; if it is two (2), it will execute the second, and so on.

## Upsizing

---

Migrating a desktop application to a client/server application is called *upsizing*. Upsizing is a complex topic and a full treatment of it is beyond the scope of this book. However, this section will address some of the most important aspects of upsizing a Delphi application.

Upsizing has two major facets:

- Upsizing the database from the desktop to the server
- Upsizing the application to address client/server considerations

Upsizing requires a shift in perspective from the desktop world to the client/server world. Desktop databases and SQL server databases are different in many respects. Desktop databases are designed for one user at a time, while servers are designed for multiuser access. Desktop databases are conceptually record-oriented, while server databases are conceptually set-oriented. Desktop databases typically store each table in a separate file, while servers store all the tables in a database together.

Client/server applications must also address some entirely new issues, the most complex of which are connectivity, network usage, and transaction handling.

## Upsizing the database

---

Upsizing a database includes the following steps:

- Defining metadata on the server, based on the existing desktop database structure.
- Migrating the data from the desktop to the server.
- Addressing issues such as:
  - Data type differences
  - Data Security and Integrity
  - Transaction control
  - Data Access Rights
  - Data Validation
  - Locking

Delphi provides two ways to upsize a database:

- Use the Database Desktop utility and choose Tools | Utilities | Copy to copy a table from desktop table to SQL format. For more information, see Appendix A, “Using Database Desktop.”
- Build a Delphi application that uses a *TBatchMove* component. For more information on *TBatchMove*, see Chapter 3, “Using data access components and tools.”

Both of these options will copy table structures and migrate data from the desktop source to the server destination. Depending on the database, it may be necessary to make changes to the tables created by these methods. For example, the datatype mappings may not be exactly as desired.

Additionally, you must add to the database any of the following features if required:

- Integrity constraints (primary and foreign keys)
- Indexes
- Check constraints
- Stored procedures and triggers
- Other server-specific features

Depending on the database, it may be most efficient to define the metadata first by using an SQL script and the server’s data definition tools and then migrate the data using one of the two methods previously mentioned. If you define the table structure manually, then Database Desktop and *TBatchMove* will copy only the data.

## Upsizing the application

---

In principle, a Delphi application designed to access local data can access data on a remote server with few changes to the application itself. If a congruent data source has been defined on an SQL server, you can re-direct the application to access it rather than the local data source, simply by changing the *DatabaseName* property of *TTable* or *TQuery* components in the application.

In practice, however, there are a number of important differences between accessing local and remote data sources. Client/server applications must also address a number of issues that are not relevant to desktop applications.

Any Delphi application can use either *TTable* or *TQuery* for data access. Desktop applications will generally use the *TTable* component. When upsizing to a SQL server, it may be more efficient to use *TQuery* objects instead in some instances. Depending on the specific application, *TQuery* may be preferable if the application will be retrieving a large number of records from database tables.

If the application uses mathematical or aggregate functions, it may be more efficient to perform these functions on the server with stored procedures. The use of stored procedures may be faster because servers are typically more powerful. This also reduces the amount of network traffic required, particularly for functions that process a large number of rows.

For example, an application might need to compute the standard deviation of values of a large number of records. If this function were performed on the client, all the values would have to be retrieved from the server to the client, resulting in a lot of network traffic. If the function were performed by a stored procedure, all the computation would

be performed on the server, so the application would only retrieve the answer from the server.

## Deploying support for remote server access

---

Deployment of general database application is discussed in Chapter 1, "Introduction." In addition to the files required to deploy a desktop database application, deployment of a client/server application requires installation of the appropriate Borland SQL Links. These are not part of the Borland Database Engine, and must be installed separately. They are redistributable, according to the terms of the license agreement.

**Note** For more information on deploying Delphi applications, refer to the file DEPLOY.TXT, installed to the DELPHI\DOC directory by default.

Each server type has a set of files for the SQL Link. In addition, a file used by all the SQL Links is BLROM800.LD, the Roman8 language driver using binary collation sequence.

### Oracle

---

The following files provide the SQL Links interface with Oracle servers. In addition, applications will require Oracle client files for interface to low-level communication protocols such as TCP/IP. Refer to your server documentation.

**Table 6.2** Oracle SQL Link files

File name	Description
SQLD_ORA.DLL	Borland SQL Link Oracle Driver
SQLD_ORA.HLP	Online help file
SQL_ORA.CNF	BDE Configuration File for Oracle Driver
ORA6WIN.DLL	Oracle Version 6.x client-side DLL
ORA7WIN.DLL	Oracle Version 7.x client-side DLL
SQL13WIN.DLL	Oracle client-side DLL
SQLWIN.DLL	Oracle client-side DLL
COREWIN.DLL	Oracle client-side DLL
ORAWE850.LD	Language driver based on DOS code page 850

---

### Sybase and Microsoft SQL servers

---

The following files provide the SQL Links interface with Sybase servers. In addition, applications will require Sybase client files for interface to low-level communication protocols such as TCP/IP. Refer to your server documentation.

**Table 6.3** Sybase SQL Link files

File name	Description
SQLD_SS.DLL	Borland SQL Link Sybase Driver
SQLD_SS.HLP	Borland SQL Link Sybase Driver Help
SQL_SS.CNF	BDE Configuration File for Sybase Driver

**Table 6.3** Sybase SQL Link files (continued)

File name	Description
W3DBLIB.DLL	Sybase/Microsoft SQL Server client-side DLL
DBNMP3.DLL	Sybase/Microsoft SQL Server client-side DLL for Named Pipes
SYDC437.LD	Language driver based on DOS code page 850
SYDC850.LD	Language driver based on DOS code page 437

## Informix

The following files provide the SQL Links interface with Informix servers. In addition, applications will require Informix client files for interface to low-level communication protocols such as TCP/IP. Refer to your server documentation.

**Table 6.4** Informix SQL Link files

File name	Description
SQLD_INF.DLL	Borland SQL Link Informix Driver
SQLD_INF.HLP	Online help file
SQL_INF.CNF	BDE Configuration File for Informix Driver
LDLLSQLW.DLL	Informix client-side DLL
ISAM.IEM	Informix error message file
OS.IEM	Informix error message file
RDS.IEM	Informix error message file
SECURITY.IEM	Informix error message file
SQL.IEM	Informix error message file

## InterBase

The following files provide the SQL Links interface to remote InterBase servers. These files are distinct from those required to access the Local InterBase Server..

**Table 6.5** InterBase SQL Link files

File name	Description
SQLD_IB.DLL	Borland SQL Link InterBase Driver
SQLD_IB.HLP	Borland SQL Link InterBase Driver Help
SQL_IB.CNF	BDE Configuration File for InterBase Driver
CONNECT.EXE	InterBase connection diagnostic tool
CONNECT.HLP	InterBase Windows connection diagnostic help file
GDS.DLL	InterBase API DLL
REMOTE.DLL	InterBase Networking interface DLL
INTERBAS.MSG	InterBase error message file

## TCP/IP Interface

The following files provide InterBase client applications their interface to Winsock 1.1 compliant TCP/IP products.

**Table 6.6** Winsock 1.1 client files

File name	Description
MVWASYNC.EXE	Asynchronous communication module
VSL.INI	TCP/IP transport initialization file
WINSOCK.DLL	Windows Socket DLL
MSOCKLIB.DLL	Maps Windows socket calls to VSL driver

For TCP/IP products that are not Winsock 1.1 compliant, InterBase client applications will require one of the following files. During installation, Delphi will prompt you to select the TCP/IP stack for which to install support. If the deployed application needs to support a different TCP/IP stack, you must copy the corresponding file from the installation disks.

**Table 6.7** Non-Winsock compliant TCP support files

File name	TCP/IP Product
M3OPEN.EXE	3Com 3+Open TCP Microsoft LAN Manager Digital Pathworks for DOS
M3OPEN.DLL	3Com 3+Open TCP Version 2.0
MBW.EXE	Beame & Whiteside TCP/IP
MFTP.EXE	FTP PC/TCP
MHPARPA.DLL	HP ARPA Service for DOS
MNETONE.EXE	Ungermann-Bass Net/One
MNOVLWP.DLL	Novell LAN WorkPlace for DOS
MPATHWAY.DLL	Wollongong Pathway Access for DOS
MPCNFS.EXE	Sun PC NFS
MPCNFS2.EXE	Sun PC NFS v3.5
MPCNFS4.DLL	Sun PC NFS v4.0
MWINTCP.EXE	Wollongong WIN TCP/IP for DOS

## Other communication protocols

The InterBase workgroup server for NetWare supports Novell SPX/IPX protocol. Two client files are required: NWIPXSPX.DLL and NWCALLS.DLL.

The InterBase Workgroup Server for Windows NT supports Microsoft Named Pipes protocol. No additional client files are required to support Named Pipes, but the client machine must have Microsoft LAN Manager or Windows for Workgroups 3.1.1 installed.

## Deploying ReportSmith support

---

To deploy an application that uses a *TReport*, you must include the .RPT files and ReportSmith Runtime in your deployment package. By default, Delphi installs the files required for ReportSmith Runtime in the RS\_RUN directory. These files require two to three megabytes of disk space. For more information about running reports, see *Creating Reports*.

**Note** For more information on deploying ReportSmith reports, refer to the file DEPLOY.TXT, installed to the DELPHI\DOC directory by default.

---

# A

## Using Database Desktop

This appendix describes Database Desktop and provides a synopsis of Database Desktop features. The complete Database Desktop *User's Guide* is available on the Delphi CD-ROM, and all features are described in Database Desktop Help.

### What is Database Desktop?

---

Database Desktop provides an easy way to create, restructure, and query tables to help you develop database applications with Delphi. You can use Database Desktop either as a standalone application on a single computer running Windows or as a multiuser application on a network.

This appendix contains information on using Database Desktop to work with data tables in a variety of formats.

### The Database Desktop window

---

This section discusses the Database Desktop window and its menus.

#### Starting Database Desktop

---

To start Database Desktop, double-click the Database Desktop icon in the Delphi program group or choose File | Run in the Program Manager and run DBD.EXE.

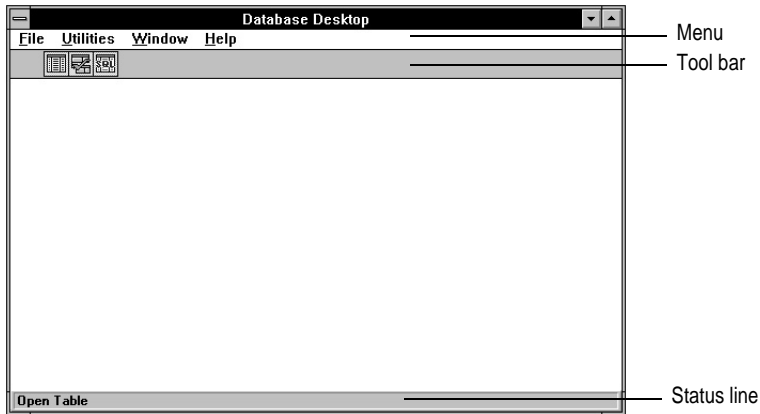

Database Desktop has several command-line options that let you control its configuration. For information on each option and its use, search for “command-line configuration” in the keyword list in Database Desktop Help.

## The Database Desktop window

---

The first time you start Database Desktop, the Database Desktop window opens. All Database Desktop windows are opened in and contained by this window.

**Figure A.1** The Database Desktop application window

Files you open in Database Desktop appear in their own type of windows. Tables appear in Table windows, queries appear in Query windows, and SQL statements appear in the SQL Editor.

Below the menu is a tool bar. The tool bar changes when the active window changes. The following figure shows the application window tool bar.

**Figure A.2** Application window tool bar

## Managing files

---

In Database Desktop you work with three types of files: QBE queries, .SQL files, and tables. Other files are created automatically by Database Desktop.

For a list of file extensions used by Database Desktop, search for "file-name extensions" in the keyword list in Database Desktop Help, and choose the topic "Types of Files."

### Opening files

To open a QBE query, SQL statement, or table, follow these steps:

- 1 Choose File | Open.
- 2 Choose the type of file to open—QBE query, SQL statement, or table.

### 3 Specify the file to open.

The Select File dialog box appears. For detailed information on the Select File dialog box, search for “Select File dialog box” in the keyword list in Database Desktop Help.

**Note** To access tables stored on a network, you must specify the location of the network control file. You do this by running the BDE Configuration Utility; double-click the BDE Configuration Utility icon in the Delphi program group. See online Help in the BDE Configuration Utility for more details.

### Setting up a working directory

The *working directory* is where Database Desktop looks first for files. The Working Directory setting controls what files are listed in File | Open and File | Save dialog boxes. So, for example, if you want to open C:\DBD\SAMPLES\BOOKORD.DB, make C:\DBD\SAMPLES your working directory so that you see BOOKORD.DB when you choose File | Open | Table.

To specify a working directory, choose File | Working Directory, then type the path to the directory.

**SQL** You cannot set your working directory to an alias on a remote server.

### Setting up a private directory

You should store temporary tables, such as *Answer*, in a private directory so they do not get overwritten by other users or applications. Choose File | Private Directory to establish a private directory.

Files stored in your private directory are listed in File | Open and File | Save dialog boxes, preceded by :PRIV: . Private directory files are visible and available to you, but not to other network users.

### Aliases

You can assign an *alias* as a shorthand for a directory using the Alias Manager dialog box. For example, if you have a collection of tables and queries in one directory (called C:\DBD\PROJECTS\CUSTLIST), you can specify the alias :MYWORK: rather than type the entire path.

Using aliases, you can avoid typing long path names, and you can use the Path list in File | Open and File | Save dialog boxes to list files in any directory for which you have defined an alias.

To create an alias, choose File | Aliases. For information on creating, changing, or removing an alias, search for “aliases” in the keyword list in Database Desktop Help.

## Creating tables

---

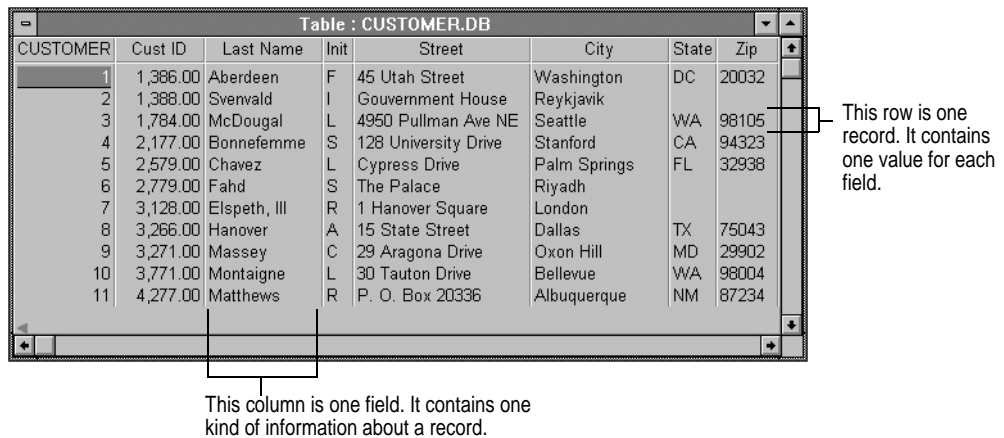

This section describes tables and discusses how to create and restructure Paradox, dBASE, and SQL tables in Database Desktop.

## Understanding tables

A database is an organized collection of information or data. An address book is an example of a database. It organizes data about people into specific categories: names, phone numbers, and addresses.

In a relational database, the data is organized into tables. Each row of a table contains information about a particular item; this is called a *record*. Each column contains one piece of the information that makes up a record; this is called a *field*.

**Figure A.3** A table

CUSTOMER	Cust ID	Last Name	Init	Street	City	State	Zip
1	1,386.00	Aberdeen	F	45 Utah Street	Washington	DC	20032
2	1,386.00	Svenvald	I	Gouvernement House	Reykjavik		
3	1,784.00	McDougal	L	4950 Pullman Ave NE	Seattle	WA	98105
4	2,177.00	Bonnefemme	S	128 University Drive	Stanford	CA	94323
5	2,579.00	Chavez	L	Cypress Drive	Palm Springs	FL	32938
6	2,779.00	Fahd	S	The Palace	Riyadh		
7	3,128.00	Elspeith, III	R	1 Hanover Square	London		
8	3,266.00	Hanover	A	15 State Street	Dallas	TX	75043
9	3,271.00	Massey	C	29 Aragona Drive	Oxon Hill	MD	29902
10	3,771.00	Montaigne	L	30 Tauton Drive	Bellevue	WA	98004
11	4,277.00	Matthews	R	P. O. Box 20336	Albuquerque	NM	87234

## Relational tables

Relational database applications such as dBASE and Paradox give you a way to link tables by comparing values stored in comparable fields in separate tables. The advantage of a relational database is that you can easily extract or combine data from several tables to get exactly the information you need, without changing the structure of the database. Also, a few small and discrete tables are more convenient to use and maintain than one large table.

The sample database files CUSTOMER.DB and BOOKORD.DB are examples of relational tables. These tables can be linked through the fields containing customers' ID numbers (*Cust ID* in the *Customer* table, *Cust* in *Bookord*). When the tables are linked, you can extract information from both tables into one table. For example, you can search for and extract a list of quantities ordered (from the *Bookord* table) and the respective last names (from *Customer*). The results are returned in an *Answer* table (see page 170).

## Planning tables

Planning is the first step in creating a table. Decide what you want the table to contain and how you want to lay it out. For tips on planning tables, search for "planning" in the keyword list in Database Desktop Help, and choose the topic "Planning Tables."

# Creating a new table

To create a new table,

- 1 Choose File | New | Table. Or right-click the Open Table tool bar button, and choose New.

The Table Type dialog box appears.

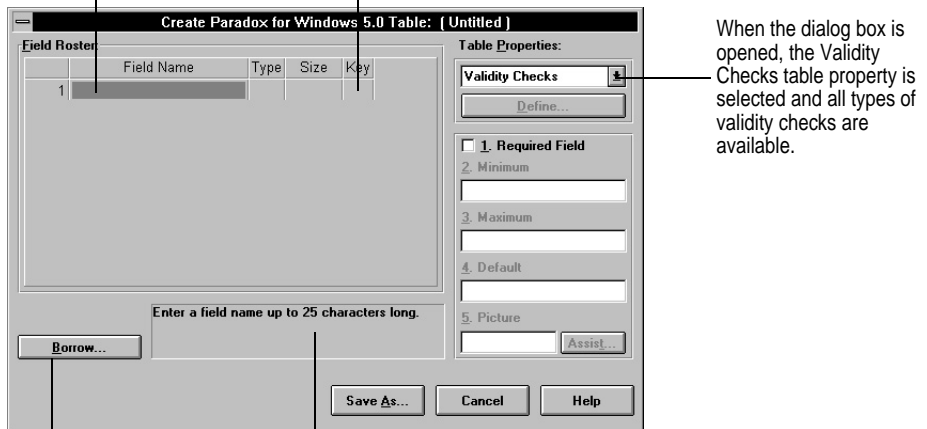

**Figure A.4** Table Type dialog box

- 2 If you want a table type other than Paradox for Windows, click the arrow next to the list box and select from the drop-down list.
- 3 Choose OK. The Create Table dialog box appears. This dialog box may have a slightly different appearance for different table types, but it will function the same.

**Figure A.5** The Create Table dialog box

Enter the field name, type, and size in the Field Roster. Press any key or double-click to key the table.

Choose this to borrow the structure of another table.

The status box gives you guidelines as you create the table.

For a step-by-step description of creating a table, search for “creating tables” in the keyword list in Database Desktop Help, and choose the topic “Creating a New Table.”

## Defining fields

---

Use the Field Roster in the Create Table dialog box (page 151) to define the fields of the new table. You can use the mouse, arrow keys, *Enter*, *Tab*, or *Shift+Tab* to move among the columns. (*Shift+Tab* moves backwards.)

### Field names

Type field names in the Field Name column of the Field Roster.

For information on rules governing field names, search for “field names” in the keyword list in Database Desktop Help, and choose the topic for the type of table you are using (Paradox, dBASE, or SQL).

### Adding, deleting, and rearranging fields

You can add, delete, and rearrange fields in the Field Roster.

For detailed information on changing fields, search for “fields” in the keyword list in Database Desktop Help.”

### Specifying field type

To specify the field type in the Create Table dialog box,

- 1 Select the Type column of the field you want.
- 2 Type the symbol (or name, for SQL tables) for the field type or select from the drop-down list. You can use the list in two ways:
  - Right-click the Type column again and click to select the field type.
  - Press *Spacebar* to see the list, then choose the field type.

For information on field types and sizes, search for “field types” in the keyword list in Database Desktop Help, and choose the topic for the type of table you are using (Paradox, dBASE, or SQL).

## Using indexes

---

The BDE uses indexes to keep track of the location of records in tables. This makes it easy to maintain a sorted order of a table and view like values together.

When you create an index for a Paradox or dBASE table, Database Desktop creates a file that contains the indexed field’s values and their locations. Database Desktop uses the index file to locate and sort the records in a table.

Indexes work differently for Paradox, dBASE, and SQL tables.

### Keys in Paradox tables

In Paradox tables, the primary index is called the *key*. A Paradox table’s key establishes the primary index and sort order for the table. A key also requires each value in the field(s) that defines the key to be unique. For example, if the Cust ID field is identified as the key of the *Customer table*, each value in the Cust ID field must be unique. Likewise, if the Cust, Date, and Item # fields are identified as the key of the *Bookord table*, the field

values (taken as an ordered group) must be unique. This guards against duplication of data within the table. Keys are required for linking tables and for using the data integrity features of Paradox tables.

To create a key, display the Create Table (page 151) or the Restructure Table (page 160) dialog box. Then move to the Key column in the Field Roster and double-click (or press any key). The key field indicator (\*) appears. Database Desktop keys the table on the selected field.

Follow these rules when defining keys:

- A table can have only one primary key. This key can be made up of one or more fields.
- If a key is defined as a single field, that field must be the first field in the Field Roster.
- If you identify more than one field as keyed, you create a *composite* key. These fields, taken as a group, must be unique for each record of the table. The composite key must be the first fields in the Field Roster.

## A dBASE table's index

When working with dBASE tables, Database Desktop uses an index to organize the records in a table according to the values in one or more fields.

When you create an index on a dBASE table, a file is created that contains the indexed field's values and their corresponding record numbers. Database Desktop refers to the index file when locating and displaying the records in a table.

Although Database Desktop supports both .MDX files and .NDX files, it is recommended that you use a dBASE production index (the .MDX file which uses the table's name as its file name) whenever possible. Although you can create nonproduction .MDX files as well as .NDX files, Database Desktop automatically maintains the production index.

For more information on dBASE indexes, search for "dBASE indexes" in the keyword list in Database Desktop Help.

**Note** Delphi does not support all dBASE index types. For more information, see Chapter 3, "Using data access components and tools."

## An SQL table's index

SQL tables use unique and non-unique indexes, but they do not use the primary keys that Paradox tables use. You can create multiple indexes for an SQL table; for each index, you specify whether it is unique or non-unique. Depending on the server, you may also be able to specify whether the index is case-sensitive and whether it is ascending or descending. SQL indexes, unlike Paradox and dBASE indexes, are always maintained.

You can use Database Desktop to create and modify indexes on SQL tables, but you cannot specify which index to use in Database Desktop.

When you use an SQL table in Database Desktop, the table should have a unique index. If it does not have a unique index you may not be able to view new records that you

insert, depending on the server. To add a unique index to an existing table, choose Utilities | Restructure.

For more information on SQL indexes, see “Creating indexes on SQL tables” on page 155.

## Defining secondary indexes

---

A *secondary index* is a field or group of fields other than the key field that can be used to sort the table or to link the table to other tables. Database Desktop enables you to create secondary indexes for Paradox tables.

You can use a secondary index to see an alternate view order for a Paradox table. For example, to view the *Customer* table by City, while keeping the table’s key order intact, you can use a secondary index on City to temporarily change the view order of the records.

For information on creating a secondary index, search for “secondary indexes” in the keyword list in Database Desktop Help, and choose the topic “Defining a Secondary Index.”

## Specifying validity checks

---

Validity checks govern the values you can enter in a field. The five types of validity checks are listed in Table A.1.

**Note** Validity checks work only on Paradox tables, not on dBASE tables. For SQL tables, the only validity check you can specify in Database Desktop is whether a field is required (not Null).

**Table A.1** Paradox validity checks

Validity check	Meaning
Required field	Every record in the table must have a value in this field. SQL tables can also use this validity check (equivalent to NOT NULL).
Minimum	The values entered in this field must be equal to or greater than the minimum you specify here.
Maximum	The values entered in this field must be less than or equal to the maximum you specify here.
Default	The value you specify here is automatically entered in this field. You can replace it with another value.
Picture	You specify a character string that acts as a template for the values that can be entered in this field. The values entered in this field are automatically formatted according to this picture.  For information on pictures, search for “picture strings” in the keyword list in Database Desktop Help, and choose the topic “Picture String Characters.”

---

For detailed information on validity checks, search for “validity checks” in the keyword list in Database Desktop Help.

**Note** A “Required field” validity check will set a Delphi *TField*’s *Required* property to True when the table is accessed from a Delphi application.

## Borrowing a table structure

When creating a table similar to one you already have, you can borrow its structure. Then you can either use it as is or change it. You must begin from a blank table structure to borrow another table's structure.

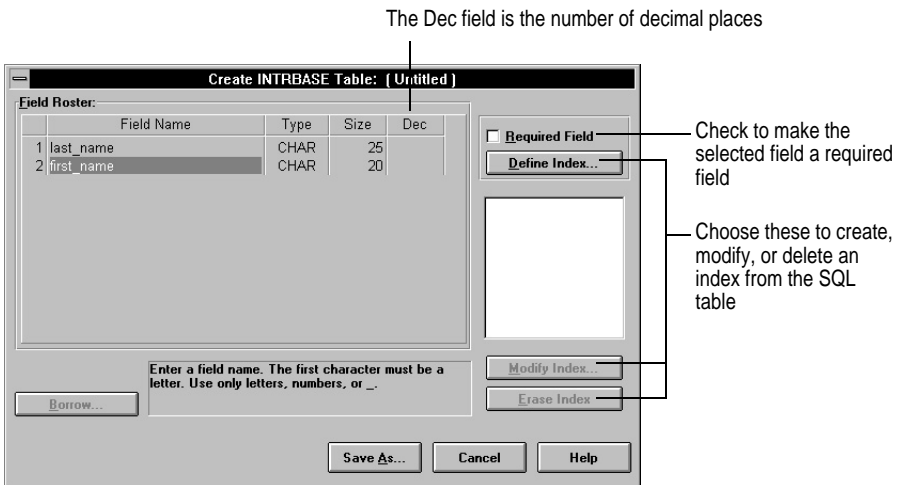

To borrow a table structure, choose Borrow from the Create Table dialog box.

For detailed information on borrowing, search for "borrow a table's structure" in the keyword list in Database Desktop Help.

## Creating an SQL table

When you create an SQL table, you can define the table structure (fields & types), specify required fields, and define indexes. The Create Table dialog box for SQL tables looks as shown in Figure A.6.

**Figure A.6** The Create Table dialog box for SQL tables

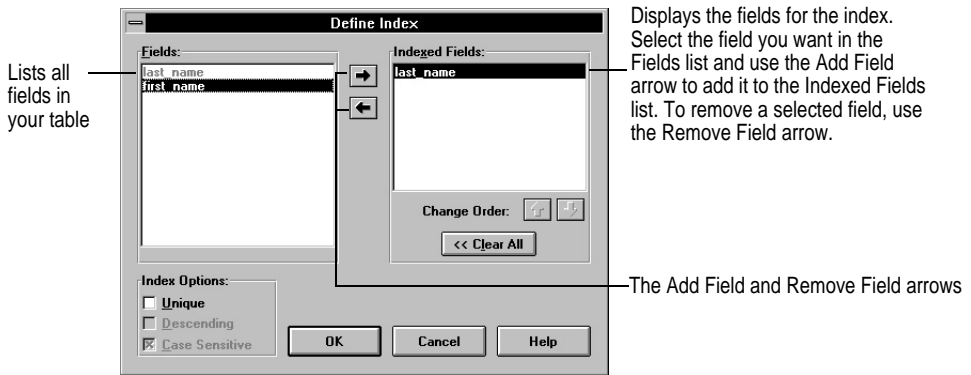

For information on valid field types for your SQL server, search for "field types" in the keyword list in Database Desktop Help, and choose the topic for your server.

