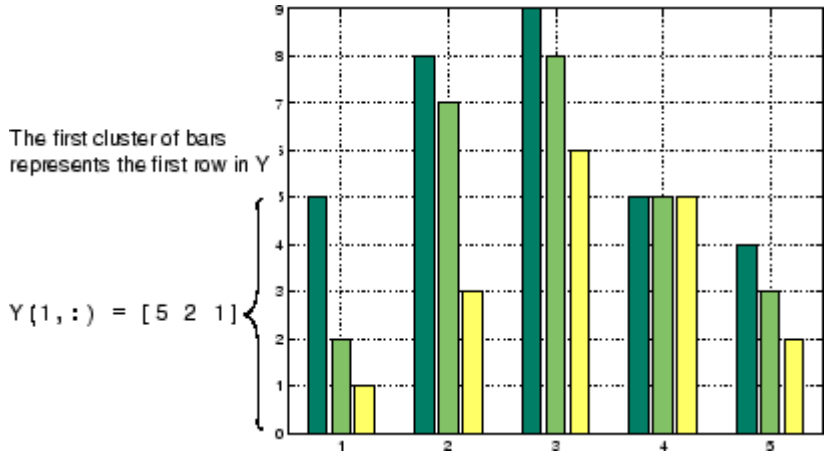
By default, a bar graph represents each element in a matrix as one bar. Bars in a 2–D bar graph, created by the `bar` function, are distributed along the *x*-axis with each element in a column drawn at a different location. All elements in a row are clustered around the same location on the *x*-axis.

For example, define `Y` as a simple matrix and issue the `bar` function in its simplest form.

```
Y = [5 2 1
     8 7 3
     9 8 6
     5 5 5
     4 3 2];
bar(Y)
```

The bars are clustered together by rows and evenly distributed along the *x*-axis.

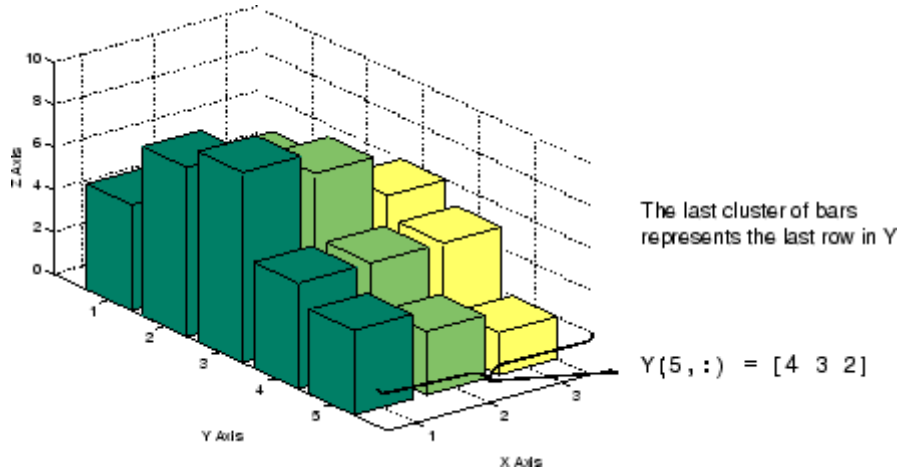


Detached 3-D Bars

The `bar3` function, in its simplest form, draws each element as a separate 3-D block, with the elements of each column distributed along the *y*-axis. Bars that represent elements in the first column of the matrix are centered at `1` along the *x*-axis. Bars that represent elements in the last column of the matrix are centered at `size(Y,2)` along the *x*-axis. For example,

```
bar3(Y)
```

displays five groups of three bars along the *y*-axis. Notice that larger bars obscure `Y(1,2)` and `Y(1,3)`.



By default, `bar3` draws detached bars. The statement `bar3(Y,'detach')` has the same effect.

Labeling the Graph. To add axes labels and *x* tick marks to this bar graph, use the statements

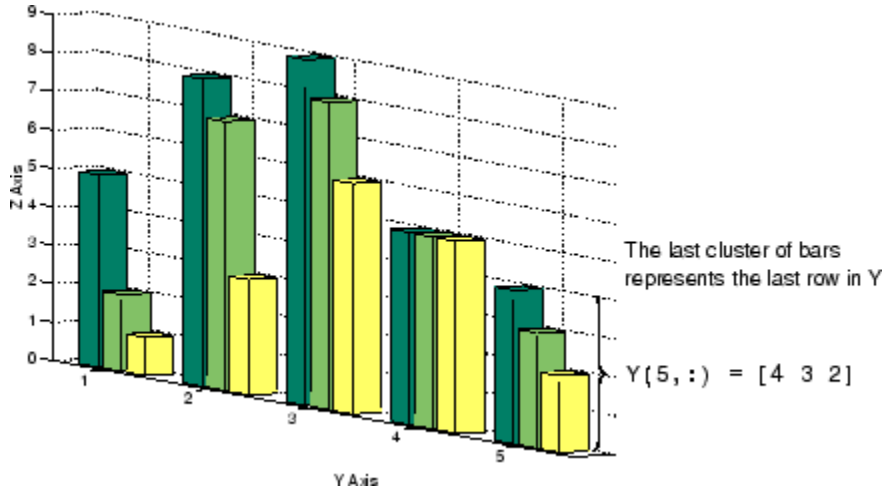
```
xlabel('X Axis')
ylabel('Y Axis')
zlabel('Z Axis')
set(gca,'XTick',[1 2 3])
```

Grouped 3-D Bars

Cluster the bars from each row beside each other by specifying the argument `'group'`. For example,

```
bar3(Y,'group')
```

groups the bars according to row and distributes the clusters evenly along the *y*-axis.

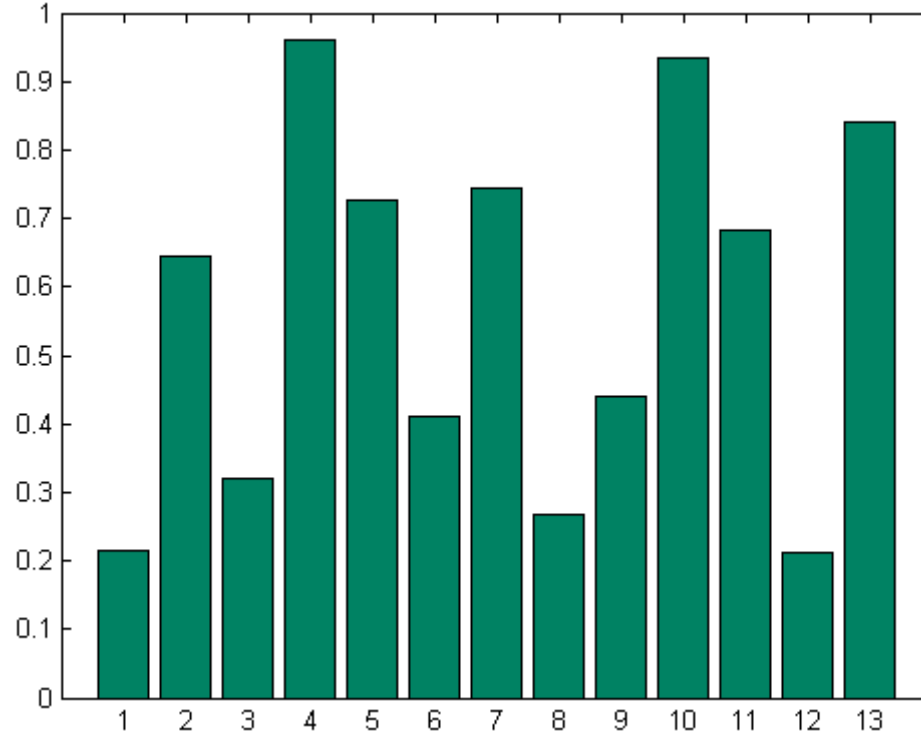


Coloring 2-D Bars According to Height

The `bar` and `barh` functions make all bars in a series the same color. With a little effort, however, you can assign a desired color to each bar. The typical approach is to associate bar colors with bar heights (Y-values). The following steps describe one way to do this, first using faceted shading and then using smooth (interpolated) shading:

1. Make up some numbers, plot a default bar plot, and assign a bichromatic colormap:

```
n = 13;
Z = rand(n,1);
h = bar(Z);
colormap(summer(n));
```



Notice that only the first color is used to color the faces.

2 Assign a new color to each bar. `bar` (and `barh`) creates a barseries object, which encapsulates a set of patch objects for the bars. The patches have face-vertex syntax. You must first get a handle for the children, and then obtain the vertices for the bars and the vertex color data:

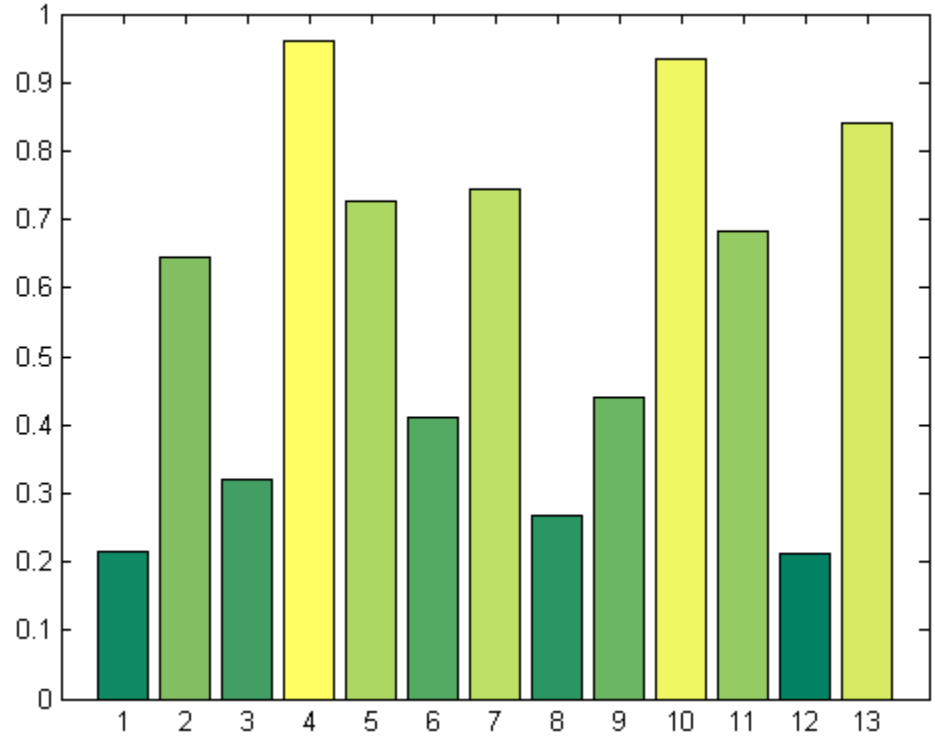
```
ch = get(h,'Children');
fvd = get(ch,'Faces');
fvcd = get(ch,'FaceVertexCData');
```

3 Sort the data to obtain an index for traversing the Faces array from the lowest to highest bar:

```
[zs, izs] = sortrows(Z,1);
```

4 Traverse the Faces and assign colors to the face-vertex color data as you go:

```
for i = 1:n
    row = izs(i);
    fvcd(fvd(row,:)) = i;
end
set(ch,'FaceVertexCData',fvcd)
```

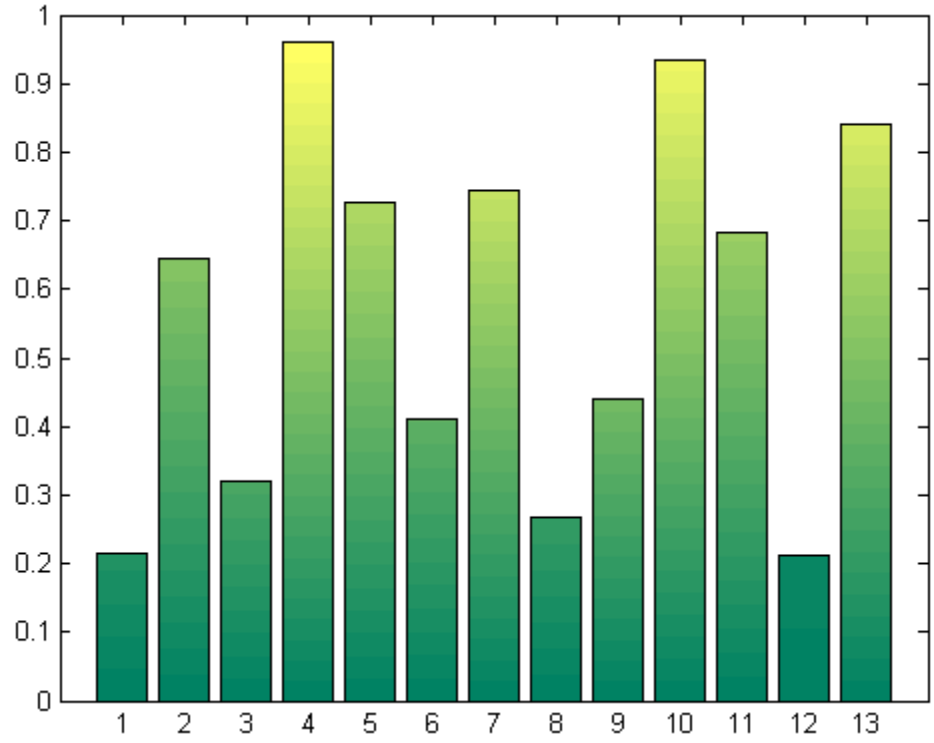


Note that the code assigns colors to bars based on their `YData` ranks, rather than by their `YData` values. This helps to distinguish bars by color, but also can assign to bars that are nearly the same height a wider range of colors than if the colors were directly mapped to `YData` values.

5 To make the graph more readable, you can set different colors for vertices on the baseline and on the top, then apply interpolated shading to change hue going up the bars. The following code colors the two vertices at the

base of each bar using the first color in the colormap, and assigns a color to the two vertices at the top proportionally to bar height. A longer color ramp than was used above is needed to obtain smooth gradiations of shading:

```
k = 128;                % Number of colors in color table
colormap(summer(k));    % Expand the previous colormap
shading interp          % Needed to graduate colors
for i = 1:n
    color = floor(k*i/n);       % Interpolate a color index
    row = izs(i);               % Look up actual row # in data
    fvcd(fvd(row,1)) = 1;       % Color base vertices 1st index
    fvcd(fvd(row,4)) = 1;
    fvcd(fvd(row,2)) = color;   % Assign top vertices color
    fvcd(fvd(row,3)) = color;
end
set(ch,'FaceVertexCData', fvcd);  % Apply the vertex coloring
set(ch,'EdgeColor','k')           % Give bars black borders
```



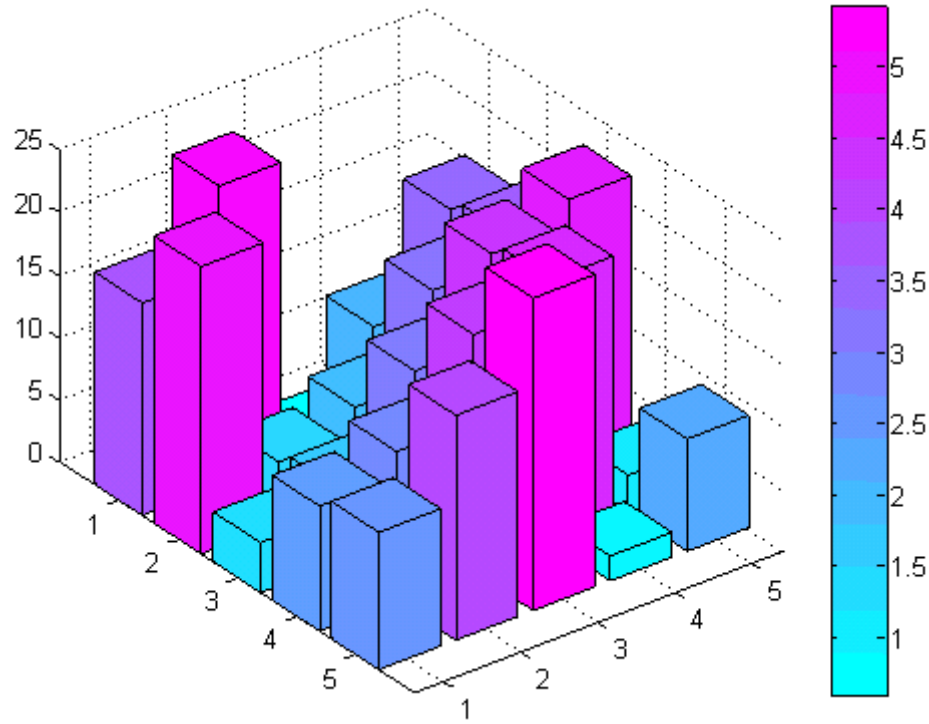
Coloring 3-D Bars According to Height

By default, all bars in a series (column) have the same color. You can modify a 3-D bar plot to color each bar according to how tall it is, but the technique is slightly different than the one used for coloring 2-D bars, described above. Applying a monochromatic or bichromatic colormap to such plots helps viewers see height distinctions more readily. Adding a colorbar can also help.

The graph will read better if you override the default behavior of `bar3` to shade the sides of the bars with contrasting hues. You can color bars by height and make the sides match the color of the top of each bar by executing the following code:

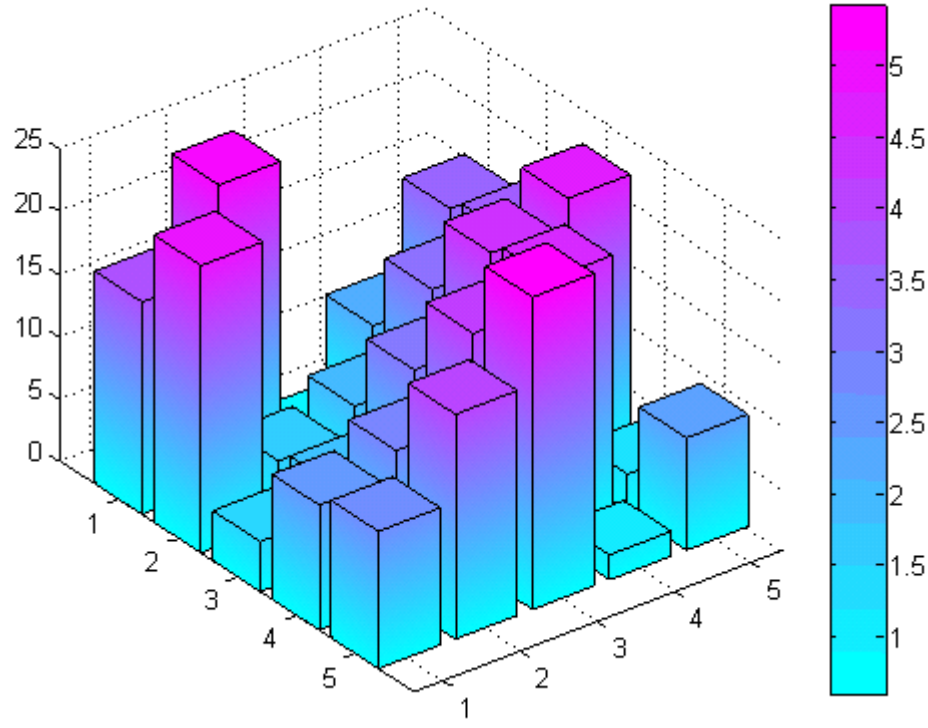
```
Z = magic(5);
h = bar3(Z);
```

```
for i = 1:length(h)
    zdata = ones(6*length(h),4);
    k = 1;
    for j = 0:6:(6*length(h)-6)
        zdata(j+1:j+6,:) = Z(k,i);
        k = k+1;
    end
    set(h(i),'Cdata',zdata)
end
colormap cool
colorbar
```



You can then make the plot even more readable by interpolating colors along the bars and giving their `EdgeColor` a contrasting color. The following code accomplishes this:

```
shading interp
for i = 1:length(h)
    zdata = get(h(i),'Zdata');
    set(h(i),'Cdata',zdata)
    set(h,'EdgeColor','k')
end
```



Stacked Bar Graphs to Show Contributing Amounts

Bar graphs can show how elements in the same row of a matrix contribute to the sum of all elements in the row. These types of bar graphs are referred to as stacked bar graphs.

Stacked bar graphs display one bar per row of a matrix. The bars are divided into *n* segments, where *n* is the number of columns in the matrix. For vertical

bar graphs, the height of each bar equals the sum of the elements in the row. Each segment is equal to the value of its respective element.

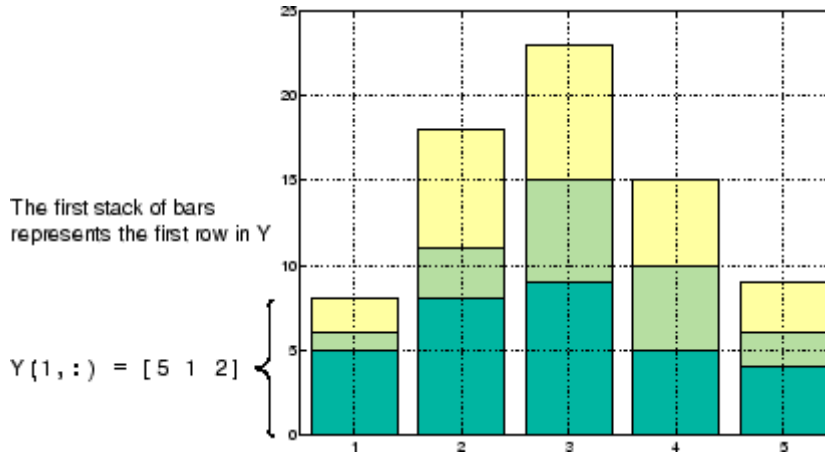
Redefining Y

```
Y = [5 1 2
     8 3 7
     9 6 8
     5 5 5
     4 2 3];
```

Create stacked bar graphs using the optional `'stack'` argument. For example,

```
bar(Y,'stack')
grid on
set(gca,'Layer','top') % display gridlines on top of graph
```

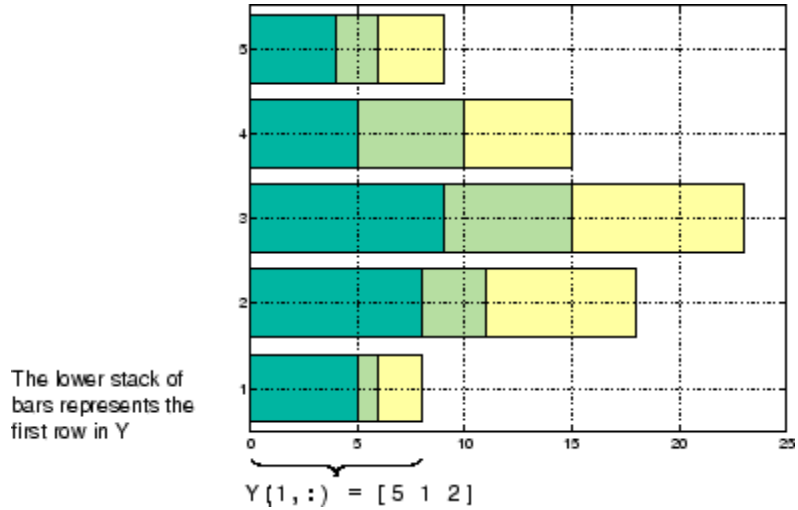
creates a 2-D stacked bar graph, where all elements in a row correspond to the same *x* location.



Horizontal Bar Graphs

For horizontal bar graphs, the length of each bar equals the sum of the elements in the row. The length of each segment is equal to the value of its respective element.

```
barh(Y,'stack')
grid on
set(gca,'Layer','top') % Display gridlines on top of graph
```



Specifying X-Axis Data

Bar graphs automatically generate *x*-axis values and label the *x*-axis tick lines. You can specify a vector of *x* values (or *y* values in the case of horizontal bar graphs) to label the axes.

For example, given temperature data,

```
temp = [29 23 27 25 20 23 23 27];
```

obtained from samples taken every five days during a thirty-five day period,

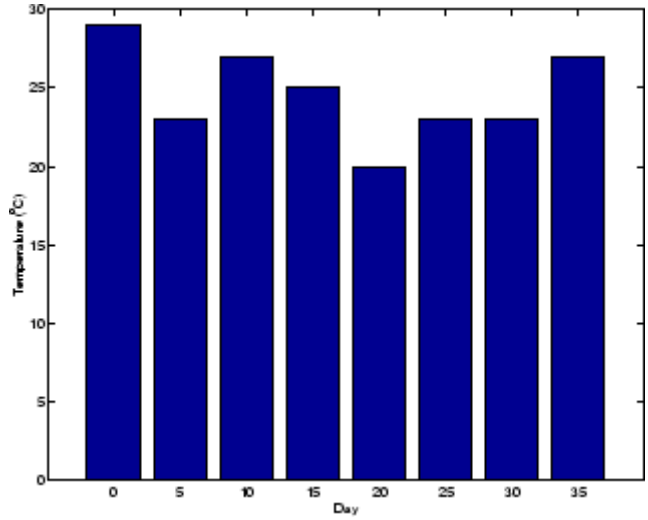
```
days = 0:5:35;
```

you can display a bar graph showing temperature measured along the *y*-axis and days along the *x*-axis using

```
bar(days,temp)
```

These statements add labels to the *x*- and *y*-axis.

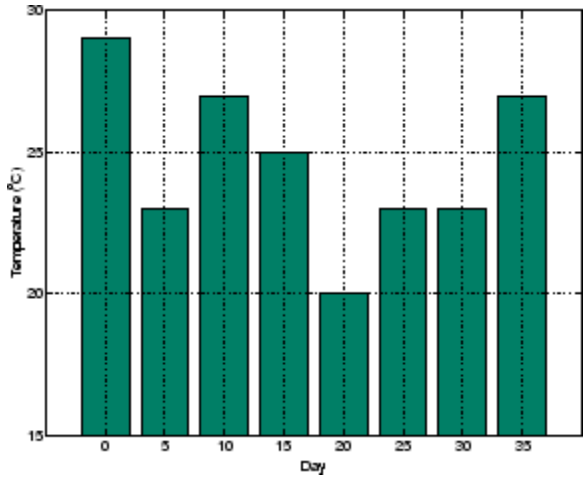
```
xlabel('Day')
ylabel('Temperature (^{o}C)')
```



Setting Y-Axis Limits

By default, the *y*-axis range is from 0 to 30. To focus on the temperature range from 15 to 30, change the *y*-axis limits.

```
set(gca,'YLim',[15 30],'Layer','top')
```



Overlaying Bar Graphs

In addition to grouping and stacking barseries, you can overlay several bars that share the same baseline and y-range by making each series of bars a different width and plotting the widest ones first. The following example shows how to accomplish this within an axes:

1 Define x and y data; it probably helps to make spacing of x-values constant:

```
x=[1 3 5 7 9];
y1=[10 25 90 35 16];
K=0.5;
```

2 Plot Series 1 in red, and set bar width to one-half an x-unit:

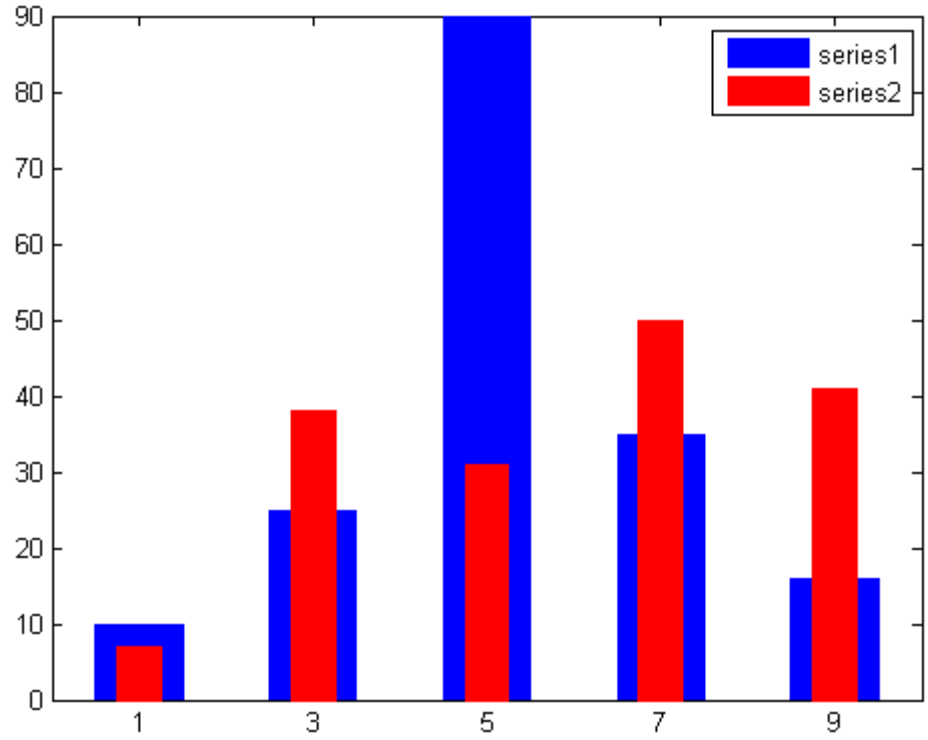
```
bar1=bar(x, y1, 'FaceColor', 'b', 'EdgeColor', 'b');
set(bar1,'BarWidth',K);
```

3 Define Series 2, and plot it in blue over the first one:

```
hold on;
y2=[7 38 31 50 41];
bar2=bar(x, y2, 'FaceColor', 'r', 'EdgeColor', 'r');
```

4 Set the width of the second series to half that of the first one:

```
set(bar2,'BarWidth',K/2);
hold off;
legend('series1','series2')
```



Overlaying Other Plots on Bar Graphs

You can overlay data on a bar graph by creating another axes in the same position. This enables you to have an independent *y*-axis for the overlaid dataset (in contrast to the `hold on` statement, which uses the same axes).

For example, consider a bioremediation experiment that breaks down hazardous waste components into nontoxic materials. The trichloroethylene (TCE) concentration and temperature data from this experiment are

```
TCE = [515 420 370 250 135 120 60 20];
temp = [29 23 27 25 20 23 23 27];
```

This data was obtained from samples taken every five days during a thirty-five day period.

```
days = 0:5:35;
```

Display a bar graph and label the *x*- and *y*-axis using the statements

```
bar(days,temp)
xlabel('Day')
ylabel('Temperature (^{o}C)')
```

Overlaying a Line Plot on the Bar Graph

To overlay the concentration data on the bar graph, position a second axes at the same location as the first axes, but first save the handle of the first axes.

```
h1 = gca;
```

Create the second axes at the same location before plotting the second dataset.

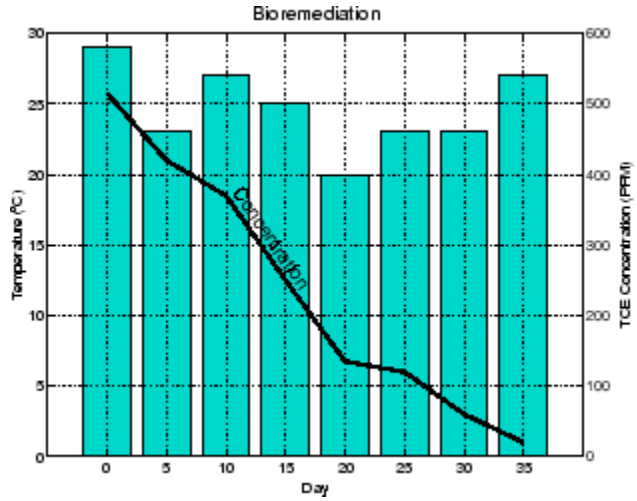
```
h2 = axes('Position',get(h1,'Position'));
plot(days,TCE,'LineWidth',3)
```

To ensure that the second axes does not interfere with the first, locate the *y*-axis on the right side of the axes, make the background transparent, and set the second axes' *x*-tick marks to the empty matrix.

```
set(h2,'YAxisLocation','right','Color','none','XTickLabel',[])
```

Align the *x*-axis of both axes and display the grid lines on top of the bars.

```
set(h2,'XLim',get(h1,'XLim'),'Layer','top')
```



Annotating the Graph. These statements annotate the graph.

```
text(11,380,'Concentration','Rotation',-55,'FontSize',16)
ylabel('TCE Concentration (PPM)')
title('Bioremediation','FontSize',16)
```

To print the graph, set the current figure's `PaperPositionMode` to `auto`, which ensures the printed output matches the display.

```
set(gcf,'PaperPositionMode','auto')
```

Area Graphs

The `area` function displays curves generated from a vector or from separate columns in a matrix. `area` plots the values in each column of a matrix as a separate curve and fills the area between the curve and the *x*-axis.

Area Graphs Showing Contributing Amounts

Area graphs are useful for showing how elements in a vector or matrix contribute to the sum of all elements at a particular *x* location. By default, `area` accumulates all values from each row in a matrix and creates a curve from those values.

Using this matrix,

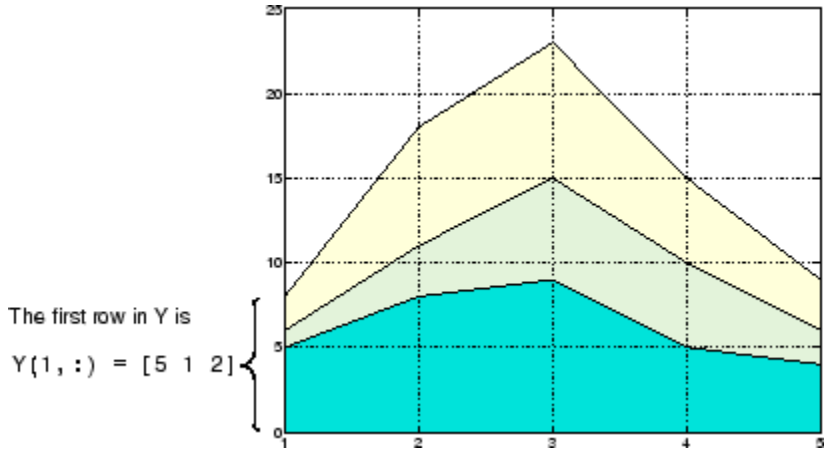
```
Y = [5 1 2
     8 3 7
     9 6 8
     5 5 5
     4 2 3];
```

the statement

```
area(Y)
```

displays a graph containing three area graphs, one per column.

The height of the area graph is the sum of the elements in each row. Each successive curve uses the preceding curve as its base.



Displaying the Grid on Top. To display the grid lines in the foreground of the area graph and display only five grid lines along the *x*-axis, use the statements

```
set(gca,'Layer','top')
set(gca,'XTick',1:5)
```

Comparing Data Sets with Area Graphs

Area graphs are useful for comparing different datasets. For example, given a vector containing sales figures,

```
sales = [51.6 82.4 90.8 59.1 47.0];
```

for the five-year period

```
x = 90:94;
```

and a vector containing profits figures for the same five-year period,

```
profits = [19.3 34.2 61.4 50.5 29.4];
```

display both as two separate area graphs within the same axes. Set the color of the area interior (`FaceColor`), its edges (`EdgeColor`), and the width of the edge lines (`LineWidth`). See `patch` for a complete list of properties.

```
area(x,sales,'FaceColor',[.5 .9 .6],...
             'EdgeColor','b',...
             'LineWidth',2)
hold on
area(x,profits,'FaceColor',[.9 .85 .7],...
               'EdgeColor','y',...
               'LineWidth',2)
hold off
```

To annotate the graph, use the statements

```
set(gca,'XTick',[90:94])
set(gca,'Layer','top')
gtext('\leftarrow Sales')
gtext('Profits')
gtext('Expenses')
xlabel('Years','FontSize',14)
ylabel('Expenses + Profits = Sales in 1,000''s','FontSize',14)
```

Pie Charts

In this section...

Creating a Pie Chart

Pie charts are a useful way to communicate the percentage that each element in a vector or matrix contributes to the sum of all elements. `pie` and `pie3` create 2-D and 3-D pie charts. A 3-D pie chart does not show any more or different information than a 2-D pie chart does; it simply adds depth to the presentation by plotting the chart on top of a cylindrical base.

This example shows how to use the `pie` function to visualize the contribution that three products make to total sales. Given a matrix `X` where each column of `X` contains yearly sales figures for a specific product over a five-year period,

```
X = [19.3 22.1 51.6;
     34.2 70.3 82.4;
     61.4 82.9 90.8;
     50.5 54.9 59.1;
     29.4 36.3 47.0];
```

sum each row in `X` to calculate total sales for each product over the five-year period.

```
x = sum(X);
```

You can offset the slice of the pie that makes the greatest contribution using the `explode` input argument. This argument is a vector of zero and nonzero values. Nonzero values offset the respective slice from the chart.

First, create a vector containing zeros.

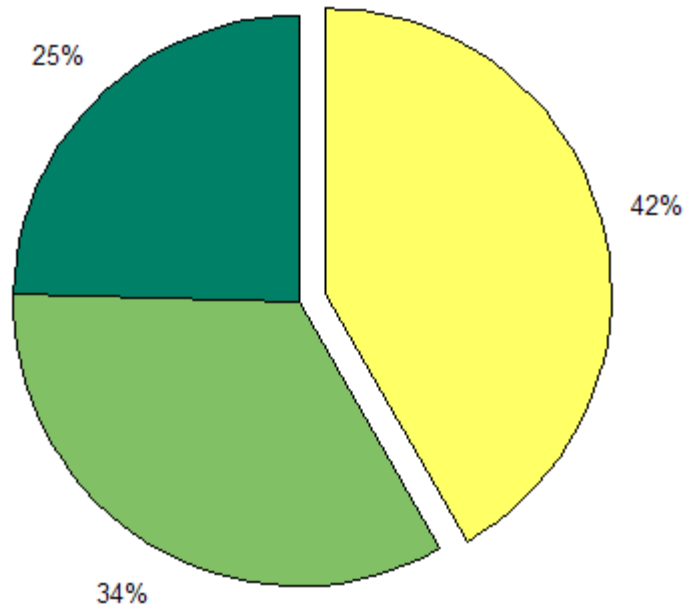
```
explode = zeros(size(x));
```

Then find the slice that contributes the most and set the corresponding `explode` element to `1`.

```
[c,offset] = max(x);
explode(offset) = 1;
```

The `explode` vector contains the elements `[0 0 1]`. To create the exploded pie chart, use the statement

```
h = pie(x,explode); colormap summer
```



Labeling the Pie Chart

The pie chart's labels are text graphics objects. To modify the text strings and their positions, first get the objects' strings and extents. Braces around a property name ensure that `get` outputs a cell array, which is important when working with multiple objects.

```
textObjs = findobj(h,'Type','text');
```

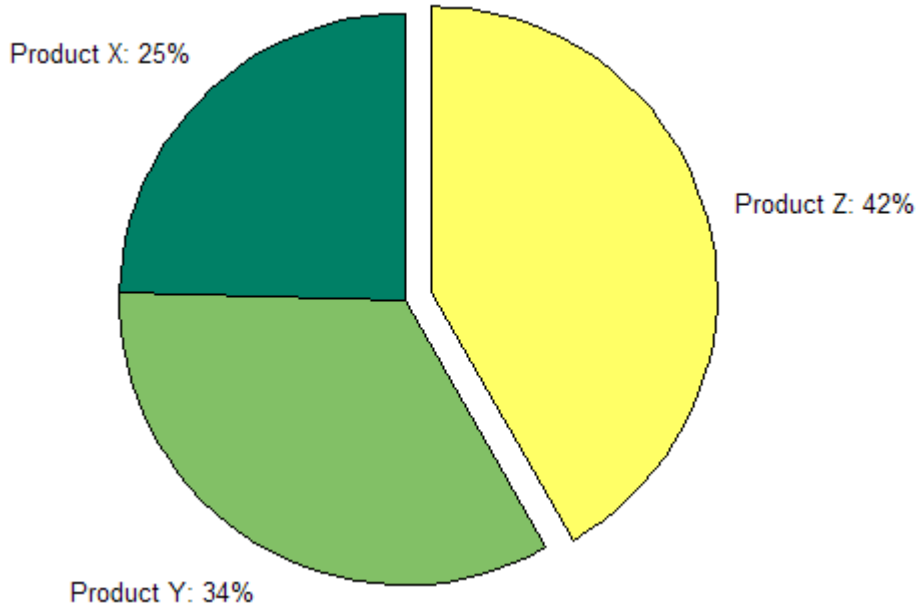
```
oldStr = get(textObjs,{'String'});
val = get(textObjs,{'Extent'});
oldExt = cat(1,val{:});
```

Create the new strings, then set the text objects' `String` properties to the new strings.

```
Names = {'Product X: ';'Product Y: ';'Product Z: '};
newStr = strcat(Names,oldStr);
set(textObjs,{'String'},newStr)
```

Find the difference between the widths of the new and old text strings and change the values of the `Position` properties.

```
val1 = get(textObjs, {'Extent'});
newExt = cat(1, val1{:});
offset = sign(oldExt(:,1)).*(newExt(:,3)-oldExt(:,3))/2;
pos = get(textObjs, {'Position'});
textPos =  cat(1, pos{:});
textPos(:,1) = textPos(:,1)+offset;
set(textObjs,{'Position'},num2cell(textPos,[3,2]))
```



Removing a Piece from a Pie Chart

When the sum of the elements in the first input argument is equal to or greater than `1`, `pie` and `pie3` normalize the values. So, given a vector of elements x, each slice has an area of $x_i / sum(x_i)$, where x_i is an element of x. The normalized value specifies the fractional part of each pie slice.

When the sum of the elements in the first input argument is less than `1`, `pie` and `pie3` do not normalize the elements of vector `x`. They draw a partial pie. For example,

```
x = [.19 .22 .41];
pie(x)
```

41%

Histograms

In this section...

Functions for Creating Histograms

Histograms show the distribution of data values across a data range. They do this by dividing the data range into a certain number of intervals (called "binning" the data), tabulating the number of values that fall into each interval (or "bin"), and plotting the values in the bins using bars or wedges of varying height. The functions that create histograms are `hist` and `rose`.

Function	Description
`hist`	Displays data in a Cartesian coordinate system
`rose`	Displays data in a polar coordinate system

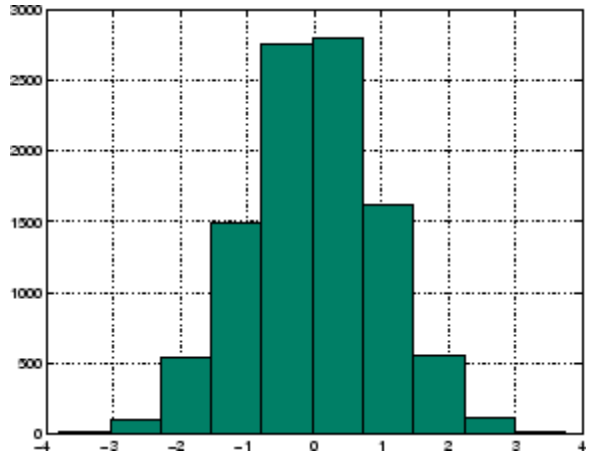
You can specify the number of bins to use as a scalar second argument. If omitted, the default is 10 (`hist`) or 20 (`rose`). Data values passed to `hist` can be in any units and can be n-by-m, but `rose` expects values to be in radians in a 1–by-n or n-by-1 vector. The height (or length when using `rose`) of the bins represents the number of values that fall in each bin. You can also vary the size of bins by specifying a vector for apportioning bin widths as the second argument.

Histograms in Cartesian Coordinates

The `hist` function shows the distribution of the elements in `Y` as a histogram with equally spaced bins between the minimum and maximum values in `Y`. If `Y` is a vector and is the only argument, `hist` creates up to 10 bins. For example,

```
yn = randn(10000,1);
hist(yn)
```

generates 10,000 random numbers and creates a histogram with 10 bins distributed along the *x*-axis between the minimum and maximum values of `yn`.

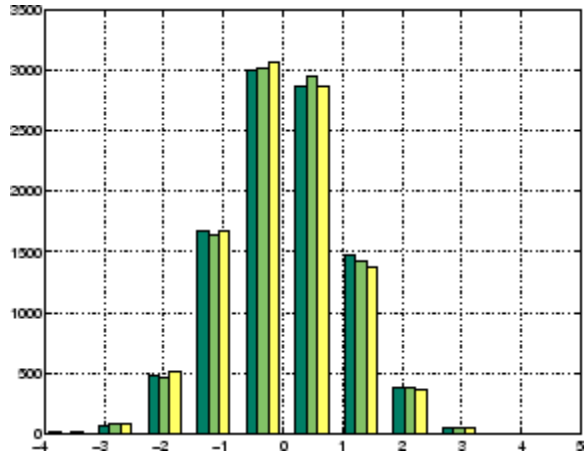


Matrix Input Argument

When `Y` is a matrix, `hist` creates a set of bins for each column, displaying each set in a separate color. The statements

```
Y = randn(10000,3);
hist(Y)
```

create a histogram showing 10 bins for each column in `Y`.



Histograms in Polar Coordinates

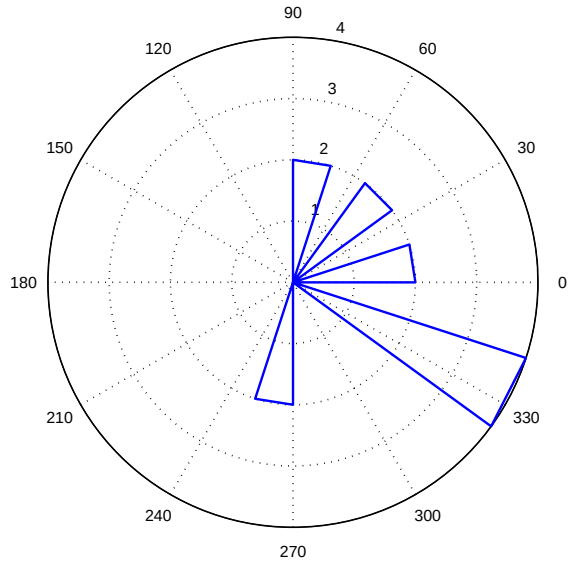
A `rose` plot is a histogram created in a polar coordinate system. For example, consider samples of the wind direction taken over a 12-hour period.

```
wdir = [45 90 90 45 360 335 360 270 335 270 335 335];
```

To display this data using the `rose` function, convert the data to radians, then use the data as an argument to the `rose` function. Increase the `LineWidth` property of the line to improve the visibility of the plot (`findobj`).

```
wdir = wdir * pi/180;
rose(wdir)
hline = findobj(gca,'Type','line');
set(hline,'LineWidth',1.5)
```

The plot shows that the wind direction was primarily 335° during the 12-hour period.



Specifying Number of Bins

`hist` and `rose` interpret their second argument in one of two ways — as the locations on the axis or the number of bins. When the second argument is a vector `x`, it specifies the locations on the axis and distributes the elements in `length(x)` bins. When the second argument is a scalar `x`, `hist` and `rose` distribute the elements in `x` bins.

For example, compare the distribution of data created by two MATLAB functions that generate random numbers. The `randn` function generates normally distributed random numbers, whereas the `rand` function generates uniformly distributed random numbers.

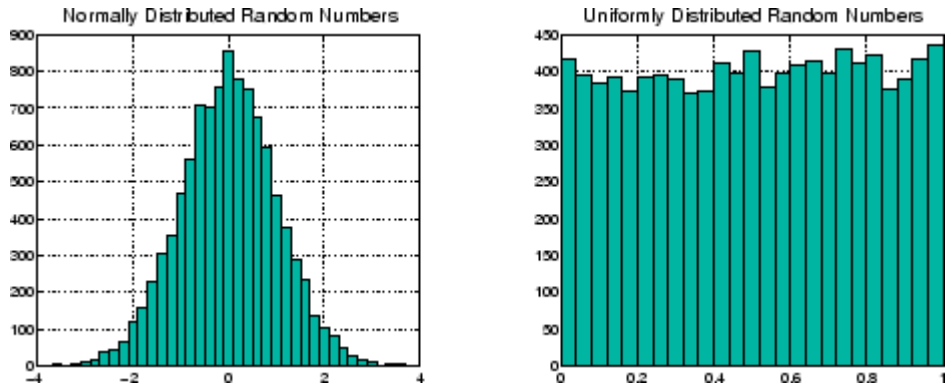
```
yn = randn(10000,1);
yu = rand(10000,1);
```

The first histogram displays the data distribution resulting from the `randn` function. The locations on the *x*-axis and number of bins depend on the vector `x`.

```
x = min(yn):.2:max(yn);
subplot(1,2,1)
hist(yn,x)
title('Normally Distributed Random Numbers','FontSize',16)
```

The second histogram displays the data distribution resulting from the `rand` function and explicitly creates 25 bins along the *x*-axis.

```
subplot(1,2,2)
hist(yu,25)
title('Uniformly Distributed Random Numbers','FontSize',16)
```



Note You can change the aspect ratio of the histogram plots using the mouse to resize the figure window. However, before creating hardcopy output, set the figure's `PaperPositionMode` to `auto` to produce printed output that matches the display. `set(gcf,'PaperPositionMode','auto')`

Discrete Data Graphs

In this section...

Functions for Creating Graphs of Discrete Data

In addition to bar graphs and pie charts, MATLAB has a number of specialized functions that are appropriate for displaying discrete data. Discrete data generally represents counts of things, such as traffic accidents by month or components produced or rejected during the course of a production run. This section describes how to use stem plots and stairstep plots to display this type of data. The functions for generating discrete data graphs provided in MATLAB are

Function	Description
`stem`	Displays a discrete sequence of *y*-data as stems from *x*-axis
`stem3`	Displays a discrete sequence of *z*-data as stems from *xy*-plane
`stairs`	Displays a discrete sequence of *y*-data as steps from *x*-axis

Two-Dimensional Stem Plots

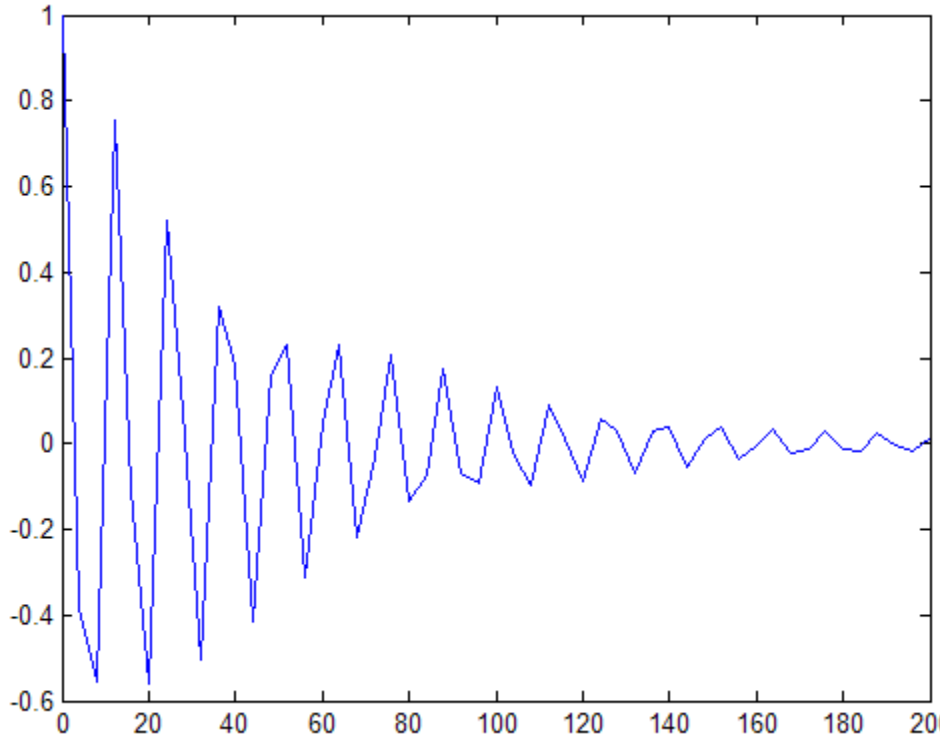
A stem plot displays data as lines (stems) terminated with a marker symbol at each data value. In a 2-D graph, stems extend from the *x*-axis.

The `stem` function displays two-dimensional discrete sequence data. For example, evaluating the function $y = e^{-\alpha t}\cos\beta t$ with the values

```
alpha = .02; beta = .5; t = 0:4:200;
y = exp(-alpha*t).*cos(beta*t);
```

yields a vector of discrete values for `y` at given values of `t`. A line plot shows the data points connected with a straight line.

```
plot(t,y)
```

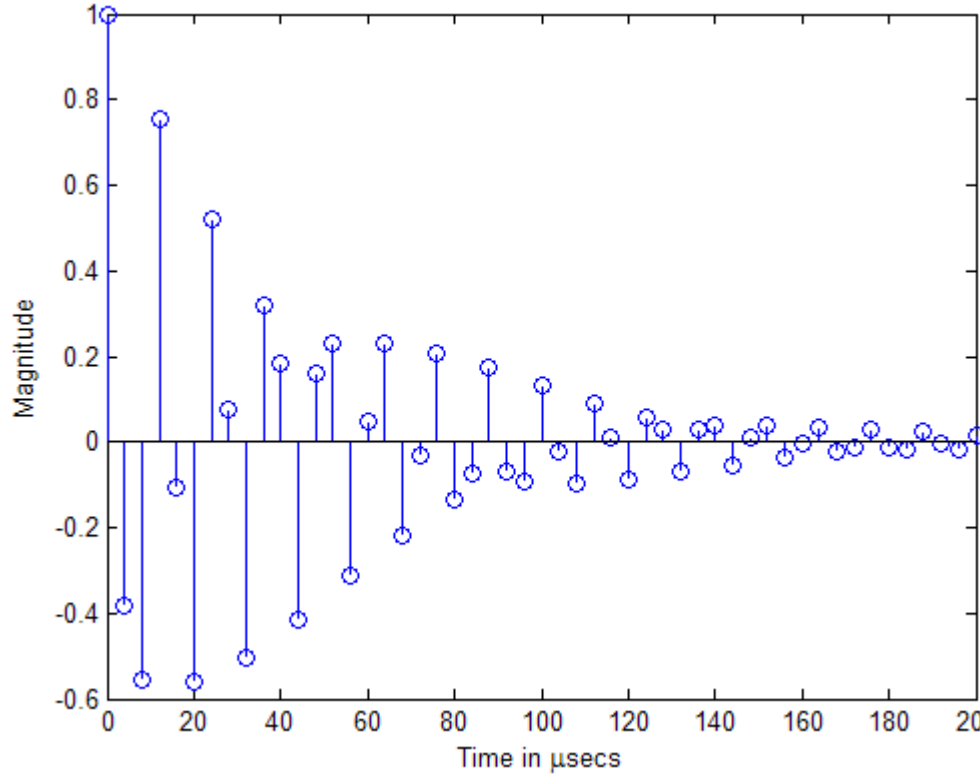


A stem plot of the same function plots only discrete points on the curve.

```
stem(t,y)
```

Add axes labels to the *x*- and *y*-axis.

```
xlabel('Time in \musecs')
ylabel('Magnitude')
```

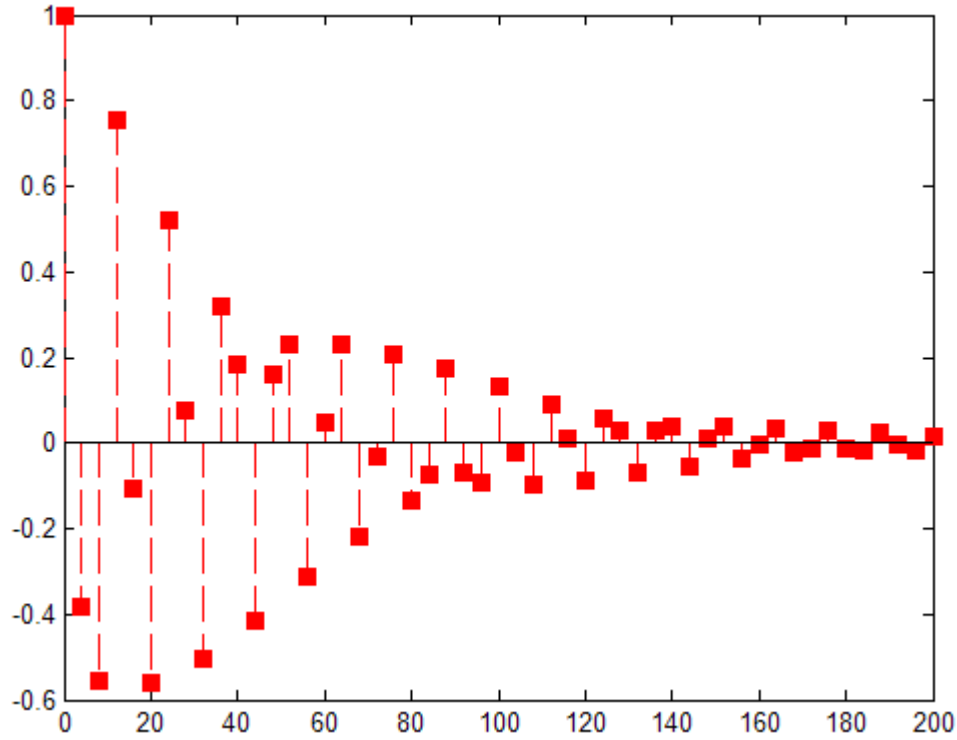


If you specify only one argument, the number of samples is equal to the length of that argument. In this example, the number of samples is a function of t, which contains 51 elements and determines the length of y.

Customizing the Graph

You can specify the line style, the type of marker, and the color used in the stem plot. For example, adding the string ':sr' specifies a dotted line (:), a square marker (s), and a red color (r). The `'fill'` argument colors the face of the marker.

```
stem(t,y,'--sr','fill')
```



Setting the aspect ratio of the *x*- and *y*-axis to 2:1 improves the utility of the graph. You can do this by setting the aspect ratio of the plot box using `pbaspect`.

```
pbaspect([2,1,1])
```

This is equivalent to setting the `PlotBoxApectRatio` property directly.

```
set(gca,'PlotBoxAspectRatio',[2,1,1])
```

See `LineSpec` for a list of line styles and marker types.

Combining Stem Plots with Line Plots

Sometimes it is useful to display more than one plot simultaneously with a stem plot to show how you arrived at a result. For example, create a linearly spaced vector with 60 elements and define two functions, `a` and `b`.

```
x = linspace(0,2*pi,60);
a = sin(x);
b = cos(x);
```

Create a stem plot showing the linear combination of the two functions.

```
stem_handles = stem(x,a+b);
```

Overlaying `a` and `b` as line plots helps visualize the functions. Before plotting the two curves, set `hold` to `on` so MATLAB does not clear the stem plot.

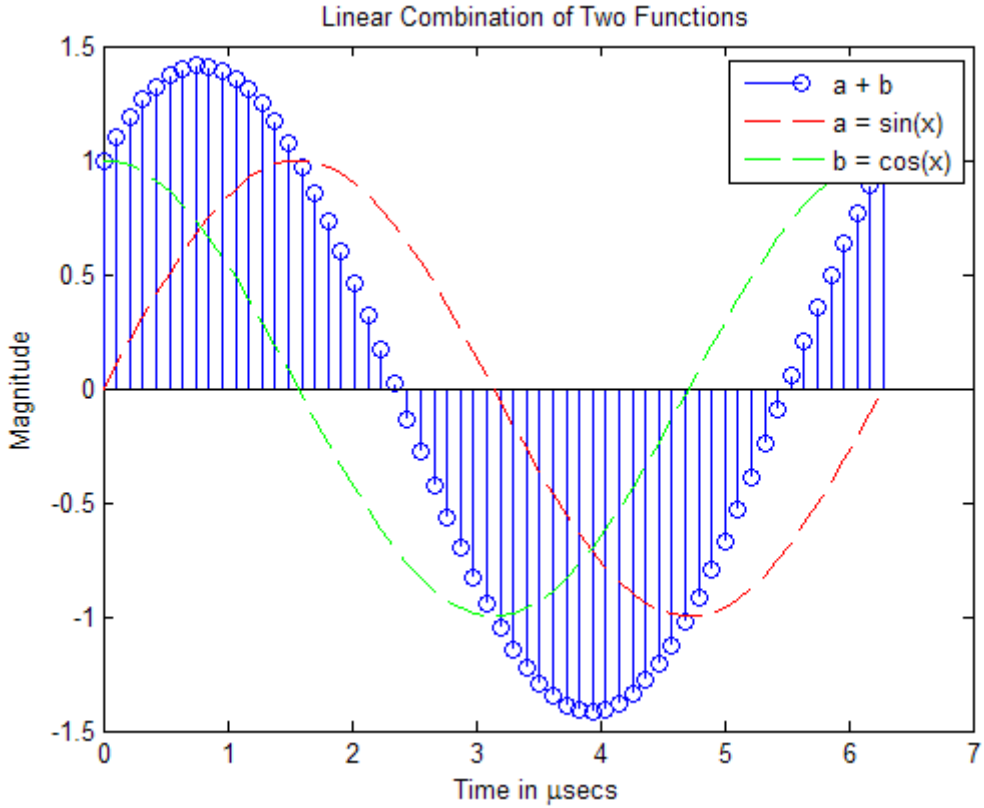
```
hold on
plot_handles = plot(x,a,'--r',x,b,'--g');
hold off
```

Use `legend` to annotate the graph. The stem and plot handles passed to `legend` identify the lines to label. Stem plots are composed of two lines; one draws the markers and the other draws the vertical stems. To create the legend, use the first handle returned by `stem`, which identifies the marker line.

```
legend_handles = [stem_handles(1);plot_handles];
legend(legend_handles,'a + b','a = sin(x)','b = cos(x)')
```

Labeling the axes and creating a title finishes the graph.

```
xlabel('Time in \musecs')
ylabel('Magnitude')
title('Linear Combination of Two Functions')
```



Three-Dimensional Stem Plots

`stem3` displays 3-D stem plots extending from the *xy*-plane. With only one vector argument, MATLAB plots the stems in one row at `x = 1` or `y = 1`, depending on whether the argument is a column or row vector. `stem3` is intended to display data that you cannot visualize in a 2-D view.

Example – 3-D Stem Plot of an FFT

Fast Fourier transforms are calculated at points around the unit circle on the complex plane. So, it is interesting to visualize the plot around the unit circle. Calculating the unit circle

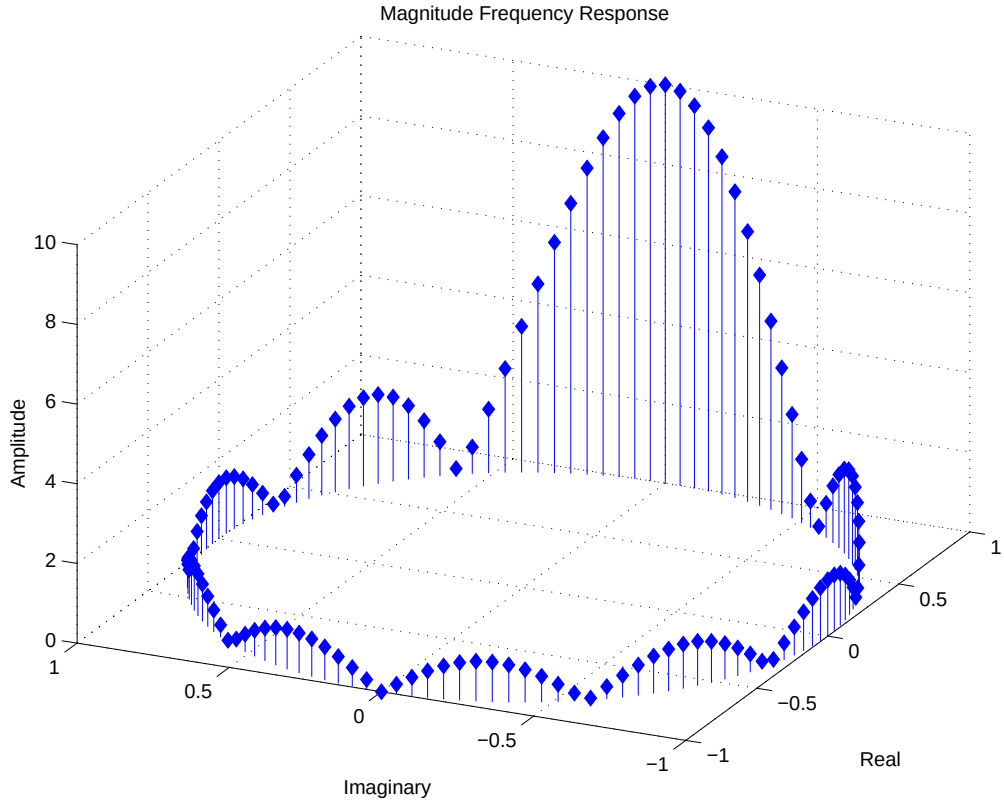
```
th = (0:127)/128*2*pi;
x = cos(th);
y = sin(th);
```

and the magnitude frequency response of a step function

```
f = abs(fft(ones(10,1),128));
```

displays the data using a 3-D stem plot, terminating the stems with filled diamond markers.

```
stem3(x,y,f','d','fill')
view([-65 30])
```



Label the Graph

Label the graph with the statements

```
xlabel('Real')
ylabel('Imaginary')
zlabel('Amplitude')
title('Magnitude Frequency Response')
```

To change the orientation of the view, turn on mouse-based 3-D rotation.

```
rotate3d on
```

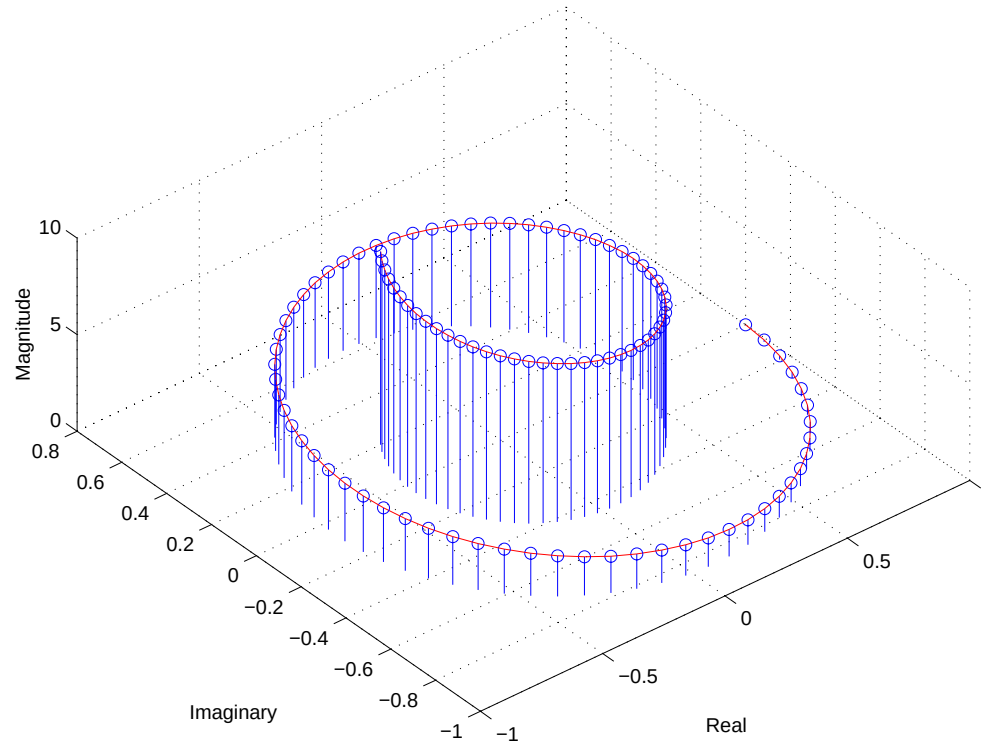
Example — Combining Stem and Line Plots

Three-dimensional stem plots work well for visualizing discrete functions that do not output a large number of data points. For example, you can use `stem3` to visualize the Laplace transform basis function, $y = e^{-st}$, for a particular constant value of `s`.

```
t = 0:.1:10; % Time limits
s = 0.1+i; % Spiral rate
y = exp(-s*t); % Compute decaying exponential
```

Using `t` as magnitudes that increase with time, create a spiral with increasing height and draw a curve through the tops of the stems to improve definition.

```
stem3(real(y),imag(y),t)
hold on
plot3(real(y),imag(y),t,'r')
hold off
view(-39.5,62)
```



Label the Graph

Add axes labels, with the statements

```
xlabel('Real')
ylabel('Imaginary')
zlabel('Magnitude')
```

Stairstep Plots

Stairstep plots display data as the leading edges of a constant interval (i.e., zero-order hold state). This type of plot holds the data at a constant *y*-value for all values between *x(i)* and *x(i+1)*, where *i* is the index into the *x* data.