## Creating indexes on SQL tables

You can use Database Desktop to create and modify indexes on SQL tables.

To create an index for an SQL table, display the Create Table (page 155) or the Restructure Table (page 160) dialog box. Then, choose Define Index. Database Desktop displays the Define Index dialog box, shown in Figure A.7.

**Figure A.7** The Define Index dialog box for SQL indexes

When you use an SQL table in Database Desktop, the table should have a unique index. If it does not have a unique index, you may not be able to view new records you insert.

For detailed information on using the Define Index dialog box, search for “Define Index Dialog Box” in the keyword list in Database Desktop Help, and choose the topic “Define Index Dialog Box (SQL Tables).”

## Naming SQL indexes

For most database servers, index names must be unique within the database (or in some other predefined workspace). When you create an index on an SQL table, Database Desktop prompts you to prefix the index name with the table name to ensure that the index name is unique.

**Sybase note** Sybase index names need only be unique within a table, not within the entire database, so Database Desktop does not prefix Sybase index names with table names.

When you create an SQL index and choose OK from the Define Index dialog box, Database Desktop supplies the prefix “<table>\_” for the index name as follows:

**Figure A.8** Save Index As dialog box

You can include the table name with the index name or omit it:

- If you type the index name following “<table>\_”, Database Desktop prefixes the index name with the table name and an underscore.
- If you delete “<table>\_”, Database Desktop omits the table name from the index name. If the index name is not unique, an error will occur when Database Desktop saves the table.

This index naming scheme also affects restructuring, as described in “Restructuring an SQL table” on page 160.

## Defining referential integrity for Paradox tables

Referential integrity means that a field or group of fields in one table (the “child” table) must refer to the key of another table (the “parent” table). Database Desktop enables you to define referential integrity rules for Paradox tables.

**Figure A.9** Referential integrity

Database Desktop accepts only those values that exist in the parent table's key as valid values for the specified field(s) of the child table. You can establish referential integrity only between like fields that contain matching values. For example, you can establish referential integrity between *Customer* and *Orders* on their *CustomerNo* fields. In both cases, the values contained in the specified fields are the same. The field names don't matter as long as the field types and sizes are identical.

**Note** You can establish referential integrity only between tables in the same directory.

Using referential integrity, Database Desktop checks the validity of a value before accepting it in the table. If you establish referential integrity between *Customer* and *Orders* on their *CustomerNo* fields, then enter a value in the *CustomerNo* field of *Orders*, Database Desktop searches the *CustomerNo* field of *Customer* and

- Accepts the value in *Orders* if it exists in *Customer*
- Rejects the value in *Orders* if it doesn't exist in *Customer*

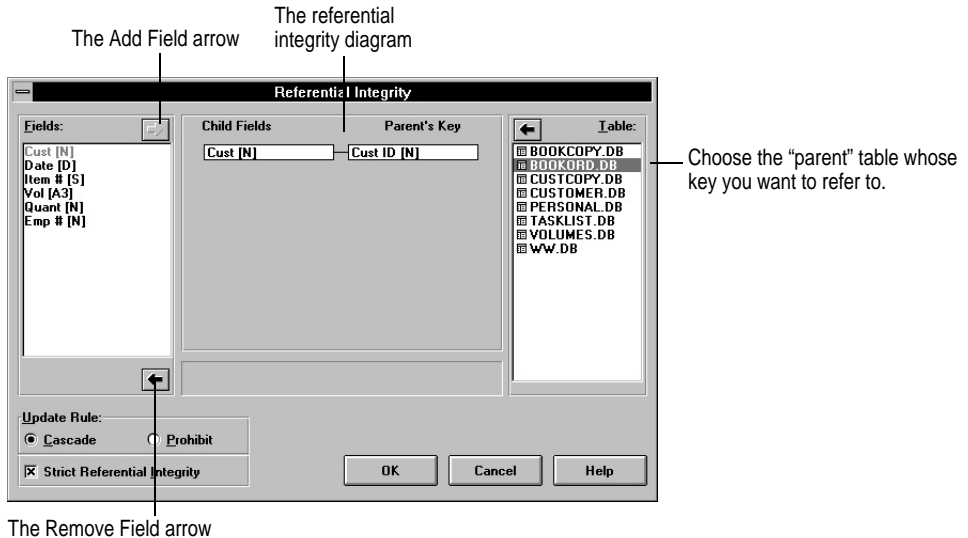

## Procedure

To define a referential integrity relationship,

- 1 In the Create Table (page 151) or Restructure Table (page 160) dialog box, choose Referential Integrity from the Table Properties list. The Define button becomes available.

## 2 Choose Define to open the Referential Integrity dialog box.

**Figure A.10** Referential Integrity dialog box

- 3 Choose the parent table from the Table list. The table's key field appears in the Parent's Key area of the referential integrity diagram.
- 4 Double-click the child table's field in the Fields list (or *Tab* to it and click the Add Field arrow or press *Alt+A*). The field name appears in the Child Fields area of the referential integrity diagram.
- 5 Choose the update rule you want.
- 6 Choose whether you want to enforce strict referential integrity.
- 7 Choose OK to name and save the referential integrity relationship.

For detailed information on defining referential integrity, search for "Referential Integrity" or "Referential Integrity Dialog Box" in the keyword list in Database Desktop Help.

## Creating table lookup

Table lookup helps you enter data in one Paradox table that already exists in the first field of another Paradox table—the *lookup* table. Table lookup lets you

- Require that the values you enter into a field exist in the first field of another table
- Refer to another table to look up the acceptable values for a field
- Copy values in the lookup table to the table you're editing

Table lookup is primarily a data entry tool. Unlike referential integrity, it doesn't track or control changes you make to the lookup table. Table lookup ensures that data is copied accurately from one table to another; referential integrity ensures that the ties between data in separate tables cannot be broken.

For detailed information on table lookup, search for “table lookup” in the keyword list in Database Desktop Help, and choose the topic “Looking up Table Values.”

**Note** Table lookup rules have no effect on Delphi applications accessing a table.

## Establishing passwords for Paradox tables

---

Sometimes it’s important to ensure that the Paradox table you create is protected from access by unauthorized users. Not only can you establish a password for a Paradox table as a whole, but you can also assign specific rights to the table or individual fields.

For detailed information on creating and using passwords, search for “passwords” in the keyword list in Database Desktop Help.

## Restructuring tables

---

Database Desktop enables you to restructure Paradox and dBASE tables to:

- Add or rename fields
- Change field types or sizes
- Modify indexes
- Modify table language drivers

Restructuring a table is very much like creating it for the first time. You will not be able to restructure a table if Delphi or any other application has the table open. For detailed information on restructuring tables, see the Database Desktop Help; choose Help | Contents | Tasks | Creating and Restructuring | Restructuring a Table.

**Note** Restructuring a table may require corresponding modifications in Delphi applications that access the table. For example, removing a column or changing its data type will raise an exception if an application has a persistent *TField* component for the modified column.

To restructure a table, choose Utilities | Restructure, then choose the table you want. If the table you want to restructure is already open in the active window, use Table | Restructure. The Restructure Table dialog box opens. The following figure shows an example of a Paradox table in the Restructure Table dialog box:

**Figure A.11** The Restructure Table dialog box for Paradox tables

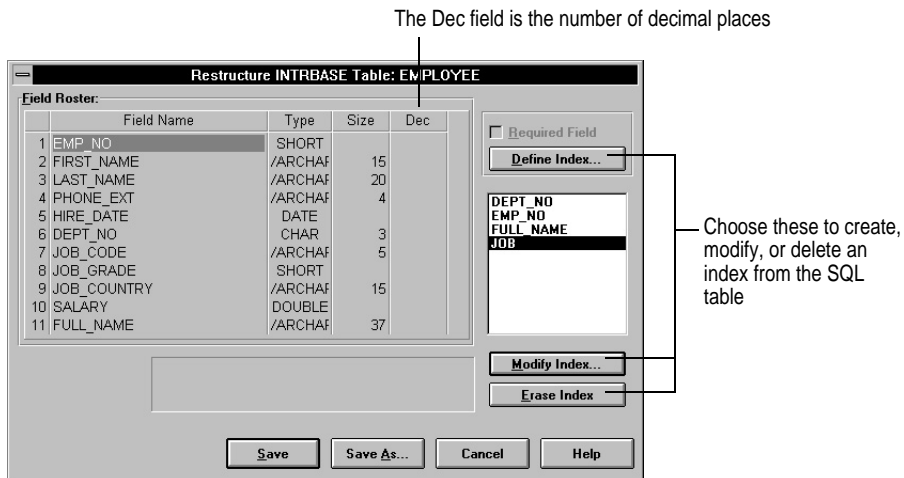

Work in the Restructure Table dialog box the same way you work in the Create Table dialog box.

Pack a table to reuse disk space left over from deleting records. Some restructure operations automatically pack your table. You can check Pack Table and choose OK when you want to be sure Paradox packs the table.

## Restructuring an SQL table

When you restructure an SQL table, you can add, modify, and drop indexes. You cannot otherwise change the structure of a table on a server. The Restructure Table dialog box for SQL tables looks as shown in Figure A.12.

**Figure A.12** The Restructure Table dialog box for SQL tables

## Prefixing the index name with the table name

Database Desktop prefixes some index names with the table name, as described in “Creating indexes on SQL tables” on page 155. These index names are also affected when you restructure an SQL table as follows:

- If you create a new index during a restructure, Database Desktop prompts you to prefix the index name with the table name.
- If you modify an index during a restructure, Database Desktop does not modify the index name, unless you rename the index as part of your modification.
- If you choose Save As during a restructure, Database Desktop prefixes all index names with the new table name, if you have not explicitly entered an index name. For example, suppose the EMPLOYEE table contains the following indexes:

```
EMPLOYEE_DEPT_NO
EMPLOYEE_EMP_NO
FULL_NAME
JOB
```

If you restructure the table and save it as MY\_DEPT, Database Desktop renames the indexes as follows:

```
MY_DEPT_DEPT_NO
MY_DEPT_EMP_NO
MY_DEPT_FULL_NAME
MY_DEPT_JOB
```

## Viewing tables

To open a table, choose File | Open | Table. Or, if the application window is empty, click the Open Table button in the tool bar. In the Open Table dialog box, choose the table to open. The table you chose opens in a Table window, and the tool bar appears as shown in the following figure:

**Figure A.13** The Table window tool bar

When you first open a table, its data appears in a Table window in View mode. Each Table window contains an independent view of a table, so different views of a single table can be open at the same time. Up to 24 tables can be open at one time.

To be able to simultaneously access tables stored on a network, you must provide Database Desktop the location of the *network control file*. You do this by running the BDE Configuration Utility; double-click the BDE Configuration Utility icon in the Delphi program group. See online Help in the BDE Configuration Utility for more details.

A Delphi application can specify the network control file in the *NetFileDir* property of *TSession*. This enables a Delphi application access to tables stored on a network.

## Using scroll lock

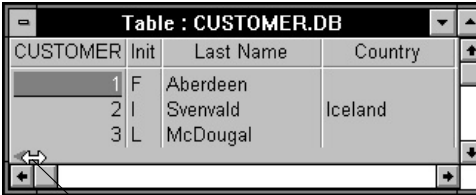

To lock one or more columns in place as you move horizontally through the table's columns, use a *scroll lock*. All columns to the left of the lock remain stationary as you move through the table's columns.

The scroll lock is a triangle in the lower left corner of the Table window. To place a lock, drag the triangle to the right side of the column(s) you want to lock. An active scroll lock appears as two triangles when you release the mouse button, as shown in Figure A.14.

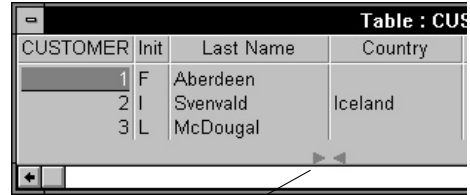

**Figure A.14** A scroll lock in the Table window

 The scroll lock triangle in the lower left corner.

CUSTOMER	Init	Last Name	Country
1	F	Aberdeen	
2	I	Svenvald	Iceland
3	L	McDougal	

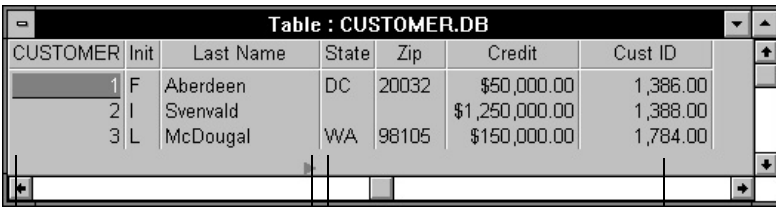

When you position the pointer over the scroll lock triangle, it changes to a double-headed arrow.

CUSTOMER	Init	Last Name	Country
1	F	Aberdeen	
2	I	Svenvald	Iceland
3	L	McDougal	

As you drag, the pointer changes to two arrows.

 After you release the mouse button, an active scroll lock appears.

CUSTOMER	Init	Last Name	State	Zip	Credit	Cust ID
1	F	Aberdeen	DC	20032	\$50,000.00	1,386.00
2	I	Svenvald			\$1,250,000.00	1,388.00
3	L	McDougal	WA	98105	\$150,000.00	1,784.00

As you scroll, these columns remain stationary.

As you scroll, these columns change.

## Customizing a table view

The *view* of a table is how it appears onscreen; you can modify and save a custom view of a table. Changing the view makes it easier to see specific fields; the actual *structure* of the table (its definition of field order and size) remains the same. To customize a view, you can rearrange, resize, and lock columns, and resize rows or table headings.

The following figure shows the *hot zones* on an open table view. Hot zones indicate areas on a table where you can drag to modify the view of the table. As the pointer passes over a hot zone, the pointer changes shape.

**Figure A.15** Hot zone pointers in the Table window

 — The pointer when changing the heading or row height

VENDORS	Vendor No	Vendor Name	Street
1	2014	Cacor Corporation	161 Southfield Rd
2	2641	Underwater	50 N 3rd Street
3	2674	J.W. Luscher Mfg.	65 Addams Street
4	3511	Scuba Professionals	3105 East Brace
5	3819	Divers' Supply Shop	5208 University Dr
6	3620	Techniques	52 Dolphin Drive

To change the heading height, drag the table name up or down.

VENDORS	Vendor No	Vendor Name	Street
1	2014	Cacor Corporation	161 Southfield Rd
2	2641	Underwater	50 N 3rd Street
3	2674	J.W. Luscher Mfg.	65 Addams Street
4	3511	Scuba Professionals	3105 East Brace
5	3819	Divers' Supply Shop	5208 University Dr
6	3620	Techniques	52 Dolphin Drive

To change the row height, drag this line up or down.

 — The pointer when changing the column width

VENDORS	Vendor No	Vendor Name	Street
1	2014	Cacor Corporation	161 Southfield Rd
2	2641	Underwater	50 N 3rd Street
3	2674	J.W. Luscher Mfg.	65 Addams Street
4	3511	Scuba Professionals	3105 East Brace
5	3819	Divers' Supply Shop	5208 University Dr
6	3620	Techniques	52 Dolphin Drive

To resize a column, drag its right grid line in its top row.

 — The pointer when moving a column

VENDORS	Vendor No	Vendor Name	Street
1	2014	Cacor Corporation	161 Southfield Rd
2	2641	Underwater	50 N 3rd Street
3	2674	J.W. Luscher Mfg.	65 Addams Street
4	3511	Scuba Professionals	3105 East Brace
5	3819	Divers' Supply Shop	5208 University Dr
6	3620	Techniques	52 Dolphin Drive

To move a column, drag its heading to the left or right.

## Rearranging and resizing columns

To move a column, position the pointer on a column's heading. When the pointer changes shape (shown at left), drag the column to its new position.

To resize a column, position the pointer on its right boundary line (either the heading area or the top row of data). When the pointer changes shape (shown at left), drag the boundary line to increase or decrease the width of the column.

## Resizing rows

To resize the height of all of the rows in a table, drag the line under the first record number. Move the line up to decrease the row height, or down to increase the row height.

## Resizing column headings

To resize the height of all the column headings, drag the line under the table name. The table name is located above the left-most column (which contains the record numbers).

## Saving a custom view

You can save a custom view, undo changes to a view, and restore the default view by using the commands on the Properties menu.

For detailed information on the Properties menu commands, search for “Properties menu” in the keyword list in Database Desktop Help.

## Editing data

This section introduces Database Desktop’s editing features. For detailed information on editing data, search for “editing data” or “Edit mode” in the keyword list in Database Desktop Help.

### Using Edit mode

To change data in a table, you must be in Edit mode. To enter Edit mode, do one of the following:

- Click the Edit Data button in the tool bar.
- Choose View | Edit Data.
- Press *F9*.

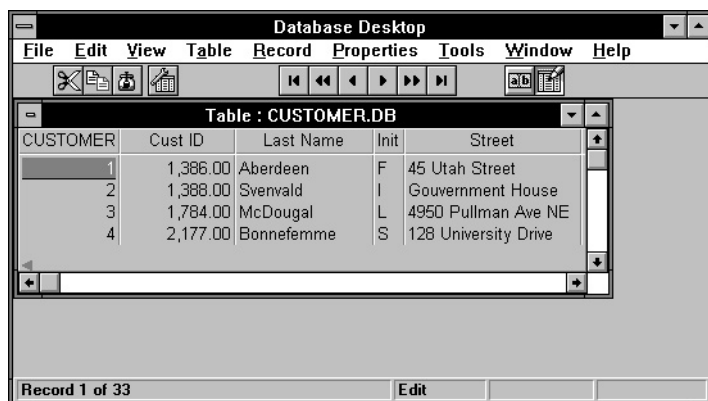

F9

In Edit mode, you can select any field and begin typing to replace its existing entry. When you enter Edit mode, the Edit Data button remains pressed in and the status line tells you Edit mode is active.

**Note** In Database Desktop you cannot edit data in the following field types:

- **Paradox:** Memo, Formatted Memo, Graphic, OLE, Autoincrement, Binary, or Bytes
- **dBASE:** Memo, OLE, or Binary
- **SQL:** any BLOB (binary large object) field or a text field that allows more than 255 characters

**Figure A.16** The *Customer* table in Edit mode

## Selecting fields and records

---

When you move to a field or click it, the field is highlighted. This indicates that the field is *selected*. In Edit mode, if you type anything into a selected field, you'll replace the existing entry with the value you type. The cut, copy, and paste operations affect the entire field entry when it's selected.

You can select more than one field at a time, or select a portion of a single field entry.

For detailed information on selecting fields and records, search for "selecting data" in the keyword list in Database Desktop Help.

## Field view

---

In Edit mode, you can change a field's entry in one of two ways:

- Select the field and type a new value. When you begin typing, the new value replaces the old entry.
- Select the field and edit the existing entry using *field view*.

For information on field view, search for "Field View" in the keyword list in Database Desktop Help.

## Adding, subtracting, and emptying records

---

Use the commands on the Utilities menu to add, subtract, or empty a table's records.

- **Add:** You can add the records from one table to another table. You can use Add on all table types. Choose Utilities | Add. Database Desktop opens the Add dialog box.

For detailed information on adding records, see Database Desktop Help; choose Help | Contents | Tasks | Using Table Utilities | Adding Records.

- **Subtract:** You can remove records that exist in one table from a different table by using the Subtract utility. You can subtract records only from a keyed Paradox table. Choose Utilities | Subtract. Database Desktop opens the Subtract dialog box.

For detailed information on subtracting records, see Database Desktop Help; choose Help | Contents | Tasks | Using Table Utilities | Subtracting Records.

**SQL** You cannot use an SQL table as the source of a Subtract operation.

- **Empty:** Use the Empty utility to remove all records from a table, leaving the table's structure (including all keys, indexes, validity checks, and so on) intact. You can use Empty on Paradox, dBASE, and SQL tables. Choose Utilities | Empty. Database Desktop opens the Empty dialog box.

For detailed information on emptying tables, see Database Desktop Help; choose Help | Contents | Tasks | Using Table Utilities | Emptying Tables.

# Sorting, copying, renaming, and deleting objects

---

You can use Database Desktop to sort tables and to copy, rename, and delete objects.

## Sorting tables

---

When you sort a table, you tell Database Desktop to rearrange the order of the records in the table and display them in the order you specify.

- If a table is keyed, Database Desktop creates a new, unkeyed table containing the sorted data. The original table remains unchanged.
- If a table is not keyed, the sort changes the actual location of the records in the table.

**SQL** You cannot sort SQL tables.

To sort a table, choose Utilities | Sort, then choose the table you want to sort from the Select File dialog box. Database Desktop opens the Sort Table dialog box.

For detailed information on sorting tables, see Database Desktop Help; choose Help | Contents | Tasks | Using Table Utilities | Sorting Tables.

## Copying objects

---

You can copy Paradox and dBASE tables, queries, SQL tables, and .SQL files from within Database Desktop. To copy an object, choose Utilities | Copy. Database Desktop opens the Copy dialog box.

When you copy a table, Database Desktop copies both the structure of the table and the data contained in it. You can copy tables from one table type to another. For example, you can copy a Paradox table to a dBASE or SQL table. To copy to an SQL table type, you must have an SQL database server and the appropriate SQL Link.

For detailed information on copying objects, see Database Desktop Help; choose Help | Contents | Tasks | Using Table Utilities | Copying Tables.

## Renaming objects

---

You can rename tables, queries, and .SQL files from within Database Desktop. You cannot rename SQL tables.

To rename an object, choose Utilities | Rename. Database Desktop opens the Rename dialog box. For detailed information on renaming objects, see Database Desktop Help; choose Help | Contents | Tasks | Using Table Utilities | Renaming Tables.

## Deleting objects

---

You can delete tables, queries, SQL tables, and .SQL files from within Database Desktop.

To delete an object, choose Utilities | Delete. Database Desktop opens the Delete dialog box. For detailed information on deleting objects, see Database Desktop Help; choose Help | Contents | Tasks | Using Table Utilities | Deleting Tables.

## Executing SQL statements

---

This section describes how to use the SQL Editor to enter and execute SQL statements.

### What is the SQL Editor?

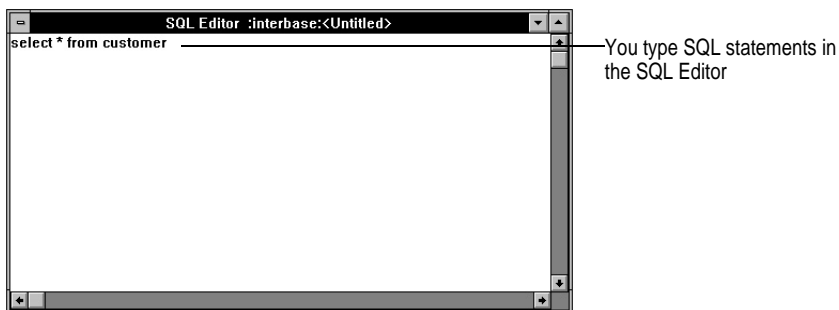

---

Programmers familiar with SQL can use the SQL Editor window to directly enter, execute, or save an SQL statement. You can save the SQL statement to a file, and then later load, modify, or execute it.

In the SQL Editor, you can enter SQL statements to be executed by a SQL database server. The syntax must conform to your server's dialect. This is referred to as *passthrough SQL*. The SQL server performs all error or syntax checking and executes the statement without any involvement by Database Desktop.

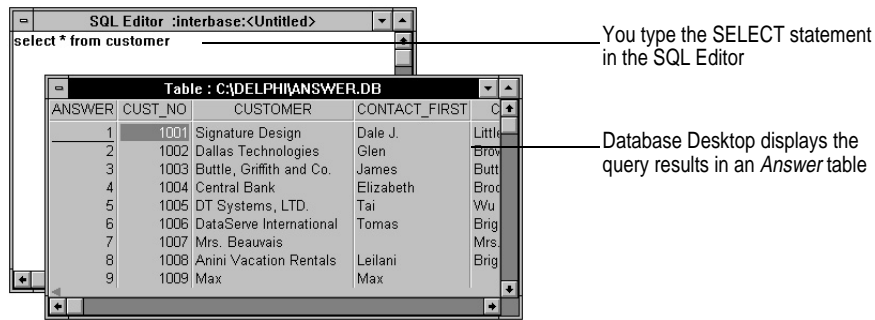

You can also use the SQL Editor to run SQL statements against Paradox or dBASE tables. This is known as local SQL, and the allowable syntax is a subset of ANSI standard SQL. For more information, see Appendix C, "Using local SQL."

**Figure A.17** The SQL Editor

If you execute a SELECT statement in the SQL Editor, Database Desktop displays the resulting data in an *Answer* table, as shown in Figure A.18.

**Figure A.18** The SQL Editor and an *Answer* table

The SQL Editor has the tool bar shown in Figure A.19.

**Figure A.19** SQL Editor Toolbar

## Opening the SQL Editor

To open the SQL Editor, do one of the following:

To do this	Do this
Enter (and execute) a new SQL statement	Choose File   New   SQL Statement Or right-click the Open SQL Script tool bar button and choose New
Open (and edit or execute) an existing .SQL file	Choose File   Open   SQL Statement Or click the Open SQL Script tool bar button Or right-click the Open SQL Script tool bar button and choose Open
View the SQL equivalent of an open QBE query	Choose Query   Show SQL Or click the Open SQL Script tool bar button

## Specifying an alias

Before running an SQL statement, you must specify the alias that the statement will run against. To specify an alias, do one of the following:

- Choose SQL | Select Alias.
- Click the Select Alias tool bar button.

Database Desktop opens the Select Alias dialog box, where you can choose one of the aliases you created in the Alias Manager dialog box. You cannot include an alias in the text of the SQL statement.

## Running an SQL statement

---

You can enter multiple SQL statements if your server allows it and you include only one SELECT statement.

To run an SQL statement that you have typed in the SQL Editor window, click the Run SQL tool bar button or choose SQL | Run SQL.

**Figure A.20** SQL statement in the SQL Editor

If your SQL statement is a query, the query results are displayed in an *Answer* table, as shown in Figure A.18 on page 168.

## Saving an SQL statement

---

To save the SQL statement in the active window, choose File | Save or File | Save As. When you save an SQL statement to your local hard disk, Database Desktop places it in an unformatted text file with an .SQL extension.

## Querying table data with QBE

---

A *query* is a question you ask about information in one or more tables. In addition to standard SQL queries, Database Desktop enables you to use a technique called query by example (QBE) to extract and manipulate data in tables. With QBE, you make the query image look like an example of the records you want to search for.

The following figure shows a query that gives examples of the fields you want to see (and a range of values within one of those fields), and the answer Database Desktop gives.

**Figure A.21** A query and its results

This example searches for book prices greater than \$28 and less than \$65 (the checkmarks specify which fields appear in the *Answer* table).

The *Answer* table displays the checked fields for records that match the example.

ANSWER	Title	Price
1	Austrian Arms and Armor	\$35.95
2	French Cooking	\$35.90
3	Hollywood's Golden Years	\$29.95
4	Organic Composting	\$31.00
5	Soccer Stars	\$31.95
6	Structural Steel	\$45.00
7	Tibetan Adventures	\$35.75
8	Vegetarian Lifestyle	\$29.90
9	Victorian Garden, The	\$35.95
10	Vinyl Fashions	\$34.00
11	Zen Influences in Japan	\$29.95

The result of a query is a temporary table called *Answer*. The *Answer* table is overwritten each time a query is run.

**SQL** If you have Borland SQL Links, you can use QBE to view and query tables on SQL servers. For more information, see the Database Desktop Help Contents.

For details on using QBE, see Database Desktop Help; choose Help | Contents | Tasks | Using Query-By-Example.