This type of plot is useful for drawing time-history plots of digitally sampled data systems.

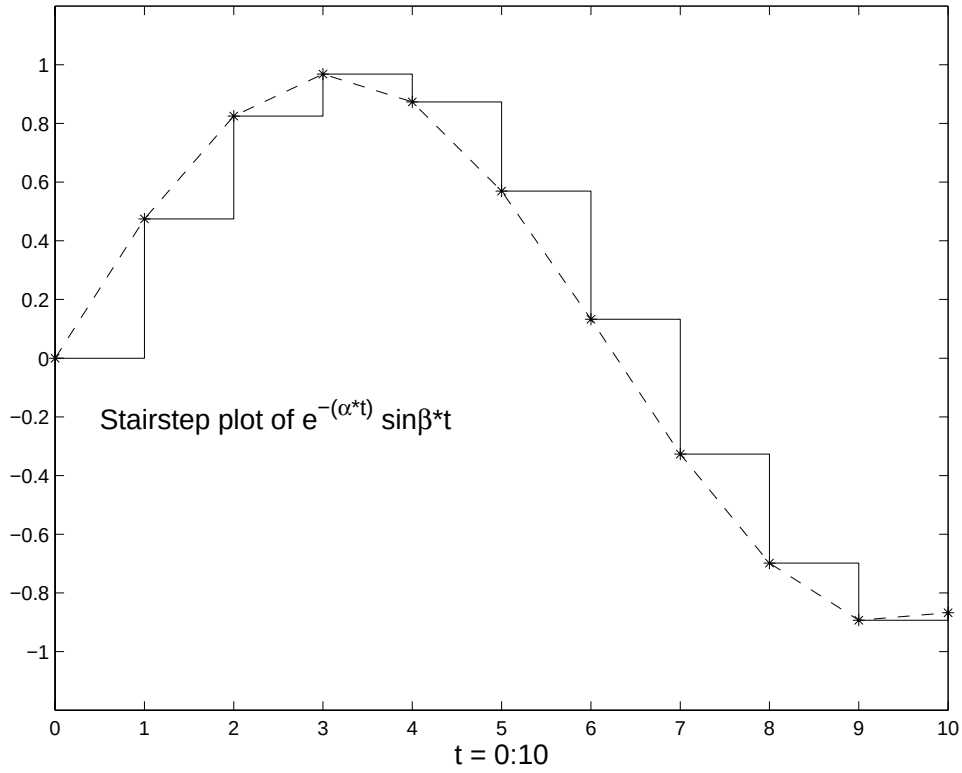
Example — Stairstep Plot of a Function

Define a function `f` that varies over time,

```
alpha = 0.01;
beta = 0.5;
t = 0:10;
f = exp(-alpha*t).*sin(beta*t);
```

Use `stairs` to display the function as a stairstep plot and a linearly interpolated function.

```
stairs(t,f)
hold on
plot(t,f,'--*')
hold off
```



Annotate the graph and set the axes limits.

```
label = 'Stairstep plot of e^{-(\alpha*t)} sin\beta*t';
text(0.5,-0.2,label,'FontSize',14)
xlabel('t = 0:10','FontSize',14)
axis([0 10 -1.2 1.2])
```

Direction and Velocity Vector Graphs

In this section...

Functions for Graphing Vector Quantities

MATLAB provides four functions for displaying data consisting of direction vectors and velocity vectors; three create 2-D plots and one creates 3-D plots:

Function	Description
`compass`	Displays vectors emanating from the origin of a polar plot
`feather`	Displays vectors extending from equally spaced points along a horizontal line
`quiver`	Displays 2-D vectors specified by (u,v) components
`quiver3`	Displays 3-D vectors specified by (u,v,w) components

For feather and compass plots, you can define the vectors using one or two arguments. The arguments specify the u and v components of the vectors relative to the origin. If you specify two arguments, the first specifies the u components of the vectors and the second the v components of the vectors. If you specify one argument, the functions treat the elements as complex numbers. The real parts are the u components and the imaginary parts are the v components.

For quiver plots, in addition to the u-v components, you also specify x,y locations (or x,y,z locations in the case of `quiver3`) to establish an origin for each vector.

Compass Plots

The `compass` function shows vectors emanating from the origin of a graph. The function takes Cartesian coordinates and plots them on a circular grid.

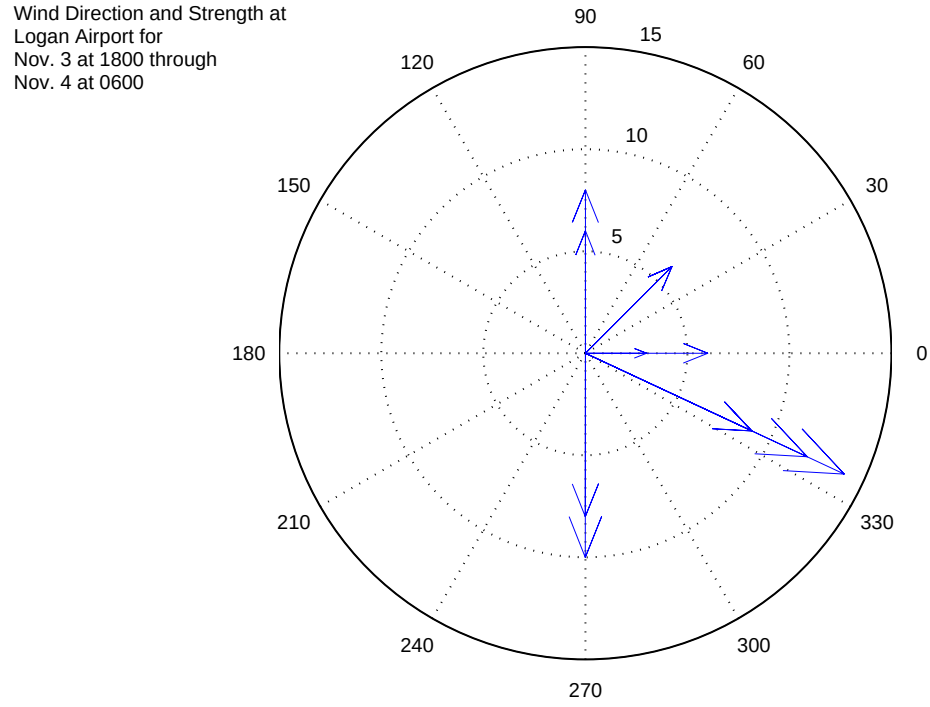
Example — Compass Plot of Wind Direction and Speed

This example shows a compass plot indicating the wind direction and strength during a 12-hour period. Two vectors define the wind direction and strength.

```
wdir = [45 90 90 45 360 335 360 270 335 270 335 335];
knots = [6 6 8 6 3 9 6 8 9 10 14 12];
```

Convert the wind direction, given as angles, into radians before converting the wind direction into Cartesian coordinates.

```
rdir = wdir * pi/180;
[x,y] = pol2cart(rdir,knots);
compass(x,y)
```



Create text to annotate the graph.

```
desc = {'Wind Direction and Strength at',
        'Logan Airport for ',
        'Nov. 3 at 1800 through',
        'Nov. 4 at 0600'};
text(-28,15,desc)
```

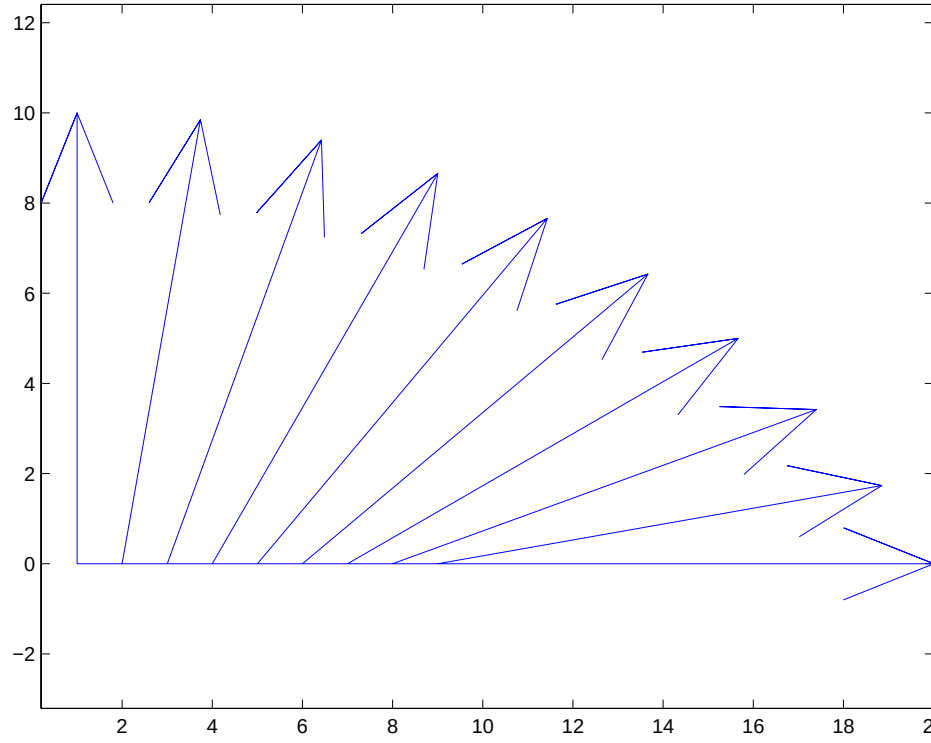
Feather Plots

The `feather` function shows vectors emanating from a straight line parallel to the *x*-axis. For example, create a vector of angles from 90° to 0° and a vector the same size, with each element equal to 1.

```
theta = 90:-10:0;
r = ones(size(theta));
```

Before creating a feather plot, transform the data into Cartesian coordinates and increase the magnitude of `r` to make the arrows more distinctive.

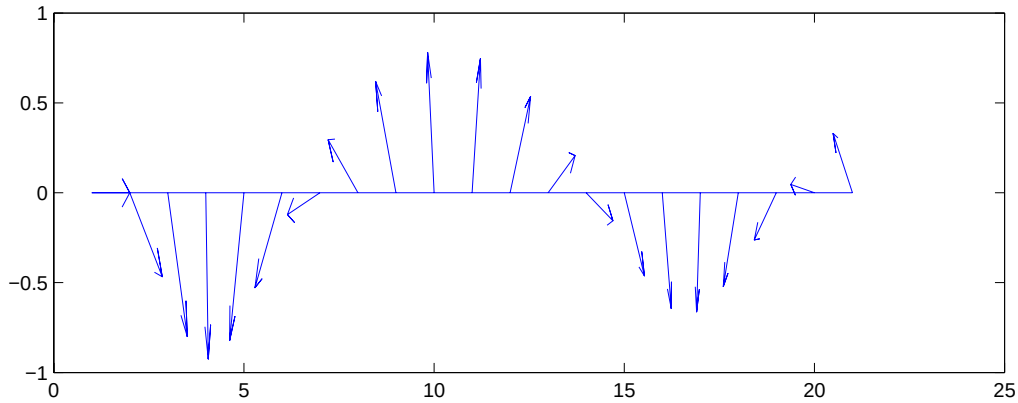
```
[u,v] = pol2cart(theta*pi/180,r*10);
feather(u,v)
axis equal
```



Plotting Complex Numbers

If the input argument `Z` is a matrix of complex numbers, `feather` interprets the real parts of `Z` as the *x* components of the vectors and the imaginary parts as the *y* components of the vectors.

```
t = 0:0.5:10;    % Time limits
s = 0.05+i;      % Spiral rate
Z = exp(-s*t);   % Compute decaying exponential
feather(Z)
```



Printing the Graph

This particular graph looks better if you change the figure's aspect ratio by stretching the figure lengthwise using the mouse. However, to maintain this shape in the printed output, set the figure's `PaperPositionMode` to `auto`.

```
set(gcf,'PaperPositionMode','auto')
```

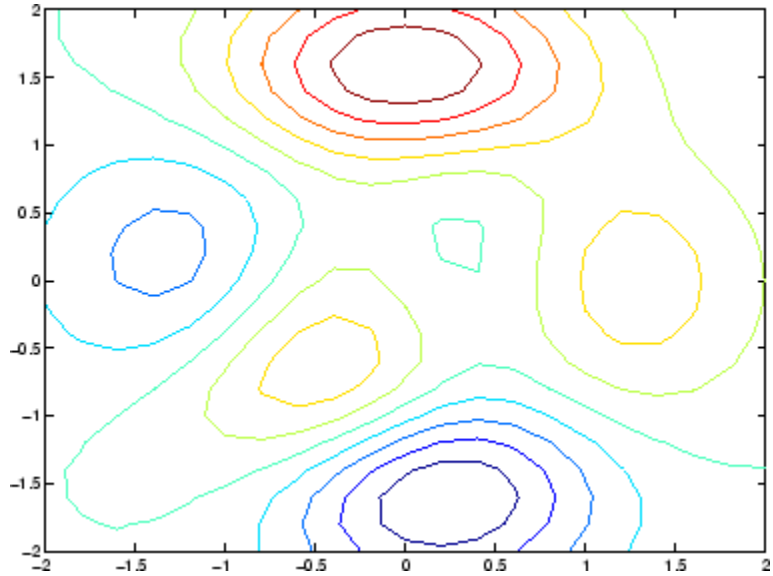
In this mode, MATLAB prints the figure as it appears on screen.

Two-Dimensional Quiver Plots

The `quiver` function shows vectors at given points in two-dimensional space. The vectors are defined by *x* and *y* components.

A quiver plot is useful when displayed with another plot. For example, create 10 contours of the `peaks` function (see “Contour Plots” on page 5-54 for more information).

```
n = -2.0:.2:2.0;
[X,Y,Z] = peaks(n);
contour(X,Y,Z,10)
```

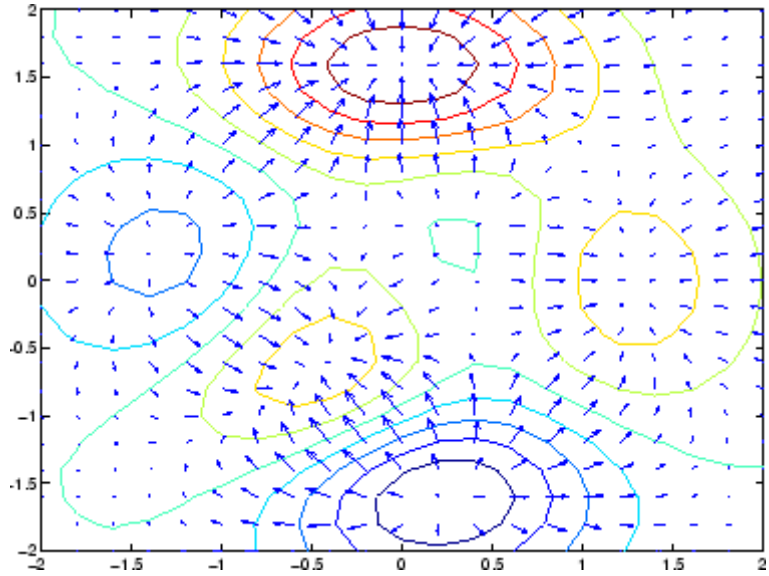


Now use `gradient` to create the vector components to use as inputs to `quiver`.

```
[U,V] = gradient(Z,.2);
```

Set `hold` to `on` and add the contour plot.

```
hold on
quiver(X,Y,U,V)
hold off
```



Three-Dimensional Quiver Plots

Three-dimensional quiver plots (`quiver3`) display vectors consisting of (u,v,w) components at (x,y,z) locations. For example, you can show the path of a projectile as a function of time, $z(t) = v_z t + \frac{a t^2}{2}$

First, assign values to the constants `vz` and `a`.

```
vz = 10;            % Velocity
a = -32;            % Acceleration
```

Then, calculate the height `z`, as time varies from `0` to `1` in increments of `0.1`.

```
t = 0:.1:1;
z = vz*t + 1/2*a*t.^2;
```

Calculate the position in the x and y directions.

```
vx = 2;
x = vx*t;
vy = 3;
y = vy*t;
```

Compute the components of the velocity vectors and display the vectors using the 3-D quiver plot.

```
u = gradient(x);
v = gradient(y);
w = gradient(z);
scale = 0;
quiver3(x,y,z,u,v,w,scale)
view([70 18])
```

Contour Plots

In this section...

Functions for Creating Contour Displays

The contouring display functions compute, plot, and label isolines (contour lines) for one or more matrices. These displays vary according to whether they plot plain contour lines, filled contour lines, raised contours, or contours in concert with mesh or surface plots. Two of the functions listed below support contouring. The low-level `contourc` function computes isolines but does not plot them. The `clabel` function places elevation labels on previously generated contours.

Function	Description
`contour`	Displays 2-D isolines generated from values given by a matrix Z
`contour3`	Displays 3-D isolines generated from values given by a matrix Z
`contourf`	Displays a 2-D contour plot and fills the area between the isolines with a solid color

Function	Description
`contourc`	Low-level function to calculate the contour matrix used by the other contour functions
`meshc`	Creates a mesh plot with a corresponding 2-D contour plot
`surfc`	Creates a surface plot with a corresponding 2-D contour plot
`clabel`	Generates labels using the contour matrix returned from calling the contouring function and displays the labels in the current figure

Creating Simple Contour Plots

`contour` and `contour3` display 2- and 3-D contours, respectively. They can be called with separate *x*, *y*, and *z* matrices, but need only one input argument — a *z* matrix interpreted as heights with respect to a plane. In this case, the contour functions determine the number of contours to display based on the minimum and maximum data values.

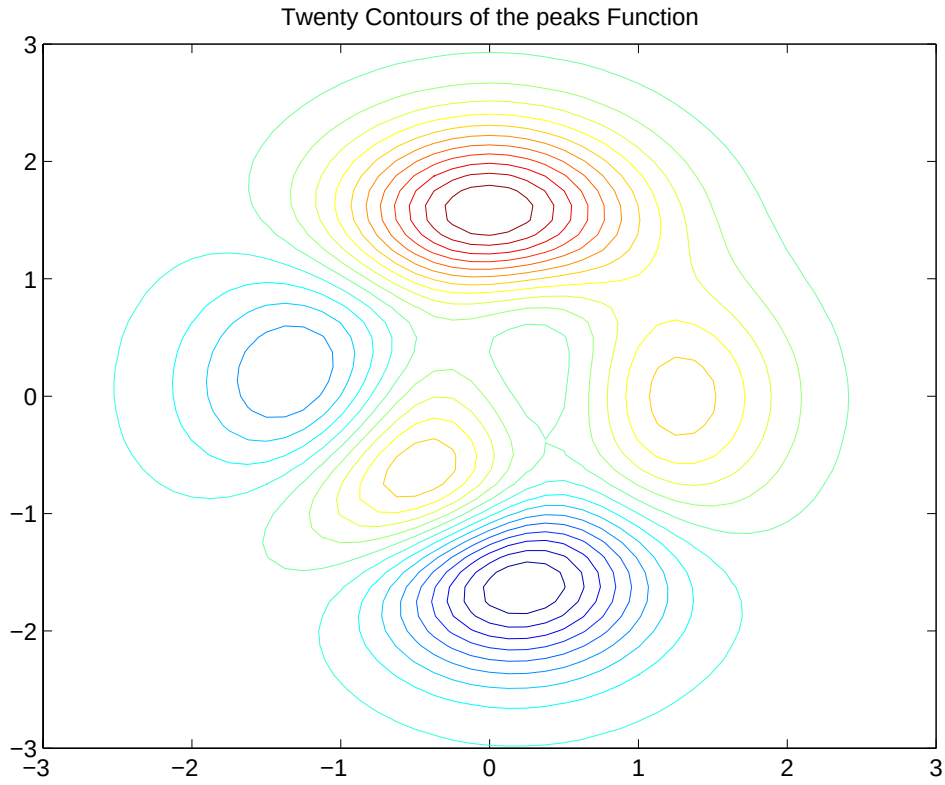
To explicitly set the number of contour levels displayed by the functions, you specify a second optional argument.

Contour Plot of the Peaks Function

The statements

```
[X,Y,Z] = peaks;
contour(X,Y,Z,20)
```

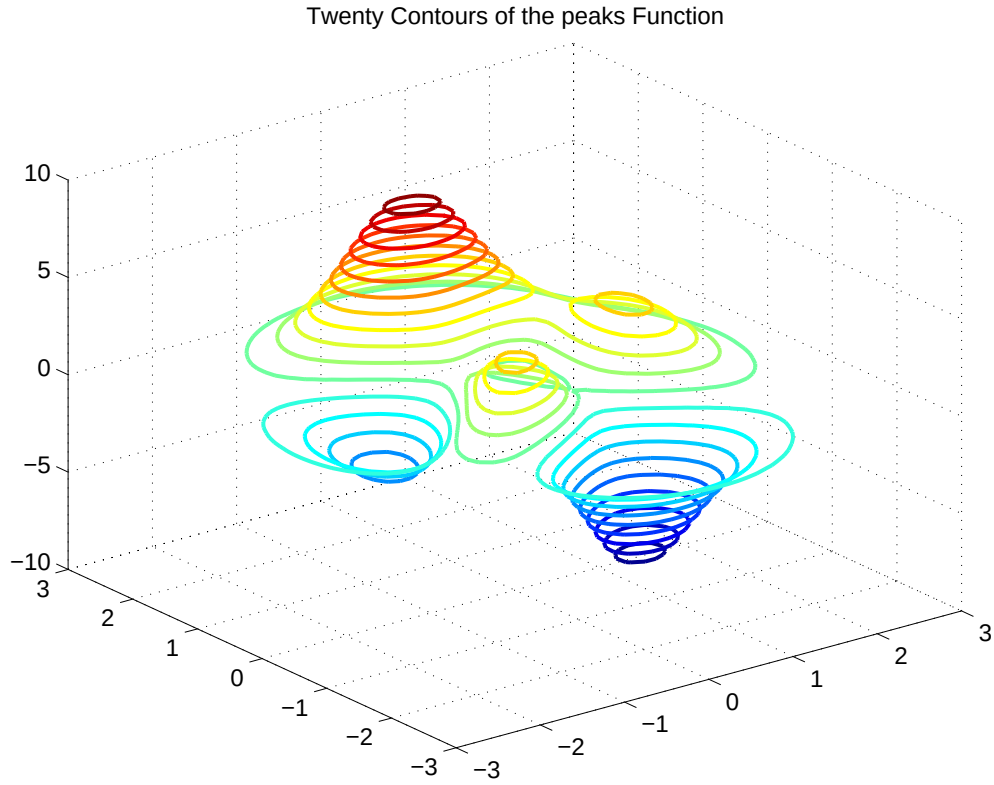
display 20 contours of the `peaks` function in a 2-D view.



The statements

```
[X,Y,Z] = peaks;
contour3(X,Y,Z,20)
h = findobj('Type','patch');
set(h,'LineWidth',2)
title('Twenty Contours of the peaks Function')
```

display 20 contours of the `peaks` function in a 3-D view and increase the line width to 2 points.



Labeling Contours

Each contour level has a value associated with it. `clabel` uses these values to display labels for 2-D contour lines. The contour matrix contains the values `clabel` uses for the labels. This matrix is returned by `contour`, `contour3`, and `contourf` and is described in “The Contouring Algorithm” on page 5-66.

`clabel` optionally returns the handles of the text objects used as labels. You can then use these handles to set the properties of the label string.

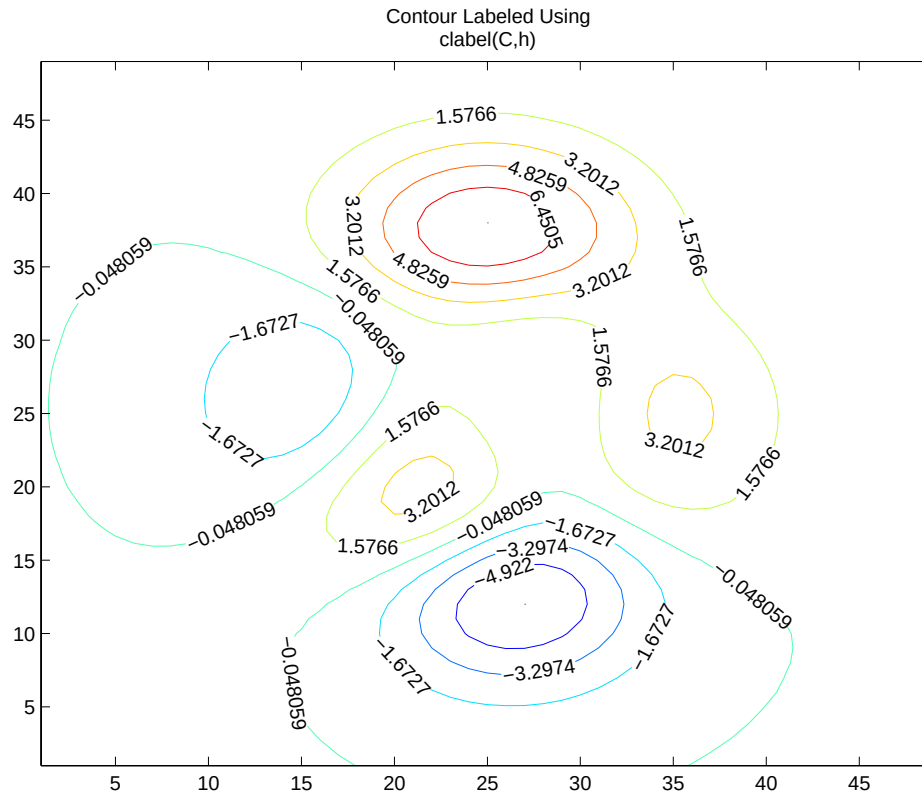
For example, display 10 contour levels of the `peaks` function,

```
Z = peaks;
[C,h] = contour(Z,10);
```

then label the contours and display a title.

```
clabel(C,h)
title({'Contour Labeled Using','clabel(C,h)'})
```

Note that `clabel` labels only those contour lines that are large enough to have an inline label inserted.



The `'manual'` option enables you to add labels by selecting the contour you want to label with the mouse.

You can also use this option to label only those contours you select interactively.

For example,

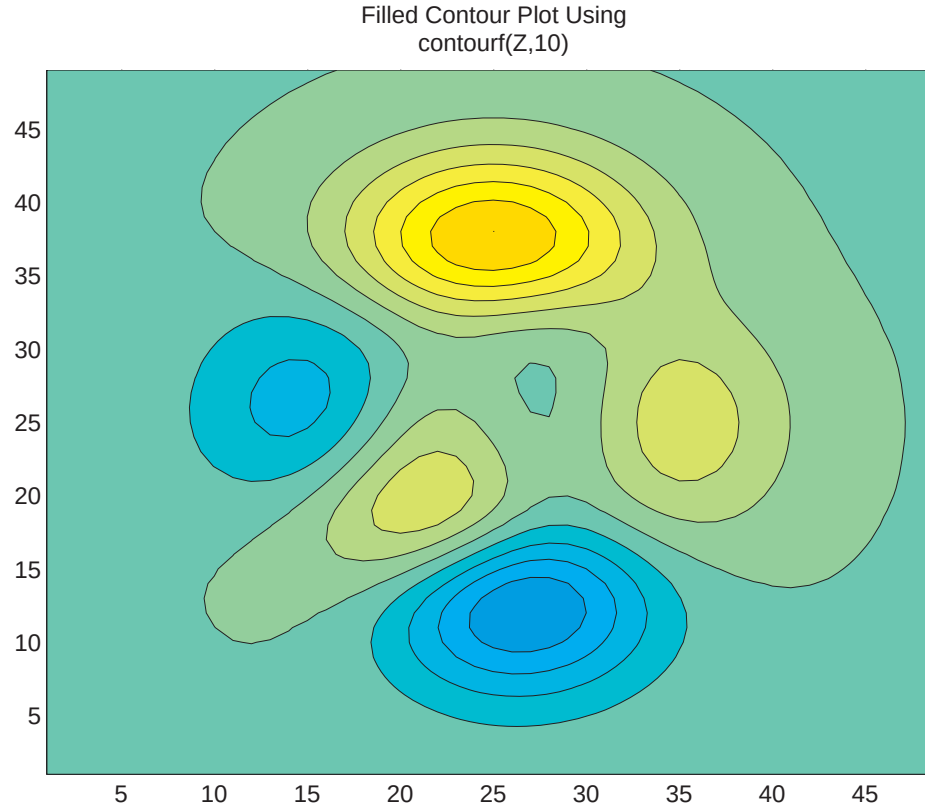
```
clabel(C,h,'manual')
```

displays a crosshair cursor when your cursor is inside the figure. Pressing any mouse button labels the contour line closest to the center of the crosshair.

Filled Contours

The `contourf` displays a two-dimensional contour plot and fills the areas between contour lines. Use `caxis` to control the mapping of contour to color. For example, this filled contour plot of the peaks data uses `caxis` to map the fill colors into the center of the colormap.

```
Z = peaks;
[C,h] = contourf(Z,10);
caxis([-20 20])
title({'Filled Contour Plot Using','contourf(Z,10)'})
```



Drawing a Single Contour Line at a Desired Level

The contouring functions permit you to specify the number of contour levels or the particular contour levels to draw. In the case of `contour`, the two forms of the function are `contour(Z,n)` and `contour(Z,v)`. `Z` is the data matrix, `n` is the number of contour lines, and `v` is a vector of specific contour levels.

MATLAB does not differentiate between a scalar and a one-element vector. So, if `v` is a one-element vector specifying a single contour at that level, `contour` interprets it as the number of contour lines, not the contour level. Consequently, `contour(Z,v)` behaves in the same manner as `contour(Z,n)`.

To display a single contour line, define `v` as a two-element vector with both elements equal to the desired contour level. For example, create a 3-D contour of the `peaks` function.

```
xrange = -3:.125:3;
yrange = xrange;
[X,Y] = meshgrid(xrange,yrange);
Z = peaks(X,Y);
contour3(X,Y,Z)
```

To display only one contour level at `Z = 1`, define `v` as `[1 1]`.

```
v = [1 1]
contour3(X,Y,Z,v)
```

Example — Visualizing Contour Construction

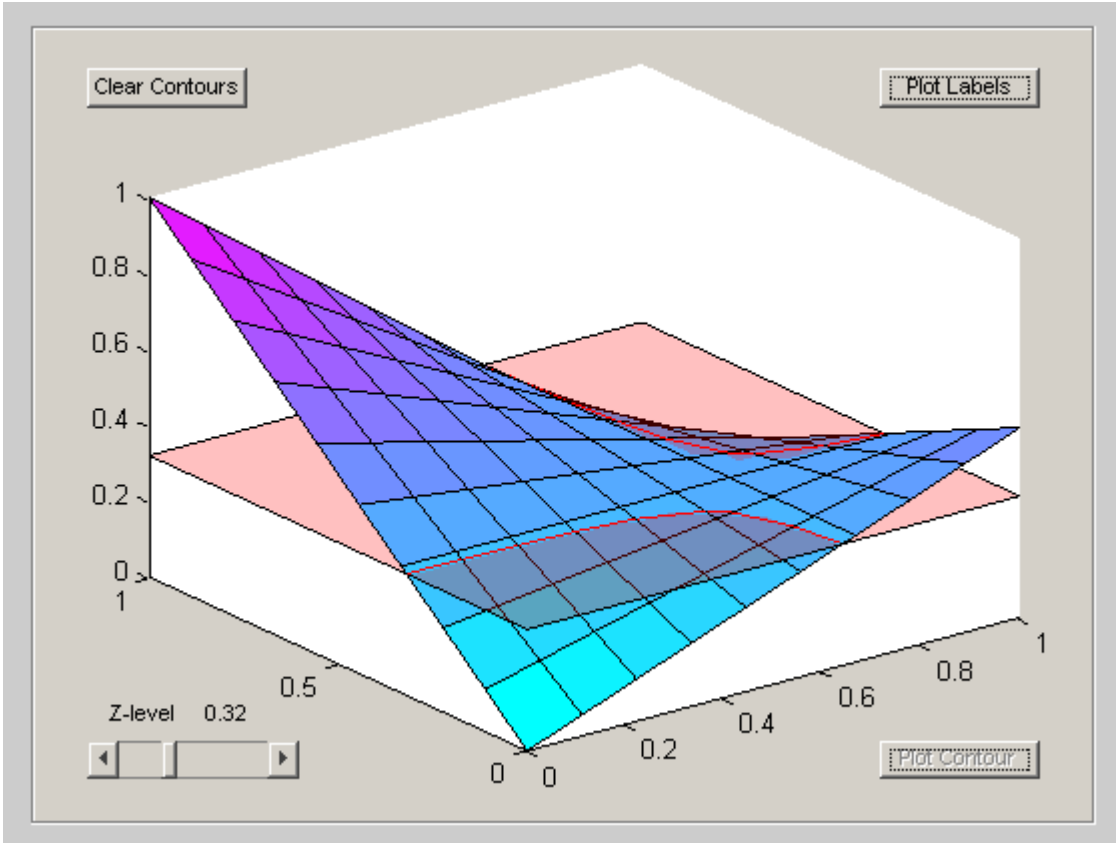
You can think of a contour as the intersection of a 3–D surface with a horizontal plane. The intersection defines 0 or more *level lines* that trace contours. The level lines either form loops or terminate at the outer edges of the surface. Contour loops can intersect at saddle points, and therefore require special handling in their vicinity.

Run the following interactive code to visualize how contour lines are constructed. Use the slider to move the plane up or down through the range of *z*-values, and click the **Plot Contour** button to draw a contour line that delineates where the plane slices through the surface. Click the **Plot Labels** button to add a label to the contour you just plotted. Click **Clear Contours** to remove all the contours and labels.

```
% Create x, y, and z arrays for a parametric surface
[x y]=meshgrid(linspace(0,1,10),linspace(0,1,10));
z = .5*x + y - 1.5*x.*y;
% Display with the surface function in 3-D
fh = figure; colormap cool;
hpl = uipanel(fh,'Units','normalized','position',[.025 .025 .95 .95]);
s=surface('xdata',x,'ydata',y,'zdata',z,'cdata',z);
view(3);hold on;
% Display a second surface, a horixontal plane at z = 0
p=surface('xdata',[0 1;0 1],'ydata',[0 0; 1 1],...
          'zdata',[0 0; 0 0],'cdata',[0 0;0 0]);
```

```
set(p,'facealpha',.25,'facecolor','red'); % Make cut plane transparent
% Create a slider control for contour elevations
hs = uicontrol(hpl,'style','slider','min',0,'max',100,...
            'units','normalized','position',[.05 .05 .2 .05],...
            'sliderstep', [.01 .05]);
set(hs,'callback',...   % Tell the slider what it should do
    ['lvl=get(hs,''value'')/100;,' ...
     'set(p,''zdata'',[lvl lvl; lvl lvl]),' ...
     'set(hto,''string'',num2str(lvl)),' ...
     'set(hbc,''enable'',''on'')']);
 lvl = 0;       % Initialize the z-level of the cutting plane
% Create a label for the slider and a text box to show its value
hst = uicontrol(hpl,'Style','text', 'String','Z-level',...
                'units','normalized','Position',[.05 .10 .1 .05]);
hto = uicontrol(hpl,'Style','text', 'String','0',...
                'units','normalized','Position',[.13 .10 .1 .05]);
% Create a pushbutton control for drawing contours with CONTOUR3
hbc = uicontrol(hpl,'style','pushbutton','enable','off',...
    'string','Plot Contour',...
    'units','normalized','position',[.80 .05 .15 .05]);
set(hbc,'callback',['[C hc] = contour3(x,y,z, [lvl lvl],''r'');' ...
    'set(hbl,''enable'',''on''), set(hbe,''enable'',''on''),' ...
    'set(hbc,''enable'',''off'')']);
% Create a pushbutton control for labelling with CLABEL,
% which uses the "contour matrix" returned from CONTOUR3
hbl = uicontrol(hpl,'style','pushbutton','enable','off',...
    'string','Plot Labels',...
    'units','normalized','position',[.80 .90 .15 ,.05]);
set(hbl,'callback',['clabel(C, hc,''color'',''r'',' ...
   '''fontweight'',''bold'');' 'set(hbl,''enable'',''off''), '...
   'set(hbe,''enable'',''on'')']);
% Create a pushbutton to clear away the contours and labels
hbe = uicontrol(hpl,'style','pushbutton','enable','off',...
    'string','Clear Contours',...
    'units','normalized','position',[.05 .90 .15 .05]);
set(hbe,'callback',['delete(findall(gca,''color'',''r''));' ...
    'set(hbe,''enable'',''off'')']);
```

Here is what the figure and its controls look like with a contour plotted at the cut line:



See “The Contouring Algorithm” on page 5-66, below, for an explanation of how MATLAB computes contour lines.

Index Contours

You can index contours to visually emphasize certain contour levels. This technique, commonly used on topographic maps to highlight contours at set altitudes such as 25, 50, 75 ... meters above sea level, provides visual cues analogous to major ticks on a graph’s axis. It is much easier to read a contour display that shows index contours because the heavier lines lessen the chance that one’s eye will jump between adjacent contours in scanning across the plot.

Example — Specifying Index Contours

The following code example highlights contours at elevations of -6, -5, -4, ... 7 for the output of the `peaks` function.

1 Generate a data matrix to contour:

```
z = peaks(100);
```

2 Compute 40 contour levels. Select contour levels so as to be round numbers; `zlevs` is the vector of contour levels to be plotted:

```
zmin = floor(min(z(:))); zmax = ceil(max(z(:)));
zinc = (zmax - zmin) / 40;
zlevs = zmin:zinc:zmax;
```

3 Specify the vertical distance between index contours; here it is unity, but it can be any modulus of values in zlevs.

```
zindex = 1;
```

4 Plot 2-D level lines with the CONTOUR function:

```
[c2,hc2] = contour(z,zlevs);
```

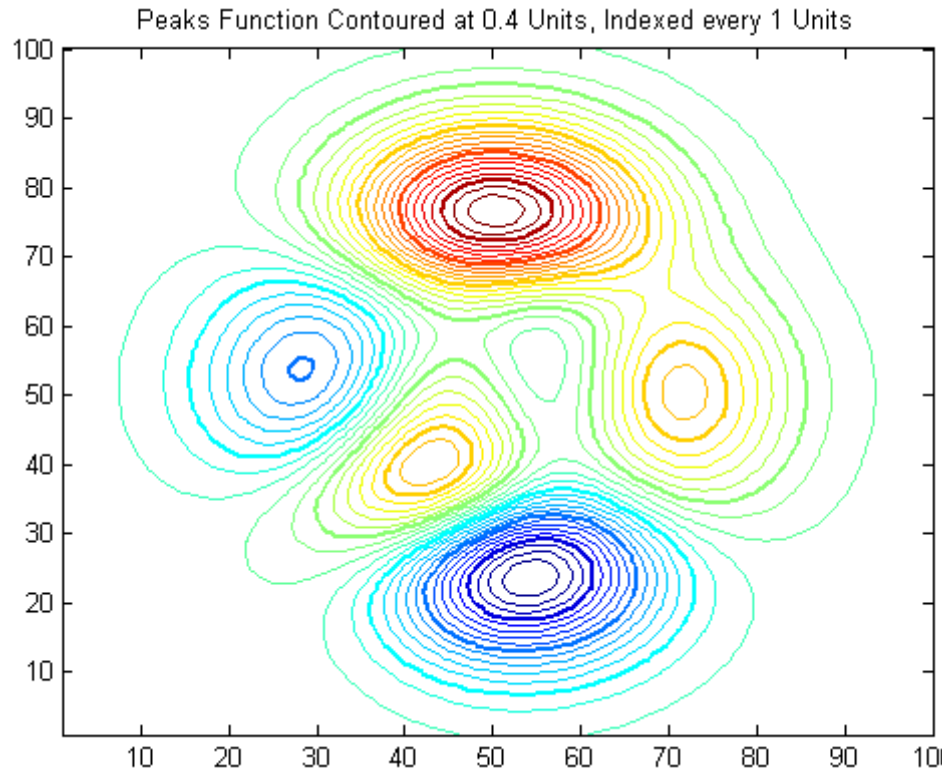
5 Create Index Contours by thickening level lines every `zindex` units

```
nc = get(hc2,'Children');
for i = 1:length(nc)
   ud = get(nc(i),'UserData');
   if (mod(ud,zindex) == 0)
       set(nc(i),'LineWidth',2);
   end
end
```

A contour line will thicken with each call to `set`.

6 Annotate to identify the contouring parameters used

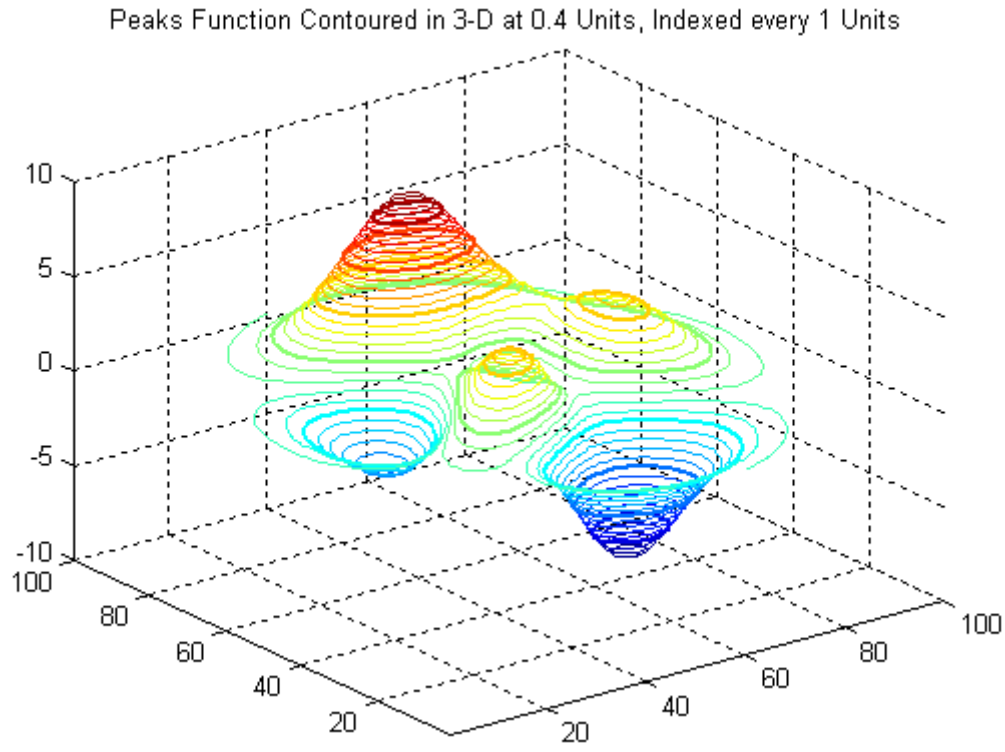
```
s = sprintf('%s %g %s %g %s', 'Peaks Function Contoured at', ...
    zinc, 'Units, Indexed every', zindex, 'Units');
title(s)
```



The loop of code in step 5 above works for `contour` but not `contour3`, because `contour3` does not create `contourgroup` objects containing `Children`. To accomplish the same result with `contour3` you must dereference the handle to the contours returned by `contour3` (`hc3`, below) differently, as follows:

```
figure;
[c3,hc3] = contour3(z,zlevs);
for i = 1:length(hc3)
   ud = get(hc3(i),'UserData');
   if (mod(ud,zindex) == 0)
       set(hc3(i),'LineWidth',2);
   end
end
s = sprintf('%s %g %s %g %s',...
```

```
    'Peaks Function Contoured in 3-D at', ...
    zinc, 'Units, Indexed every', zindex, 'Units');
title(s)
```



The Contouring Algorithm

The `contourc` function calculates the contour matrix for the other contour functions. It is a low-level function that is not called from the command line.

The contouring algorithm first determines which contour levels to draw. If you specified the input vector `v`, the elements of `v` are the contour level values, and `length(v)` determines the number of contour levels generated. If you do not specify `v`, the algorithm chooses no more than 20 contour levels that are divisible by 2 or 5.

The height matrix `Z` has either has associated `X` and `Y` matrices that locate each value in `Z` at the intersection of a row and a column, or these are inferred when they are unspecified. The width of rows and columns can vary, but typically is constant (i.e. `Z` is a regular grid).

Set the current level, `c`, equal to the lowest contour level to be plotted within the range `[min(Z) max(Z)]`. The contouring algorithm checks each edge of every square in the grid to see if `c` is between the two *z*-values for the edge points. If so, then a contour at that level crosses the edge, and a linear interpolation is performed:

`t=(c-Z0)/(Z1-Z0)`, where `Z0` is the *z*-value at one edge point, and `Z1` is the *z*-value at the other edge point.

Start indexing a new contour line (`i = 1`) for level `c` by interpolating *x* and *y*:

```
cx(i) = X0+t*(X1-X0)
cy(i) = Y0+t*(Y1-Y0)
```

Walk around the edges of the square just entered; the next edge with *z*-values that bracket `c` is where the contour exits. Increment `i`, compute `t` for the edge, and then `cx(i)` and `cy(i)`, as above.

Mark the square as having been visited. Keep checking the edges of each square entered to determine the exit edge until the line`(cx,cy)` closes on its initial point or exits the grid. If the square being entered is already marked, the contour line closes there. Copy `cx`, `cy`, `c`, and `i` to the contour line data structure (the matrix returned by contouring functions, described below).

Reinitialize `cx`, `cy`, and `i`. Move to an unmarked square and test its edges for intersections; when you find one at level `c`, repeat the above operations. Any number of contour lines can exist for a given level.

Clear all the markers, increment the contour level, and repeat until `c` exceeds `max(Z)`.

Extra logic is needed for squares where a contour passes through all four edges (saddle points) to determine which pairs of edges to connect.

`contour`, `contour3`, and `contourf` return a two-row matrix specifying all the contour lines. The format of the matrix is

```
C = [    value1    xdata(1)    xdata(2)...
         numv      ydata(1)    ydata(2)...]
```

The first row of the column that begins each definition of a contour line contains the value of the contour, as specified by `v` and used by `clabel`. Beneath that value is the number of (x,y) vertices in the contour line. Remaining columns contain the data for the (x,y) pairs. For example, the contour matrix calculated by `C = contour(peaks(3))` is

Three vertices at v = −0.2

Three vertices at v = 0

Five vertices at v = 0.8

```

Column 36
 2.0000
 2.2657
```

The circled values begin each definition of a contour line.

Changing the Offset of a Contour

The `surfc` and `meshc` functions display contours beneath a surface or a mesh plot. These functions draw the contour plot at the axes' minimum z-axis limit.

To specify your own offset, you must change the `ZData` values of the contour lines. First, save the handles of the graphics objects created by `meshc` or `surfc`.

```
h = meshc(peaks(20));
```

The first handle belongs to the mesh or surface. The remaining handles belong to the contours you want to change. To raise the contour plane, increment the *z* coordinate of each contour line by some amount by resetting its `Zdata` value:

```
for i = 2:length(h);
    newz = get(h(i),'Zdata') + 5;
    set(h(i),'Zdata',newz)
end
```

Displaying Contours in Polar Coordinates

You can contour data defined in the polar coordinate system. As an example, set up a grid in polar coordinates and convert the coordinates to Cartesian coordinates.

```
[th,r] = meshgrid((0:5:360)*pi/180,0:.05:1);
[X,Y] = pol2cart(th,r);
```

Then generate the complex matrix `Z` on the interior of the unit circle.

```
Z = X+i*Y;
```

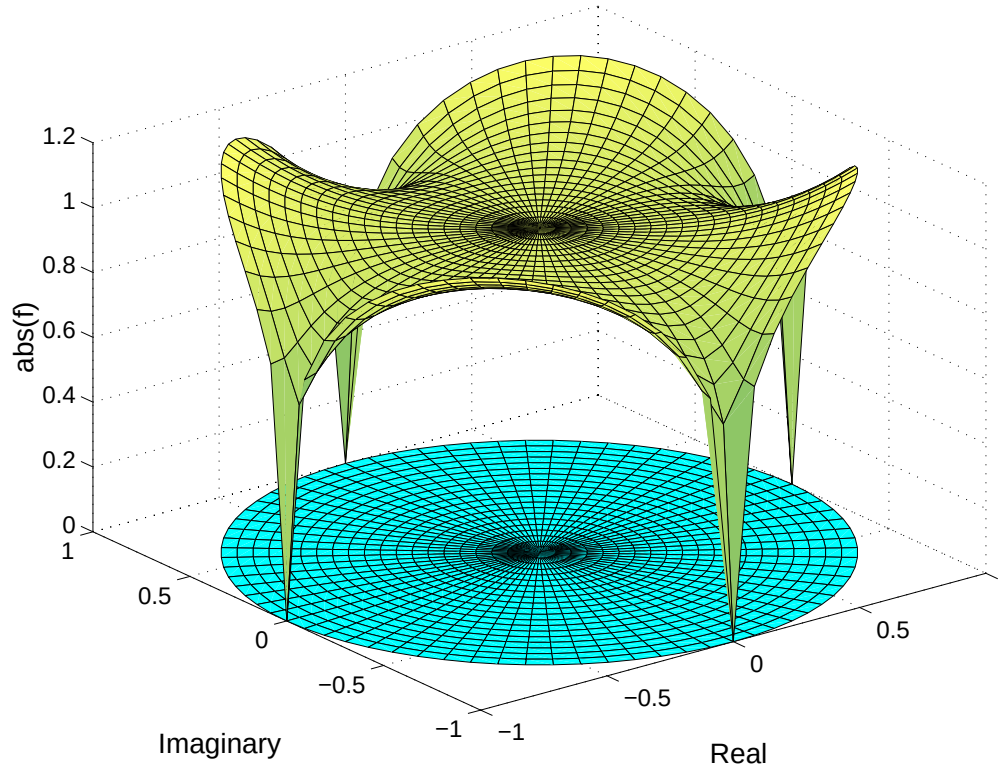
`X`, `Y`, and `Z` are points inside the circle.

Create and display a surface of the function $\sqrt[4]{Z^4 - 1}$.

```
f = (Z.^4-1).^(1/4);
surf(X,Y,abs(f))
```

Display the unit circle beneath the surface using the statements

```
hold on
surf(X,Y,zeros(size(X)))
hold off
```



Labeling the Graph

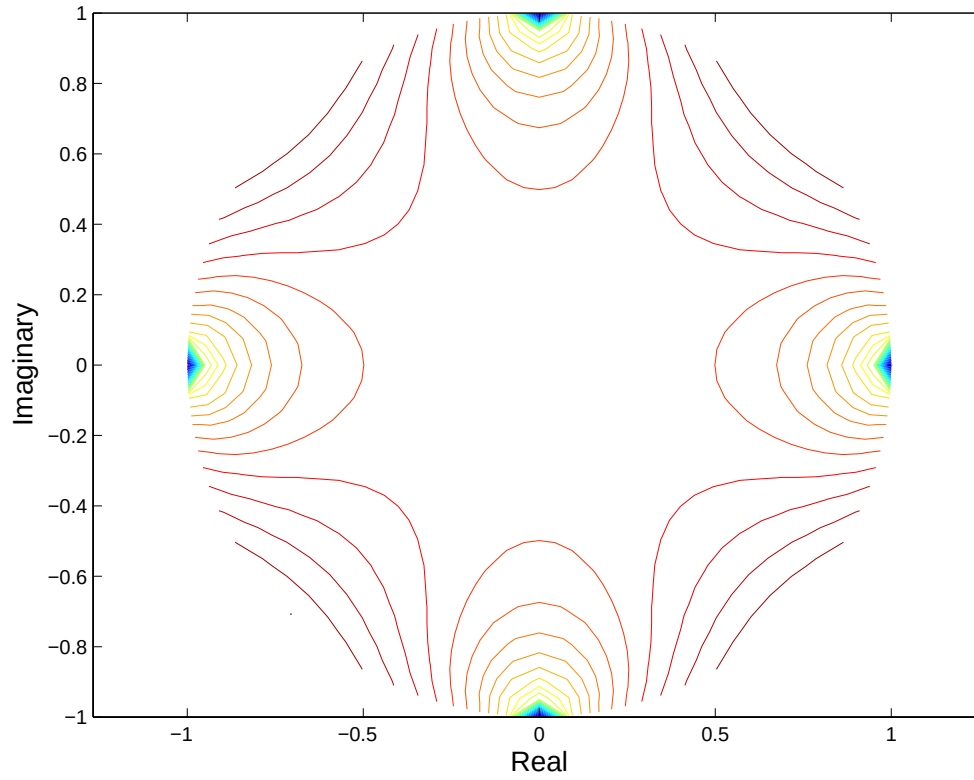
These statements add labels.

```
xlabel('Real','FontSize',14);
ylabel('Imaginary','FontSize',14);
zlabel('abs(f)','FontSize',14);
```

Contours in Cartesian Coordinates

These statements display a contour of the surface in Cartesian coordinates and label the *x*- and *y*-axis.

```
contour(X,Y,abs(f),30)
axis equal
xlabel('Real','FontSize',14);
ylabel('Imaginary','FontSize',14);
```



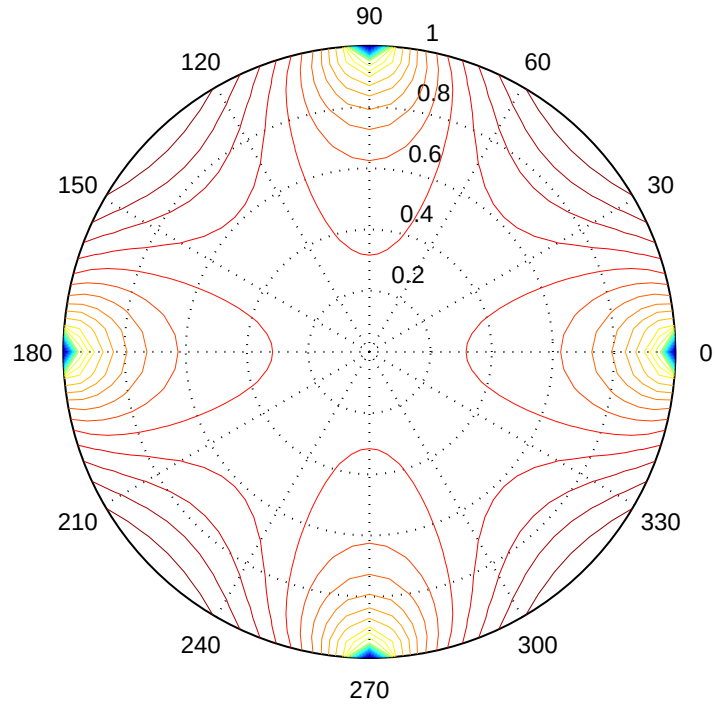
Contours on a Polar Axis

You can also display the contour within a polar axes. Create a polar axes using the `polar` function, and then delete the line specified with `polar`.

```
h = polar([0 2*pi], [0 1]);
delete(h)
```

With `hold on`, display the contour on the polar grid.

```
hold on
contour(X,Y,abs(f),30)
```



Preparing Data for Contouring

The various *contour* plotting functions, as well as the *mesh* and *surface* families of functions, accept 2-D matrices as inputs. For most applications, these input grids will represent continuous functions of two variables or relatively continuous fields of data. In many applications, source data might consist of *z*-values sampled over a two-dimensional domain in an irregular fashion, such as discrete spot elevations from GPS measurements (in the form of *x*, *y*, and *z* data vectors). To prepare such data for contour or mesh display, you need to *interpolate* it in some fashion.

MATLAB provides methods for interpolating data into vectors, grids and triangulated (Delaunay) tessellations. Input observations can be one-, two-, three- or higher-dimensional. By choosing and using these functions carefully you can control parameters and constraints for interpolation to model your assumptions about the underlying nature of the raw data. Typically, you would use the `interp2`, `meshgrid`, and `griddata` functions to interpolate *z*-values for scattered *x*-*y* data points into a 2-D grid. See "Interpolation" in the MATLAB Mathematics documentation for discussion and examples of data interpolation using these and other functions.

If the surface you are contouring is "noisy," contours depicting it will exhibit jaggedness. When you analyze and explore such data, you can filter it to attentuate high-frequency variations. One way to do this is with a convolution (with `conv2` or `filter2`) filter, as the following example demonstrates:

Example — Smoothing a Matrix for Plotting Contours

The `conv2` and `filter` functions can remove high-frequency components from a matrix representing a continuous surface or field to make the underlying data easier to visualize. This requires few assumptions

1. Create a function of two variables and plot contour lines at a specified, fixed interval.

```
Z = peaks(100);
figure;
set (gcf,'position',[400,100,600,600], 'color','w')
subplot(2,2,1);
cl = [-7:1:10];         % Define contour levels for all plots
contour(Z, cl)
```

```
axis([0 100 0 100]); colormap autumn;
set(gca,'Xtick',[0 100],'Ytick',[0 100]);
title('Peaks Surface (underlying data)')
```

2. Add uniform random noise with mean of 0 to the surface and plot resulting contours. Irregularities in the contours tend to obscure the trend of the data:

```
ZN = Z + rand(100) - .5;
subplot (2,2,2)
contour(ZN, cl)
axis([0 100 0 100]);
set(gca,'Xtick',[0 100],'Ytick',[0 100]);
title('Peaks Surface (noise added)')
```

3. Specify a 3x3 convolution kernal, `F`, for smoothing the matrix and use the `conv2` function to attenuate high spatial frequencies in the surface data:

```
F = [.05 .1 .05; .1 .4 .1; .05 .1 .05];
ZC = conv2(ZN,F,'same');
```

4. Visually compare the smoothed surface to the original and the noisy ones:

```
subplot (2,2,3)
contour(ZC, cl)
axis([0 100 0 100]);
set(gca,'Xtick',[0 100],'Ytick',[0 100]);
title('Noisy Surface (smoothed once)')
```

5. Smooth the surface one more time using the same operator and compare (a larger or more uniform kernal could have achieved this in one pass):

```
ZC2 = conv2(ZC,F,'same');
subplot (2,2,4)
contour(ZC2, cl)
axis([0 100 0 100]);
set(gca,'Xtick',[0 100],'Ytick',[0 100]);
title('Noisy Surface (smoothed twice)')
```

Interactive Plotting

Example — Selecting Plotting Points from the Screen

You can interact with graphs or generate *x-y* coordinates interactively. The `ginput` function enables you to use the mouse or the arrow keys to select points to plot. `ginput` returns the coordinates of the pointer's position, either the current position or the position when a mouse button or key is pressed. See the `ginput` function for more information. You can use it to pick points on a graph to return their *x* and *y* values for processing, to outline an area of interest, or to draw arbitrary shapes.

This example illustrates the use of `ginput` with the `spline` function to create a curve by interpolating in two dimensions.

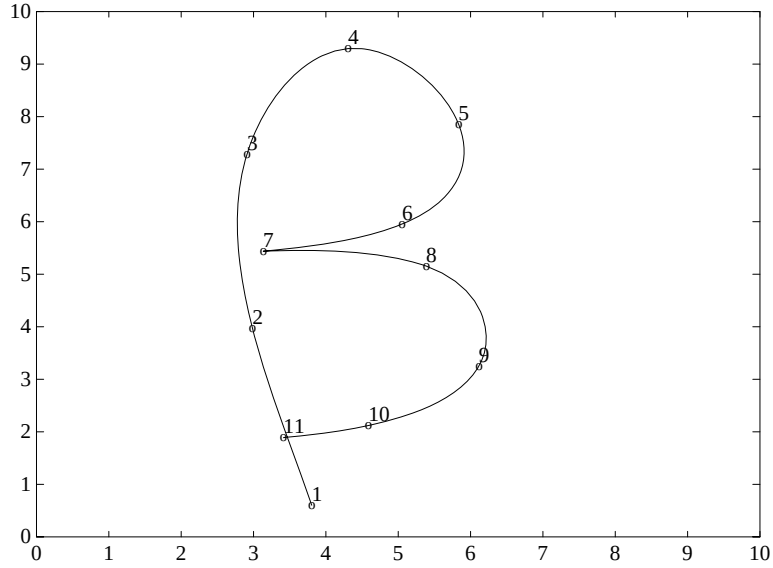
First, select a sequence of points, `[x,y]`, in the plane with `ginput`. Then pass two one-dimensional splines through the points, evaluating them with a spacing one-tenth of the original spacing.

```
axis([0 10 0 10])
hold on
% Initially, the list of points is empty.
xy = [];
n = 0;
% Loop, picking up the points.
disp('Left mouse button picks points.')
disp('Right mouse button picks last point.')
but = 1;
while but == 1
    [xi,yi,but] = ginput(1);
    plot(xi,yi,'ro')
    n = n+1;
    xy(:,n) = [xi;yi];
end
% Interpolate with a spline curve and finer spacing.
t = 1:n;
ts = 1: 0.1: n;
xys = spline(t,xy,ts);

% Plot the interpolated curve.
```

```
plot(xys(1,:),xys(2,:),'b-');
hold off
```

This plot shows some typical output.



Animation

In this section...

Ways to Animate Plots

You can create animated sequences with MATLAB in two different ways:

- Save a number of different pictures and then play them back as a movie.
- Continually erase and then redraw the objects on the screen, making incremental changes with each redraw.

Movies are better suited to situations where each frame is fairly complex and cannot be redrawn rapidly. You create each movie frame in advance so the original drawing time is not important during playback, which is just a matter of blitting the frame to the screen. A movie is not rendered in real time; it is simply a playback of previously rendered frames.

The second technique, drawing, erasing, and then redrawing, makes use of different drawing modes supported by MATLAB. These modes allow faster redrawing at the expense of some rendering accuracy, so you must consider which mode to select.

This section provides an example of each technique. To see more sophisticated demonstrations of these features, type `demo` at the MATLAB prompt and explore the animation demonstrations.

Movies

You can save any sequence of graphs and then play the sequence back in a short *movie*. There are two steps to this process:

- Use `getframe` to generate each movie frame. Be sure that your computer is not in screen saver mode when `getframe` is called, and in the event that you are using several virtual desktops, that the one on which MATLAB is running is visible on your monitor.
- Use `movie` to run the movie a specified number of times at the specified rate.

Typically, you use `getframe` in a `for` loop to assemble the array of movie frames. `getframe` returns a structure having the following fields:

- `cdata` — Image data in a `uint8` matrix. The matrix has dimensions of height-by-width on indexed-color systems and height-by-width-by-3 on truecolor systems.
- `colormap` — The colormap in an n-by-3 matrix, where n is the number of colors. On truecolor systems, the `colormap` field is empty.

See `image` for more information on images.

Example — Visualizing an FFT as a Movie

This example illustrates the use of movies to visualize the quantity `fft(eye(n))`, which is a complex *n*-by-*n* matrix whose elements are various powers of the nth root of unity, `exp(i*2*pi/n)`.

Creating the Movie

Create the movie in a `for` loop calling `getframe` to capture the graph. Since the `plot` command resets the axes properties, call `axis equal` within the loop before `getframe`.

```
for k = 1:16
 plot(fft(eye(k+16)))
 axis equal
 M(k) = getframe;
end
```

Running the Movie

After generating the movie, you can play it back any number of times. To play it back 30 times, type

```
movie(M,30)
```

You can readily generate and smoothly play back movies with a few dozen frames on most computers. Longer movies require large amounts of primary memory or a very effective virtual memory system.

Movies that Include the Entire Figure

If you want to capture the contents of the entire figure window (for example, to include GUI components in the movie), specify the figure's handle as an argument to the `getframe` command. For example, suppose you want to add a slider to indicate the value of `k` in the previous example.

```
h = uicontrol('style','slider','position',...
 [10 50 20 300],'Min',1,'Max',16,'Value',1)
for k = 1:16
 plot(fft(eye(k+16)))
 axis equal
 set(h,'Value',k)
 M(k) = getframe(gcf);
end
```

In this example, the movie frame contains the entire figure. To play so that it looks like the original figure, make the playback axes fill the figure window.

```
clf
axes('Position',[0 0 1 1])
movie(M,30)
```

Erase Modes

You can select the method MATLAB uses to redraw graphics objects. One event that causes MATLAB to redraw an object is changing the properties of that object. You can take advantage of this behavior to create animated sequences. A typical scenario is to draw a graphics object, then change its position by respecifying the *x*-, *y*,- and *z*-coordinate data by a small amount with each pass through a loop.

You can create different effects by selecting different erase modes. This section illustrates how to use the three modes that are useful for dynamic redrawing:

- `none` — MATLAB does not erase the objects when it is moved.
- `background` — MATLAB erases the object by redrawing it in the background color. This mode erases the object and anything below it (such as grid lines).
- `xor` — This mode erases only the object and is usually used for animation.

All three modes are faster (albeit less accurate) than the normal mode used by MATLAB.

Example — Animating with Erase Modes

It is often interesting and informative to see 3-D trajectories develop in time. This example involves chaotic motion described by a nonlinear differential equation known as the Lorenz strange attractor. It can be written in the form $\frac{dy}{dt} = Ay$

with a vector-valued function *y(t)* and a matrix *A* that depends upon *y*.

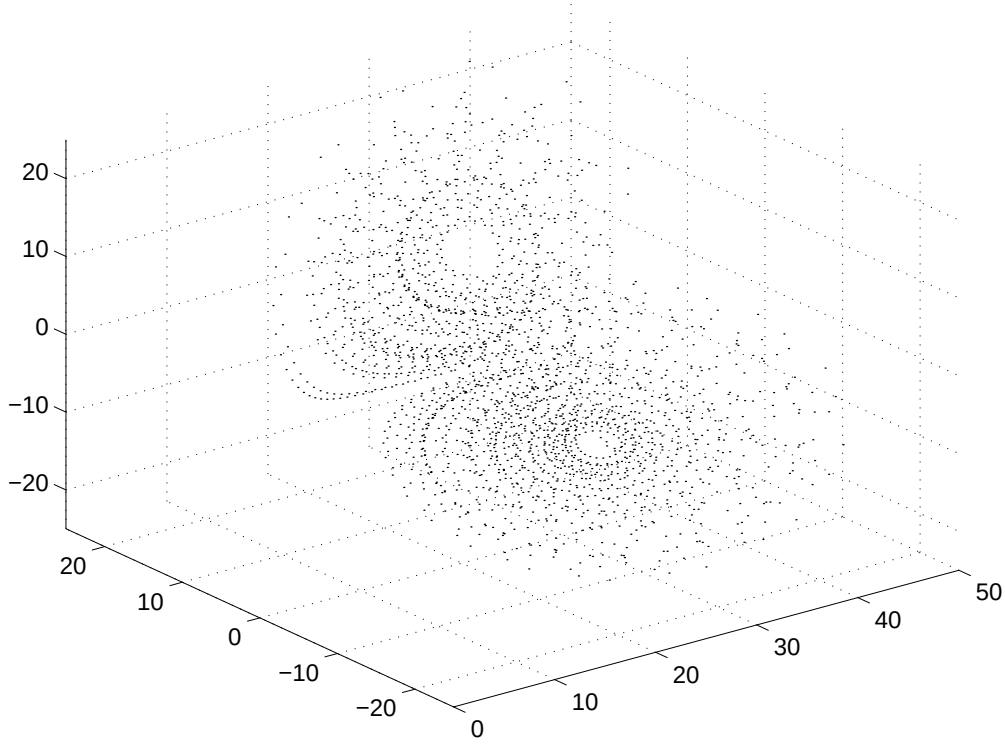
$$A(y) = \begin{bmatrix} -\frac{8}{3} & 0 & y(2) \\ 0 & -10 & 10 \\ -y(2) & 28 & -1 \end{bmatrix}$$

The solution orbits about two different attractive points without settling into a steady orbit about either. This example approximates the solution with the simplest possible numerical method — Euler's method with fixed step size. The result is not very accurate, but it has the same qualitative behavior as other methods.

```
A = [ -8/3 0 0; 0 -10 10; 0 28 -1 ];
y = [35 -10 -7]';
h = 0.01;
p = plot3(y(1),y(2),y(3),'.', ...
    'EraseMode','none','MarkerSize',5); % Set EraseMode to none
axis([0 50 -25 25 -25 25])
hold on
for i=1:4000
    A(1,3) = y(2);
```

```
    A(3,1) = -y(2);
    ydot = A*y;
    y = y + h*ydot;
 % Change coordinates
    set(p,'XData',y(1),'YData',y(2),'ZData',y(3))
    drawnow
end
```

The `plot3` statement sets `EraseMode` to `none`, indicating that the points already plotted should not be erased when the plot is redrawn. In addition, the handle of the plot object is saved. Within the `for` loop, a `set` statement references the plot object and changes its internally stored coordinates for the new location. While this manual cannot show the dynamically evolving output, this picture shows a snapshot.



Note that, as far as MATLAB is concerned, the graph created by this example contains only one dot. What you see on the screen are remnants of previous plots that MATLAB has been instructed not to erase. The only way to print this graph from MATLAB is with a screen capture.

Background Erase Mode. To see the effect of `EraseMode background`, add these statements to the previous program.

```
p = plot3(y(1),y(2),y(3),'square', ...
    'EraseMode','background','MarkerSize',10,...
    'MarkerEdgeColor',[1 .7 .7],'MarkerFaceColor',[1 .7 .7]);
```

```
for i=1:4000
    A(1,3) = y(2);
    A(3,1) = -y(2);
    ydot = A*y;
    y = y + h*ydot;
    set(p,'XData',y(1),'YData',y(2),'ZData',y(3))
    drawnow
end
hold off
```

Since `hold` is still `on`, this code erases the previously created graph by setting the `EraseMode` property to `background` and changing the marker to a "pink eraser" (a square marker colored pink).

Xor Erase Mode. If you change the `EraseMode` of the first `plot3` statement from `none` to `xor`, you will see a moving dot (`Marker '.'`) only. `Xor` mode is used to create animations where you do not want to leave remnants of previous graphics on the screen. However, you should not rely on `Xor` mode to work properly in all situations. Some platforms and graphics subsystems do not support it and where it does work, performance can be much slower compared to other erase modes or animation methods.

Additional Examples

The MATLAB demo `lorenz` provides a more accurate numerical approximation and a more elaborate display of the Lorenz strange attractor example. Other MATLAB demos illustrate animation techniques.

6

Displaying Bit-Mapped Images

Images in MATLAB

In this section...

What Is Image Data?

The basic data structure in MATLAB is the *array*, an ordered set of real or complex elements. This object is naturally suited to the representation of *images*, real-valued, ordered sets of color or intensity data. (MATLAB does not support complex-valued images.)

MATLAB stores most images as two-dimensional arrays (i.e., matrices), in which each element of the matrix corresponds to a single pixel in the displayed image. For example, an image composed of 200 rows and 300 columns of different colored dots would be stored in MATLAB as a 200-by-300 matrix. Some images, such as RGB, require a three-dimensional array, where the first plane in the third dimension represents the red pixel intensities, the second plane represents the green pixel intensities, and the third plane represents the blue pixel intensities.

This convention makes working with graphics file format images in MATLAB similar to working with any other type of matrix data. For example, you can select a single pixel from an image matrix using normal matrix subscripting.

```
I(2,15)
```

This command returns the value of the pixel at row 2, column 15 of the image `I`.

The following sections describe the different data and image types you can use, and give details on how to read, write, work with, and display graphics images; how to alter the display properties and aspect ratio of an image during display; how to print an image; and how to convert the data type or graphics format of an image.

Data Types

MATLAB supports three different numeric classes for image display: double-precision floating-point (`double`), 16-bit unsigned integer (`uint16`), and 8-bit unsigned integer (`uint8`). The image display commands interpret data values differently depending on the numeric class the data is stored in. Details on the inner workings of the storage for 8- and 16-bit images are included in "Working with 8-Bit and 16-Bit Images" on page 6-10.

By default, MATLAB stores most data in arrays of class `double`. The data in these arrays is stored as double-precision (64-bit) floating-point numbers. All MATLAB functions and capabilities work with these arrays.

For images stored in one of the graphics file formats supported by MATLAB, however, this data representation is not always ideal. The number of pixels in such an image can be very large; for example, a 1000-by-1000 image has a million pixels. Since each pixel is represented by at least one array element, this image would require about 8 megabytes of memory if it were stored as class `double`.

To reduce memory requirements, MATLAB supports storing image data in arrays of class `uint8` and `uint16`. The data in these arrays is stored as 8-bit or 16-bit unsigned integers. These arrays require one-eighth or one-fourth as much memory as data in `double` arrays.

Bit Depth

MATLAB supports reading the most commonly used bit depths (bits per pixel) of any of the supported graphics file formats. When the data is in memory, it can be stored as `uint8`, `uint16`, or `double`. For details on which bit depths are appropriate for each supported format, see `imread` and `imwrite`.

Supported Image Formats

MATLAB provides commands for reading, writing, and displaying several types of graphics file formats for images. As with MATLAB-generated images, once a graphics file format image is displayed, it becomes a Handle Graphics image object. MATLAB supports the following graphics file formats, along with others:

- BMP (Microsoft Windows Bitmap)

- GIF (Graphics Interchange Files)
- HDF (Hierarchical Data Format)
- JPEG (Joint Photographic Experts Group)
- PCX (Paintbrush)
- PNG (Portable Network Graphics)
- TIFF (Tagged Image File Format)
- XWD (X Window Dump)

For more information concerning the bit depths and image types supported for these formats, see `imread` and `imwrite`.

Functions for Reading, Writing and Displaying Images

Since images are essentially two-dimensional matrices, many MATLAB functions are capable of operating on and displaying images. The following are the most useful ones, and are discussed in the sections that follow:

Function	Purpose	Function Group
`axis`	Plot axis scaling and appearance	Display
`image`	Display image (create image object)	Display
`imagesc`	Scale data and display as image	Display
`imread`	Read image from graphics file	File I/O
`imwrite`	Write image to graphics file	File I/O
`imfinfo`	Get image information from graphics file	Utility
`ind2rgb`	Convert indexed image to RGB image	Utility

Image Types

In this section...

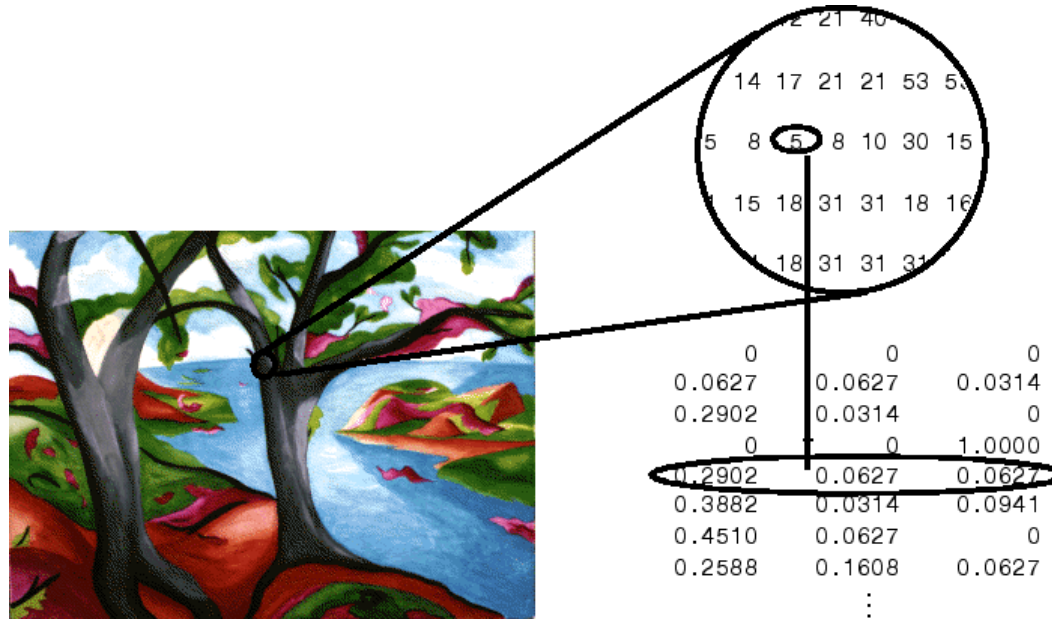
Indexed Images

An indexed image consists of a data matrix, `X`, and a colormap matrix, `map`. `map` is an *m*-by-3 array of class `double` containing floating-point values in the range [0, 1]. Each row of `map` specifies the red, green, and blue components of a single color. An indexed image uses "direct mapping" of pixel values to colormap values. The color of each image pixel is determined by using the corresponding value of `X` as an index into `map`. Values of `X` therefore must be integers. The value 1 points to the first row in `map`, the value 2 points to the second row, and so on. You can display an indexed image with the statements

```
image(X); colormap(map)
```

A colormap is often stored with an indexed image and is automatically loaded with the image when you use the `imread` function. However, you are not limited to using the default colormap — you can use any colormap that you choose. The description for the property `CDataMapping` describes how to alter the type of mapping used.

The next figure illustrates the structure of an indexed image. The pixels in the image are represented by integers, which are pointers (indices) to color values stored in the colormap.

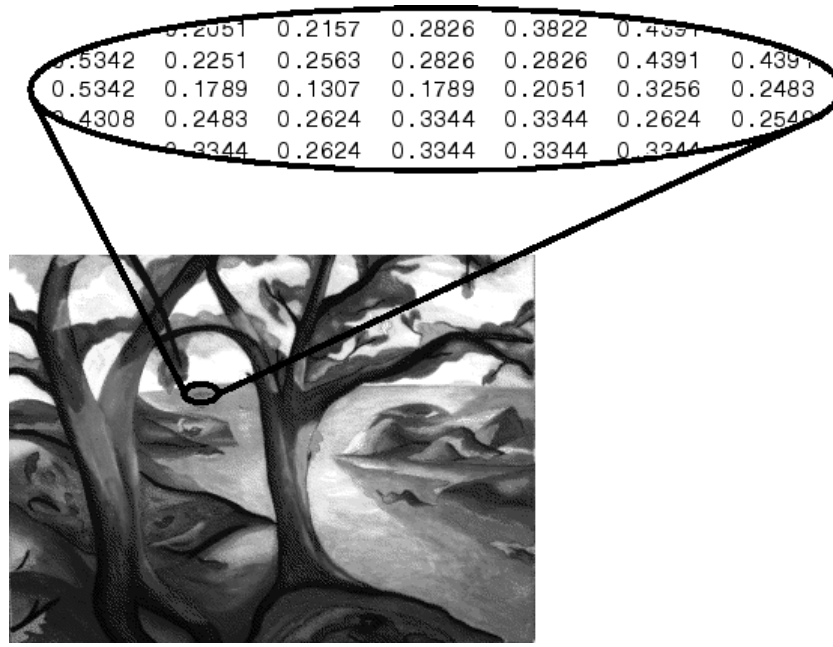


The relationship between the values in the image matrix and the colormap depends on the class of the image matrix. If the image matrix is of class `double`, the value 1 points to the first row in the colormap, the value 2 points to the second row, and so on. If the image matrix is of class `uint8` or `uint16`, there is an offset — the value 0 points to the first row in the colormap, the value 1 points to the second row, and so on. The offset is also used in graphics file formats, to maximize the number of colors that can be supported. In the image above, the image matrix is of class `double`. Because there is no offset, the value 5 points to the fifth row of the colormap.

Intensity Images

An intensity image is a data matrix, `I`, whose values represent intensities within some range. MATLAB stores an intensity image as a single matrix, with each element of the matrix corresponding to one image pixel. The matrix can be of class `double`, `uint8`, or `uint16`. While intensity images are rarely saved with a colormap, MATLAB uses a colormap to display them. In essence, MATLAB handles intensity images as indexed images.

This figure depicts an intensity image of class `double`.



To display an intensity image, use the `imagesc` ("image scale") function, which enables you to set the range of intensity values. `imagesc` scales the image data to use the full colormap. Use the two-input form of `imagesc` to display an intensity image. For example,

```
imagesc(I,[0 1]); colormap(gray);
```

The second input argument to `imagesc` specifies the desired intensity range. The function `imagesc` displays `I` by mapping the first value in the range (usually 0) to the first colormap entry, and the second value (usually 1) to the last colormap entry. Values in between are linearly distributed throughout the remaining colormap colors.

Although it is conventional to display intensity images using a grayscale colormap, it is possible to use other colormaps. For example, the following statements display the intensity image `I` in shades of blue and green.

```
imagesc(I,[0 1]); colormap(winter);
```

To display a matrix `A` with an arbitrary range of values as an intensity image, use the single-argument form of `imagesc`. With one input argument, `imagesc` maps the minimum value of the data matrix to the first colormap entry, and maps the maximum value to the last colormap entry. For example, these two lines are equivalent.

```
imagesc(A); colormap(gray)
imagesc(A,[min(A(:)) max(A(:))]); colormap(gray)
```

RGB (Truecolor) Images

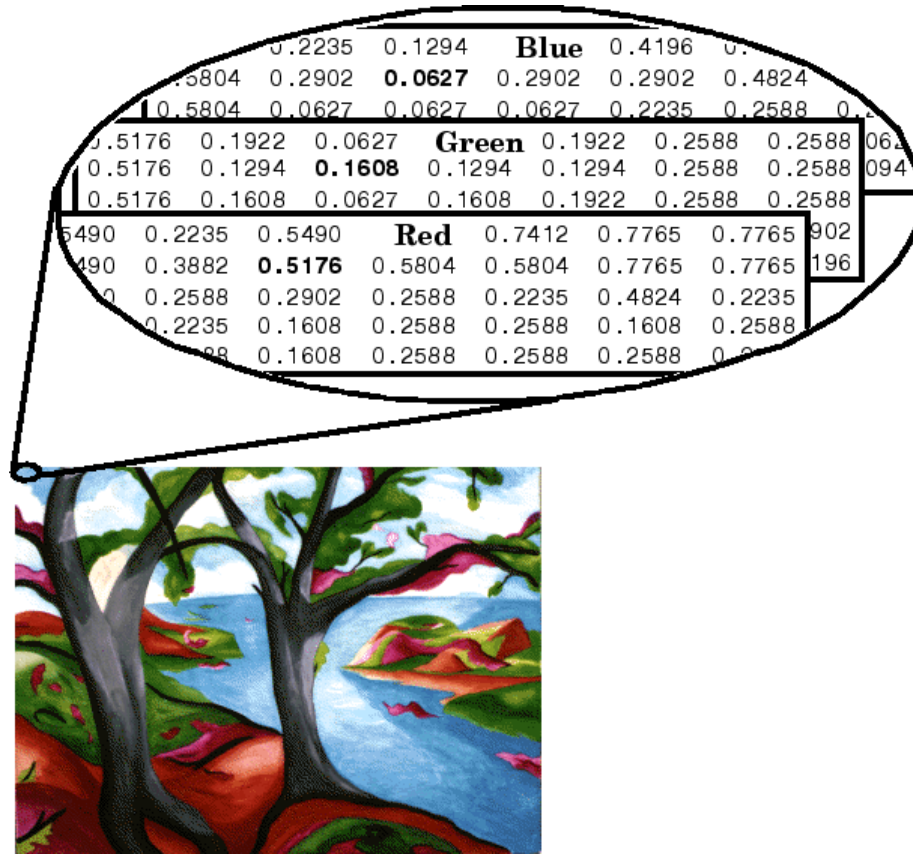
An RGB image, sometimes referred to as a "truecolor" image, is stored in MATLAB as an *m*-by-*n*-by-3 data array that defines red, green, and blue color components for each individual pixel. RGB images do not use a palette. The color of each pixel is determined by the combination of the red, green, and blue intensities stored in each color plane at the pixel's location. Graphics file formats store RGB images as 24-bit images, where the red, green, and blue components are 8 bits each. This yields a potential of 16 million colors. The precision with which a real-life image can be replicated has led to the nickname "truecolor image."

An RGB MATLAB array can be of class `double`, `uint8`, or `uint16`. In an RGB array of class `double`, each color component is a value between 0 and 1. A pixel whose color components are (0,0,0) is displayed as black, and a pixel whose color components are (1,1,1) is displayed as white. The three color components for each pixel are stored along the third dimension of the data array. For example, the red, green, and blue color components of the pixel (10,5) are stored in `RGB(10,5,1)`, `RGB(10,5,2)`, and `RGB(10,5,3)`, respectively.

To display the truecolor image `RGB`, use the `image` function. For example,

```
image(RGB)
```

The next figure shows an RGB image of class `double`.



To determine the color of the pixel at (2,3), you would look at the RGB triplet stored in (2,3,1:3). Suppose (2,3,1) contains the value `0.5176`, (2,3,2) contains `0.1608`, and (2,3,3) contains `0.0627`. The color for the pixel at (2,3) is

```
0.5176 0.1608 0.0627
```

Working with 8-Bit and 16-Bit Images

In this section...

8-Bit and 16-Bit Indexed Images

MATLAB usually works with double-precision (64-bit) floating-point numbers. However, to reduce memory requirements for working with images, MATLAB provides support for storing images as 8-bit or 16-bit unsigned integers by using the numeric classes `uint8` or `uint16`, respectively. An image whose data matrix has class `uint8` is called an 8-bit image; an image whose data matrix has class `uint16` is called a 16-bit image.

The `image` function can display 8- or 16-bit images directly without converting them to double precision. However, `image` interprets matrix values slightly differently when the image matrix is `uint8` or `uint16`. The specific interpretation depends on the image type.

If the class of `X` is `uint8` or `uint16`, its values are offset by 1 before being used as colormap indices. The value 0 points to the first row of the colormap, the value 1 points to the second row, and so on. The `image` command automatically supplies the proper offset, so the display method is the same whether `X` is `double`, `uint8`, or `uint16`.

```
image(X); colormap(map);
```

The colormap index offset for `uint8` and `uint16` data is intended to support standard graphics file formats, which typically store image data in indexed form with a 256-entry colormap. The offset allows you to manipulate and

display images of this form in MATLAB using the more memory-efficient `uint8` and `uint16` arrays.

Because of the offset, you must add 1 to convert a `uint8` or `uint16` indexed image to `double`. For example,

```
X64 = double(X8) + 1;
 or
X64 = double(X16) + 1;
```

Conversely, subtract 1 to convert a `double` indexed image to `uint8` or `uint16`.

```
X8 = uint8(X64 - 1);
 or
X16 = uint16(X64 - 1);
```

8-Bit and 16-Bit Intensity Images

Whereas the range of `double` image arrays is usually [0, 1], the range of 8-bit intensity images is usually [0, 255] and the range of 16-bit intensity images is usually [0, 65535]. Use the following command to display an 8-bit intensity image with a grayscale colormap.

```
imagesc(I,[0 255]); colormap(gray);
```

To convert an intensity image from `double` to `uint16`, first multiply by 65535.

```
I16 = uint16(round(I64*65535));
```

Conversely, divide by 65535 after converting a `uint16` intensity image to `double`.

```
I64 = double(I16)/65535;
```

8-Bit and 16-Bit RGB Images

The color components of an 8-bit RGB image are integers in the range [0, 255] rather than floating-point values in the range [0, 1]. A pixel whose color components are (255,255,255) is displayed as white. The `image` command displays an RGB image correctly whether its class is `double`, `uint8`, or `uint16`.

```
image(RGB);
```

To convert an RGB image from `double` to `uint8`, first multiply by 255.

```
RGB8 = uint8(round(RGB64*255));
```

Conversely, divide by 255 after converting a `uint8` RGB image to `double`.

```
RGB64 = double(RGB8)/255
```

To convert an RGB image from `double` to `uint16`, first multiply by 65535.

```
RGB16 = uint16(round(RGB64*65535));
```

Conversely, divide by 65535 after converting a `uint16` RGB image to `double`.

```
RGB64 = double(RGB16)/65535;
```

Mathematical Operations Support for uint8 and uint16

To use the following MATLAB functions with `uint8` and `uint16` data, first convert the data to type `double`: `conv2`, `convn`, `fft2`, `fftn`. For example, if `X` is a `uint8` image, cast the data to type `double`:

```
fft(double(X))
```

In these cases, the output is always `double`.

The `sum` function returns results in the same type as its input, but provides an option to use double precision for calculations.

Integer Mathematics in MATLAB

See "Arithmetic Operations on Integer Data Types" for more information on how mathematical functions work with data types that are not doubles.

Most of the functions in Image Processing Toolbox accept `uint8` and `uint16` input. If you plan to do sophisticated image processing on `uint8` or `uint16` data, you should consider adding Image Processing Toolbox to your MATLAB computing environment.

Other 8-Bit and 16-Bit Array Support

MATLAB supports several other operations on `uint8` and `uint16` arrays, including

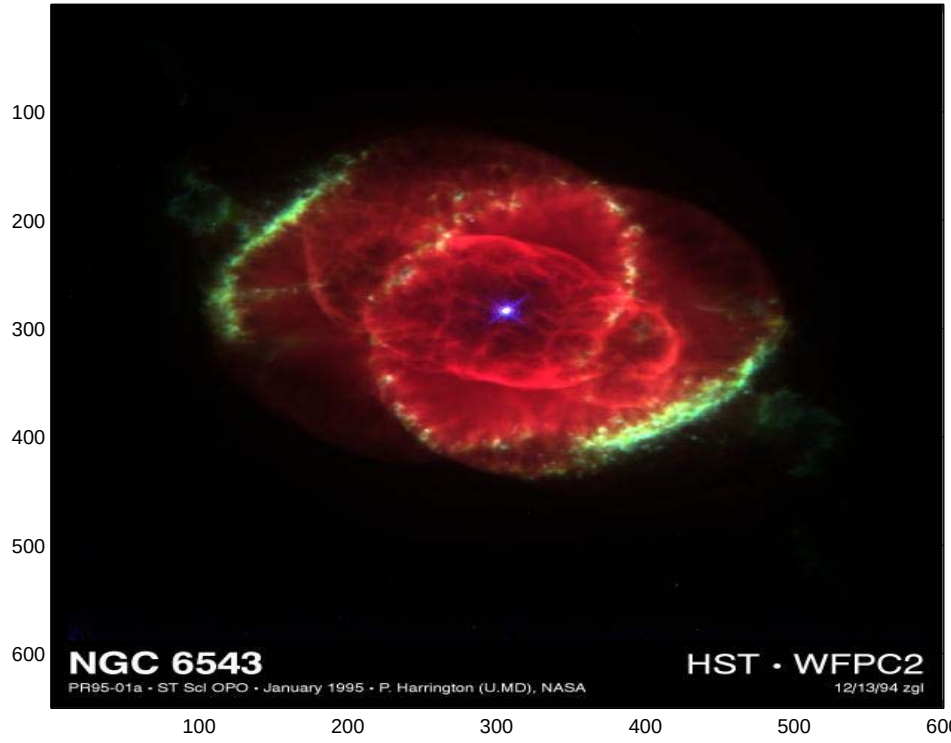
- Reshaping, reordering, and concatenating arrays using the functions `reshape`, `cat`, `permute`, and the `[]` and `'` operators
- Saving and loading `uint8` and `uint16` arrays in MAT-files using `save` and `load`. (Remember that if you are loading or saving a graphics file format image, you must use the commands `imread` and `imwrite` instead.)
- Locating the indices of nonzero elements in `uint8` and `uint16` arrays using `find`. However, the returned array is always of class `double`.
- Relational operators

Converting an 8-Bit RGB Image to Grayscale

MATLAB can perform arithmetic operations on integer data, which enables you to convert image types without first converting the numeric class of the image data.

This example reads an 8-bit RGB image into MATLAB and converts it to a grayscale image.

```
rgb_img = imread('ngc6543a.jpg'); % Load the image
image(rgb_img) % Display the RGB image
```



Now calculate the monochrome luminance by combining the RGB values according to the NTSC standard, which applies coefficients related to the eye's sensitivity to RGB colors.

```
I = .2989*rgb_img(:,:,1)...
 +.5870*rgb_img(:,:,2)...
 +.1140*rgb_img(:,:,3);
```

`I` is an intensity image with integer values ranging from a minimum of zero,

```
min(I(:))
ans =
```

```
    0
```

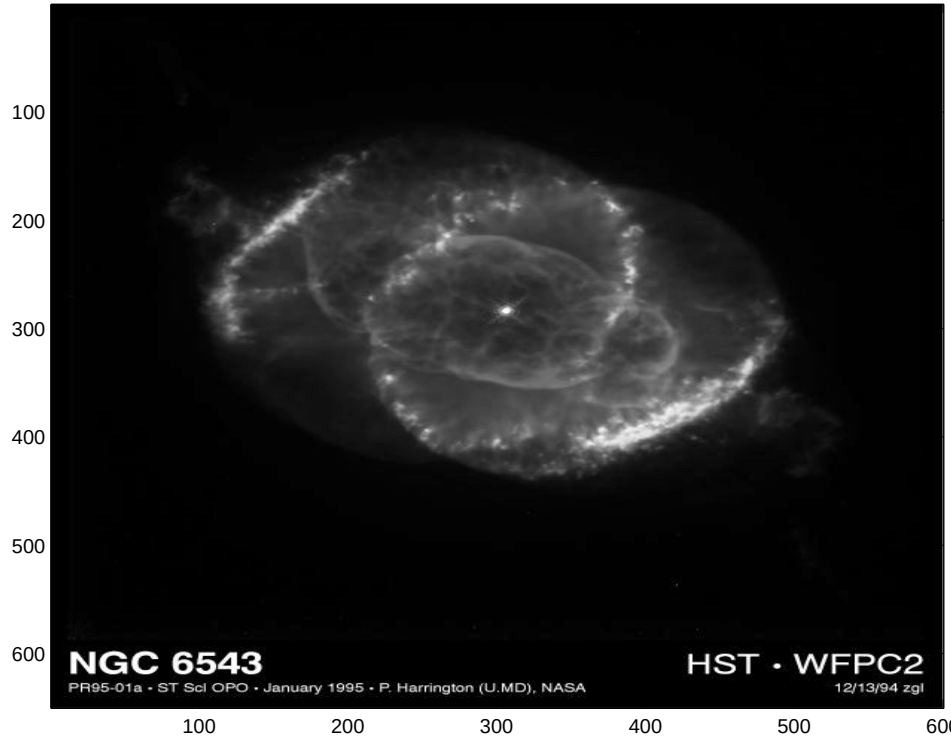
to a maximum of 255,

```
max(I(:))
ans =
 255
```

To display the image, use a grayscale colormap with 256 values. This avoids the need to scale the data-to-color mapping, which would be required if you used a colormap of a different size. You can use the `imagesc` function in cases where the colormap does not contain one entry for each data value.

Now display the image in a new figure using the gray colormap.

```
figure; colormap(gray(256)); image(I)
```



Related Information

Other colormaps with a range of colors that vary continuously from dark to light can produce usable images. For example, try `colormap(summer(256))` for a classic oscilloscope look. See `colormap` for more choices.

The `brighten` function enables you to increase or decrease the color intensities in a colormap to compensate for computer display differences or to enhance the visibility of faint or bright regions of the image (at the expense of the opposite end of the range).

Summary of Image Types and Numeric Classes

This table summarizes the way MATLAB interprets data matrix elements as pixel colors, depending on the image type and data class.

Image Type	double Data	uint8 or uint16 Data
Indexed	Image is an m-by-n array of integers in the range $[1, p]$. Colormap is a p-by-3 array of floating-point values in the range [0, 1].	Image is an m-by-n array of integers in the range $[0, p - 1]$. Colormap is a p-by-3 array of floating-point values in the range [0, 1].
Intensity	Image is an m-by-n array of floating-point values that are linearly scaled by MATLAB to produce colormap indices. Typical range of values is [0, 1]. Colormap is a p-by-3 array of floating-point values in the range [0, 1] and is typically grayscale.	Image is an m-by-n array of integers that are linearly scaled by MATLAB to produce colormap indices. The typical range of values is [0, 255] or [0, 65535]. Colormap is a p-by-3 array of floating-point values in the range [0, 1] and is typically grayscale.
RGB (Truecolor)	Image is an m-by-n-by-3 array of floating-point values in the range [0, 1].	Image is an m-by-n-by-3 array of integers in the range [0, 255] or [0, 65535].

Reading, Writing, and Querying Graphics Image Files

In this section...

Working with Image Formats

In its native form, a graphics file format image is not stored as a MATLAB matrix, or even necessarily as a matrix. Most graphics files begin with a header containing format-specific information tags, and continue with bitmap data that can be read as a continuous stream. For this reason, you cannot use the standard MATLAB I/O commands `load` and `save` to read and write a graphics file format image.

MATLAB provides special functions for reading and writing image data from graphics file formats. To read a graphics file format image use `imread`; to write a graphics file format image, use `imwrite`; to obtain information about the nature of a graphics file format image, use `imfinfo`.

This table gives a clearer picture of which MATLAB commands should be used with which image types.

Procedure	Functions to Use
Load or save a matrix as a MAT-file	`load` `save`
Load or save graphics file format image, e.g. BMP, TIFF	`imread` `imwrite`

Procedure	Functions to Use
Display any image loaded into MATLAB	`image` `imagesc`
Utilities	`imfinfo` `ind2rgb`

Reading a Graphics Image

The function `imread` reads an image from any supported graphics image file in any of the supported bit depths. Most of the images that you will read are 8-bit. When these are read into memory, MATLAB stores them as class `uint8`. The main exception to this rule is that MATLAB supports 16-bit data for PNG and TIFF images. If you read a 16-bit PNG or TIFF image, it is stored as class `uint16`.

Note For indexed images, `imread` always reads the colormap into an array of class `double`, even though the image array itself can be of class `uint8` or `uint16`.

The following statement reads the image `ngc6543a.jpg` into the workspace variable `RGB` and then displays the image using the `image` function.

```
RGB = imread('ngc6543a.jpg');
image(RGB)
```

You can write (save) image data using the `imwrite` function. The statements

```
load clown % An image that is included with MATLAB
imwrite(X,map,'clown.bmp')
```

create a BMP file containing the clown image.

Writing a Graphics Image

When you save an image using `imwrite`, the default behavior is to automatically reduce the bit depth to `uint8`. Many of the images used in

MATLAB are 8-bit, and most graphics file format images do not require double-precision data. One exception to the MATLAB rule for saving the image data as `uint8` is that PNG and TIFF images can be saved as `uint16`. Because these two formats support 16-bit data, you can override the MATLAB default behavior by specifying `uint16` as the data type for `imwrite`. The following example shows writing a 16-bit PNG file using `imwrite`.

```
imwrite(I,'clown.png','BitDepth',16);
```

Subsetting a Graphics Image (Cropping)

Sometimes you want to work with only a portion of an image file or would like to break it up into subsections. You can specify the pixel coordinates of the rectangular subsection you want to work with and save it to a file from the command line. If you do not know the coordinates of the corner points of the subsection, you can choose them interactively, as the following example shows:

```
% Read demo RGB image from graphics file.
im = imread('street2.jpg');

% Display image with true aspect ratio
image(im); axis image

% Use ginput to select corner points of a rectangular
% region by pointing and clicking the mouse twice
p = ginput(2);

% Get the x and y corner coordinates as integers
sp(1) = min(floor(p(1)), floor(p(2))); %xmin
sp(2) = min(floor(p(3)), floor(p(4))); %ymin
sp(3) = max(ceil(p(1)), ceil(p(2)));   %xmax
sp(4) = max(ceil(p(3)), ceil(p(4)));   %ymax

% Index into the original image to create the new image
MM = im(sp(2):sp(4), sp(1): sp(3),:);

% Display the subsetted image with appropriate axis ratio
figure; image(MM); axis image

% Write image to graphics file.
imwrite(MM,'street2_cropped.tif')
```

If you knew what the image corner coordinates should be, you could manually define `sp` in the above example rather than using `ginput`.

You can also make MATLAB display a "rubber band box" as you interact with the image to subset it. See the code example for `rbbox` for details. For further information, see the documentation for the MATLAB functions `ginput` and `image`.

Obtaining Information About Graphics Files

The `imfinfo` function enables you to obtain information about graphics files in any of the standard formats listed above. The information you obtain depends on the type of file, but it always includes at least the following:

- Name of the file, including the directory path if the file is not in the current directory
- File format
- Version number of the file format
- File modification date
- File size in bytes
- Image width in pixels
- Image height in pixels
- Number of bits per pixel
- Image type: RGB (truecolor), intensity (grayscale), or indexed

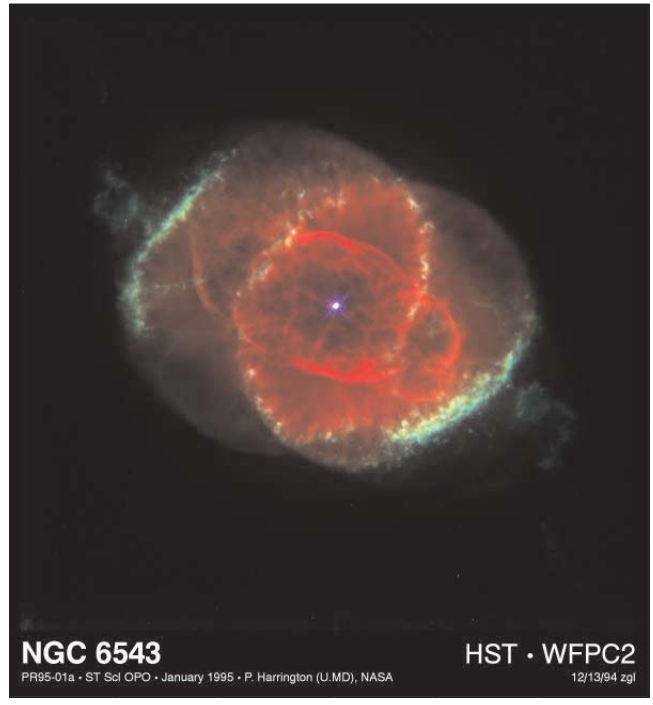
Displaying Graphics Images

In this section...

Summary of Image Types and Display Methods

To display a graphics file image, use either `image` or `imagesc`. For example, assuming `RGB` is an image,

```
figure('Position',[100 100 size(RGB,2) size(RGB,1)]);
image(RGB); set(gca,'Position',[0 0 1 1])
```



(This image was created with the support of the Space Telescope Science Institute, operated by the Association of Universities for Research in

Astronomy, Inc., from NASA contract NAs5-26555, and is reproduced with permission from AURA/STScI. Digital renditions of images produced by AURA/STScI are obtainable royalty-free. Credits: J.P. Harrington and K.J. Orkowski (University of Maryland), and NASA.)

This table summarizes display methods for the three types of images.

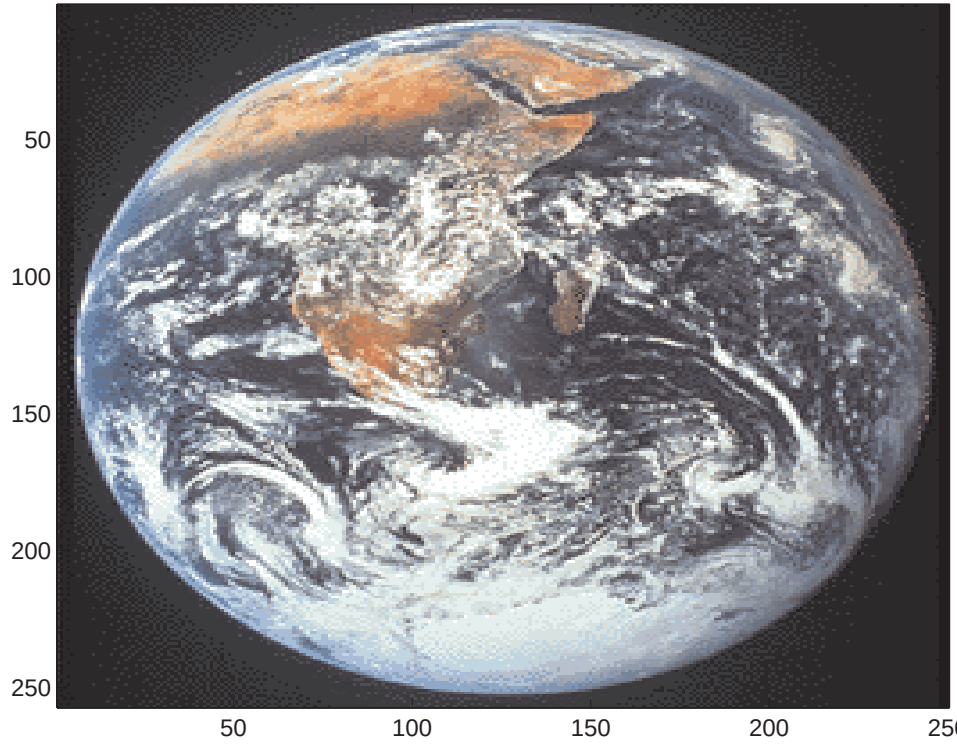
Image Type	Display Commands	Uses Colormap Colors
Indexed	`image(X);` `colormap(map)`	`Yes`
Intensity	`imagesc(I,[0 1]);` `colormap(gray)`	`Yes`
RGB (truecolor)	`image(RGB)`	`No`

Controlling Aspect Ratio and Display Size

The `image` function displays the image in a default-sized figure and axes. MATLAB stretches or shrinks the image to fit the display area. Sometimes you want the aspect ratio of the display to match the aspect ratio of the image data matrix. The easiest way to do this is with the command `axis image`.

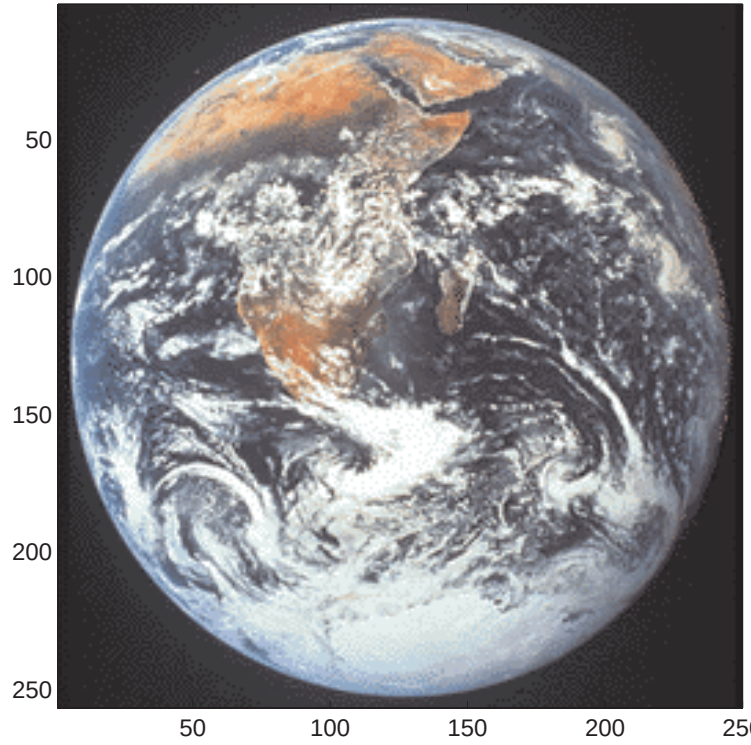
For example, these commands display the `earth` image in the `demos` directory using the default figure and axes positions.

```
load earth
image(X); colormap(map)
```



The elongated globe results from stretching the image display to fit the axes position. Use the `axis image` command to force the aspect ratio to be one-to-one.

```
axis image
```



The command `axis image` works by setting the `DataAspectRatio` property of the axes object to [1 1 1]. See `axis` and `axes` for more information on how to control the appearance of axes objects.

Sometimes you might want to display an image so that each element in the data matrix corresponds to a single screen pixel. To display an image with this one-to-one matrix-element-to-screen-pixel mapping, you need to resize the figure and axes. For example, these commands display the earth image so that one data element corresponds to one screen pixel.

```
[m,n] = size(X);
figure('Units','pixels','Position',[100 100 n m])
image(X); colormap(map)
set(gca,'Position',[0 0 1 1])
```

The figure's `Position` property is a four-element vector that specifies the figure's location on the screen as well as its size. The second statement above positions the figure so that its lower left corner is at position (100,100) on the screen and so that its width and height match the image width and height. Setting the axes position to [0 0 1 1] in normalized units creates an axes that fills the figure. The resulting picture is shown.

The Image Object and Its Properties

In this section...

Image CData

Note The commands `image` and `imagesc` create image objects. Image objects are children of axes objects, as are line, patch, surface, and text objects. Like all Handle Graphics objects, the image object has a number of properties you can set to fine-tune its appearance on the screen. The most important properties of the image object with respect to appearance are `CData`, `CDataMapping`, `XData`, `YData` and `Erasemode`. These properties are discussed in this and the following sections. For detailed information about these and all the properties of the image object, see `image`.

The `CData` property of an image object contains the data array. In the commands below, `h` is the handle of the image object created by `image`, and the matrices `X` and `Y` are the same.

```
h = image(X); colormap(map)
Y = get(h,'CData');
```

The dimensionality of the `CData` array controls whether MATLAB displays the image using colormap colors or as an RGB image. If the `CData` array is two-dimensional, then the image is either an indexed image or an intensity image, and in either case the image is displayed using colormap colors. If, on the other hand, the `CData` array is *m*-by-*n*-by-3, then MATLAB displays it as a truecolor image, ignoring the colormap colors.

Image CDataMapping

The CDataMapping property controls whether an image is indexed or intensity. An indexed image is displayed by setting the CDataMapping property to 'direct', in which case the values of the CData array are used directly as indices into the figure's colormap. When the image command is used with a single input argument, it sets the value of CDataMapping to 'direct'.

```
h = image(X); colormap(map)
get(h,'CDataMapping')
ans =

direct
```

Intensity images are displayed by setting the CDataMapping property to 'scaled'. In this case the CData values are linearly scaled to form colormap indices. The scale factors are controlled by the axes CLim property. The imagesc function creates an image object whose CDataMapping property is set to 'scaled', and it also adjusts the CLim property of the parent axes. For example,

```
h = imagesc(I,[0 1]); colormap(map)
get(h,'CDataMapping')
ans =

scaled

get(gca,'CLim')
ans =

[0 1]
```

XData and YData

The XData and YData properties control the coordinate system of the image. For an *m*-by-*n* image, the default XData is [1 n] and the default YData is [1 m]. These settings imply the following:

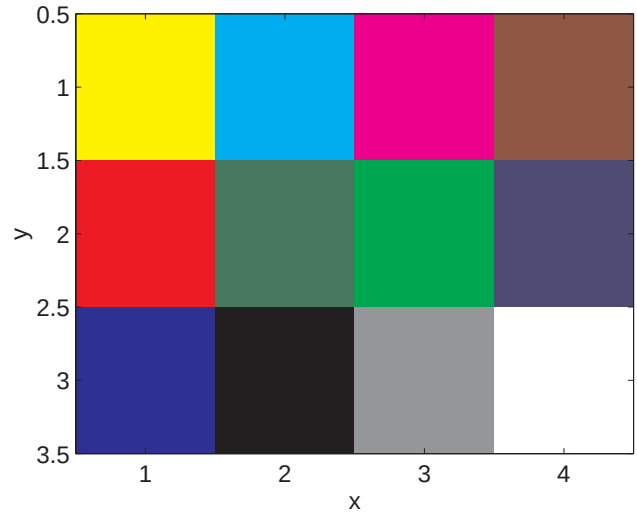
- The left column of the image has an *x*-coordinate of 1.
- The right column of the image has an *x*-coordinate of *n*.

- The top row of the image has a *y*-coordinate of 1.
- The bottom row of the image has a *y*-coordinate of *m*.

For example, the statements

```
X = [1 2 3 4; 5 6 7 8; 9 10 11 12];
h = image(X); colormap(colorcube(12))
xlabel x; ylabel y
```

produce the following picture.



The `XData` and `YData` properties of the resulting image object have the default values shown below.

```
get(h,'XData')
ans =

     1     4

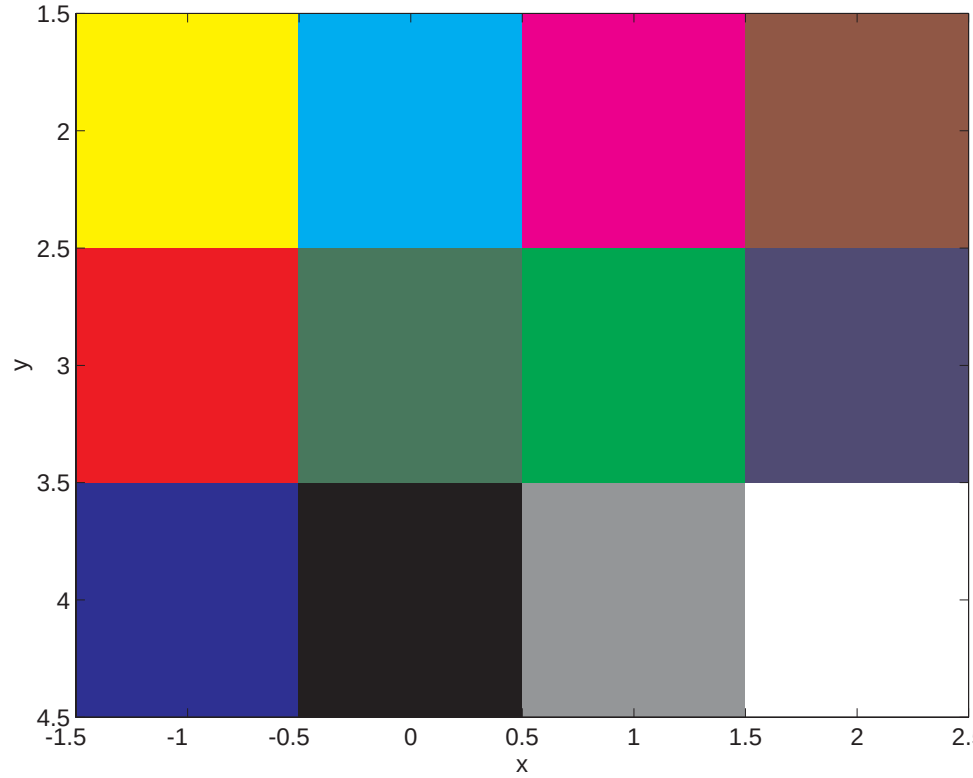
get(h,'YData')
ans =
```

```
     1     3
```

However, you can override the default settings to specify your own coordinate system. For example, the statements

```
X = [1 2 3 4; 5 6 7 8; 9 10 11 12];
image(X,'XData',[-1 2],'YData',[2 4]); colormap(colorcube(12))
xlabel x; ylabel y
```

produce the following picture.



EraseMode

The `EraseMode` property controls how MATLAB updates the image on the screen if the image object's `CData` property changes. The default setting of `EraseMode` is `'normal'`. With this setting, if you change the `CData` of the image object using the `set` command, MATLAB erases the image on the screen before redrawing the image using the new `CData` array. The erase step is a problem if you want to display a series of images quickly and smoothly.

You can achieve fast and visually smooth updates of displayed images as you change the image `CData` by setting the image object `EraseMode` property to `'none'`. With this setting, MATLAB does not take the time to erase the displayed image — it immediately draws the updated image when the `CData` changes.

Suppose, for example, that you have an *m*-by-*n*-by-3-by-*x* array `A`, containing *x* different truecolor images of the same size. You can display them dynamically with

```
h = image(A(:,:,:,1),'EraseMode','none');
for i = 2:x
    set(h,'CData',A(:,:,:,i))
end
```

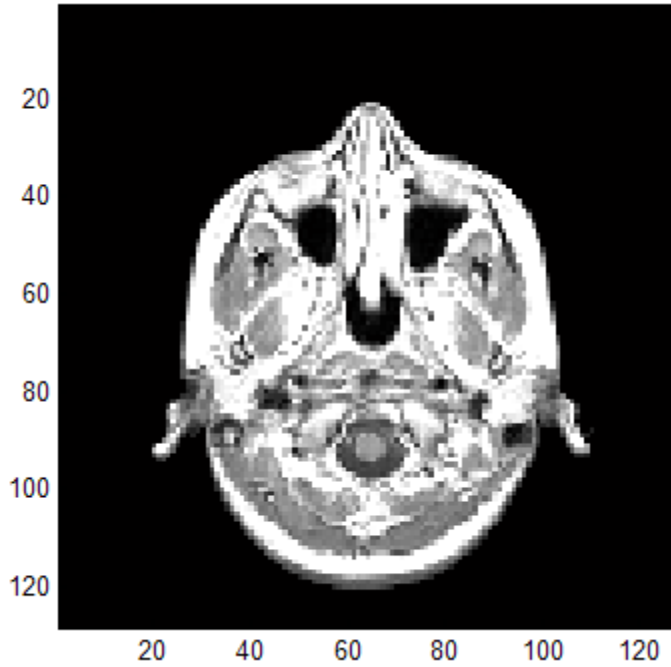
Rather than creating a new image object each time through the loop, this code simply changes the `CData` of the image object (which was created on the first line using the `image` command). Because the image `EraseMode` is set to `'none'`, changes to the `CData` do not cause the image on the screen to be erased each time through the loop.

Try the following code example that displays the `mri.mat` medical image sequence that ships with MATLAB; it sets `erasemode` to `none`, so that there is no flashing between images when`CData` is updated:

```
load mri
x = size(D);
frames = x(4);
instant = 0.05;  % Seconds to pause between frames
h = image(D(:,:,:,1),'EraseMode','none');
colormap(map); axis image;
% Color axes yellow to illustrate differences in erase modes
```

```
set(gca,'color','y')
for i = 2:frames  % Loop to the last image, replacing CData
    set(h,'CData',D(:,:,:,i))
    pause(instant)
end
for i =frames:-1:1  % Loop back to the first image
    set(h,'CData',D(:,:,:,i))
     pause(instant)
end
```

The first and last frames are the same and look like this:



Now set `erasemode` to `normal` or `background` and again execute the code in the `for` loops; you will see the yellow background flash in between image updates.

Note Setting `erasemode` to `xor` can have unpredictable and undesirable results, depending on your platform and its display system, and may not be particularly efficient.

When you are using this animation technique with larger data sets, in order to achieve maximum speed you can turn off double buffering for the figure, as follows:

```
set(gcf,'doubleBuffer','off')
```

Adding Text to Images

You can use basic array indexing to rasterize text strings into an existing image, as follows:

Draw the text strings using `text`, and then capture a bitmapped version of them using `getframe`. Then find the black pixels and convert their subscripts to indexes using `sub2ind`. Use these subscripts to "paint" the text into the image into which you want to add the text string, then save that image. Here is an example using the image in the demo MAT-file `mandrill.mat`:

```
% Create the text in an axis:
t = text(.05,.1,'Mandrill Face', ...
         'FontSize',12, 'FontWeight','demi');

% Capture the text from the screen:
F = getframe(gca,[10 10 200 200]);

% Close the figure:
close

% Select any plane of the resulting RGB image:
c = F.cdata(:,:,1);

% Note: If you have Image Processing Toolbox installed,
% you can convert the RGB data from the frame to black or white:
% c = rgb2ind(F.cdata,2);

% Determine where the text was (black is 0):
```

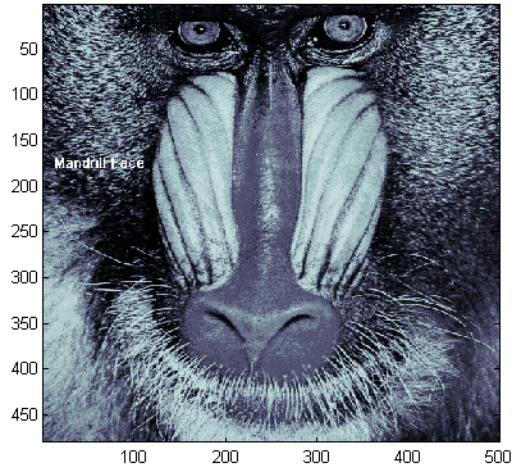
```
[i,j] = find(c == 0);

% Read in or load the image that is to contain the text:
load mandrill

% Use the size of that image, plus the row/column locations
% of the text, to determine locations in the new image:
ind = sub2ind(size(X),i,j);

% Index into new image, replacing pixels with white:
X(ind) = uint8(255);

% Display and color the new image:
imagesc(X)
axis image
colormap(bone)
```



Additional Techniques for Fast Image Updating

To increase the rate at which MATLAB can update the `CData` property of an image object you can optimize `CData` and set some related figure and axes properties:

- Use the smallest datatype possible. Using a `uint8` datatype for your image will be faster than using a `double` datatype.

  Part of the process of setting the image's `CData` property includes copying the matrix for the image's use. The overall size of the matrix is dependent on the size of its individual elements. Using smaller individual elements (i.e., a smaller datatype) decreases matrix size,and reduces the amount of time needed to copy the matrix.

- Use the smallest acceptable matrix.

  If the speed at which the image is displayed is your highest priority, you may need to compromise on the size and quality of the image. Again, decreasing the size will reduce the time needed to copy the matrix.

- Make the axes exactly the same size (in pixels) as the `CData` matrix.

  Maintaining a one-to-one correspondence between the data and the onscreen pixels will eliminate the need for interpolation. For example:

  ```
  set(gca,'Units','pixels')
  pos = get(gca,'Position')
  width = pos(3);
  height = pos(4);
  ```

  When the size of your `CData` exactly equals `[width height]`, each element of the array corresponds directly to a pixel. Otherwise, MATLAB must interpolate the values in the "CData" array, so it will fit the axes at their current size.

- Set the limit mode properties (`XLimMode` and `YLimMode`) of your axes to `manual`.

  If they are set to `auto`, then every time an object (such as an image, line, patch, etc.) changes some aspect of its data, the axes must recalculate its related properties. For example, if you specify

  ```
  image(firstimage);
  set(gca, 'xlimmode','manual',...
  'ylimmode','manual',...
  'zlimmode','manual',...
  'climmode','manual',...
  'alimmode','manual');
  ```

the axes will not recalculate any of the limit values before redrawing the image.

- Set the figure's `DoubleBuffer` property to `off`.

  ```
  set(gcf,'doublebuffer','off');
  ```

  Set the `DoubleBuffer` property `on` for to obtain flicker-free animation. However, to maximize rendering speed, set `DoubleBuffer` to `off`.

- Alternately, you might consider using a `movie` object if the main point of your task is to simply display a series of images onscreen.

  The MATLAB `movie` object utilizes underlying system graphics resources directly, instead of executing MATLAB object code. This is faster than repeatedly setting an image's `CData` property, as outlined above.

Printing Images

When you set the axes `Position` to `[0 0 1 1]` so that it fills the entire figure, the aspect ratio is not preserved when you print because MATLAB adjusts the figure size when printing according to the figure's `PaperPosition` property. To preserve the image aspect ratio when printing, set the figure's `PaperPositionMode` to `'auto'` from the command line.

```
set(gcf,'PaperPositionMode','auto')
print
```

When `PaperPositionMode` is set to `'auto'`, the width and height of the printed figure are determined by the figure's dimensions on the screen, and the figure position is adjusted to center the figure on the page. If you want the default value of `PaperPositionMode` to be `'auto'`, enter this line in your `startup.m` file.

```
set(0,'DefaultFigurePaperPositionMode','auto')
```

Printed images may not always be the same size as they are on your monitor. The size depends on accurately specifying the numbers of pixels per inch that you monitor is displaying.

To specify the pixels-per-inch on your display, you need to do the following (in Windows):

1. Go into your Display Properties by right-clicking on an empty space on your desktop and choose Properties.
2. Click the Settings pane
3. Click the Advanced pushbutton and choose the General pane
4. Switch DPI setting to Custom setting and hold a real ruler up to the picture of the ruler on the screen and drag until they match.

Until you do this, neither MATLAB nor any other software can determine how big images on the screen are, and printed images cannot match the size.

Note that on the Macintosh platform, pixels per inch is hard-coded to 72.

Converting the Data or Graphic Type of Images

Converting between data types changes the way MATLAB interprets the image data. If you want the resulting array to be interpreted properly as image data, you need to rescale or offset the data when you convert it. (See the earlier sections "Image Types" on page 6-5 and "8-Bit and 16-Bit Indexed Images" on page 6-10 for more information about offsets.)

For certain operations, it is helpful to convert an image to a different image type. For example, if you want to filter a color image that is stored as an indexed image, you should first convert it to RGB format. To do this efficiently, use the `ind2rgb` function, which originated in Image Processing Toolbox. When you apply the filter to the RGB image, MATLAB filters the intensity values in the image, as is appropriate. If you attempt to filter the indexed image, MATLAB simply applies the filter to the indices in the indexed image matrix, and the results may not be meaningful.

You can also perform certain conversions just using MATLAB syntax. For example, if you want to convert a grayscale image to RGB, you can concatenate three copies of the original matrix along the third dimension.

```
RGB = cat(3,I,I,I);
```

The resulting RGB image has identical matrices for the red, green, and blue planes, so the image is displayed as shades of gray.

Sometimes you will want to change the graphics format of an image, perhaps for compatibility with another software product. This process is very straightforward. For example, to convert an image from a BMP to a PNG, load the BMP using `imread`, set the data type to `uint8`, `uint16`, or `double`, and then save the image using `imwrite`, with `'PNG'` specified as your target format. See `imread` and `imwrite` for the specifics of which bit depths are supported for the different graphics formats, and for how to specify the format type when writing an image to file.

7

Printing and Exporting

Choosing a Printer Driver (p. 7-85)	Factors to consider when using a nondefault print driver, and information specific to drivers supported by MATLAB
Troubleshooting (p. 7-94)	Solutions to frequently asked questions and common problems encountered while printing or exporting graphics

Overview of Printing and Exporting

In this section...

Print and Export Operations

There are four basic operations that you can perform in printing or transferring figures you've created in MATLAB to specific file formats for other applications to use.

Operation	Description
Print	Send a figure from the screen directly to the printer.
Print to File	Write a figure to a PostScript file to be printed later.
Export to File	Export a figure in graphics format to a file, so that you can import it into an application.
Export to Clipboard	Copy a figure to the Windows clipboard, so that you can paste it into an application.

Graphical User Interfaces

In addition to typing MATLAB commands, you can use interactive tools for either Microsoft Windows or UNIX to print and export graphics. The table below lists the GUIs available for doing this and explains how to open them from figure windows.

Dialog Box	How to Open	Description
Print (Windows and UNIX)	**File > Print** or `printdlg` function	Send figure to the printer, select the printer, print to file, and several other options
Print Preview	**File > Print Preview** or `printpreview` function	View and adjust the final output
Export	**File > Export**	Export the figure in graphics format to a file
Copy Options	**Edit > Copy Options**	Set format, figure size, and background color for Copy to Clipboard
Figure Copy Template	**File > Preferences**	Change text, line, axes, and UI control properties

You can open the Print and Print Preview dialog boxes from an M-file or from the command line with the `printdlg` and `printpreview` functions.

Command Line Interface

You can print a MATLAB figure from the command line or from an M-file. Use the `set` function to set the properties that control how the printed figure looks. Use the `print` function to specify the output format and start the print or export operation.

Note Printed output from MATLAB and Print Previews of it are not guaranteed to duplicate the look of figures on your display screen in every detail. Many factors, including the complexity of the figure, available fonts, and whether a native printer driver or a driver built in to MATLAB is used, affect the final output and can cause printed output to differ from what you see on your screen.

Modifying Properties with set

The `set` function changes the values of properties that control the look of a figure and objects within it. These properties are stored with the figure; some

are also properties of children such as axes or annotations. When you change one of the properties, the new value is saved with the figure and affects the look of the figure each time you print it until you change the setting again.

To change the print properties of the current figure, the `set` command has the form

```
set(gcf, 'Property1', value1, 'Property2', value2, ...)
```

where `gcf` is a function call that returns the handle of the current figure, and each property-value pair consists of a named property followed by the value to which the property is set.

For example,

```
set(gcf, 'PaperUnits', 'centimeters', 'PaperType', 'A4', ...)
```

sets the units of measure and the paper size. “Changing a Figure’s Settings” on page 7-43 describes commonly used print properties. The Figure Properties reference page contains a complete list of the properties.

Examining Properties with get

You can also use the `get` function to retrieve the value of a specific property.

```
a = get(gcf, 'Property')
```

Note You can also peruse and modify figure and other object properties with the Property Inspector GUI, which you can open with the `inspect` command. To open the current figure in the Property Inspector, type `inspect(gcf)`

Printing and Exporting with print

The `print` function performs any of the four actions shown in the table below. You control what action is taken, depending on the presence or absence of certain arguments.

Action	Print Command
Print a figure to a printer	`print`
Print a figure to a file for later printing	`print` *`filename`*
Copy a figure in graphics format to the clipboard	`print -dfileformat`
Export a figure to a graphics format file that you can later import into an application	`print -dfileformat filename`

You can also include optional arguments with the `print` command. For example, to export Figure No. 2 to file `spline2d.eps`, with 600 dpi resolution, and using the EPS color graphics format, use

```
print -f2 -r600 -depsc spline2d
```

The functional form of this command is

```
print('-f2', '-r600', '-depsc', 'spline2d');
```

Printing on UNIX without a Display

If you run MATLAB with the `-nodisplay` startup option, or run without the `DISPLAY` environment variable set, you can use most `print` options that apply to the UNIX platform, but some restrictions apply. See XXX for details.

Specifying Parameters and Options

The table below lists parameters you can modify for the figure to be printed or exported. To change one of these parameters, use the Print Preview or the UNIX Print dialog box, or use the `set` or `print` function.

See “Changing a Figure’s Settings” on page 7-43 for more detailed instructions.