## B

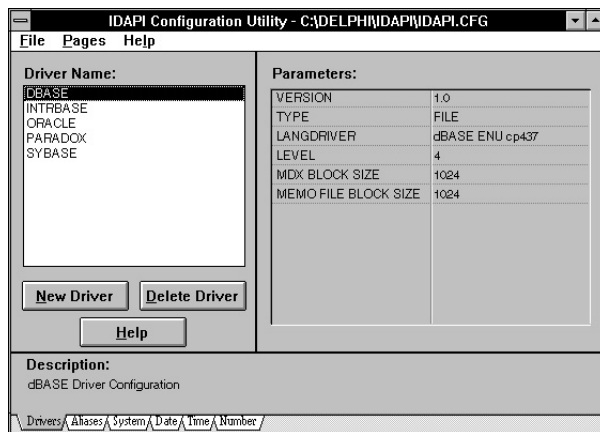

## Using the BDE configuration utility

The Borland Database Engine configuration utility (BDECFG.EXE) enables you to configure BDE aliases and change the settings reflecting your specific environment in the BDE configuration file, IDAPI.CFG.

To run the BDE Configuration Utility, double-click the BDE configuration utility icon in the Delphi program group. The BDE Configuration Utility opens:

**Figure B.1** BDE Configuration Utility main window

## Creating and managing aliases

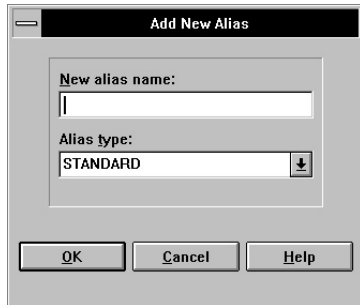

It is usually best to use an alias in your application instead of a hard-coded file or directory name. Setting up a standard alias consists of assigning a name to, and specifying the path name for a directory containing Paradox or dBASE files or the directory path and database name on a SQL server.

## Adding a new alias

To add a new alias,

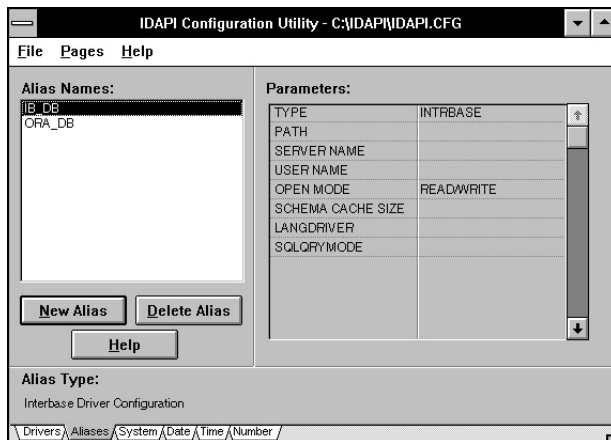

- 1 Select the Alias Manager (Aliases page) and choose the New Alias button. The Add New Alias dialog box appears. The type can be STANDARD or SQL-specific.

**Figure B.2** Sample Add New Alias dialog box

- 2 Enter the new alias name and select the SQL-specific alias type. Then choose OK to begin the setup process. The Alias Manager displays all the configuration parameters you can change to customize the new alias.

**Figure B.3** Customizing the new alias

- 3 If desired, edit the settings for the category you selected. If you leave any categories blank, the Alias Manager assumes you want to use the default for driver type.
- 4 When you are finished, select File | Save to save the new alias in the default configuration file; select File | Save as to save the new alias in a configuration file with a different name.

**Note** The other pages contain settings that can also be customized. See online help for specifics.

Page	Settings modified
Driver Manager	Those BDE uses to determine how an application creates, sorts, and handles tables.
System Manager	Those BDE uses to start an application.
Date Manager	Those used to convert string values into date values.
Time Manager	Those used to convert string values into time values.
Number Manager	Those used to convert string values to number values.

If you save the new alias in a configuration file with a different name, the BDE Configuration Utility displays:

**Figure B.4** BDE non-system configuration dialog box

Choose Yes if you want to activate this configuration file next time you start your application. Choose No if you want to keep using the current default configuration file. Your changes take effect the next time you start your application.

## Modifying an existing alias

To modify an existing alias,

- 1 Scan the list of Alias Names available through the current configuration file. If the alias you want to modify was stored in a different configuration file, use File | Open to load that configuration file.
- 2 Highlight the name of the alias you want to modify. The configuration for that alias appears in the Parameters section of the Alias Manager page.
- 3 Highlight the configuration parameter you want to change, and enter the desired value. If you leave any categories blank, the Alias Manager assumes you want to use the driver's default value.
- 4 When you are finished, select File | Save to save the new alias in the default configuration file; select File | Save As to save the new alias in a configuration file with a different name.

When you modify a driver parameter, all aliases that use the default setting for that parameter inherit the new setting.

Your changes take effect the next time you start your application.

## Deleting an alias

---

To delete an alias,

- 1 Scan the list of Alias Names available through the current configuration file. If the alias you want to delete was stored in a different configuration file, use File | Open to load that configuration file.
- 2 Highlight the name of the alias you want to modify, and select the Delete Alias button.
- 3 Select File | Save to save your changes in the default configuration file; select File | Save As to save your changes in a different configuration file.

**Note** If an application attempts to use an alias that has been deleted, Delphi will raise an exception. If a Delphi form was saved with a table or query open, Delphi will attempt to open the dataset when the form is loaded and the exception will occur at that time. In many cases, modifying an alias can also cause an exception in Delphi forms if the changes to the alias require changes to the Delphi application.

## Using local SQL

The BDE enables limited access to database tables through local SQL (also called “client-based SQL”). Local SQL is a subset of ANSI-standard SQL enhanced to support Paradox and dBASE naming conventions for tables and fields (called “columns” in SQL). Two categories of SQL statements are supported:

- Data Manipulation Language (DML) for selecting, inserting, updating, and deleting table data.
- Data Definition Language (DDL) for creating, altering, and dropping tables, and for creating and dropping indexes.

This appendix describes naming conventions, syntax enhancements, and syntax limitations for local SQL. For a complete introduction to ANSI-standard SQL, see one of the many third-party books available at your local computer book store.

### Naming conventions for tables

---

ANSI-standard SQL confines each table name to a single word comprised of alphanumeric characters and the underscore symbol (`_`). Local SQL is enhanced to support full file and path specifications for table names. Table names with path or file-name extensions must be enclosed in single or double quotes. For example,

```
SELECT * FROM 'PARTS.DBF'  
SELECT * FROM "C:\SAMPLE\PARTS.DBF"
```

Local SQL also supports BDE aliases for table names. For example,

```
SELECT * FROM :PDOX:TABLE1
```

Finally, local SQL permits table names to duplicate SQL keywords as long as those table names are enclosed in single or double quotes. For example,

```
SELECT PASSID FROM "PASSWORD"
```

# Naming conventions for columns

---

ANSI-standard SQL confines each column name to a single word of alphanumeric characters and the underscore symbol (\_). Local SQL is enhanced to support Paradox and dBASE multi-word column names and column names that duplicate SQL keywords as long as those column name are

- Enclosed in single or double quotes.
- Prefaced with an SQL table name or table correlation name.

For example, the following column name is two words:

```
SELECT E."Emp Id" FROM EMPLOYEE E
```

In the next example, the column name duplicates the SQL DATE keyword:

```
SELECT DATELOG."DATE" FROM DATELOG
```

# Data manipulation

---

With some restrictions, local SQL supports the following statements for data manipulation:

SELECT, for retrieving existing data

INSERT, for adding new data to a table

UPDATE, for modifying existing data

DELETE, for removing existing data from a table

The following sections describe parameter substitution, aggregate, string, and date functions, and operators available to DML statements in local SQL.

## Parameter substitutions in DML statements

---

Variables or parameter markers (?) can be used in DML statements in place of values. Variables must always be preceded by a colon (:). For example,

```
SELECT LAST_NAME, FIRST_NAME  
FROM "CUSTOMER.DB"  
WHERE LAST_NAME > :var1 AND FIRST_NAME < :var2
```

## Supported set (aggregate) functions

---

The following ANSI-standard SQL set (or “aggregate”) functions are available to local SQL for use with data retrieval:

- SUM(), for totaling all numeric values in a column
- AVG(), for averaging all non-NULL numeric values in a column
- MIN(), for determining the minimum value in a column

- MAX(), for determining the maximum value in a column
- COUNT(), for counting the number of values in a column that match specified criteria

**Note** Expressions are not allowed in set functions.

## Supported string functions

---

Local SQL supports the following ANSI-standard SQL string manipulation functions for retrieval, insertion, and updating:

- UPPER(), to force a string to uppercase
- LOWER(), to force a string to lowercase
- SUBSTRING(), to return a specified portion of a string
- TRIM(), to remove repetitions of a specified character from the left, right, or both sides of a string

## Supported date function

---

Local SQL supports the EXTRACT() function for isolating a single numeric field from a date/time field on retrieval using the following syntax:

```
EXTRACT (extract_field FROM field_name)
```

For example, the following statement extracts the year value from a DATE field:

```
SELECT EXTRACT(YEAR FROM HIRE_DATE)
FROM EMPLOYEE
```

You can also extract MONTH, DAY, HOUR, MINUTE, and SECOND using this function.

**Note** EXTRACT does not support the TIMEZONE\_HOUR or TIMEZONE\_MINUTE clauses.

## Supported operators

---

Local SQL supports the following arithmetic operators:

```
+, -, *, /
```

Local SQL supports the following comparison operators:

```
<, >, =, <>, IS NULL
```

Local SQL supports the following logical operators:

```
AND, OR, NOT
```

Local SQL supports the following string concatenation operator:

```
||
```

## Using SELECT

---

The SELECT statement is used to retrieve data from one or more tables. A SELECT that retrieves data from multiple tables is called a “join.” Local SQL supports the following form of the SELECT statement:

```
SELECT [DISTINCT] column_list
FROM table_reference
[WHERE search_condition]
[ORDER BY order_list]
[GROUP BY group_list]
[HAVING having_condition]
```

Except as noted below, all clauses are handled as in ANSI-standard SQL. Clauses in square brackets are optional.

The *column\_list* indicates the columns from which to retrieve data. For example, the following statement retrieves data from two columns:

```
SELECT PART_NO, PART_NAME
FROM PARTS
```

### Using the FROM clause

The FROM clause specifies the table or tables from which to retrieve data. *table\_reference* can be a single table, a comma-delimited list of tables, or can be an inner or outer join as specified in the SQL-92 standard. For example, the following statement specifies a single table:

```
SELECT PART_NO
FROM "PARTS.DBF"
```

The next statement specifies a left outer join for *table\_reference*:

```
SELECT * FROM PARTS LEFT OUTER JOIN INVENTORY
ON PARTS.PART_NO = INVENTORY.PART_NO
```

### Using the WHERE clause

The optional WHERE clause reduces the number of rows returned by a query to those that match the criteria specified in *search\_condition*. For example, the following statement retrieves only those rows with PART\_NO greater than 543:

```
SELECT * FROM PARTS
WHERE PART_NO > 543
```

The WHERE clause can now include the IN predicate, followed by a parenthesized list of values. For example, the next statement retrieves only those rows where a part number matches an item in the IN predicate list:

```
SELECT * FROM PARTS
WHERE PART_NO IN (543, 544, 546, 547)
```

**Important** A *search\_condition* cannot include subqueries.

## Using the ORDER BY clause

The ORDER BY clause specifies the order of retrieved rows. For example, the following query retrieves a list of all parts listed in alphabetical order by part name:

```
SELECT * FROM PARTS
ORDER BY PART_NAME ASC
```

The next query retrieves all part information ordered in descending numeric order by part number:

```
SELECT * FROM PARTS
ORDER BY PART_NO DESC
```

Calculated fields can be ordered by correlation name or ordinal position. For example, the following query orders rows by FULL\_NAME, a calculated field:

```
SELECT LAST_NAME || ', ' || FIRST_NAME AS FULL_NAME, PHONE
FROM CUSTOMERS
ORDER BY FULL_NAME
```

## Using the GROUP BY clause

The GROUP BY clause specifies how retrieved rows are grouped for aggregate functions. In local SQL, any column names that appear in the GROUP BY clause must also appear in the SELECT clause.

## Heterogeneous joins

Local SQL supports joins of tables in different database formats; such a join is called a “heterogeneous join.” For example, it is possible to retrieve data from a Paradox table and a dBASE table as follows:

```
SELECT DISTINCT C.CUST_NO, C.STATE, O.ORDER_NO
FROM "CUSTOMER.DB" C, "ORDER.DBF" O
WHERE C.CUST_NO = O.CUST_NO
```

You can also use BDE aliases in place of table names.

## Using INSERT

---

In local SQL, INSERT is restricted to a list of values:

```
INSERT INTO CUSTOMER (FIRST_NAME, LAST_NAME, PHONE)
VALUES (:fname, :lname, :phone_no)
```

Insertion from one table to another through a subquery is not allowed.

## Using UPDATE

---

There are no restrictions on or extensions to the ANSI-standard UPDATE statement.

## Using DELETE

---

There are no restrictions on or extensions to the ANSI-standard DELETE statement.

# Data definition

---

Local SQL supports data definition language (DDL) for creating, altering, and dropping tables, and for creating and dropping indexes. All other ANSI-standard SQL DDL statements are not supported. In particular, views are not supported.

Local SQL does not permit the substitution of variables for values in DDL statements.

## Using CREATE TABLE

---

CREATE TABLE is supported with the following limitations:

- Column definitions based on domains are not supported.
- Constraints are limited to PRIMARY KEY for Paradox. Constraints are unsupported in dBASE.

For example, the following statement creates a Paradox table with a PRIMARY KEY constraint on the LAST\_NAME and FIRST\_NAME columns:

```
CREATE TABLE "employee.db"
(
  LAST_NAME CHAR(20),
  FIRST_NAME CHAR(15),
  SALARY NUMERIC(10,2)
  DEPT_NO SMALLINT,
  PRIMARY KEY(LAST_NAME, FIRST_NAME)
)
```

The same statement for a dBASE table should omit the PRIMARY KEY definition:

```
CREATE TABLE "employee.db"
(
  LAST_NAME CHAR(20),
  FIRST_NAME CHAR(15),
  SALARY NUMERIC(10,2)
  DEPT_NO SMALLINT
)
```

The following table lists SQL syntax for data types used with CREATE TABLE, and describes how those types are mapped to Paradox and dBASE types by the BDE:

**Table C.1** Data type mappings

SQL Syntax	BDE Logical	Paradox	dBASE
SMALLINT	fldINT16	fldPDXSHORT	fldDBNUM
INTEGER	fldINT32	fldPDXLONG	fldDBNUM
DECIMAL(x,y)	fldBCD	fldPDXBCD	N/A
NUMERIC(x,y)	fldFLOAT	fldPDXNUM	fldDBNUM(x,y)
FLOAT(x,y)	fldFLOAT	fldPDXNUM	fldDBFLOAT(x,y)
CHARACTER(n)	fldZSTRING	fldPDXALPHA	fldDBCHAR

**x = precision (default: specific to driver); y = scale (default: 0);  
n = length in bytes (default: 0); s = BLOB subtype (default: 1)**

**Table C.1** Data type mappings

SQL Syntax	BDE Logical	Paradox	dBASE
VARCHAR(n)	fldZSTRING	fldPDXALPHA	fldDBCHAR
DATE	fldDATE	fldPDXDATE	fldDBDATE
BOOLEAN	fldBOOL	fldPDXBOOL	fldDBBOOL
BLOB(n,s)	See Subtypes below	See Subtypes below	See subtypes below
TIME	fldTIME	fldPDXTIME	N/A
TIMESTAMP	fldTIMESTAMP	fldPDXTIMESTAMP	N/A
MONEY	fldFLOAT, fldstMONEY	fldPDXMONEY	fldDBFLOAT(20,4)
AUTOINC	fldINT32, fldstAUTOINC	fldPDXAUTOINC	N/A
BYTES(n)	fldBYTES(n)	fldPDXBYTES	fldDBBYTES (in-memory tables only)

**x = precision (default: specific to driver); y = scale (default: 0);  
n = length in bytes (default: 0); s = BLOB subtype (default: 1)**

The following table specifies how BLOB subtypes translate from SQL to Paradox and dBASE through the BDE:

**Table C.2** BLOB subtype mappings

SQL Subtype	BDE Logical	Paradox	dBASE
1	fldstMEMO	fldPDXMEMO	fldDBMEMO
2	fldstBINARY	fldPDXBINARY	fldDBBINARY
3	fldstFMTMEMO	fldPDXFMTMEMO	N/A
4	fldstOLEOBJ	fldPDXOLEBLOB	fldDBOLEBLOB
5	fldstGRAPHIC	fldPDXGRAPHIC	N/A

## Using ALTER TABLE

Local SQL supports the following subset of the ANSI-standard ALTER TABLE statement. You can add new columns to an existing table using this ALTER TABLE syntax:

```
ALTER TABLE table ADD column_name data_type [, ADD column_name data_type . . .]
```

For example, the following statement adds a column to a dBASE table:

```
ALTER TABLE "employee.dbf" ADD BUILDING_NO SMALLINT
```

You can delete existing columns from a table using the following ALTER TABLE syntax:

```
ALTER TABLE table DROP column_name [, DROP column_name . . .]
```

For example, the next statement drops two columns from a Paradox table:

```
ALTER TABLE "employee.db" DROP LAST_NAME, DROP FIRST_NAME
```

ADD and DROP operations can be combined in a single statement. For example, the following statement drops two columns and adds one:

```
ALTER TABLE "employee.dbf" DROP LAST_NAME, DROP FIRST_NAME, ADD FULL_NAME CHAR[30]
```

## Using DROP TABLE

---

DROP TABLE deletes a Paradox or dBASE table. For example, the following statement drops a Paradox table:

```
DROP TABLE "employee.db"
```

## Using CREATE INDEX

---

CREATE INDEX enables users to create indexes on tables using the following syntax:

```
CREATE INDEX index_name ON table_name (column [, column . . .])
```

Using CREATE INDEX is the only way to create indexes for dBASE tables. For example, the following statement creates an index on a dBASE table:

```
CREATE INDEX NAMEX ON "employee.dbf" (LAST_NAME)
```

Paradox users can only create secondary indexes with CREATE INDEX. Primary Paradox indexes can only be created by specifying a PRIMARY KEY constraint when creating a new table with CREATE TABLE.

## Using DROP INDEX

---

Local SQL provides the following variation of the ANSI-standard DROP INDEX statement for deleting an index. It is modified to support dBASE and Paradox file names.

```
DROP INDEX table_name.index_name | PRIMARY
```

The PRIMARY keyword is used to delete a primary Paradox index. For example, the following statement drops the primary index on EMPLOYEE.DB:

```
DROP INDEX "employee.db".PRIMARY
```

To drop any dBASE index, or to drop secondary Paradox indexes, provide the index name. For example, the next statement drops a secondary index on a Paradox table:

```
DROP INDEX "employee.db".NAMEX
```

## D

## The MAST database

This appendix describes the MAST sample database provided with Delphi and used for the MASTAPP sample application. The basic MAST database is in Paradox format. A SQL version that uses the Local InterBase Server is also provided. See README.TXT for a complete list of sample databases and applications.

MAST is the fictional Marine Adventures and Sunken Treasures company. MAST's customers are dive shops around the world. They sell products and supplies to these shops; the shops place orders for equipment. The following tables are used to track MAST's sales:

**Table D.1** MAST tables

Table name	Information in table
CUSTOMER.DB	Customer dive shop data, including customer number, name, etc.
EMPLOYEE.DB	MAST employee information
ITEMS.DB	Specific items that makes up customer orders
NEXTORD.DB	Table that maintains the next unique order number
ORDERS.DB	Orders placed by customer dive shops
PARTS.DB	Inventory information about items on hand at MAST
VENDOR.DB	MAST suppliers that sell goods to MAST

Each table contains a primary key. To link tables, some fields and data must be duplicated among tables. A table must have a primary key or secondary index assigned to the duplicate field before it can be linked to another table. Fields that are duplicated between tables use referential integrity to make sure their values match in all tables.

The following tables describe each of the MAST database tables by showing the fields contained in the table, the type of each field, the size of the alphanumeric fields, and the fields that are key fields.

The CUSTOMER table is structured as follows:

Field	Type	Size	Key
CustNo	Numeric		*
Company	Alphanumeric	30	
Addr1	Alphanumeric	30	
Addr2	Alphanumeric	30	
City	Alphanumeric	15	
State	Alphanumeric	20	
Zip	Alphanumeric	10	
Country	Alphanumeric	20	
Phone	Alphanumeric	15	
FAX	Alphanumeric	15	
TaxRate	Numeric		
Contact	Alphanumeric	20	
LastInvoiceDate	Timestamp		

In CUSTOMER, the CustNo field is a primary key because orders in the ORDERS table must be linked to customers. The secondary index on Company is named "ByCompany". ORDERS itself contains only information about each order placed by a customer.

The structure of the EMPLOYEE table is as follows:

Field	Type	Size	Key
EmpNo	Long integer		*
LastName	Alphanumeric	20	
FirstName	Alphanumeric	15	
PhoneExt	Alphanumeric	4	
HireDate	Timestamp		
Salary	Numeric		

The ITEMS table is structured as follows:

Field	Type	Size	Key
ItemNo	Numeric		*
OrderNo	Numeric		
PartNo	Numeric		
Qty	Long integer		
Discount	Numeric		

OrderNo is a secondary index and is used in the master-detail link in the Orders form.

The NEXTORD tables is a single-column table used to generate unique, sequential order numbers. In a multi-user environment using Paradox tables, the only way to guarantee

that an order number is unique is to store the last-used number in a table, and increment it each time a new number is fetched. The table is structured as follows:

Field	Type	Size	Key
NewKey	Numeric		

The ORDERS table is structured as follows:

Field	Type	Size	Key
OrderNo	Numeric		*
CustNo	Numeric		
SaleDate	Timestamp		
ShipDate	Timestamp		
EmpNo	Long integer		
ShipToContact	Alphanumeric	20	
ShipToAddr1	Alphanumeric	30	
ShipToAddr2	Alphanumeric	30	
ShipToCity	Alphanumeric	15	
ShipToState	Alphanumeric	20	
ShipToZip	Alphanumeric	10	
ShipToCountry	Alphanumeric	20	
ShipToPhone	Alphanumeric	15	
ShipVIA	Alphanumeric	7	
PO	Alphanumeric	15	
Terms	Alphanumeric	6	
PaymentMethod	Alphanumeric	7	
ItemsTotal	Money		
TaxRate	Numeric		
Freight	Money		
AmountPaid	Money		

In ORDERS, the link to CUSTOMER is through the CustNo field. A secondary index is defined on CustNo to ensure that ORDERS and CUSTOMERS can be sorted and linked in the same order. To be sure that values entered as CustNo in ORDERS match exactly one record in CUSTOMER, referential integrity is used to constrain values entered in the CustNo field to valid customer numbers already in the CUSTOMER table.

The primary key in ITEMS is a composite of the OrderNo and ItemNo fields; these fields also have secondary indexes. This enables ITEMS to link to ORDERS (using OrderNo) in the MASTAPP Orders form. Referential integrity is used to validate the information in PARTS.

The PARTS table tracks the inventory of products. PARTS is structured as follows so that it can be linked to VENDORS:

Field	Type	Size	Key
PartNo	Numeric		*
VendorNo	Numeric		
Description	Alphanumeric	30	
OnHand	Numeric	20	
OnOrder	Numeric		
Cost	Money		
ListPrice	Money		

PartNo is the primary key for this table. Because PartNo is a secondary index, the two tables can be linked. VendorNo is the primary key of VENDORS, so it is a secondary index in PARTS and is defined to use referential integrity to make sure values entered in VendorNo match a single VendorNo entry in the VENDORS table.

The VENDORS table has the following structure:

Field	Type	Size	Key
VendorNo	Numeric		*
VendorName	Alphanumeric	30	
Address1	Alphanumeric	30	
Address2	Alphanumeric	30	
City	Alphanumeric	20	
State	Alphanumeric	20	
Zip	Alphanumeric	10	
Country	Alphanumeric	15	
Phone	Alphanumeric	15	
FAX	Alphanumeric	15	
Preferred	Logical		

Using these tables, a customer's information is entered only once, and then referred to in other tables. Likewise, order, item, inventory, and vendor information is entered only once, reducing storage requirements, and the chance for data entry error.