Parameter	Description
Figure size	Set size of the figure on printed page
Figure position	Set position of figure on printed page
Paper size	Select printer paper, specified by dimension or type
Paper orientation	Specify way figure is oriented on page
Position mode	Specify figure position yourself or have MATLAB determine position automatically
Graphics format	Select format for exported data (e.g., EPS, JPEG)
Resolution	Specify how finely your figure is to be sampled
Renderer	Select method (algorithm) for drawing graphics
Renderer mode	Specify the renderer yourself or have MATLAB automatically determine which renderer to use
Axes tick marks	Keep axes tick marks and limits as shown or have MATLAB adjust depending on figure size
Background color	Keep background color as shown on screen or force it to white
Line and text color	Keep line and text objects as shown on screen or print them in black and white
UI controls	Show or hide all user interface controls in figure
Bounding box	Leave space between outermost objects in plot and edges of its background area
CMYK	Automatically convert RGB values to CMYK values
Character set encoding	Select character set for PostScript printers

Default Settings and How to Change Them

If you have not changed the default print and export settings, MATLAB prints or exports the figure

- 8-by-6 inches with no window frame

- Centered, in portrait format, on 8.5-by-11 inch paper if available
- Using white background color for the figure and axes
- Scaling ticks and limits of the axes to accommodate the printed size

Setting Defaults for a Figure

In general, to change the property settings for a specific figure, follow the instructions given in the section “Changing a Figure’s Settings” on page 7-43.

Any settings you change with the Print Preview and Print dialog boxes or with the `set` function are saved with the figure and affect each printing of the figure until you change the settings again.

The settings you change with the **Figure Copy Template Preferences** and **Copy Options Preferences** panels alter the figure as it is displayed on the screen.

Setting Defaults for the Session

MATLAB enables you to set the session defaults for figure properties. Set the session default for a property using the syntax

```
set(0, 'DefaultFigurepropertyname', 'value')
```

where *`propertyname`* is one of the named figure properties. This example sets the paper orientation for all subsequent print operations in the current MATLAB session.

```
set(0, 'DefaultFigurePaperOrientation', 'landscape')
```

The Figure Properties reference page contains a complete list of the properties.

To see what default properties you can set that will be applied to all subsequent figures in the same MATLAB session, type

```
set(0,'default')
```

To see their current settings, type

```
get(0,'default')
```

Setting Defaults Across Sessions

MATLAB enables you to set the session-to-session defaults for figure properties, the print driver, and the `print` function.

Print Device and Print Command. Set the default print driver and the default print command in your `printopt.m` file. This file contains instructions for changing these settings and for displaying the current defaults. Open `printopt.m` in your editor by typing the command

```
edit printopt
```

Scroll down about 40 lines until you come to this comment line:

```
%---> Put your own changes to the defaults here (if needed)
```

Add your changes after that line. For example, to change the default driver, first find the line that sets `dev`, and then replace the text string with an appropriate value. So, to set the default driver to HP LaserJet III, modify the line to read

```
dev = '-dljet3';
```

For the full list of values for `dev`, see the Drivers section of the `print` reference page.

Note If you set `dev` to be a graphics format, such as `-djpeg`, MATLAB exports the figure to that type of file rather than printing it.

Figure Properties. Set the session-to-session default for a property by including commands like the following in your `startup.m` file:

```
set(0, 'DefaultFigure'propertyname', 'value')
```

where *`propertyname`* is one of the named figure properties. For example,

```
set(0, 'DefaultFigureInvertHardcopy', 'off')
```

keeps the figure background in the screen color.

This is the same command you use to change a session default, except by adding it to your `startup.m` file, it executes automatically every time MATLAB is invoked.

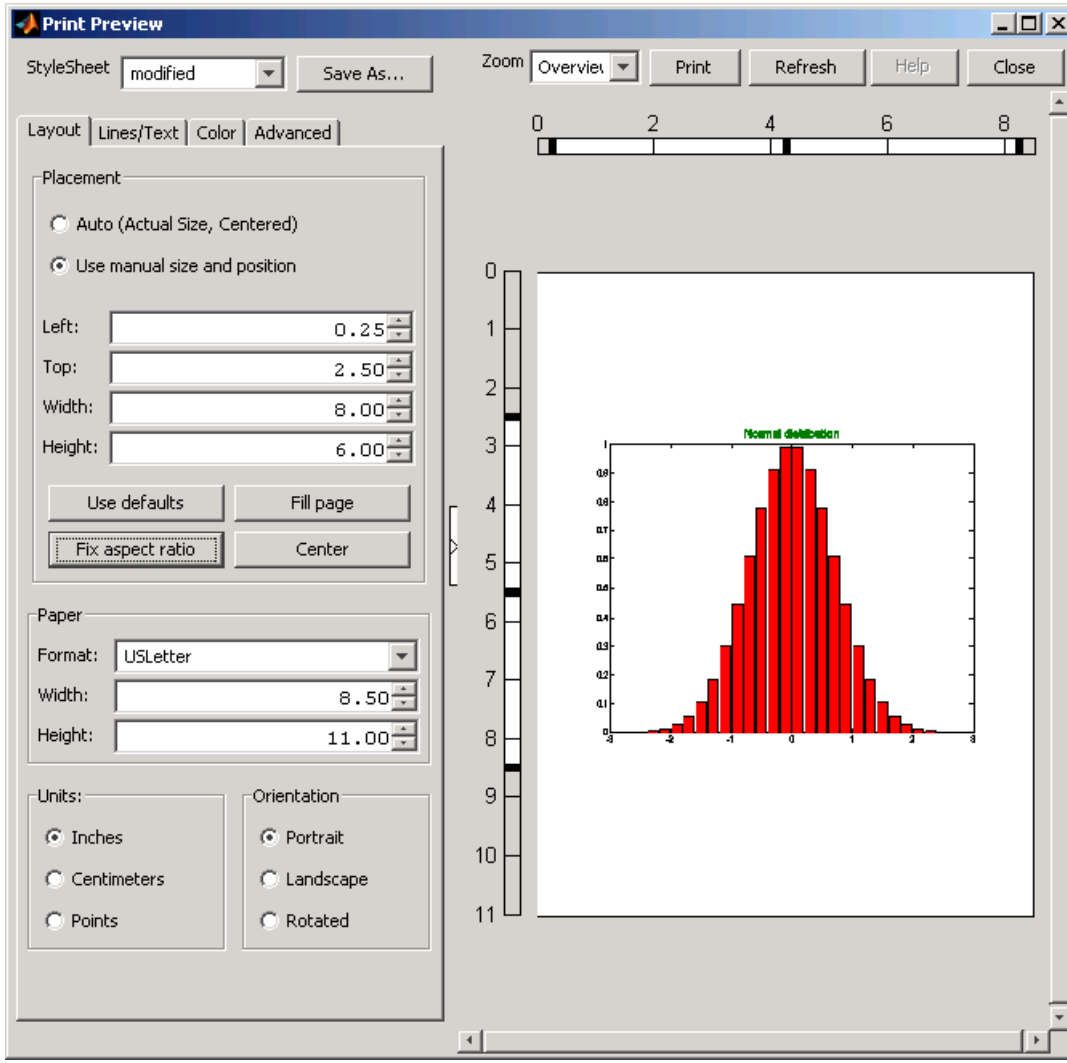
Note Options you specify in arguments to the `print` command override properties set using MATLAB commands or the Print Preview dialog box, which in turn override any MATLAB default settings specified in `printopt.m` or `startup.m`.

How to Print or Export

In this section...

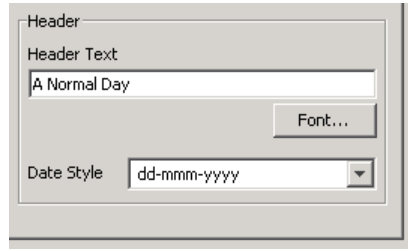
Using Print Preview

Before you print or export a figure, preview the image by selecting **Print Preview** from the figure window's **File** menu. If necessary, you can use the `set` function to adjust specific characteristics of the printed or exported figure. Adjustments that you make in the Print Preview dialog also set figure properties; these changes can affect the output you get should you print the figure later with the `print` command. See "Changing a Figure's Settings" on page 7-43 for details.

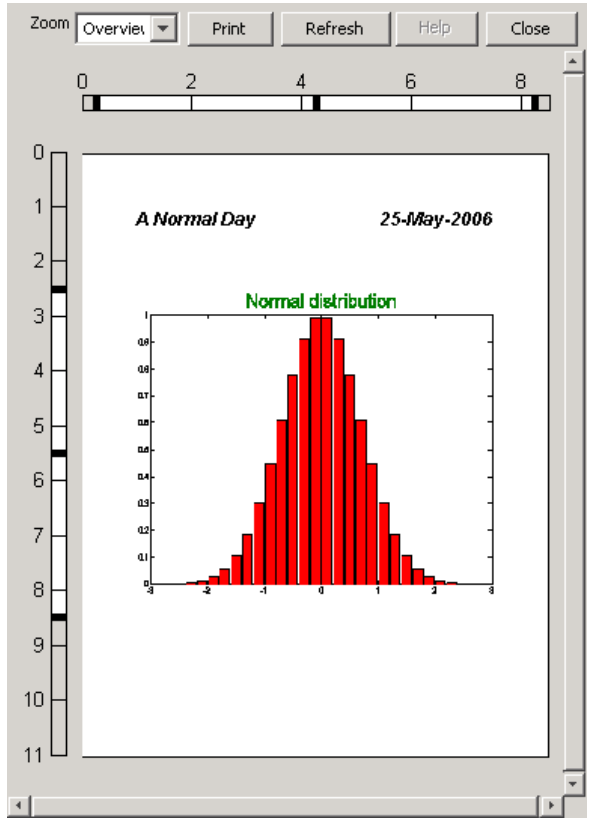


Adding a Header to the Printed Page

You can add a header to the page you are about to print by clicking the **Lines/Text** tab at the top of the Print Preview dialog box. At the bottom of that panel are the **Header** controls, as shown here:



The print header includes any text you want to appear at the top of the printed page. It can also include the current date. In the **Header Text** edit box, enter the text of the header. Under `Date Type`, select from a number of possible formats with which to display the current date and/or time. The default is to include no date. Click the **Font** button to change the font, font style, font size, or script type for the header text and date format. If you don't see the header as you specified it, click the **Refresh** button over the preview pane. A page containing a header plus date in bold italics is shown in the preview below:



Click **Print** to open the standard print dialog box to print the page. Click **Close** to close the dialog box and apply these settings to your figure.

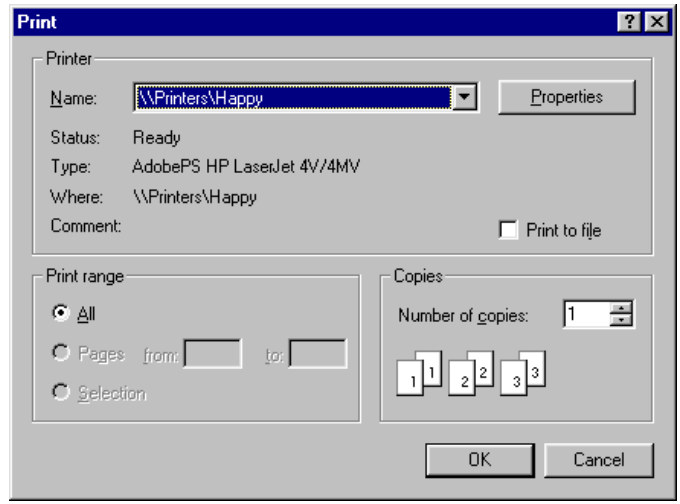
Printing a Figure

This section tells you how to print your figure to a printer:

- “Printing with the Print GUI on Windows” on page 7-15
- “Printing with the Print GUI on UNIX” on page 7-16
- “Printing Using MATLAB Commands” on page 7-19

Printing with the Print GUI on Windows

MATLAB for Windows uses the standard Windows Print dialog box, which most Windows software products share. To open the Windows Print dialog box, select **Print** from the figure window's **File** menu or click the **Print** button in the Print Preview dialog box.



- To print a figure, first select a printer from the list box, then click **OK**.
- To save it to a file, click the **Print to file** check box, click **OK**, and when the Print to File window appears, enter the filename you want to save the figure to. MATLAB creates the file in your current working directory.

Settings you can change in the Windows Print dialog box are as follows:

Properties. To make changes to settings specific to a printer, click the **Properties** button. This opens the Windows Document Properties window.

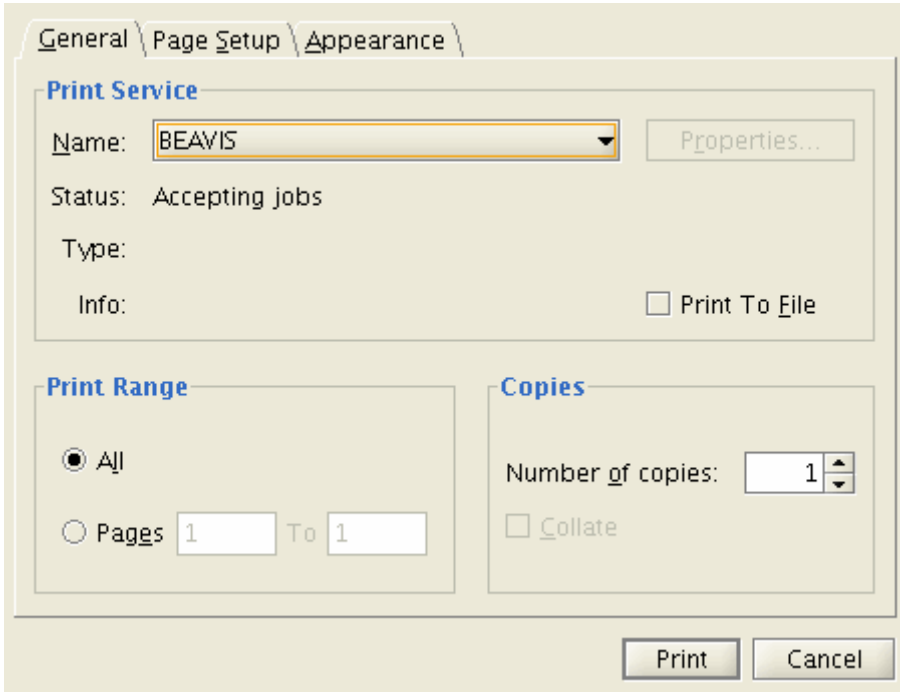
Print range. You can only select **All** in this panel. The selection does not affect your printed output.

Copies. Enter the number of copies you want to print.

You can also open the Print dialog programmatically via the `printdlg` function.

Printing with the Print GUI on UNIX

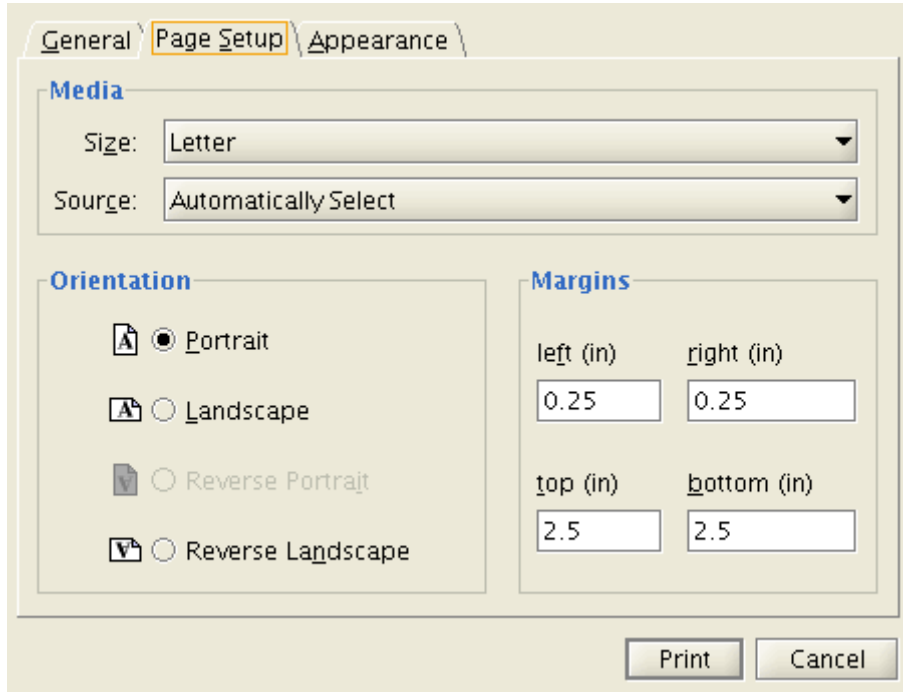
MATLAB for UNIX has a Print dialog box containing three tabs. To open the Print dialog box, select **Print** from the figure window's **File** menu. It opens showing the **General** tab's contents:



To print a figure, click the **Name** button under **Print Service** and select a printer from the list box.

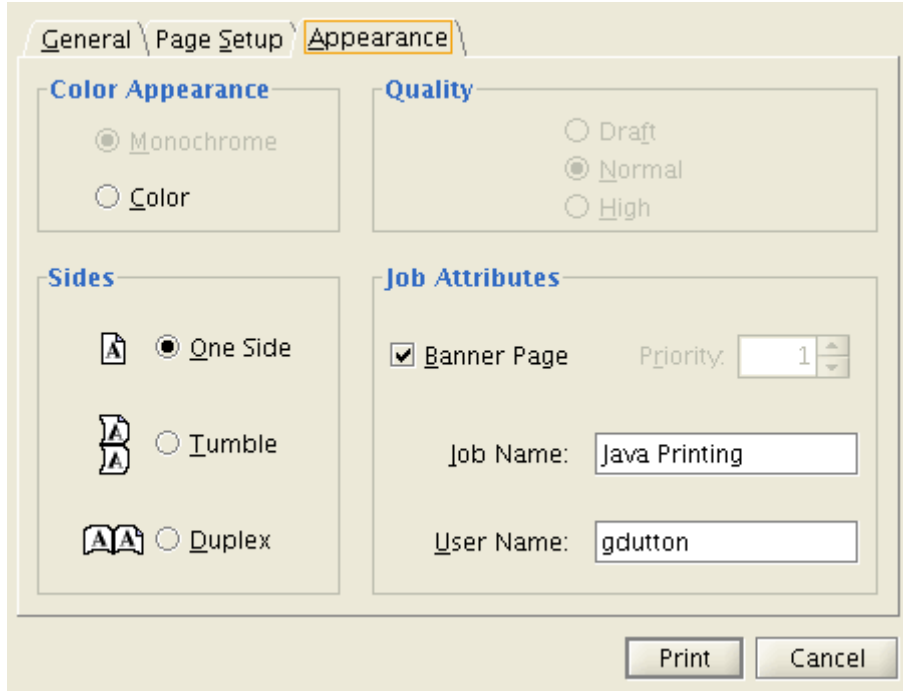
Note MATLAB assumes printers accessed from the Print dialog are PostScript-enabled. If you want to print to a non-PostScript device, you will need to use **File > Save As** and specify the **Save as type** or issue a `print` command specifying the appropriate driver with the `-d` flag.

The **Page Setup** tab on the Print dialog looks like this:



You can set paper characteristics and margins with the controls on this tab. You might want to use the Print Preview dialog instead, however, as it allows you to do the same things and gives you visual feedback at the same time. For details, see “Using Print Preview” on page 7-11.

The **Appearance** Print dialog tab lets you control several aspects of your print jobs:



The **Appearance** options include Duplex and Tumble printing, whether a banner page should precede the printed page, whether to print in color, and what quality of printing to use. You can also use **Print Preview** to control color.

Related settings in the Print Preview dialog box include

Printing in Color. Depending on the capabilities of the printer you are using, you can print in black and white, grayscale, or color by selecting the appropriate button in the **Color Scale** panel of the Print Preview **Color** tab. You can also choose a background color that is the same or different from the figure's color.

Figure Size and Position on Printed Page. If you want the printed plot to have the same size as it does on your screen, select **Auto (Actual Size, Centered)** on the **Layout** tab. If you want the printed output to have a specific size, select **Use manual size and position**.

See “Setting the Figure Size and Position” on page 7-47 for more information.

Axes Limits and Ticks. To force MATLAB to print the same number of ticks and the same limit values for the axes as used on the screen, select **Keep screen limits and ticks** on the **Advanced** tab of the Print Preview dialog box. To let MATLAB scale the limits and ticks of the axes based on the size of the printed figure, select **Recompute limits and ticks**.

See “Setting the Axes Ticks and Limits” on page 7-60 for more information.

Printing Using MATLAB Commands

Use the `print` function to print from the MATLAB command line or from a program. See “Printing and Exporting with print” on page 7-5 for more information.

To send the current or most recently active figure to a printer, simply type

```
print
```

The Printing Options table on the `print` reference page shows a full list of options that you can use with the `print` function. For example, the following command prints Figure No. 2 with 600 dpi resolution, using the Canon BubbleJet BJ200 printer driver:

```
print -f2 -r600 -dbj200
```

Printing to a File

Instead of sending your figure to the printer right now, you have the option of “printing” it to a file, and then sending the file to the printer later on. You can also append additional figures to the same file using the `print` command.

This section tells you how to save your figure to a file:

Printing to a File with the Print GUI on Windows

1. To open the Print dialog box, select **Print** from the figure window's **File** menu.
2. Select the check box labeled **Print to file**, and click the **OK** button.
3. The **Print to file** dialog box appears, allowing you to specify the output directory and filename.

Printing to a File with the Print GUI on UNIX

1. To open the Print dialog box, select **Print** from the figure window's **File** menu.
2. Select the radio button labeled **File**, and either fill in or browse for the directory and filename.

Printing to a File Using MATLAB Commands

To print the figure to a PostScript file, type

```
print filename
```

If you don't specify the filename extension, MATLAB uses an extension that is appropriate for the print driver being used.

You can also include an `-options` argument when printing to a file. For example, to append the current figure to an existing file, type

```
print -append filename
```

The only way to append to a file is by using the `print` function. There is no dialog box that enables you to do this.

Note If you print a figure to a file, the file can only be printed and cannot be imported into another application. If you want to create a figure file that you can import into an application, see the next section, "Exporting to a File"

Appending Additional Figures to a File. Once you have printed one figure to a PostScript file, you can append other figures to that same file using the `-append` option of the `print` function. You can only append using the `print` function.

This example prints Figure No. 2 to PostScript file `myfile.ps`, and then appends Figure No. 3 to the end of the same file:

```
print -f2 myfile
print -f3 -append myfile
```

Exporting to a File

Export a figure in a graphics format to a file if you want to import it into another application, such as a word processor. You can export to a file from the Windows or UNIX Export Setup dialog box or from the command line.

This section tells you how to export your figure to a file:

- "Using the Export Setup GUI" on page 7-21
- "Exporting Using MATLAB Commands" on page 7-28

It also covers

- "Exporting with getframe" on page 7-29
- "Saving Multiple Figures to an AVI File" on page 7-30
- "Importing MATLAB Graphics into Other Applications" on page 7-30

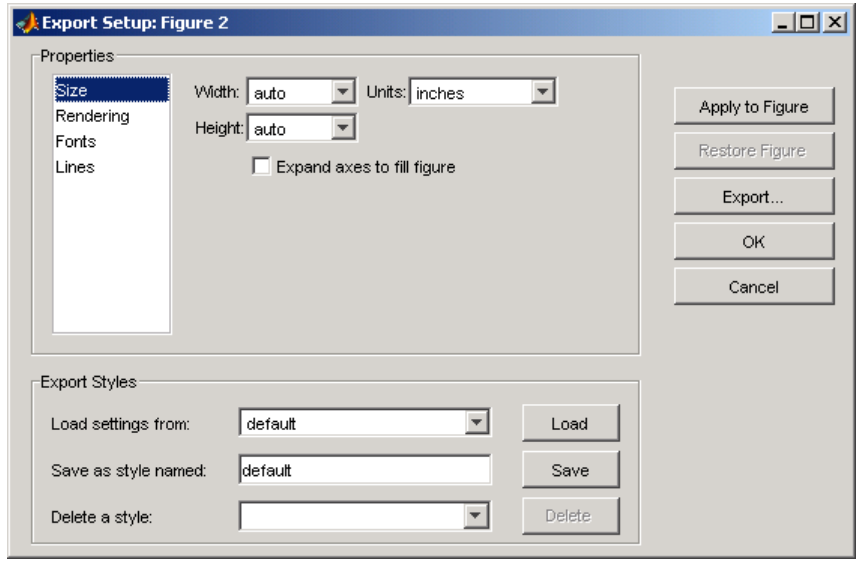
For further information, see "Choosing a Graphics Format" on page 7-73.

Using the Export Setup GUI

MATLAB displays the export Setup GUI when you select **Export Setup** from the **File** menu of a figure window. This GUI has four dialog boxes that enable you to adjust the size, rendering, font, and line appearance of your figure prior to exporting it. You select each of these dialog boxes by clicking **Size**, **Rendering**, **Fonts**, or **Lines** from the**Properties** list. For a description of each dialog box, see

Adjusting the Figure Size

Click **Size** in the Export Setup dialog box to display this dialog box.

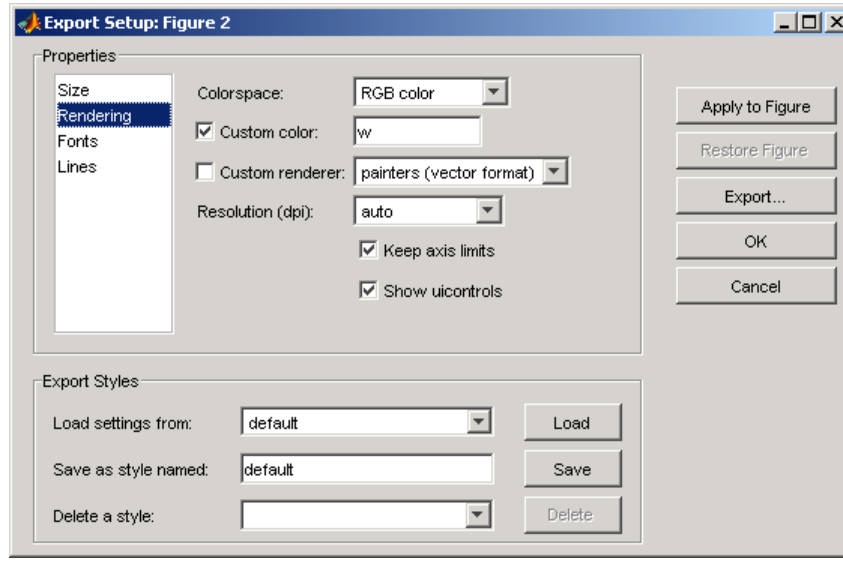


The Size dialog box modifies the size of the figure as it will appear when imported from the export file into your application. If you leave the **Width** and **Height** settings on `auto`, the figure remains the same size as it appears on your screen. You can change the size of the figure by entering new values in the **Width** and **Height** text boxes and then clicking **Apply to Figure**. To go back to the original settings, click **Restore Figure**.

To save any settings that you change, or to load settings that you used earlier, see "Saving and Loading Settings" on page 7-27.

Changing the Rendering

Click **Rendering** in the Export Setup dialog box to display this dialog box.



You can change the settings in this dialog box as follows:

Colorspace. Use the drop-down list to select a colorspace. Your choices are

- `Black and white`
- `Grayscale`
- `RGB color`
- `CMYK color`

Custom Color. Click the check box and enter a color to be used for the figure background. Valid entries are

- `white`, `yellow`, `magenta`, `red`, `cyan`, `green`, `blue`, or `black`
- Abbreviated name for the same colors — `w`, `y`, `m`, `r`, `c`, `g`, `b`, `k`
- Three-element RGB value — See the help for `colorspec` for valid values. Examples: `[1 0 1]` is magenta. `[0 .5 .4]` is a dark shade of green.

Custom Renderer. Click the check box and select a renderer from the drop-down list:

- `painters (vector format)`
- `OpenGL (bitmap format)`
- `Z-buffer (bitmap format)`

Resolution. You can select one of the following from the drop-down list:

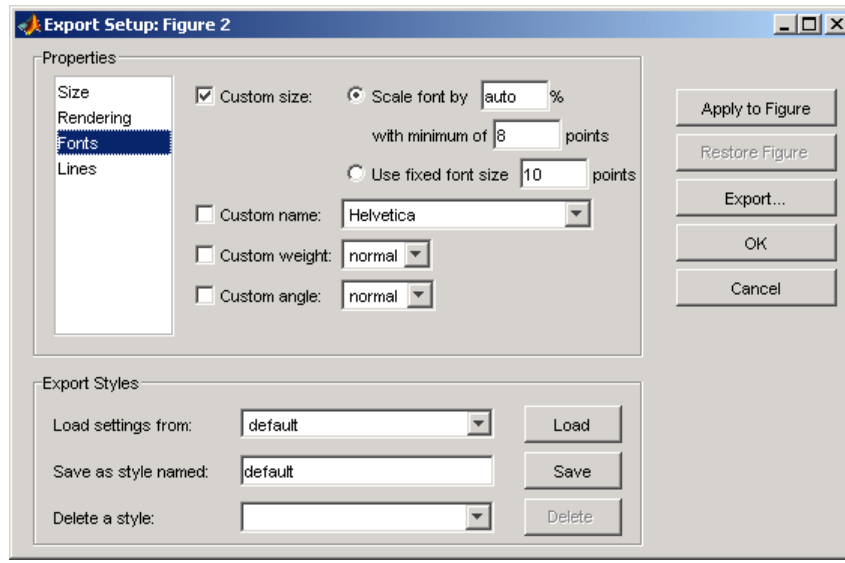
- `Screen` — The same resolution as used on your screen display
- A specific numeric setting — 150, 300, or 600 dpi
- `auto` — MATLAB selects a suitable setting

Keep axis limits. Click the check box to keep axis tick marks and limits as shown. If unchecked, have MATLAB adjust depending on figure size.

Show uicontrols. Click the check box to show all user interface controls in the figure. If unchecked, hide user interface controls.

Changing Font Characteristics

Click **Fonts** in the Export Setup dialog box to display this dialog box.



You can change the settings in this dialog box as follows:

Custom Size. Click the check box and use the radio buttons to select a relative or absolute font size for text in the figure.

- **Scale font by N %** — Increases or decreases the size of all fonts by a relative amount, N percent. Enter the word `auto` to have MATLAB select the appropriate font size.
- **With minimum of N points** — You can specify a minimum font size when scaling the font by a percentage.
- **Use fixed font size N points** — Sets the size of all fonts to an absolute value, N points.

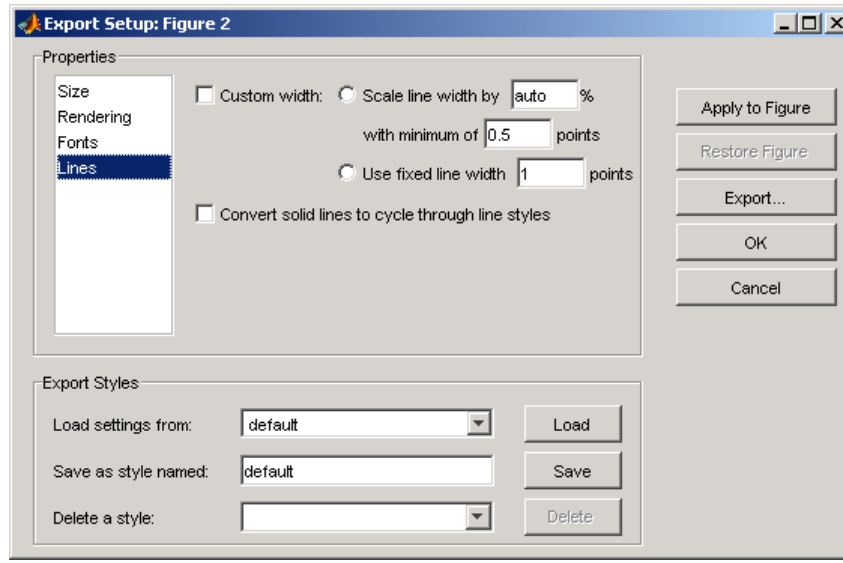
Custom Name. Click the check box and use the drop-down list to select a font name from those offered in the drop-down list.

Custom Weight. Click the check box and use the drop-down list to select the weight or thickness to be applied to text in the figure. Choose from `normal`, `light`, `demi`, or `bold`.

Custom Angle. Click the check box and use the drop-down list to select the angle to be applied to text in the figure. Choose from `normal`, `italic`, or `oblique`.

Changing Line Characteristics

Click **Lines** in the Export Setup dialog box to display this dialog box.



You can change the settings in this dialog box as follows:

Custom width. Click the check box and use the radio buttons to select a relative or absolute line size for the figure.

- **Scale line width by N %** — Increases or decreases the width of all lines by a relative amount, N percent. Enter the word `auto` to have MATLAB select the appropriate line width.

- **With minimum of N points** — Specify a minimum line width when scaling the font by a percentage.
- **Use fixed line width N points** — Sets the width of all lines to an absolute value, N points.

Convert solid lines to cycle through line styles. When colored graphics are imported into an application that does not support color, lines that could formerly be distinguished by unique color are likely to appear the same. For example, a red line that shows an input level and a blue line showing output both appear as black when imported into an application that does not support colored graphics.

Clicking this check box causes MATLAB to export lines using different line styles, such as solid, dotted, or dashed lines rather than differentiating between lines based on color.

Saving and Loading Settings

If you think you might use these export settings at another time, you can save them now and reload them later. At the bottom of each Export Setup dialog box, there is a panel labeled **Export Styles**. To save your current export styles, type a name into the **Save as style named** text box, and then click **Save**.

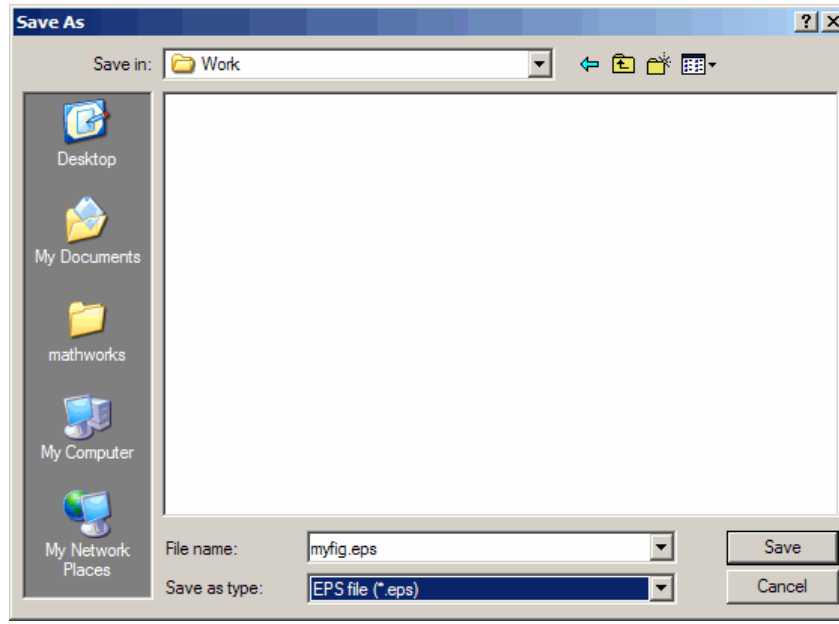
If you then click the **Load settings from** drop-down list, the name of the style you just saved appears among the choices of export styles you can load. To load a style, select one of the choices from this list and then click **Load**.

To delete any style you no longer have use for, select that style name from the **Delete a style** drop-down list and click **Delete**.

Exporting the Figure

When you finish setting the export style for your figure, you can export the figure to a file by clicking the **Export** button on the right side of any of the four Export Setup dialog boxes. As new window labeled **Save As** opens.

Select a directory to save the file in from the **Save in** list at the top. Select a file type for your file from the **Save as type** drop-down list at the bottom, and then enter a file name in the **File name** text box. Click the **Save** button to export the file.



For information on the graphics file formats supported by MATLAB, see "Choosing a Graphics Format" on page 7-73.

Exporting Using MATLAB Commands

Use the `print` function to print from the MATLAB command line or from a program. See "Printing and Exporting with print" on page 7-5 for basic information on printing from the command line.

To export the current or most recently active figure, type

```
print -dfileformat filename
```

where `fileformat` is a graphics format supported by MATLAB and `filename` is the name you want to give to the export file. MATLAB selects the filename extension, if you don't specify it.

You can also specify a number of options with the `print` function. These are shown in the Printing Options table on the `print` reference page.

For example, to export Figure No. 2 to file `spline2d.eps`, with 600 dpi resolution and using the EPS color graphics format, type

```
print -f2 -r600 -depsc spline2d
```

Graphics file formats are explained in more detail in the sections "Choosing a Graphics Format" on page 7-73 and "Description of Selected Graphics Formats" on page 7-80.

Exporting with getframe

You can use the `getframe` function with `imwrite` to export a graphic. `getframe` is often used in a loop to get a series of frames (figures) with the intention of creating a movie. Note that no matter what the intrinsic resolution of the graphics might be, `getframe` only captures them at screen resolution.

Some of the benefits of using this export method over using `print` are

- You can use `getframe` to capture a portion of the figure, rather than the whole figure.
- `imwrite` offers greater flexibility for setting format-specific options, such as the bit depth and compression.

The drawbacks of using this method are

- `imwrite` uses built-in MATLAB formats only
- `getframe` and `imwrite` are limited to screen resolution

.Consequently, you do not have access to the Ghostscript formats available to you when exporting with the `print` function or **Export** menu.

How to Use getframe and imwrite. Use `getframe` to capture a figure and `imwrite` to save it to a file. `getframe` returns a structure containing the fields `cdata` and `colormap`. The `colormap` field is empty on true color displays. The following example captures the current figure and exports it to a PNG file.

```
I = getframe(gcf);
imwrite(I.cdata, 'myplot.png');
```

You should use the proper syntax of `imwrite` for the type of image captured. In the example above, the image is captured from a true color display. Because the `colormap` field is empty, it is not passed to `imwrite`.

Example — Exporting a Figure Using getframe and imwrite. This example offers device independence—it works for either RGB-mode or indexed-mode monitors.

```
X=getframe(gcf);
if isempty(X.colormap)
   imwrite(X.cdata, 'myplot.bmp')
else
   imwrite(X.cdata, X.colormap, 'myplot.tif')
end
```

For information about available file formats and format-specific options, see the `imwrite` reference page. For information about creating a movie from a series of frames, see the reference pages for `getframe` and `movie`, or see “Movies” on page 5-78 in Chapter 5, “Creating Specialized Plots”.

Saving Multiple Figures to an AVI File

You can also save multiple figures to an AVI file using the MATLAB `avifile` and `addframe` functions. AVI files can be used for animated sequences and do not need MATLAB to run, but do require an AVI viewer. For more information, see “Exporting Audio/Video Data” in the MATLAB Programming documentation.

Importing MATLAB Graphics into Other Applications

You can include MATLAB graphics in a wide variety of applications for word processing, slide preparation, modification by a graphics program,

presentation on the Internet, and so on. In general, the process is the same for all applications:

1. Use MATLAB to create the figure you want to import into another application.
2. Export the MATLAB figure to one of the supported graphics file formats, selecting a format that is both appropriate for the type of figure and supported by the target application. See “Choosing a Graphics Format” on page 7-73 for help.
3. Use the import features of the target application to import the graphics file.

Edit Before You Export. Vector graphics may be fully editable in a few high-end applications, but most applications do not support editing beyond simple resizing. Bitmaps cannot be edited with quality results unless you use a software package devoted to image processing. In general, you should try to make all the necessary settings while your figure is still in MATLAB.

Importing into Microsoft Applications. To import your exported figure into a Microsoft application, select **Picture** from the **Insert** menu. Then select **From File** and navigate to your exported file. If you use the clipboard to perform your export operations, you can take advantage of the recommended MATLAB settings for Word and PowerPoint.

Example — Importing an EPS Graphic into LaTeX. This example shows how to import an EPS file named `peaks.eps` into LaTeX.

```
\documentclass{article}

\usepackage{graphicx}

\begin{document}

\begin{figure}[h]
\centerline{\includegraphics[height=10cm]{peaks.eps}}
\caption{Surface Plot of Peaks}
\end{figure}

\end{document}
```

EPS graphics can be edited after being imported to LaTeX. For example, you can specify the height in any LaTeX-compatible dimension. To set the height to 3.5 inches, use the command

```
height=3.5in
```

You can use the `angle` function to rotate the graph. For example, to rotate the graph 90 degrees, add

```
angle=90
```

to the same line of code that sets the height, i.e., `[height=10cm,angle=90]`.

Exporting to the Windows or Macintosh Clipboard

You can export a figure to the Windows or Macintosh clipboard. The formats used are discussed below.

Windows Clipboard Format

MATLAB uses one of two graphics formats to write clipboard data on Windows: EMF color vector or BMP 8-bit color bitmap.

By default, MATLAB chooses the graphics format for you, based on the rendering method used to display the figure. For figures rendered with OpenGL or Z-buffer, MATLAB uses the BMP format. For figures rendered with Painter's, the EMF format is used. For information about how MATLAB selects a rendering method, see "The Default Renderer for MATLAB" on page 7-55.

To override the selection by MATLAB, specify the format of your choice using either the Windows Copy Options Preferences dialog box, or the `-d` switch in the print command.

Macintosh Clipboard Format

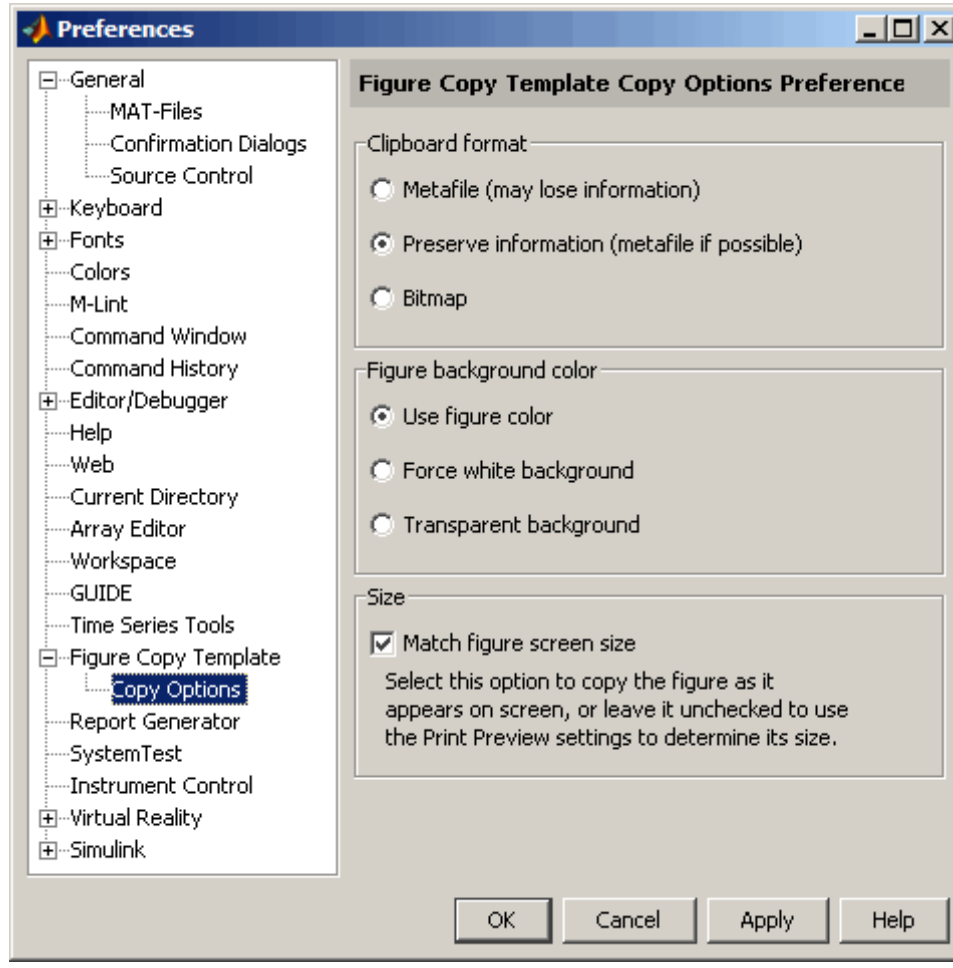
On Macintosh (using Java figures, the default), clipboard data are always written as RGB truecolor bitmaps. The entire figure window is captured.

Exporting to the Clipboard Using GUIs

Before you export the figure to the clipboard, you can use the Copy Options Preferences dialog box to select a nondefault graphics format, or to adjust certain figure settings. These settings become the new defaults for all figures exported to the clipboard.

Note When exporting to the clipboard in Windows metafile format (e.g., `print -dmeta`), the settings from the figure Copy Options Preferences template are ignored.

To open the Copy Options Preferences dialog box, select **Copy Options** from the figure window's **Edit** menu. Any changes you make with this dialog box affect only the clipboard copy of the figure; they do not affect the way the figure looks on the screen.



Settings you can change in the Copy Options Preferences dialog box are as follows:

Clipboard format. To copy the figure in EMF color vector format, select **Metafile**. To have MATLAB select the format for you, select **Preserve information**. To use BMP 8-bit color bitmap format, select **Bitmap**. MATLAB uses the metafile format whenever possible.

Note On Macintosh, the **Copy Options** dialog box does not have the **Clipboard format** options.

Figure background color. To keep the background color the same as it appears on the screen, select **Use figure color**. To make the background white, select **Force white background**. For a background that is transparent, for example, a slide background to frame the axes part of a figure, select **Transparent background**.

Size. Select **Match figure screen size** to copy the figure as it appears on the screen, or leave it unselected to use the **Width** and **height** options in the Export Setup dialog to determine its size.

1. Open the Copy Options Preferences dialog box if you need to make any changes to those preferences used in copying to the clipboard.
2. Click **OK** to see the new preferences. These will be used for all future figures exported to the clipboard.
3. Select **Copy Figure** from the figure window's **Edit** menu to copy the figure to the clipboard.

Exporting to the Windows or Macintosh Clipboard Using MATLAB Commands

Export to the clipboard using the `print` function with a graphics format, but no filename. You must use one of the following clipboard formats: `-dbitmap` or `-dmeta`. These switches create a Windows bitmap (BMP) or an enhanced metafile (EMF), respectively.

For example, to export the current figure to the clipboard in enhanced metafile format, type

```
print -dmeta
```

Note When printing, the `print -d` option specifies a printer driver. When exporting, the `print -d` option specifies a graphics format.

Examples of Printing and Exporting

In this section...

Printing a Figure at Screen Size

By default, MATLAB prints your figure at 8-by-6 inches. This size includes the area delimited by the background. This example shows how to print or export your figure the same size it is displayed on your screen.

Using the Graphical User Interface

1. Resize your figure window to the size you want it to be when printed.
2. Select **Print Preview** from the figure window's **File** menu, and select the **Layout** tab.
3. In the **Placement** panel, select **Auto (Actual Size, Centered)**.
4. Click **Print** in the upper right corner to print the figure.
5. The Print dialog box opens for you to print the figure.

Using MATLAB Commands

Set the `PaperPositionMode` property to `auto` before printing the figure.

```
set(gcf, 'PaperPositionMode', 'auto');
print
```

If later you want to print the figure at its original size, set `PaperPositionMode` back to `'manual'`.

Printing with a Specific Paper Size

By default, MATLAB uses 8.5-by-11 inch paper. This example shows how to change the paper size to 8.5-by-14 inches by selecting a paper type (Legal).

Using the Graphical User Interface

1. Select **Print Preview** from the figure window's **File** menu, and select the **Layout** tab.
2. Select the `Legal` paper type from the list in the **Paper** panel. The `Width` and `Height` fields update to `8.5` and `14`, respectively.
3. Make sure that **Units** is set to `inches`.
4. Click **Print** in the upper right corner to print the figure.
5. The Print dialog box opens for you to print the figure.

Using MATLAB Commands

Set the `PaperUnits` property to `inches` and the `PaperType` property to `Legal`.

```
set(gcf, 'PaperUnits', 'inches');
set(gcf, 'PaperType', 'Legal');
```

Alternatively, you can set the `PaperSize` property to the size of the paper, in the specified units.

```
set(gcf, 'PaperUnits', 'inches');
set(gcf, 'PaperSize', [8.5 14]);
```

Printing a Centered Figure

This example sets the size of a figure to 5.5-by-3 inches and centers it on the paper.

Using the Graphical User Interface

1. Select **Print Preview** from the figure window's **File** menu, and select the **Layout** tab.
2. Make sure **Use manual size and position** is selected.
3. Enter `5.5` in the **Width** field and `3` in the **Height** field.
4. Make sure that **Units** field is set to `inches`.
5. Click **Center**.
6. Click **OK**.
7. Click **Print** to open the Print dialog box and print the figure.

Using MATLAB Commands

1. Start by setting `PaperUnits` to `inches`.

```
set(gcf, 'PaperUnits', 'inches')
```

2. Use `PaperSize` to return the size of the current paper.

```
papersize = get(gcf, 'PaperSize')

papersize =
              8.5000   11.0000
```

3. Initialize variables to the desired width and height of the figure.

```
width = 5.5;         % Initialize a variable for width.
height = 3;          % Initialize a variable for height.
```

4. Calculate a left margin that centers the figure horizontally on the paper. Use the first element of `papersize` (width of paper) for the calculation.

```
left = (papersize(1)- width)/2

left =
          1.5000
```

5 Calculate a bottom margin that centers the figure vertically on the paper. Use the second element of `papersize` (height of paper) for the calculation.

```
bottom = (papersize(2)- height)/2

bottom =
          4
```

6 Set the figure size and print.

```
myfiguresize = [left, bottom, width, height];
set(gcf, 'PaperPosition', myfiguresize);
print
```

Exporting in a Specific Graphics Format

Export a figure to a graphics-format file when you want to import it at a later time into another application such as a word processor.

Using the Graphical User Interface

1 Select **Save As** from the figure window's **File** menu.

2 Use the **Save in** field to navigate to the directory in which you want to save your file.

3 Select a graphics format from the **Save as type** list.

4 Enter a filename in the **File name** field. An appropriate file extension, based on the format you chose, is displayed.

5 Click **Save** to export the figure.

Using MATLAB Commands

From the command line, you must specify the graphics format as an option. See the `print` reference page for a complete list of graphics formats and their corresponding option strings.

This example exports a figure to an EPS color file, `myfigure.eps`, in your current directory.

```
print -depsc myfigure
```

This example exports Figure No. 2 at a resolution of 300 dpi to a 24-bit JPEG file, `myfigure.jpg`.

```
print -djpeg -f2 -r300 myfigure
```

This example exports a figure at screen size to a 24-bit TIFF file, `myfigure.tif`.

```
set(gcf, 'PaperPositionMode', 'auto')   % Use screen size
print -dtiff myfigure
```

Exporting in EPS Format with a TIFF Preview

Use the `print` function to export a figure in EPS format with a TIFF preview. When you import the figure, the application can display the TIFF preview in the source document. The preview is color if the exported figure is color, and black and white if the exported figure is black and white.

This example exports a figure to an EPS color format file, `myfigure.eps`, and includes a color TIFF preview.

```
print -depsc -tiff myfigure
```

This example exports a figure to an EPS black-and-white format file, `myfigure.eps`, and includes a black-and-white TIFF preview.

```
print -deps -tiff myfigure
```

Exporting a Figure to the Clipboard

Export a figure to the clipboard in graphics format when you want to paste it into another Windows or Macintosh application such as a word processor.

Using the Graphical User Interface

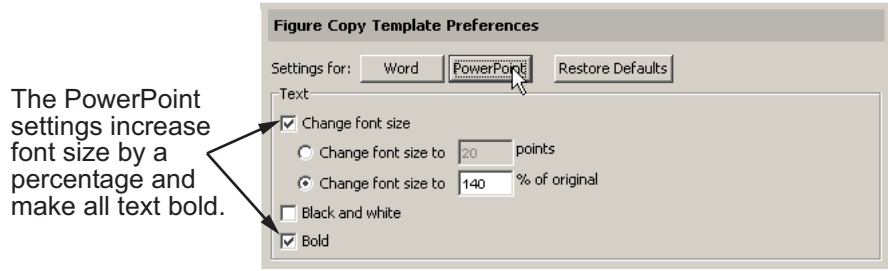
This example exports a figure to the clipboard in enhanced metafile (EMF) format. Figure settings are chosen that would make the exported figure suitable for use in a Microsoft Word™or PowerPoint™ slide. Note that changing the settings modifies the figure displayed on the screen.

1 Create a figure containing text. You can use the following code.

```
x = -pi:0.01:pi;
h = plot(x, sin(x));
title('Sine Plot');
```

2 Select **Preferences** from the **File** menu of either the figure or main desktop window. Then select **Figure Copy Template** from the Preferences dialog box.

3 In the **Figure Copy Template Preferences** panel, click the **PowerPoint** button. The MATLAB suggested settings for PowerPoint are added to the template.



The Text Panel after pushing the **PowerPoint** button

4 In the **Lines** panel, change the **Custom width** to 4 points.

5 In the **Uicontrols and axes** panel, select **Keep axes limits and tick spacing** to prevent MATLAB from possibly rescaling tick marks and limits when you export.

6 Click **Apply to Figure**. The changes appear in the figure window.

If you don't like the way your figure looks with the new settings, restore it to its original settings by clicking the **Restore Figure** button.

7 In the left pane of the Preferences dialog box, expand the **Figure Copy Template** topic. Select **Copy Options**.

8 In the **Copy Options** panel, select **Metafile** to tell MATLAB to export the figure in EMF format.

9 Check that **Transparent background** is selected. This choice makes the figure background transparent and allows the slide background to frame the axes part of the figure.

10 Clear the **Match figure screen size** check box so that you can use your own figure size settings.

11 Click **OK**.

12 Select **Export Setup** from the figure window's **File** menu.

13 Select the **Size** properties, and set **Width** to `6` and **Height** to `4.5`. Make sure that **Units** are set to `inches`.

14 Click **Close**.

15 Select **Copy Figure** from the **Edit** menu. Your figure is now exported to the clipboard and can be pasted into another Windows application, such as PowerPoint.

Using MATLAB Commands

Use the `print` function and one of two clipboard formats (`-dmeta`, `-dbitmap`) to export a figure to the clipboard. Do *not* specify a filename.

This example exports a figure to the clipboard in enhanced metafile (EMF) format.

```
print -dmeta
```

This example exports a figure to the clipboard in bitmap (BMP) 8-bit color format.

```
print -dbitmap
```

Changing a Figure's Settings

In this section...

Parameters that Affect Printing

The table below shows parameters that you can set before submitting your figure to the printer.

The Parameter column lists all parameters that you can change.

The Default column shows the default setting that MATLAB uses.

The Dialog Box column shows which dialog box to use to set that parameter. If you can make this setting on only one platform, this is noted in parentheses: (W) for Windows, and (U) for UNIX.

Some dialog boxes have tabs at the top to enable you to select a certain category. These categories are denoted in the table below using the format `<dialogbox>/<tabname>`. For example, **Print Preview/Layout...** in this column means to use the Print Preview dialog box, selecting the **Layout** tab.

The `print` Command or `set` Property column shows how to set the parameter using the MATLAB `print` or `set` function. When using `print`, the table shows the appropriate command option (for example, `print -loose`). When using `set`, it shows the property name to set along with the type of object (for example, (Line) for line objects).

Parameter	Default	Dialog Box	`print` Command or `set` Property
Select figure	Last active window	None	`print -f`*`handle`*
Select printer	System default	**Print**	`print -p`*`printer`*
Figure size	8-by-6 inches	**Print Preview/Layout**	`PaperSize` (Figure) `PaperUnits` (Figure)
Position on page	0.25 in. from left, 2.5 in. from bottom	**Print Preview/Layout**	`PaperPosition` (Figure) `PaperUnits` (Figure)
Position mode	Manual	**Print Preview/Layout**	`PaperPositionMode` (Figure)
Paper type	Letter	**Print Preview/Layout**	`PaperType` (Figure)
Paper orientation	Portrait	**Print Preview/Layout**	`PaperOrientation` (Figure)
Renderer	Selected by MATLAB	**Print Preview/Advanced**	`print -zbuffer | -painters | -opengl`
Renderer mode	Auto	**Print Preview/Advanced**	`RendererMode` (Figure)
Resolution	Depends on driver or graphics format	**Print Preview/Advanced**	`print -r`*`resolution`*

Parameter	Default	Dialog Box	`print` Command or `set` Property
Axes tick marks	Recompute	**Print Preview/Advanced**	`XTickMode, etc.` (Axes)
Background color	Force to white	**Print Preview/Color**	`Color` (Figure) `InvertHardCopy` (Figure)
Font size	As in the figure	**Print Preview/Lines/Text**	`FontSize` (Text)
Bold font	Regular font	**Print Preview/Lines/Text**	`FontWeight` (Text)
Line width	As in the figure	**Print Preview/Lines/Text**	`LineWidth` (Line)
Line style	Black or white	**Figure Copy Template**	`LineStyle` (Line)
Line and text color	Black and white	**Print Preview/Lines/Text**	`Color` (Line, Text)
CMYK color	RGB color	**Print Preview/Color** (U)	`print -cmyk`
UI controls	Printed	**Print Preview/Advanced**	`print -noui`
Bounding box	Tight	N/A	`print -loose`
Copy background	Transparent	**Copy Options** (W)	See "Background color"
Copy size	Same as screen size	**Copy Options** (W)	See "Figure Size"

Selecting the Figure

By default, MATLAB prints the current figure. If you have more than one figure open, the current figure is the last one that was active. To make a different figure active, click it to bring it to the foreground.

Using MATLAB Commands

Specify a figure handle using the command

```
print -fhandle
```

This example sends Figure No. 2 to the printer. A figure's number is usually its handle.

```
print -f2
```

Selecting the Printer

You can select the printer you want to use with the Print dialog box or with the `print` function.

Using the Graphical User Interface

1. Select **Print** from the figure window's **File** menu.
2. Select the printer from the list box near the top of the Print dialog box.
3. Click **OK**.

Using MATLAB Commands

You can select the printer using the `-P` switch of the `print` function.

This example prints Figure No. 3 to a printer called `Calliope`.

```
print -f3 -PCalliope
```

If the printer name has spaces in it, put single quotation marks around the `-P` option, as shown here.

```
print '-Pmy local printer'
```

Using a Network Print Server. On Windows systems, you can print to a network print server using the form shown here for a printer named `trinity` located on a computer named `PRINTERS`.

```
print -P\\PRINTERS\trinity
```

Note On Windows, when you use the `-P` option to identify a printer to use, if you specify any driver other than `-dwin` or `-dwinc`, MATLAB writes the output to a file with an appropriate extension but does not send it to the printer; you can then copy that file to a printer.

Setting the Figure Size and Position

The default output figure size is 8 inches wide by 6 inches high, which maintains the aspect ratio (width to height) of the MATLAB figure window. The figure's default position is centered both horizontally and vertically when printed to a paper size of 8.5-by-11 inches.

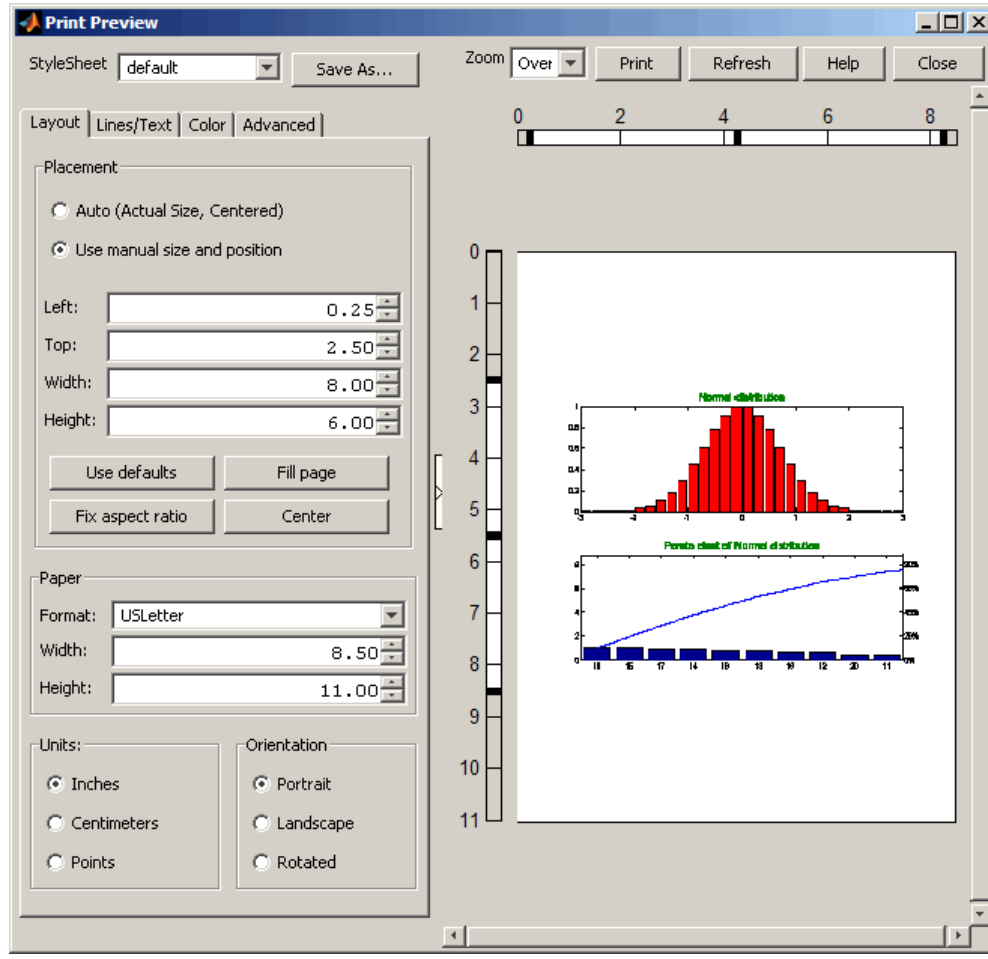
You can change the size and position of the figure:

- "Using the Graphical User Interface" on page 7-47
- "Using MATLAB Commands" on page 7-49

Using the Graphical User Interface

Select **Print Preview** from the figure window's **File** menu to open the Print Preview dialog box. Click the **Layout** tab to make changes to the size and position of your figure on the printed page.

Use the text edit boxes on the left to enter new dimensions for your figure. Or, use the handlebars on the rulers in the right-hand pane to drag the margins and location of your figure with the mouse. The outer handlebars move the figure toward or away the nearest margin, while the central handlebar repositions the figure on the page without changing its proportions. Guidelines appear while you are using the handlebars.



Settings you can change in the **Layout** tab are as follows:

Placement. Choose whether you want the figure to be the same size as it is displayed on your screen, or you want to manually change its size using the options in the **Layout** pane.

When you select the **Use manual size and position** mode, type the widths of any of the four margins and the preview image responds after each entry you

make. Select units of measure (inches/centimeters/points) with pushbuttons on the **Units** section on the bottom of the pane.

You can use the four buttons at the bottom of the Placement section to expand the figure to fill the page, make its aspect ratio (ratio of y-extent to x-extent) as printed match that of the figure, center the figure on the page, or restore the setup to what it was when you opened the Print Preview dialog. Selecting **Fill page** can alter the aspect ratio of your image. To get the maximum figure size without altering the aspect ratio, select **Fix aspect ratio**.

Auto (actual size, centered). Select this option to center the figure on the page; it will be the same size as it is in the figure window. The four buttons below the control are dimmed when you select this option.

Note Changes you make using Print Preview affect the printed output only. They do not alter the figure displayed on your screen.

Using MATLAB Commands

To print your figure with a specific size or position, make sure the `PaperPositionMode` property is set to `manual` (the default). Then set the `PaperPosition` property to the desired size and position.

The `PaperPosition` property references a four-element row vector that specifies the position and dimensions of the printed output. The form of the vector is

```
[left bottom width height]
```

where

- `left` specifies the distance from the left edge of the paper to the left edge of the figure.
- `bottom` specifies the distance from the bottom of the paper to the bottom of the figure.
- `width` and `height` specify the figure's width and height.

The MATLAB default values for `PaperPosition` are

```
[0.25 2.5 8.0 6.0]
```

This example sets the figure size to a width of 4 inches and height of 2 inches, with the origin of the figure positioned 2 inches from the left edge of the paper and 1 inch from the bottom edge.

```
set(gcf, 'PaperPositionMode', 'manual');
set(gcf, 'PaperUnits', 'inches');
set(gcf, 'PaperPosition', [2 1 4 2]);
```

Note `PaperPosition` specifies a bottom margin, rather than a top margin as Print Preview does. When you set the top margin using Print Preview, MATLAB uses this setting to calculate the bottom margin, and updates the `PaperPosition` property appropriately.

Setting the Paper Size or Type

Set the paper size by specifying the dimensions or by choosing from a list of predefined paper types. If you do not set a paper size or type, MATLAB uses the default paper size of 8.5-by-11 inches.

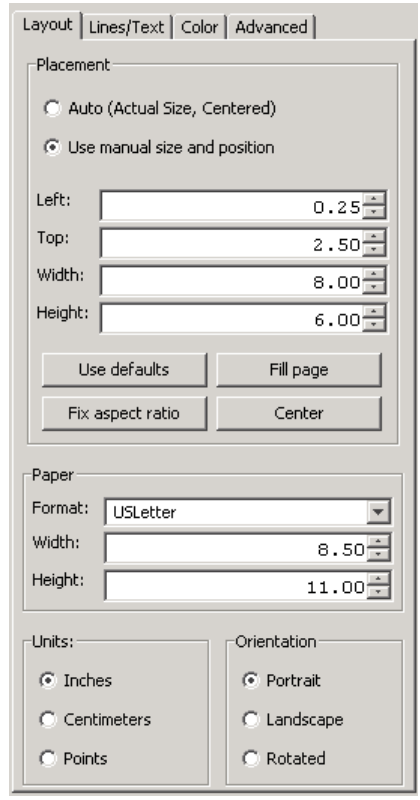
Paper-size and paper-type settings are interrelated—if you set a paper type, MATLAB updates the paper size. For example, if you set the paper type to `US Legal`, MATLAB updates the width of the paper to 8.5 inches and the height to 14 inches.

You can change the paper size and orientation:

- "Using the Graphical User Interface" on page 7-50
- "Using MATLAB Commands" on page 7-52

Using the Graphical User Interface

Select **Print Preview** from the figure window's **File** menu to open the Print Preview dialog box. Click the **Layout** tab to make changes to the paper type and orientation of the figure on the printed page.



Settings you can change in the **Layout** tab are as follows:

Paper Format, Units and Orientation. Select a paper type from the list under **Format**. If there is no paper type with suitable dimensions, enter your own dimensions in the **Width** and **Height** fields. Make sure **Units** is set appropriately to `inches`, `centimeters`, or `points`. If you change units after setting a paper width and height, the **Width** and **Height** fields update to use the units you just selected. The page region in the preview pane updates to show the new paper format or size when you change them.

Use the **Orientation** buttons to select how you want the figure to be oriented on the printed page. The illustration under "Setting the Paper Orientation" on page 7-52 shows the three types of orientation you can choose from.

Note Changes you make using Print Preview affect the printed output only. They do not alter the figure displayed on your screen.

Using MATLAB Commands

Set the `PaperType` property to one of the built-in MATLAB paper types, or set the `PaperSize` property to the dimensions of the paper.

When you select a paper type, the unit of measure is not automatically updated. We recommend that you set the `PaperUnits` property first.

For example, these commands set the units to `centimeters` and the paper type to `A4`.

```
set(gcf, 'PaperUnits', 'centimeters');
set(gcf, 'PaperType', 'A4');
```

This example sets the units to `inches` and sets the paper size of 5-by-7 inches.

```
set(gcf, 'PaperUnits', 'inches');
set(gcf, 'PaperSize', [5 7]);
```

If you set a paper size for which there is no matching paper type, the `PaperType` property is automatically set to `'custom'`.

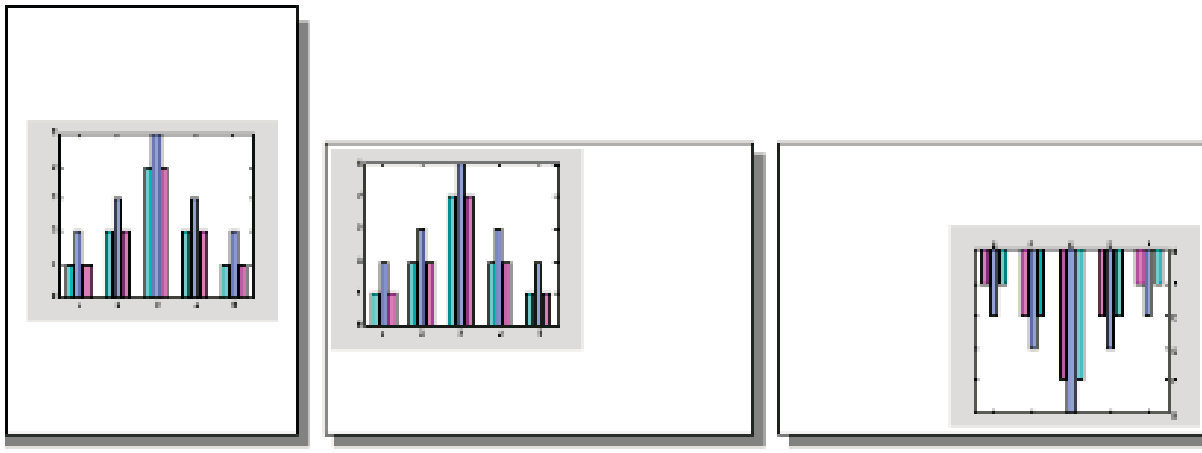
Setting the Paper Orientation

Paper orientation refers to how the paper is oriented with respect to the figure. The choices are **Portrait** (the default), **Landscape**, and **Rotated**.

You can change the orientation of the figure:

- "Using the Graphical User Interface" on page 7-53
- "Using MATLAB Commands" on page 7-53

The figure below shows the same figure printed using the three different orientations.



Note The **Rotated** orientation is not supported by all printers. When the printer does not support it, landscape is used.

Using the Graphical User Interface

1. Select **Print Preview** from the figure window's **File** menu and select the **Layout** tab. (See "Using the Graphical User Interface" on page 7-50).
2. Select the appropriate option button under **Orientation**.
3. Click **Close**.

Using MATLAB Commands

Use the `PaperOrientation` figure property or the `orient` function. Use the `orient` function if you always want your figure centered on the paper.

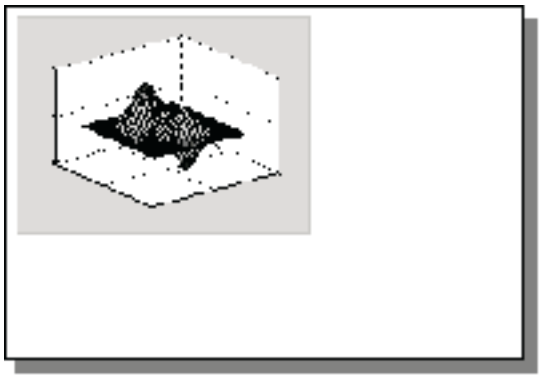
The following example sets the orientation to `landscape`:

```
set(gcf, 'PaperOrientation', 'landscape');
```

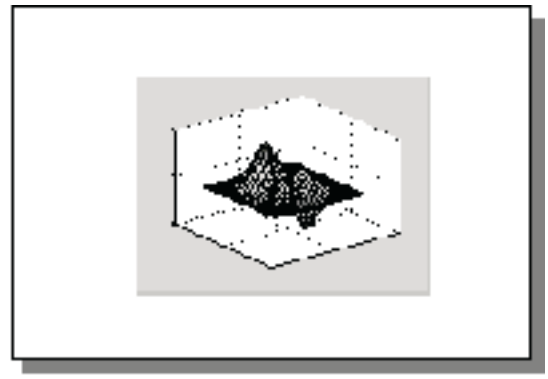
Centering the Figure. If you set the `PaperOrientation` property from `portrait` to either of the other two orientation schemes, you might find that what was previously a centered image is now positioned near the paper's edge. You can either adjust the position (use the `PaperPosition` property), or you can use the `orient` function, which always centers the figure on the paper.

The `orient` function takes the same argument names as `PaperOrientation`. For example,

```
orient rotated;
```



Orientation set to '`landscape`' using '`PaperOrientation`' property.



Orientation set to '`landscape`' using `orient` function.

Selecting a Renderer

A renderer is software and/or hardware that processes graphics data (such as vertex coordinates) to display, print, or export a figure. You can change the renderer that MATLAB uses when printing a figure:

- "Using the Graphical User Interface" on page 7-56
- "Using MATLAB Commands" on page 7-57

Renderers Supported by MATLAB

MATLAB supports three rendering methods with the following characteristics:

Painter's

- Draws figures using vector graphics
- Generally produces higher resolution results
- The fastest renderer when the figure contains only simple or small graphics objects
- The only renderer possible when printing with the HPGL print driver or exporting to an Adobe Illustrator file
- The best renderer for creating PostScript or EPS files
- Cannot render figures that use RGB color for patch or surface objects
- Does not show lighting or transparency

Z-buffer

- Draws figures using bitmap (raster) graphics
- Faster and more accurate than Painter's
- Can consume a lot of system memory if MATLAB is displaying a complex scene
- Shows lighting, but not transparency

OpenGL

- Draws figures using bitmap (raster) graphics
- Generally faster than Painter's or Z-buffer
- In some cases, enables MATLAB to access graphics hardware that is available on some systems
- Shows both lighting and transparency

For more detailed information about the rendering methods, see `Renderer` on the Figure Properties reference page.

The Default Renderer for MATLAB

By default, MATLAB tries to optimize the rendering method based on the attributes of the figure (its complexity and the settings of various Handle Graphics properties) and in some cases, the printer driver or file format used.

In general, MATLAB uses

- Painter's for line plots, area plots (bar graphs, histograms, etc.), and simple surface plots
- Z-buffer when the computer screen is not true color or when the `opengl` function was called with `selection_mode` set to `neverselect`
- OpenGL for complex surface plots using interpolated shading and any figure using lighting

The `RendererMode` property tells MATLAB whether to automatically select the renderer based on the contents of the figure (when set to `auto`), or to use the `Renderer` property that you have indicated (when set to `manual`).

Reasons for Manually Setting the Renderer

Two reasons to set the renderer yourself are

- To make your printed or exported figure look the same as it did on the screen. The rendering method used for printing and exporting the figure is not always the same method used to display the figure.
- To avoid unintentionally exporting your figure as a bitmap within a vector format. For example, MATLAB typically renders high-complexity plots using OpenGL or Z-buffer. If you export a high-complexity figure to the EPS or EMF vector formats without specifying a rendering method, MATLAB might use OpenGL or Z-buffer, each of which creates bitmap graphics.

  Storing a bitmap in a vector file can generate a very large file that takes a long time to print. If you use one of these formats and want to make sure that your figure is saved as a vector file, be sure to set the rendering method to Painter's.

Using the Graphical User Interface

1. Open the Print Preview dialog box by selecting **Print Preview** from the figure window's **File** menu. Select the **Advanced** tab.
2. In the `Renderer` drop-down menu, select the desired rendering method from the list box.

3 Click **Close**.

Using MATLAB Commands

You can use the `Renderer` property or a switch with the `print` function to set the renderer for printing or exporting. These two lines each set the renderer for the current figure to Z-buffer.

```
set(gcf, 'Renderer', 'zbuffer');
```

or

```
print -zbuffer
```

The first example saves the new value of `Renderer` with the figure; the second example only affects the current print or export operation.

Note that when you set the `Renderer` property, the `RendererMode` property is automatically reset from `auto` (the factory default) to `manual`.

Setting the Resolution

Resolution refers to how accurately your figure is rendered when printed or exported. Higher resolutions produce higher quality output. The specific definition of resolution depends on whether your figure is output as a bitmap or as a vector graphic.

You can change the resolution that MATLAB uses to print a figure:

- "Using the Graphical User Interface" on page 7-59
- "Using the Graphical User Interface on UNIX" on page 7-71
- "Using MATLAB Commands" on page 7-59

Default Resolution and When You Can Change It

The default resolution depends on the renderer used and the graphics format or printer driver specified. The following two tables summarize the default resolutions and whether you can change them.

Resolutions Used with Graphics Formats

Graphics Format	Default Resolution	Can Be Changed?
Built-in MATLAB export formats, (except for EMF, EPS, and ILL)	150 dpi (always use OpenGL or Z-buffer)	Yes
EMF export format (Enhanced Metafile)	150 dpi	Yes
EPS (Encapsulated PostScript)	150 dpi, if OpenGL or Z-buffer; 864 dpi if Painter's	Yes
ILL export format (Adobe Illustrator)	72 dpi (always uses Painter's)	No
Ghostscript export formats	72 dpi (always uses OpenGL or Z-buffer)	No

Resolutions Used with Printer Drivers

Printer Driver	Default Resolution	Can Be Changed?
Windows and PostScript drivers	150 dpi, if OpenGL or Z-buffer; 864 dpi if Painter's	Yes
Ghostscript driver	150 dpi, if OpenGL or Z-buffer; 864 dpi if Painter's	Yes
HPGL driver	1116 dpi (always uses Painter's)	Yes

Choosing a Setting

You might need to determine your resolution requirements through experimentation, but you can also use the following guidelines.

For Printing. The default resolution of 150 dpi is normally adequate for typical laser-printer output. However, if you are preparing figures for high-quality printing, such as a textbook or color brochures, you might want to use 200 or 300 dpi. The resolution you can use can be limited by the printer's capabilities.

For Exporting. If you are exporting your figure, base your decision on the resolution supported by the final output device. For example, if you will import your figure into a word processing document and print it on a printer that supports a maximum resolution setting of 300 dpi, you could export your figure using 300 dpi to get a precise one-to-one correspondence between pixels in the file and dots on the paper.

Note The only way to set resolution when exporting is with the `print` function.

Impact of Resolution on Size and Memory Needed

Resolution affects file size and memory requirements. For both printing and exporting, the higher the resolution setting, the longer it takes for MATLAB or your printer to render your figure.

Using the Graphical User Interface

To set the resolution for built-in MATLAB printer drivers:

1. From the Print dialog box, click **Properties**. This opens a new dialog box. (This box can differ from one printer to another.)
2. You may be able to set the resolution from this dialog. If not, then click **Advanced** to get to a dialog box that enables you to do this.
3. Set the resolution, and then click **OK**. (The resolution setting might be labeled by another name, such as "Print Quality.")

Using MATLAB Commands

If you use a Windows printer driver, you can only set the resolution using the Windows Document Properties dialog box.

Otherwise, to set the resolution for printing or exporting, the syntax is

```
print -rnumber
```

where `number` is the number of dots per inch. To print or export a figure using screen resolution, set `number` to `0` (zero).

This example prints the current figure with a resolution of 100 dpi:

```
print -r100
```

This example exports the current figure to a TIFF file using screen resolution:

```
print -r0 -dtiff myfile.tif
```

Setting the Axes Ticks and Limits

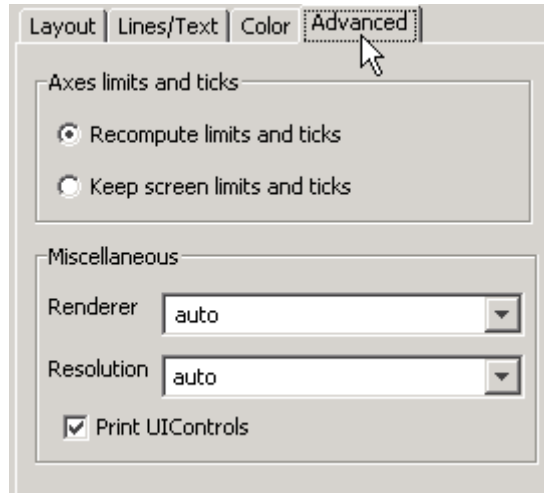
The MATLAB default output size, 8-by-6 inches, is normally larger than the screen size. If the size of your printed or exported figure is different from its size on the screen, MATLAB scales the number and placement of axes tick marks to suit the output size. This section shows you how to lock them so that they are the same as they were when displayed.

You can change the resolution that MATLAB uses to print a figure:

- "Using the Graphical User Interface" on page 7-61
- "Using MATLAB Commands" on page 7-62

Using the Graphical User Interface

Select **Print Preview** from the figure window's **File** menu to open the Print Preview dialog box. Select the **Advanced** tab to make changes to the axes, UI controls, or renderer settings.



Settings you can change in the **Advanced** tab are as follows, by panel:

Axes limits and ticks. If the size of your printed or exported figure is different from its size on the screen, MATLAB scales the number and placement of axes tick marks to suit the output size. Select **Keep screen limits and ticks** to lock them so that they are the same as they were when displayed. If you want MATLAB to adjust the ticks and limits when scaling for printing, select **Recompute limits and ticks**.

Miscellaneous. Use the **Renderer** drop-down menu to tell MATLAB which renderer to use in printing the figure. Set the renderer to `Painters`, `Z-buffer`, or `OpenGL`, or select `auto` to let MATLAB decide which one to use, depending on the characteristics of the figure. (See "Selecting a Renderer" on page 7-54).

Use the **Resolution** drop-down menu to specify the resolution, in dots per inch (DPI), at which to render and print the figure. You can select `150`, `300`, or `600` DPI, or type in a different value (positive integer).

Figure UI Controls. By default, user interface controls are included in your printed or exported figure. Clear the **Print UIControls** check box to exclude them. (See "Excluding User Interface Controls form Printed Output" on page 7-71).

Note Changes you make using Print Preview affect the printed output only. They do not alter the figure displayed on your screen.

Using MATLAB Commands

To set the `XTickMode`, `YTickMode`, and `ZTickMode` properties to `manual`, type

```
set(gca, 'XTickMode', 'manual');
set(gca, 'YTickMode', 'manual');
set(gca, 'ZTickMode', 'manual');
```

Setting the Background Color

You can keep the background the same as is shown on the screen when printed, or change the background to white. There are two types of background color settings in a figure: the axes background and the figure background. The default displayed color of both backgrounds is gray, but you can set them to any of several colors.

Regardless of the background colors in your displayed figure, by default, MATLAB always changes them to white when you print or export. This section shows you how to retain the displayed background colors in your output.

Using the Graphical User Interface

To retain the background color on a per figure basis:

1. Open the Print Preview dialog box by selecting **Print Preview** from the figure window's **File** menu. Select the **Color** tab.
2. Select **Same as figure**.
3. Click **Close**.

If you are exporting your figure using the clipboard, use the **Copy Options** panel of the Preferences dialog box.

Using MATLAB Commands

To retain your background colors, use

```
set(gcf, 'InvertHardCopy', 'off');
```

The following example sets the figure background color to `blue`, the axes background color to `yellow`, and then sets `InvertHardCopy` to `off` so that these colors appear in your printed or exported figure.

```
set(gcf, 'color', 'blue');
set(gca, 'color', 'yellow');
set(gcf, 'InvertHardCopy', 'off');
```

Setting Line and Text Characteristics

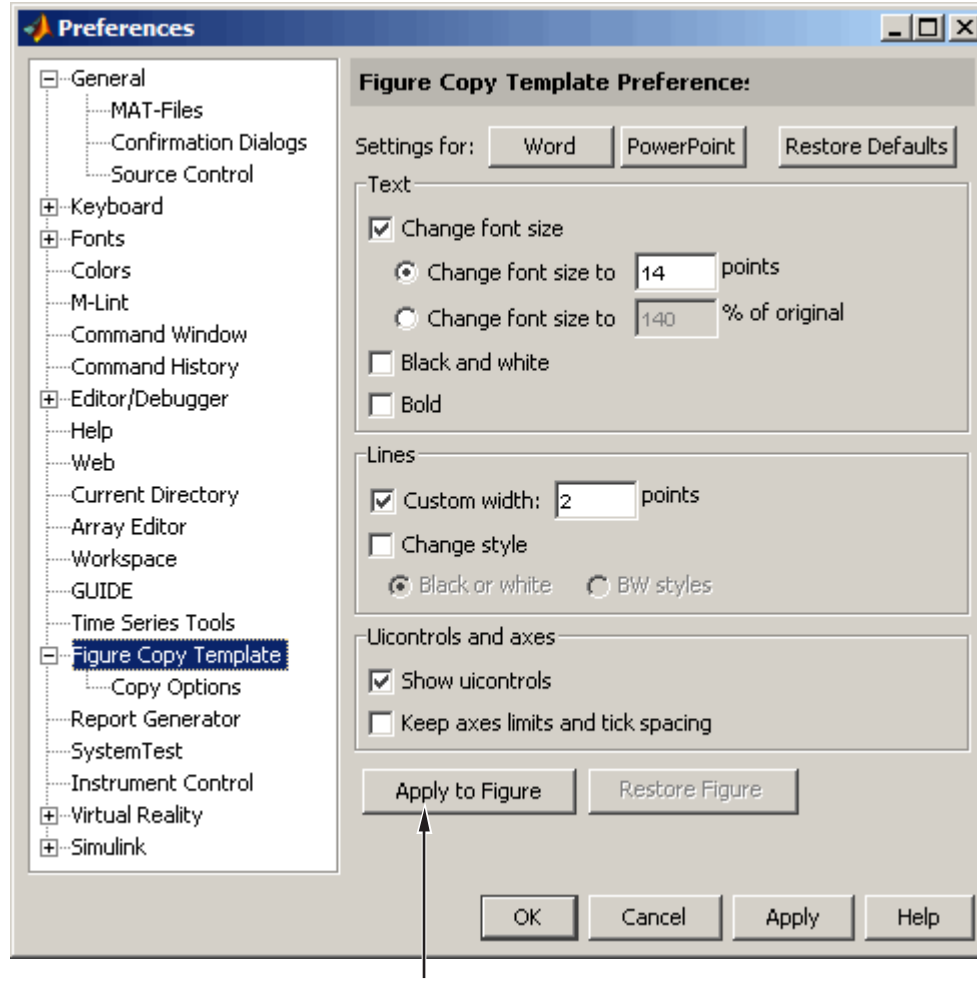
If you transfer your figures to Word or PowerPoint applications, you can set line and text characteristics to values recommended for those applications. The Figure Copy Template Preferences dialog box provides Word and PowerPoint options to make these settings, or you can set certain line and text characteristics individually.

You can change line and text characteristics:

- "Using the Graphical User Interface" on page 7-64
- "Using MATLAB Commands" on page 7-65

Using the Graphical User Interface

To open Figure Copy Template Preferences, select **Preferences** from the **File** menu, and then click **Figure Copy Template** in the left pane.



Note the difference between **Apply to Figure** and **Apply**.
Use **Apply to Figure** to modify the figure in the figure window.
Use **Apply** or **OK** to save your preferences.

Settings you can change in the Figure Copy Template Preferences dialog box are as follows:

Word or PowerPoint. Click **Word** or **PowerPoint** to apply settings recommended for MATLAB.

Text. Use options under **Text** to modify the appearance of all text in the figure. You can change the font size, change the text color to black and white, and change the font style to bold.

Lines. Use the **Lines** options to modify the appearance of all lines in the figure:

- **Custom width** — Change the line width.
- **Change style (Black or white)** — Change colored lines to black or white.
- **Change style (B&W styles)** — Change solid lines to different line styles (e.g., solid, dashed, etc.), and black or white color.

UIControls and axes. If your figure includes user interface controls, you can choose to show or hide them by clicking **Show uicontrols**. Also, to keep axes limits and tick marks as they appear on the screen, click **Keep axes limits and tick spacing**. To allow MATLAB to scale axes limits and tick marks based on the size of the printed figure, clear this box.

Note Changes you make using Print Preview affect the printed output only. They do not alter the figure displayed on your screen.

Using MATLAB Commands

You can use the `set` function on selected graphics objects in your figure to change individual line and text characteristics.

For example, to change line width to `1.8` and line style to a dashed line, use

```
lineobj = findobj('type', 'line');
set(lineobj, 'linewidth', 1.8);
set(lineobj, 'linestyle', '--');
```

To change the font size to 15 points and font weight to bold, use

```
textobj = findobj('type', 'text');
set(textobj, 'fontunits', 'points');
set(textobj, 'fontsize', 15);
set(textobj, 'fontweight', 'bold');
```

Setting the Line and Text Color

When colored lines and text are dithered to gray by a black-and-white printer, it does not produce good results for thin lines and the thin lines that make up text characters. You can, however, force all line and text objects in the figure to print in black and white, thus improving their appearance in the printed copy. When you select this setting, the lines and text are printed all black or all white, depending on the background color.

The default is to leave lines and text in the color that appears on the screen.

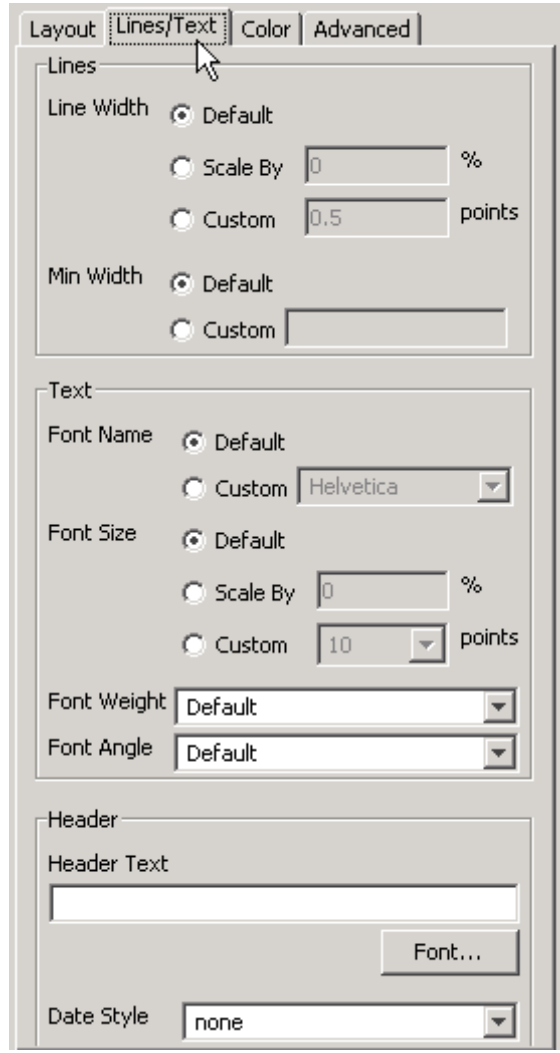
Note Your background color might not be the same as what you see on the screen. See the **Color** tab for an option that preserves the background color when printing.

You can change the resolution that MATLAB uses to print a figure:

- "Using the Graphical User Interface" on page 7-66
- "Using MATLAB Commands" on page 7-68

Using the Graphical User Interface

Select **Print Preview** from the figure window's **File** menu to open the Print Preview dialog box. Select the **Lines and Text** tab to make changes to the color of all lines and text on the printed page. The controls for the **Lines and Text** tab are shown below:



Settings you can change in **Lines and Text** are as follows:

Lines. The default option in this panel causes lines to print at the same width they are portrayed in the figure window. You can scale line width from 0 percent upwards for printing using the **Scale By** field. To print lines at a particular point size, select **Custom**. All lines on the plot will be the same weight when you use the **Custom** option; the **Scale By** option respects relative line weight.

When you scale lines downward, you can prevent them from becoming too faint by setting the **Min Width** option to **Custom** and specifying a minimum line width in points in that field.

Text. The default is to print text in the same font and at the same size as it is in the figure. To change the font (for all text) select **Custom** and choose a new font from the drop-down list that is then enabled. Scale the font size using the **Scale By** option. To print text at a particular point size, select **Custom**. All text on the plot will be printed at the point size you specify when you use the **Custom** option; the **Scale By** option respects relative font size. You can specify the **Font Weight** (normal, light, demi, or bold) and **Font Angle** (`normal`, `italic`, or `oblique`) for all text as well, using the drop-down menus at the bottom of the **Text** panel.

Header. Type any text that you want to appear at the top of the printed figure in the **Header Text** edit field. If you want today's date and/or time appended to the header text, select the appropriate format from the **Date Style** popup menu. To specify and style the header font (which is independent of the font used in the figure), click the **Font** button and choose a font name, size, and style from the **Font** selection window that appears.

Note Changes you make using Print Preview affect the printed output only. They do not alter the figure displayed on your screen.

Using MATLAB Commands

There is no equivalent MATLAB command that sets line and text color depending on background color. Set the color of lines and text using the `set` function on either line or text objects in your figure.

This example sets all lines and text to black:

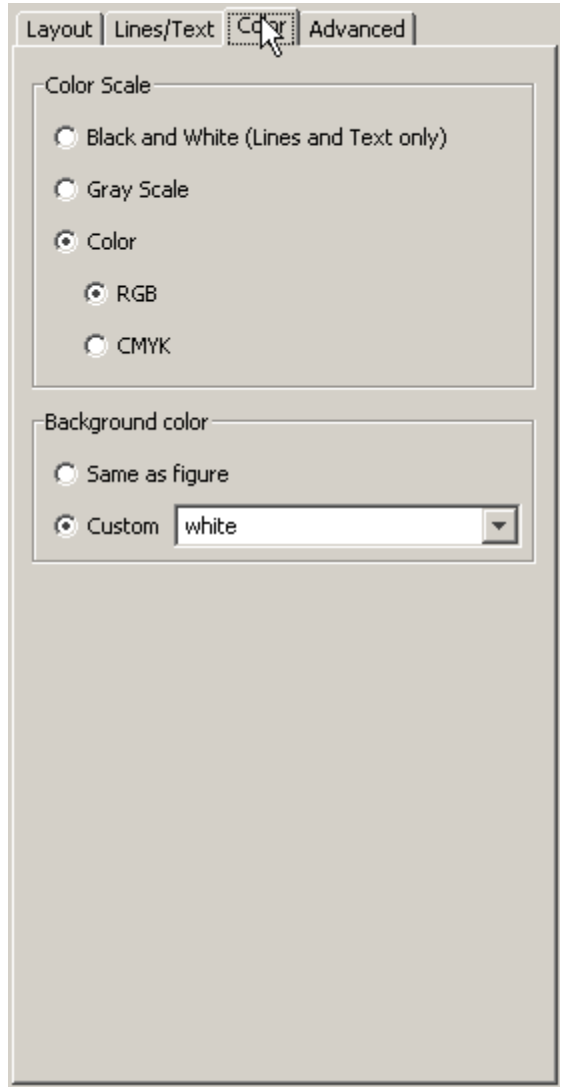
```
set(findobj('type', 'line'), 'color', 'black');
set(findobj('type', 'text'), 'color', 'black');
```

Specifying a Colorspace for Printing and Exporting

By default, MATLAB produces color output in the RGB color space (red, green, blue). If you plan to publish and print MATLAB figures using printing industry standard four-color separation, you might want to use the CMYK color space (cyan, magenta, yellow, black).

Using the Graphical User Interface on Windows

Select **Print Preview** from the figure window's **File** menu to open the Print Preview dialog box. Select the **Color** tab to make changes to the color of all lines and text on the printed page. The controls for the **Color** tab are shown below:



You can print the contents of your figure in color, grayscale, or black-and-white by selecting the appropriate button in the panel. When you select **Color**, you can choose between an **RGB** (red/green/blue) or a **CMYK** (cyan/magenta/yellow/black) color specification, if your printer is capable of it.

Independently of the **Color Scale** controls, you can specify a **Background color** for printing. Select **Same as figure** to use the color used in the figure itself (default is gray), or specify a **Custom** color from the combo box popup menu. The choices are `black`, `white`, and several RGB color triplet values; you type any valid MATLAB colorspec in this field as well, such as `g`, `magenta`, or `.3 .4 .5`.

The background color you specify is respected even if you choose **Black and White** or **Gray Scale** in the **Color Scale** panel.

Using the Graphical User Interface on UNIX

1. Select **Print** from the figure window's **File** menu.
2. Click the **Appearance** tab.
3. In the **Color Appearance** panel, select **Color**.
4. Click **Print**.

On any platform, you can also indicate whether to print in color, grayscale or black-and-white with the Print Preview dialog box.

Using MATLAB Commands

Use the `-cmyk` option with the `print` function. This example prints the current figure in CMYK using a PostScript Level II color printer driver.

```
print -dpsc2 -cmyk
```

Excluding User Interface Controls form Printed Output

User interface controls are objects that you create and add to a figure. For example, you can add a button to a figure that, when clicked, conveniently runs another M-file. By default, user interface controls are included in your printed or exported figure. This section shows how to exclude them.

Using the Graphical User Interface

1. Open the Print Preview dialog box by selecting **Print Preview** from the figure window's **File** menu, and then select the **Advanced** tab.
2. Under **Miscellaneous**, clear the **Print UIControls** check box.
3. Click **Close**.

Using MATLAB Commands

Use the `-noui` switch. This example specifies a color PostScript driver and excludes UI controls.

```
print -dpsc -noui
```

This example exports the current figure to a color EPS file and excludes UI controls.

```
print -depsc -noui myfile.eps
```

Producing Uncropped Figures

In most cases, MATLAB crops the background tightly around the objects in the figure. Depending on the printer driver or file format you use, you might be able to produce uncropped output. An uncropped figure has increased background area and is often desirable for figures that contain UI controls.

The setting you make in MATLAB changes the PostScript `BoundingBox` property saved with the figure.

Using MATLAB Commands

Use the `-loose` option with the `print` function. For Windows, the uncropped option is only available if you print to a file.

This example exports the current figure, uncropped, to an EPS file.

```
print -deps -loose myfile.eps
```

Choosing a Graphics Format

In this section...

What Are Graphic Formats?

A graphics file format is a specification for storing and organizing data in a file. MATLAB supports many different graphics file formats. Some are built into MATLAB and others are Ghostscript formats. File formats also differ in color support, graphics style (bitmap or vector), and bit depth.

This section provides information to help you decide which graphics format to use when exporting your figure to a file or to the Windows clipboard. It covers

Before deciding on a graphics format, check what formats are supported by your target application and platform. See the `print` reference page for a complete list of graphics formats supported in MATLAB. Once you decide on which format to use in exporting your figure, follow the instructions in "Exporting to a File" on page 7-21 or "Exporting to the Windows or Macintosh Clipboard" on page 7-32.

Frequently Used Graphics Formats

Here are some of the more frequently used graphics formats. For a complete list, see the Graphics Format table on the `print` reference page. For a more complete description of these formats, see "Description of Selected Graphics Formats" on page 7-80.

Format	Description	Command Line -device Parameter
EPS color, and black and white	Export line plots or simple graphs to a file. **Note** An EPS file does not display within some applications unless you add a TIFF preview image to it. See the example "Exporting in EPS Format with a TIFF Preview" on page 7-40.	`-deps` (black and white) `-depsc` (color) `-depsc -tiff` (TIFF preview)
JPEG 24-bit	Export plots with surface lighting or transparency to a file. This format can be displayed by most Web browsers.	`-djpeg` `-djpeg`*`number`*, where *`number`* is the compression.
TIFF 24-bit bitmap color	Export plots with surface lighting or transparency to a file. Widely available. A good format to choose if you are not sure what formats your application supports.	`-dtiff`
BMP 8-bit color bitmap	Export a figure to the clipboard (Windows only).	`-dbitmap`
EMF color vector format	Export a figure to the clipboard (Windows only).	`-dmeta`

Factors to Consider in Choosing a Format

There are at least five main factors to consider when choosing a graphics format to use in exporting a figure:

- Implementation — Is it a built-in MATLAB or Ghostscript format?
- Graphics Format — Is it bitmap or vector graphics format?
- Bit Depth — What bit depth does the format offer?
- Color Support — What color support does it have?
- Model/Publication — Is it a Simulink® model or specific publication type?

The Graphics Format table on the `print` reference page provides information on the first four of these factors for each format that MATLAB supports.

Built-In MATLAB or Ghostscript Formats

Some graphics formats are built-in MATLAB formats and others are provided by Ghostscript. In some cases (such as the Windows Bitmap format), the format is available both as a built-in format and a Ghostscript format. In general, when this is the case, we recommend that you choose the MATLAB format, especially if you plan to read the image back into MATLAB later.

The choice of MATLAB versus Ghostscript is important when any of these properties affects your output:

- "Font Support" on page 7-77
- "Resolution" on page 7-78
- "Importing into MATLAB" on page 7-78

Choosing Bitmap or Vector Graphic Output

MATLAB file formats are created using either bitmap or vector graphics. Bitmap formats store graphics as 2-D arrays of pixels. Vector formats use drawing commands to store graphics as geometric objects. Whether to use a bitmap or vector format depends mostly on the type of objects in your figure.

The choice of bitmap versus vector graphics is important when any of these properties or capabilities affects your output:

- "Degree of Complexity" on page 7-78
- "Lighting and Transparency" on page 7-78

- Line and text quality
- "File Size" on page 7-79
- "Resizing After Import" on page 7-79

To create vector output, the Painters renderer is required. Under some circumstances you might need to manually select it in the Print Preview or Export Setup GUI. The painters renderer does not support lighting or transparency.

To create bitmap output, either the OpenGL or the Z-buffer renderer is required. Under some circumstances you might need to manually select one of these in the Print Preview or Export Setup GUI. These renderers both support lighting, but only OpenGL supports transparency.

See "Impact of Rendering Method on the Output" on page 7-80 for more information.

Bit Depth

Bit depth is the number of bits a format uses to store each pixel. This determines the number of colors the exported figure can contain.

Bit depth applies mostly to bitmap graphics. An 8-bit image uses 8 bits per pixel (bpp), enabling it to define 2^8, or 256, unique colors. The other supported bit depths are 1-bit (2 colors), 4-bit (16 colors), and 24-bit (16 million colors).

In vector files that don't normally have a bit depth, the color of objects is specified by drawing commands stored in the file. However, vector files can contain bitmaps under the following conditions:

- Image objects saved in vector formats are always saved as bitmaps, regardless of the rendering method used.
- For vector files created using the OpenGL or Z-buffer renderer, everything in the figure is saved as a bitmap.

The Graphics Format table on the `print` reference page indicates the bit depth of each format. If file size is not critical, make sure you choose a format with a bit depth that supports the number of colors or shades of gray in your displayed figure.

Color Support

Each graphics format can produce color, grayscale, or monochrome output. Check the Graphics Format table to see the level of color support for each format type. To preserve the color in your exported file, you must select a color graphics format. Bit depth also affects color.

Exporting Simulink Models

Simulink models can only be exported to EPS or a Ghostscript format. Note that you can only use the `print` function to export a model, not the Export dialog box.

High Resolution or Web Publications

If you want to use a figure in a journal or other publication, use a format that enables you to set a high resolution, such as TIFF or EPS.

If you want to use a figure in a Web publication, use either the PNG or the JPEG format. If you need to save an image as a GIF file, you can use the `imwrite` function. You need to convert M-by-N-by-3 truecolor CData (such as the `getframe` function provides) to an M–by–N 8–bit array and a colormap in order to write a GIF. Alternatively, you can export your figure as a TIFF file and convert it to a GIF using another software application, or capture a figure as an image using a screen capture utility and save it in formats the utility supports.

Properties Affected by Choice of Format

The figure properties listed in this section are affected when you select a graphics format when exporting to a file or the Windows clipboard.

Font Support

Ghostscript formats support a limited number of fonts. If you use an unsupported font, MATLAB substitutes Courier. See “PostScript and Ghostscript Supported Fonts” on page 7-88 for more information.

Resolution

Generally, higher resolution means higher quality. Your choice of resolution should be based in part on the device to which you will ultimately print it. Experimentation with different resolution settings can be helpful.

You cannot change the resolution of a Ghostscript format. The resolution is low (72 dpi) and might not be appropriate for publications.

Importing into MATLAB

If you want to read an exported figure back into MATLAB, it is best to use one of the built-in MATLAB formats. You should not use PostScript or a proprietary format such as Adobe Illustrator (`.ai`), Windows metafile (`.emf`), or portable document format (`.pdf`) files.

Degree of Complexity

Bitmaps are preferable for high-complexity plots, where complexity is determined by the number of polygons, the number of polygons with interpolated shading, the number of markers, the presence of truecolor images, and other factors. An example of a high-complexity plot is a surface plot that uses interpolated shading.

Vector formats are preferable for most 2-D plots and for some low-complexity surface plots.

Lighting and Transparency

Surface lighting and transparency are only supported by bitmap graphics formats. If you use a vector format, the lighting and transparency disappear. Note that of the two renderers intended for bitmaps (OpenGL and Z-buffer) only OpenGL supports transparency.

Note If you export to an EPS (vector) file using the Painters renderer and include a TIFF preview, the preview image is a bitmap and shows lighting or transparency when displayed on your screen. Remember that the underlying format vector file, which is what normally gets printed, does not support these features.

Lines and Text

Generally, vector formats create better lines and text than bitmap formats. MATLAB renderers do not antialias lines or text.

File Size

In general, bitmap formats produce smaller files for complex plots than vector formats, and vector formats produce smaller files for simple plots than bitmap formats.

You can calculate the size of a figure exported to an uncompressed bitmap by multiplying the figure size by its resolution and the bit depth of the chosen format. For example, if a figure is 2 inches by 3 inches and has a resolution of 100 dpi (dots per inch), it will consist of (2x100)x(3x100), or 60,000 pixels. If exported to an 8-bit file, it uses 480,000 bits, or 60 KB. If exported to a 24-bit file, it uses three times the number of bytes, or 180 KB.

Vector format file size is affected by the complexity and number of objects in your figure. As the complexity and number of objects increase, the number of drawing commands increases.

Resizing After Import

You can resize a vector graphics figure after importing it into another software application without losing quality. (Not all applications that support vector formats enable you to resize them.)

This is not true of bitmap formats. Resizing a bitmap causes round-off errors that result in jagged edges and degradation of picture quality. This degradation is particularly obvious in lines and text and is highly discouraged.

Color

The Graphics Format table on the `print` reference page indicates the color support and bit depth of each format. If file size is not critical, make sure you choose a format with a bit depth that supports the number of colors or shades of gray in your displayed figure.

Impact of Rendering Method on the Output

If you specify a bitmap format when exporting, the exported file always contains a bitmap regardless of your current renderer setting. If you have the renderer set to Painters, which normally produces a vector format, that setting is ignored under these circumstances.

Vector format files, however, can store your figure as a vector or bitmap graphic depending on the renderer used to export it. If you do not specify a rendering method and MATLAB chooses the OpenGL or Z-buffer renderer, your exported vector file contains a bitmap. If you want your figure exported as a vector graphic, be sure to set the rendering method to Painter's.

Description of Selected Graphics Formats

This section contains details about some of the export file formats MATLAB supports. For information about formats not listed here, consult a graphics file format reference.

Formats covered in this section are

Adobe Illustrator 88 Files

Adobe Illustrator (ILL) is a vector format that is fully compatible with Adobe Illustrator software. An Illustrator file created in MATLAB can be further processed with Adobe Illustrator running on any platform. (Note that when you view it in Illustrator, it has no template.)

By default, Illustrator files are color and saved in portrait orientation. The Illustrator `group` command is used to give the illustrations a hierarchy similar to that of the Handle Graphics or Simulink graphic.

Some limitations of the Illustrator format are

- Interpolated patches and surfaces cannot be created. The color of each polygon is determined by the average of the `CData` values for all of the polygon's vertices.
- Images cannot be exported in this format.
- The resolution setting of 72 dpi cannot be changed.
- No fonts are downloaded to the Illustrator file. Any unavailable fonts are replaced with fonts that are available.

EMF Files

Enhanced Metafiles (EMF) are vector files similar in nature to Encapsulated PostScript (EPS), capable of producing near publication-quality graphics. EMF is an excellent format to use if you plan to import your image into a Microsoft application and want the flexibility to edit and resize your image once it has been imported. It is the only MATLAB supported vector format you can edit from within a Microsoft application. (Note that your editing ability is limited. For the best results, do all your editing in MATLAB.)

A drawback of using EMF files is that they are generally only supported by Windows-based applications.

EPS Files

The Encapsulated PostScript (EPS) vector format is the most reliable and consistent file format MATLAB supports. It is widely recognized in desktop publishing and word processing packages on both UNIX and Windows platforms. EPS is the only MATLAB supported export format that can produce CMYK output. (PostScript printer drivers also support this feature.)

This format is your best choice for producing publication-quality graphics. It might not be appropriate for figures containing interpolated shading because it creates a very large file that is difficult to print. For such figures, use the TIFF format with a high-resolution setting. For more information about format choices, see "Choosing Bitmap or Vector Graphic Output" on page 7-75.

When imported into Microsoft applications, an EPS file does not display unless you add a TIFF preview image to it.

The preview image is simple to add (see the next section, “Creating a Preview Image”). However, if you print your file to a non-PostScript printer, the TIFF preview is used as the printed image. The resolution of the preview image is 72 dpi, resulting in much lower quality than the EPS image. If there is no preview image, your printout to a non-PostScript printer contains an error message in place of the graphic. Many high-end graphics packages, like Adobe Illustrator, can print an EPS file to a non-PostScript printer.

You cannot edit figures when using EPS files in Microsoft applications; they can only be annotated.

Note The best vector format to use with Microsoft applications is EMF. See “EMF Files” on page 7-81.

EPS format has limited font support. When MATLAB exports a graphic to the EPS file format, it does not try to determine whether the fonts you have used in your axes text objects are supported by the EPS format. Unsupported fonts are replaced with Courier.

Creating a Preview Image. You cannot create TIFF preview images using the graphical user interface. Use the `print` command with the `-tiff` switch. For example, to create an EPS Level 2 image with TIFF preview in file `myfile.eps`, type

```
print -depsc2 -tiff myfile.eps
```

TIFF Files

The Tagged Image File Format (TIFF) is a very widely used bitmap format and can produce publication-quality graphics if you use a high-resolution setting (such as 200 or 300 dpi).

TIFF is a good format to choose if you are not sure what formats your target application supports, or if you want to import the graphic into more than one application without having to export it to several different formats. It can also be imported into most image-processing applications and converted to other formats, if necessary. For example, the `print` command does not produce GIF files, but there are many applications that can convert TIFF files to GIF.

You can also use `getframe` to create a snapshot of a figure and `imwrite` to save that image as a GIF file.

JPEG Files

The Joint Photographic Experts Group (JPEG) bitmap format is one of the dominant formats used in Web graphics. The 24-bit version MATLAB supports more colors than the popular GIF format.

JPEG files always use JPEG compression. This is a lossy compression scheme, meaning that some data is thrown away during compression. When you export to a JPEG image, you can set the amount of compression to use. The more compression you use, the more data is thrown away. The compression amount is referred to as JPEG quality, where the highest setting results in the highest quality image, but the lowest amount of compression.

Setting JPEG Quality. You cannot set the quality using the graphical user interface. Use the `print` command with the `-djpeg` format switch, including the desired quality value as a suffix. This example exports to a JPEG file using a quality setting of 100.

```
print -djpeg100 myfile.jpg
```

By default, MATLAB uses a quality setting of 75. Possible values are from 1 to 100. Note that the highest setting of 100 still results in some data loss, although the result is usually visually indistinguishable from the original.

How to Specify a Format for Exporting

To select a graphics format to use when exporting, choose a format from the Graphics Format table on the `print` reference page, and specify that format in either the Export dialog box or in the MATLAB `print` function.

Using the Graphical User Interface

When exporting your figure to a file:

1. Select **Export** from the figure window's **File** menu.
2. Select a format from the **Save as type** list box.

3 Enter the filename you want to use and browse for the directory to save the file in.

4 Click **Save**.

Using MATLAB Commands

To specify a nondefault graphics format for the figure you are exporting, include the `-d` switch with the `print` command. For example, to export the current figure to file `spline2d.eps`, with 600 dpi resolution, and using the EPS color graphics format, type

```
print -r600 -depsc spline2d
```

Note When printing, the `print -d` option specifies a printer driver. When exporting, the `print -d` option specifies a graphics format.

Choosing a Printer Driver

In this section...

What Are Printer Drivers?

A MATLAB printer driver formats your figure into instructions that your printer understands. There are two main types of MATLAB printer drivers: built-in MATLAB, and Ghostscript. See the Printer Driver table on the `print` reference page for a complete list of supported drivers. Specifying the printer driver does not change the selected printer. This following sections provide information to help you decide which printer driver to use when printing your figure.

Built-in MATLAB Drivers

Built-in MATLAB drivers are written specifically for MATLAB and include Windows, PostScript, and HPGL.

MATLAB provides built-in Windows printer drivers so that your print requests can work with the Windows Print Manager. The Print Manager enables you to monitor printer queues and control various aspects of the printing process.

HPGL support is provided for the HP 7475A plotter and fully compatible plotters. HPGL files can also be imported into documents of other applications, such as Microsoft Word, although add-on filters for them may be needed.

Ghostscript Drivers

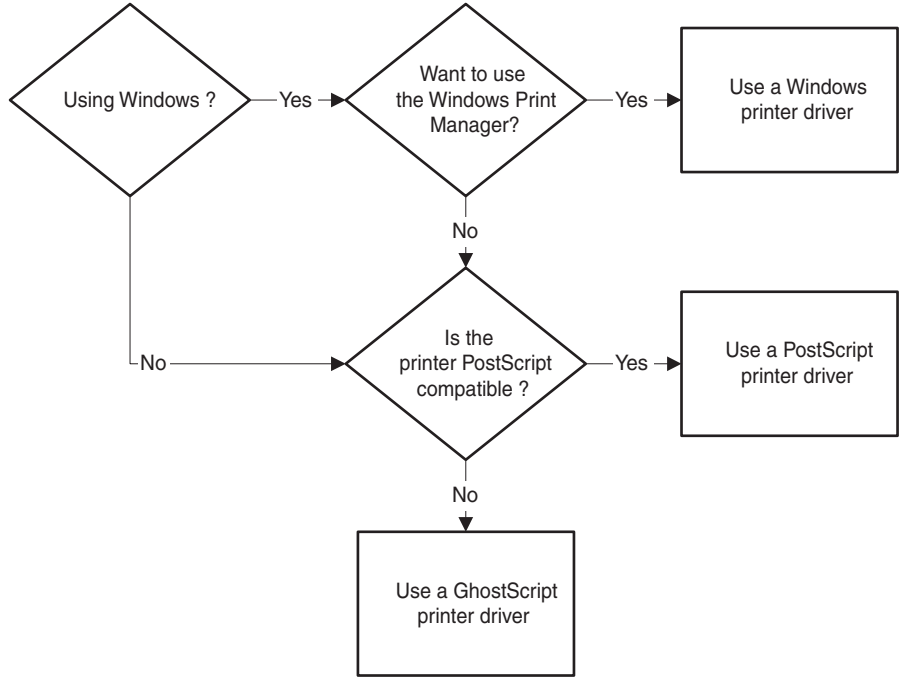
Ghostscript drivers use Ghostscript to convert your figure into printer-model-specific instructions. MATLAB generates a PostScript representation of the figure and Ghostscript generates the printer instructions from that. Examples of Ghostscript drivers are Epson and HP.

Factors to Consider in Choosing a Driver

The choice of printer driver depends upon several considerations:

- What platform you are using
- What kind of printer you have
- What color model you want to use
- What font support you need
- Any driver-specific settings you need

The following flowchart gives an overview of how to choose a driver based on the platform you are using and the type of printer you have.



Deciding What Type of Printer Driver to Use

Platform Considerations

On Windows, you can use any of the driver types shown in the flowchart. If you use the Windows driver, you can use the Windows Print Manager.

On UNIX, you can use either PostScript or Ghostscript drivers.

On either platform, if you have a PostScript-compatible printer, it is better to use a PostScript driver than a Ghostscript driver, because doing so avoids the unnecessary Ghostscript conversion step and is likely to create more accurate renditions.

Printer Type

Printer support is different among the Windows, PostScript, and Ghostscript drivers. Consult the manual for your printer to see what driver to use.

Windows drivers support most printer models, but sometimes the printer's native driver is incompatible with the MATLAB Windows driver. If you are getting printing errors, see "Trouble with Native Drivers on Windows" on page 7-90.

Some Ghostscript drivers are specific to certain printer models. For example, MATLAB provides different drivers to support the HP DeskJet 500, 500C, and 550C models, plus a generic driver for the series. When this is the case, try the model-specific driver first. If that doesn't work, try the generic driver.

Color Model

By default, MATLAB uses a black-and-white driver. The built-in MATLAB and Ghostscript drivers print both color and black and white. The Printer Drivers table on the `print` reference page indicates which drivers are color.

Colored surfaces and images print in grayscale when you use a black-and-white driver. Colored lines and text can be printed in color, grayscale, or black and white, depending on the color support of the driver and color capability of your printer. Results can vary depending on whether images, text, lines, patches, or surfaces are being printed.

Font Support

In MATLAB, the fonts supported for printing depend upon the MATLAB printer driver you specify and sometimes upon which platform you are using.

PostScript and Ghostscript Supported Fonts. The table below lists the fonts supported by the MATLAB PostScript and Ghostscript drivers. This same set of fonts is supported on both Windows and UNIX. If you use a font that is not on this list, it is replaced with Courier.

AvantGarde	Helvetica-Narrow	Times-Roman
Bookman	NewCenturySchlbk	ZapfChancery
Courier	Palatino	ZapfDingbats
Helvetica	Symbol	

If you set the font using the `set` function, use the names exactly as shown above. This example sets the font of the current text object to Helvetica-Narrow using MATLAB commands.

```
set(gca, 'FontName', 'Helvetica-Narrow');
```

If you use the Property Editor dialog box (available under **Axes Properties** or **Current Object Properties** on the **Edit** menu) to set the font, the list of available fonts shows those that are supported by your system. If you choose one that is not in the table above, your resulting file uses `Courier`.

Windows Drivers Supported Fonts. The MATLAB Windows drivers support any system-supported font. To see the list of fonts installed on your system, open the **Font name** list on the **Text** or **Style** tab of the Property Editor.

If you use the `set` function to set fonts, type in the name exactly as it appears in the Property Editor. For example, if you have the Script font installed on your system, set the title of your figure to `Script` using the following code.

```
h = get(gca, 'Title');
set(h, 'FontName', 'Script');
```

If you specify a font supplied with MATLAB that is not available on your platform as a system font, figures might not print or export properly.

HPGL Driver Supported Fonts. HPGL drivers support only one font. However, you can set its size and color.

Settings That Are Driver Specific

Some print settings are only supported by specific drivers. This table summarizes the settings and which driver supports them.

Setting	Driver(s)
Appending figures to a PostScript file	PostScript
BoundingBox (setting figure to print uncropped)	PostScript, Ghostscript
CMYK	PostScript
Resolution set with user interface	PostScript, Windows
Resolution set with `print` function	PostScript

Driver-Specific Information

This section provides additional information about the various types of printer drivers available to MATLAB users. It covers the following topics:

Setting the Windows Driver

When you specify a Windows driver (`-dwin` or `-dwinc`), MATLAB interprets this to mean that the print request will use the Windows Print Manager. It also means that MATLAB will assign the default Windows driver based on your current printer's color property setting. In other words, MATLAB does not differentiate between `-dwin` or `-dwinc` in `printopt.m` and you might not get the expected output color: if you choose `-dwin`, lines and text will print in black and white; with `-dwinc`, lines and text print in their screen colors (assuming your printer does print in color).

There are two ways to ensure that MATLAB uses `-dwin` or `-dwinc`: specify the driver when you print, or use the printer's Document Properties dialog box to set the default driver.

You can use the printer's Document Properties dialog box to set the default driver for all print requests. This dialog box sets the printer's color property, which in turn sets the default Windows driver.

To access this dialog box, click the **Properties** button on the Windows Print or Print Setup dialog box. See your Windows and printer's documentation if you need help with this dialog box. Document Properties dialog boxes vary from printer to printer.

Sometimes, even when you use the Windows Document Properties dialog box, you can receive incorrect color results because some Windows printers return inaccurate information about their color property setting.

Trouble with Native Drivers on Windows

Occasionally, printing problems are due to a bug in the native printer driver or an incompatibility between the native printer driver and the MATLAB driver.

If you are having trouble, try installing a different native printer driver. A newer version might be available from the manufacturer or reseller. You may also be able to use the native driver from a different printer, such as an earlier model from the same manufacturer.

If this doesn't help, try using a PostScript or Ghostscript driver.

Level 1 or Level 2 PostScript Drivers

Choosing between the Level 1 and Level 2 MATLAB PostScript drivers does not affect the quality of your output. Make the choice based on what your printer supports and on any file size or speed concerns.

Level 1 PostScript produces good results on a Level 2 printer, but Level 2 PostScript does not print properly on a Level 1 printer.

Level 2 PostScript files are generally smaller and render more quickly than Level 1 files. If your printer supports Level 2 PostScript, use one of the Level 2 drivers. If your printer does not support Level 2, or if you're not sure, use a Level 1 driver.

Early PostScript 1 Printers

If you have an early PostScript 1 printer, such as some of the PostScript printers manufactured before 1990, you may notice problems in the text of MATLAB printouts. Your printer might not support the `ISOLatin1Encoding` operator that MATLAB uses for PostScript files. If this is the case, use Adobe's PostScript default character-set encoding. You can specify this by using the `-adobecset` option with the `print` command.

Background Fills in HPGL Drivers

The HPGL driver cannot do background fills. Therefore, you should ensure that your figure is set to print with a white background (the default), and that any lines and text in your figure are drawn in a color dark enough to be seen on a white background. For more information about background color, see "Setting the Background Color" on page 7-62.

Color Selection in HPGL Drivers

The HP 7475A plotter supports six pens, none of which can be white. If MATLAB tries to draw in white while rendering in HPGL mode, the driver ignores all drawing commands until a different color is chosen.

Pen 1, which is assumed to be black, is used for drawing axes. The remaining pens are used for the first five colors specified in the `ColorOrder` property of the current axes object. If `ColorOrder` specifies fewer than five colors, the unspecified pens are not used.

For Simulink systems, which ordinarily use a maximum of eight colors, the six pens available on the plotter are assumed to be

- Pen 1: black
- Pen 2: red
- Pen 3: green
- Pen 4: blue
- Pen 5: cyan
- Pen 6: magenta

If you attempt to draw a MATLAB object containing a color that is not a known pen color, the driver chooses the nearest approximation to the unlisted color.

Limitations of HPGL Drivers

The HPGL driver has these limitations:

- Display colors and plotted colors sometimes differ.
- Areas (faces on mesh and surface plots, patches, blocks, and arrowheads) are not filled.
- There is no hidden line or surface removal.
- Text is printed in the plotter's default font.
- Line width is determined by pen width.
- Images and UI controls cannot be plotted.
- Interpolated edge lines between two vertices are drawn with the pen whose color best matches the average color of the two vertices.
- Figures cannot be rendered using Z-buffer or OpenGL; this driver always uses the Painter's algorithm.

How to Specify the Printer Driver to Use

If you need to use a driver other than the default driver for your system, choose a new driver from the Printer Driver table on the `print` reference page, and set it either as a new default or just for the current figure you are working on.

Setting the Default Driver for All Figures

If you do not indicate a specific printer driver, MATLAB uses the default driver specified by the variable `dev` in the `printopt.m` file. The factory default driver depends on the platform.

Platform	Factory Default Printer Driver	Driver Code
Windows	Black-and-white Windows	`-dwin`
UNIX & MAC	Black-and-white Level II PostScript	`-dps2`

To change the default driver for all figures, edit `printopt.m` and change the value for `dev` to match one of the driver codes listed in the Printer Drivers table on the `print` reference page (`printopt.m` contains instructions for modifying it). See "Setting Defaults Across Sessions" on page 7-9 for details.

Setting a Driver for the Current Figure Only

You can change the printer driver from the MATLAB command line. To specify a nondefault printer driver for the figure you are printing, include the `-d` switch with the `print` command. For example, to print the current figure using the MATLAB built-in Windows color printer driver `winc`, type

```
print -dwinc
```

Note When printing, the `print -d` option specifies a printer driver. When exporting, the `print -d` option specifies a graphics format.

Troubleshooting

In this section...

Introduction

This section describes some common problems you might encounter when printing or exporting your figure. If you don't find your problem listed here, try searching the Knowledge Base maintained by the MathWorks Technical Support Department. Go to `http://www.mathworks.com/support` and enter a topic in the search field.

Common Problems

- **Printing Problems**
  - "Printer Drivers" on page 7-95
  - "Default Settings" on page 7-96
  - "Color vs. Black and White" on page 7-97
  - "Printer Selection" on page 7-97
  - "Rotated Text" on page 7-98
  - "ResizeFcn Warning" on page 7-98
- **Exporting Problems**
  - "Background Color" on page 7-98
  - "Default Settings" on page 7-99
  - "Microsoft Word" on page 7-99
  - "File Format" on page 7-100

Printing Problems

Printer Drivers

I am using a Windows printer driver and encountering problems such as segmentation violations, general protection faults, application errors, and unexpected output.

Try one of the following solutions:

- Check the table of `drivers` in the `print` reference page to see if there are other drivers you can try.
  - If your printer is PostScript compatible, try printing with one of the MATLAB built-in PostScript drivers.
  - If your printer is not PostScript compatible, see if one of the MATLAB built-in Ghostscript devices is appropriate for your printer model. These devices use Ghostscript to convert PostScript files into other formats, such as HP LaserJet and Canon BubbleJet.
- Contact the printer vendor to obtain a different native printer driver. The behavior you are experiencing might occur only with certain versions of the native printer driver. If this doesn't help and you are using Windows, try

reinstalling the drivers that were shipped with your Windows installation disk.

- Export the figure to a graphics-format file, and then import it into another application before printing it. For information about exporting figures with MATLAB, see “Exporting to a File” on page 7-21.

PostScript Output

When I use the print function with the `-deps` switch, I receive this error message.

```
Encapsulated PostScript files cannot be sent to the printer.
File saved to disk under name 'figure2.eps'
```

As the error message indicates, your figure was saved to a file. EPS is a graphics file format and cannot be sent to a printer using a printer driver. To send your figure directly to a printer, try using one of the PostScript driver switches. See the table of drivers in the `print` reference page. To print an EPS file, you must first import it into a word processor or other software program.

Default Settings

My printer uses a different default paper type than the MATLAB default type of letter. How can I change the default paper type so that I don’t have to set it for each new figure?

You can set the default value for any property by adding a line to `startup.m`. Adding the following line sets the default paper type to A4.

```
set(0, 'DefaultFigurePaperType', 'A4');
```

In your call to `set`, combine the word `Default` with the name of the object `Figure` and the property name `PaperType`.

I set the paper orientation to landscape, but each time I go to print a new figure, the orientation setting is portrait again. How can I change the default orientation so that I won’t have to set it for each new figure?

See the explanation for the previous question. Adding the following line to `startup.m` sets the default paper orientation to landscape.

```
set(0, 'DefaultFigurePaperOrient', 'landscape')
```

Color vs. Black and White

I want the lines in my figure to print in black, but they keep printing in color.

You must be using a color printer driver. You can specify a black-and-white driver using the `print` function or the Print Preview dialog box to force the lines for the current figure to print in black. See “Setting the Line and Text Color” on page 7-66 for instructions.

A white line in my figure keeps coming out black when I print it.

There are two things that can cause this to happen. Most likely, the line is positioned over a dark background. By default, MATLAB inverts your background to white when you print, and changes any white lines over the background to black. To avoid this, retain your background color when you print. See “Setting the Background Color” on page 7-62.

The other possibility is that you are using a Windows printer driver and the printer is sending inaccurate color information to MATLAB. See .

I am using a color printer, but my figure keeps printing in black and white.

By default, MATLAB uses a black-and-white printer driver. You need to specify a color printer driver. For instructions, see “Choosing a Printer Driver” on page 7-85. If you are already using a Windows color driver, the printer might be returning inaccurate information about its color property. See .

Printer Selection

I have more than one printer connected to my system. How do I specify which one to print my figure with?

You can use either the Print dialog box, or the MATLAB `print` function, specifying the printer with the `-P` switch. For instructions using either method, see "Selecting the Printer" on page 7-46.

Rotated Text

I have some rotated text in my figure. It looks fine on the screen, but when I print it, the resolution is poor.

You are probably using bitmapped fonts, which don't rotate well. Try using TrueType fonts instead.

ResizeFcn Warning

I get a warning about my `ResizeFcn` being used when I print my figure.

By default, MATLAB resizes your figure when converting it to printer coordinates. Therefore, MATLAB calls any `ResizeFcn` you have created for the figure and issues a warning. You can avoid this warning by setting the figure to print at screen size.

Exporting Problems

Background Color

I generated a figure with a black background and selected "Use figure color" from the Copy Options panel of the Preferences dialog box. But when I exported my figure, its background was changed to white.

You must have exported your figure to a file. The settings in **Copy Options** only apply to figures copied to the clipboard.

There are two ways to retain the displayed background color: use the Print Preview dialog box or set the `InvertHardCopy` property to `off`. See "Setting the Background Color" on page 7-62 for instructions on either method.

Default Settings

I want to export all of my figures using the same size. Is there some way to do this so that I don't have to set the size for each individual figure?

You can set the default value for any property by adding a line to `startup.m`. Adding the following line sets the default figure size to 4-by-3 inches.

```
set(0, 'DefaultFigurePaperPosition', [0 0 4 3]);
```

In your call to `set`, combine the word `Default` with the name of the object `Figure` and the property name `PaperPosition`.

I use the clipboard to export my figures as metafiles. Is there some way to force all of my copy operations to use the metafile format?

On Windows, use the **Copy Options** panel of the Preferences dialog box. Any settings made here, including whether MATLAB copies your figure as a metafile or bitmap, apply to all copy operations. See "Exporting to the Windows or Macintosh Clipboard" on page 7-32 for instructions.

Microsoft Word

I exported my figure to an EPS file, and then tried to import it into my Word document. My printout has an empty frame with an error message saying that my EPS picture was not saved with a preview and will only print to a PostScript printer. How do I include a TIFF preview?

Use the `print` command with the `-tiff` switch. For example,

```
print -deps -tiff filename
```

Note that if you print to a non-PostScript printer with Word, the preview image is used for printing. This is a low-resolution image that lacks the quality of an EPS graphic. For more information about preview images and other aspects of EPS files, see "EPS Files" on page 7-81.

When I try to resize my figure in Word, its quality suffers.

You must have used a bitmap format. Bitmap files generally do not resize well. If you are going to export using a bitmap format, try to set the figure's size while it's still in MATLAB. See "Setting the Figure Size and Position" on page 7-47 for instructions.

As an alternative, you can use one of the vector formats, EMF or EPS. Figures exported in these formats can be resized in Word without affecting quality.

I exported my figure as an EMF to the clipboard. When I paste it into Word, some of the labels are printed incorrectly.

This problem occurs with some versions of Word and Windows. Try editing the labels in Word.

File Format

I tried to import my exported figure into a word processing document, but I got an error saying the file format is unrecognized.

There are two likely causes: you used the `print` function and forgot to specify the export format, or your word processing program does not support the export format. Include a format switch when you use the `print` function; simply including the file extension is not sufficient. For instructions, see "Exporting to a File" on page 7-21.

If this does not solve your problem, check what formats the word processor supports.

I tried to append a figure to an EPS file, and received an error message

You cannot append figures to an EPS file. The `-append` option is only valid for PostScript files, which should not be confused with EPS files. PostScript is a printer driver; EPS is a graphics file format.

Of the supported export formats, only HDF supports storing multiple figures, but you must use the `imwrite` function to append them. For an example, see the reference page for `imwrite`.

Size of Exported File

I've always used the EPS format to export my figures, but recently it started to generate huge files. Some of my files are now several megabytes!

Your graphics have probably become complicated enough that MATLAB is using the OpenGL or Z-buffer renderer instead of the Painter's renderer. It does this to improve display time or to handle attributes that Painter's cannot, such as lighting. However, using OpenGL or Z-buffer causes a bitmap to be stored in your EPS file, which with large figures leads to a large file.

There are two ways to fix the problem. You can specify the Painter's renderer when you export to EPS, or you can use a bitmap format, such as TIFF. The best renderer and type of format to use depend upon the figure. See "Choosing Bitmap or Vector Graphic Output" on page 7-75 if you need help deciding. For information about the rendering methods and how to set them, see "Selecting a Renderer" on page 7-54.