# Contents

<b>Chapter 1</b>	
<b>Introduction</b>	<b>1</b>
What you should know first . . . . .	1
Overview of Delphi's database features and capabilities . . . . .	2
What is a database? . . . . .	4
What is data? . . . . .	5
What is data access? . . . . .	5
Data sources . . . . .	6
Understanding Delphi database architecture . . . . .	6
Overview of the Data Access page . . . . .	7
Understanding TTable . . . . .	8
Understanding TQuery . . . . .	9
Understanding TDataSource . . . . .	10
Overview of the Data Controls page . . . . .	10
Overview of the Database Forms Expert . . . . .	11
Overview of the Database Desktop . . . . .	12
Developing applications for desktop and remote servers . . . . .	12
Database application development methodology . . . . .	13
Development scenarios . . . . .	13
Database application development cycle . . . . .	13
Design phase . . . . .	14
Implementation phase . . . . .	15
Deployment phase . . . . .	15
Deploying an application . . . . .	16
Deploying BDE support . . . . .	16
Language drivers . . . . .	17
ODBC Socket . . . . .	18
<b>Chapter 2</b>	
<b>Building a sample database application: MASTAPP</b>	<b>19</b>
Building forms . . . . .	19
MASTAPP aliases . . . . .	20
Building a single-table form . . . . .	21
Building a master-detail form . . . . .	24
Building a one-many-many form . . . . .	27
Working with fields . . . . .	30
Creating Tfield components . . . . .	30
Setting Tfield properties at design time . . . . .	32
Reading field values . . . . .	34
Assigning values to fields . . . . .	35
Defining a calculated field . . . . .	37
Formatting field values at design time . . . . .	39
Formatting field values at run time . . . . .	40
Searching for field values . . . . .	42
Validating data entry . . . . .	43
Using lists and lookups . . . . .	44
Writing code to check field values . . . . .	46
Using queries and ranges . . . . .	47
Setting a range . . . . .	50
Printing reports and forms . . . . .	52
<b>Chapter 3</b>	
<b>Using data access components and tools</b>	<b>55</b>
Database components hierarchy . . . . .	55
Using the TSession component . . . . .	56
Controlling database connections . . . . .	56
Getting database information . . . . .	57
Using datasets . . . . .	57
Dataset states . . . . .	58
Opening and closing datasets . . . . .	59
Navigating datasets . . . . .	60
The Next and Prior methods . . . . .	60
The First and Last methods . . . . .	60
The BOF and EOF properties . . . . .	61
The MoveBy function . . . . .	62
Modifying data in datasets . . . . .	63
The CanModify property . . . . .	63
Posting data to the database . . . . .	63
Editing records . . . . .	63
Adding new records . . . . .	64
Deleting records . . . . .	64
Canceling changes . . . . .	64
Working with entire records . . . . .	64
Setting the update mode . . . . .	65
Bookmarking data . . . . .	66
Disabling, enabling, and refreshing data-aware controls . . . . .	67
Using dataset events . . . . .	68
Abort a method . . . . .	68
Using OnCalcFields . . . . .	68
Using TTable . . . . .	69
Specifying the database table . . . . .	69
The TableType property . . . . .	69
Searching a table . . . . .	70
Using Goto functions . . . . .	70
Using Find functions . . . . .	72
The KeyExclusive property . . . . .	72
Limiting records retrieved by an application . . . . .	72
Using partial keys . . . . .	73
The KeyExclusive property . . . . .	74

Indexes . . . . .	74	Displaying data as labels with TDBText. . . . .	101
The Exclusive property . . . . .	75	Displaying and editing fields with TDBEdit. . . . .	102
Other properties and methods . . . . .	75	Editing a field. . . . .	102
The ReadOnly and CanModify properties . . . . .	75	Viewing and editing data with TDBGrid . . . . .	103
The GoToCurrent method . . . . .	76	Setting grid options . . . . .	103
Creating master-detail forms . . . . .	76	Editing in the grid . . . . .	104
The Field Link Designer. . . . .	76	Rearranging column order at run time. . . . .	105
Using TDataSource . . . . .	77	Controlling grid drawing. . . . .	105
Using TDataSource properties . . . . .	77	Using events to control grid behavior . . . . .	105
The DataSet property . . . . .	77	Navigating and manipulating records with TDBNavigator. . . . .	106
The Enabled property . . . . .	77	Hiding and showing navigator buttons . . . . .	107
The AutoEdit property . . . . .	77	Displaying fly-by help . . . . .	107
Using TDataSource events . . . . .	78	Displaying and editing BLOB text with TDBMemo . . . . .	107
The onDataChange event . . . . .	78	Displaying BLOB graphics with TDBImage . . . . .	108
The OnUpdateData event. . . . .	78	Using list and combo boxes . . . . .	109
The OnStateChange event . . . . .	78	TDBComboBox. . . . .	109
Using TFields and the Fields Editor . . . . .	79	TDBListBox . . . . .	110
What are TField components? . . . . .	79	TDBLookupCombo . . . . .	111
Using the Fields Editor. . . . .	80	TDBLookupList . . . . .	112
Starting the Fields Editor . . . . .	80	TDBCheckBox . . . . .	113
Adding a TField component . . . . .	81	TDBRadioGroup . . . . .	114
Deleting a TField component . . . . .	81	<b>Chapter 5</b>	
Defining a new TField component . . . . .	82	<b>Using SQL in applications</b>	<b>115</b>
Defining a calculated field . . . . .	82	Using TQuery . . . . .	115
Programming a calculated field . . . . .	82	When to use TQuery . . . . .	116
Editing a TField component. . . . .	83	How to use TQuery . . . . .	116
Editing Display properties . . . . .	83	The SQL property . . . . .	117
Using the Input Mask Editor . . . . .	84	Creating the query text . . . . .	117
Formatting fields. . . . .	85	Using the Visual Query Builder . . . . .	118
Handling TField events . . . . .	85	Executing a query . . . . .	119
Using TField conversion functions . . . . .	86	The UniDirectional property . . . . .	119
Accessing TField properties programmatically. . . . .	86	Getting a live result set . . . . .	120
Displaying data with standard controls. . . . .	87	Syntax requirements for live result sets . . . . .	120
Using the Fields property . . . . .	87	Dynamic SQL statements . . . . .	121
Using the FieldByName method. . . . .	87	Supplying values to parameters. . . . .	121
Incorporating reports in an application . . . . .	88	Preparing a query . . . . .	121
Using TBatchMove . . . . .	89	Using the Params property. . . . .	122
Batch move modes . . . . .	89	Using the ParamByName method . . . . .	122
Data type mappings . . . . .	90	Using the DataSource property . . . . .	123
Executing a batch move . . . . .	92	Dynamic SQL example . . . . .	124
Handling batch move errors . . . . .	92	Creating heterogenous queries . . . . .	124
Accessing the BDE directly . . . . .	92	<b>Chapter 6</b>	
Application examples . . . . .	93	<b>Building a client/server application</b>	<b>127</b>
Creating a master-detail form. . . . .	93	Portability versus optimization . . . . .	127
Displaying multiple views of a table. . . . .	95	Server portability . . . . .	128
<b>Chapter 4</b>			
<b>Using Data Controls</b>	<b>99</b>		
Data Control component basics . . . . .	100		
Updating fields . . . . .	101		

Client/server communication		Relational tables . . . . .	150
portability . . . . .	128	Planning tables . . . . .	150
Using the Local InterBase Server . . . . .	129	Creating a new table. . . . .	151
Building an application to access any		Defining fields . . . . .	152
server . . . . .	129	Field names . . . . .	152
Building an application to access		Adding, deleting, and rearranging	
InterBase . . . . .	130	fields . . . . .	152
Using InterBase in upsizing. . . . .	130	Specifying field type . . . . .	152
Connecting to a database server . . . . .	130	Using indexes. . . . .	152
Connectivity. . . . .	131	Keys in Paradox tables. . . . .	152
Using TCP/IP . . . . .	131	A dBASE table's index. . . . .	153
Connection parameters . . . . .	131	An SQL table's index. . . . .	153
Using ODBC. . . . .	132	Defining secondary indexes . . . . .	154
Handling server security . . . . .	132	Specifying validity checks . . . . .	154
Using the TDatabase component. . . . .	133	Borrowing a table structure . . . . .	155
The Connected property. . . . .	134	Creating an SQL table. . . . .	155
Creating application-specific aliases. . . . .	134	Creating indexes on SQL tables . . . . .	155
Understanding transaction control . . . . .	135	Naming SQL indexes . . . . .	156
Handling transactions in applications. . . . .	135	Defining referential integrity for Paradox	
Implicit transaction control . . . . .	136	tables . . . . .	157
Explicit transaction control . . . . .	136	Procedure . . . . .	157
Setting the SQL passthrough mode . . . . .	136	Creating table lookup . . . . .	158
Transaction isolation levels . . . . .	137	Establishing passwords for Paradox	
Using stored procedures. . . . .	138	tables . . . . .	159
Input and output parameters. . . . .	138	Restructuring tables. . . . .	159
Executing a stored procedure. . . . .	139	Restructuring an SQL table. . . . .	160
Oracle overloaded stored procedures . . . . .	140	Prefixing the index name with the	
Upsizing . . . . .	140	table name . . . . .	160
Upsizing the database . . . . .	140	Viewing tables . . . . .	161
Upsizing the application. . . . .	141	Using scroll lock . . . . .	162
Deploying support for remote server access .	142	Customizing a table view. . . . .	162
Oracle. . . . .	142	Rearranging and resizing columns . . . . .	163
Sybase and Microsoft SQL servers. . . . .	142	Resizing rows . . . . .	163
Informix . . . . .	143	Resizing column headings . . . . .	163
InterBase . . . . .	143	Saving a custom view . . . . .	163
TCP/IP Interface . . . . .	144	Editing data . . . . .	164
Other communication protocols . . . . .	144	Using Edit mode . . . . .	164
Deploying ReportSmith support . . . . .	145	Selecting fields and records . . . . .	165
		Field view . . . . .	165
		Adding, subtracting, and emptying	
		records. . . . .	165
<b>Appendix A</b>		Sorting, copying, renaming, and	
<b>Using Database Desktop</b>	<b>147</b>	deleting objects. . . . .	166
What is Database Desktop? . . . . .	147	Sorting tables . . . . .	166
The Database Desktop window . . . . .	147	Copying objects . . . . .	166
Starting Database Desktop . . . . .	147	Renaming objects . . . . .	166
The Database Desktop window . . . . .	148	Deleting objects . . . . .	166
Managing files. . . . .	148	Executing SQL statements . . . . .	167
Opening files . . . . .	148	What is the SQL Editor? . . . . .	167
Setting up a working directory. . . . .	149	Opening the SQL Editor . . . . .	168
Setting up a private directory . . . . .	149	Specifying an alias . . . . .	168
Aliases . . . . .	149	Running an SQL statement. . . . .	169
Creating tables. . . . .	149	Saving an SQL statement . . . . .	169
Understanding tables . . . . .	150		

Querying table data with QBE . . . . .	169	Using SELECT . . . . .	178
<b>Appendix B</b>		Using the FROM clause . . . . .	178
<b>Using the BDE configuration utility</b>	<b>171</b>	Using the WHERE clause . . . . .	178
Creating and managing aliases . . . . .	171	Using the ORDER BY clause . . . . .	179
Adding a new alias . . . . .	172	Using the GROUP BY clause . . . . .	179
Modifying an existing alias . . . . .	173	Heterogeneous joins . . . . .	179
Deleting an alias . . . . .	174	Using INSERT . . . . .	179
<b>Appendix C</b>		Using UPDATE . . . . .	179
<b>Using local SQL</b>	<b>175</b>	Using DELETE . . . . .	179
Naming conventions for tables . . . . .	175	Data definition. . . . .	180
Naming conventions for columns . . . . .	176	Using CREATE TABLE . . . . .	180
Data manipulation . . . . .	176	Using ALTER TABLE . . . . .	181
Parameter substitutions in DML		Using DROP TABLE . . . . .	182
statements . . . . .	176	Using CREATE INDEX . . . . .	182
Supported set (aggregate) functions . . . . .	176	Using DROP INDEX . . . . .	182
Supported string functions . . . . .	177	<b>Appendix D</b>	
Supported date function. . . . .	177	<b>The MAST database</b>	<b>183</b>
Supported operators . . . . .	177	<b>Index</b>	<b>187</b>

# Tables

1.1	Database features summary . . . . .	2	3.8	TField formatting routines . . . . .	.85
1.2	Additional Delphi Client/Server database features . . . . .	4	3.9	Published TField events . . . . .	.85
1.3	Delphi data sources. . . . .	6	3.10	TField conversion functions . . . . .	.86
1.4	Data Access components . . . . .	8	3.11	Important TReport methods. . . . .	.88
1.5	Data Controls components . . . . .	11	3.12	Batch move modes . . . . .	.89
1.6	Redistributable Borland Database Engine files . . . . .	17	3.13	Physical data type translations from Paradox tables to tables of other driver types . . . . .	.90
2.1	Important TTable properties for a single-table form . . . . .	22	3.14	Physical data type translations from dBASE tables to tables of other driver types . . . . .	.90
2.2	Important TDataSource properties for a single-table form . . . . .	22	3.15	Physical data type translations from InterBase tables to tables of other driver types . . . . .	.91
2.3	Important TDBGrid properties for a single-table form . . . . .	23	4.1	Data controls . . . . .	.99
2.4	Important TDBNavigator properties for a single-table form . . . . .	23	4.2	Expanded TDBGrid Options properties. . .	104
2.5	Important detail table properties. . . . .	26	4.3	TDBGrid events . . . . .	105
2.6	Important component properties for a master-detail form . . . . .	26	4.4	TDBNavigator buttons . . . . .	106
2.7	Important component properties for a one-many-many form . . . . .	29	4.5	Data-aware list box and combo box controls . . . . .	109
2.8	Important TField design-time properties. . .	33	5.1	Types of query result sets . . . . .	120
2.9	Important TField design-time properties. . .	40	6.1	Server transaction isolation levels. . . . .	138
2.10	Important TDBComboBox properties. . . . .	44	6.2	Oracle SQL Link files . . . . .	142
2.11	Important TDBComboBox properties. . . . .	45	6.3	Sybase SQL Link files . . . . .	142
2.12	Important TReport properties . . . . .	52	6.4	Informix SQL Link files. . . . .	143
3.1	TSession methods. . . . .	57	6.5	InterBase SQL Link files . . . . .	143
3.2	Dataset states . . . . .	58	6.6	Winsock 1.1 client files . . . . .	144
3.3	Navigational methods and properties . . . .	60	6.7	Non-Winsock compliant TCP support files . . . . .	144
3.4	Methods to insert, update and delete data in datasets . . . . .	63	A.1	Paradox validity checks. . . . .	154
3.5	Methods used to work with entire records. .	64	C.1	Data type mappings. . . . .	180
3.6	Dataset events . . . . .	68	C.2	BLOB subtype mappings. . . . .	181
3.7	TField properties . . . . .	83	D.1	MAST tables . . . . .	183

Graphics

Sound

User Input

Real-Time Event-Driven Programming

Basic Game Architecture

Initialization

Introduction

Game Startup

The Game Loop

Game Ending

Shutdown and Exit

The Game Loop

Retrieve User Input

Perform Antagonist AI and Other Game Logic

Update Sprite Positions

Check for Collisions

Start Sound Effects

Start Music

Render the Next Frame

Check for Game End

Speed Delay

Game States

The Demo State

The Playing State

The Intermission State

The Paused State

The Game Over State

Case Study

Summary

## CHAPTER 3—Basic Graphics Programming

The Graphical Device Interface

Graphical Elements

Pixels

Lines

Polygons

Bitmaps

Graphical Element Classifications

Video Mode Resolutions and Color Depth

Resolution

Color Depth

Video Board Memory

The Components of a Color

Palettized Modes

Non-palettized Modes

Graphics Output Techniques

The Device Context

Painting on the Canvas

Bitmap Essentials

Bitmap Types: DDB and DIB

The TBitmap Object

Raster Operations

Simulating Transparency

Palettes

Logical vs. System Palettes

Using a Palette

Further Adventures in Windows Programming

Summary

CHAPTER 4—An Introduction to DirectX

What is DirectX?

The Promise of DirectX

Benefits and Drawbacks of DirectX Programming

The DirectX Architecture

DirectX Components

DirectX and Delphi

The DirectX SDK

Project JEDI

Other Components and Headers

A DirectDraw Tutorial

Features

Functional Overview

COM Fundamentals

Surfaces

Page Flipping

Resolution, Color Depth, and Video Memory

Windowed Versus Full-Screen

Initializing DirectDraw

Rendering with GDI

Flipping the Surfaces

Displaying Bitmaps

Surface Memory Location

Loading and Displaying the Bitmap

Blitting Surfaces

Lost Surfaces

Retrieving DirectDraw Capabilities

The DirectX Baseline Application

DirectX Result Codes

Retrieving the DirectX Version

Summary

CHAPTER 5—Palettes

What is a Palette?

The IDirectDrawPalette Object

Creating the Palette Object

Defining Palette Colors

Using the Palette Object

Disconnecting Palettes

Palettes and GDI Functions

Palette Animation

Animating the Palette

## Introduction

In the beginning, there was darkness. In this Age of Innocence, the unwashed masses practiced the art of entertainment with small pieces of paper bearing symbolic images of kings, queens, and jesters. Sometimes, they used minute pieces of metal and plastic, shaped like various real-world objects, moving them about on large, colored cardboard sheets in accordance with the runes inscribed upon small white cubes. To the casual observer, all was content, but in the minds of the newest generation born of this age, there was a yearning for more. Unbeknownst to the world, this yearning grew, and soon these young pioneers began working in the dark recesses of colleges and universities to bring about a change that would alter the course of history in ways no learned scholar could have ever imagined. Brandishing vacuum tube sabers and using arcane words of power such as RAM, ROM, Bit, and Byte, these acolytes of technology brought forth a new creation known as the Computer. But, their new creation was naive, and lacked intelligence or sophistication; to control it, they had to use a mystical, magical language known as Code. Thus, the Art was born, and a new era had begun.

The First Age was marked by the genesis of immense, hulking beasts that required enormous resources to sustain life. These new life forms were rare, but typically stood several stories tall and required incredible life support systems to maintain an agreeable environment. These giants were moody and possessed little intelligence, but through great effort, they could be trained to perform incredible feats, for their day. The digital landscape was dotted with few of these behemoths, and their trainers were monk-like in their dedication. Unable to break free of their confines due to the immense size of their charges, these monks were forced to toil maddeningly long hours. Their torturous task of preparing the vegetarian meal of holy leaves consumed by these monsters had them working late into the night, and the Art required to create these holy leaves was arcane indeed.

These monks practiced the great Art in the same dark recesses from whence it was conceived, and the Art grew. The once young pioneers had become pedantic, wizened old masters. These old wizards were still rebellious and, yearning for a new form of entertainment, they used the Art in ways that the Powers That Be felt were unproductive. Away from the watchful eyes of their overseers, they shaped the Art in ways that previously existed only in their dreams.

In the dark hours of the morning, these masters used the Art to coax the new creations into providing their

long-sought-after entertainment, and they played games such as Tic-Tac-Toe and Pong. Several of these wizards used the Art to create much more sophisticated forms of entertainment, and played games such as Checkers and Chess with their silicon automatons. In the wake of the First Age, walking in the shadow of the evolving Art, a new form of the Art began to grow.

Like dinosaurs, the reign of these behemoths was relatively short-lived. A new catalyst known as the Corporation had used the knowledge learned in the First Age to effect an evolutionary step known as the Home PC. Thus, the Second Age began.

In the Second Age, the pantheon of overlord gods began to form, controlling the evolution of this new creation from on high. Deities known as Gates and Jobs worked their mystical creation power behind the curtains of reality, but their new creations were protozoan in nature. A step back from their massive predecessors, these new single-cell machines were much less sophisticated and powerful, and teetered on the edge of extinction almost as soon as they had appeared. However, these new creatures had become visible to the unwashed masses, and began to elicit their attention. At first, few of the Untrained could afford to adopt one as a pet, but their popularity grew, and soon many of these creations made their homes on desktops in homes and businesses. The Art, still arcane in nature, had begun to emerge from its dark recesses, and several of the Untrained began to delve into its mystical powers.

The Net, the once-dark netherworld populated solely by the wizards and masters of the Art, has now become a tourist attraction, replete with amusement parks, rest stops, and gift shops. Rumors of new CPUs with speeds in excess of 1,000 MHz are being whispered in the dark corners of cyber cafés and coffee shops. Thus, we stand at the dawn of yet another New Age. As the sun breaks over the distant horizon, its golden, shimmering rays cascading over the silicon juggernaut that stands before us, the prospects of the future are at once both exciting and frightening.

Thus, our journey begins.

## The Purpose of This Book

The primary goal of this book is to teach readers graphics and game programming using 8-bit color images under DirectX in the Delphi environment.

The majority of the book is dedicated to the mechanics of creating a game in Delphi, and will therefore be concerned mainly with exactly how to do something, such as fast flicker-free animation. Some parts address more theoretical issues, such as game design, and are very light in their coverage. Other parts are at a more intermediate level, such as artificial intelligence and optimization techniques. The techniques discussed in this book are very practical and can be put to use right away, as opposed to being academic theory. The goal is to give the Delphi games programmer the tools he/she needs to start competing in the shareware games market right away. This book will not cover marketing, package design, distribution, or other topics that do not deal directly with creating the game.

Due to the popularity of DirectX in the game programming industry, this book does not cover anything related to OpenGL. However, Wordware publishes an excellent OpenGL book aimed at Delphi programmers titled *Delphi Developer's Guide to OpenGL* (ISBN 1-55622-657-8). Although this book is DirectX-specific, some chapters may include code examples that run directly under Windows in order to illustrate a complex topic more clearly. This book is concerned with high-performance graphics programming under DirectX, and as such will concentrate only on full-screen, exclusive mode DirectX programming techniques.

This book will not, as others have, create a “framework” from which examples are drawn, nor will it create wrappers or attempt to hide the low-level DirectX API. This is so that readers become familiar with DirectX, not some artificial abstraction layer that might not work for their purposes. The closest to a “framework” that we’ll get in this book is the creation of a baseline application that simply gets a page flipping, full-screen DirectDraw application up and running, including mouse support. This was done in order to simplify the creation of all the examples included in the book, but it certainly doesn’t shield the developer from any of the nuances or pitfalls of DirectX programming. If you want to do game programming, you have to get in bed with the operating system, the API, and the hardware.

## Conventions

Descriptive text that details steps for implementing or using a specific technique, or narrative text that explains an algorithm or theory, uses a font style similar to the one used for this sentence. Text that contains program code uses a monospaced font style similar to the code snippet below:

```
{draw the paddle graphic to the back buffer}

SrcRect := Rect(252, 500, 339, 506);

FBackBuffer.BltFast(XPos, YPos, FGraphics, SrcRect,
                    DDBLTFAST_NOCOLORKEY OR DDBLTFAST_WAIT);
```

Additionally, the text contains several callouts that point out a specific detail or area of note that the developer should be aware of. These include notes, tips, cautions, and glossaries.

## Notes

These are general points of interest that detail specific items the developer should keep in mind when using the described techniques.

## Tips

Tips are general suggestions or hints for improving a specific technique. Tips may also point out an alternative to some specific detail of a technique or algorithm.

## Cautions

A caution callout alerts the developer to specific hazards with a technique or algorithm that could potentially crash the application or the system. These are specific details of which the developer should be keenly aware.

## Glossary

Being somewhat of an introductory text for game programming, and as the vast majority of readers of this book will have little to no game programming knowledge, glossary callouts identify specific words or phrases that are commonly used in the game programming industry. Game programming, like many specialty areas, tends to have a language all its own, and these glossary items will help the novice user get up to speed on the various jargon and technical terms used when describing game programming techniques.

## What This Book Is

This book is a tutorial that explains DirectX programming within the Delphi environment. Unfortunately, there are not very many professional Delphi programmers working with DirectX, and there are fewer still

who have full-time jobs making games using Delphi. The vast majority of Delphi programmers who will likely pick up this book are application and database programmers professionally, but dabble in game programming at night as a hobby or just to satisfy their curiosity. Thus, this book is aimed at those programmers who are curious and interested in game programming, but have little to no experience. As such, the chapters are arranged in a “how-to” style so that you can easily learn about one aspect of DirectX or another. Additionally, those chapters that deal with DirectX-specific components have a subtle reference layout, so that you can go back and easily find a specific detail about a particular DirectX component or function.

This book could be considered an introductory text for game programmers. To this end, it concentrates on the most common DirectX core components, such as DirectDraw, DirectSound, and DirectInput. Although it covers some advanced techniques, such as force feedback, it is aimed primarily at 2D sprite-based graphics techniques, and does not cover 3D techniques or Direct3D. The techniques herein can be used in scientific or other types of visualization applications, but it is slanted toward game programming.

## What This Book is Not

By necessity, this book is not a tutorial on the use of Delphi or the lexical constructions of the Object Pascal language. This book is also not a DirectX reference. The reference documentation that ships with the DirectX SDK is pretty good, and definitely expansive. Any decent DirectX reference would span many volumes. While many of the more common DirectX function calls are examined in detail, you would be wise to download the DirectX SDK so you can have the full reference documentation at your disposal.

Additionally, since we are concerned only with creating high-performance game and graphics applications, this book does not cover windowed DirectX programming techniques or overlays. Plus, so we can squeeze the maximum amount of performance out of the widest range of hardware, we focus only on 8-bit color video modes, and do not discuss non-palettized video modes.

## Reader Requirements

This book assumes that the reader is familiar with the Delphi IDE and with Object Pascal programming in general. It also helps to have a working knowledge of Windows API programming. While some graphics programming experience is helpful, it is not necessarily a requirement.

## Software Requirements

The applications in this book were tested using Delphi 3, 4, and 5 running under Windows 95 and 98. DirectX is not fully supported under Windows NT, so while some of the examples may work under Windows NT, most will not, and none were tested.

The examples in this book make use of the excellent DirectX header files written by Erik Unger for the JEDI project. You will find these files off of the root of the CD-ROM in a directory labeled DXSDK. This directory should be copied to your hard drive, and you will need to add the path to this directory to Delphi’s library path. This can be accomplished by clicking the Tools | Environment Options menu item in the Delphi IDE, selecting the Library tab, and clicking on the button next to the Library Path edit box. Adding the path to the DXSDK in this dialog box and clicking OK should allow Delphi to find the necessary files when compiling the examples.

---

### Note:

You must add the path to the DXSDK directory to Delphi’s Library Path before any of the examples will compile.

---

## Hardware Requirements

All examples were tested on a Pentium 450 with 32 MB of ram and an 8 MB video card. While this is, at the time of this writing, a respectably advanced machine, the examples should run on anything from Pentium 166 with 16 MB of RAM and a 2 MB video card or higher. Additionally, you will need a sound card and speakers for the examples using sound or music output, as well as a joystick or similar device for examples that retrieve input from game devices. Obviously, you will need a force feedback joystick in order to use any of the examples from the force feedback chapter.

## Chapter Organization

Due to the “how-to” nature of this book, the chapters have been arranged in a way to facilitate an interesting read from cover to cover. However, this book could also be used as a limited reference manual, so the chapters have been arranged in a somewhat logical order to keep similar topics together.

The first few chapters serve as a basic introduction to game programming. Several common concepts and terms are explained early on so as to facilitate an easier understanding of the topics to come. Basic game application architecture is also discussed, including some entry-level graphics programming techniques using regular Windows GDI function calls. DirectX is also introduced at this point, specifically covering DirectDraw.

Many intermediate techniques are then covered. These include techniques for use of the system palette as well as many sprite drawing and manipulation techniques. User input is then covered in some detail, including reading input from keyboard, mouse, and game controllers, such as joysticks, using DirectInput. Force feedback is covered to some extent, although this is a more advanced and specialized topic. Sound and music programming is discussed, examining various ways to output sound and music through both DirectSound and Windows multimedia functions.

Advanced topics include various ways to optimize game applications, as well as artificial intelligence techniques. Several more specific algorithms are covered that detail how to manipulate bitmaps and create graphical special effects. Most of these techniques are wrapped up into a case study application that highlights how these pieces come together to form a complete game. Installation of DirectX is also covered.

## Chapter Summaries

**Chapter 1: The Lure of Game Programming** looks at game programming in general, and examines why the game programming industry is so special in the world of computer science.

**Chapter 2: The Anatomy of a Game** looks at what goes into a game from a high-level perspective. It divides game applications into three constituent parts and examines each in detail.

**Chapter 3: Basic Graphics Programming** introduces the reader to basic concepts in graphics programming. Several Windows GDI graphics programming techniques are discussed in order to prepare the reader for more advanced topics.

**Chapter 4: An Introduction to DirectX** introduces the reader to the world of DirectX programming. DirectX is examined in a general manner, and then DirectDraw is discussed in detail.

**Chapter 5: Palettes** looks at palette control and manipulation from a DirectX application.

**Chapter 6: Sprite Techniques** examines how 2-D sprites work. Several different techniques are discussed, including sprite animation and collision detection.

**Chapter 7: Input Techniques** discusses the various methods for reading input from external devices. The keyboard, joystick, and mouse peripherals are discussed in detail, examining how input can be received using both Win32 API functions as well as DirectInput.

**Chapter 8: Force Feedback** examines the force feedback API and how it can be used to create tactile

feedback on hardware devices.

**Chapter 9: Sound and Music** looks at what it takes to output sound and music from a game application. Using both Windows multimedia functions as well as DirectSound, this chapter examines digital audio output, MIDI music output, and CD audio output.

**Chapter 10: Optimization Techniques** discusses various methods to optimize and enhance the performance of applications. These include Delphi compiler settings as well as programmatic techniques.

**Chapter 11: Special Effects** discusses how the Lock method of a DirectDraw surface gives developers incredible control over visual images. Several techniques are discussed for bitmap manipulation as well as dynamic image creation.

**Chapter 12: Artificial Intelligence Techniques** looks at various methods for implementing simplistic reasoning and logic functions for game antagonists. Such topics include finite state machines and pathing techniques.

**Chapter 13: Putting It All Together** takes many of the techniques discussed throughout the book and puts them together to form a full, working game called Delphi Blocks.

**Appendix: Installing DirectX** contains a short but concise explanation of how the DirectSetup API simplifies the process of installing DirectX to a user's machine.

**Glossary** contains an alphabetical listing of all of the glossary entries introduced throughout the book.

## Foreword

Welcome to *Delphi Graphics and Game Programming Exposed!y with DirectX*. This excellent book is a joy to read. It takes a difficult subject, game programming, breaks it down into its constituent parts, and renders each facet of the whole in clear, engaging language. The text sparkles like a well-cut stone, and the code lights the way for programmers who want to explore new territory in the world of game programming.

This book introduces programmers to the key facts they need to know to create games with Borland Delphi. It carefully describes graphics programming, DirectX programming, gathering user input, playing sounds and music, programming game hardware, and discovering the right architecture for a robust game.

Many technical books are bought simply because they cover an important subject. For those who love games and graphics, certainly this book meets that requirement. However, the text is given a certain additional luster because its author crafted it so carefully. Over the last few years John Ayres has been slowly developing a reputation as one of the major voices in Delphi programming. The high quality of the books that he works on and the talks that he gives have made him a figure of significant stature to Delphi developers.

When John explains a subject, it stays explained. He writes in well-formed sentences and creates logically structured paragraphs that combine to form the framework of a text that fully elucidates a subject. Some programmers have the skills necessary to write great code, but lack the knowledge of how to craft a useful text that comprehensibly encapsulates their knowledge. Other programmers are gifted with the prerequisite writing skills, but they lack a deep knowledge of their subject. John is gifted in both areas, and as a result his work is interesting, well thought out, and easy to understand.

Because of my love for the Delphi programming environment, I'm particularly pleased that this text does such a fine job of showing how to take advantage of what's best in the Object Pascal language, the Delphi VCL, and Borland's many high-performance tools. Delphi is one of the great, if not the greatest, programming environments ever created. John shows you the right way to take advantage of all that raw power to build robust games that will stand the test of time.