Making Movies

I am processing a large number of frames in MATLAB. I would like these frames to be saved as individual files for later conversion into a movie. How can I do this?

Use `getframe` to capture the frames, `imwrite` to write them to a file, and `movie` to create a movie from the files. For more information about using `getframe` and `imwrite` to capture and write the frames, see "Exporting with getframe" on page 7-29. For more information about creating a movie from the captured frames, see the reference page for `movie`.

You can also save multiple figures to an AVI file. AVI files can be used for animated sequences that do not need MATLAB to run. However, they do require an AVI viewer. For more information, see "Exporting Audio/Video Data" in the MATLAB Programming documentation.

Extended Operations

There are some export operations that cannot be performed using the Export dialog box.

You need to use the `print` function to do any of the following operations:

- Export to a supported file format not listed in the Export dialog box. The formats not available from the Export dialog box include HDF, some variations of BMP and PCX, and the raw data versions of PBM, PGM, and PPM.
- Specify a resolution.
- Specify one of the following options:
  - TIFF preview
  - Loose bounding box for EPS files
  - Compression quality for JPEG files
  - CMYK output on Windows
- Perform batch exporting.

General Problems

Background Color

When I output my figure, its background is changed to white. How can I get it to have the displayed background color?

By default, when you print or export a figure, MATLAB inverts the background color to white. There are two ways to retain the displayed background color: use the Print Preview dialog box or set the `InvertHardCopy` property to `off`. See “Setting the Background Color” on page 7-62 for instructions on either method.

If you are exporting your figure to the clipboard, you can also use the **Copy Options** panel of the Preferences dialog box. Setting the background here sets it for all figures copied to the clipboard.

Default Settings

I need to produce diagrams for publications. There is a list of requirements that I must meet for size of the figure, fonts types, etc. How can I do this easily and consistently?

You can set the default value for any property by adding a line to `startup.m`. As an example, the following line sets the default axes label font size to 12.

```
set(0, 'DefaultAxesFontSize', 12);
```

In your call to `set`, combine the word `Default` with the name of the object `Axes` and the property name `FontSize`.

Dimensions of Output

The dimensions of my output are huge. How can I make it smaller?

Check your settings for figure size and resolution, both of which affect the output dimensions of your figure.

The default figure size is 8-by-6 inches. You can use the Print Preview dialog box or the `PaperPosition` property to set the figure size. See "Setting the Figure Size and Position" on page 7-47.

The default resolution depends on the export format or printer driver used. For example, built-in MATLAB bitmap formats, like TIFF, have a default resolution of 150 dpi. You can change the resolution by using the `print` function and the `-r` switch. For default resolution values and instructions on how to change them, see "Setting the Resolution" on page 7-57.

I selected "Auto (actual size, centered)" from the Print Preview menu, but my output looks a little bigger, and my font looks different.

You probably output your figure using a higher resolution than your screen uses. Set your resolution to be the same as the screen's.

As an alternative, if you are exporting your figure, see if your application enables you to select a resolution. If so, import the figure at the same resolution it was exported with. For more information about resolution and how to set it when exporting, see "Setting the Resolution" on page 7-57.

Axis and Tick Labels

When I resize my figure below a certain size, my x-axis label and the bottom half of the x-axis tick labels are missing from the output.

Your figure size might be too small to accommodate the labels. Labels are positioned a fixed distance from the *x*-axis. Since the *x*-axis itself is positioned a relative distance away from the window's edge, the label text might not fit. Try using a larger figure size or smaller fonts. For instructions on setting the size of your figure, see "Setting the Figure Size and Position" on page 7-47. For information about setting font size, see the Text Properties reference page.

In my output, the x-axis has fewer ticks than it did on the screen.

MATLAB has rescaled your ticks because the size of your output figure is different from its displayed size. There are two ways to prevent this: select **Keep screen limits and ticks** from the **Advanced** tab of the Print Preview dialog box, or set the `XTickMode`, `YTickMode`, and `ZTickMode` properties to `manual`. See "Setting the Axes Ticks and Limits" on page 7-60 for details.

UI Controls

My figure contains UI controls. How do I prevent them from appearing in my output?

Use the `print` function with the `-noui` switch. For details, see "Excluding User Interface Controls form Printed Output" on page 7-71.

Cropping

I can't output my figure using the uncropped setting (i.e., a loose BoundingBox).

Only PostScript printer drivers and the EPS export format support uncropped output. There is a workaround for Windows printer drivers, however. Using the `print` function, save your figure to a file that can be printed later. For an example see "Producing Uncropped Figures" on page 7-72.

Text Object Font

I have a problem with text objects when printing with a PostScript printer driver or exporting to EPS. The fonts are correct on the screen, but are changed in the output.

You have probably used a font that is not supported by EPS and PostScript. All unsupported fonts are converted to Courier. See “PostScript and Ghostscript Supported Fonts” on page 7-88 for the list of the supported fonts.

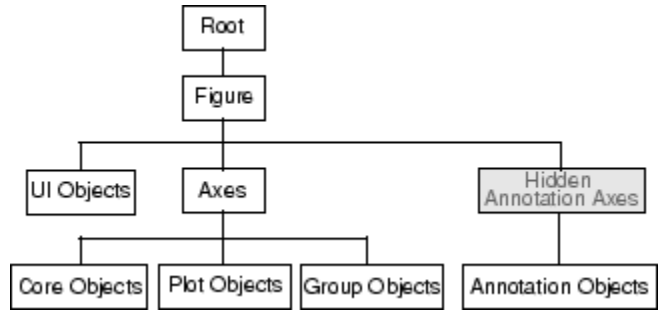
Handle Graphics Objects

Organization of Graphics Objects

Graphics objects are the basic drawing elements used by MATLAB to display data. Each instance of an object is associated with a unique identifier called a *handle*. Using this handle, you can manipulate the characteristics (called object *properties*) of an existing graphics object. You can also specify values for properties when you create a graphics object.

These objects are organized into a hierarchy, as shown by the following diagram.



The hierarchical nature of Handle Graphics is based on the interdependencies of the various graphics objects. For example, to draw a line object, MATLAB needs an axes object to orient and provide a frame of reference to the line. The axes, in turn, needs a figure window to display the axes and its child objects.

Types of Graphics Objects

In this section...

Introduction

There are two basic types of graphics objects:

- Core graphics objects — Used by high-level plotting functions and by composite objects to create plot objects
- Composite objects — Composed of core graphics objects that have been grouped together to provide a more convenient interface

Composite objects form the basis for four subcategories of graphics objects.

- Plot objects — Composed of basic graphics objects, but enable properties to be set on plot object level
- Annotation objects — Exist on a layer separate from other graphics objects
- Group objects — Create groups of objects that can behave as one in certain respects. You can parent any axes child object (except light) to a group object, including other group object.
- UI objects — User interface objects are used to construct graphical user interfaces.

Graphics objects are interdependent, so the graphics display typically contains a variety of objects that, in conjunction, produce a meaningful graph or picture.

Information on Specific Graphics Objects

See the following sections for more information on the various types of graphics objects:

- "Graphics Windows — the Figure" on page 8-6

For information on user interface objects and their application, see “Creating Graphical User Interfaces” in the MATLAB documentation.

Graphics Windows — the Figure

In this section...

Introduction

Figures are the windows in which MATLAB displays graphics. Figures contain menus, toolbars, user-interface objects, context menus, axes and, as axes children, all other types of graphics objects.

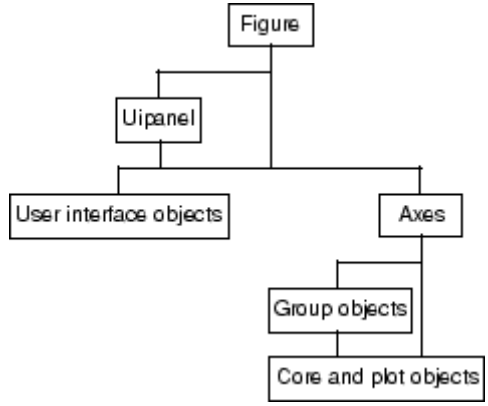
MATLAB places no limits on the number of figures you can create (your computer systems might impose limitations, however).

Figures play two distinct roles in MATLAB:

- Containing data graphs
- Containing graphical user interfaces

Figures can contain both graphs and GUIs components at the same time. For example, a GUI might be designed to plot data and therefore contain an axes as well as user interface objects. See "Example — Using Figure Panels" on page 8-90 for an example of such a GUI.

The following diagram illustrates the types of objects that figures can contain.



Note that both figures and axes have children that act as containers. A uipanel can contain user interface objects and be parented to a figure and group objects (hggroup and hgtransform) can contain axes children (except light objects) and be parented to an axes.

See “Objects That Can Contain Other Objects” on page 8-88 for more information.

Figures Used for Graphing Data

MATLAB functions that draw graphics (e.g., `plot` and `surf`) create figures automatically if none exist. If there are multiple figures open, one figure is always designated as the “current” figure, and is the target for graphics output.

The `gcf` command returns the handle of the current figure or creates a new figure if one does not exist. For example, you can enter the following command to see a list of figure properties.

```
get(gcf)
```

The root object `CurrentFigure` > property returns the handle of the current figure, if one exists, or returns empty if there are no figures open. For example,

```
get(0,'CurrentFigure')
ans =
[]
```

See “Controlling Graphics Output” on page 8-69 for more information on how MATLAB determines where to display graphics.

Figure Children for Graphs

Figures that display graphs need to contain axes to provide the frame of reference for objects such as lines and surfaces, which are used to represent data. These data representing objects can be contained in group objects or contained directly in the axes. See “Example — Transforming a Hierarchy of Objects” on page 8-36 for an example of how to use group objects.

Figures can contain multiple axes arranged in various locations within the figure and can be of various sizes. See “Automatic Axes Resize” on page 10-9 and “Multiple Axes per Figure” on page 10-15 for more information on axes.

Figures Used for GUIs

GUIs range from sophisticated applications to simple warning dialog boxes. You can modify many aspects of the figure to fit the intended use by setting figure properties. For example, the following figure properties are often useful when creating GUIs.

- Show or hide the figure menu, while displaying custom-designed menus (`MenuBar`)
- Change the figure title (`Name`)
- Control user access to the figure handle (`HandleVisibility`)
- Create a callback that executes whenever the user resizes the figure (`ResizeFcn`)
- Control display of the figure toolbar (`Toolbar`)
- Assign a context menu (`UIContextMenu`)
- Define callbacks that execute when users click drag or release the mouse over the figure (`WindowButtonDownFcn`, `WindowButtonMotionFcn`, `WindowButtonUpFcn`). Also see the `ButtonDownFcn` property.
- Specify whether the figure is modal (`WindowStyle`)

See the Figure Properties reference page for more information on figure characteristics you can specify.

See the “Creating Graphical User Interfaces” documentation for more information about using `figure` to create GUIs.

Root Object — the Figure Parent

The parent of a figure is the root object. You cannot instantiate the root object because its purpose is only to store information. It maintains information on the state of MATLAB, your computer system, and some MATLAB defaults.

There is only one root object and all other objects are its descendants. You do not create the root object; it exists when you start MATLAB. You can, however, set the values of root properties and thereby affect the graphics display.

For more information see Root Properties object properties.

More Information on Figures

See the `figure` reference page for information on creating figures.

See “Callback Properties for Graphics Objects” on page 8-107 for information on figure events for which you can define callbacks.

See Chapter 9, “Figure Properties” for information on other figure properties.

Core Graphics Objects

In this section...

Introduction

Core graphics objects include basic drawing primitives like line, text, and polygon shells (patch objects); specialized objects like surfaces, which are composed of a rectangular grid of vertices; images; and light objects, which are not visible but affect the way some objects are colored.

Axes contain objects that represent data, such as line, surfaces, contourgroups, etc.

The following table lists the core graphics objects and links to the reference pages of the functions used to create each object.

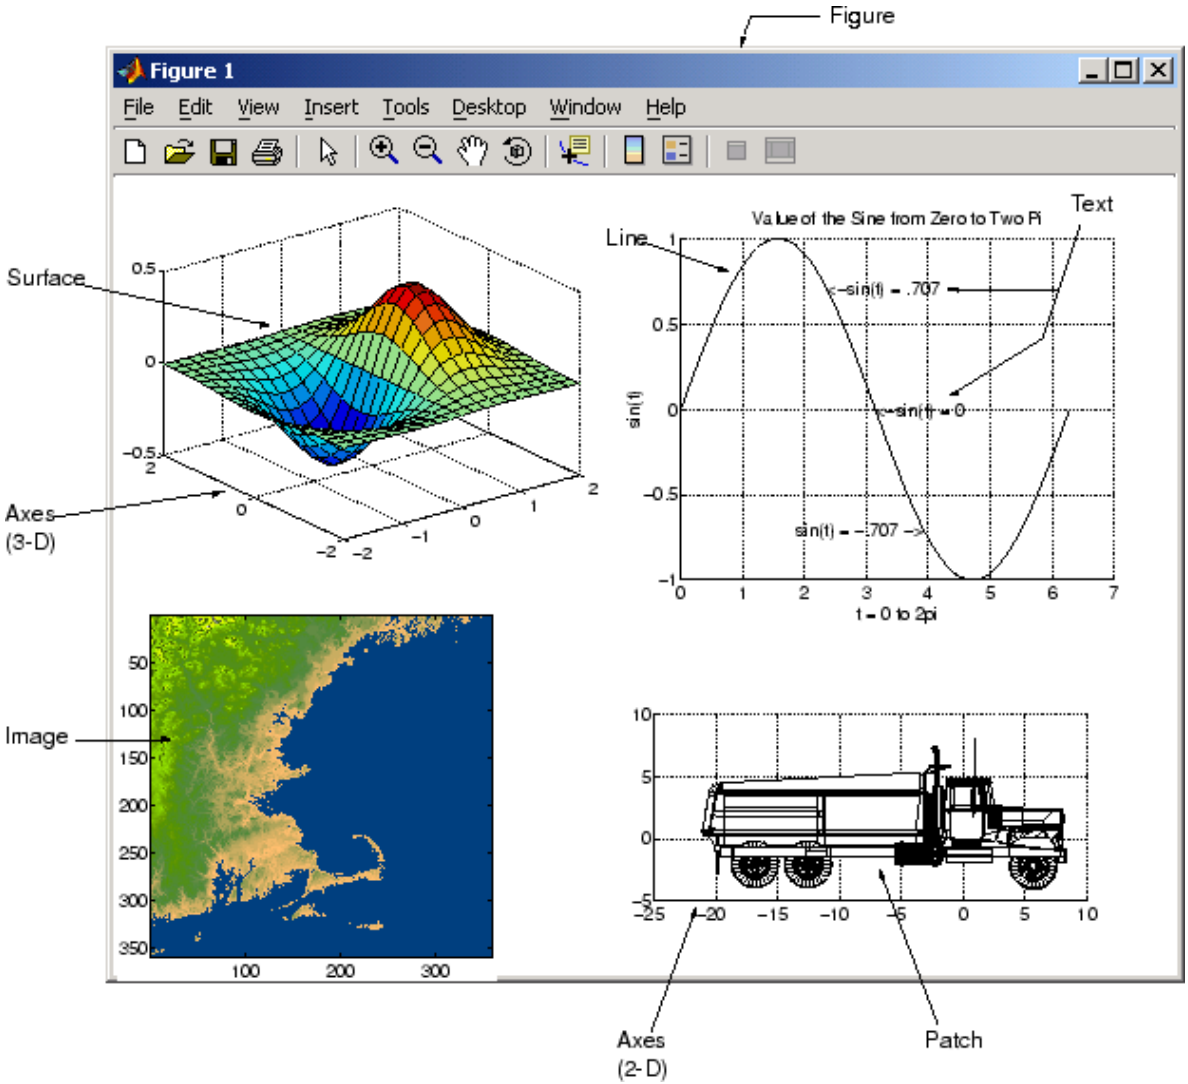
Core Graphics Objects

Function	Purpose
`axes`	Axes objects define the coordinate system for displaying graphs. Axes are always contained within a figure.
`image`	2-D representation of a matrix where numeric values are mapped to colors. Images can also be 3-D arrays of RGB values.
`light`	Directional light source located within the axes. Lights affect patches and surfaces, but cannot themselves be seen.

Core Graphics Objects (Continued)

Function	Purpose
`line`	A line is drawn by connecting the data points that define it.
`patch`	Filled polygons with separate edge properties. A single patch can contain multiple faces, each colored independently with solid or interpolated colors.
`rectangle`	2-D object that has settable edge and face color, and variable curvature (can draw ellipses)
`surface`	3-D grid of quadrilaterals created by plotting the value of each element in a matrix as a height above the *x-y* plane
`text`	Character strings positioned in the coordinate system defined by the axes

The following picture illustrates some typical core graphics objects.



Description of Core Graphics Objects

This section describes the core graphics objects.

Axes

Axes objects define a frame of reference in a figure window for the display objects that are generally defined by data. For example, MATLAB creates a line by connecting each data point with a line segment. The axes determines the location of each data point in the figure by defining axis scales (x, y, and z or radius and angle, etc.)

Axes are children of figures and are parents of core, plot, and group objects.

Note that, while annotation objects are also children of axes, they can be parented only to the hidden annotation axes (see the `annotation` function for more information).

All functions that draw graphics (e.g., `plot`, `surf`, `mesh`, and `bar`) create an axes object if one does not exist. If there are multiple axes within the figure, one axes is always designated as the "current" axes, and is the target for display of the above-mentioned graphics objects (uicontrols and uimenus are not children of axes).

Image

A MATLAB image consists of a data matrix and possibly a colormap. There are three basic image types that differ in the way that data matrix elements are interpreted as pixel colors — indexed, intensity, and truecolor. Since images are strictly 2-D, you can view them only at the default 2-D view.

Light

Light objects define light sources that affect all patch and surface objects within the axes. You cannot see lights, but you can set properties that control the style of light source, color, location, and other properties common to all graphics objects.

Line

Line objects are the basic graphics primitives used to create most 2-D and some 3-D plots. High-level functions `plot`, `plot3`, and `loglog` (and others)

create line objects. The coordinate system of the axes positions and orients the line.

Patch

Patch objects are filled polygons with edges. A single patch can contain multiple faces, each colored independently with solid or interpolated colors. `fill`, `fill3`, and `contour3` create patch objects. The coordinate system of the axes positions and orients the patch.

Rectangle

Rectangle objects are 2-D filled areas having a shape that can range from a rectangle to an ellipse. Rectangles are useful for creating flow-chart-type drawings.

Surface

Surface objects are 3-D representations of matrix data created by plotting the value of each matrix element as a height above the *x*-*y* plane. Surface plots are composed of quadrilaterals whose vertices are specified by the matrix data. MATLAB can draw surfaces with solid or interpolated colors or with only a mesh of lines connecting the points. The coordinate system of the axes positions and orients the surface.

The high-level function `pcolor` and the `surf` and `mesh` group of functions create surface objects.

Text

Text objects are character strings. The coordinate system of the parent axes positions the text. The high-level functions `title`, `xlabel`, `ylabel`, `zlabel`, and `gtext` create text objects.

Example — Creating Core Graphics Objects

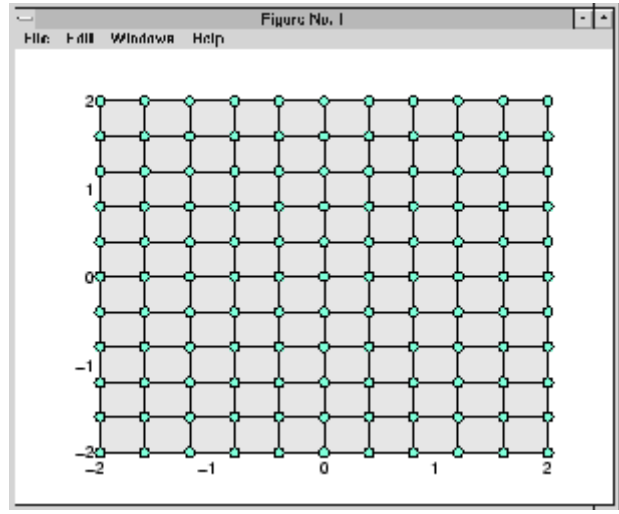
Object creation functions have a syntax of the form

```
handle = function('propertyname',propertyvalue,...)
```

You can specify a value for any object property (except those that are read only) by passing property name/value pairs as arguments. The function returns the handle of the object it creates, which you can use to query and modify properties after creating the object.

This example evaluates a mathematical function and creates three graphics objects using the property values specified as arguments to the `figure`, `axes`, and `surface` commands. MATLAB uses default values for all other properties.

```
[x,y] = meshgrid([-2:.4:2]);
Z = x.*exp(-x.^2-y.^2);
fh = figure('Position',[350 275 400 300],'Color','w');
ah = axes('Color',[.8 .8 .8],'XTick',[-2 -1 0 1 2],...
          'YTick',[-2 -1 0 1 2]);
sh = surface('XData',x,'YData',y,'ZData',Z,...
             'FaceColor',get(ah,'Color')+.1,...
             'EdgeColor','k','Marker','o',...
             'MarkerFaceColor',[.5 1 .85]);
```

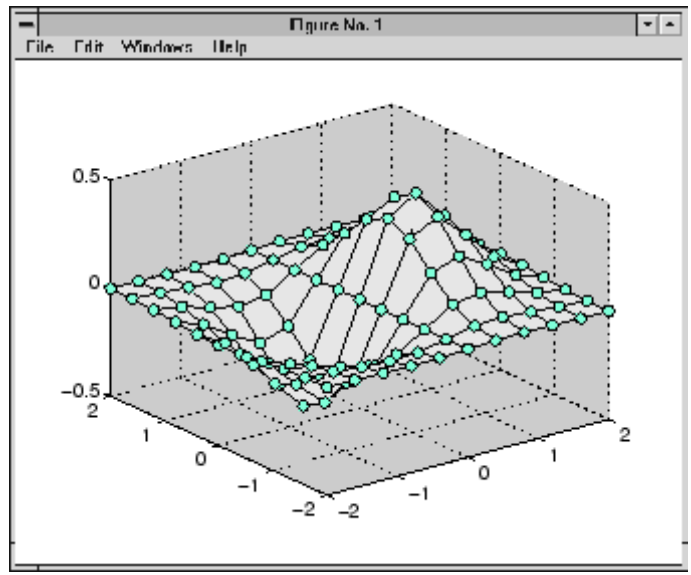


Note that the `surface` function does not use a 3-D view like the high-level `surf` functions. Object creation functions simply add new objects to the current axes without changing axes properties, except the `Children` property,

which now includes the new object and the axis limits (`XLim`, `YLim`, and `ZLim`), if necessary.

You can change the view using the camera commands or use the `view` command.

```
view(3)
```



Parenting

By default, all statements that create graphics objects do so in the current figure and the current axes (if the object is an axes child). However, you can specify the parent of an object when you create it. For example, the statement

```
axes('Parent',figure_handle,...)
```

creates an axes in the figure identified by `figure_handle`. You can also move an object from one parent to another by redefining its `Parent` property.

```
set(gca,'Parent',figure_handle)
```

High-Level Versus Low-Level

Many MATLAB graphics functions call the object creation functions to draw graphics objects. However, high-level routines also clear the axes or create a new figure, depending on the settings of the axes and figure `NextPlot` properties.

In contrast, core object creation functions simply create their respective graphics objects and place them in the current parent object. They do not respect the settings of the figure or axes `NextPlot` property.

For example, if you call the `line` function,

```
line('XData',x,'YData',y,'ZData',z,'Color','r')
```

MATLAB draws a red line in the current axes using the specified data values. If there is no axes, MATLAB creates one. If there is no figure window in which to create the axes, MATLAB creates it as well.

If you call the `line` function a second time, MATLAB draws the second line in the current axes without erasing the first line. This behavior is different from high-level functions like `plot` that delete graphics objects and reset all axes properties (except `Position` and `Units`). You can change the behavior of high-level functions by using the `hold` command or by changing the setting of the axes `NextPlot` property.

See “Controlling Graphics Output” on page 8-69 for more information on this behavior and on using the `NextPlot` property.

Simplified Calling Syntax

Object creation functions have convenience forms that allow you to use a simpler syntax. For example,

```
text(.5,.5,.5,'Hello')
```

is equivalent to

```
text('Position',[.5 .5 .5],'String','Hello')
```

Note that using the convenience form of an object creation function can cause subtle differences in behavior when compared to formal property name/property value syntax.

A Note About Property Names

By convention, MATLAB documentation capitalizes the first letter of each word that makes up a property name, such as `LineStyle` or `XTickLabelMode`. While this makes property names easier to read, MATLAB does not check for uppercase letters. In addition, you need use only enough letters to identify the name uniquely, so you can abbreviate most property names.

In M-files, however, using the full property name can prevent problems with futures releases of MATLAB if a shortened name is no longer unique because of the addition of new properties.

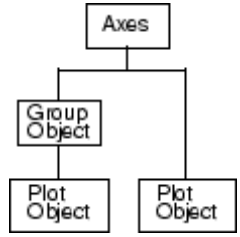
Plot Objects

In this section...

Introduction

A number of high-level plotting functions create plot objects. The properties of plot objects provide easy access to the important properties of the core graphics objects that the plot objects contain.

Plot object parents can be axes or group objects (`hggroup` or `hgtransform`). See “Objects That Can Contain Other Objects” on page 8-88 for examples.



This table lists the plot objects and the graphing functions that use them. Click object names to see a description of their properties.

Plot Objects

Object	Purpose
`areaseries`	Used to create `area` graphs
`barseries`	Used to create `bar` graphs
`contourgroup`	Used to create `contour` graphs
`errorbarseries`	Used to create `errorbar` graphs

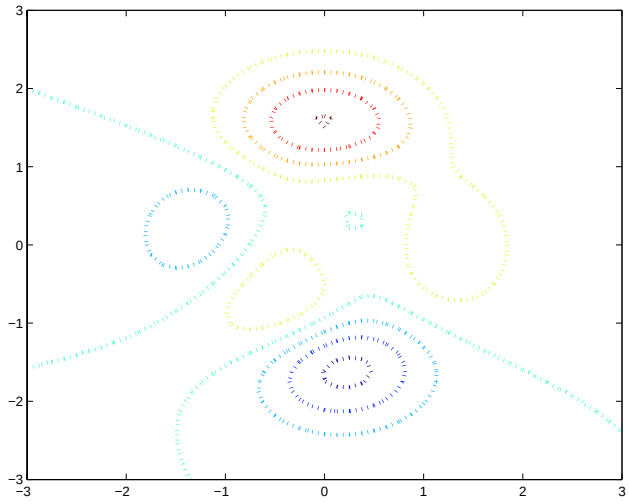
Plot Objects (Continued)

Object	Purpose
`lineseries`	Used by line plotting functions (`plot`, `plot3`, etc.)
`quivergroup`	Used to create `quiver` and `quiver3` graphs
`scattergroup`	Used to create `scatter` and `scatter3` graphs
`stairseries`	Used to create stairstep graphs (`stairs`)
`stemseries`	Used to create `stem` and `stem3` graphs
`surfaceplot`	Used by the `surf` and `mesh` group of functions

Creating a Plot Object

For example, the following statements create a contour graph of the `peaks` function and then set the line style and width of the contour lines.

```
[x,y,z] = peaks;
[c,h] = contour(x,y,z);
set(h,'LineWidth',3,'LineStyle',':')
```



The contour plot object enables you to set the line width and style of the contour graph by setting two properties. Looking at the core objects contained in the contour plot object reveals a number of patch objects whose edges are used to implement the contour line, which you would otherwise need to set individually.

```
child_handles = get(h,'Children');
get(child_handles,'Type')
ans =
    'patch'
    'patch'
    'patch'
    'patch'
    'patch'
    'patch'
    'patch'
    'patch'
    'patch'
    'patch'
    'patch'
    'patch'
```

Identifying Plot Objects Programmatically

Plot objects all return `hggroup` as the value of the `Type` property. If you want to be able to identify plot objects programmatically but do not have access to the object's handle, set a value for the object's `Tag` property.

For example, the following statements create a bar graph with five `barseries` objects and assign a different value for the `Tag` property on each object.

```
h = bar(rand(5));
set(h,{'Tag'},{'bar1','bar2','bar3','bar4','bar5'}')
```

Note that the cell array of property values must be transposed (`'`) to have the proper shape. See the `set` function for more information on setting properties.

No User Default Values

Note that you cannot define default values for plot objects.

Plot Objects and Backward Compatibility

Note The `v6` option discussed in this section is now obsolete and will be removed in a future version of MATLAB.

Plotting functions that create plot objects can introduce incompatibilities with code written before MATLAB Version 7.x. However, all plotting functions that return handles to plot objects support an optional argument (`'v6'`) that forces the functions to use core objects, as was the case in MATLAB before Version 7.

- See "Plot Objects" on page 8-19 for a list of functions that create plot objects.
- See "Core Graphics Objects" on page 8-10 for a list of core graphics objects.

Saving Figures That Are Compatible with Previous Version of MATLAB

Create backward-compatible FIG-files by following these two steps.

- Ensure that any plotting functions used to create the contents of the figure are called with the `'v6'` argument, where applicable.
- Use the `'-v6'` option with the `hgsave` command.

For example,

```
h = figure;
t = 0:pi/20:2*pi;
plot('v6',t,sin(t).*2)
hgsave(h,'myFigFile','-v6')
```

You can set a general MATLAB preference to ensure that figures saved by selecting the **Save** item under the figure **File** menu are backward compatible. To access MATLAB preferences, select **Preferences** from the Desktop **File** menu. Expand the **General** node and select **MAT Files**. Click **Ensure backward compatibility (-v6)**. Note that this setting affects all FIG-files and MAT-files that you create.

Linking Graphs to Variables — Data Source Properties

In this section...

Introduction

Plot objects enable you to link a MATLAB expression with properties that contain data. For example, the `lineseries` object has data source properties associated with the `XData`, `YData`, and `ZData` properties. These properties are called `XDataSource`, `YDataSource`, and `ZDataSource`.

To use a data source property,

1. Assign the name of a variable to the data source property that you want linked to an expression.
2. Calculate a new value for the variable.
3. Call the `refreshdata` function to update the plot object data.

`refreshdata` enables you to specify whether to use a variable in the base workspace or the workspace of the function from which you call `refreshdata`.

Data Source Example

The following example illustrates how to use this technique.

```
function datasource_ex
t = 0:pi/20:2*pi;
y = exp(sin(t));
h = plot(t,y,'YDataSource','y');
for k = 1:.1:10
 y = exp(sin(t.*k));
 refreshdata(h,'caller') % Evaluate y in the function workspace
 drawnow; pause(.1)
end
```

Changing the Size of Data Variables

If you change one data source property to a variable that contains data of a different dimension, you might cause the function to generate a warning and not render the graph until you have changed all data source properties to appropriate values.

Annotation Objects

In this section...

Introduction

Users typically create annotation objects from the Plot Edit toolbar or the **Insert** menu (select **Plot Edit** in the **View** menu to display the Plot Edit toolbar). However, you can also create annotation objects using the `annotation` function.

Annotation objects are created in a hidden axes that extends the full width and height of the figure. This enables you to specify the locations of annotation objects anywhere in the figure using normalized coordinates (the lower left corner is the point 0,0, the upper right corner is the point 1,1).

Annotation Object Properties

Note You should not change any of the properties of the annotation axes or parent any graphics objects to this axes. Use the `annotation` function or the graphics tools to create annotation objects.

The following links access descriptions of the properties you can set on the respective annotation objects.

- Annotation arrow properties
- Annotation doublearrow properties
- Annotation ellipse properties
- Annotation line properties
- Annotation rectangle properties

- Annotation textarrow properties
- Annotation textbox properties

To modify the appearance of annotation objects created with the plotting tools, use “The Property Editor” on page 1-28.

Example — Enclosing Subplots with an Annotation Rectangle

The following example shows how to create a rectangle annotation object and use it to highlight two subplots in a figure. This example uses the axes properties `Position` and `TightInset` to determine the location and size of the annotation rectangle.

1 First create an array of subplots.

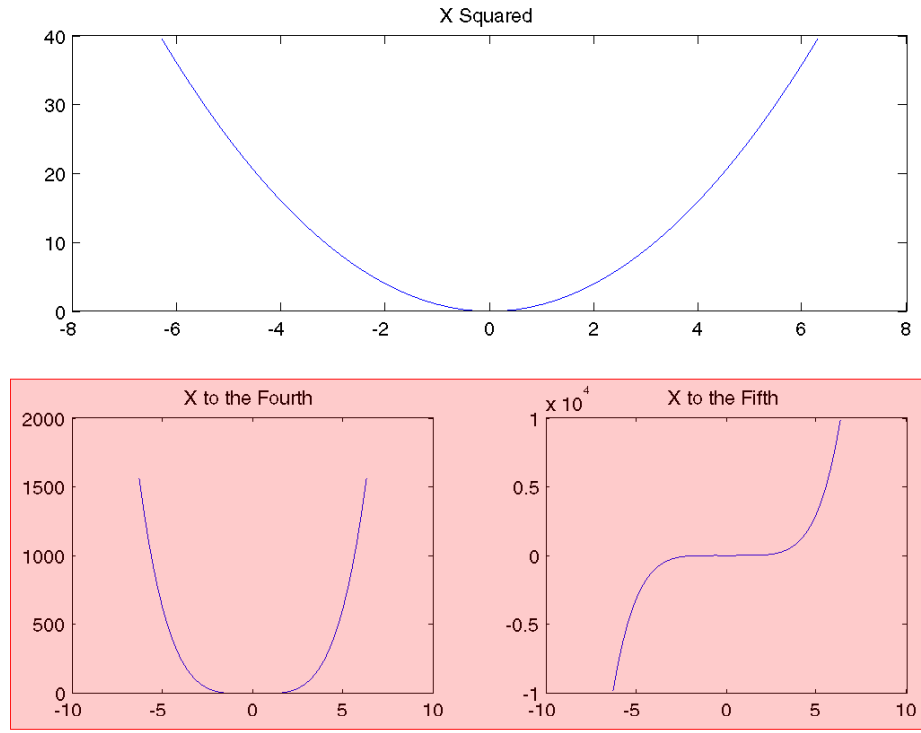
```
x = -2*pi:pi/12:2*pi;
y = x.^2;
subplot(2,2,1:2)
plot(x,y)
h1=subplot(223);
y = x.^4;
plot(x,y)
h2=subplot(224);
y = x.^5;
plot(x,y)
```

2 Determine the location and size of the annotation rectangle required to enclose axes, tick mark labels, and title using the axes `Position` and `TightInset` properties.

```
p1 = get(h1,'Position');
t1 = get(h1,'TightInset');
p2 = get(h2,'Position');
t2 = get(h2,'TightInset');
x1 = p1(1)-t1(1); y1 = p1(2)-t1(2);
x2 = p2(1)-t2(1); y2 = p2(2)-t2(2);
w = x2-x1+t1(1)+p2(3)+t2(3); h = p2(4)+t2(2)+t2(4);
```

3 Create the annotation rectangle to enclose the lower two subplots. Make the rectangle a translucent red with a solid border.

```
annotation('rectangle',[x1,y1,w,h],...
 'FaceAlpha',.2,'FaceColor','red','EdgeColor','red');
```



Group Objects

In this section...

Introduction

Group objects enable you to treat a number of axes child objects as one group. For example, you can make the entire group visible or invisible, select all objects when only one is clicked, or apply a transform matrix to reposition the objects by setting only one property on the group object.

There are two group objects:

- hggroup — Use when you want to create a group of objects and control the visibility or selectability of the group based on what happens to any individual object in the group. Create hggroup objects with the `hggroup` function.
- hgtransform — Use when you want to transform a group of objects. Transforms include rotation, translation, scaling, etc. See "Example — Transforming a Hierarchy of Objects" on page 8-36 for an example. Create hgtransform objects with the `hgtransform` function.

Note that the difference between the hggroup and hgtransform objects is ability of the hgtransform object to apply a transform matrix (via its `Matrix` property) to all objects for which it is the parent.

Note You cannot parent light objects to hggroup or hgtransform objects.

Creating a Group

You create a group by parenting axes children to an hggroup or hgtransform object. For example,

```
hb = bar(rand(5)); % creates 5 barseries objects
hg = hggroup;
set(hb,'Parent',hg) % parent the barseries to the hggroup
set(hg,'Visible','off') % makes all barseries invisible
```

Group objects can be the parent of any number of axes children, including other group objects.

Note Many plotting functions clear the axes (i.e., remove axes children) before drawing the graph. Clearing the axes also deletes any hggroup or hgtransform objects in the axes.

Transforming Objects

The hgtransform object's `Matrix` property enables you to apply a transform to all the hgtransform's children in unison. Typical transforms include rotation, translation, and scaling. You define a transform with a four-by-four transformation matrix, which is described in the following sections.

Creating a Transform Matrix

The `makehgtform` function simplifies the construction of matrices to perform rotation, translation, and scaling. See the "Example — Transforming a Hierarchy of Objects" on page 8-36 section for information on creating transform matrices using `makehgtform`.

Rotation

Rotation transforms rotate objects about the *x*-, *y*-, or *z*-axis, with positive angles rotating counterclockwise while sighting along the respective axis toward the origin. If the desired angle of rotation is [[THETA]], the following matrices define this rotation about the respective axis.

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta_x & -\sin\theta_x & 0 \\ 0 & \sin\theta_x & \cos\theta_x & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

To create a transform matrix for rotation about an arbitrary axis, use the `makehgtform` function.

Translation

Translation transforms move objects with respect to their current locations. Specify the translation as distances t_x, t_y, and t_z in data space units. The following matrix shows the location of these elements in the transform matrix.

$$\begin{bmatrix} 1 & 0 & 0 & t_x \\ 0 & 1 & 0 & t_y \\ 0 & 0 & 1 & t_z \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

Scaling

Scaling transforms change the sizes of objects. Specify scale factors s_x, s_y, and s_z and construct the following matrix.

$$\begin{bmatrix} s_x & 0 & 0 & 0 \\ 0 & s_y & 0 & 0 \\ 0 & 0 & s_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

The Default Transform

The default transform is the identity matrix, which you can create with the `eye` function. Here is the identity matrix:

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

See “Undoing Transform Operations” on page 8-32 for related information.

Absolute vs. Relative Transforms

Transforms are specified in absolute terms, not relative to the current transform. For example, if you apply a transform that translates the hgtransform object 5 units in the *x* direction and then you apply another transform that translates it 4 units in the *y* direction, the resulting position of the object is 4 units in the *y* direction from its original position.

If you want transforms to accumulate, you must concatenate the individual transforms into a single matrix. See “Combining Transforms into One Matrix” on page 8-31 for more information.

Combining Transforms into One Matrix

It is usually more efficient to combine various transform operations into one matrix by concatenating (multiplying) the individual matrices and setting the `Matrix` property to the result. Note that matrix multiplication is not commutative, so the order in which you multiply the matrices affects the result. For example, suppose you want to perform an operation that scales, translates, and then rotates. You would multiply the matrices as follows:

```
C = R*T*S % operations are performed from right to left
```

where S is the scaling matrix, T is the translation matrix, R is the rotation matrix, and C is the composite of the three operations. You then set the hgtransform object’s `Matrix` property to C:

```
set(hgtransform_handle,'Matrix',C)
```

Note that the following sets of statements are not equivalent:

```
set(hgtransform_handle,'Matrix',C)% Transform as above
set(hgtransform_handle,'Matrix',eye(4) ) % Undo transform
```

versus

```
C = eye(4)*R*T*S % Multiply identity matrix as last step
set(hgtransform_handle,'Matrix',C)
```

Concatenating the identity matrix to other matrices has no effect on the composite matrix.

Undoing Transform Operations

Since transform operations are specified in absolute terms (not relative to the current transform), you can undo a series of transforms by setting the current transform to the identity matrix. For example, the following statement

```
set(hgtransform_handle,'Matrix',eye(4))
```

returns the object *hgtransform_handle* to its untransformed orientation.

Rotations Away From the Origin

Since rotations are performed about the origin, it is often necessary to translate the hgtransform object so that the desired axis of rotation is temporarily at the origin. After applying the rotation transform matrix, you then translate the hgtransform object back to its original position. The following example illustrates how to do this.

Suppose you want to rotate a surface about the *y*-axis at the center of the surface (the *y*-axis that passes through the point `x = 20` in this example).

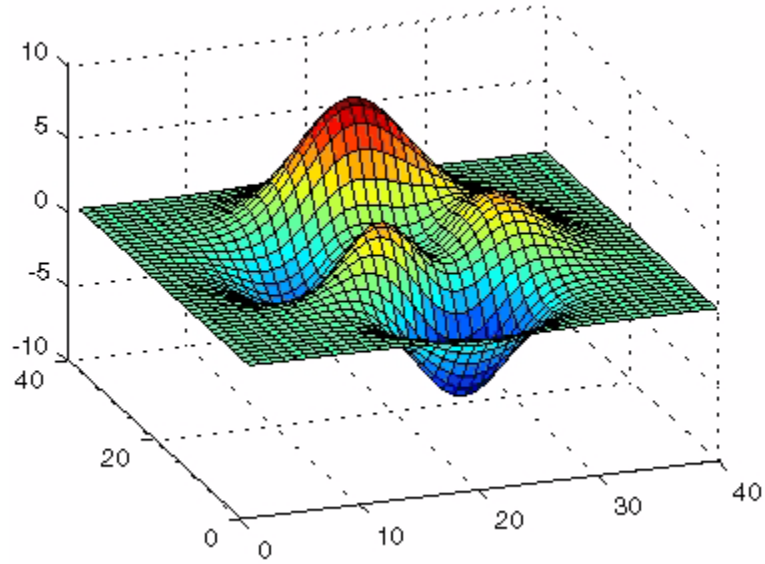
Note If you are using the MATLAB Help browser, you can run this example or open it in the MATLAB editor.

---

1 Create a surface and an hgtransform object. Parent the surface to the hgtransform object.

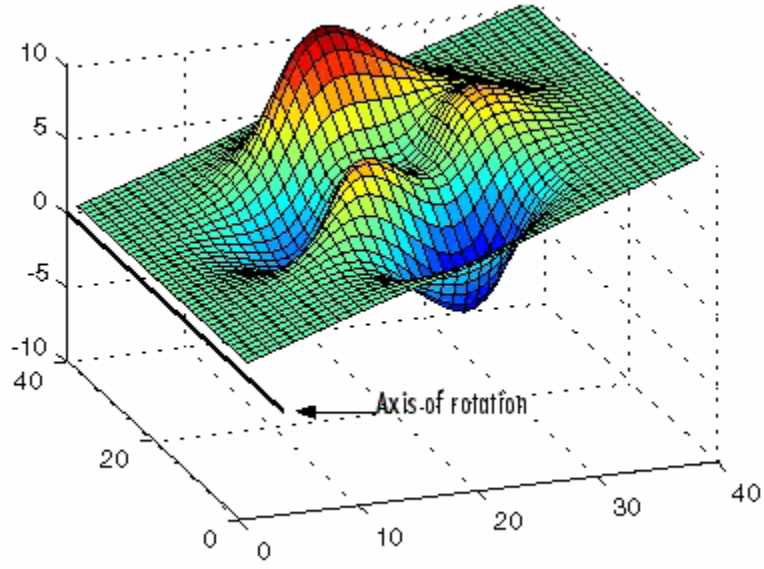
```
h = surf(peaks(40)); view(-20,30)
t = hgtransform;
set(h,'Parent',t)
```

The following picture shows the surface.



2 Create and set a *y*-axis rotation matrix to rotate the surface by -15 degrees.

```
ry_angle = -15*pi/180; % Convert to radians
Ry = makehgtform('yrotate',ry_angle);
set(t,'Matrix',Ry)
```



Notice that the surface rotated -15 degrees about the *y*-axis that passes through the origin. However, to rotate about the *y*-axis that passes through the point `x = 20`, you must translate the surface in *x* by 20 units.

3 Create two translation matrices, one to translate the surface -20 units in *x* and another to translate 20 units back. Concatenate the two translation matrices with the rotation matrix in the correct order and set the transform.

```
Tx1 = makehgtform('translate',[-20 0 0]);
Tx2 = makehgtform('translate',[20 0 0]);
set(t,'Matrix',Tx2*Ry*Tx1)
```

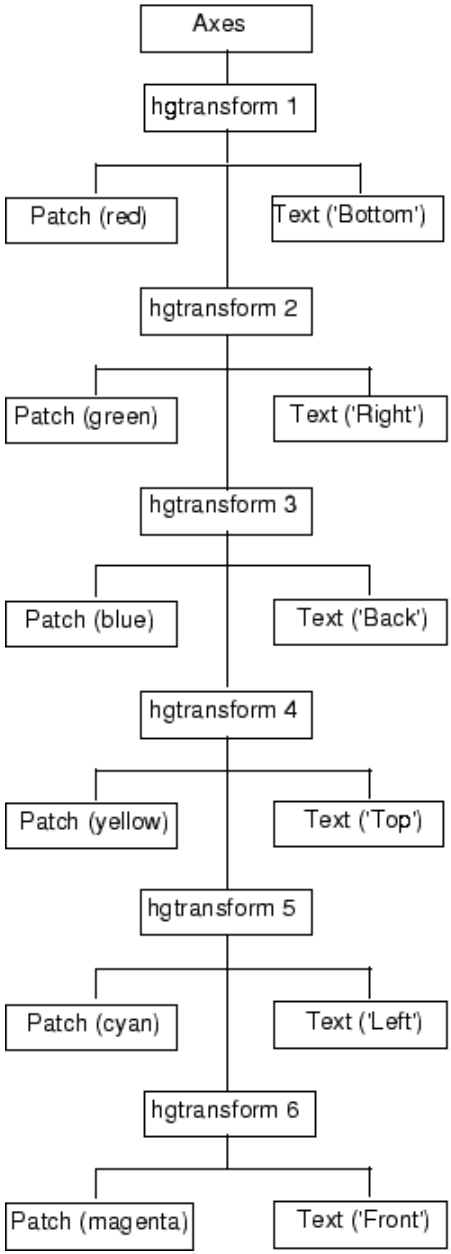
Example — Transforming a Hierarchy of Objects

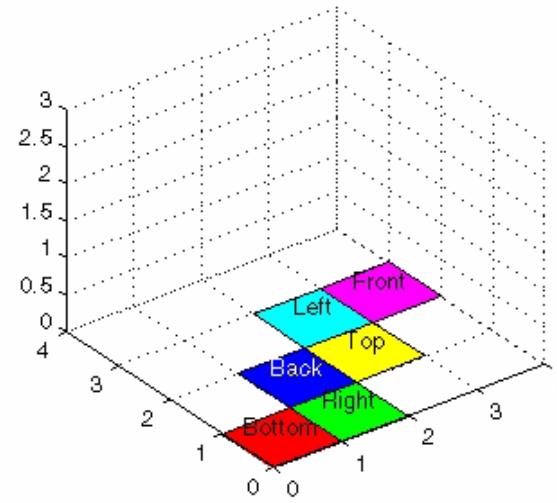
This example creates a hierarchy of hgtransform objects, which are then transformed in sequence to create a cube from six squares. The example illustrates how you can parent hgtransform objects to other hgtransform objects to create a hierarchy and how transforming members of a hierarchy affects subordinate members.

The following picture illustrates the hierarchy.



The diagram on the left represents the object hierarchy in the picture below.

Through a series of simple rotations and translations, the six squares are folded into a cube.



Note If you are using the MATLAB Help browser, you can run this example or open it in the MATLAB editor.

1. Set the figure `Renderer` property to `zbuffer` so MATLAB uses double buffering to prevent flashing during the loop. Set up the figure and the view.

```
set(gcf,'Renderer','zbuffer');
% Set axis limits and view
set(gca,'XLim',[0 4], 'YLim',[0 4], 'ZLim', [0 3]);
view(3); axis equal; grid on
```

2. Define a hierarchy of hgtransform objects.

```
t(1) = hgtransform;
t(2) = hgtransform('parent',t(1));
t(3) = hgtransform('parent',t(2));
t(4) = hgtransform('parent',t(3));
t(5) = hgtransform('parent',t(4));
t(6) = hgtransform('parent',t(5));
```

3. Create the patch and text objects and parent each pair to the respective hgtransform object.

   Note that the data defining each patch object and the locations of all text objects are the same and are assigned by a single call to `set`. The objects are then translated to the desired positions on screen.

```
% Patch data
X = [0 0 1 1];
Y = [0 1 1 0];
Z = [0 0 0 0];
% Text data
Xtext = .5;
Ytext = .5;
Ztext = .15;
% Parent corresponding pairs of objects (patch and text)
% into the object hierarchy
p(1) = patch('FaceColor','red','Parent',t(1));
txt(1) = text('String','Bottom','Parent',t(1));
```

```
p(2) = patch('FaceColor','green','Parent',t(2));
txt(2) = text('String','Right','Parent',t(2));
p(3) = patch('FaceColor','blue','Parent',t(3));
txt(3) = text('String','Back','Color','white','Parent',t(3));
p(4) = patch('FaceColor','yellow','Parent',t(4));
txt(4) = text('String','Top','Parent',t(4));
p(5) = patch('FaceColor','cyan','Parent',t(5));
txt(5) = text('String','Left','Parent',t(5));
p(6) = patch('FaceColor','magenta','Parent',t(6));
txt(6) = text('String','Front','Parent',t(6));
% Set the patch x, y, and z data
set(p,'XData',X,'YData',Y,'ZData',Z)
% Set the position and alignment of the text
set(txt,'Position',[Xtext Ytext Ztext],...
    'HorizontalAlignment','center',...
    'VerticalAlignment','middle')
```

4 Translate the squares (patch objects) to the desired locations. Note that as hgtransform object 2 is translated, all its children (including hgtransform objects 3 through 6) are also translated. Therefore, each translation requires moving the square by only one unit in either the x or y direction. Hgtransform object 1 is left at its original position.

```
% Set up initial translation transform matrices
% Translate 1 unit in x
Tx = makehgtform('translate',[1 0 0]);
% Translate 1 unit in y
Ty = makehgtform('translate',[0 1 0]);
% Set the Matrix property of each hgtransform object (2-6)
set(t(2),'Matrix',Tx);
drawnow
set(t(3),'Matrix',Ty);
drawnow
set(t(4),'Matrix',Tx);
drawnow
set(t(5),'Matrix',Ty);
drawnow
set(t(6),'Matrix',Tx);
```

Object Properties

In this section...

Introduction

A graphics object's properties control many aspects of its appearance and behavior. Properties include general information such as the object's type, its parent and children, and whether it is visible, as well as information unique to the particular class of object.

For example, from any given figure object you can obtain the identity of the last key pressed in the window, the location of the pointer, or the handle of the most recently selected menu.

Note The simplest way to access the documentation of all object properties is using the Handle Graphics Property Browser.

Storing Object Information

MATLAB organizes graphics information into a hierarchy and stores information about objects in properties. For example, root properties contain the handle of the current figure and the current location of the pointer (cursor), figure properties maintain lists of their descendants and keep track of certain events that occur within the window, and axes properties contain information about how each child object uses the figure colormap and the color order used by the `plot` function.

Changing Values

You can query the current value of any property and specify most property values (although some are set by MATLAB and are read only). Property values apply uniquely to a particular instance of an object; setting a value for one object does not change this value for other objects of the same type.

Order Dependence of Setting Property Values

MATLAB sets the values of properties in the order in which properties are assigned values in a statement. For example, the following calls to the `figure` function create very different results. This statement,

```
figure('Position',[1 1 400 300],'Units','inches')
```

creates a figure in the lower left corner of the screen that is 400 pixels in width and 300 pixels in height. If you reverse the order of the `Position` and `Units` properties, MATLAB creates a figure that is too large to display (400 by 300 inches):

```
figure('Units','inches','Position',[1 1 400 300])
```

Properties Are Interpreted from Left to Right

In the first figure above, MATLAB creates a figure of the specified size using the default `Units` (pixels) and then sets the `Units` to inches. In the second case MATLAB sets the `Units` to inches and uses these units to interpret the specified figure `Position`. MATLAB interprets the property values from left to right:

```
set(gcf,'Units','pixels')
get(gcf,'Position')
ans =
  1.0e+004 *
    0.0097    2.7760    0.1924    0.1137
% Change the Units, set the Position,
% and change Units again in one statement
set(gcf,'Units','pixels','Position',[1 1 400 300],'Units','inches')
get(gcf,'Position')
ans =
         0         0    4.1667    3.1250
```

Default Values

You can set default values that affect all subsequently created objects. Whenever you do not define a value for a property, either as a default or when you create the object, MATLAB uses “factory-defined” values.

Note that plot objects do not allow you to set default values.

The reference entry for each object creation function provides a complete list of the properties associated with the graphics object.

Properties Common to All Objects

Some properties are common to all graphics objects, as illustrated in the following table.

Property	Description
`BeingDeleted`	Has a value of `on` when object’s `DeleteFcn` has been called
`BusyAction`	Controls the way MATLAB handles callback routine interruption defined for the particular object
`ButtonDownFcn`	Callback routine that executes when button press occurs
`Children`	Handles of all this object’s child objects
`Clipping`	Mode that enables or disables clipping (meaningful only for axes children)
`CreateFcn`	Callback routine that executes when this type of object is created
`DeleteFcn`	Callback routine that executes when you issue a command that destroys the object
`HandleVisibility`	Allows you to control the availability of the object’s handle from the command line and from within callback routines
`HitTest`	Determines if object can become the current object when selected by a mouse click
`Interruptible`	Determines whether a callback routine can be interrupted by a subsequently invoked callback routine
`Parent`	The object’s parent
`Selected`	Indicates whether object is selected

Property	Description
`SelectionHighlight`	Specifies whether object visually indicates the selection state
`Tag`	User-specified object label
`Type`	The type of object (figure, line, text, etc.)
`UserData`	Any data you want to associate with the object
`Visible`	Determines whether or not the object is visible

Properties Common to All Objects

Some properties are common to all graphics objects, as illustrated in the following table.

Property	Description
`BeingDeleted`	Has a value of `on` when object's `DeleteFcn` has been called
`BusyAction`	Controls the way MATLAB handles callback routine interruption defined for the particular object
`ButtonDownFcn`	Callback routine that executes when button press occurs
`Children`	Handles of all this object's child objects
`Clipping`	Mode that enables or disables clipping (meaningful only for axes children)
`CreateFcn`	Callback routine that executes when this type of object is created
`DeleteFcn`	Callback routine that executes when you issue a command that destroys the object
`HandleVisibility`	Allows you to control the availability of the object's handle from the command line and from within callback routines
`HitTest`	Determines if object can become the current object when selected by a mouse click
`Interruptible`	Determines whether a callback routine can be interrupted by a subsequently invoked callback routine
`Parent`	The object's parent
`Selected`	Indicates whether object is selected
`SelectionHighlight`	Specifies whether object visually indicates the selection state
`Tag`	User-specified object label
`Type`	The type of object (figure, line, text, etc.)
`UserData`	Any data you want to associate with the object
`Visible`	Determines whether or not the object is visible

Setting and Querying Property Values

In this section...

Using Set and Get

The `set` and `get` functions specify and retrieve the value of existing graphics object properties. They also enable you to list possible values for properties that have a fixed set of values. (You can also use the Property Editor to set many property values.

The basic syntax for setting the value of a property on an existing object is

```
set(object_handle,'PropertyName','NewPropertyValue')
```

To query the current value of a specific object's property, use a statement like

```
returned_value = get(object_handle,'PropertyName');
```

Property names are always quoted strings. Property values depend on the particular property.

See “Accessing Object Handles” on page 8-58 and the `findobj` command for information on finding the handles of existing objects.

Setting Property Values

You can change the properties of an existing object using the `set` function and the handle returned by the creating function. For example, this statement moves the *y*-axis to the right side of the plot on the current axes.

```
set(gca,'YAxisLocation','right')
```

If the handle argument is a vector, MATLAB sets the specified value on all identified objects.

You can specify property names and property values using structure arrays or cell arrays. This can be useful if you want to set the same properties on a number of objects. For example, you can define a structure to set axes properties appropriately to display a particular graph.

```
view1.CameraViewAngleMode = 'manual';
view1.DataAspectRatio = [1 1 1];
view1.ProjectionType = 'Perspective';
```

To set these values on the current axes, type

```
set(gca,view1)
```

Listing Possible Values

You can use `set` to display the possible values for many properties without actually assigning a new value. For example, this statement obtains the values you can specify for line object markers.

```
set(obj_handle,'Marker')
```

MATLAB returns a list of values for the `Marker` property for the type of object specified by `obj_handle`. Braces indicate the default value.

```
[ + | o | * | . | x | square | diamond | v | ^ | > | < | pentagram
| hexagram | {none} ]
```

To see a list of all settable properties along with possible values of properties that accept string values, use `set` with just an object handle.

```
set(object_handle)
```

For example, for a surface object, MATLAB returns

```
CData
CDataScaling: [ {on} | off]
EdgeColor: [ none | {flat} | interp ] ColorSpec.
EraseMode: [ {normal} | background | xor | none ]
FaceColor: [ none | {flat} | interp | texturemap ] ColorSpec.
LineStyle: [ {-} | -- | : | -. | none ]
  .
  .
```

```
  .
Visible: [ {on} | off ]
```

If you assign the output of the `set` function to a variable, MATLAB returns the output as a structure array. For example,

```
a = set(gca);
```

The field names in `a` are the object's property names and the field values are the possible values for the associated property. For example,

```
a.GridLineStyle
ans =

    '-'
    '--'
    ':'
    '-.'
    'none'
```

returns the possible values for the axes grid line styles. Note that while property names are not case sensitive, MATLAB structure field names are. For example,

```
a.gridlinestyle
??? Reference to non-existent field 'gridlinestyle'.
```

returns an error.

Querying Property Values

Use `get` to query the current value of a property or of all the object's properties. For example, check the value of the current axes `PlotBoxAspectRatio` property.

```
get(gca,'PlotBoxAspectRatio')
ans =
     1     1     1
```

MATLAB lists the values of all properties, where practical. However, for properties containing data, MATLAB lists the dimensions only (for example, `CurrentPoint` and `ColorOrder`).

```
AmbientLightColor = [1 1 1]
Box = off
CameraPosition = [0.5 0.5 2.23205]
CameraPositionMode = auto
CameraTarget = [0.5 0.5 0.5]
CameraTargetMode = auto
CameraUpVector = [0 1 0]
CameraUpVectorMode = auto
CameraViewAngle = [32.2042]
CameraViewAngleMode = auto
CLim: [0 1]
CLimMode: auto
Color: [0 0 0]
CurrentPoint: [ 2x3  double]
ColorOrder: [ 7x3  double]
  .
  .
  .
Visible = on
```

Querying Individual Properties

You can obtain the data from the property by getting that property individually.

```
get(gca,'ColorOrder')
ans =
         0         0    1.0000
         0    0.5000         0
    1.0000         0         0
         0    0.7500    0.7500
    0.7500         0    0.7500
    0.7500    0.7500         0
    0.2500    0.2500    0.2500
```

Returning a Structure

If you assign the output of `get` to a variable, MATLAB creates a structure array whose field names are the object property names and whose field values are the current values of the named property.

For example, if you plot some data, `x` and `y`,

```
h = plot(x,y);
```

and get the properties of the line object created by `plot`,

```
a = get(h);
```

you can access the values of the line properties using the field name. This call to the `text` command places the string 'x and y data' at the first data point and colors the text to match the line color.

```
text(x(1),y(1),'x and y data','Color',a.Color)
```

If `x` and `y` are matrices, `plot` draws one line per column. To label the plot of the second column of data, reference that line.

```
text(x(1,2),y(1,2),'Second set of data','Color',a(2).Color)
```

Querying Groups of Properties

You can define a cell array of property names and conveniently use it to obtain the values for those properties. For example, suppose you want to query the values of the axes "camera mode" properties. First define the cell array.

```
camera_props(1) = {'CameraPositionMode'};
camera_props(2) = {'CameraTargetMode'};
camera_props(3) = {'CameraUpVectorMode'};
camera_props(4) = {'CameraViewAngleMode'};
```

Use this cell array as an argument to obtain the current values of these properties.

```
get(gca,camera_props)
ans =
     'auto' 'auto' 'auto' 'auto'
```

Factory-Defined Property Values

MATLAB defines values for all properties, which are used if you do not specify values as arguments or as defaults. You can obtain a list of all factory-defined values with the statement

```
a = get(0,'Factory');
```

`get` returns a structure array whose field names are the object type and property name concatenated, and field values are the factory value for the indicated object and property. For example, this field,

```
UimenuSelectionHighlight: 'on'
```

indicates that the factory value for the `SelectionHighlight` property on uimenu objects is `on`.

You can get the factory value of an individual property with

```
get(0,'FactoryObjectTypePropertyName')
```

For example,

```
get(0,'FactoryTextFontName')
```

Setting Default Property Values

In this section...

Factory- and User-Defined Values

All object properties have values built into MATLAB (i.e., factory-defined values). You can also define your own default values at any point in the object hierarchy.

Note that you cannot define default values for plot objects.

How MATLAB Searches for Default Values

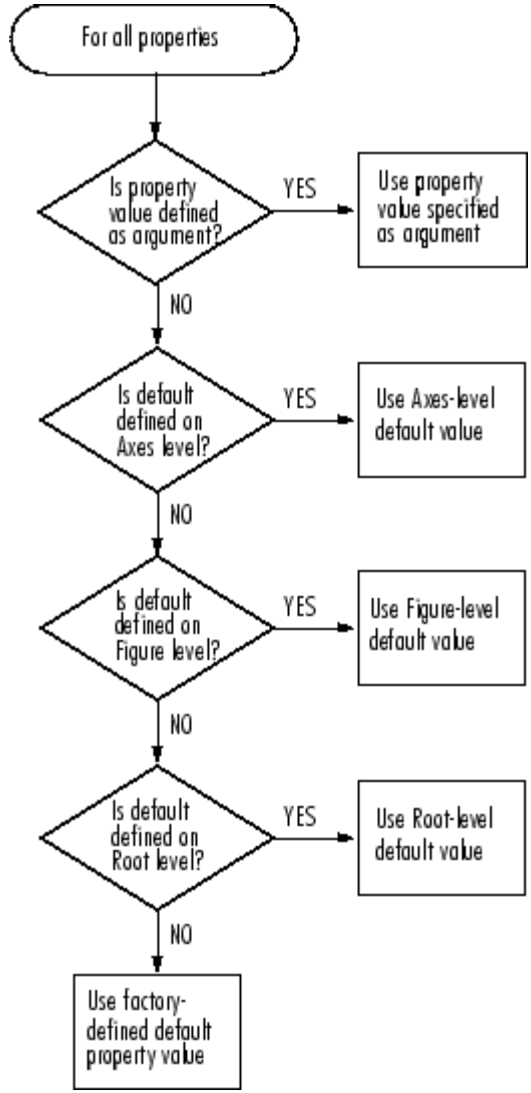
MATLAB searches for a default value beginning with the current object and continuing through the object's ancestors until it finds a user-defined default value or until it reaches the factory-defined value. Therefore, a search for property values is always satisfied.

The closer to the root of the hierarchy you define the default, the broader its scope. If you specify a default value for line objects on the root level, MATLAB uses that value for all lines (because the root is at the top of the hierarchy). If you specify a default value for line objects on the axes level, then MATLAB uses that value for line objects drawn only in that axes.

If you define default values on more than one level, the value defined on the closest ancestor takes precedence because MATLAB terminates the search as soon as it finds a value.

Note that setting default values affects only those objects created after you set the default. Existing graphics objects are not affected.

This diagram shows the steps MATLAB follows in determining the value of a graphics object property.



Defining Default Values

To specify default values, create a string beginning with the word `Default` followed by the object type and finally the object property. For example, to specify a default value of 1.5 points for the line property `LineWidth` at the level of the current figure, use the statement

```
set(gcf,'DefaultLineLineWidth',1.5)
```

The string `DefaultLineLineWidth` identifies the property as a line property. To specify the figure color, use `DefaultFigureColor`. Note that it is meaningful to specify a default figure color only on the root level.

```
set(0,'DefaultFigureColor','b')
```

Use `get` to determine what default values are currently set on any given object level; for example,

```
get(gcf,'default')
```

returns all default values set on the current figure.

Setting Properties to the Default

Specifying a property value of `'default'` sets the property to the first encountered default value defined for that property. For example, these statements result in a green surface `EdgeColor`:

```
set(0,'DefaultSurfaceEdgeColor','k')
h = surface(peaks);
set(gcf,'DefaultSurfaceEdgeColor','g')
set(h,'EdgeColor','default')
```

Because a default value for surface `EdgeColor` exists on the figure level, MATLAB encounters this value first and uses it instead of the default `EdgeColor` defined on the root.

Removing Default Values

Specifying a property value of `'remove'` gets rid of user-defined default values. The statement

```
set(0,'DefaultSurfaceEdgeColor','remove')
```

removes the definition of the default Surface `EdgeColor` from the root.

Setting Properties to Factory-Defined Values

Specifying a property value of `'factory'` sets the property to its factory-defined value. (Theproperty descriptions provides access to the factory settings for properties having predefined sets of values.)

For example, these statements set the `EdgeColor` of surface `h` to black (its factory setting) regardless of what default values you have defined.

```
set(gcf,'DefaultSurfaceEdgeColor','g')
h = surface(peaks);
set(h,'EdgeColor','factory')
```

Reserved Words

Setting a property value to `default`, `remove`, or `factory` produces the effects described in the previous sections. To set a property to one of these words (e.g., a text or uicontrol `String` property set to the word `Default`), you must precede the word with the backslash character. For example,

```
h = uicontrol('Style','edit','String','\Default');
```

Examples — Setting Default Line Styles

The `plot` function cycles through the colors defined by the axes `ColorOrder` property when displaying multiline plots. If you define more than one value for the axes `LineStyleOrder` property, MATLAB increments the line style after each cycle through the colors.

You can set default property values that cause the `plot` function to produce graphs using varying linestyles, but not varying colors. This is useful when you are working on a monochrome display or printing on a black and white printer.