Delphi is indeed one of the best tools available for creating computer games, and John Ayres rises to the challenge of his subject by creating a lucid, easy to understand text that covers the full range of relevant

technology. A number of excellent programmers have done much to advance the Delphi programming world. These people include the translator of the DirectX headers: Erik Unger; Delphi R&D members Chuck Jazdzewski and Danny Thorpe; Delphi Games Creator programmers Paul Bearne, John Pullen, and Jeff Kurtz; and DelphiX creator Hiroyuki Hori. To that list of names we can now add John Ayres, who has created an excellent resource of use to all Delphi programmers who aspire to write high-quality game and graphics code.

## Acknowledgments

While this book may bear only one name on the cover, it is the result of input from many people who made its production possible. In an effort to recognize the contributions of those who helped bring this book to life, I would like to acknowledge and give thanks to the following:

First and foremost, I must thank Erik Unger for his excellent translation of the DirectX headers. Without his dedication to the furthering of Delphi games programming, this book simply would not have been possible. He constantly strives to stay abreast of new DirectX developments, and makes new DirectX headers available almost as soon as Microsoft releases an update. He also has many other headers available for both OpenGL and the Glide API. I hope to shake your hand someday at an Inprise convention somewhere.

I must also mention Ari Feldman, who was generous enough to create the freeware sprite library SpriteLib. SpriteLib is included on the CD, and many of the images from this library are used in the examples and illustrations throughout the book. Ari Feldman's creation allowed me to include some quality artwork whereas little stick men and solid polygons would've been used in its absence.

Additionally, John Marshall provided some of the graphic artwork gracing the examples in the chapter on bitmap manipulation and special effects. John is an awesome artist, and it's an honor and a pleasure to have his work in this book.

Thanks to the folks at Beachware who were generous enough to donate 50 excellent sound effects from their *A Zillion Sounds 2.0* CD. This CD contains thousands of sound effects in WAV format that are perfect for use in many games, from button clicks to explosions and laser blasts. Beachware also offers many other CDs filled with textures and musical interludes that you will find useful in your gaming endeavors. Take a look at <http://www.beachware.com>.

I must also thank David Strahan. An extraordinary musician, he provided several MIDI music compositions used in some of the examples.

I also owe a debt of gratitude to Eric Best, Mark Harwell, Jeff Amano, and Dr. Jim Beckett for putting up with this extracurricular activity of mine while in the middle of many, many time-critical projects, and for

providing me with a nice, quiet place to write on my off hours.

Wordware Publishing deserves a big salute. Jim Hill, Russ Stultz, Beth Kohler, and all the fine people there do a wonderful job. Without Wordware Publishing, many of the more specialized Delphi books would never be published. These more targeted titles help the Delphi community to grow and foster a sense of maturity; may other publishers take note.

Of course, no acknowledgment would be complete without mentioning the people who brought us Delphi: Inprise. Inprise is starting to recognize the existence of the many game programmers out there interested in Delphi. Indeed, both Danny Thorpe and Charlie Calvert (native Borlanders) are big proponents of DirectX programming with Delphi. At last year's Inprise convention, I gave a very successful presentation on Delphi games programming, I believe the first one ever, and I've been invited to repeat it this year. I hope that this increased awareness of Delphi game programmers results in more direct support for DirectX and other core gaming APIs.

I would also like to mention Kenneth Harrison, Mike Tobin, and Burleigh Wood, three great friends of mine who served as sounding boards for my ideas and tolerated my absences from many multiplayer gaming sessions while I wrote. Burleigh even loaned me his force feedback joystick so I could write the force feedback chapter. They took time out of their schedules to look over several of the examples herein, and I appreciate their feedback and criticisms.

Many of you may have heard of the JEDI Project by now. This is an international organization of Delphi developers who are dedicated to converting API headers so that Delphi programmers worldwide have access to a greater range of Windows functionality. The members of this organization, through their many e-mails and discussion threads, provided many of the answers to tough dilemmas experienced while researching many of DirectX's nuances. For more information on the JEDI Project, see the page at the back of the book.

The Delphi Developers of Dallas user group was also very helpful in times of need. I gave many lectures and presentations based on the subject material for this book, and the questions and feedback of the membership helped to solidify and fine-tune many of the topics contained herein.

And were it not for the efforts of the growing community of Delphi game programmers, this book would have had no inspiration. Their efforts are slowly fostering acceptance of Delphi within the gaming industry. Indeed, there are several games being published that are written in Delphi, many of which use either freeware Delphi DirectX components or Erik's DirectX headers included with this book. Keep it up; the next game of the year just might have a "Powered by Delphi" logo somewhere in the About box.

Finally, I must give thanks to my family for putting up with the late nights and long hours it took to finish this project. I owe my wife special thanks and gratitude; she was pregnant with our first child during the course of this activity. Even though she denies it, I know that I've neglected her, and yet she still gives me her unconditional love. Without her constant support and encouragement, I would not have had the patience or desire to continue when the going got tough. Thanks, baby.

## **Dedication**

To my first child, Cassandra Marie Ayres. She and my wife were still part of each other during most of the production of this book, and as I write this, her "birth day" draws alarmingly near. I've never known such panic and such joy as children bring to their parents. It will be good to experience the world again through her eyes, as I intend to vicariously relive my childhood through her as best I can. Only a parent knows how the emotions of panic, alarm, joy, and jubilation can intermingle and become one; may your children bring you the same emotional gratification. Hero, mentor, role model, playmate, dance partner, confidant, keeper of secrets, and healer of wounds—to me, all these things add up to Fatherhood. I hope to live up to my daughter's expectations of a father, and may she grow to be more than the sum of her parents.

## CHAPTER 1 The Lure of Game Programming

This chapter covers the following topics:

- The good and bad side of the game programming industry in general
- The requirements of a game development language
- The advantages and disadvantages of using Delphi as a game development platform
- Opportunities within the game programming industry
- The types of games currently under production

What pushes the advance of computing technology more than any other influence? Computer games. What provides a never-ending stream of content for dozens of colorful, flashy magazines? Computer games. What do hundreds of thousands, perhaps millions, of people play in their spare time for entertainment and competition? Computer games. What do the technologically adept talk about in newsgroups, in person, and in e-mail? Computer games. What inspires producers to create major motion pictures that flop at the box office and embarrass the people that both worked on them and created the original concept from which they were spawned? Computer games.

Well, perhaps the computer gaming buzz isn't quite that bad, but the computer gaming industry is a multibillion dollar industry that grows every year, and is filled with enough strife, antagonism, competition, and tactical warfare to fill several novels. Tens of thousands of web sites are dedicated to both the production and play of computer games. Dozens of magazines exist that also cover both sides of the gaming coin. Dozens of books have been written on game programming, such as this one, and even more books cover strategies and tactics for playing specific games. The gaming industry is very competitive and dynamic, and by this very nature, a little hostile. Gaming companies are formed and disbanded at an alarming rate, with new ones being born as others, both old and new, die miserable deaths.

As is true with just about anything in this world, the gaming industry comes with a light side and a dark side. There are many things about the gaming industry that would make most programmers cower in fear, yet there are just as many alluring attributes that serve as a powerful seduction towards pursuing a career in it. Although this book is not geared toward dwelling on the negative aspect of such things, let's start by taking a

reality check and examining the dark side of the game programming industry. Then we'll look at why the light side is so attractive to intrepid and enthusiastic programmers.

## The Dark Side of the Game Programming Industry

Game programming and the gaming industry in general have several negative aspects that may dissuade the casual programmer from doing much more than dabbling in it as a hobby. The items we're about to examine should not be considered an exhaustive list of condemning attributes, nor should they be considered a list of excuses for not pursuing a dream. As a purchaser of this book, you're at least a little curious about game programming, and perhaps considering a career change. Don't let these things convince you otherwise. Use the discussion of the following topics merely as food for thought to keep your hopes and plans in perspective.

### Difficult Learning Curve

Computer games push manufacturers to produce better, faster hardware because it is very difficult to produce some gaming effects that perform adequately enough to be believable. Although the PC is now capable of supporting some very intense graphics engines, it was never designed to do so. Without the assistance of dedicated hardware, some games would not be possible without very clever programming solutions.

They say knowledge is power, and that isn't more true than in the game programming industry. A new algorithm for shading or texture mapping more polygons in a shorter amount of time can mean the difference between a best-selling game (and thus a profitable company) or a flop (and thus layoffs, bankruptcy, and failed businesses). Because of this, game programmers and gaming companies tend to guard game programming techniques as if it were a matter of national security. Application programmers benefit from the assistance that Delphi (or MFC) gives them, and they can almost always find some example of how to accomplish their goal somewhere on the web or in a book. Game programmers, on the other hand, are often left to their own devices when attempting to solve a problem. Sure, one can usually find a basic example of how to accomplish a desired effect, but only if it has been done before and the technology is a few months old.

**Microsoft Foundation Classes (MFC):** Microsoft's object-oriented component hierarchy, similar to Delphi's VCL.

By its very nature, in order to create a commercial quality game that can compete with other games on a retail shelf, the programmers must employ advanced mathematical equations, professional quality music and sound, and highly detailed and artistic graphical images. Application programmers, on the other hand, usually have demands no greater than knowledge of client/server programming techniques, middleware, and database methodologies. These demands are by no means easy, but the knowledge for accomplishing these feats is usually more attainable than what a game programmer is called upon to know.

### Long Hours

Everyone logs extended time at the keyboard when under crunch mode. However, game programmers tend to be in crunch mode longer and more often than application programmers. This is often due to promises that the marketing department makes that the engineering department is required to keep. Because the gaming industry is so volatile, game applications need to be completed and out the door before a competitor releases a similar title. This requires game programmers to put in long hours; 16-hour days as a norm are not unheard of. Crunch mode for application programmers typically means 10- to 12-hour days. For the game programmer, it typically means that they sleep in their cube for an hour or two each night, shower at work (if they're lucky enough to have one), and get to go home after the title passes quality control.

**Tip:** If you're touring a company's offices during an interview, look for cots or blankets in people's cubes. That's a good indication of the type of hard work and dedication you'll be expected to demonstrate.

---

## Corporate Instability

The gaming industry is dynamic and cutthroat. Because there are so many game companies out there, with more appearing daily, competition is fierce. As technology marches on, generating better, more powerful machines, the demands on gamers rise at an ever increasing rate. The incredible burden on game developers to keep up with the demands of consumers, as well as to keep ahead of competitors, causes the production costs of mainstream game titles to approach that of Hollywood movies. The result is an ever narrowing profit margin.

Unfortunately, this tends to translate into a need for game companies to continually crank out best-selling titles. Extremely large game companies can afford a bad title or two, but smaller companies may be dramatically affected by bad sales of even a single title. This is especially true for startups; if that first title doesn't at least break even, it may be impossible to even meet employee payroll requirements, let alone to find enough capital or investors to fund further projects. Even companies that have been around for years could suddenly find themselves in financial stress after only a few bad games.

With the exception of only a few large gaming companies, this volatility seems to be the norm rather than the exception. This is all the more obvious by the number of computer gaming businesses that come and go daily. The end result is that gaming companies tend to be unstable, and are not a good place to go if you want a job that you can work at until retirement.

## **The Light Side of the Game Programming Industry**

In stark contrast to its negative aspects, the game programming industry exhibits a number of positive aspects that fuel its continued growth. The game programming industry in general is very exciting, in part due to its dynamic nature, but mostly because of the people you can meet and the technology you will work with.

### **Fun and Rewarding**

What sounds more exciting: creating a client/server application for tracking customer purchases and transactions (complete with reports and custom querying capabilities), or creating a first-person adventure game that lets you run through castles and destroy evil demons? If you chose the client/server application, close this book right now. Perhaps the coolest and most seductive trait of game programming is that you can use your imagination in creative ways not possible with application programming.

As opposed to conforming to Windows user interface guidelines, the game programmer can create highly specialized and flashy user interface elements that are both fun to code and exciting to behold. Creating buildings, cities, continents, and worlds to explore is tremendously entertaining for both the programmer and the user. While creating a tool that allows someone to accomplish a job quickly and efficiently is rewarding, creating a diversion that immerses one into a world of exploration and wonder for hours on end is even more so.

## Fame and Fortune

A good gaming engine is the holiest of holy grails in the programming industry. Pretty much anyone could make a client/server database if they wanted to (given the right training and education), but few can create a game the likes of Quake, Tomb Raider, or Wing Commander. Those that do, however, are elevated to the status of rock star, and are worshiped by thousands of adoring fans. It's always nice to be complimented for your work, perhaps even developing a reputation for quality products and performance amongst your peers. However, actually having groupies and fans takes the meaning of "good job" a bit further.

Another intriguing aspect of game programming is that it is one of the last remaining industries where individuals have the potential to make a lot of money in a short amount of time. With the continued growth of the Internet, it is feasible for a developer to create a game and make tons of money by selling it online. It may also be possible to sell a completed game to a gaming company, netting a nice large chunk or a share of royalties over time, but this practice is in a decline. Success stories of this nature are more the exception than the rule, but the potential does exist for a hard-working, dedicated game programmer to transform his or her labor of love into a cash cow.

---

**Tip:** If you're lucky, your company will agree to give you a cut of the royalties of any game you work on. Unfortunately, this is a rare and vanishing benefit, but could potentially make you a lot of money if the game sells well.

---

## The People

A psychology major could probably write a doctoral thesis on how the personalities of people in their chosen industry seem to be very similar. This at least seems true of those in the programming profession. What this means is that you'll most likely be working with people of similar interests, usually resulting in friendships and group social activities. Many gaming companies double as sites for late-night Dungeons and Dragons sessions, impromptu multiplayer Quake tournaments, and any number of other fun recreational activities. People in the game programming industry tend to be intelligent and have a good sense of humor, and in general are very enjoyable to work with.

## Game Programming, In Delphi?

When most people hear about Delphi, they think of rapid database application development. They think of its uses in the corporate environment as a wonderful tool for making myriad database accessing applications, a task for which it is indeed well suited. They compare it to other RAD tools like Visual Basic and PowerBuilder, contrasting their relative strengths and weaknesses in data access, speed, scalability, etc. This attitude has been prevalent since Delphi 1, and is indeed one of the reasons Delphi has done so well. Unfortunately, most people do not consider Delphi to be a viable choice for any other type of application development. Considering the fact that Delphi is built on a long line of well-used Pascal compilers, has full access to the Windows API, creates actual executable binary code, and shares the same back-end linker with Inprise's excellent C++ product, Delphi is indeed capable of doing much more than just enterprise-wide database applications.

In the game programming industry, the dominant language in the U.S. is C/C++. Let's think for a moment why that may be the case. Specifically, let's consider what could arguably be the most important attributes that a development language must offer in order for it to be considered a viable platform for games development.

1. It must compile fast, natively executable code. C/C++ offers this, and indeed you can find benchmarks that supposedly prove which compiler offers the fastest code. However, Delphi uses the same back-end linker that C++ Builder uses, and its compiled code is as fast as that of C++ Builder. Besides, the most computationally intensive parts of gaming applications are usually written in hand-optimized assembly in order to gain the maximum speed advantage. C/C++ may have a few lexical tricks that allow one to squeeze an extra clock cycle or two out of a few instructions, but you can

accomplish the same task in Delphi with creative programming efforts. In the speed department, some C/C++ compilers may create faster compiled code than Delphi, but you can always make up for it where it counts using hand-optimized assembly (just like the C/C++ boys do). Remember, a Pentium 166 with 16 MB of RAM is considered obsolete by today's standards, so these marginal speed advantages offered by some C/C++ compilers are much less important than they used to be. The bottom line is that Delphi is as fast as most C/C++ compilers when it comes to the natively compiled form of raw code, and when speed is absolutely essential, Delphi can compile hand-optimized assembly language as well as any C/C++ compiler.

2. It must offer true pointer access to memory. As with C/C++, it's quite easy in Delphi to create a pointer, point it to some location in memory, and commence reading or writing as necessary. Like C/C++, Delphi also allows you to perform pointer arithmetic, moving the location to which the pointer points. This is a very powerful technique which, when used incorrectly, can cause spectacular system-wide crashes. C/C++ does not have any advantages over Delphi when it comes to using pointers.
3. It must offer the ability to manage memory allocation. This goes hand in hand with the ability to use pointers. Game applications typically push the limit on the hardware, and some must specifically manage the memory used by the application in order to realize maximum performance. Like C/C++, Delphi offers many ways to allocate memory, from the automatic memory management offered by the VCL, all the way to Pascal commands for memory management and Windows API functions for allocating and deallocating memory.
4. It must offer full access to operating system resources. Again, just like C/C++, Delphi has full, open access to the entire Windows API. Indeed, Delphi can use any DLL or type library to which it has an import unit. This is one area where C/C++ does have an advantage over Delphi. Since Windows is written in C/C++, DLLs and other resources created by Microsoft and other third-party developers typically have header units for C/C++ access before someone translates it into a Delphi unit. However, thanks to the efforts of the JEDI Project and other individuals, Delphi import units for hundreds of APIs are becoming available to the general public. Typically, Delphi will probably always be one step behind on access to the latest technologies. However, it's not too difficult a task to convert C/C++-headers into Delphi units, and you can usually find the converted unit on the Web or buy one from a Delphi vendor.

Most people will argue that there are several more attributes by which a development language must be judged before determining if it is a viable games development platform. As we've discussed, Delphi meets or exceeds all expectations for the above requirements, and could probably do the same for any other requirement that one could think of. Pascal is an old language; it's been around for quite a while, and is mature, stable, and proven.

It's unfortunate that many people still think of Pascal as a beginner's language, fit for little more than hobby applications. This is probably due to the irrational Western mentality that if something looks complex, or if it is hard to understand, it must be powerful. Bear in mind that a high-level language like C/C++ or Pascal is just an interface to assembly language that is easier for humans to understand. Each language has a few small advantages over the other, but ultimately an application written in either language is transformed into a final

assembly language form. The only differences lay in how this transformation is accomplished by the compiler, and Delphi's compiler can create assembly language that competes with the best of them.

## Delphi as a Games Development Platform

So, Delphi is indeed a viable game development platform. What, then, can we expect to encounter when developing a game using Delphi? Delphi's incredible debugging features will be almost unusable if you are creating a DirectX game, primarily because of how DirectX monkeys with the display hardware. However, certain aspects of how the VCL encapsulates the Windows API will take a lot of the drudgery out of DirectX programming, and will indeed make some tasks extremely easy. Most notably, the TBitmap object will be very useful for loading graphics into DirectX memory blocks, and the TCanvas object can be quite handy when performing standard GDI functions, such as outputting text to the screen. Of course, if you will be using Delphi to create non-DirectX games, the full power of the debugging features as well as the GDI encapsulation will make the task of programming a game just as easy as that of developing a database application. In this book, we will focus on creating DirectX games, and we will examine how the VCL can make some aspects of DirectX programming almost trivial.

As a whole, Delphi offers many advantages over other game development platforms. Every language has advantages and disadvantages over every other, which is why there are so many languages to choose from. While the following discussion is by no means an exhaustive look at Delphi versus C/C++, Delphi does have some specific advantages and disadvantages when compared to C/C++ that merit further investigation.

### Advantages

This is a truly opinionated and arguable statement, but Delphi's Object Pascal is a much better language than C/C++ for two reasons: It is not as arcane, and it is much stronger typed. While it is possible to write easily understandable code in C/C++, it is just as easy to write code that is completely unintelligible and unmanageable. C/C++ has a precompiler that allows one to redefine function names (among other things). While this can be quite useful in some instances, if used indiscriminately it can lead to a major headache when trying to decipher what a piece of code accomplishes. C/C++ has many other language constructs that allow one to write very archaic instructions decipherable only by its author or a C/C++ guru. The primary reason this is important is because, in today's development shops, a section of code may be written by one programmer but modified or updated by several others. It is an incredible waste of time and energy if a programmer tasked with the responsibility of updating a section of code has to spend several hours just determining what it does. The archaic quality of C/C++ code, which can be worsened by arrogant or apathetic programmers, tends to make the arduous task of modifying existing code very difficult, if not impossible. Alternatively, Pascal syntax is closer to regular English, and although it is possible to write some very arcane Pascal code, it is typically much easier to understand from a glance than C/C++. Some will argue that C/C++ was written by programmers for programmers, resulting in the greatly abbreviated lexical tokens perpetuating the language. While it is true that this may save a few keystrokes, in the opinion of this writer, Pascal syntax is much easier to understand from a brief glance and its format and construction make it much easier to decipher an algorithm from its implementation.

This goes along with the strong typing imposed by Pascal compilers. Pascal is used as a beginner's language in universities and colleges because it forces programmers to write in a very structured, easily understood manner. The result is that programmers are forced to develop good programming practices. C/C++'s language structure is much more open and unrestricted. While this does allow one to perform some lexical tricks that may be difficult to reproduce in Delphi, it can result in code containing bugs that are very difficult to find. Delphi's strongly typed compiler helps find logical errors and mistakes that may have compiled without so much as a warning in a C/C++ compiler. Writing Delphi code is never bug free, but the strong typing imposed by its compiler helps the programmer find some bugs faster than would be possible with the same code in a C/C++ compiler.

Another great advantage to using Delphi is the overall attitude of the Delphi community at large. Overall, the Delphi community has a very helpful attitude. There are literally thousands of Delphi sites featuring thousands and thousands of free objects, code tips, and applications with source code. There are dozens of sites available that deal specifically with Delphi game programming, and there are several freely available game programming examples and objects, complete with source code. The JEDI Project, the Delphi Games Creator, and DelphiX are just a few examples of the type of free source code that one can obtain when searching the Web for Delphi game programming knowledge (many of these are contained on the accompanying CD). While you can find just as many (if not more) resources for C/C++ game programming, the Delphi community has an overall helpful attitude, indicative of the type of Delphi programmers that exist in the world.

### **Disadvantages**

The biggest disadvantage that one may face when pursuing Delphi game programming is in the lack of knowledge available in the industry. Almost every book you see discussing game programming will contain examples written in C/C++. Fortunately, the algorithms discussed in these books can be implemented in just about any language, but the code examples will be almost worthless unless you have a working knowledge of C/C++. This may require the aspiring Delphi game programmer to take a course or two in C/C++ in order to gain the knowledge to put the examples in the myriad of C/C++ game programming books to work in Object Pascal. Unfortunately, the result is an increased learning curve for future Delphi game programmers. It is interesting to note that when Delphi appeared several prominent figures in the game programming industry took note of its abilities and even heralded it as the next great game development platform. The editor of a

major gaming industry periodical even predicted that the best games of the coming year would be written in Delphi. This same periodical, and others, have run several articles illustrating game programming techniques using Delphi, written by some of the most visible programmers in the Delphi industry (most notably Charlie Calvert). Hopefully in the future we will see more books written about game programming in Delphi, spreading the knowledge of game application algorithms and generating more jobs for the Delphi games programmer.

Another major disadvantage already touched upon is the fact that Delphi programmers will probably have slower access to the newest programming technologies than C/C++ programmers. We can use DirectX technology as the perfect example. Microsoft has seen fit not to include a type library for the DirectX COM objects. Had a type library been included, Delphi could directly import the library and offer developers immediate access to all of the functions and procedures offered by DirectX. Instead, Delphi developers must translate the C/C++ headers that define the function calls, constants, and data structures by hand. This is a very onerous, time-consuming task, prone to errors that may be difficult to fix. Unfortunately, this means that most Delphi programmers must either write an import unit themselves or wait for one to be made available (for free or for purchase) before using the latest technologies. Thanks to the efforts of the JEDI Project and the individuals participating in it, many technologies previously out of reach of Delphi programmers are now becoming available. Indeed, Erik Unger, a JEDI Project participant, wrote the DirectX import units around which this book is based. Hopefully in the future we will see more cooperation between Microsoft and Inprise, which will result in immediate access to the latest technology by Delphi programmers.

## Opportunities

The game programming industry is as competitive and hostile as the movie production industry. Venture capitalists and investors are quick to throw millions of dollars—more than \$2.5 billion a year— at promising startups in hopes of grabbing a piece of the pie. Production costs of games typically average in the millions, and game companies rise and fall almost as frequently as most people change socks. In such a volatile environment, how can one expect to make any progress without being trampled?

Fortunately, the gaming industry is one of the few industries in which someone can compete from their garage or home office. For example, take the game Solitaire, a standard game shipping with Windows. Solitaire is arguably the most popular game in existence today. Probably everyone who has ever taken a look at Windows has played it at least once, and there are many who play it daily. This is a simple game that by no means pushes the envelope of technology, yet it offers an addictive, entertaining pastime that many people enjoy. A similar phenomenon, Tetris, has been copied and cloned to the point where you can find freeware Delphi Tetris components ready to be dropped on a form for instant gaming satisfaction. Theoretically, if Solitaire and Tetris can be such runaway hits, anyone with a good idea that translates into a simplistic game can do just as well.

For example, take a look at Deer Hunter. It's a relatively simplistic game using technology that is well documented, yet it is one of the best-selling games in recent history. It took the developers three months to complete, and it is certainly nothing that would be beyond the reach of a Delphi developer. Its concept is simple, it's aimed at the mass market, and the price point is right (it runs for about \$20).

With the global distribution available in the form of the Internet, and third-party companies offering the ability to take credit card orders for your software (for a nominal fee or percentage), it is possible for even the most remote programmer to compete with the big boys. The market for game software is much more open than the vertical markets (such as exist for word processors and spread sheets), and has a wider audience than that available for niche markets. Although you may not get rich from selling a \$5 shareware game, you could become quite wealthy by selling several \$5 to \$10 games.

As a reality check, bear in mind that the process of making games is no longer a one-man operation. Most games consist of good programming, good graphics, and good sound, and the combination of programmer, artist, and musician would be the equivalent of a modern-day Renaissance man. Indeed, to compete with such games as Quake, Wing Commander, or StarCraft, a team of several programmers, artists, content writers, game designers, actors, musicians, and sound engineers would be required to make a serious effort. Even for the most simplistic game, the talents of an artist should be sought out for all but the most elementary of graphical resources. Although it is possible to compete from one's garage, employing the talents of several

individuals may be required to meet the demands of your users.

### Untapped Markets

The most actively pursued market for games are males from age 16 to 25 who buy several games a year. These are what you would call "hard-core gamers," and are the type of individuals who buy games like Quake, Tomb Raider, and Command & Conquer. This market is the most competitive, results in the biggest profit margin, and is pretty tied up by all of the big names in the game programming industry. It is these types of people who demand games that would require the aforementioned team of people to make any serious effort to create.

Are males ages 16 to 25 the only demographic to which games should be marketed? Certainly not. There are many untapped age groups and individuals that potentially offer an even greater market share of the gaming industry.

### Children

Children's software can be big business, with companies like Microsoft and others offering software that interacts with animatronic dolls or other devices. However, given the wide range of age groups and the commensurate knowledge to be learned at these ages, a plethora of software can be aimed at this group that combines education with entertainment. Several big-name companies are starting to dominate in this market, but there is still a lack of software for certain age groups that could be filled by the enthusiastic Delphi game programmer.

### Females

Women and girls use computers just as much as men and boys do, yet there is an incredible void in available software aimed specifically at this group. In a very generalized manner of speaking, most gaming software aimed at males is violent, bloody, and very fast paced. Taking into account that there are exceptions for every rule, this type of software typically does not interest most females. A huge untapped market exists for game software aimed specifically at women and younger girls, and any research into recent articles in gaming magazines can turn up scores of discussions and analyses of the types of games that would do well with this group.

## Casual Gamers

This group is starting to receive a lot of press coverage. A seemingly elusive and hard to reach group, the casual gamer is one who uses his or her computer for entertainment, but does not play the games aimed at hard-core gamers. These people like Solitaire and Tetris, and include everyone from housewives/househusbands taking a break while the baby sleeps to business people looking for something to do during lunch. Typically, this group doesn't like games that require long commitments, as you would see in games like Shogo or Final Fantasy. They like games that you can play quickly, something you can drop into and out of during lunch or a quick break. Many people are now trying to market to this group, and some are having better luck than others. This group presents the largest potential, as there are many more housewives/househusbands and business people out there than there are hard-core gamers.

---

*Note:* For a look at some professional games written in Delphi targeted for this market, visit <http://www.gametropolis.com>.

---

## Types of Games

There are almost as many game type categories as there are games. Limited only by the imagination of the programmer, a game can take literally any form, as long as it is entertaining and interactive. There are probably many more game genres left to be discovered by inventive programmers than what is listed here. When Id came out with Wolfenstein 3D, and later Doom, an entirely new category was launched that spawned many successful imitations. Games such as Dune 2 and WarCraft heralded the real-time strategy genre, perhaps even more popular than first-person shooters. Below is an arbitrary categorization of different game genres, discussing the features typically implemented in a game of that category. Delphi, like C/C++, is adequately suited for producing games that fit into any category.

### Real-Time Strategy

This genre, made popular by games such as Dune 2 and Command & Conquer, is one of the most prevalent in the industry. Real-time strategy games are typically war games that require the user to manage various units and other resources, attacking opponents and gathering supplies while the computer (or other human opponents) does the same. This action takes place in real time, meaning that everyone's activity occurs simultaneously and continuously, and while the player is gathering resources in one area, other units owned by that player may be under attack somewhere else. Games such as StarCraft, Command & Conquer, and Myth all fall under this category.

### Turn-Based Strategy

This category is similar to real-time strategy, in that these games are typically war games where the user manages various units and resources. However, unlike real-time strategy games, the action in a turn-based strategy game does not happen simultaneously. One player takes a turn ordering units to attack, defend, or gather supplies, while all other players wait. When the current player is finished, the next player in line takes a turn. Games such as X-Com and Civilization fall under this category.

### First-Person Shooters

By far the most popular of all games, first-person shooters place the user in a virtual world, offering a first-person perspective of the surroundings and featuring freedom of movement and interaction with the virtual environment. These games typically have a multiplayer aspect, and offer a feature known as deathmatch. In a deathmatch, players usually hunt each other down in a virtual game of tag. Highly addictive and incredibly entertaining, games in this category are usually the most complex and competitive of all games in the entire industry. Games such as Quake, Halflife, and X-Wing vs. Tie Fighter fall under this category.

### Adventure Games

While some first-person shooters could arguably be categorized under this heading, adventure games typically portray a virtual world with the player depicted in a third-person environment, usually in an isometric perspective. Interaction with the environment is usually very detailed and extensive, and a complex plot line gets the player involved in the story around which the game is based. Games such as the Ultima series and Fallout are in this category.

### Action Games

This broad category involves games that have more action than substance, such as pinball games and arcade style games. Quick action is the focus of these games, and while there may be a little bit of a plot line or “purpose,” it usually serves as little more than a thin justification for the action taking place. These “twitch” games are fun, highly addictive, and do not require long-term commitment. Games such as Asteroids and Missile Command fall under this category.

### Puzzle Games

Another broad category, puzzle games are games of logic that challenge players to exercise their cerebral muscles. Typically, they are abstract games that involve various fundamental abilities such as pattern matching or color grouping. This category includes games such as Tetris or Lose Your Marbles.

### Sports Games

Arguably a category all its own, sports games are computerized simulations of various real-world sports. Several big development houses have created some very realistic simulations of various sports, going so far as to include current rosters of professional athletes, their likenesses, and an estimation of their talents. Games such as NHL 99, Madden 99, and BFL fall under this category.

### Board and Card Games

Perhaps the most common category for casual game programmers, this category is composed of games that could be played with cards, dice, or similar real- world gaming instruments. Typically, they simulate well-known games such as chess, checkers, or poker. These games are typically the easiest for first- time game programmers to create, as they tend to have well-defined rules that translate into well-structured algorithms, and their graphical requirements are not as severe as those of other games. Games such as FreeCell and Monopoly are in this category.

### Simulations

More a software toy than a game, these are applications that attempt to simulate some real-world process as precisely and accurately as possible. They tend to be very detailed, and while fun, typically require a long-term commitment from the player in order to obtain maximum gaming pleasure. This commitment is required in order to see the simulation grow from a beginning or newborn stage into a mature, elder stage. Games such as Sim City and Sim Tower fall under this category.

### Windows, Delphi, and Games

It goes without saying that Windows 95/98 is the most popular platform for computer games. Delphi, as we've discussed, is as powerful and capable as C/C++ when it comes to making games (or any type of Windows application, for that matter). Given the fact that there are many open markets as yet untapped by the big names in the gaming industry, there exists a huge potential for the enthusiastic and dedicated Delphi game programmer to compete and make a profit. Although this book won't show you how to design or market your game, it will show you the basics of game and graphics programming that will serve as a starting point for a future in game programming.

### Summary

In this chapter, we discussed several aspects about game programming in general and Delphi in particular as it relates to game programming. When contemplating a game application concept or analyzing Delphi as a game development platform, it is important to keep these points in mind:

- As is true with just about anything in this world, the gaming industry comes with a light side and a dark side. There are many things about the gaming industry that would make most programmers cower in fear, yet there are just as many alluring attributes that serve as a powerful seduction towards pursuing a career in it. In general, the game programming industry is plagued by difficult learning curves, long hours, and an unstable business environment. However, programming games can be a lot of fun and very rewarding, and can earn the successful individual a substantial amount of notoriety and wealth.
- When most people hear about Delphi, they think of rapid database application development. They think of its uses in the corporate environment as a wonderful tool for making myriad database accessing applications, a task for which it is indeed well suited. However, in the game programming industry, the dominant language in the U.S. is C/C++. If the most important attributes for a language to be considered a viable game development platform are fast, natively executable code, true pointer access to memory, memory allocation, and access to operating system resources, Delphi easily meets or exceeds all of these requirements. Ultimately, Delphi is as capable a game development platform as any other language, including C/C++.
- As a whole, Delphi offers many advantages over other game development platforms. Every language has advantages and disadvantages over every other, which is why there are so many languages to choose from. In general, the Object Pascal language is much more readable than C/C++, and its strong typing typically results in decreased debug time. There are also many free resources available to the Delphi programmer, and several enthusiastic mailing lists, web sites, and organizations dedicated to helping Delphi programmers at all experience levels. Unfortunately, most of the current game programming knowledge exists in the form of C/C++ examples, requiring the potential Delphi game programmer to have at least a passing knowledge of C/C++ in order to grow and learn new game programming algorithms. Delphi programmers also typically do not have immediate access to new technologies introduced by Microsoft due to lack of type libraries and Object Pascal import units.
- The game programming industry is as competitive and hostile as the movie production industry. Venture capitalists and investors are quick to throw millions of dollars—more than \$2.5 billion a year—at promising startups in hopes of grabbing a piece of the pie. Fortunately, the gaming industry is one of the few industries in which someone can compete from their garage or home office. Games such as Solitaire, Deer Hunter, and Tetris are very popular and successful, even though they don't push the envelope of current technology. With the global distribution available in the form of the Internet, and third-party companies offering the ability to take credit card orders for your software (for a nominal fee or percentage), it is possible for even the most remote programmer to compete with the big boys. Untapped markets such as the homebound, children, women, and casual gamers represent a potentially huge opportunity for enterprising Delphi game programmers.
- There are almost as many game type categories as there are games. Limited only by the imagination of the programmer, a game can take literally any form, as long as it is entertaining and interactive. In general, games can be segregated into the following categories: real-time strategy, turn-based strategy, first-person shooters, adventure, action, puzzle, sports, board and card games, and simulations. Delphi is suited for creating games that fit into any of these categories.

## CHAPTER 2 The Anatomy of a Game

This chapter covers the following topics:

- The three vital elements of a game
- Basic game architecture
- Game loops
- Game states

Application design is an art unto itself. Several books have been written on the topic of effectively designing an application. Indeed, in the computer industry one can even specialize in such a discipline (if you're a programmer, you probably know someone with the title of "Chief Architect" who only designs applications and no longer writes any code). Application design can be childishly simple or diabolically complex, depending on the task the final application must perform.

However, from a purely academic perspective, all computer applications pretty much do the same thing: receive input, process it, and create output. In typical business applications, the input comes from either a device (commonly a mouse or keyboard) or a database connection, the processing typically involves mathematical calculations, and the output generally results in either a spreadsheet style of data display or (more excitingly) a colorful graph. By contrast, game applications must accept input from several different devices, processing the input by moving onscreen objects around, performing collision detection, playing sound and music as the situation demands, and deciding if missiles are fired or something has died. A game application's output involves drawing the results of these frantic calculations to the screen.

Game application architecture can vary as wildly as business application architecture. However, all games must perform similar actions, usually in a common order. In this chapter, we examine the various components that make up a typical game application. We will study an arbitrary application architecture that can be used for games, and we will discuss the individual subsystems of this architecture, focusing on the functionality they provide to the overall game application. The focus on this chapter is on the theory of game application construction, and as such presents very little actual code examples. However, several pseudo-code listings will be illustrated that encapsulate the techniques discussed in this chapter. Additionally, a

simplistic game example is included on the CD for this chapter that demonstrates this architectural theory in a more real-world implementation.

## **Game Dissection: The Vital Organs**

Games can be incredibly complex, with several different subsystems performing any number of functions that control the overall application. Many developers may feel a little overwhelmed by all the details that go into creating a game. However, like most things in life, game programming is not nearly as complex as one might at first imagine. It's certainly not an easy discipline; one must be very skilled in their talents and have the ability to apply them in creative ways in order to produce new and exciting effects and gaming environments. Fortunately, dozens of books have been written that discuss various game programming techniques in many genres, from 2-D turn-based board games to 3-D fast action, first-person shooters. Anything that one person can learn, another person can learn as well; game programming is a constant quest for new knowledge and new techniques, which gives the field one of its many enticements.

The many game programming books on the market (this one included) typically deal with very specific game programming techniques that demonstrate how some particular game environment or effect can be produced. This allows one to learn specific talents in specific areas, possibly specializing if so desired. While game programming is as varied and diversified as business applications programming, when viewed from a high-level standpoint all games can be reduced to three necessary parts: graphics, sound, and input.

### **Graphics**

With the exception of user interactivity, graphics are probably the most important part of a game in today's market. Game developers are now using software that was once only used by movie and television production houses to develop graphics for games, and the results are nothing short of amazing. Tools such as TrueSpace, LightWave, and SoftImage, which have all been used to create outstanding special effects for both movies and television, are a necessity for serious game graphics production. Almost any major game includes several animated sequences (usually produced by one of these tools), some of which are on par with action sequences seen in a major motion picture. Game element graphics have also seen amazing improvement over the last several years, with many interactive elements starting their lives as high-resolution 3-D models. However, as important as good graphics are to today's games, it is equally important to realize that just because a game has good graphics, it does not mean it is fun to play. Too many games are made with the theory that if you put in good graphics, users will buy it. Graphics are important for that first impression when a potential consumer picks up the box to have a look, and indeed for the continued enjoyment of the game, but graphics should functionally act as only a complement to the overall game design and playability.

Game graphics can further be broken down into two elements: background graphics and interactive images, or sprites.

### **Background Graphics**

Background graphics set the mood for a game. Usually, they define the environment in which the game world is set, and they provide a reference point for the user. Typically, background graphics are static, and represent objects that the user either cannot or rarely interacts with. For example, background graphics include the vehicle fuselage of a cockpit in a flight simulator, the radar control console casing in a real-time strategy game, or the surface over which puzzle pieces slide in a pattern matching game. Sometimes, background images may animate in some way, providing more realism to the environment and enhancing the overall gameplay experience (for example, moving the heads of spectators in a tennis game).

### **Interactive Images**

The most important graphical element of any game are those graphics with which the user interacts. Either by directly controlling the movement and actions of a specific graphical element, or by indirectly affecting the movement and actions of graphical elements through the direct manipulation of other graphical elements, it is these interactive images that represent the actual game play. Typically called sprites, these images generally move about the screen, animating as they change position from place to place.

---

**sprite:** An image that animates and moves around the screen in some fashion. Typically associated with images that the user can interact with, either directly or through interaction with other sprites.

[Previous](#) [Table of Contents](#) [Next](#)

Sprites take many forms, and serve as a powerful element for increasing realism and improving a user's overall enjoyment of the game. For example, sprites include asteroids in a space game, attacking orcs in a war game, and even your brave soldiers who are about to get butchered by the attacking orcish hordes. Sprites can even be used solely for improved background animation, such as birds flying overhead or vultures picking at the remains of dead orcs and human soldiers.

*Note:* Creating art for games can be difficult if you're not an artist and do not have access to one. However, there are several freeware art libraries available on the web that contain sprite images. Check out the SpriteLib sprite graphics library by Ari Feldman on the accompanying CD.

## Sound

Sounds in a game application can add depth and richness that is simply impossible to achieve with graphics alone. Sound immerses a player in the world represented by the game, increasing both the realism and the enjoyment of the experience. Technically speaking, it is possible to create a game without sounds of any kind. However, such a game, while possibly enjoyable, will have a feeling of incompleteness and will leave the user with the impression that something is missing.

Just as graphics have progressed from their once-primitive lines and flat polygons, game sound creation has become a specialty field in its own right. Indeed, it is now common for well-known rock musicians to provide music for today's hottest games. Larger game companies are hiring Hollywood sound designers to create realistic sound effects. Even some movie and television production houses are now selling their sound effect libraries for use in game applications.

Game sounds can be broken into two component parts: sound effects and music.

## Sound Effects

Good sound effects can add great depth to any game. An Asteroids clone might be fun enough to play

without sound effects, but when you add the whine of laser blasts, the explosions of destroyed asteroids, the thrust of acceleration, and some blips and whirs to go along with normal UI elements such as buttons and menus, the game takes on a whole new dimension. Hearing the scrape of metal as your hero unsheathes his sword and a solid thud as the orcish leader's head falls to the ground after being severed adds both realism and drama to a game. Such a sequence would not be nearly as effective without the accompanying sound effects.

More importantly, sound effects can give the user audible clues as to changing game states. The typical game screen is busy enough, with the user trying desperately to outrun marauding pirates while avoiding cannon fire and shallow water and rocks. Sound effects can relate important information to the player, freeing her up to attend to the situation at hand instead of scanning the game interface to make sure that some critical system isn't on the verge of destruction. For example, a space flight simulator may feature a ship with a shield rating. As the user flies around trying to avoid destruction while accumulating the maximum number of kills, the shield readout must be continually checked to make sure that the ship is still safe from harm. Implementing a sound effect such as a voice saying "Shields Low" will both free the user from a repetitive task as well as induce a sense of urgency when the user hears the sound effect. Another example of this type of audible clue is the typical "We're under attack" heard in real-time strategy games. This frees the user from constantly scanning the map, which can quickly become a tiring chore, if not impossible. Even simple clicks or beeps on buttons and menus can greatly add to the realism and enjoyment of a game.

*Note:* Magazines and books that cover the movie industry, particularly the special effects field, sometimes contain information on how to make sound effects. These same techniques can be used to create awesome sound effects for games.

---

## Music

Like sound effects, music can add a tremendous amount of depth to a game. Music helps to define the mood for a game, and can work wonders for building tension during climactic moments, a sense of euphoria after a victory, or a sense of melancholy after a defeat. The best games use music that changes with the context of the game, building a sense of anticipation during slow moments just before an ambush, and changing to a heart-pounding rhythm during the attack. The best example of the effective use of music to evoke emotions is in movies. Pay attention to how ballads can produce a feeling of romance or loss, and how anthems can just as effectively make you feel king of the world. A game that can use music as effectively as a movie will generally provide a greater level of enjoyment for its users.

Unlike the other constituent elements of a game application, music may not always be an appropriate addition. While it may add depth to some games, it may be distracting or even a bit annoying in others. An upbeat, urgent rhythm played with electric guitars may be almost essential to a fast-paced aerial dogfight game, but the user may prefer total silence when playing a deeply tactical game such as chess. Thus, it is usually a good practice to include an option to turn off music (or even sound effects).

## User Input

User input is by far the most important part of any game. It is the reason that a game is played in the first place. Without a means of providing some sort of interface so that the user can interact with the game elements, the game is little more than an elaborate animation. The entertainment value of a game comes from this user/game element interaction. If the user wanted to watch a non-interactive animation, she would have watched TV or gone to the movies.

Providing a natural means of user interaction is a very important part in the overall design of a game. While a game may be pretty to look at and pleasant to listen to, if it is difficult to use, it won't be used long. The most appropriate means of user interaction will depend on the type of game. Obviously, flight simulators would best be controlled through a joystick of some sort, while games with lots of moving pieces that can be repositioned freely should probably use the mouse. For other games, the keyboard may be the most natural means of user interaction. Regardless of the most appropriate input device, it is good practice to support input from a wide variety of input devices. This gives users more control over what feels intuitive to them, as some

may feel more comfortable using the keyboard over the mouse, and vice versa.

User input can be broken down into two parts: standard input devices and peripheral input devices.

## Standard Input Devices

Since games must provide some method for the user to interact with the game world, it would be nice to know if the end user's machine had a specific input device attached. Fortunately, it would be a rare occurrence indeed to find a machine that did not come with both a mouse and a keyboard as standard attachments. For many games, this combination of input devices works best, and most games may not need any other type of input device. Therefore, it is pretty safe to assume that the user will have at least the mouse and the keyboard available as input devices. Most, if not all, games now support both of these devices, in addition to others.

## Peripheral Input Devices

Peripheral input devices consist of game controllers that are not standard equipment with new computers. Such devices include joysticks, game pads, rudder pedals, and a plethora of other types of input devices of every shape and size. These devices are generally suited for use with "twitch" style games that require good hand-eye coordination, such as flight simulators or first-person shooters. However, several of the more esoteric devices may provide a much more intuitive feel for the user, as opposed to using just a plain keyboard or mouse or joystick. Fortunately, most of these devices are accessed programmatically in a very standard way. This allows the developer to support several devices using the same code base, although some specialty devices may require slightly different coding methods to support their use. As stated above, it is a good practice to support a wide variety of peripheral input devices so that the user will have a choice as to which device feels the most comfortable.

## Real-Time Event-Driven Programming

Anyone who has done any amount of serious work in Delphi is now intimately familiar with the event-driven model of application programming. Delphi developers routinely write event handlers, either by creating them manually through the IDE or by hooking them up programmatically in code. It's an inescapable practice, and it makes application coding and debugging both faster and easier.

Game programming, under Delphi or any language, is similar to application programming in many ways, but it is fundamentally different in a few areas. While object-oriented game programming shares the practice of

hooking up events, there's a slight twist to this model that is required for supporting the types of games that are commonly created today.

The model most programmers, especially Delphi programmers, are now very familiar and comfortable with is known as event-driven programming. The application is written in such a way that its functionality is triggered by external events. These events can take the form of programmatic signals from other applications or devices, but for the most part, these events are triggered from user input. Until some event is triggered, it simply sits there waiting for an event to fire. For example, consider a word processor. It might have a few events that are triggered from a programmatic source, such as an autosave function fired off of a timer event. However, if you open a word processor and do nothing, it will simply sit there until the user either presses a keyboard button or activates something with the mouse. Event-driven programming is a very effective and useful method by which very robust applications can be effectively written.

Game applications, on the other hand, are in continuous motion. Events are constantly being fired based on the current game world situation, and the application continues to process with or without user input. This is the most fundamental difference between game programming and application programming, and is known as the real-time event-driven model. The game application cannot sit there and wait until the user moves the joystick before continuing. The user expects enemy ships and objects to be in constant motion, and would probably be surprised if they were not killed in some spectacular way if they just sat there. Sure, some games are written with the same event-driven model as regular applications, such as a Solitaire game, a chess game, or some other turn-based game. However, arcade-style action games that exhibit constant motion must be written using the real-time event-driven model.

**Note:** It is possible to use Delphi's input events such as OnKeyDown to provide event-driven input to a game. However, while this may work for some games, this is generally not the best approach. We'll look at more desirable techniques in Chapter 7, Input Techniques.

## Basic Game Architecture

There are probably as many different ways to design and architect game application code as there are game applications themselves. Each game will have unique and individual requirements based on the style of game and what it does. However, most games must perform similar tasks, usually in a similar order. With this in mind, let's examine an arbitrary game architecture that will support the real-time event-driven model as discussed above.

**Figur 2-1:** Basic game architecture

Basically, every game can be divided into six different modules:

- Initialization
- Game Introduction
- Game Startup
- The Game Loop
- Game Ending
- Shutdown and Exit

Typically, the Initialization and Game Introduction modules are performed at the start of program execution, and usually only run once. The user is then presented with the Game Startup module, which generally contains code for letting the user customize the game in some manner. The Game Loop module is then entered, which contains the primary logic for the game. When the game is over, the Game Ending module presents the user with information on their game performance, and then jumps back into the Game Startup

module. The Shutdown and Exit module is finally called when the user wishes to discontinue the game and shut it down.

## Initialization

The initialization module is responsible for setting up the beginning game state. It allocates needed memory, initializes global variables, creates lookup tables, and loads resources such as graphics, sound, and music files. Typically, the initialization module will display a splash screen at the beginning of the initialization code so that the user has something to look at. This is an especially good practice if game initialization takes a while; otherwise the user may suspect that the application has frozen or stopped executing.

**ISBN:** 1556226373 **Pub Date:** 12/01/99

**Search this book:**

[Previous](#) [Table of Contents](#) [Next](#)

In Delphi applications, the developer has a number of areas where initialization code can be located. The main form's OnCreate event is the most obvious location, but such code can also be placed in the OnActivate event or even in the initialization section of the unit. The initialization module typically contains code that is only run once at the beginning of application startup. Any variables that will be reset when a new game is started, such as the player's score or starting level, should be modified in the game startup module.

**Caution:** Pay attention to any dynamically created objects or dynamically allocated memory, and make sure to free these upon termination. Games that leak resources and cause the user to reboot the machine after play are not looked upon favorably.

**Introduction**

The introduction module is responsible for introducing the player to the game and welcoming them into the game world. Typically, this takes the form of some sort of animated introduction. Most games, especially those constructed by professional game production houses, will display an elaborate animated sequence that gives a little background to the game and sets the overall mood. Some opening sequences are as good as action movie trailers, and may even feature live actors. The goal with these introductory animations is to immediately pull the player into the game world by eliciting the appropriate emotions and generally getting them into the right mood. Even a simple text display of a short story can be effective if written correctly. Usually, the game will provide a method by which the user can view the introduction again if they so desire, to review the overall game goals and objectives or to simply experience some cool animation again.

While introductory animations are important for setting the mood and the story, it is equally important to remember that all introductions, no matter how cool, will become boring at some point. Some games will only show the introduction when the game is executed for the very first time. Introductory sequences will slow down users who play the game often, so it is important to remember to provide some method to skip the introduction, such as a keypress.

*Tip:* Always allow users to bypass any animation sequence by pressing a hot key.

---

## Game Startup

The game startup module is responsible for two things. First, it should reset any variables that need to be initialized when a new game is started, such as a player's score, their level, the number of lives left, etc. Second, game startup should allow the user to customize the game in any way supported. For example, game startup should include the code that allows the user to select which input device will be used, what side he'll be playing, or other game-specific options.

## The Game Loop

The game loop module is the focal point of the game application. It contains the primary game logic, and executes the code that creates the game environment and controls all game objects. Its primary responsibility is processing user input and rendering the game output.

The game loop itself is a set of actions that are performed in rapid succession. These actions are performed over and over in a loop, updating the screen to reflect the current state of the game world. These actions are performed with or without any input from the user. Each pass through the game loop updates the screen one time, and represents one frame of animation. The code located in the game loop usually receives the most attention throughout the development cycle of a game, as this code must be highly optimized to run fast enough to achieve an acceptable game speed.

What should be in the loop? That depends on the specific game, and varies on an individual basis. However, most game loops perform similar functions. The game loop is examined more closely below.

## Game Ending

The game ending module is responsible for reporting to the player their overall game performance. This can take many forms, from a simple display of high scores to a summary of several different game statistics, or even an ending animation displaying a different scenario dependent upon whether the user won or lost. Whatever the method, the game ending module should let the user know that the game is over, and provide them with a choice to either start a new game or exit. If the user wishes to play another game, it should give control to the game startup module; otherwise it should execute the shutdown and exit module.

## Shutdown and Exit

The shutdown and exit module is responsible for de-initializing variables and terminating the game application. It should free any dynamically allocated resources that were created in the initialization module, delete any temporary files, and generally ensure that the application will terminate without memory leaks or other artifacts. If the game offers the user a method by which it can be saved, it is usually a good idea to ask the user if they wish to save the current game before exiting. This will avoid frustrated and angry users who have spent several hours playing the game just to have their efforts destroyed by accidentally choosing the wrong option.

*Tip:* Always ask the user if they wish to save the game before exiting (if game saving is supported).

---

This module should be reachable from several different points in the game. At any time, a user may want to end the game and exit the application, and this should be obtainable from the game startup, game loop, and game ending modules. Typically, several different methods are employed that allow the user to exit the

game. For example, there is usually a button or menu item in the game startup and game ending modules that will exit the game. Hot keys are usually available from within the game loop that either give control to the shutdown and exit module or return the user to the game ending or game startup modules so that they can exit from there.

**The Game Loop**

As mentioned above, the actual game loop is usually the focal point of a game application. The game loop is where all of the action takes place. It processes a series of instructions over and over as quickly as possible to produce the on- screen images that reflect the current state of the game. This processing continues with or without user interaction, and is precisely the method by which the real-time event-driven model discussed previously is implemented.

Technically speaking, a game loop is responsible for three things: retrieving input, updating game objects, and rendering a new frame of animation. Of course, there's a lot more to a game loop than this oversimplified description suggests. What actually occurs in a game loop is very arbitrary and will depend on the needs of the individual game. However, all games perform similar tasks, usually in a similar order. Expanding upon the three tasks listed above, Figure 2-2 illustrates an example game loop that might be found in a simple action arcade game.

**Figure 2-2:** A simplistic game loop

There are several different techniques by which this game loop architecture could be implemented. In the examples in this book, we will be implementing the primary game loop inside the Application.OnIdle event.

This technique is used for several reasons. First, the main game loop will automatically be entered whenever the application becomes idle (after initializing everything in the OnCreate or OnActivate form event handlers or the initialization section of the unit). Second, the application object controls when the OnIdle event is called, meaning that any standard Windows events will be processed and the application never needs to call Application.ProcessMessages. Third, it's simply an easy, Delphi-centric technique for implementing the game loop that should be easy to understand and reproduce.

Alternatively, a while..do or repeat..until loop could be used to implement the game loop. The advantages of this technique are that the developer will have more control over the application, and it will run a little faster than the OnIdle technique. The application could even exit the game loop for some reason, perhaps to display a simple options screen that didn't need the complex animation capabilities afforded by the game loop. The disadvantages to this method of game loop implementation are that these types of loops are generally a little harder to work with when trying to support general Windows events. Application.ProcessMessages must certainly be called at some point within the loop so that standard Windows messages can be handled. Also, the variable controlling the loop's execution must be set so that the loop can exit before the application can terminate; simply calling Close or Application.Terminate will not work. Using this technique can result in little issues such as these that interfere with the normal operation of a Windows application. They can usually be handled with minor workarounds, however, so using a loop such as this may be advantageous depending on the type of game being produced. The following listing demonstrates an implementation of the arbitrary game loop using a while..do loop.

***Listing 2-1: Arbitrary game loop example***

---

```
procedure GameLoop;
var
    TimeStart: Longint; // used to time the length of one loop iteration
begin
    {this while..do loop will continue processing the same commands in
    rapid succession until instructed to exit from the loop}
    while GameRunning do
    begin
        {record the current time upon starting the loop}
        TimeStart := GetCurrentTime;

        {retrieve input from the user by accessing whichever input device
        the user has chosen}
        RetrieveInput;
```

```
{perform any enemy artificial intelligence and other logic  
associated with game elements not controlled by the user}
```

```
PerformEnemyAI;
```

```
{iterate through all sprites, updating their positions accordingly,  
taking into account user input and enemy AI calculations}
```

```
UpdateSpritePositions;
```

```
{check for any collisions between objects that would result in a  
change in the current game state, such as missiles colliding with a  
target or the player's sprite impacting a wall or other object}
```

```
CheckForCollisions;
```

```
{start any sound effects needed, based on collision detection or  
other game states}
```

```
StartSounds;
```

```
{start any music needed, again based on collision detection or other  
game states}
```

```
StartMusic;
```

```
{all processing has been completed, so draw the current state of the  
game to the screen}
```

```
DrawFrame;
```

```
{determine if the game is still running, based on whether the player  
has died or some other deciding threshold has been reached}
```

```
GameRunning := IsGameOver;
```

```
{determine how long this cycle has taken; if it has been too short,  
    pause for the difference so that the game does not run too fast}  
If GetCurrentTime-TimeStart<TimingValue then  
    Pause(GetCurrentTime-TimeStart);  
  
    {process any Windows messages that are waiting}  
Application.ProcessMessages;  
  
end; // repeat this process over and over until the game has ended  
end;
```

---

As a matter of practice, several of these tasks may be combined or performed simultaneously. For example, since an application must iterate through every game object to update its position, it would be practical to draw each object as its position is updated. Also, collisions usually result in an object being destroyed or its course being altered, so appropriate sound effects could be started at the time of the collision detection. The point is that these steps represent an arbitrary game loop, and may be rearranged or combined (or even split apart) as the individual circumstances warrant.