First Example

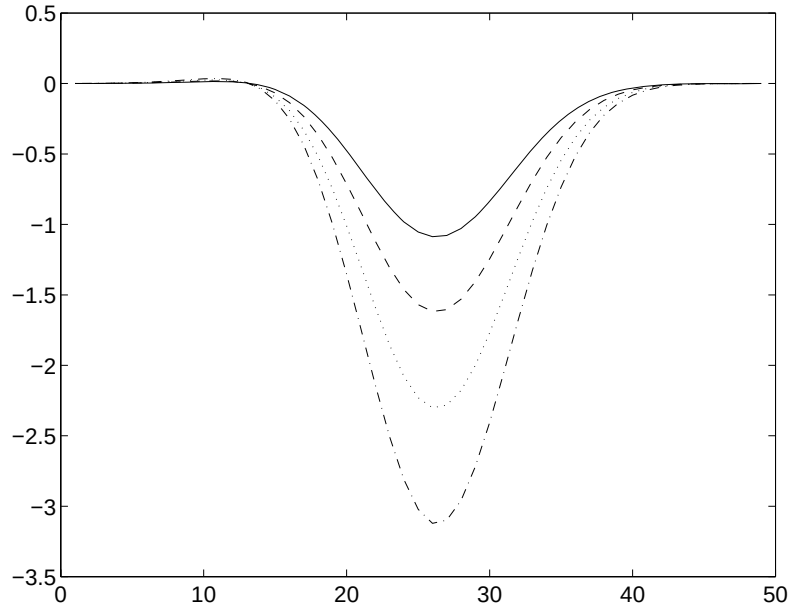
This example creates a figure with a white plot (axes) background color, then sets default values for axes objects on the root level.

```
whitebg('w') %create a figure with a white color scheme
set(0,'DefaultAxesColorOrder',[0 0 0],...
      'DefaultAxesLineStyleOrder','-|--|:|-.')
```

Whenever you call `plot`,

```
Z = peaks; plot(1:49,Z(4:7,:))
```

it uses one color for all data plotted because the axes `ColorOrder` contains only one color, but cycles through the linestyles defined for `LineStyleOrder`.



Second Example

This example sets default values on more than one level in the hierarchy. These statements create two axes in one figure window, setting default values on the figure level and the axes level.

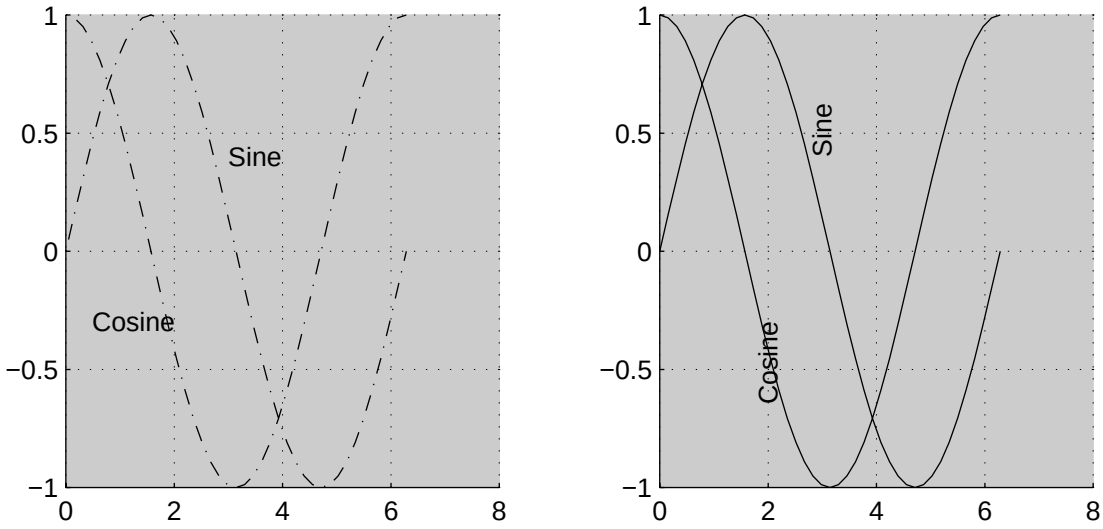
```
t = 0:pi/20:2*pi;
s = sin(t);
c = cos(t);
% Set default value for axes Color property
```

```
figh = figure('Position',[30 100 800 350],...
              'DefaultAxesColor',[.8 .8 .8]);

axh1 = subplot(1,2,1); grid on
% Set default value for line LineStyle property in first axes
set(axh1,'DefaultLineLineStyle','-.')
line('XData',t,'YData',s)
line('XData',t,'YData',c)
text('Position',[3 .4],'String','Sine')
text('Position',[2 -.3],'String','Cosine',...
     'HorizontalAlignment','right')

axh2 = subplot(1,2,2); grid on
% Set default value for text Rotation property in second axes
set(axh2,'DefaultTextRotation',90)
line('XData',t,'YData',s)
line('XData',t,'YData',c)
text('Position',[3 .4],'String','Sine')
text('Position',[2 -.3],'String','Cosine',...
     'HorizontalAlignment','right')
```

Issuing the same `line` and `text` statements to each subplot region results in a different display, reflecting different default settings.



Because the default axes `Color` property is set on the figure level of the hierarchy, MATLAB creates both axes with the specified gray background color.

The axes on the left (subplot region 121) defines a dash-dot line style (`-.`) as the default, so each call to the `line` function uses dash-dot lines. The axes on the right does not define a default line style, so MATLAB uses solid lines (the factory setting for lines).

The axes on the right defines a default text `Rotation` of 90 degrees, which rotates all text by this amount. MATLAB obtains all other property values from their factory settings, which results in nonrotated text on the left.

To install default values whenever you run MATLAB, specify them in your `startup.m` file. Note that MATLAB might install default values for some appearance properties when started by calling the `colordef` command.

Accessing Object Handles

In this section...

Introduction

MATLAB assigns a handle to every graphics object it creates. All object creation functions optionally return the handle of the created object. If you want to access the object's properties (e.g., from an M-file) you should assign its handle to a variable at creation time to avoid searching for it later.

You can always obtain the handle of an existing object with the `findobj` function or by listing its parent's `Children` property.

See "Searching for Objects by Property Values — findobj" on page 8-60 for examples.

See "Protecting Figures and Axes" on page 8-77 for more information on how object handles are hidden from normal access.

Special Object Handles

The root object's handle is always zero. The handle of a figure is either

- An integer that, by default, is displayed in the window title bar
- A floating point number requiring full MATLAB internal precision

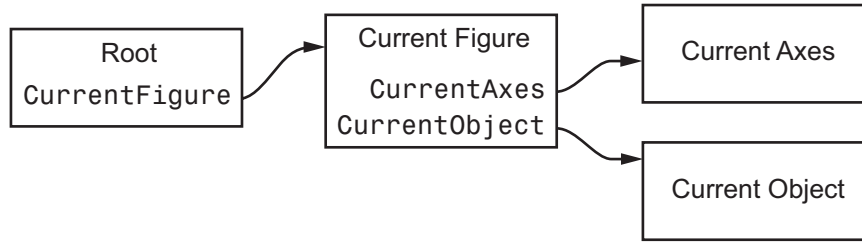
The figure `IntegerHandle` property controls the type of handle the figure receives.

All other graphics object handles are floating-point numbers. You must maintain the full precision of these numbers when you reference handles. Rather than attempting to read handles off the screen and retype them, you must store the value in a variable and pass that variable whenever MATLAB requires a handle.

The Current Figure, Axes, and Object

An important concept in Handle Graphics is that of being current. The current figure is the window designated to receive graphics output. Likewise, the current axes is the target for commands that create axes children. The current object is the last graphics object created or clicked on by the mouse.

MATLAB stores the three handles corresponding to these objects in the ancestor's property list.



These properties enable you to obtain the handles of these key objects.

```
get(0,'CurrentFigure');
get(gcf,'CurrentAxes');
get(gcf,'CurrentObject');
```

The following commands are shorthand notation for the `get` statements.

- `gcf` — Returns the value of the root `CurrentFigure` property
- `gca` — Returns the value of the current figure's `CurrentAxes` property
- `gco` — Returns the value of the current figure's `CurrentObject` property

You can use these commands as input arguments to functions that require object handles. For example, you can click on a line object and then use `gco` to specify the handle to the `set` command,

```
set(gco,'Marker','square')
```

or list the values of all current axes properties with

```
get(gca)
```

You can get the handles of all the graphic objects in the current axes (except those with hidden handles),

```
h = get(gca,'Children');
```

and then determine the types of the objects.

```
get(h,'type')
ans =
      'text'
      'patch'
      'surface'
      'line'
```

While `gcf` and `gca` provide a simple means of obtaining the current figure and axes handles, they are less useful in M-files. This is particularly true if your M-file is part of an application layered on MATLAB where you do not necessarily have knowledge of user actions that can change these values.

See “Controlling Graphics Output” on page 8-69 for information on how to prevent users from accessing the handles of graphics objects that you want to protect.

Searching for Objects by Property Values — findobj

The `findobj` function provides a means to traverse the object hierarchy quickly and obtain the handles of objects having specific property values. To serve as a means of identification, all graphics objects have a `Tag` property that you can set to any string. You can then search for the specific property/value pair.

For example, suppose you create a checkbox that is sometimes inactivated in the GUI. By assigning a unique value for the `Tag` property, you can always find that particular instance and set its properties.

```
uicontrol('Style','checkbox','Tag','save option')
```

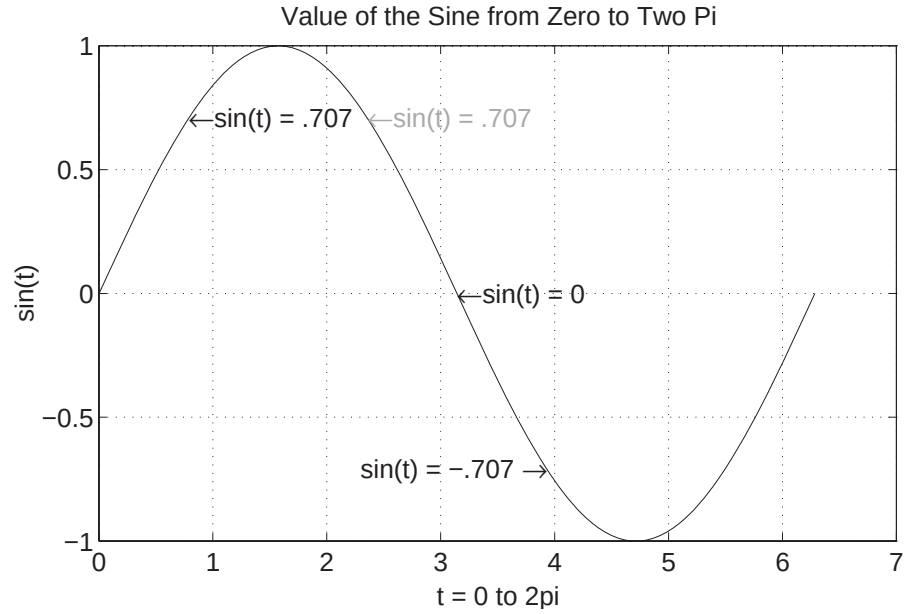
Use `findobj` to locate the object whose `Tag` property is set to `'save option'` and disable it.

```
set(findobj('Tag','save option'),'Enable','off')
```

If you do not specify a starting object, `findobj` searches from the root object, finding all occurrences of the property name/property value combination that you specify.

Example — Finding Objects

This plot of the sine function contains text objects labeling particular values of the function.



Suppose you want to move the text string labeling the value sin(t) = .707 from its current location at `[pi/4,sin(pi/4)]` to the point `[3*pi/4,sin(3*pi/4)]` where the function has the same value (shown grayed out in the picture). To do this, you need to determine the handle of the text object labeling that point and change its `Position` property.

To use `findobj`, pick a property value that uniquely identifies the object. This example uses the text `String` property.

```
text_handle = findobj('String','\leftarrowsin(t) = .707');
```

Next move the object to the new position, defining the text `Position` in axes units.

```
set(text_handle,'Position',[3*pi/4,sin(3*pi/4),0])
```

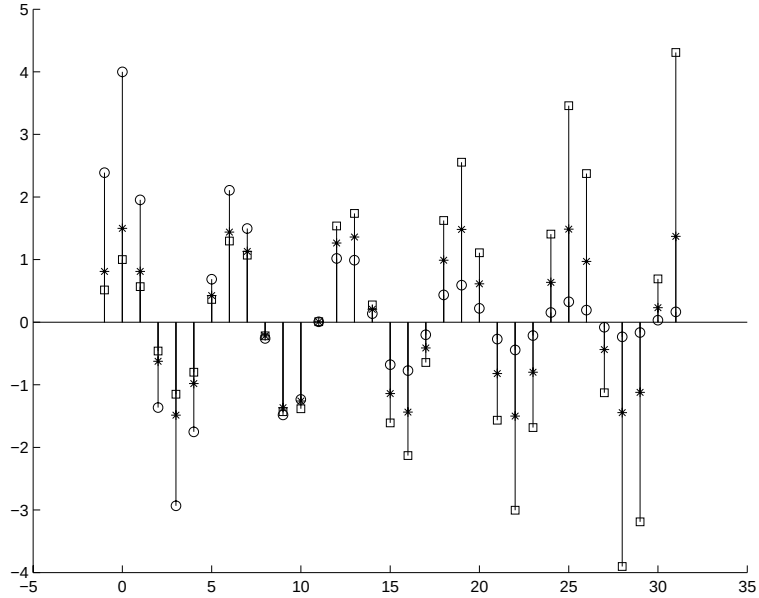
`findobj` also lets you restrict the search by specifying a starting point in the hierarchy, instead of beginning with the root object. This results in faster searches if there are many objects in the hierarchy. In the previous example, you know the text object of interest is in the current axes, so you can type

```
text_handle = findobj(gca,'String','\leftarrowsin(t) = .707');
```

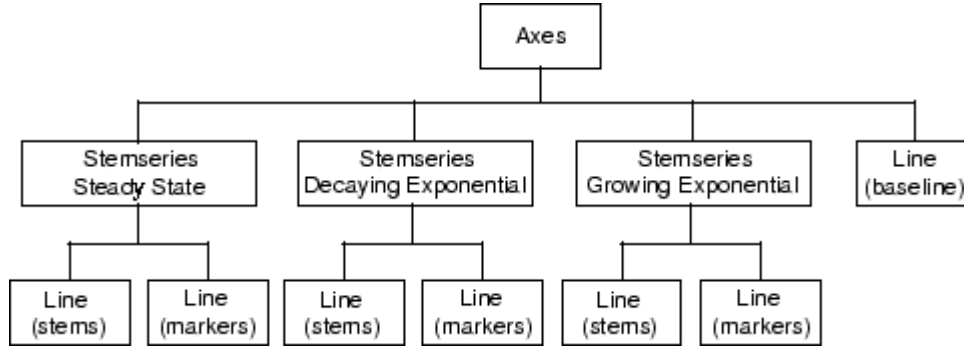
Example — Using Logical Operators and Regular Expression

Suppose you create the following graph and want to modify certain properties of the objects created.

```
x = 0:30;
y = [1.5*cos(x);4*exp(-.1*x).*cos(x);exp(.05*x).*cos(x)]';
h = stem(x,y);
set(h(1),'Color','black',...
            'Marker','o',...
            'Tag','Decaying Exponential')
set(h(2),'Color','black',...
            'Marker','square',...
            'Tag','Growing Exponential')
set(h(3),'Color','black',...
            'Marker','*',...
            'Tag','Steady State')
```



The following instance diagram shows the graphics objects created in the graph. Each of the three sets of data produces a stemseries object, which in turn uses two lines to create the stem graph; one line for the stems and one for the markers that terminate each stem. There is also a line used for the baseline.



Controlling the Depth of the Search. Now make the baseline into a dashed line. Because it is parented directly to the axes, you can use the following statement to access only this line:

```
set(findobj(gca,'-depth',1,'Type','line'),'LineStyle','--')
```

By setting `-depth` to `1`, `findobj` searches only the axes and its immediate children. As you can see from the above instance diagram, the baseline is the only line object parented directly to the axes.

Limiting the Search with Regular Expressions. Increase the value of the `MarkerSize` property by 2 points on all stemseries objects that do not have their property `Tag` set to `'Steady State'`.

```
h = findobj('-regexp','Tag','^(?!Steady State$).');
set(h,{'MarkerSize'},num2cell(cell2mat(get(h,'MarkerSize'))+2))
```

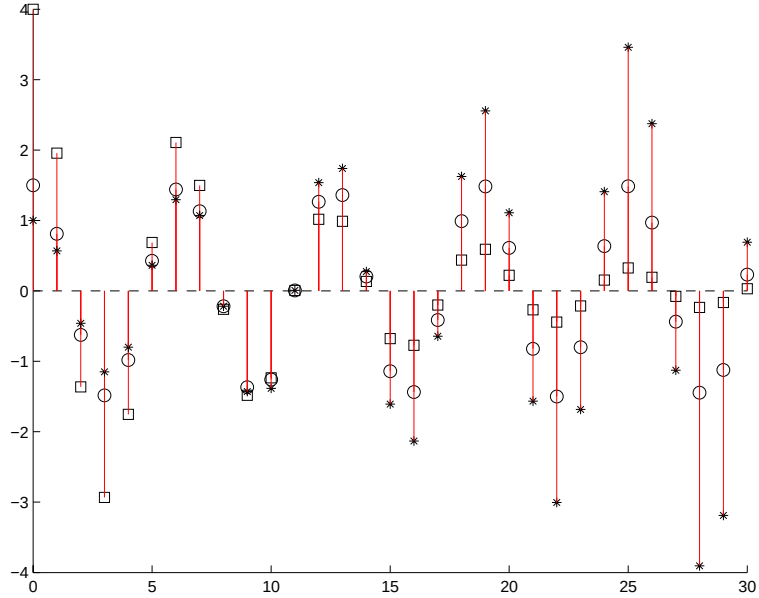
See the `regexp` function for more information on using regular expressions in MATLAB.

Using Logical Operators. Change the color of the stem lines, but not the stem markers. To do this, you must access the line objects contained by the three stemseries objects. You cannot just set the stemseries `Color` property because it sets both the line and marker colors.

Search for objects that are of `Type` `line`, have `Marker` set to `none`, and do not have `LineStyle` set to `'--'`, which is the baseline.

```
h = findobj('type','line','Marker','none',...
    '-and','-not','LineStyle','--');
set(h,'Color','red')
```

The following picture shows the graph after making the various changes described in this section.



Copying Objects

You can copy objects from one parent to another using the `copyobj` function. The new object differs from the original object only in the value of its `Parent` property and its handle; it is otherwise a clone of the original. You can copy a number of objects to a new parent, or one object to a number of new parents, as long as the result maintains the correct parent/child relationship.

When you copy an object having child objects, MATLAB copies all children as well.

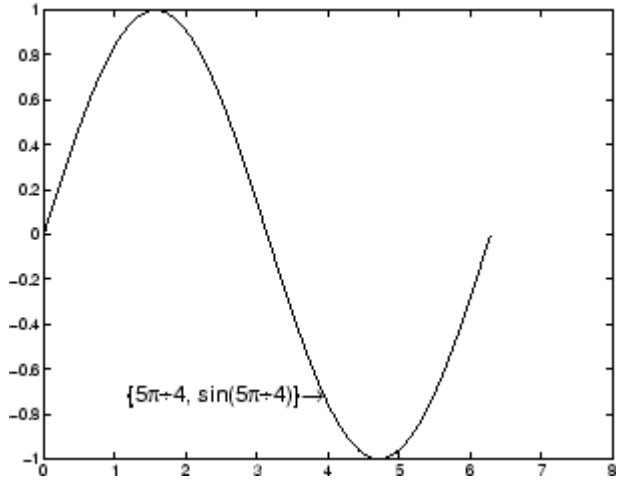
Example — Copying Objects

Suppose you are plotting a variety of data and want to label the point having the *x*- and *y*-coordinates determined by $5\pi \div 4$, $\sin(5\pi \div 4)$ in each plot. The `text` function allows you to specify the location of the label in the coordinates defined by the *x*- and *y*-axis limits, simplifying the process of locating the text.

```
text('String','\{5\pi\div4, sin(5\pi\div4)\}\rightarrow',...
     'Position',[5*pi/4,sin(5*pi/4),0],...
     'HorizontalAlignment','right')
```

In this statement, the `text` function

- Labels the data point with the string $\{5\pi \div 4, \sin(5\pi \div 4)\}$ using TeX commands to draw a right-facing arrow and mathematical symbols
- Specifies the `Position` in terms of the data being plotted
- Places the data point to the right of the text string by changing the `HorizontalAlignment` to `right` (the default is `left`)

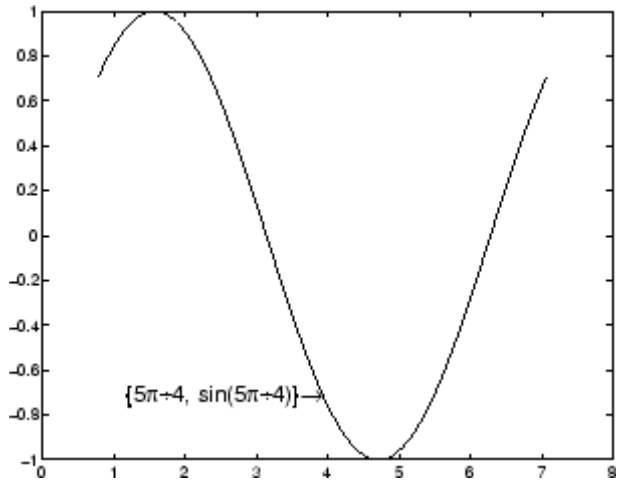


To label the same point with the same string in another plot, copy the text using `copyobj`. Because the last statement did not save the handle to the text object, you can find it using `findobj` and the `'String'` property.

```
text_handle = findobj('String',...
              '\{5\pi\div4,sin(5\pi\div4)\}\rightarrow');
```

After creating the next plot, add the label by copying it from the first plot.

```
copyobj(text_handle,gca).
```



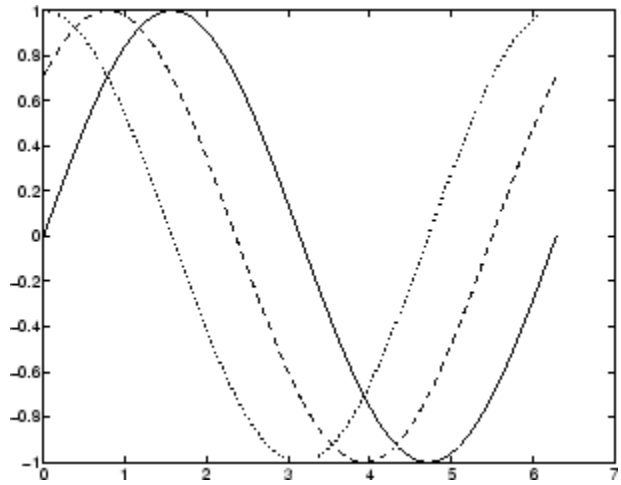
This particular example takes advantage of the fact that text objects define their location in the axes data space. Therefore the text `Position` property did not need to change from one plot to another.

Deleting Objects

You can remove a graphics object with the `delete` command, using the object's handle as an argument. For example, you can delete the current axes (and all of its descendants) with the statement

```
delete(gca)
```

You can use `findobj` to get the handle of a particular object you want to delete. For example, to find the handle of the dotted line in this multiline plot,



use `findobj` to locate the object whose `LineStyle` property is `':'`

```
line_handle = findobj('LineStyle',':');
```

then use this handle with the `delete` command.

```
delete(line_handle)
```

You can combine these two statements, substituting the `findobj` statement for the handle.

```
delete(findobj('LineStyle',':'))
```

Controlling Graphics Output

In this section...

Figure Targets

MATLAB allows many figure windows to be open simultaneously during a session. A MATLAB application might create figures to display graphical user interfaces as well as plotted data. It is necessary then to protect some figures from becoming the target for graphics display and to prepare (e.g., reset properties and clear existing objects from) others before receiving new graphics.

Specifying the Target for Graphics Output

By default, MATLAB functions that create graphics objects display them in the current figure and current axes (if an axes child). You can direct the output to another parent by explicitly specifying the `Parent` property with the creating function. For example,

```
plot(1:10,'Parent',axes_handle)
```

where *axes_handle* is the handle of the target axes. The `uicontrol` and `uimenu` functions have a convenient syntax that enables you to specify the parent as the first argument,

```
uicontrol(figure_handle,...)
uimenu(parent_menu_handle,...)
```

or you can set the Parent property. Many plotting functions accept an axes handle as the first argument as well.

Making a Figure and Axes Current

You can specify which figure and which axes within the figure are the target for graphics output. There are two ways to do this, each with different associated behavior.

Making Current and Update. If figure_handle is the handle to an existing figure, then the following statement,

```
figure(figure_handle)
```

- Makes figure_handle the current figure
- Restacks figure_handle to be the front-most figure displayed
- Makes figure_handle visible if it was not
- Refreshes figure_handle and process all pending window events

The same behavior applies to axes. Therefore, the following statement,

```
axes(axes_handle)
```

- Makes axes_handle the current axes
- Restacks axes_handle to be the front-most axes displayed
- Makes axes_handle visible if it was not
- Refreshes the figure containing the axes and process all pending window events for that figure

Make Current Without Changing State. You can make a figure or axes current without causing MATLAB to change the object's state by setting the figure's root object CurrentFigure property or the figure object's CurrentAxes property to the handle of the figure or axes you want to accept graphics output.

If figure_handle is the handle to an existing figure, then the following statement,

```
set(0,'CurrentFigure',figure_handle)
```

makes `figure_handle` the current figure without changes its state. Similarly, if axes_handle is the handle of an axes object, then the following statement

```
set(h,'CurrentAxes',axes_handle)
```

makes it the current axes assuming `h` is the handle of the figure that contains it.

Preparing Figures and Axes for Graphics

By default, commands that generate graphics output display the graphics objects in the current figure without clearing or resetting figure properties. However, if the graphics objects are axes children, MATLAB clears the axes and resets most axes properties to their default values before displaying the objects.

You can change this behavior by setting the figure and axes `NextPlot` properties.

Using NextPlot to Control Output Target

MATLAB high-level graphics functions check the values of the `NextPlot` properties to determine whether to add, clear, or clear and reset the figure and axes before drawing. Low-level object creation functions do not check the `NextPlot` properties. They simply add the new graphics objects to the current figure and axes.

Low-level functions are designed primarily for use in M-files where you can implement whatever drawing behavior you want. However, when you develop a MATLAB-based application, controlling MATLAB drawing behavior is essential to creating a program that behaves predictably.

This table summarizes the possible values for the `NextPlot` property.

NextPlot	Figure	Axes
`new`	Create a new figure and use it as the current figure.	Not an option for axes.

NextPlot	Figure	Axes
`add`	Add new graphics objects without clearing or resetting the current figure. (Default setting)	Add new graphics objects without clearing or resetting the current axes.
`replacechildren`	Remove all child objects, but do not reset figure properties. Equivalent to `clf`.	Remove all child objects, but do not reset axes properties. Equivalent to `cla`.
`replace`	Remove all child objects and reset figure properties to their defaults. Equivalent to `clf reset`.	Remove all child objects and reset axes properties to their defaults. Equivalent to `cla reset`. (Default setting)

Note that a `reset` returns all properties, except `Position` and `Units`, to their default values.

The `hold` command provides convenient access to the `NextPlot` properties. The statement

```
hold on
```

sets both figure and axes `NextPlot` properties to `add`.

The statement

```
hold off
```

sets the axes `NextPlot` property to `replace`.

Targeting Graphics Output with newplot

MATLAB provides the `newplot` function to simplify the process of writing graphics M-files that conform to the settings of the `NextPlot` properties.

`newplot` checks the values of the `NextPlot` properties and takes the appropriate action based on these values. You should place `newplot` at the beginning of any M-file that calls object creation functions.

When your M-file calls `newplot`, the following possible actions occur:

1. `newplot` checks the current figure's `NextPlot` property:
   - If there are no figures in existence, `newplot` creates one and makes it the current figure.
   - If the value of `NextPlot` is `add`, `newplot` makes the figure the current figure.
   - If the value of `NextPlot` is `new`, `newplot` creates a new figure and makes it the current figure
   - If the value of `NextPlot` is `replacechildren`, `newplot` deletes the figure's children (axes objects and their descendants) and makes this figure the current figure.
   - If the value of `NextPlot` is `replace`, `newplot` deletes the figure's children, resets the figure's properties to the defaults, and makes this figure the current figure.
2. `newplot` checks the current axes' `NextPlot` property:
   - If there are no axes in existence, `newplot` creates one and makes it the current axes.
   - If the value of `NextPlot` is `add`, `newplot` makes the axes the current axes.
   - If the value of `NextPlot` is `replacechildren`, `newplot` deletes the axes' children and makes this axes the current axes.
   - If the value of `NextPlot` is `replace`, `newplot` deletes the axes' children, resets the axes' properties to the defaults, and makes this axes the current axes.

MATLAB Default Behavior

Consider the default situation where the figure `NextPlot` property is `add` and the axes `NextPlot` property is `replace`. When you call `newplot`, it

1. Checks the value of the current figure's `NextPlot` property (which is `add`) and determines MATLAB can draw into the current figure with no further action. If there is no current figure, `newplot` creates one, but does not recheck its `NextPlot` property.

2. Checks the value of the current axes' `NextPlot` property (which is `replace`), deletes all graphics objects from the axes, resets all axes properties (except `Position` and `Units`) to their defaults, and returns the handle of the current axes.

Example — Using newplot

To illustrate the use of `newplot`, this example creates a function that is similar to the built-in `plot` function, except it automatically cycles through different line styles instead of using different colors for multiline plots.

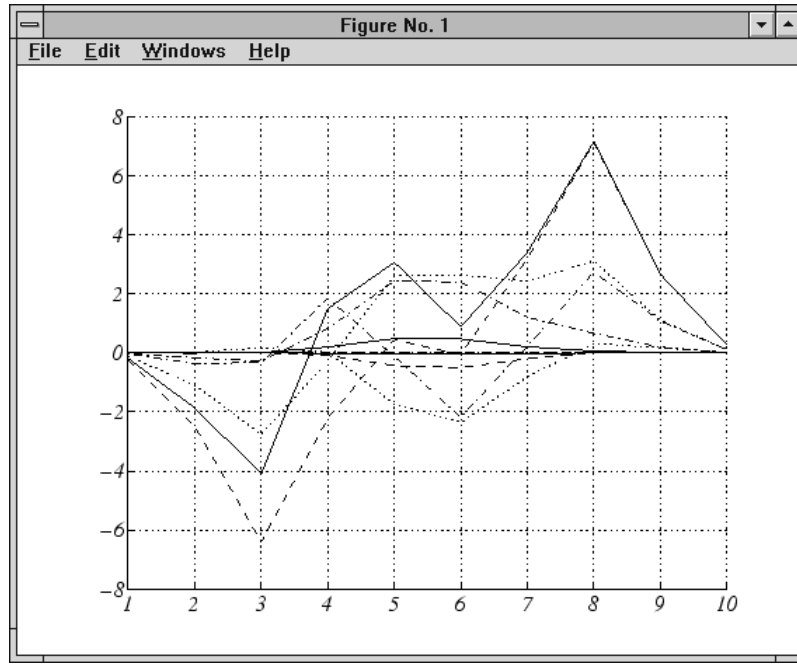
```
function my_plot(x,y)
cax = newplot;   % newplot returns handle of current axes
LSO = ['- ';'--';': ';'-.'];
set(cax,'FontName','Times','FontAngle','italic')
set(get(cax,'Parent'),'MenuBar','none') %
line_handles = line(x,y,'Color','b');
style = 1;
for i = 1:length(line_handles)
    if style > length(LSO), style = 1;end
    set(line_handles(i),'LineStyle',LSO(style,:))
    style = style + 1;
end
grid on
```

The function `my_plot` uses the high-level `line` function syntax to plot the data. This provides the same flexibility in input argument dimension that the built-in `plot` function supports. The `line` function does not check the value of the figure or axes `NextPlot` property. However, because `my_plot` calls `newplot`, it behaves the same way the high-level `plot` function does — with default values in place, `my_plot` clears and resets the axes each time you call it.

`my_plot` uses the handle returned by `newplot` to access the target figure and axes. This example sets axes font properties and disables the figure's menu bar. Note how the figure handle is obtained via the axes `Parent` property.

This picture shows typical output for the `my_plot` function.

```
my_plot(1:10,peaks(10))
```



Basic Plotting M-File Structure

This example illustrates the basic structure of graphics M-files:

- Call `newplot` early to conform to the `NextPlot` properties and to obtain the handle of the target axes.
- Reference the axes handle returned by `newplot` to set any axes properties or to obtain the figure's handle.
- Call object creation functions to draw graphics objects with the desired characteristics.

The MATLAB default settings for the NextPlot properties facilitate writing M-files that adhere to the standard behavior: reuse the figure window, but clear and reset the axes with each new graph. Other values for these properties allow you to implement different behaviors.

Replacing Only the Child Objects — replacechildren

The replacechildren value for NextPlot causes newplot to remove child objects from the figure or axes, but does not reset any property values (except the list of handles contained in the Children property).

This can be useful after setting properties you want to use for subsequent graphs without having to reset properties. For example, if you type on the command line

```
set(gca,'ColorOrder',[0 0 1],'LineStyleOrder','-|--|:|-.',...
        'NextPlot','replacechildren')
plot(x,y)
```

plot produces the same output as the M-file my_plot in the previous section, but only within the current axes. Calling plot still erases the existing graph (i.e., deletes the axes children), but it does not reset axes properties. The values specified for the ColorOrder and LineStyleOrder properties remain in effect.

Testing for Hold State

There are situations in which your M-file should change the visual appearance of the axes to accommodate new graphics objects. For example, if you want the M-file my_plot from the previous example to accept 3-D data, it makes sense to set the view to 3-D when the input data has *z*-coordinates.

However, to be consistent with the behavior of the MATLAB high-level routines, it is good practice to test whether hold is on before changing parent axes or figure properties. When hold is on, the axes and figure NextPlot properties are both set to add.

The M-file my_plot3 accepts 3-D data and also checks the hold state, using ishold, to determine whether it should change the view.

```
function my_plot3(x,y,z)
```

```
cax = newplot;
hold_state = ishold; % ishold tests the current hold state
LSO = ['- ';'--';': ';'-.'];
if nargin == 2
    hlines = line(x,y,'Color','k');
    if ~hold_state % Change view only if hold is off
        view(2)
    end
elseif nargin == 3
    hlines = line(x,y,z,'Color','k');
    if ~hold_state % Change view only if hold is off
        view(3)
    end
end
ls = 1;
for hindex = 1:length(hlines)
    if ls > length(LSO),ls = 1;end
    set(hlines(hindex),'LineStyle',LSO(ls,:))
    ls = ls + 1;
end
```

If `hold` is `on` when you call `my_plot3`, it does not change the view. If `hold` is `off`, `my_plot3` sets the view to 2-D or 3-D, depending on whether there are two or three input arguments.

Protecting Figures and Axes

There are situations in which it is important to prevent particular figures or axes from becoming the target for graphics output (i.e., preventing them from becoming the `gcf` or `gca`). An example is a figure containing the uicontrols that implement a user interface.

You can prevent MATLAB from drawing into a particular figure or axes by removing its handle from the list of handles that are visible to the `newplot` function, as well as any other functions that either return or implicitly reference handles (i.e., `gca`, `gcf`, `gco`, `cla`, `clf`, `close`, and `findobj`). Two properties control handle hiding: `HandleVisibility` and `ShowHiddenHandles`.

HandleVisibility Property

`HandleVisibility` is a property of all objects. It controls the scope of handle visibility within three different ranges. Property values can be

- `on` — The object's handle is available to any function executed on the MATLAB command line or from an M-file. This is the default setting.
- `callback` — The object's handle is hidden from all functions executing on the command line, even if it is on the top of the screen stacking order. However, during callback routine execution (MATLAB statements or functions that execute in response to user action), the handle is visible to all functions, such as `gca`, `gcf`, `gco`, `findobj`, and `newplot`. This setting enables callback routines to take advantage of the MATLAB handle access functions, while ensuring that users typing at the command line do not inadvertently disturb a protected object.
- `off` — The object's handle is hidden from all functions executing on the command line and in callback routines. This setting is useful when you want to protect objects from possibly damaging user commands.

For example, if a GUI accepts user input in the form of text strings, which are then evaluated (using the `eval` function) from within the callback routine, a string such as `'close all'` could destroy the GUI. To protect against this situation, you can temporarily set `HandleVisibility` to `off` on key objects.

```
user_input = get(editbox_handle,'String');
set(gui_handles,'HandleVisibility','off')
eval(user_input)
set(gui_handles,'HandleVisibility','commandline')
```

Values Returned by gca and gcf. When a protected figure is topmost on the screen, but has unprotected figures stacked beneath it, `gcf` returns the topmost unprotected figure in the stack. The same is true for `gca`. If no unprotected figures or axes exist, calling `gcf` or `gca` causes MATLAB to create one in order to return its handle.

Accessing Protected Objects

The root `ShowHiddenHandles` property enables and disables handle visibility control. By default, `ShowHiddenHandles` is `off`, which means MATLAB obeys the setting of the `HandleVisibility` property. When `ShowHiddenHandles` is

set to `on`, all handles are visible from the command line and within callback routines. This can be useful when you want access to all graphics objects that exist at a given time, including the handles of axes text labels, which are normally hidden.

The `close` function also allows access to nonvisible figures using the `hidden` option. For example,

```
close('hidden')
```

closes the topmost figure on the screen, even if it is protected. Combining `all` and `hidden` options,

```
close('all','hidden')
```

closes all figures.

Handle Validity Versus Handle Visibility

All handles remain valid regardless of whether they are visible or not. If you know an object's handle, you can set and get its properties. By default, figure handles are integers that are displayed at the top of the window.

You can provide further protection to figures by setting the `IntegerHandle` property to `off`. MATLAB then uses a floating-point number for figure handles.

The Figure Close Request Function

In this section...

Introduction

MATLAB executes a callback routine defined by the figure's `CloseRequestFcn` whenever you

- Issue a `close` command on a figure.
- Quit MATLAB while there are visible figures. (If a figure's `Visible` property is set to `off`, MATLAB does not execute its close request function when you quit MATLAB; the figure is just deleted).
- Close a figure from the windowing system using a close box or a close menu item.

The close request function enables you to prevent or delay the closing of a figure or the termination of a MATLAB session. This is useful to perform such actions as

- Displaying a dialog box requiring the user to confirm the action
- Saving data before closing
- Preventing unintentional command-line deletion of a graphical user interface built with MATLAB

The default callback routine for the `CloseRequestFcn` is an M-file called `closereq`. It contains the statements

```
if isempty(gcbf)
   if length(dbstack) == 1
      warning('MATLAB:closereq',...
      'Calling closereq from the command line is now obsolete, use close instead');
```

```
    end
    close force
else
    delete(gcbf);
end
```

This callback honors `HandleVisibility` and therefore does not delete the figure when you use the `close` command without specifying the figure handle. For example,

```
h = figure('HandleVisibility','off')
close     % figure does not close
close all % figure does not close
close(h)  % figure closes
```

Quitting MATLAB

When you quit MATLAB, the current figure's `CloseRequestFcn` is called, and if the figure is deleted, the next figure in the root's list of children (i.e., the root's `Children` property) becomes the current figure, and its `CloseRequestFcn` is in turn executed, and so on. You can use `gcbf` to specify the figure handle from within a user-written close request function.

If you change a figure's `CloseRequestFcn` so that it does not delete the figure, then issuing the close command on that figure does not cause it to be deleted. Furthermore, if you attempt to quit MATLAB, the quit is aborted because MATLAB does not delete the figure.

Errors in the Close Request Function

If the `CloseRequestFcn` generates an error when executed, MATLAB aborts the close operation. However, errors in the `CloseRequestFcn` do not abort attempts to quit MATLAB. If an error occurs in a figure's `CloseRequestFcn`, MATLAB closes the figure unconditionally following a `quit` or `exit` command.

Overriding the Close Request Function

The `delete` command always deletes the specified figure, regardless of the value of its `CloseRequestFcn`. For example, the statement

```
delete(get(0,'Children'))
```

deletes all figures whose handles are not hidden (i.e., the figures' `HandleVisibility` property is not set to `off`). If you want to delete all figures regardless of whether their handles are hidden, you can set the root `ShowHiddenHandles` property to `on`. The root `Children` property then contains the handles of all figures. For example, the statements

```
set(0,'ShowHiddenHandles','yes')
delete(get(0,'Children'))
```

unconditionally delete all figures.

Saving Handles in M-Files

In this section...

About Saving Handles

Graphics M-files frequently use handles to access property values and to direct graphics output to a particular target. MATLAB provides utility routines that return the handles to key objects (such as the current figure and axes). In M-files, however, these utilities might not be the best way to obtain handles because

- Querying MATLAB for the handle of an object or other information is less efficient than storing the handle in a variable and referencing that variable.
- The current figure, axes, or object might change during M-file execution because of user interaction.

Save Information First

It is good practice to save relevant information about the MATLAB state in the beginning of your M-file. For example, you can begin an M-file with

```
cax = newplot;
cfig = get(cax,'Parent');
hold_state = ishold;
```

rather than querying this information each time you need it. Remember that utility commands like `ishold` obtain the values they return whenever called. (The `ishold` command issues a number of `get` commands and string compares (`strcmp`) to determine the hold state.)

If you are temporarily going to alter the hold state within the M-file, you should save the current values of the `NextPlot` properties so you can reset them later.

```
ax_nextplot = lower(get(cax,'NextPlot'));
fig_nextplot = lower(get(cfig,'NextPlot'));
```

```
.
.
.
set(cax,'NextPlot',ax_nextplot)
set(cfig,'NextPlot',fig_nextplot)
```

Properties Changed by Built-In Functions

To achieve their intended effect, many built-in functions change axes properties, which can then affect the workings of your M-file. This table lists the MATLAB built-in graphics functions and the properties they change. Note that these properties change only if `hold` is `off`.

Function	Axes Property: Set To
`fill`	`Box: on` `CameraPosition`: 2-D view `CameraTarget`: 2-D view `CameraUpVector`: 2-D view `CameraViewAngle`: 2-D view

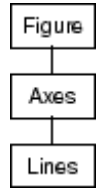
`fill3`	`CameraPosition`: 3-D view
	`CameraTarget`: 3-D view
	`CameraUpVector`: 3-D view
	`CameraViewAngle`: 3-D view
	`XScale`: `linear`
	`YScale`: `linear`
	`ZScale`: `linear`

Function	Axes Property: Set To
image (high-level)	Box: on Layer: top CameraPosition: 2-D view CameraTarget: 2-D view CameraUpVector: 2-D view CameraViewAngle: 2-D view XDir: normal XLim: [0 size(CData,2)]+0.5 XLimMode: manual YDir: reverse YLim: [0 size(CData,1)]+0.5YLimMode: manual
loglog	Box: on CameraPosition: 2-D view CameraTarget: 2-D view CameraUpVector: 2-D view CameraViewAngle: 2-D view XScale: log YScale: log
plot	Box: on CameraPosition: 2-D view CameraTarget: 2-D view CameraUpVector: 2-D view CameraViewAngle: 2-D view

Function	Axes Property: Set To
plot3	CameraPosition: 3-D view CameraTarget: 3-D view CameraUpVector: 3-D view CameraViewAngle: 3-D view XScale: linear YScale: linear ZScale: linear
semilogx	Box: on CameraPosition: 2-D view CameraTarget: 2-D view CameraUpVector: 2-D view CameraViewAngle: 2-D view XScale: log YScale: linear
semilogy	Box: on CameraPosition: 2-D view CameraTarget: 2-D view CameraUpVector: 2-D view CameraViewAngle: 2-D view XScale: linear YScale: log

Objects That Can Contain Other Objects

Certain graphics objects can contain other objects. Consider a graph for example. In a graph, data is represented by an object like a line. Normally, the parent of the line is an axes (i.e., the handle of the line's `Parent` property is set to the handle of the axes that contains it). A figure is normally the parent of an axes. A typical object diagram of a graph would look like this:



When graphs become more complicated and represent data with multiple objects, it can be useful to group these objects together so you can perform operations on the group as a whole.

The following sections discuss how to use two container objects that group axes children within a graph and user interface components within a figure.

Using Panel Containers in Figures — Uipanels

In this section...

Introduction

Figures can contain axes and user interface objects directly, or you can parent these objects to uipanels, which you then parent to a figure. Uipanels are useful for the design of GUIs because they enable you to define subregions in a figure in which you can lay out components.

MATLAB interprets the `Position` property of all objects parented to a uipanel relative to the uipanel's position. If you move the uipanel, the children automatically move with it.

Uipanels can also contain other uipanels, as well as axes, uicontrols, and uibuttongroups. See the `uipanel` reference page for more information on uipanels.

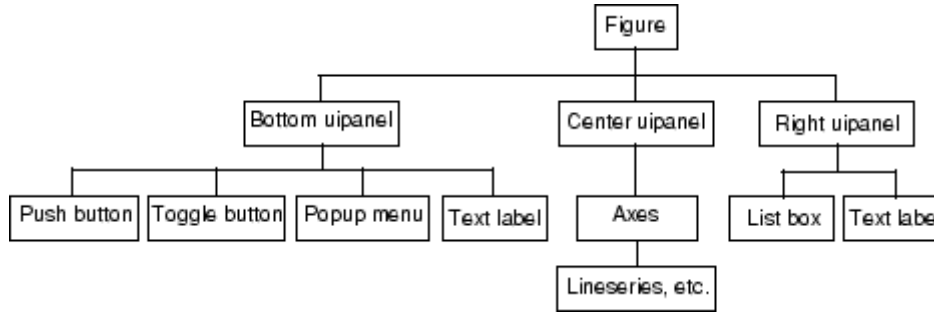
You can create multiple axes in a uipanel and direct plotting into any of them. However, some plotting functions do not allow you to specify the parent of the graphics objects they create, so they create a new axes (and possibly a figure). To include such a graph in a uipanel, you can reparent the axes to the panel once the plot is made.

Figure Resize Functions

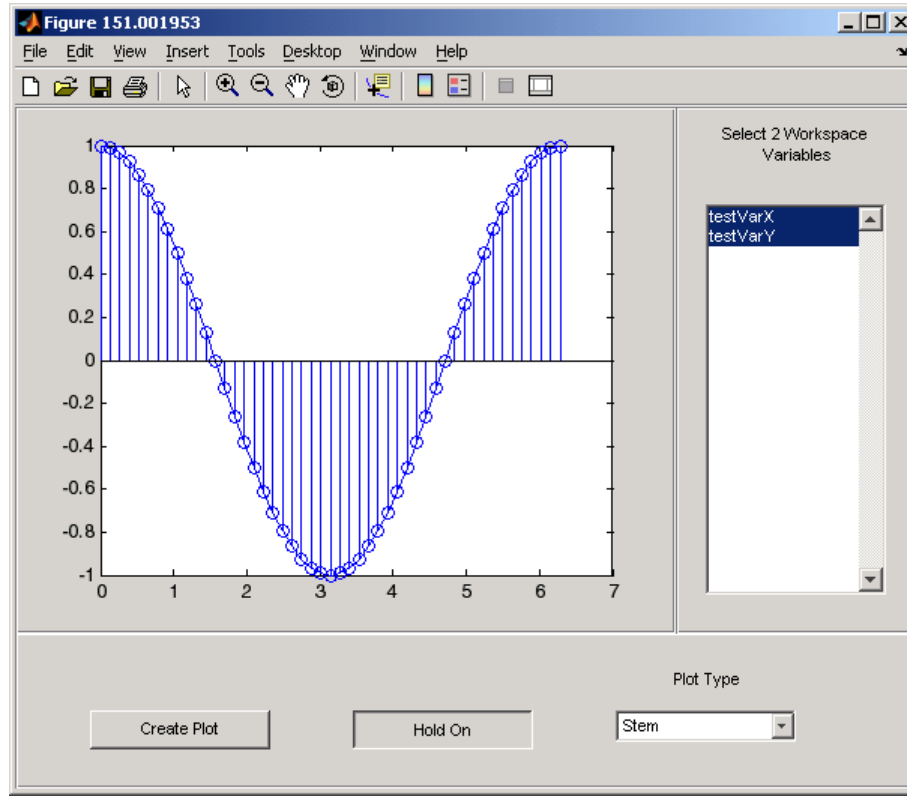
Containing various parts of a GUI in uipanels simplifies the process of programming figure resize behavior because you can write a separate resize function for each panel. The following example illustrates how to do this.

Example — Using Figure Panels

This example uses three uipanel objects as containers for the GUI's components. All three uipanels are then parented to the figure, as shown in the following containment hierarchy.



Here is a picture of the GUI with some data plotted in the axes.



Complete Example Code

Note If you are using the MATLAB Help browser, you can run this example or open it in the MATLAB editor.

This GUI enables you to select workspace variables from a list box and select a plot type from a pop-up menu. You can add plots to the existing graph by clicking the **Hold** toggle button and initiate the plot by clicking the **Create Plot** button.

Use the link above to run the example and open the GUI code in the MATLAB editor.

Creating the Uipanels

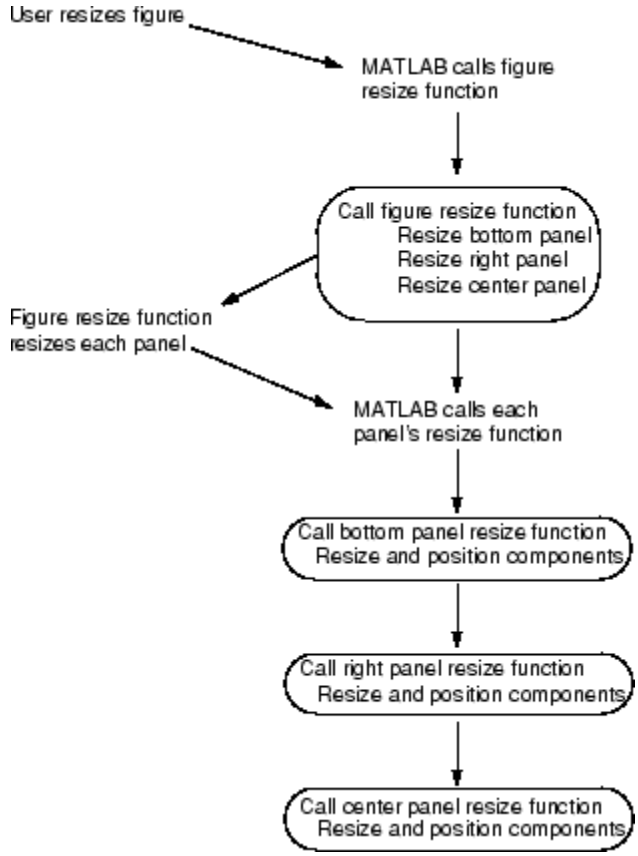
The following code shows the definition of the figure and the bottom panel. Setting `Units` to `characters` ensures that your GUI is properly sized on different computer systems. The `Position` property specifies the location and size of each component in units set by the `Units` property.

```
% Create the figure
f = figure('Units','characters',...
  'Position',[30 30 120 35],...
  'Color',panelColor,...
  'HandleVisibility','callback',...
  'IntegerHandle','off',...
  'Renderer','painters',...
  'ResizeFcn',@figResize);
% Create the bottom uipanel
botPanel = uipanel('BorderType','etchedin',...
  'BackgroundColor',panelColor,...
  'Units','characters',...
  'Position',[1/20 1/20 119.9 8],...
  'Parent',f,...
  'ResizeFcn',@botPanelResize);
```

Programming the Resize Functions

As you resize the figure, MATLAB calls the figure resize function (specified by the object's `ResizeFcn` property), which, in this example, computes a new size for each uipanel. Because the figure resize function resizes the uipanels, MATLAB automatically calls the resize function of each uipanel once the figure resize function completes execution. The uipanel resize functions then adjust the sizes and locations of the components they contain.

The following diagram illustrates the sequence of events that occurs when a user resizes the figure.



The following code shows the figure, bottom panel, and right panel resize functions. As each function is called, it sets the object's size and position to values that are proportional to the original layout.

See "Nested Functions" for more information.

```
% Figure resize function
function figResize(src,evt)
 fpos = get(f,'Position');
```

```
 set(botPanel,'Position',...
  [1/20 1/20 fpos(3)-.1 fpos(4)*8/35])
 set(rightPanel,'Position',...
   [fpos(3)*85/120 fpos(4)*8/35 fpos(3)*35/120 fpos(4)*27/35])
 set(centerPanel,'Position',...
  [1/20 fpos(4)*8/35 fpos(3)*85/120 fpos(4)*27/35]);
end
% Bottom panel resize function
function botPanelResize(src,evt)
 bpos = get(botPanel,'Position');
 set(plotButton,'Position',...
  [bpos(3)*10/120 bpos(4)*2/8 bpos(3)*24/120 2])
 set(holdToggle,'Position',...
  [bpos(3)*45/120 bpos(4)*2/8 bpos(3)*24/120 2])
 set(popUp,'Position',...
  [bpos(3)*80/120 bpos(4)*2/8 bpos(3)*24/120 2])
 set(popUpLabel,'Position',...
  [bpos(3)*80/120 bpos(4)*4/8 bpos(3)*24/120 2])
end
% Right panel resize function
function rightPanelResize(src,evt)
 rpos = get(rightPanel,'Position');
 set(listBox,'Position',...
  [rpos(3)*4/32 rpos(4)*2/27 rpos(3)*24/32 rpos(4)*20/27]);
 set(listBoxLabel,'Position',...
  [rpos(3)*4/32 rpos(4)*24/27 rpos(3)*24/32 rpos(4)*2/27]);
end
```

Note that the center panel does not need a resize function because the axes automatically resize to fit the container (either a figure or uipanel).

To see the complete code listing for this example, see “Complete Example Code” on page 8-91.

Grouping Objects Within Axes — hgtransform

In this section...

Introduction

MATLAB provides two objects that are designed to group any of the objects normally parented to axes. These two objects are

- Hggroup — Parent objects to an hggroup object when you want to reference the objects as a group. For example, to select or control visibility of all the group members.
- Hgtransform — This object also enables you to transform (rotate, translate, etc.) the objects as a group.

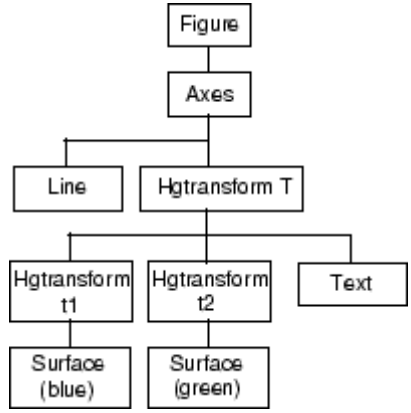
See "Group Objects" on page 8-28 for more information about hggroup and hgtransform objects.

Example — Translating Grouped Objects

This example shows how using a hierarchy of hgtransform objects makes it possible to translate the contained graphics objects both independently and as a group. The example creates a cross-like cursor with a text readout in the center, which displays data values.

The cursor is constructed from two surfaces, each of which is contained in an hgtransform object so they can be translated independently to overlap, and a text object. These two hgtransform objects are then contained by a third hgtransform object, which also contains the text. This third hgtransform (with handle `T` in the diagram and code) enables the cursor to be transformed as a group.

The following diagram shows the containment hierarchy for this example. The axes contains a line, which is used to plot the data that the cursor moves along. The axes also contains the hierarchy of hgtransform objects that construct the cursor.



Note If you are using the MATLAB Help browser, you can run this example or open it in the MATLAB editor.

Set Up the Axes and Figure

The first step is to create an axes with fixed limits so MATLAB does not rescale the limits as the cursor moves along the line. Creating the axes automatically creates a figure to contain it.

Set figure properties to use the OpenGL renderer:

```
h_axes = axes('XLim',[-10 10],'YLim',[-5 5]);
set(get(h_axes,'Parent'),'Renderer','opengl')
```

Define the Transform Matrices and Hgtransform Objects

The cross part of the cursor is formed from two surface objects, which are translated to overlap. Each surface is contained in its own hgtransform object (handles `t1` and `t2`) because they are translated in different directions. Both hgtransform objects are themselves contained in another hgtransform object (handle `T`).

See `makehgtform`, `hgtransform`.

```
% Create transform matrices
tmtx1 = makehgtform('translate',[-.5 0 0]);
tmtx2 = makehgtform('translate',[0 -.5 0]);

% Create hgtransform objects
T = hgtransform; % Contains the cursor
t1 = hgtransform('Parent',T,'Matrix',tmtx1);
t2 = hgtransform('Parent',T,'Matrix',tmtx2);
```

Create the Surface and Text Objects

The cursor is composed of two surface objects and a text object (to display data values). The two surfaces are parented to their respective hgtransform objects. The text is parented directly to the top-level hgtransform. The text object does not need coordinates because it is translated along with the surfaces in the top-level hgtransform object (`T`).

See `cylinder`, `surface`, `text`.

```
% Define surfaces and text
[sx,sy,sz] = cylinder([0 2 0]); % Use cylinder to generate data
surface(sz,sy,sx,'FaceColor','green',...
                 'EdgeColor','none','FaceAlpha',.2,'Parent',t1);
surface(sx,sz./1.5,sy,'FaceColor','blue',...
                 'EdgeColor','none','FaceAlpha',.2,'Parent',t2);
h_text = text('FontSize',12,'FontWeight','bold',...
                 'HorizontalAlignment','center',...
                 'VerticalAlignment','Cap','Parent',T);
```

Generate Data and Plot a Line

This example uses a line plot of a mathematical function to create a path along which to move the cursor.

```
% Plot the data x, y, and z
x = -10:.05:10;
y = [cos(x) + exp(-.01*x).*cos(x) + exp(.07*x).*sin(3*x)];
z = 1:length(x);
line(x,y)
```

Translate the Cursor Along the Plotted Line

To move the cursor along the line, a new transform matrix is calculated using each set of `x`, `y`, and `z` data points and used to set the `Matrix` property of the top-level hgtransfrom `T`. At the same time, the text object `String` property is updated to display the value of the current `y` data point.

The surfaces and the text translate together because all are contained in the top-level hgtransform object.

```
% Loop through the line data to move the cursor
for ind = 1:length(x)
    set(T,'Matrix',...
   makehgtform('translate',[x(ind) y(ind) z(ind)]))
    set(h_text,'String',num2str(y(ind)))
    drawnow,pause(.01)
end
```

Controlling Legends

In this section...

Legend Control Options

Graphics objects that are used to represent data, such as lines, surfaces, patches, etc. can be represented in figure legends (see legend for information on creating legends). By setting object properties, you can:

- Include a particular graphics object in the legend (the default)
- Exclude a particular graphics object from the legend
- Group graphics object together by parenting them to an hggroup or hgtransform object and represent the group as a single item in the legend ("Group Objects" on page 8-28)
- Display only the children of an object and not the parent in the legend. This is useful when the graph contains plot objects ("Plot Objects" on page 8-19)
- You can specify the text label used in the legend for any object

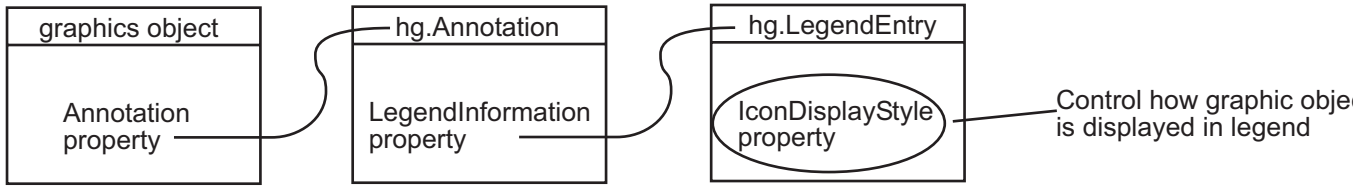
Properties for Controlling Legend Content

Graphics objects have two properties that control the options described above:

- `Annotation` — controls whether the graphics object appears in the legend and determines if the object or its children appear in the legend.

- `DisplayName` — specifies the text label used by the legend for the object. However, specifying a string with the legend commands resets the value of `DisplayName` property.

Accessing the Annotation Control Objects



Querying the `Annotation` property returns the handle of an `hg.Annotation` object. The `hg.Annotation` object has a property called `LegendInformation`, which contains an `hg.LegendEntry` object. The `hg.LegendEntry` object has a property called `IconDisplayStyle` that you can set to one of three values.

IconDisplayStyle Value	Behavior
`on`	Represent this object in a figure legend
`off`	Do not include this object in a figure legend
`children`	Display legend entries for this object's children and not the object itself (applies only to objects that have children, otherwise, the same a `on`)

For example, if `object_handle` is the handle of a graphics object, you can use the following statements to set the object's `IconDisplayStyle`. In this case, the graphics object, `object_handle`, is not included in the legend because its `IconDisplayStyle` property is set to `off`.

```
hAnnotation = get(object_handle,'Annotation');
hLegendEntry = get(hAnnotation','LegendInformation');
set(hLegendEntry,'IconDisplayStyle','off')
```

Updating a Legend

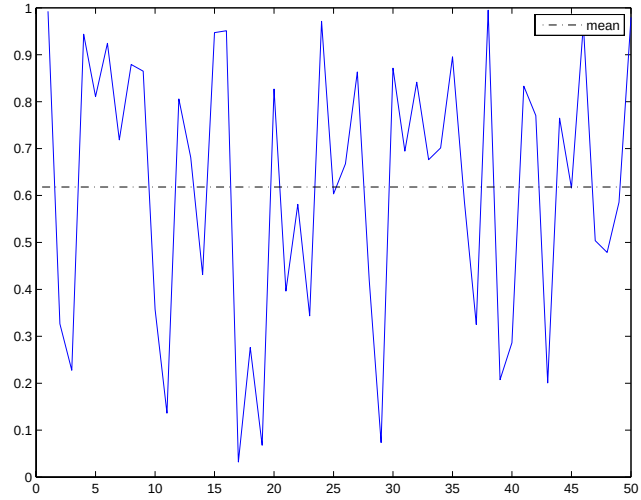
If a legend exist and you change its `IconDisplayStyle` setting, you must call `legend` to update the display. See the legend command for the options available.

Example — Excluding a Particular Object From a Legend

This example creates a graph (using random data in this case) and also draws a line that indicates the mean value of the data. The legend displays a key for the mean data line only because the blue data line object has its.`IconDisplayStyle` property of the associated `LegendEntry` object set to `off`.

```
function annotation_property_line
dat = rand(50,1);
hLine = plot(dat);
plotMean % Nested function draws a line at mean value
set(get(get(hLine,'Annotation'),'LegendInformation'),...
    'IconDisplayStyle','off'); % Exclude line from legend
legend('mean')
    function plotMean
    xlimits = get(gca,'XLim');
    meanValue = mean(dat);
    meanLine = line([xlimits(1) xlimits(2)],[meanValue meanValue],...
        'Color','k','LineStyle','-.');
    end
end
```

Here is the graph:



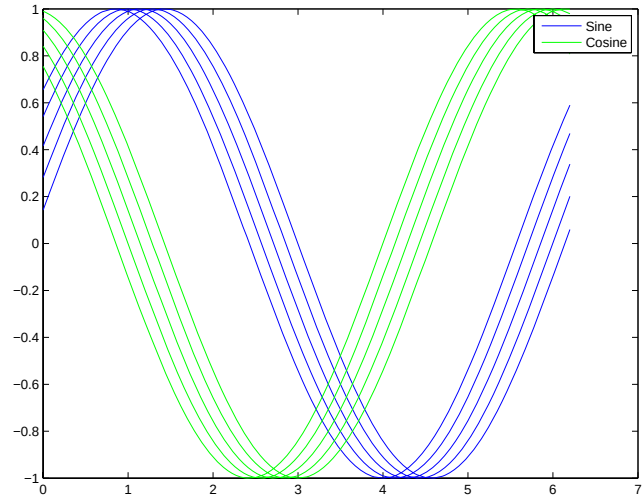
Example — One Legend Entry for a Group of Objects

You can group graphics objects in an hggroup or hgtransform object and represent the whole group as one item in a legend. This example creates two series of graphs (sines and cosines of the same data).