Even with this expanded view of a game loop implementation, many of the details attended to within the loop are not fully exposed. Throughout this book, we will examine many game examples that contain highly varied game loops, containing various functions as required by the individual game type. Later chapters will discuss in depth the tasks performed by an individual game example's game loop, but for now, let's examine an overview of what each segment is responsible for within our arbitrary game loop.

## Retrieve User Input

Retrieving user input involves reading the input values from whatever device is supported or that the user has chosen, and translating that information into a form relevant to the control of the game. Most Delphi applications typically handle user input through event handlers, such as `OnKeyDown` or `OnMouseMove`. For business applications and even most strategy or turn-based games, this method is fine. However, fast action arcade games typically require more control over the process, and handling user input through events may impede or interfere with the proper execution of the game.

[Previous](#) [Table of Contents](#) [Next](#)

Thus, most games use a polling technique for retrieving user input. Polling involves directly accessing the device at a specific point within the game loop and reading its data. Theoretically, this polling could take place at any time, but it usually occurs at the beginning of the game loop so that the most recent movement can be reflected in the next frame of animation. Direct polling gives the application developer precise control over the processing of input, and can even allow the detection of multiple input events simultaneously (i.e., check if two keys are pressed at the same time).

**polling:** A method for retrieving input or checking some data value manually (as opposed to letting a separate thread check it automatically), usually repeated often at regular intervals.

The primary drawback to the direct polling technique is that user input events can get lost if the polling happens infrequently. This is generally a symptom of a slow game loop, where a large amount of processing takes place before the input device is again polled.

**Figure 2-3:** Missing a user input event

One method to remedy this situation is to conduct device polling at several different places throughout the game loop, and then process the sum of the movement data when it is time to update game world objects. However, another more accurate technique is to buffer user input events. To perform this technique efficiently, a separate thread must be utilized to perform the device polling and event queuing. Fortunately, DirectX provides several methods that make this technique viable, and we'll examine a demonstration of this in the chapter on input techniques.

Once the input has been retrieved, it is translated into events that are meaningful in the context of the game. For example, if the joystick button was pressed, the function for starting a missile or a bullet volley would be

called. How the input is translated is, of course, dependent on the type of game itself. The result of such user actions will be apparent after the sprite updating segment has been called and the next frame of animation has been drawn to the screen.

## Perform Antagonist AI and Other Game Logic

In this segment, algorithms that control the behavior of enemy units or other non-player units are performed, with the results being used to update the appropriate sprite positions or to execute any other appropriate actions. This may include deciding if an enemy spacecraft pursues the player or flees, but it also includes other, perhaps more mundane, decision making processes that affect other parts of the game. For example, background sprites that are never interacted with during the game may contain a little logic for changing their animation so that it does not appear repetitive.

This segment may run some very complex code depending on the type of game and its objectives. Some games, such as chess, may have a very advanced thinking engine that examines the current configuration of the board and makes a movement decision based upon the prediction of the next move that the opponent may make. Other games, such as real-time strategy war games, may have several smaller decision engines that determine the most direct route a unit may take to its destination. In general, this segment executes the artificial intelligence code that determines how the game objects will react to the actions of the player.

**artificial intelligence (AI):** The concept of cognitive software that thinks and reacts to situations in a sentient manner. In relation to game programming, this is the section of code responsible for determining the actions and reactions of game protagonists in relation to the actions and reactions of the player.

---

Artificial intelligence is a specialty area in its own right, and some game companies hire programmers specifically for their AI expertise. Some AI techniques are well documented and are easy to implement, such as chasing or evading the player or converging on a specific position. Others, such as natural speech generation or pattern recognition, are very difficult to implement and are either closely guarded trade secrets or the province of advanced academic research.

## Update Sprite Positions

The positions of all game objects are updated in this segment. Their velocities are added to their current positions, which are then usually checked to make sure that they are still within the boundaries of the game world. This segment is where the results of user input and artificial intelligence logic are realized. A ship is accelerated or turned according to how the user moved the joystick, and enemy soldiers and cannons are advanced forward or animated per the decisions of the artificial intelligence segment.

Since all objects in the game world need to be updated, the game loop typically iterates through each object, one at a time, applying the position translations as required. The game loop itself needs to run as quickly as possible, so other actions that are performed for each game object are typically executed in this segment as well. The most common action performed at the same time as position updating is probably drawing the sprite image into an offscreen buffer. However, other actions may include collision detection, artificial intelligence processing, or other functions. The process of actually drawing the sprite, as well as other sprite specific procedures, will be examined in Chapter 6, Sprite Techniques.

## Check for Collisions

The collision detection segment is necessary for determining if two sprites or game objects have collided, and the action that is a result thereof. Most games are driven off of events where two sprites come into contact. For example, when a bullet that was fired several frames ago finally touches the enemy ship at which it was targeted, something should happen.

There are hundreds of different methods by which to detect if two or more objects have collided. Some games may require that every object be checked against every other object; others may be interested in the

collision between only certain types of objects. Whatever the case, collision detection algorithms vary in complexity according to the task they must perform and the number of objects involved. Accuracy is also an area of great variation. Some may detect only a close collision, and may not be very accurate at all. Others may go as far as comparing the pixels of each bitmap at a certain frame of animation and at a certain position within the game world to see if any pixels actually overlap (a highly accurate method indeed). Speed also becomes a very important issue with the collision detection scheme put into production, as the more accurate the collision detection, typically the slower it will run. Collision detection algorithms will be covered in the chapter on sprite techniques.

### Start Sound Effects

Games would tend to get boring without sound effects to accompany the actions of various game objects. The responsibility of this segment is to commence the output of various sound effects as warranted by the actions of both the user and the game controlled objects. Technically speaking, sound effect playback will probably be handled during other segments of the game loop. For example, when the user presses a button to fire a missile the user input retrieval segment will probably call a function that both starts the missile object as well as commences the playback of an appropriate sound effect. Other sound effects, such as idle background chatter or other appropriate noises that would be generated from non-interactive game objects, will probably be started when the artificial intelligence section makes one of these objects perform some action. Any other sound effects not handled by an appropriate segment, such as ambient sounds or user interface activation sounds, may be generated from this segment. We will see techniques for sound effect output in Chapter 9, Sound and Music.

### Start Music

As with sound effects, music enhances the gaming experience, and this segment is responsible for starting musical output or changing the tune of the existing output. Again, music playback may be handled by another, more appropriate segment. However, music is commonly used to reflect the overall mood or state of the game. As such, this segment would be responsible for examining the current state as it would reflect from the user's standpoint, and start or change the music as appropriate. For example, a neutral musical interlude may be output when the user is just flying along to the next waypoint. This could be changed, on the fly, to a more intense, urgent musical number when the user goes into combat. It could be changed to an even more intense score if the player or enemy is heavily damaged, and finally an appropriate tune could be played based on the user's victory or defeat. This segment would need to perform the necessary actions to determine the current state of the game, playing a specific musical piece as appropriate. The chapter on sound and music contains examples of musical score playback techniques.

### Render the Next Frame

This segment is responsible for the most important part of the game loop, that of displaying the current state of the game from the user's perspective in graphical form. Depending on the complexity of the game, this

may simply entail drawing two-dimensional bitmap images to the screen, or rendering a complex, realistic view based on the positions of three-dimensional models. Of all the segments in a game loop, this segment has the greatest variety of implementations. Like all game programming topics, some techniques are well documented, such as simple sprite output or even three-dimensional raycasting or rendering techniques. Other techniques, such as true three-dimensional space rendering, are trade secrets and are poorly documented, if at all.

Typically, rendering a frame of animation starts by drawing the background. This may be as simple as a game board or something more complex, like a textured, scaled wall. Sprite images are then drawn over this background. All of this drawing generally takes place in an offscreen graphical buffer. After all drawing and rendering has been completed, this buffer is then blasted to the screen, at which point it becomes visible as the next frame of animation. As sprite positions are modified, their images drawn to reflect these new positions, and the results displayed to the screen in rapid succession, the illusion of animation is achieved. DirectX provides several methods for performing graphical output, both simplistic and complex.

## Check for Game End

At some point, the current state of the game needs to be compared with a known state to see if a state change is in order. For example, if all of the player's lives have been used up, the game is over. Additionally, when all of the enemy creatures have been eliminated or the exit is found, the current level has ended and it is time to advance to the next level of difficulty.

Advanced games may potentially contain several states that affect how the overall game loop is processed. For example, when a level is completed, the game may go into a temporary intermission state where, instead of performing the normal gameplay animation, it displays a summary of the previous level's accomplishments as well as the name or number of the next level being entered. A discussion of expanding the game loop to support different game states is covered below.

## Speed Delay

The one constant in the computer industry is that machines will only get faster and faster as time marches on. Therefore, a game that plays at an acceptable speed today may be too fast to be humanly playable on a new machine six months from now. To ensure that the game runs at a specific speed on every machine, this segment determines if enough time has passed since the rendering of the last frame to constrain the game to a specific speed.

One technique for controlling the speed of a game is to time the duration of the processing of the current animation frame. A starting time is recorded at the beginning of the game loop. At the end of the loop, this starting time is subtracted from the current time. If the result is less than a specific amount of time that will constrain the game speed to a certain rate, the execution is paused for the difference.

This results in a game that should run at a constant speed on any machine equal to or faster than the minimum recommended system for the game. The sprite techniques chapter and other chapters throughout this book contain implementations of timing algorithms for controlling game speed.

**Note:** To accommodate slower systems, some games perform timing tests to see how fast animation can be performed. If it is slower than a certain threshold, the game may compensate by dropping animation frames or turning off some features. The result will be a scaled-down, probably less attractive version of the game, but it has the advantage of running on older systems, which may be a selling point for the customer.

---

## Game States

The game loop example detailed above provides the application with a framework that makes game animation and user input control easy and intuitive for the developer. However, it is not as robust as it needs to be for real-world applications. How many games jump right into the action immediately upon launching

them? Most games display some sort of mission briefing or demonstration while waiting for the user to actually start a game. Typically, action games will also display some sort of information when a user has completed a level. Still others allow the user to input their name when a game has ended.

[Previous](#) [Table of Contents](#) [Next](#)

We have examined games in terms of the general tasks that are performed. Additionally, games can be examined from the standpoint of their current mode of execution. When a game is first launched, it is considered to be in one mode of execution, but when a new game is started and the user is actually playing, it is in a totally different mode of execution.

Our current game loop does not support this functionality. What is needed is a technique by which the game can be put into specific modes of execution, or states. For example, when the game is first launched, it should be initialized to a demo state. Other states, such as an intermission state or a game over state, will control what parts of the game loop are executed, and will display the appropriate output.

To extend our game loop, we will assume that it supports a game with five states:

- Demo
- Playing
- Intermission
- Paused
- Game Over

Each different state would involve executing code appropriate only for that state. Through each iteration of the game loop, the current state is checked, and an appropriate set of functions is executed that produces output (and retrieves input) commensurate with that state.

**Figure 2-4:** Controlling the game through states

This could be implemented by using a case statement. The game states could be represented as an enumerated type. Then, when the game loop is executed, the case statement would jump to the appropriate

```

                                {paused code}

                                end;

gsGameOver : begin

{game over code}

                                end;

                                end;

end;

```

This technique requires the case statement to be executed over and over. If this becomes a speed issue, this technique could be modified such that each case statement entry jumps to a function that contains its own internal loop. That internal loop would then continue until the game state changes. When this occurs, the internal loop exits, and the main game loop must be called again to switch execution into another function with its own internal loop. This modification is illustrated in Figure 2-5. Technically, an internal loop may simply display a static graphic and then pause for an appropriate period of time, such as for an intermission, instead of performing some sort of animation loop. However, static screens are usually pretty boring.

**Figure 2-5:** A modified game state looping architecture

Designing a game application in this manner allows it to be controlled in a very logical and ordered manner. The state of a game can flow from one state to another as appropriate, changing between logical states and ultimately creating a circuit or loop from game beginning through game play to game end and back again. For example, games may start in the demo state, switching into the playing state when a user starts a game. This state will move back and forth between the paused state and the intermission state as the user finishes levels and plays the game. Ultimately, the user will finish the game or will die, at which point the state will switch to the game over state, and finally back to the demo state, where the entire process can be restarted anew. Figure 2-6 illustrates the flow of game logic through a typical game loop constructed in this manner.

**Figure 2-6:** The flow of game states

Each state's code is responsible for supplying specific output or retrieving specific input, as appropriate for the intention of that state. Some games may have more states than others; other games may not use this design at all, opting for another, more applicable control method. Even so, whether a game uses this technique or not, the execution of a game can be described in terms of states.

### The Demo State

This state typically provides some sort of animation while waiting for the user to start a new game. This may take the form of simple animations within user interface controls (such as animated images on buttons) or something more complex. This state could even be used to play the opening animation sequence introducing players to the game.

Some games provide a demonstration of game play as the background animation. This is certainly a popular technique with hot first-person shooters, and even with most action arcade-like games. Displaying a demonstration of actual game play can whet users' appetites for the game and help to familiarize them with the environment before actually diving in.

To appropriately show a demonstration of game play, this state must run some code elements of the state that is used for actual game play. Artificial intelligence routines could be used to simulate the input of a user and generate some interesting animation. Alternatively, input from an actual game session could be saved to an output file. If designed correctly, the functions that interpret user input could take their values from either a user input device or this digitized user input file. Thus, the demo state would simply open this file and begin streaming the data to the input routines, resulting in an exact duplication of the player's movements and actions.

**Figure 2-7:** Input coming from devices or files

This technique has many benefits. For one, the developer can control exactly what the user will see in the demonstration, which could avoid accidentally showing off hidden rooms or other surprises. Additionally, the developer could digitize walkthroughs that could then be used in separate game hint packages. Also, this method lends itself directly to instant replay functionality, highly desirable in sports and racing games.

### The Playing State

This state is responsible for the code that makes up the actual game play. All of the segments of the previous game loop presented above will be found here, such as user input processing, sprite updating, and screen drawing. The code run in this state will probably look similar to the example game loop implementation previously discussed.

### The Intermission State

When a user has completed a level (or a series of levels or a mission), games usually enter a type of intermission state. In this state, a report is given to the user that, depending on the type of game, details the user's accomplishments in the completed level. Such things as the number of kills, the number of secrets found or unnoticed, and the accuracy of shots are typically highlighted, as is the found or unnoticed, and the accuracy of shots are typically highlighted, as is the number of the next level or the name of the next mission. Sometimes, even an animation will be used to provide a transition from one level to the next, especially if a "chapter" of the game has been completed and an entirely new set of environments and enemies are about to be introduced. Intermission states only last a short while, setting the game state to playing once the intermission state is over.

**Tip:** It is a good practice to provide a hot key or some other mechanism whereby a user can skip the intermission state and proceed directly back to the playing state.

### The Paused State

The paused state is simply a suspension of game play. All game object logic and processing should be halted, including the output of sound effects and possibly even the output of music. Typically, pausing a game should simply toggle between the paused state and the playing (or intermission) state. Pausing a game should usually have no effect during a demo or game over state. Paused states are generally entered through either a hot key activation or by interacting with a user interface control (such as a button or menu item).

## The Game Over State

In the game over state, an expanded report of the user's accomplishments throughout the course of the game could be displayed. This includes the information displayed during the intermission state as it applies to the overall game achievements. End game animations could also be played, perhaps varying the exact animation dependent upon whether the player won or lost. The game over state usually only lasts for a short amount of time, perhaps only a little longer than the intermission state, before proceeding to the demo state.

## Case Study

In order to further demonstrate the concepts discussed in this chapter, we should examine the case study provided on the CD in this chapter's directory. It is a game titled Shoot 'em, where the player simply fires at oncoming enemy spaceships. It is a simple game using simple graphics, but it should serve as an example of implementing several of the topics we just covered. This is not a complete game, and many of the tasks required by a commercial quality game have been left out (such as sound and music output) so as not to complicate the code. The architecture used in this example game will be the basis for examples to come.

Of particular interest to this chapter is the game loop itself. The example implements a simplistic game loop similar to the first loop architecture we've discussed. It is state driven, and throughout the code you can see where this state is modified and how it affects the overall game processing. This game loop is embodied in the DrawSurfaces procedure. Take a look at this procedure to get a taste of how to implement an actual game loop.

This case study example is presented in its entirety to get you familiar with the types of examples demonstrated throughout the book. There are several programming techniques implemented in this example that we have yet to discuss, such as sprite manipulation. This example also contains some DirectX initialization code that we haven't yet discussed. Peruse the first part of the example to get familiar with the function calls that we'll be exploring in subsequent chapters. Beginning with the DrawSurfaces procedure, we see some techniques that we've outlined in this chapter. This example also demonstrates how to logically control such entities as sprites and background animation elements with arrays. Later in the book, we'll extend this to a more general approach for controlling game entities.

*Listing 2-3: The Shoot 'em example game*

```
unit ShootEmU;
```

```
{*****
```

```
    Shoot Example Application
```

```
Author: John Ayres
```

Like most examples in the book, this one takes advantage of the baseline DirectX application code. It implements a very simplistic game in order to demonstrate basic game architecture. The architecture of a game is arbitrary and will in part be determined by the type of game being created. However, most games share similar tasks in order to generate a frame of animation, and this example should serve to familiarize the user with some of the more common gaming application tasks.

## Summary

In this chapter, we discussed the most important and most basic issues involved in designing game application software. When designing the architecture of game application software, it is important to keep these points in mind:

- Every game, no matter how complex, can be broken down into three constituent parts: graphics, sound, and user

input.

- The specific architecture of a game will vary widely depending on the type of game and its inherent functionality. Even so, most games usually perform similar tasks in a similar order. From a high-level standpoint, game software can be thought of in terms of six elements that perform necessary tasks: Initialization, Game Introduction, Game Startup, the Game Loop, Game Ending, and Shutdown and Exit.
- The game loop is usually the focal point of a game application, and is where all of the action takes place. It processes a series of instructions over and over as quickly as possible to produce the on-screen images that reflect the current state of the game. This processing continues with or without user interaction. It can be implemented in a variety of ways, and must perform several different tasks as rapidly as possible. Technically speaking, a game loop is responsible for three things: retrieving input, updating game objects, and rendering a new frame of animation. Additionally, it must perform collision detection, enemy AI, and other tasks commensurate with the specific type of game.
- Games can be examined from the standpoint of their current mode of execution, or state. A state based gaming architecture allows the game to be controlled in a more logical and ordered manner. The state of a game can flow from one state to another as appropriate, changing between logical states and ultimately creating a circuit from game beginning through game play to game end and back again. In general, games can be considered to execute in five different states: Demo, Playing, Intermission, Paused, and Game Over.

## CHAPTER 3 Basic Graphics Programming

This chapter covers the following topics:

- Graphical elements, such as pixels, lines, and polygons
- Video mode resolutions and color depth, and the difference between palettized and non-palettized video modes
- Device contexts and their use
- Using the TCanvas object for graphical output
- Essential bitmap techniques
- Color palettes

Like other industries, the computer industry has matured to the point that it can be thought of in terms of specialties. There are specialists in hardware installation, technical support, client/server architecture, etc. Some fields, such as programming, are further divided. Programming offers many areas of specialization, including database programming, speech recognition, or even communications. Of these, graphics programming is one of the most fun, rewarding, and sought-after specialties. All client-side applications that interact directly with the user make some use of graphics programming techniques, be they simple GDI commands for drawing basic Windows interface elements or full-fledged, 3-D rendered landscapes in games. At some point, any programmer working on an application to be used by end users will need to have some knowledge of graphical programming techniques.

This book's primary focus is on high-performance graphics and games programming using DirectX. Although the techniques discussed throughout the book are advanced by their very nature, the neophyte to graphics programming should not be ignored. Many people have used Delphi solely for client/server database applications or business related programs, and are just now experimenting with its broader range of functionality. There have been several shareware games written in Delphi, and retail games created with Delphi, while rare, are starting to emerge. Thus, many readers of this book are probably new to graphics programming, and may be a little fearful of the advanced topics presented in the coming chapters.

To this end, this chapter has been dedicated to acclimating the Delphi programmer to terms and concepts

common in graphics programming. Although no one concept is discussed in any great depth, after reading this chapter, the casual Delphi programmer will be familiar with many of the terms and concepts that will be expounded upon in later chapters. This should give Delphi programmers a good base of knowledge to prepare them for the graphics programming techniques to come. Readers who are familiar with basic graphics programming topics, such as pixels, lines, polygons, bitmaps, and using the TCanvas object, may want to skip ahead to the next chapter, which introduces DirectX. However, if you're not familiar with these topics, read on.

## The Graphical Device Interface

One of the fundamental pieces of Windows is the Graphical Device Interface, or the GDI. This important subsystem is responsible for all of the graphical output displayed to the screen during a Windows session. The GDI subsystem is accessed through a wide variety of functions and procedures. Buttons, lines, scroll bars, application windows themselves, even text, are all drawn by these GDI functions and procedures.

**Graphical Device Interface (GDI):** The Windows subsystem responsible for all graphical output during a Windows session.

One of Windows's strongest attributes is its device independence, or its ability to be run on a wide variety of hardware combinations. Due to this requirement, the GDI's primary purpose is to provide a mechanism by which an application can output graphical content without the programmer being concerned about what type of hardware upon which the application will be running. It accomplishes this goal superbly; it is incredibly easy to draw lines, buttons, bitmaps, etc., without being concerned with hardware.

Unfortunately, as a direct consequence of this device independence, the GDI is notorious for its slow performance. Even with this reputation, the GDI is very useful when creating tools for games. While most games today are written in DirectX, it is very common for the game programmers to write tools under regular Windows using the GDI. Strictly speaking, while games run faster under DirectX, it's usually quicker to write the tools used to build the game using good ol' Windows and the GDI. The tools themselves rarely need the performance achievable with DirectX, and the incredible richness of the GDI API makes it simple and quick to produce the tools. It is now common for games to include some of the tools used in its creation, such as level editors. However, today's incredibly fast processors and Windows accelerated video cards are making this speed issue less of a problem. Although many would argue that a commercial quality game could not be accomplished using standard GDI techniques, several commercial and shareware games have been successfully created using nothing more than an intelligent application of GDI programming techniques.

**Figure 3-1:** Games using GDI techniques

*Earthworm Jim for Windows 95 by Activision*

*Pitfall: The Mayan Adventure by Activision*

*Mission: Moon by Beckett Interactive*

Later in the chapter, we'll explore how Delphi and the TCanvas class unlock the power of the GDI and make it incredibly easy for the application developer to take advantage of some very powerful graphics programming techniques. First, however, we need to cover a number of concepts that are critical to understanding graphics programming.

## Graphical Elements

To begin exploring the topic of graphics programming, one must be familiar with a number of terms that describe various graphical elements. Like any specialty, graphics programming has its share of jargon, much of which will be discovered throughout the pages of this book. However, there are several terms that describe concepts in just about every application of graphics programming. These are: the pixel, the line, polygons, and bitmaps.

### Pixels

When the GDI displays an image to the screen, whether it's an application window, a button, text, etc., it draws the graphic in a series of different colored dots. As these dots are drawn to the screen, they eventually form an image that is recognizable to the user. This dot is called a pixel, and it is the smallest graphic that can be drawn to the screen. This action of "drawing" individual colored dots to the computer screen happens so fast (usually) that it appears instantaneous to the viewer.

---

**pixel:** The smallest, single element in a graphical image or on the display surface.

The entire computer screen can be thought of as a grid of dots, or pixels. The size of this grid determines the video mode resolution, and the number of colors in which an individual pixel can be drawn determines the color depth (more on this later).

**Figure 3-2:** The screen is composed of dots, or pixels

## Lines

Next to pixels, lines are the most common graphical element seen in user interfaces. The GDI uses lines of different colors to simulate the beveled surfaces common in Windows user interfaces. Of course, lines have several thousand other practical uses, from representing scales and rulers to graphs and other more complex graphical content. Strictly speaking, a line is simply a collection of pixels arranged in a linear fashion.

**line:** A collection of pixels, usually arranged in a linear or connecting configuration.

Lines have a mathematical discipline all their own, known as geometry. The study of lines and the mathematics that manipulate them is almost a fundamental requirement for any serious graphics programming. Even if the application will not be strictly output lines, it is sometimes useful to utilize geometry (and trigonometry, see below) to produce incredibly realistic scene generation. We'll see more of this when we cover ray casting engines later in the book.

**Figure 3-3:** A line is a collection of pixels

## Polygons

Polygons are quite prevalent in the world of 2-D graphics programming. Buttons are usually square or rectangular in shape, and it's not uncommon to see controls or graphics that are triangular, pentagonal, or configured into some other shape. Simply put, a polygon is a collection of lines, connected at the end to form some sort of closed shape.

**polygon:** A collection of lines, arranged in such a way that the ends are connected to form a continuous, closed shape.

Circles, ovals, and curves can be lumped into this category. The concept of polygons is absolutely critical to 3-D programming. Like lines, polygons are governed by a mathematical discipline known as trigonometry (actually, trigonometry and geometry are almost joined at the hip, and I use the relationship to lines and polygons loosely). Trigonometry is the study of angles, and this coupled with polygonal shapes allows the creation of incredibly realistic 3-D environments. We'll see some examples of this later in the book.

**Figure 3-4:** A polygon is a collection of lines

## Bitmaps

Computer graphics would quickly get boring if only lines and polygons could be used to construct a scene in a game or an interface for a business application. The human brain has incredible pattern recognition skills, and utilizing this in a game or user interface can bring to life exotic locales or make a business application easy and intuitive to use. Take a look at the Windows desktop or any business application, and the prevalent use of icons and other graphical metaphors to indicate a function. Generally speaking, these can be considered bitmaps. Like lines, a bitmap is a collection of pixels arranged in such a way that they represent a picture.

**bitmap:** A collection of pixels arranged in a rectangular configuration in such a way that they form a recognizable shape, such as a picture or texture.

Digitized photos, the little images of floppy disks, printers, and pieces of paper on buttons in a business application, and the texture on the walls of the latest 3-D first-person shooter are all considered bitmaps. To coin a cliché, a picture is indeed worth a thousand words, and their liberal use in games and applications can result in several hundred, or perhaps even thousands, of bitmap images in use in any one program. By their very nature, bitmaps consume lots of memory, but few serious applications can succeed without employing them.

**Figure 3-5:** A bitmap is a collection of pixels

## Graphical Element Classifications

Apart from the basic graphical elements described above, conversations in graphical programming sometimes indicate a broader subdivision of graphic types. Graphical output can generally be divided into two classifications: raster and vector. It is rare to hear about game applications being described as one or the other, but it is very common to discuss graphically based business applications or tools in terms of a raster-based or vector-based application.

## Raster Graphics

Raster graphics are images that are composed of individual pixels statically arranged in such a way as to represent a picture or image. Realistically, this refers to images such as icons and bitmaps.

**raster graphics:** Graphics that are composed of a collection of pixels that together form a picture or image. Generally refers to bitmaps, icons, and other such graphical types.

In general, raster graphics are very resolution dependent, and tend to lose resolution when scaled to a different size. The algorithms necessary for scaling or rotating raster graphics are generally very complex, and the quality of the results varies wildly depending upon the implementation.

The most common raster graphic file format is the humble Windows bitmap. Bitmaps can be created using the Paint application that comes with Windows. Delphi contains an Images directory that includes several bitmap files to be used as button glyphs or backgrounds within applications.

## Vector Graphics

Vector graphics are images that are described as a series of connected points in a virtual 2-D or 3-D grid. This type of graphic includes lines, polygons, circles, and curves. TrueType fonts, being described by a collection of connected points, are also considered to be vector graphics.

**vector graphics:** Graphics that are represented by a series of connected points in a virtual 2-D or 3-D Cartesian (or similar) coordinate system. Generally refers to lines, polygons, curves, and other such graphical types.

Unlike raster graphics, vector graphics are resolution independent, and can be scaled to any size without degradation of image quality. Although somewhat complex, the algorithms for scaling and rotating vector graphics are well documented and easily implemented, and the quality of the results is identical from implementation to implementation.

A common vector graphic file format is the Windows metafile. Its most prevalent use is with clip art type graphics that come with word processors and presentation programs. Because of its resolution independence, clip art stored in this format can be enlarged or shrunk as the user requires.

## Video Mode Resolutions and Color Depth

Discussions of graphics programming usually start from a consideration of what resolution the video driver is currently in, and how many colors are available in which to draw the graphics. These two concepts are directly related, and are generally referred to in a combined sense as the video mode.

**video mode:** The video hardware state which dictates the display resolution and number of available colors for graphical output.

These two items will have a profound effect on the graphics programming techniques involved in drawing the graphical elements previously discussed. Both the resolution and the color depth of the current video mode will affect the perceived quality of the displayed graphical images. The greater the resolution and color depth, the more realistic and detailed the displayed graphics will become. However, on the downside, higher resolution and deeper color depth mean greater memory usage and slower speed.

### Resolution

The resolution of the current video mode controls how many pixels can be displayed on the screen.

**resolution:** A measurement of the number of pixels displayed on the screen.

As the resolution increases, more and more pixels are available for displaying graphics. This will directly affect the perceived size of graphical images. This is especially true for raster graphics, as vector graphics can be adjusted accordingly. For example, if a bitmap image is 50 pixels by 50 pixels in size, it will appear larger when displayed at its original resolution when the video mode is set to 800 x 600 pixels than it will when the video mode is set to 1024 x 768 pixels. As illustrated in Figure 3-6, a fixed size bitmap image will appear smaller in higher resolution video modes because individual pixels must be smaller in order to fit more of them onto the screen.

**Figure 3-6:** Two different disEplay resolutions

Supported resolutions are dependent upon the video card installed in the machine, the video driver, and the monitor upon which the output is displayed. The video driver and video card dictate the video modes available for use. However, occasionally the monitor connected to the machine will be unable to handle the new video mode.

**Caution:** Switching to a video mode that is unsupported by the monitor can potentially damage it, and should be avoided.

Perhaps the most common display resolution employed by desktop machines today is 800 pixels wide and 600 pixels high. However, it is usually wise to develop for the smallest common denominator in order to take advantage of a broader market (and subsequent revenue potential). Thus, many developers create games based on a 640 x 480 resolution. Generally speaking, it is harder to write code that will support a wide variety of resolution sizes. Nevertheless, the extra effort that allows users to take advantage of new equipment usually pays off, and makes your customers very happy.

### Color Depth

The color depth of the current video mode controls how many colors in which an individual pixel can be drawn. Color depth is measured in bits per pixel, meaning that the more bits used to describe a color, the more colors there are available in which to draw a pixel.

**color depth:** A measurement of the number of bits per pixel required to describe the color of an individual pixel.

The color depth of the current video mode will affect the techniques used to draw graphics more so than the display resolution. Color depth determines if the video mode will be palettized or non-palettized (discussed below). As this affects how pixels are stored, different techniques must be employed when drawing graphics. As the bits per pixel increase, the number of colors available for each individual pixel increases, but so does the amount of memory required to hold a bitmap. The following table summarizes common color depths and the amount of colors available per pixel under each:

Bits Per Pixel	Number of Colors Available
4	16 colors
8	256 colors
16	65,536 colors (high color mode)
24	16,777,216 colors (true color mode)
32	16,777,216 colors plus 256 levels of transparency (true color)

Color depths of only 4 bits per pixel are no longer used for games. Perhaps the most common color depth used in games is 8 bits per pixel, as this makes it very easy to manipulate individual pixels in a bitmap, or to move large amounts of pixels around in memory. However, thanks to hardware acceleration, faster processors, and other advances, higher color depths are starting to be used in more games. 16-bit color games are becoming more prevalent, but 24-bit and 32-bit color depths are still too slow to be used for games that run on anything other than today's higher end PCs.

## Video Board Memory

Apart from the video modes supported by the video driver and the graphics card itself, available video modes are further restricted by the amount of video RAM available on the graphics card. Only video RAM can be used support various video modes, and as the resolution and color depth of a video mode increase, so does the amount of video RAM required to support it. For example, a video mode of 800 x 600 pixels at a color depth of 8 bits per pixel requires 480,000 bytes, almost half a MB. If a video mode requires more memory than is available on the video card, it cannot be supported. For example, a video mode of 1024 x 760 at 16 bits per pixel cannot be supported unless the video card has at least 1,572,864 bytes of RAM available. This will become much more important later when we discuss DirectX surfaces.

## The Components of a Color

When discussing pixel colors and color depth, it is important to understand how colors are represented internally. The color of every pixel drawn to the screen is determined by three components: a red intensity, a blue intensity, and a green intensity. As these intensities increase or decrease, the color of an individual pixel is affected accordingly. Each intensity can have a minimum value of 0, and a maximum value of 255. If the intensity of each component is 0, the resulting color is black, while if each component is at 255, the resulting color is white. This gives a maximum of 16,777,216 colors, well beyond the scope of what the human eye can accurately detect from shade to shade. This is referred to as RGB color, standing for red, green, and blue, respectively.

**RGB color:** Refers to the method by which colors are represented, usually in the form of a red, green, and blue component, respectively.

Most of the time, colors are used in this RGB format. However, occasionally colors will be used in a reverse format (BGR), depending on which GDI functions are being used.

**Palettized Modes**

Four and eight bits-per-pixel color depths are the only palettized video modes. As 4 bits-per-pixel color depths are no longer used for games, we will discuss only 8 bits-per-pixel color depths. At 8 bits-per-pixel, each pixel can assume a value between 0 and 255. These values act as an index into what can be considered a 256-entry array known as the color palette. Now, each entry in this array contains an 8-bit value for the blue, green, and red intensity of a color. In effect, this gives 8 bits-per-pixel color depths access to 16,777,216 potential colors, but only 256 of them can be shown at one time.

**Figure 3-7:** An 8 bits-per-pixel bitmap's pixels act as indices into a color palette

There are many things to consider when working with 8 bits-per-pixel color modes. A major disadvantage to this mode is that all bitmaps to be displayed simultaneously must be drawn using the same palette. This requires a lot of careful planning on the part of art production, and can limit the creativity of artists and the variety of artwork that can be displayed on screen. Bitmaps that are drawn using one palette but displayed on a device in which a different palette is currently being used, will have unpredictable results.

A bitmap's pixels could be mapped to the closest approximation of the appropriate color in the current palette, but this process is slow, usually produces inadequate results, and is not appropriate for fast action games. Different palettes can be used between scenes, however, which can reduce this effect. However, 8 bits-per-pixel video modes give the greatest speed advantage, and a tremendous number of colors can potentially be used while taking up the least amount of RAM. Up to four pixels can be moved simultaneously by using 32-bit memory movement instructions, allowing bitmaps to be moved about at blindingly fast speeds.

Another major advantage comes from palette animation. If colors within the palette are moved about, or cycled, every pixel drawn using that color is affected simultaneously and automatically. This can be used for various special effects, such as flowing water or lighting. Palette animation is not available under non-palettized video modes. Since this book is concerned with high-performance games and graphics programming, all examples will use only 8 bits-per-pixel video modes in order to squeeze out as much speed

as possible.

## Non-palettized Modes

16, 24, and 32 bits-per-pixel video modes directly store the color value for each pixel. This color value is encoded according to the bits-per-pixel used, and can vary from video board to video board. In general, 16 bits-per-pixel color depths use five bits to describe each of the red, green, and blue intensities of a color. 24 bits-per-pixel uses a full eight bits to describe each intensity, and 32 bits-per-pixel uses the same format with eight extra bits used as a translucency value.

Non-palettized video modes have the advantage of total freedom to display any number of bitmaps simultaneously, without worrying about color problems or palette management. The downside to this is that more memory is required for both display and bitmap storage, and games tend to run slower as it requires longer to move a bitmap from one place in memory to another. This book will concentrate on using only 8 bits-per-pixel color depths, so any further discussion of non-palettized video modes is beyond our scope.

## Graphics Output Techniques

As stated above, the GDI provides the primary functions and procedures by which graphics can be drawn to the screen. There are literally hundreds of functions and procedures, and covering all of them is well beyond the scope of this book. However, we will discuss a number of the most common GDI graphical output functions and will look at several examples that demonstrate their use.

### The Device Context

A device context represents a surface upon which graphical output can be drawn. Specifically, a device context represents the surface of an output device such as a monitor, printer, or plotter, and gives the developer access to modify its appearance. This access is accomplished through the specific device's device driver.

**device context (DC):** Represents the surface of an output device such as a monitor, printer, or plotter, allowing the application to perform graphical output.

Under regular Windows programming, the device context provides the only way to render graphics to the screen. Device contexts can be used with Direct-Draw functions to make certain tasks easier, as we'll see in later chapters. Most, if not all, GDI API functions require a handle to the device context upon which the specified graphical operation will be performed. Device contexts represent certain areas on the screen, from the surface of a control (such as a button) to the entire surface of a window or even the screen itself. To retrieve a handle to a device context, an application calls the GetDC function, passing it the handle of the window whose surface is to be drawn upon. It is very important to call the ReleaseDC function when the application is finished drawing its output, as neglecting to release the device context can cause Windows to lock up. Fortunately, we will not need to be concerned much with device contexts, as the TCanvas object encapsulates the functionality of the device context and makes graphical output much easier.

### Painting on the Canvas

Objects derived from TGraphicControl and TCustomControl provide a TCanvas property for performing graphical output. This allows the developer to determine the appearance of the control. The TCanvas object, as an encapsulation of the device context, contains numerous methods for drawing graphics, making the use of most GDI function calls unnecessary. However, when using GDI API functions that are not encapsulated by the TCanvas object, the Handle property can be used in parameters that require a handle to a device context. Lines, polygons, even individual pixels can be drawn on the surface of a TCanvas object with relative ease. Again, like the device context, the TCanvas object represents the surface of a window, such as a control or the application window itself. Thus, when anything is drawn on the canvas, it will appear on screen in the position of the control or window which it represents.

---

**Note:** Graphics output is controlled by specifying a horizontal and vertical coordinate, with the horizontal coordinate increasing from left to right and the vertical coordinate increasing from top to bottom. Since the TCanvas object represents an individual window or control, the origin of its coordinates is relative to the window or control it represents. Thus, the coordinate 0, 0 will be in the upper left-hand corner of the window or control it represents, which may or may not be the upper left-hand corner of the physical screen.

---

Now let's examine some techniques for drawing graphics. These techniques will be concerned with drawing graphics primitives, or simple lines, dots, and polygons. These simplistic techniques demonstrate how easy it is to use the TCanvas encapsulation of a device context for performing graphical output. They all use the Canvas property of the main form for the drawing surface.

**Pens and Brushes**

TCanvas objects contain several properties, two of which are extremely important when performing graphical output: the Pen property and the Brush property. The Pen property determines the characteristics of lines drawn on the TCanvas, such as a line's thickness and color. The Brush property determines the appearance of the interiors of polygons, such as the color and pattern. Using the TPen and TBrush objects, several pens and brushes can be constructed by the application and assigned to the appropriate properties when necessary. However, most of the time, it is sufficient to simply change the properties of the TCanvas as needed.

**Drawing Pixels**

The Pixels property of the TCanvas object gives the application access to individual pixels of the surface. This is accessed like a two-dimensional array, with the first index acting as the horizontal coordinate and the second index acting as the vertical coordinate. The Pixels property reports or receives a color in the form of a TColor type (which is an RGB color value, regardless of the video mode). The following example demonstrates using the Pixels property of a TCanvas object to draw random pixels.

*Listing 3-1: Using the Pixels property*

---

```
procedure TfrmPixelDemo.TimerTimer(Sender: TObject);  
  
var  
    iCount: Integer;  
  
begin  
    {draw 100 random pixels in a random RGB color}  
    for iCount := 0 to 99 do  
        Canvas.Pixels[Random(ClientWidth),Random(ClientHeight)] := RGB(Random(256),
```

```
Random(256),  
Random(256));
```

```
end;
```

---

Unfortunately, this method of accessing individual pixels of an image is incredibly slow, and should never be used for fast graphical output.

**Figure 3-8:** Drawing individual pixels

## Drawing Lines

Lines are drawn using the attributes set by the Pen property. The PenPos property determines the current position of the pen or the starting point of any drawing operation that uses the pen (such as drawing lines). This position can be modified by directly setting the PenPos property or by calling the MoveTo method. The LineTo method is called to actually draw the line, from the position indicated by the PenPos property to the position passed in the LineTo method. This pen position is updated to the coordinates passed to the LineTo position after the line is drawn. The following example demonstrates how to use these methods to draw various lines of random length, color, and width.

*Listing 3-2: Using the MoveTo and LineTo methods*

---

```
procedure TfrmLineDemo.TimerTimer(Sender: TObject);  
  
begin  
    {set a random pen color and width}  
  
    Canvas.Pen.Color := RGB(Random(256), Random(256), Random(256));  
  
    Canvas.Pen.Width := Random(5);  
  
    {draw a line between two random points}  
  
    Canvas.MoveTo(Random(ClientWidth), Random(ClientHeight));  
  
    Canvas.LineTo(Random(ClientWidth), Random(ClientHeight));  
  
end;
```

---

**Figure 3-9:** Drawing random lines

## Drawing Polygons

Polygons are drawn using the attributes set by both the Pen and Brush properties. The Pen property determines the outline of the polygon, and the Brush property determines how the polygon is filled. Several methods exist that draw polygons of different shapes, from rectangles to circles. The Polygon method can be used to draw polygons of any arbitrary shape simply by passing it an open array of TPoint structures. The following example demonstrates how to use several polygon drawing methods to draw polygons of various shapes and colors.

*Listing 3-3: Using various polygon drawing methods*

---

```
procedure TfrmPolygonDemo.TimerTimer(Sender: TObject);

type
    {enumerated type representing several standard polygon drawing routines}
    TPolyType = (ptChord, ptEllipse, ptPie, ptRectangle, ptRoundRect);

var
    X1, X2, X3, X4, Y1, Y2, Y3, Y4: Integer;

begin
    {initialize a set of random coordinates}

    X1 := Random(ClientWidth);
    X2 := Random(ClientWidth);
    X3 := Random(ClientWidth);
    X4 := Random(ClientWidth);

    Y1 := Random(ClientHeight);
    Y2 := Random(ClientHeight);
    Y3 := Random(ClientHeight);
    Y4 := Random(ClientHeight);

    {set the brush to a random RGB color}

    Canvas.Brush.Color := RGB(Random(256), Random(256), Random(256));
```

```

{draw a random polygon}

case TPolyType(Random(Ord(ptRoundRect)+1)) of

    ptChord      : Canvas.Chord(X1, Y1, X2, Y2, X3, Y3, X4, Y4);
    ptEllipse    : Canvas.Ellipse(X1, Y1, X2, Y2);
    ptPie        : Canvas.Pie(X1, Y1, X2, Y2, X3, Y3, X4, Y4);
    ptRectangle  : Canvas.Rectangle(X1, Y1, X2, Y2);
    ptRoundRect  : Canvas.RoundRect(X1, Y1, X2, Y2, X3, Y3);

end;

end;

```

---

**Figure 3-10:** Drawing random polygons

## Drawing Text

Perhaps the most common use of TCanvas graphical output techniques is for drawing text. The Font property of the TCanvas object determines the attributes of the text, including its typeface, size, and style. The TextOut method is used to draw the specified string at the indicated coordinates. These coordinates denote the top left corner of the text string. The following example demonstrates how to use the TextOut method to draw randomly colored text at random positions on the form.

**Tip:** By setting the Style property of the canvas's Brush property to bsClear, the background behind text will be transparent. This allows images underneath the text to show through, and is useful for drawing text on top of bitmap images.

---

### *Listing 3-4: Using the TextOut method*

---

```

procedure TfrmTextDemo.TimerTimer(Sender: TObject);

begin
    {set a random text color}

    Canvas.Font.Color := RGB(Random(256), Random(256), Random(256));

    {set a random text size}

```

```
Canvas.Font.Size := Random(10)+5;

{set the text typeface}

Canvas.Font.Name := Arial';

{set the brush style to clear so that the image behind the text
will be visible}

Canvas.Brush.Style := bsClear;

{draw text at a random coordinate}

Canvas.TextOut(Random(ClientWidth), Random(ClientHeight), Delphi Graphics');

end;
```

**Figure 3-11:** Drawing random text

## Bitmap Essentials

It is quite possible for one to create a really engaging and entertaining game using nothing but line and polygon drawing techniques. However, if such graphical output were used in all games, everything would look very similar, and there would be little visual variety. In order to achieve the desired visual quality and variety that would be necessary in almost any game, bitmaps must be used.

Bitmaps come in many varieties, from two color to true color, and in many different formats, such as the Windows BMP format, JPEG, TIFF, GIF, etc. Each format presents its own benefits and weaknesses, and each is useful under specific circumstances. Obviously, the only format native to Windows is the Windows BMP format. This format can easily be accessed by low-level Windows API functions as well as Delphi VCL objects and functions, so the BMP format is the one on which we will focus.

### Bitmap Types: DDB and DIB

Most bitmap formats have subformats that allow an image to be stored similarly to the original format but with slight modifications, and the Windows bitmap format is no exception. Typically, subformats come about as a result of updated technology. New technology may contain enhanced functionality that was not available when the original format was created. Thus, subformats are born containing attributes that allow the image to take advantage of the new technological achievements. Windows bitmaps come in two flavors: DDB and DIB.

### Device-Dependent Bitmaps

The device-dependent bitmap, or DDB, is an older bitmap format and is kept around solely for backward compatibility. This format is so named because it is very dependent on the device upon which it is displayed for certain information. The DDB format does not store any color palette information or resolution information, storing only its width, height, color depth, and array of pixels that make up the image. DDBs always use the system color palette when they are displayed. Coupled with the lack of original resolution information, it is very difficult to accurately display a DDB in its original form on anything other than the original device upon which it was created. Additionally, the image itself can only be modified through the use of GDI functions. The storage and display of a DDB is handled natively by the video driver and video hardware. Naturally, this makes the use and display of DDBs very fast, but they are not very flexible.

**device-dependent bitmap (DDB):** An older bitmap image format that stores only height, width, color depth, and image pixels.

### Device-Independent Bitmaps

The device-independent bitmap, or DIB, stores all the information required to accurately display the image on any device. Such information includes the color palette for the image, the resolution of the device upon which the bitmap was originally created, and a data compression flag. The pixels defining the DIB image are also directly accessible to the developer, making this format incredibly flexible. The DIB bitmap format describes a standardized pixel format, making the storage and display of such images a responsibility of generic GDI functions and global memory. As such, the use and display of DIBs is not quite as fast as DDBs, but their flexibility more than makes up for the loss in speed.

---

**device-independent bitmap (DIB):** A flexible bitmap image format that includes all necessary information to accurately reproduce the image on any device.

## The TBitmap Object

The Delphi TBitmap object encapsulates the functionality of both the DDB and DIB image formats. By default, when a TBitmap object is created, it holds an image in the DDB format. When a bitmap is loaded into it, the image will be stored in the DIB format. The TBitmap object contains many useful properties and methods that make the manipulation of bitmap images incredibly easy.

## Loading Images

Using regular GDI calls to simply load an image from a file may take half a dozen lines of code or more. With the TBitmap object, a simple call to its LoadFromFile method will load the image data and its palette, at which point the bitmap is ready for use. If the image is stored in a resource attached to the executable (or a DLL), the TBitmap's LoadFromResourceID or LoadFromResourceName methods give the developer flexibility in determining how the image is extracted from the resource. These methods alone more than justify the use of a TBitmap object over hard-core GDI function calls.

## Displaying Images

The TBitmap object itself does not contain any methods that deal directly with its display. This functionality lies in the domain of the TCanvas object. There are several methods by which a bitmap can be displayed, and they all have similar ancestors in the form of GDI function calls. The act of copying bitmap pixels to the screen for display is known as a bitblt, or blit.

---

**bitblt:** bit block transfer. Pronounced “blit,” this is the act of copying the pixels of a bitmap image onto the screen or other graphical output surface for display.

The easiest TCanvas method available for displaying an image is Draw. It simply takes three parameters: a horizontal and vertical position of the upper left-hand corner of the image and the image object itself. This draws the entire image with its upper left-hand corner located at the specified coordinate. Other methods include CopyRect, which allows only a portion of an image to be drawn (scaling as necessary), and StretchDraw, which allows the image to be drawn larger or smaller than its original size. Listing 3-5 illustrates loading a bitmap and displaying it on the surface of a form.

### *Listing 3-5: Loading and displaying a bitmap image*

---

```
procedure TForm1.FormCreate(Sender: TObject);
begin
    {create the bitmap object}

    Bitmap := TBitmap.Create;

    {load in a bitmap image}

    Bitmap.LoadFromFile(ExtractFilePath(ParamStr(0))+'Athena.bmp');
end;
```

```

procedure TForm1.FormDestroy(Sender: TObject);
begin
    {free the bitmap object}
    Bitmap.Free;
end;

procedure TForm1.FormPaint(Sender: TObject);
begin
    {display the bitmap using the Draw method}
    Canvas.Draw(8, 24, Bitmap);

    {display the bitmap using the CopyRect method}
    Canvas.CopyRect(Rect(192, 24, 344, 104),Bitmap.Canvas,Rect(62, 39, 111, 74));

    {display the bitmap using the StretchDraw method}
    Canvas.StretchDraw(Rect(8, 184, 352, 264), Bitmap);
end;

```

**Figure 3-12:** An image displayed using several different methods

### Direct Pixel Access

One of the biggest benefits of using a DIB over a DDB is the fact that individual pixels can be directly accessed. This makes feasible many advanced graphical rendering techniques, such as ray casting. Accessing the individual pixels of a DDB (and even using the Pixels property of a TCanvas) is incredibly slow and could never be used for such advanced graphical output techniques.

To access individual pixels using the TBitmap object, the ScanLine property must be used. The ScanLine property is an indexed property that requires a row number and returns a pointer to the block of memory that contains the specified rows of pixels. The actual format of the information stored in this block of memory is dependent upon the value of the TBitmap's PixelFormat property. The PixelFormat value reflects the number of bits required to describe one pixel in the image. Refer to the color depth topic discussed previously for more information on bits-per-pixel and its relation to the number of colors an image can contain. Thus, it is very important to know how the image information is stored before accessing it.

Since this book is primarily concerned with 256-color images and graphical modes, assume that a TBitmap object

has been loaded with a 256-color bitmap image. A variable of type PByteArray can be used to access the pixels pointed to by the ScanLine property. PByteArray is defined as a pointer to an array of bytes. The result of accessing the ScanLine property is assigned to our PByteArray variable, at which point the individual pixels can be accessed by a simple index into the array. Since a 256-color bitmap defines one pixel as 8 bits, or a byte, using a PByteArray variable allows the developer to access individual pixels correctly. If the image were of any other color depth, a different approach to accessing the pixels would need to be used. Listing 3-6 demonstrates accessing individual pixels through the ScanLine property.

*Listing 3-6: Accessing individual pixels through the ScanLine property*

```
procedure TForm1.Button1Click(Sender: TObject);
var
    Bitmap: TBitmap;
    Pixels: PByteArray;
    iBand, iRow, iCol: Integer;
    DrawColor: Byte;
begin
    {create the bitmap object}
    Bitmap := TBitmap.Create;

    {initialize the appropriate properties so we can access individual pixels
    in a known way}
    Bitmap.Width := 169;
    Bitmap.Height := 128;
    Bitmap.PixelFormat := pf8Bit;
```

```
{create 8 horizontal bands of alternating colors}

DrawColor := 19;

for iBand := 0 to 7 do

begin

    {flip-flop the color. this is an 8 bit image, so we specify the color
    as an index into the palette.}

    if DrawColor = 16 then

        DrawColor := 19

    else

        DrawColor := 16;

    {each band is comprised of 16 rows of color}

    for iRow := 0 to 15 do

    begin

        {retrieve a pointer to the row of pixels}

        Pixels := Bitmap.ScanLine[(iBand*16)+iRow];

        {set each pixel in the row to the specific color}

        for iCol := 0 to Bitmap.Width-1 do

            Pixels[iCol] := DrawColor;

        end;

    end;

    {draw the bitmap to the screen}

    Canvas.Draw(8, 8, Bitmap);

    {free the bitmap}

    Bitmap.Free;

end;
```

## Raster Operations

In addition to simply copying bitmap pixels from place to place, certain functions can modify exactly how the pixels are drawn onto their destination according to a specified setting. This is known as a raster operation, or ROP, and it determines how the pixels from the source, the destination, and the destination device context's selected brush are combined. The pixels are combined using boolean operations.

**raster operation (ROP):** A Boolean function performed on pixels when they are copied from bitmap to bitmap that determines how the pixels from the source, the destination, and the destination device context's selected brush are combined.

There are 256 total raster operations, each producing a different output based on the Boolean operator used and the order in which pixels are combined. Of these, only 16 are commonly used in Windows graphics programming. There are several GDI functions, such as `BitBlt` and `StretchBlt`, that allow a developer full access to all 256 raster operations. Using the Delphi VCL, the `CopyMode` property of the `TCanvas` object specifies the raster operation to be used, and can be set to one of 16 constants that represent the 16 most commonly used raster operations.

Raster operations are incredibly useful under certain circumstances. They can be used to easily implement specific special effects which, without raster operations, would be more difficult to implement otherwise. For example, using raster operations, it is very easy to simulate transparent pixels in a bitmap when it is displayed over a background. This effect and others could be implemented using any one of a hundred different techniques, but raster operations make their implementation fast and simple.

## Simulating Transparency

Perhaps the most common function performed by the graphical output code of a game is to display one bitmap over another, with the pixels of the background showing through the "transparent" pixels of the displayed bitmap or sprite. Without transparency, every sprite image would have to be rectangular, or the resulting animation would look horrible. Figure 3-14 graphically illustrates the importance of transparency.

**Figure 3-14:** The effect of transparency

The easiest method by which sprites can be transparently drawn to the background is known as masking. Masking uses two bitmaps for each sprite image, as each bitmap will be used with a different raster operation when the sprite is drawn.

**masking:** The act of using two bitmaps, an AND bitmap and an OR bitmap, along with raster operations to draw one bitmap over another while simulating transparent pixels in the source bitmap.

This method is precisely what happens when an application sets a TBitmap object's Transparent property to True and then calls TCanvas.Draw. This is a very convenient encapsulation in Delphi. However, the only drawback is that the transparent color is either the color of the pixel in the bottom leftmost pixel of the bitmap or is specified in the TBitmap's TransparentColor property, depending on the value of its TransparentMode property. The result is that this specified transparent color cannot be used elsewhere in the image, and unless proper care is taken when constructing the image, the result may not be what is expected. Using the direct approach as explained below gives the developer more control over the appearance of the final image. Figure 3-15 displays the difference between using the TransparentColor property and using the technique described below.

The two sprite images consist of an AND mask and an OR mask. The OR mask is the actual sprite image as it should appear in the destination. The only requirement for the OR mask is that pixels that should be transparent must be totally black (this must be palette slot zero for 256 color images). The AND mask is a monochrome bitmap consisting of only black and white. The black areas should match those of the actual sprite image in the OR mask, and the white areas represent pixels that should be transparent (opaque, or sprite image pixels, must be palette slot 0, and transparent pixels must be palette slot 255). Figure 3-16 illustrates a sprite image (the OR mask) and its accompanying silhouette (the AND mask).

**Figure 3-15:** Using the TBitmap.Transparent property versus the direct approach

**Figure 3-16:** A sprite AND and OR mask