- The lines drawn to represent the sine are parented to one hggroup object
- The lines drawn to represent the cosine are parented to another hggroup object
- Both hggroup objects need their associated `IconDisplayStyle` property set to `on`
- The legend then displays entries for both hggroup objects, but not their children (the plotted lines)

```
t = 0:.1:2*pi;
for k=1:5
    offset = k/7;
    m(:,k) = t+offset';
end
```

```
hSLines = plot(t,sin(m),'Color','b');hold on
hCLines = plot(t,cos(m),'Color','g');
hSGroup = hggroup;
hCGroup = hggroup;
set(hSLines,'Parent',hSGroup)
set(hCLines,'Parent',hCGroup)
set(get(get(hSGroup,'Annotation'),'LegendInformation'),...
    'IconDisplayStyle','on'); % Include this hggroup in the legend
set(get(get(hCGroup,'Annotation'),'LegendInformation'),...
    'IconDisplayStyle','on'); % Include this hggroup in the legend
legend('Sine','Cosine')
```

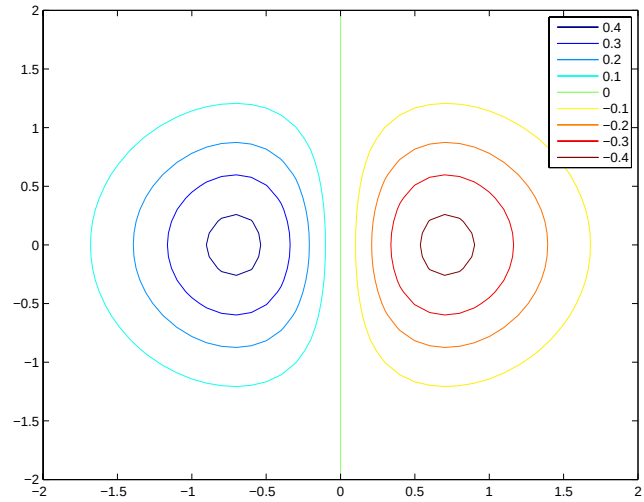


Example — Showing Children of Group Objects in Legend

You can include the children of a group in the legend by setting the group object's `IconDisplayStyle` to `children`. This is useful when graphs contain plot objects, which are groups of core graphics objects. For example, consider the following contour graph.

```
[X,Y] = meshgrid(-2:.1:2);
```

```
Z = X.*exp(-X.^2-Y.^2);
[mC hC] = contour(X,Y,Z);
set(get(get(hC,'Annotation'),'LegendInformation'),...
    'IconDisplayStyle','Children');
%{
Assigns each line object's DisplayName property a string
based on the value of the contour interval it represents
%}
k =1; ind = 1; hLines = get(hC,'Children');
while k < size(mC,2),
   set(hLines(ind),'DisplayName',num2str(mC(1,k)))
   k = k+mC(2,k)+1; ind = ind+1;
end
% Display the legend using DisplayName labels
legend('show')
```



Example — Grouping Objects to Reduce the Legend Entries

Some functions that visualize large data sets create many objects to render graphs. For example, `contourslice` uses patch objects to generate contour

slices of volume data. This example groups the 1829 patch objects into hggroup objects according to which plane the objects represent and sets corresponding values for the `DisplayName` property, resulting in a legend with only three items.

```
load mri
D = squeeze(D);
phandles = contourslice(D,[],[],[1,15,27],8);view(3)
gh(1) = hggroup; gh(2) = hggroup; gh(3) = hggroup;
%set(gh,'Parent',gca)
for k=1:length(phandles)
   zd = get(phandles(k),'ZData');
   plane = num2str(zd(1));
   switch plane
      case '1'
         set(phandles(k),'Parent',gh(1),'EdgeColor','r')
      case '15'
         set(phandles(k),'Parent',gh(2),'EdgeColor','g')
      case '27'
         set(phandles(k),'Parent',gh(3),'EdgeColor','b')
      otherwise
         disp('Don''t know what to do with it')
   end
end
hA = get(gh,'Annotation');
hLL = get([hA{:}],'LegendInformation');
set([hLL{:}],{'IconDisplayStyle'},...
   {'on','on','on'}')
set(gh,{'DisplayName'},{'Level=1','Level=15','Level=27'}')
legend show
```

Callback Properties for Graphics Objects

In this section...

What is a Callback?

A *callback* is a function that executes when a specific event occurs on a graphics object. You specify a callback by setting the appropriate property of the object. This section describes the events (specified via properties) for which you can define callbacks. See "Function Handle Callbacks" on page 8-109 for information on how to define callbacks.

Graphics Object Callbacks

All graphics objects have three properties for which you can define callback routines:

- `ButtonDownFcn` — Executes when users click the left mouse button while the cursor is over the object or within a 5-pixel border around the object
- `CreateFcn` — Executes during object creation after all properties are set
- `DeleteFcn` — Executes just before deleting the object

User Interface Object Callbacks

User interface objects (e.g., uicontrol and uimenu) have a `Callback` property through which you define the function to execute when users activate these devices (e.g., click a push button or select a menu).

Figure Callbacks

Figures have additional properties that execute callback routines with the appropriate user action. Only the `CloseRequestFcn` property has a callback defined by default:

- `CloseRequestFcn` — Executes when a request is made to close the figure (by a `close` command, by the window manager menu, or by quitting MATLAB)
- `KeyPressFcn` — Executes when users press a key while the cursor is within the figure window
- `ResizeFcn` — Executes when users resize the figure window
- `WindowButtonDownFcn` — Executes when users click a mouse button while the cursor is over the figure background, a disabled uicontrol, or the axes background
- `WindowButtonMotionFcn` — Executes when users move the mouse button within the figure window (but not over menus or title bar)
- `WindowButtonUpFcn` — Executes when users release the mouse button, after having pressed the mouse button within the figure

Function Handle Callbacks

In this section...

Introduction

Handle Graphics objects have a number of properties for which you can define callback functions. When a specific event occurs (e.g., a user clicks a push button or deletes a figure), the corresponding callback function executes. You can specify the value of a callback property as a

- String that is a MATLAB command or the name of an M-file
- Cell array of strings
- Function handle or a cell array containing a function handle and additional arguments

The following sections illustrate how to define function handle callbacks for Handle Graphics objects.

- "Introduction" on page 8-109 describes how to define a function handle callback.
- "Why Use Function Handle Callbacks" on page 8-111 provides information on the advantages of using function handle callbacks.
- "Example — Using Function Handles in GUIs" on page 8-113 shows how to create a simple GUI that uses function handle callbacks.

For general information on function handles, see the function handle reference page.

Function Handle Syntax

In Handle Graphics, functions that you want to use as function handle callbacks must define at least two input arguments in the function definition:

- The handle of the object generating the callback (the source of the event)
- The event data structure (can be empty for some callbacks)

MATLAB passes these two arguments implicitly whenever the callback executes. For example, consider the following statements, which are contained in a single M-file.

```
function myGui
% Create a figure and specify a callback
figure('WindowButtonDownFcn',@myCallback)
   .
   .
   .
% Callback subfunction defines two input arguments
function myCallback(src,eventdata)
   .
   .
   .
```

The first statement creates a figure and assigns a function handle to its `WindowButtondownFcn` property (created by using the @ symbol before the function name). This function handle points to the subfunction `myCallback`. The definition of `myCallback` must specify the two required input arguments in its function definition line.

Passing Additional Input Arguments

You can define the callback function to accept additional input arguments by adding them to the function definition. For example,

```
function myCallback(src,eventdata,arg1,arg2)
```

When using additional arguments for the callback function, you must set the value of the property to a cell array (i.e., enclose the function handle and arguments in curly braces). For example,

```
figure('WindowButtonDownFcn',{@myCallback,arg1,arg2})
```

Defining Callbacks as a Cell Array of Strings — Special Case

Defining a callback as a cell array of strings is a special case because MATLAB treats it differently from a simple string. Setting a callback property to a string causes MATLAB to evaluate that string in the base workspace when the callback is invoked. However, setting a callback to a cell array of strings requires the following:

- The cell array must contain the name of an M-file that is on the MATLAB path as the first string element.
- The M-file callback must define at least two arguments (the handle of the callback object and an empty matrix).
- Any additional strings in the cell array are passed to the M-file callback as arguments.

For example,

```
figure('WindowButtonDownFcn',{myCallback,arg1})
```

requires you to define a function M-file that uses three arguments,

```
function myCallback(src,eventdata,arg1)
```

Why Use Function Handle Callbacks

Using function handles to specify callbacks provides some advantages over the use of strings, which must be either MATLAB commands or the name of an M-file that will be on the MATLAB path at run-time.

Single File for All Code

Function handles enable you to use a single M-file for all callbacks. This is particularly useful when you are creating graphical user interfaces, because you can include both the layout commands and callbacks in one file.

For information on how to access subfunctions, see the “Calling a Function Using Its Handle” section of MATLAB Programming.

Keeping Variables in Scope

When MATLAB evaluates function handles, the same variables are in scope as when the function handle was created. (In contrast, callbacks specified as strings are evaluated in the base workspace.) This simplifies the process of managing global data, such as object handles in a GUI.

For example, suppose you create a GUI with a list box that displays workspace variables and a push button whose callback creates a plot using the variables selected in the list box. The push button callback needs the handle of the list box to query the names of the selected variables. Here's what to do.

1. Create the list box and save the handle:

```
h_listbox = uicontrol('Style','listbox',... etc.);
```

2. Pass the list box handle to the push button's callback, which is defined in the same M-file:

```
h_plot_button = uicontrol('Style','pushbutton',...
 'Callback',{@plot_button_callback,h_listbox},...,etc.);
```

The handle of the list box is now available in the plot button's callback without relying on global variables or using `findobj` to search for the handle. See "Example — Using Function Handles in GUIs" on page 8-113 for an example that uses this technique.

Callback Object Handle and Event Data

MATLAB passes additional information to the callback when it is executed. This information includes the handle of the callback object (the source of the callback event) and event data that is specific to the particular callback property.

For example, the event data returned for the figure `KeyPressFcn` property is a structure that contains information about which keys were pressed.

Information about the event data associated with any given callback property is included with the property's documentation. Use the Handle Graphics Property Browser to access property documentation.

Function Handles Stay in Scope

A function handle can point to a function that is not in scope at the time of execution. For example, the function can be a subfunction in another M-file.

For a general discussion of function handles, see the "Function Handles" and "Anonymous Functions" in the MATLAB documentation.

Example — Using Function Handles in GUIs

This example creates a simple GUI that plots workspace variables. It is defined in a single M-file that contains both the layout commands and the callbacks. This example uses function handles to specify callback functions. Callbacks are implemented as nested functions to reduce the need to pass variables as arguments.

Complete Example Code

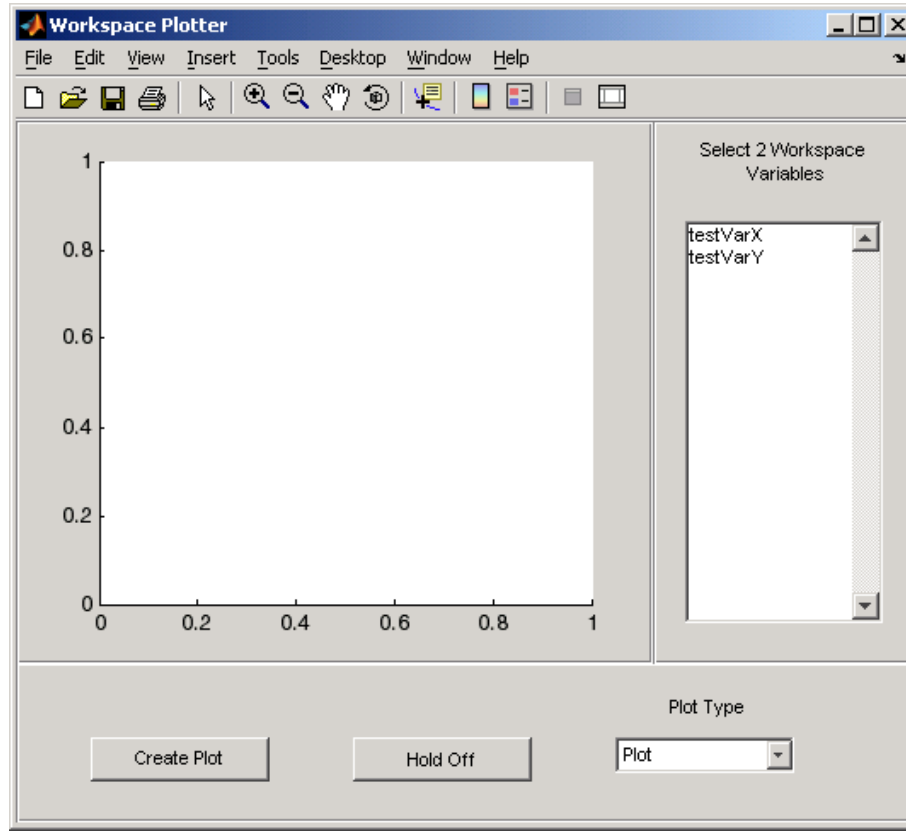
The documentation for this example does not list all the code used to lay out and program the GUI. To see a complete code listing, use the links in the note box below.

Note If you are using the MATLAB Help browser, you can run this example or open it in the MATLAB editor.

See "Function Handle Callbacks" on page 8-109 for more information on the use of function handle callbacks.

The GUI Layout

The following picture shows the GUI after running the example code. The program creates two variables (`testvarX` and `testVarY`) in the base workspace for testing purposes.



The GUI layout is split among three uipanel containers. One contains the axes, the right side panel contains a list box to display workspace variables, and the bottom panel contains the plot and hold buttons and the plot type pop-up menu.

Initialize the GUI

The list box and the hold toggle button need to be initialized before the GUI is ready to use. This is accomplished by executing their callbacks. Note that because you are calling these functions directly, MATLAB does not implicitly pass the first two arguments, as it would if these functions were executed as callbacks in response to an event. You therefore must explicitly pass all arguments in these function calls.

```
% Initialize list box and make sure
% the hold toggle is set correctly
listBoxCallback(listBox,[])
holdToggleCallback(holdToggle,[])
```

The Callback Functions

The GUI components that have callbacks are the list box, toggle button, and plot push button. In addition, the figure's three uipanels define resize functions that MATLAB executes whenever users resize the figure.

See "Programming the Resize Functions" on page 8-92 for information on writing callback functions for the figure and uipanel `ResizeFcn` properties.

List Box Callback. The list box callback generates a list of the current variables in the base workspace using the `evalin` and `who` functions. It then assigns this list to the list box `String` property so that it displays these variable names.

Note how the function takes advantage of the fact that the first argument passed to the callback is the handle of the callback object (i.e., the source of the callback event, which is the list box). Therefore, whenever you click in the list box, MATLAB updates the list to display the current workspace variables.

```
%% Callback for list box
function listBoxCallback(src,evt)
 % Load workspace vars into list box
 vars = evalin('base','who');
 set(src,'String',vars)
end % listBoxCallback
```

Plot Button Callback. The plot button callback performs three tasks:

- Gets the names of the variables selected by the user in the list box
- Gets the type of plot selected by the user in the pop-up menu
- Constructs and evaluates the plotting command in the base workspace

```
%% Callback for plot button
function plotButtonCallback(src,evt)
 % Get workspace variables
```

```
    vars = get(listBox,'String');
    var_index = get(listBox,'Value');
    if length(var_index) ~= 2
     errordlg('You must select two variables',...
     'Incorrect Selection','modal')
     return
    end
    % Get data from base workspace
    x = evalin('base',vars{var_index(1)});
    y = evalin('base',vars{var_index(2)});
    % Get plotting command
    selected_cmd = get(popUp,'Value');
    % Make the GUI axes current and create plot
    axes(a)
    switch selected_cmd
    case 1 % user selected plot
     plot(x,y)
    case 2 % user selected bar
     bar(x,y)
    case 3 % user selected stem
     stem(x,y)
    end
  end % plotButtonCallback
```

Hold State Toggle Button Callback. The toggle button callback requires the handles of the GUI figure and axes. Because these callbacks are written as nested functions, the figure handle (`f`) and the axes handle (`a`) are in scope within the callback.

You want the GUI to toggle the hold state, but the GUI figure handle is hidden. It is necessary, therefore, to use the axes handle as the first argument to the `hold` function.

```
%% Callback for hold state toggle button
function holdToggleCallback(src,evt)
 button_state = get(src,'Value');
 if button_state == get(src,'Max')
  % toggle button is depressed
  hold(a,'on')
  set(src,'String','Hold On')
```

```
 elseif button_state == get(src,'Min')
  % toggle button is not depressed
  hold(a,'off')
  set(src,'String','Hold Off')
 end
end % holdToggleCallback
```

Optimizing Graphics Performance

In this section...

Introduction

This section discusses techniques that can help increase the speed with which MATLAB creates graphs. These techniques generally apply to cases where you are creating many graphs of similar data and can therefore improve rendering speed by preventing MATLAB from performing unnecessary operation.

Whether a given technique improves performance depends on the particular application. The `profile` function can help you determine where your code is consuming the most time.

General Performance Guidelines

The following list provides some general guidelines for optimizing performance:

- Set automatic-mode properties to manual whenever possible to prevent MATLAB from performing unnecessary operations.
- Modify existing objects instead of creating new ones.
- Use low-level core objects when creating objects repeatedly.
- Do not recreate legends or other annotations in a program loop; add these after you finish modifying the graph.

- Set the text `Interpreter` property to `none` if you are not using T_eX characters.
- Try various renderers and erase modes. MATLAB might not have auto-selected the fastest renderer for your application.

The remainder of this section provides more details on these and other techniques.

- "Disable Automatic Modes" on page 8-119 — information on optimizing the use of axes objects.
- "Changing Graph Data Rapidly" on page 8-121 — an example of techniques for interactive plotting.
- "Performance of Bit-Mapped Images" on page 8-125 — information on optimizing the use of image objects.
- "Performance of Patch Objects" on page 8-126 — information on optimizing the use of patch objects.
- "Performance of Surface Objects" on page 8-127 — information on optimizing the use of surface objects.

Disable Automatic Modes

Graphics objects have properties that control many aspects of their behavior and appearance. The axes object in particular has many mode properties that enables it to respond to changes in the data represented in a graph.

For example, when you plot data, the axes determines appropriate axis limits, tick-mark placement, and labeling. Any changes you make to the plotted data (adding another line graph, for example) causes the axes to recompute the axis limits and to determine what values to use for the tick marks.

Fixing Axis Limits

The process of recalculating axis limits and the locations of the tick marks along each axis contributes to the time it takes to create a graph. If you are plotting data into the same axes repeatedly, you can improve performance by manually setting some or all of the axis limits, which, in turn, disables axis scaling and tick picking.

For example, suppose you are plotting time series graphs in which you always view a 200 second time interval along the x-axis and your data ranges from -1 to 1. The following statement creates an axes with these limits and, in the process, sets the limit-picking mode to manual. Thereafter, MATLAB does not change the limits or recalculate tick mark locations (as long as you do not call a high-level plotting function like `plot`):

```
axes('XLim',[0 200],'YLim',[-1 1])
```

Set All Modes to Manual

To maximize the efficiency with which MATLAB can update your graphs, you should disable all automatic operation so that MATLAB does not need to spend time determining if it is even necessary to recalculate a property value. The following steps illustrate this technique:

1. Create a figure and select the renderer you want to use. Line graphs should use `painters` to take advantage of its line thinning algorithm.

   ```
   figure('Renderer','painters')
   ```

   Setting a property automatically sets its associated mode property to manual.

2. Create an axes explicitly and set all properties (such as the axis limits) for which you can predetermine the appropriate value.

3. Set all other mode property values to `manual` (see table below).

4. If you are creating line graphs using the `painters` renderer, set the axes `DrawMode` property to `fast`.

5. If you cannot determine the appropriate value for all mode properties, create your first graph and then use the `set` command to set mode properties to `manual`. See “Changing Graph Data Rapidly” on page 8-121 for an example.

The following table lists the axes mode properties and provides an explanation of what the mode controls.

Mode Property	What It Controls
`ALimMode`	Transparency limits mode
`CameraPositionMode`	Positioning of the viewpoint
`CameraTargetMode`	Positioning of the camera target in the axes
`CameraUpVectorMode`	The direction of "up" in 2-D and 3-D views
`CameraViewAngleMode`	The size of the projected scene and stretch-to-fit behavior
`CLimMode`	Mapping of data values to colors
`DataAspectRatioMode`	Relative scaling of data units along x-, y-, and z-axes and stretch-to-fit behavior
`DrawMode`	Controls the way MATLAB renders graphics objects (use with line graphs)
`PlotBoxAspectRatioMode`	Relative scaling of plot box along x-, y-, and z-axes and stretch-to-fit behavior
`TickDirMode`	Direction of axis tick marks (in for 2-D, out for 3-D)

`XLimMode`
`YLimMode`
`ZLimMode`
	Limits of the respective x, y, and z axes

`XTickMode`
`YTickMode`
`ZTickMode`
	Tick mark spacing along the respective x-, y-, and z-axes

`XTickLabelMode`
`YTickLabelMode`
`ZTickLabelMode`
	Tick mark labels along the respective x-, y-, and z-axes

Changing Graph Data Rapidly

MATLAB plotting functions perform a wide variety of operations in the process of creating a graph to make plotting easier. For example, the `plot`

function clears the current axes before drawing new lines, selects a line color or a marker type, searches for user-defined default values, and so on.

Low-Level Functions for Speed

The features that make plotting functions easy to use also consume computer resources. If you want to maximize graphing performance, you should use low-level functions and disable certain automatic features.

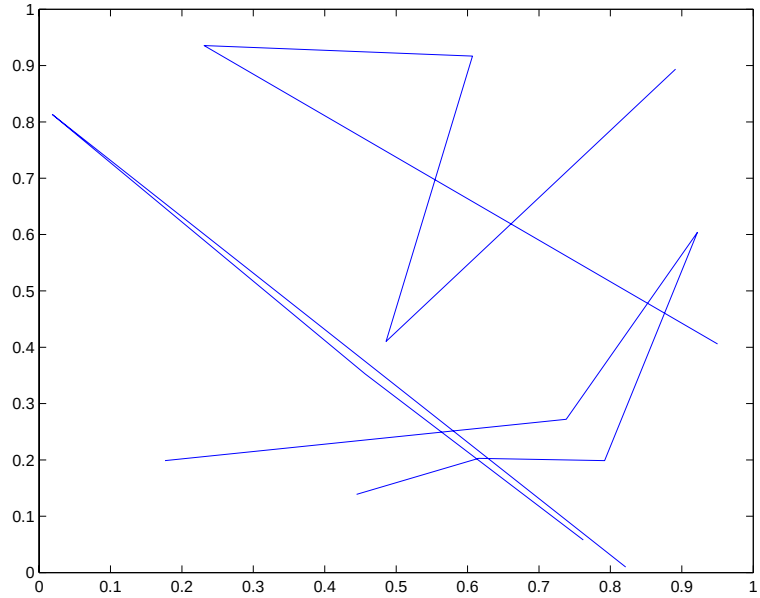
Low-level graphics functions (e.g., `line` vs. `plot`, surface vs. surf) perform fewer operation and therefore can be faster when you are creating many graphics objects. See "High-Level Versus Low-Level" on page 8-17 for more information on how these functions differ.

Avoid Creating Graphics Objects

Each graphics object requires a certain amount of the computer's resources to create and store information, such as the value of all the object's properties. It is therefore more efficient to use fewer graphics objects if possible.

For example, you can add NaNs to vertex data (which causes that vertex to not be rendered) to create line segments that look like separate lines. You must place the NaNs at identical locations in each vector of data:

```
x = [rand(5,1);nan;rand(4,1);nan;rand(6,1)];
y = [rand(5,1);nan;rand(4,1);nan;rand(6,1)];
line(x,y);
```



Update the Object's Data

If you want to view different data on what is basically the same graph, it is more efficient to update the data of the existing objects (lines, text, etc.) rather than recreating the entire graph.

For example, suppose you want to visualize the effect on your data of varying certain parameters. Follow these steps:

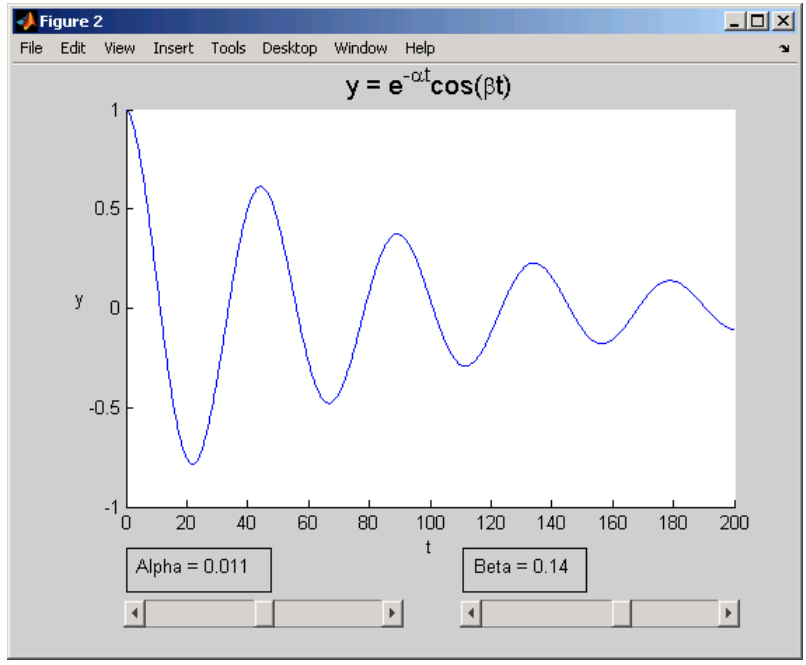
1. Set the limits of any axis that can be determined in advance (you can use `max` and `min` to determine the range of your data).

2. Recalculate the data using the new parameters.

3. Use the new data to update the data properties of the lines, text, etc. objects used in the graph.

4 Call `drawnow` to flush the event queue and update the figure (and all child objects in the figure).

The following example illustrates the use of these techniques in a GUI that uses sliders to vary two parameters in a mathematical expression, which is then plotted.



Note If you are using the MATLAB Help browser, you can run this example or open it in the MATLAB editor.

Specify Axes with Plotting Function for Better Performance

Most plotting functions accept an axes handle as an argument. This handle determines the target axes for the plot. Specifying the parent axes as an argument is often faster than using the `axes` function to make a particular

axes the current axes. For example, suppose you want six subplot in one figure and want to plot to each one in sequence:

```
x = 0:.05:2*pi;
for k=1:6
    h(k) = subplot(6,1,k);
end
for k=1:6
    y = sin(x*100*rand)*rand;
    plot(h(k),x,y) % Specify target axes in plotting function
    % Avoid using axes(h(k); plot(x,y) in a loop
end
```

Keeping Track of the Target Figure and Axes

You can also explicitly set the figure `CurrentAxes` property to avoid specifying the axes handle with a number of functions that can operate on the current axes by default. For example, in the code below, both `stem` and `axis` operate on the current axes if you do not specify an axes as an argument.

```
fHandle = figure;
for k=1:6
    h(k) = subplot(6,1,k);
end
x = 0:.1:2*pi;
for k=1:6
    y = sin(x*100*rand)*rand;
    % Explicitly set current axes as a figure property
    set(fHandle,'CurrentAxes',h(k)); stem(x,y); axis([0 6.28 -1 1])
end
```

Both techniques described in this section give better performance than calling the `axes` function to control the current axes.

Performance of Bit-Mapped Images

Images can be defined with lower precision (than `double`) values to reduce the total amount of data required. MATLAB performs many operations on nondouble data types you can use smaller image data without converting the data to type `double`. See “Working with 8-Bit and 16-Bit Images” on page 6-10 for more information.

Direct Color Mapping

Where possible, use indexed images because this type of image can apply direct mapping of pixel values to colormap values (`CDataMapping` set to `direct`). With direct mapping, MATLAB does not need to scale the data and then map it to values in the colormap.

See the `CDataMapping` image property for more information.

Use Truecolor for Smaller Images

The use of truecolor (red, green, and blue values) eliminates the need for color mapping. However, with very large images, the data can be quite large and thereby slow performance.

Direct Mapping of Transparency Values

If you are using an alphamap of transparency values, prescale the alpha data so you can use the most efficient alpha data mapping (`AlphaDataMapping` set to `none`)

See the `AlphaDataMapping` image property for more information.

Performance of Patch Objects

You can improve the speed with which MATLAB renders patch objects using the following techniques.

Define Patch Faces as Triangles

If you are using patch objects that have many vertices per patch face, you should modify your data so that each face has only three vertices, but still looks like your original object. This eliminates the tessellation step from the rendering process.

Use Data Thinning

It is sometimes possible (or even desirable) to reduce the number of vertices in a patch and still produce the desired results.

See the `reducepatch` and `reducevolume` functions for more information.

Direct Color Mapping

Where possible, use direct color mapping for coloring patches. (`CDataMapping` set to `direct`). With direct mapping, MATLAB does not need to scale the data and then map it to values in the colormap.

See the `CDataMapping` patch property for more information.

Use Truecolor for Smaller Patches

The use of truecolor (red, green, and blue values) eliminates the need for color mapping. However, with very large patches, the data can be quite large and thereby slow performance.

Direct Mapping of Transparency Values

If you are using an alphamap of transparency values, prescale the alpha data so you can use the most efficient alpha data mapping (`AlphaDataMapping` set to `none`)

See the `AlphaDataMapping` patch property for more information.

Performance of Surface Objects

You can improve the speed with which MATLAB renders surface objects using the following techniques.

Direct Color Mapping

Where possible, use direct color mapping for coloring surfaces. (`CDataMapping` set to `direct`). With direct mapping, MATLAB does not need to scale the data and then map it to values in the colormap.

See the `CDataMapping` surface property for more information.

Use Truecolor for Smaller Surfaces

The use of truecolor (red, green, and blue values) eliminates the need for color mapping. However, with very large surfaces, the data can be quite large and thereby slow performance.

Mapping of Transparency Values

If you are using an alphamap of transparency values, prescale the alpha data so you can use the most efficient alpha data mapping (`AlphaDataMapping` set to `none`)

See the `AlphaDataMapping` surface property for more information.

Use Texture-Mapped Face Color

If you are using surface objects in an animation or want to be able to pan and rotate them quickly, you can achieve better rendering performance with large surfaces by setting `EdgeColor` to `none` and `FaceColor` to `texture`.

This technique is particularly useful if you want a high resolution surface without creating an objects whose data is large and therefore, very slow to transform. For example,

```
h1 = surf(peaks(1000));
shading interp
cd1 = get(h1,'CData');
surf(peaks(24),'FaceColor','Texture','EdgeColor','none',...
 'CData',cd1)
```

9

Figure Properties

Figure Objects

Figure graphics objects are the windows in which MATLAB displays graphics. Figure properties enable you to control many aspects of these windows, such as their size and position on the screen, the coloring of graphics objects displayed within them, and the scaling of printed pictures.

This section discusses some of the features that are implemented through figure properties and provides examples of how to use these features.

See Figure Properties for a description of each property

Docking Figures in the Desktop

In this section...

Introduction

You can dock figures in the MATLAB desktop by clicking the **dock** button, , which appears on the right end of the menu bar. Once docked, figures are placed in a figure group container, which you can also dock and undock.

You can select from a variety of arrangements of the figures in the container. The following picture shows how to select various figure arrangements. Once docked, the figure container displays the toolbar and menubar of the figure with focus.

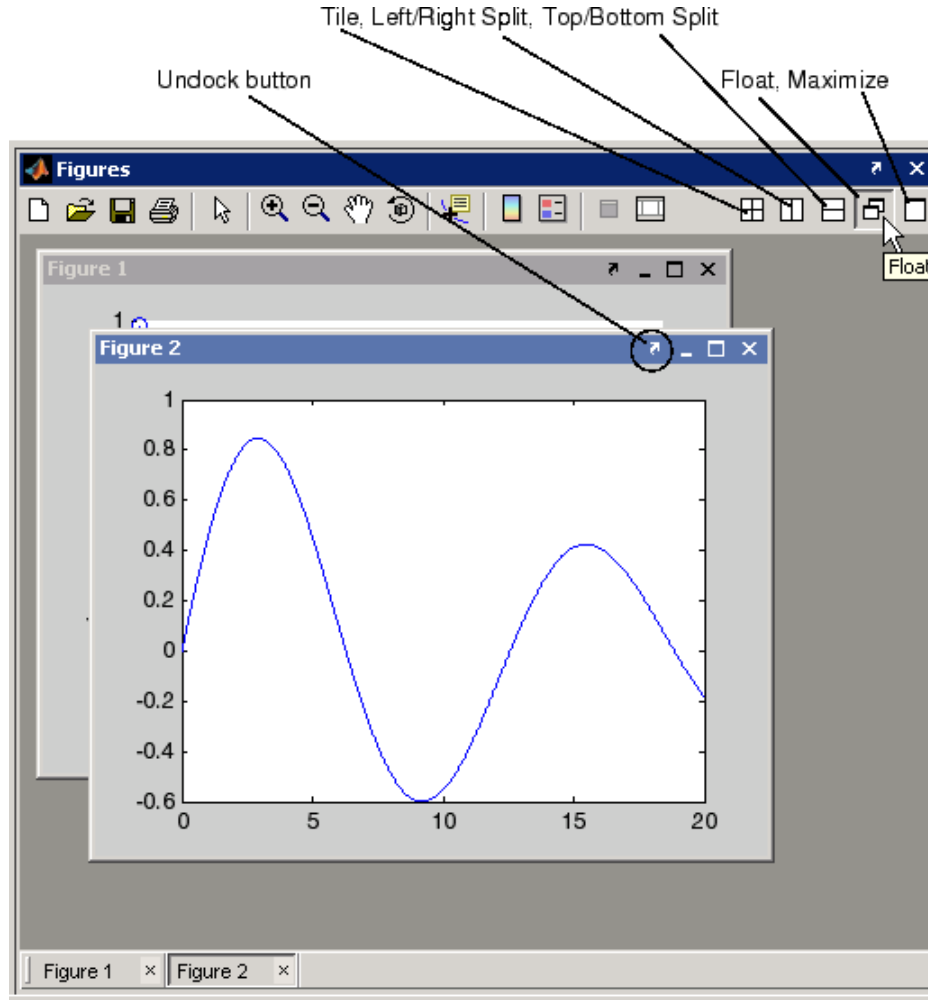

Figure Properties That Affect Docking

There are two figure properties that are related to figure docking — `DockControls` and `WindowStyle`.

DockControls

The `DockControls` property controls the display of the controls used to dock figures. Setting `DockControls` to `off` removes the **dock** button from the menubar and disables docking from the figure **Desktop** menu.

WindowStyle

When you set the `WindowStyle property` to `docked`, MATLAB docks the figure in the desktop within a figure group container.

If `WindowStyle` is set to `docked`,

- MATLAB automatically sets `DockControls` to `on`.
- You cannot set the `DockControls` property to `off`.
- You cannot set the figure `Position` property.

Docking Figures Automatically

If you want MATLAB to always dock figures, set the default value of the `WindowStyle` property to `docked`. The following statement,

```
set(0,'DefaultFigureWindowStyle','docked')
```

creates a default value for the `WindowStyle` property on the root level. Issuing this statement on the command line sets the `WindowStyle` of all figures for the duration of your MATLAB session (unless you change the value).

Place this statement in your `startup.m` file to make MATLAB always dock figures. See `startup` for more information on `startup.m`.

Creating a Nondockable Figure

In cases where you do not want users to be able to dock figures (e.g., figures used for GUIs), you should set figure properties as follows:

- `DockControls` to `off`
- `WindowStyle` to `normal` or `modal`
- `HandleVisibility` to `off` or `callback`

Positioning Figures

In this section...

Introduction

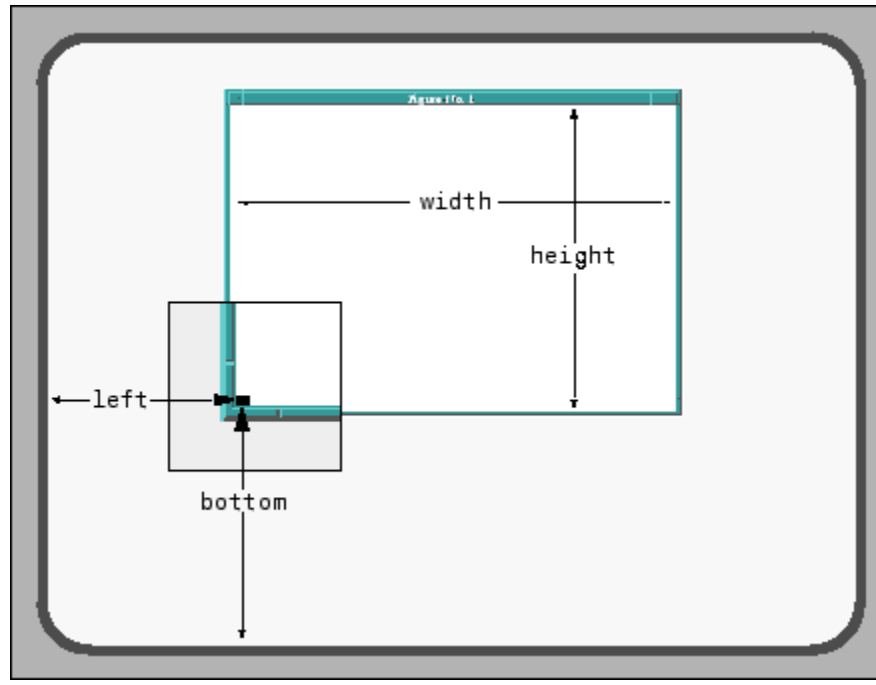
The figure `Position` property controls the size and location of the figure window on the root screen. At startup, MATLAB determines the size of your computer screen and defines a default value for `Position`. This default creates figures about one-quarter of the screen's size and places them centered left to right and in the top half of the screen.

The Position Vector

MATLAB defines the figure `Position` property as a vector.

```
[left bottom width height]
```

`left` and `bottom` define the position of the first addressable pixel in the lower left corner of the window, specified with respect to the lower left corner of the screen. `width` and `height` define the size of the interior of the window (i.e., exclusive of the window border).



MATLAB does not measure the window border when placing the figure; the `Position` property defines only the internal active area of the figure window.

Because figures are windows under the control of your computer's windowing system, you can move and resize figures as you would any other windows. MATLAB automatically updates the `Position` property to the new values.

Figure Position for Docked Figures

When a figure is docked in the MATLAB desktop, the `Position` property is defined with respect to the figure group container within the desktop. See "Docking Figures in the Desktop" on page 9-3 for more information.

Units

The figure's `Units` property determines the units of the values used to specify the position on the screen. Possible values for the `Units` property are

```
set(gcf,'Units')
[ inches | centimeters | normalized | points | {pixels} |
characters]
```

with `pixels` being the default. These choices allow you to specify the figure size and location in absolute units (such as inches) if you want the window always to be a certain size, or in units relative to the screen size (such as pixels).

Characters are units that enable you to define the location and size of the figure in units that are based on the size of the default system font. See "Example — Using Figure Panels" on page 8-90 for an example that uses character units.

Determining Screen Size

Whatever units you use, it is important to know the extent of the screen in those units. You can obtain this information from the root `CDataMapping` property. For example,

```
get(0,'ScreenSize')
ans =
    1 1 1152 900
```

In this case, the screen is 1152 by 900 pixels. MATLAB returns the `ScreenSize` in the units determined by the root `Units` property. For example,

```
set(0,'Units','normalized')
```

normalizes the values returned by `ScreenSize`.

```
get(0,'ScreenSize')
ans =
    0 0 1 1
```

Defining the figure `Position` in terms of the `ScreenSize` in normalized units makes the specification independent of variations in screen size. This is useful if you are writing an M-file that is to be used on different computer systems.

Example — Specifying Figure Position

Suppose you want to define two figure windows that occupy the upper third of the computer screen (e.g., one for uicontrols and the other to display data). To position the windows precisely, you must consider the window borders when calculating the size and offsets to specify for the `Position` properties.

1 The figure `Position` property does not include the window borders, so this example uses a width of 5 pixels on the sides and bottom and 30 pixels on the top.

```
bdwidth = 5;
topbdwidth = 30;
```

2 Ensure root units are pixels and get the size of the screen:

```
set(0,'Units','pixels')
scnsize = get(0,'ScreenSize');
```

3 Define the size and location of the figures:

```
pos1  = [bdwidth,...
 2/3*scnsize(4) + bdwidth,...
 scnsize(3)/2 - 2*bdwidth,...
 scnsize(4)/3 - (topbdwidth + bdwidth)];
pos2 = [pos1(1) + scnsize(3)/2,...
 pos1(2),...
 pos1(3),...
 pos1(4)];
```

4 Create the figures:

```
figure('Position',pos1)
figure('Position',pos2)
```

The two figures now occupy the top third of the screen.

Figure Colormaps — The Colormap Property

In this section...

Introduction

MATLAB defines a colormap as a three-column array. Each row of the array defines a particular color by giving three values in the range [0...1]. These values specify the RGB values; the intensity of the red, green, and blue video components.

Colormaps enable you to control how MATLAB maps data values to colors in surfaces, patches, images, and plotting functions that are based on these objects. See the following sections for more information.

- "Coloring Mesh and Surface Plots" in 3-D Visualization
- "Specifying Patch Coloring" in 3-D Visualization
- "The Image Object and Its Properties" on page 6-27

Specifying the Figure Colormap

The figure `Colormap` property contains the colormap array. You can specify the figure colormap by setting this property to an *m*-by-3 array, where *m* is the number of colors in the colormap.

For example, the following statement creates a figure with a colormap having 128 random colors.

```
figure('Colormap',rand(128,3));
```

The `colormap` function is an easy way to specify the colormap. MATLAB also provides a number of functions that generate colormaps. For example,

```
colormap(hsv(96))
```

sets the colormap of the current figure to a 96 element version of the `hsv` colormap. See the `colormap` reference page for a list of predefined colormaps. Note that the default colormap is `jet(64)`.

Selecting Drawing Methods

In this section...

Double Buffering

Overview

Set `DoubleBuffer` to `on` when you are animating lines rendered in `painters` with `EraseMode` set to `normal`.

More Details

Double buffering is the process of drawing into an offscreen pixel buffer and then blitting the buffer contents to the screen once the drawing is complete (instead of drawing directly to the screen, where the process of drawing is visible as it progresses). Double buffering generally produces flash-free rendering for simple animations (such as those involving lines, as opposed to objects containing large numbers of polygons).

The figure `DoubleBuffer` property accepts the values `on` and `off`, with `on` being the default. You can select double buffering only when the figure `Renderer` property is set to `painters`. `zbuffer` and `opengl` always use double buffering and ignore this property.

Use double buffering with the animated object's `EraseMode` property set to `normal`.

Selecting a Renderer

Overview

MATLAB automatically selects the best renderer based on the complexity of the graphics objects and the options available on your system.

More Details

A renderer is the software that processes graphics data (such as vertex coordinates) into a form that MATLAB can use to draw into the figure. MATLAB supports three renderers:

- Painters
- Z-buffer
- OpenGL

Painters

Painters method is faster when the figure contains only simple or small graphics. It cannot be used with lighting.

Z-Buffer

Z-buffering is the process of determining how to render each pixel by drawing only the front-most object, as opposed to drawing all objects back to front, redrawing objects that obscure those behind. The pixel data is buffered and then blitted to the screen all at once.

Z-buffering is generally faster for more complex graphics, but can be slower for very simple graphics. You can set the `Renderer` property to whatever produces the fastest drawing (either `zbuffer` or `painters`), or let MATLAB decide which method to use by setting the `RendererMode` property to `auto` (the default).

Printing from Z-Buffer. You can select the resolution of the PostScript file produced by the `print` command using the `-r` option. By default, MATLAB prints Z-buffered figures at a medium resolution of 150 dpi (the default with `Renderer` set to `painters` is 864 dpi).

The size of the file generated from a Z-buffer figure does not depend on its contents, just the size of the figure. To decrease the file size, make the `PaperPosition` property smaller before printing (or set `PaperPositionMode` to `auto` and resize the figure window).

OpenGL

OpenGL is available on many computer systems. It is generally faster than either painters or Z-buffer and in some cases enables MATLAB to use the system's graphics hardware (which results in significant speed increase). See the figure `Renderer` property for more information.

Limitations of OpenGL. OpenGL has two limitations when compared to painters and Z-buffer:

- OpenGL does not interpolate colors within the figure colormap; all color interpolation is performed through the RGB color cube, which can produce unexpected results.
- OpenGL does not support Phong lighting.

Specifying the Figure Pointer

In this section...

Predefined Figure Pointer Symbols

MATLAB indicates the position of the pointer (cursor) within the figure window using a graphical symbol. You can select a pointer from 15 predefined symbols (see table below) or you can define your own symbol. By convention, each of the predefined symbols has a purpose associated with it (although MATLAB enforces no rules for the use of any symbols).

You specify the pointer symbol by setting the value of the figure `Pointer` property. For example, this statement sets the pointer in the current figure (`gcf`) to an arrow.

```
set(gcf,'Pointer','arrow')
```

The following table shows the predefined symbols, the associated specifier, and describes typical use.

Purpose	Specifier	Typical Symbol
Use for editing text	`ibeam`	
Locate a point on a graphics object	`crosshair`	
Select a point anywhere in the figure	`arrow`	
Indicate the system is busy	`watch`	
Resize an object from the top-left corner	`topl`	
Resize an object from the top-right corner	`topr`	

Purpose	Specifier	Typical Symbol
Resize an object from the bottom-left corner	`botl`	
Resize an object from the bottom-right corner	`botr`	
View the actual hot spot	`circle`	
Locate a point	`cross`	
Use as popular symbol	`fleur`	
Resize an object from the left side	`left`	
Resize an object from the right side	`right`	
Resize an object from the top	`top`	
Resize an object from the bottom	`bottom`	
Align a point with other objects on the display	`fullcross`	
See the next section for information on defining your own pointer shape	`custom`	

Defining Custom Pointers

When you set the `Pointer` property to `custom`, MATLAB displays the pointer you define using the `PointerShapeCData` and the `PointerShapeHotSpot` properties. Custom pointers are 16-by-16 pixels, where each pixel can be either black, white, or transparent.

Specify the pointer by creating a 16-by-16 matrix containing elements that are

- 1's where you want the pixel black
- 2's where you want the pixel white
- `NaN`s where you want the pixel transparent

Assign the matrix to the figure `PointerShapeCData` property. MATLAB displays the defined pointer whenever the pointer is in the figure window.

The `PointerShapeHotSpot` property specifies the pixel that indicates the pointer location. MATLAB then stores this location in the root `PointerLocation` property. Set the `PointerShapeHotSpot` property to a two-element vector specifying the row and column indices in the `PointerShapeCData` matrix that correspond to the pixel specifying the location. The default value for this property is [1 1], which corresponds to the upper left corner of the pointer.

Example — Two Custom Pointers

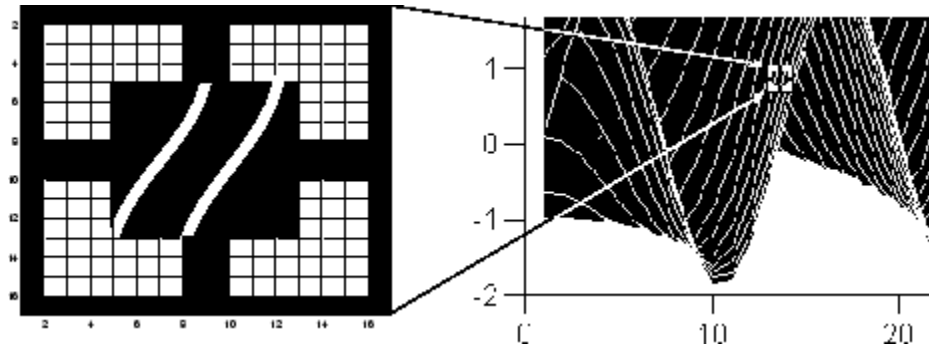
One way to create a custom pointer is to assign values to a 16-by-16 matrix by hand, as illustrated in the following example.

First, initialize the matrix, setting all values to 2. Create a black border 1 pixel wide. Add alignment marks.

```
P = ones(16)+1;
P(1,:) = 1; P(16,:) = 1;
P(:,1) = 1; P(:,16) = 1;
P(1:4,8:9) = 1; P(13:16,8:9) = 1;
P(8:9,1:4) = 1; P(8:9,13:16) = 1;
P(5:12,5:12) = NaN;     % Create a transparent region in the center
set(gcf,'Pointer','custom','PointerShapeCData',P,...
        'PointerShapeHotSpot',[9 9])
```

The last statement sets the `Pointer` property to `custom`, assigns the matrix to the `PointerShapeCData` property, and selects element (9,9) as the “hot spot.”

MATLAB now uses the custom pointer within the figure window.

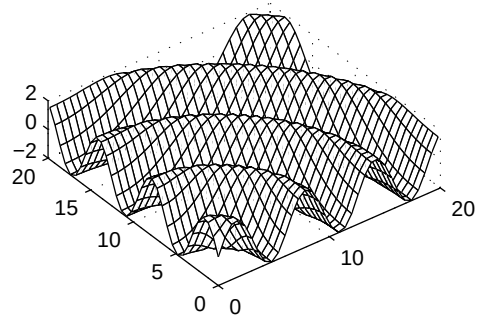


Creating Pointers from Functions. You can use a mathematical function to define the `PointerShapeCData` matrix. For example, evaluating the function

$$2(\sin(\sqrt{x^2 + y^2}))$$

```
g = 0:.2:20;
[X,Y] = meshgrid(g);
Z = 2*sin(sqrt(X.^2 + Y.^2));
mesh(Z);
```

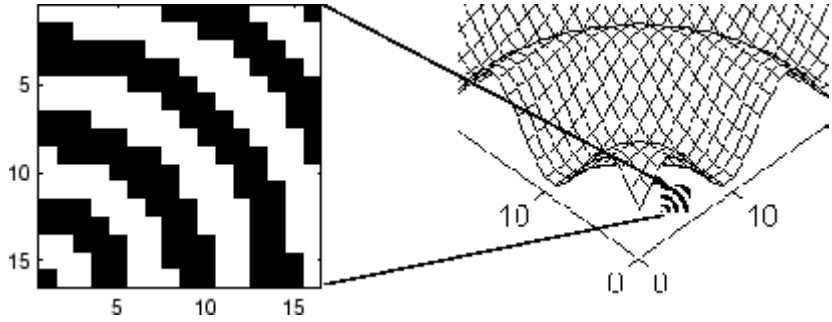
produces an interesting surface.



Use the values of `Z` to create a pointer sampling fewer points so that `Z` is a 16-by-16 matrix.

```
g = linspace(0,20,16);
[X,Y] = meshgrid(g);
Z = 2*sin(sqrt(X.^2 + Y.^2));
set(gcf,'Pointer','custom',...
        'PointerShapeCData',flipud((Z>0) + 1))
```

The statement `flipud((Z>0) + 1)` sets all values in `Z` that are greater than 0 to 2 (in MATLAB, true + 1 = 2), less than 0 to 1 (false + 1 = 1) and then flips the data around so that element (1,1) is the upper left corner.



Axes Properties

Axes Objects — Defining Coordinate Systems for Graphs

MATLAB uses graphics objects to create visual representations of data. For example, a two-dimensional array of numbers can be represented as lines connecting the data points defined by each column, as a surface constructed from a grid of rectangles whose vertices are defined by each element of the array, as a contour graph where equal values in the array are connected by lines, and so on.

In all these cases, there must be a frame of reference that defines where to place each data point on the graph. This frame of reference is the coordinate system defined by the axes. Axes orient and scale graphs to produce the view of the data that you see on screen.

MATLAB creates axes to define the coordinate system of each graph. Axes are always contained within a figure object and themselves contain the graphics objects that make up the graph.

Axes properties control many aspects of how MATLAB displays graphical information. This section discusses some of the features that are implemented through axes properties and provides examples of how to uses these features.

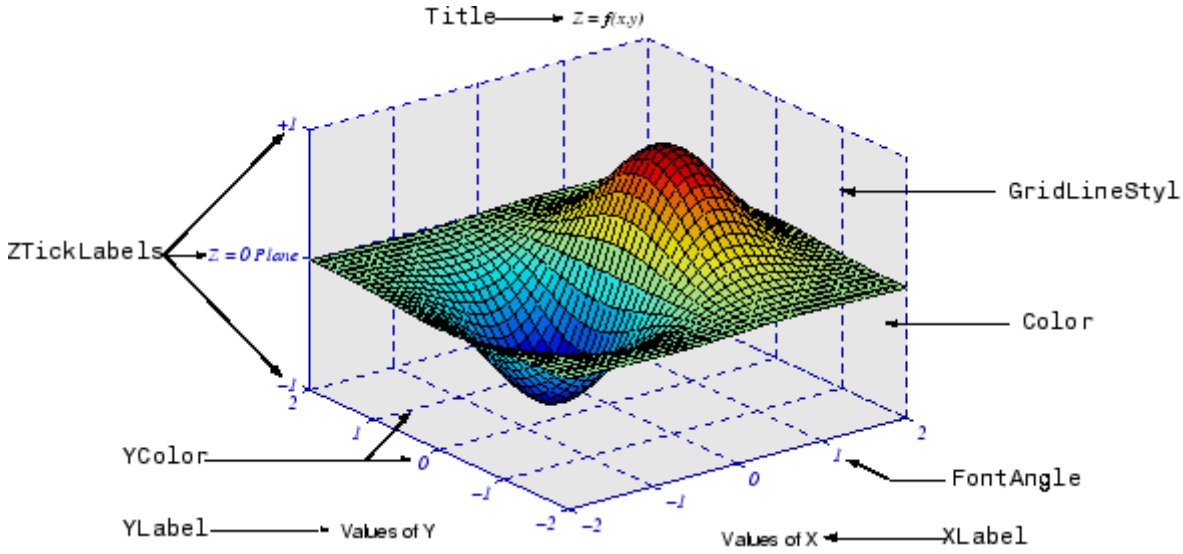
The Axes Properties list all axes properties and provide an overview of the characteristics that are affected by each property.

Labeling and Appearance Properties

In this section...

Introduction

MATLAB provides a number of properties for labeling and controlling the appearance of axes. For example, this surface plot shows some of the labeling possibilities and indicates the controlling property.



Creating Axes with Specific Characteristics

To create this axes, specify values for the indicated properties.

```
h = axes('Color',[.9 .9 .9],...
        'GridLineStyle','--',...
        'ZTickLabels','-1|Z = 0 Plane|+1',...
```

```
'FontName','times',...
'FontAngle','italic',...
'FontSize',14,...
'XColor',[0 0 .7],...
'YColor',[0 0 .7],...
'ZColor',[0 0 .7]);
```

Axis Labels

The individual axis labels are text objects whose handles are normally hidden from the command line (their `HandleVisibility` property is set to `callback`). You can use the `xlabel`, `ylabel`, `zlabel`, and `title` functions to create axis labels. However, these functions affect only the current axes. If you are labeling axes other than the current axes by referencing the axes handle, then you must obtain the text object handle from the corresponding axes property.

Getting the Text Object Handle

For example,

```
get(axes_handle,'XLabel')
```

returns the handle of the text object used as the *x*-axis label. Obtaining the text handle from the axes is useful in M-files and MATLAB-based applications where you cannot be sure the intended target is the current axes.

The following statements define the *x*- and *y*-axis labels and title for the axes above.

```
set(get(axes_handle,'XLabel'),'String','Values of X')
set(get(axes_handle,'YLabel'),'String','Values of Y')
set(get(axes_handle,'Title'),'String','\fontname{times}\itZ =
f(x,y)')
```

Because the labels are text, you must specify a value for the `String` property, which is initially set to the empty string (i.e., there are no labels).

MATLAB overrides many of the other text properties to control positioning and orientation of these labels. However, you can set the `Color`, `FontAngle`, `FontName`, `FontSize`, `FontWeight`, and `String` properties.

Specifying Axis Label Fonts

Note that both axes objects and text objects have font specification properties. The call to the `axes` function on the previous page set values for the `FontName`, `FontAngle`, and `FontSize` properties.

If you want to specify the font for the labels and title, set the font property values when defining their `String` property. For example, the *x*-axis label statement would be

```
set(get(h,'XLabel'),'String','Values of X',...
                    'FontName','times',...
                    'FontAngle','italic',...
                    'FontSize',14)
```

Bitmapped Vs. Truetype Fonts — Text Does Not Rotate

Bitmapped fonts (e.g., Courier) cannot be rotated on the display. Therefore, when you specify a bitmapped font with the `FontName` property, this text might not be rotated correctly, for example, when used as the *y*-axis label.

To avoid problems with bitmapped fonts, use TrueType fonts. For example, you might have a TrueType font named Courier New that you can use instead of Courier. See your system documentation for information on which fonts are installed on your system.

Positioning Axes

In this section...

Introduction

The axes `Position` property controls the size and location of an axes within a figure. The default axes has the same aspect ratio (ratio of width to height) as the default figure and fills most of the figure, leaving a border around the edges. However, you can define the axes position as any rectangle and place it wherever you want within a figure.

The Position Vector

MATLAB defines the axes `Position` property as a vector.

```
[left bottom width height]
```

`left` and `bottom` define a point in the figure that locates the lower left corner of the axes rectangle. `width` and `height` specify the dimensions of the axes rectangle. Viewing the axes in 2-D (azimuth = 0°, elevation = 90°) orients the *x*-axis horizontally and the *y*-axis vertically. From this angle, the plot box (the area used for plotting, exclusive of the axis labels) coincides with the axes rectangle.

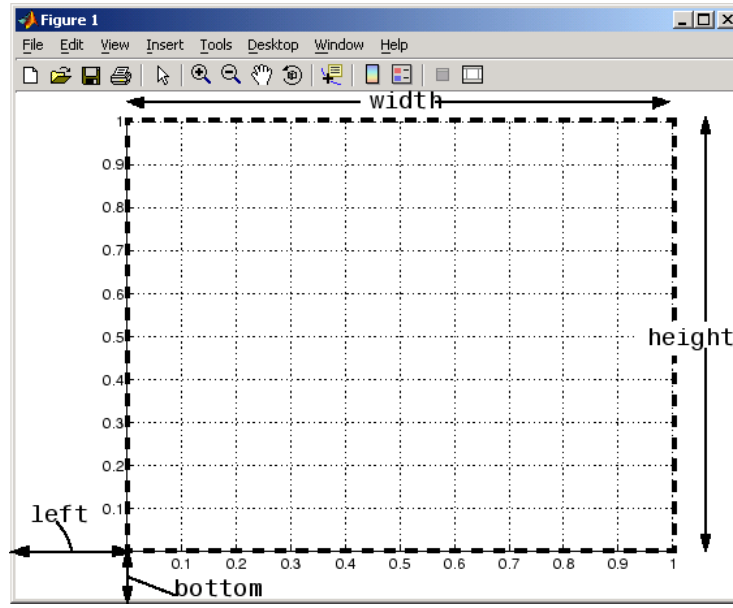


Figure 1

By default, MATLAB draws the plot box to fill the axes rectangle, regardless of its shape. However, axes properties enable control over the shape and scaling of the plot box.

Position Units

The axes `Units` property determines the units of measurement for the `Position` property. Possible values for this property are

```
set(gca,'Units')
[ inches | centimeters | {normalized} | points | pixels ]
```

with `normalized` being the default. Normalized units map the lower left corner of the figure to the point (0,0) and the upper right corner to (1.0,1.0), regardless of the size of the figure. Normalized units cause axes to resize automatically whenever you resize the figure. All other units are absolute measurements that remained fixed as you resize the figure.

Automatic Axes Resize

In this section...

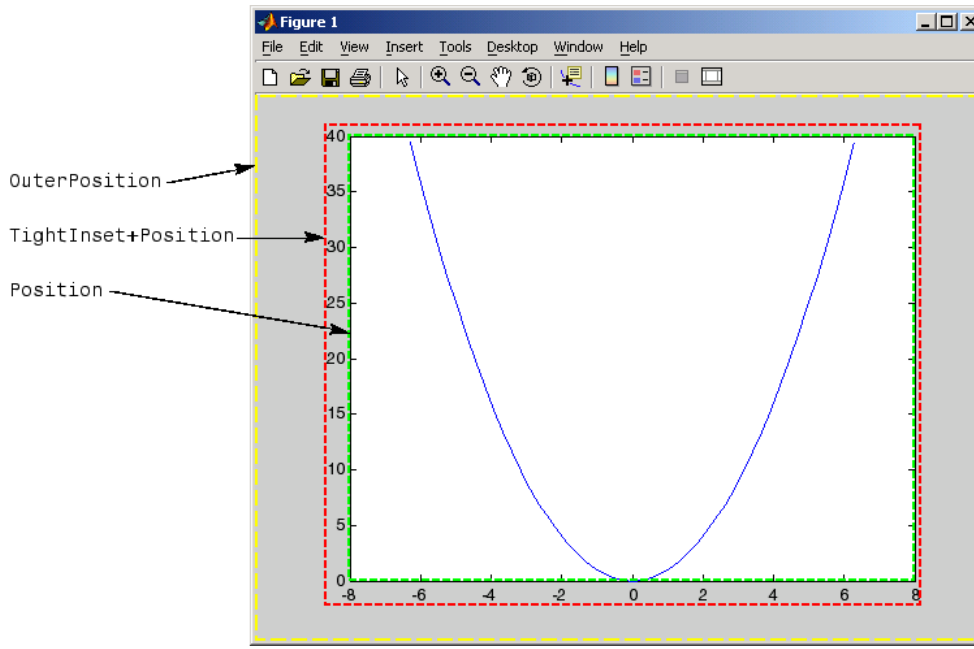
Properties Controlling Axes Size

When you create a graph, MATLAB automatically creates an axes to display the graph. The axes is sized to fit in the figure and automatically resizes as you resize the figure. Note, however, that MATLAB applies the automatic resize behavior only when the axes `Units` property is set to `normalized` (the default).

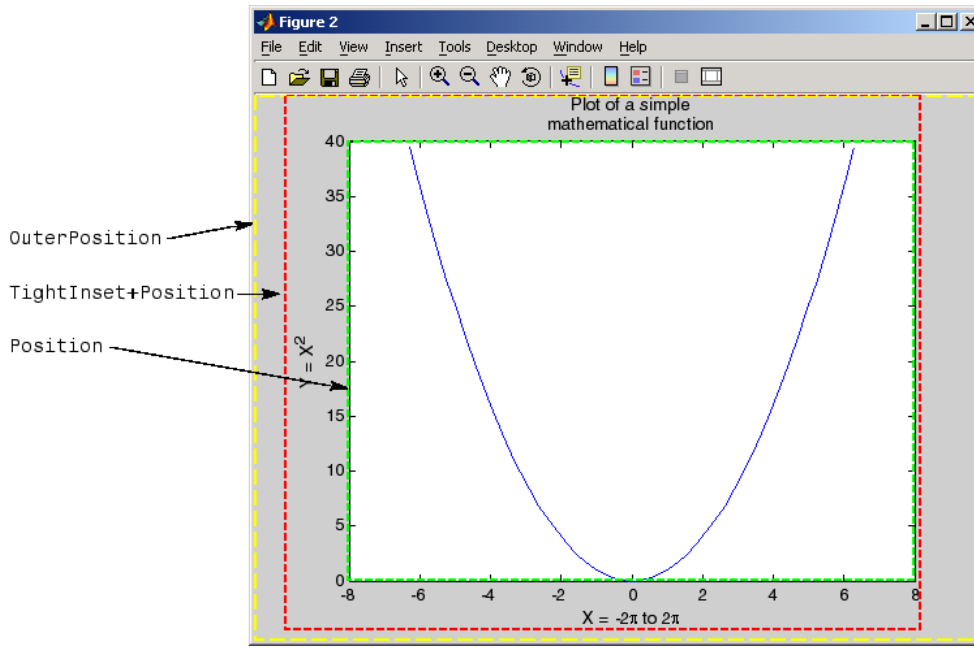
You can control the resize behavior of the axes using the following axes properties.

- `OuterPosition` — The boundary of the axes including the axis labels, title, and a margin. For figures with only one axes, this is the interior of the figure.
- `Position` — The boundary of the axes, excluding the tick marks and labels, title, and axis labels.
- `ActivePositionProperty` — Specifies whether to use the `OuterPosition` or the `Position` property as the size to preserve when resizing the figure containing the axes.
- `TightInset` — The margins added to the width and height of the `Position` property to include text labels, title, and axis labels.
- `Units` — Keep this property set to `normalized` to enable automatic axes resizing.

The following graph shows the areas defined by the `OuterPosition`, `TightInset + Position`, and `Position` properties.



When you add axis labels and a title, the `TightInset` changes to accommodate the additional text, as shown in the following graph.

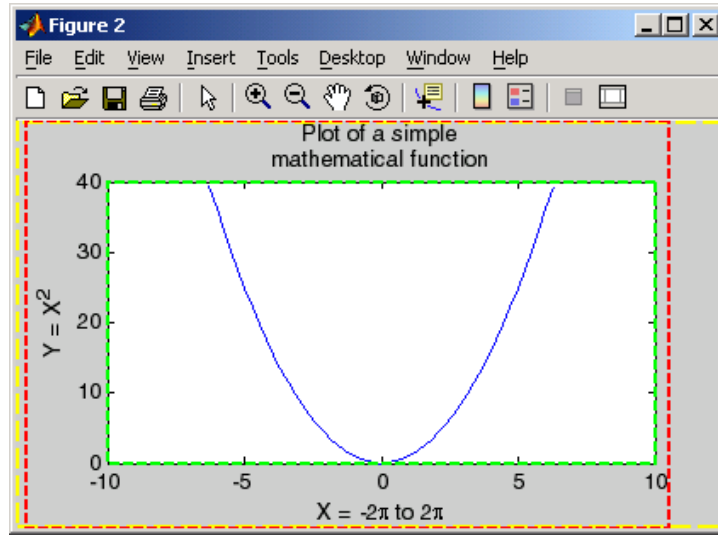


Now the size of the rectangle defined by the `TightInset + Position` properties includes all graph text. The `Position` and `OuterPosition` properties remain unchanged.

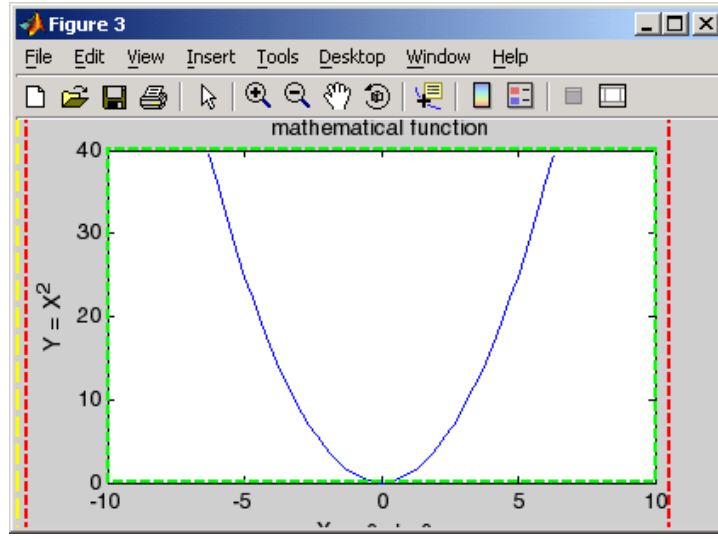
Using OuterPosition as the ActivePositionProperty

As you resize the figure, MATLAB maintains the area defined by the `TightInset + Position` so the test is not cut off. Compare the next two graphs, which have both been resized to the same figure size.

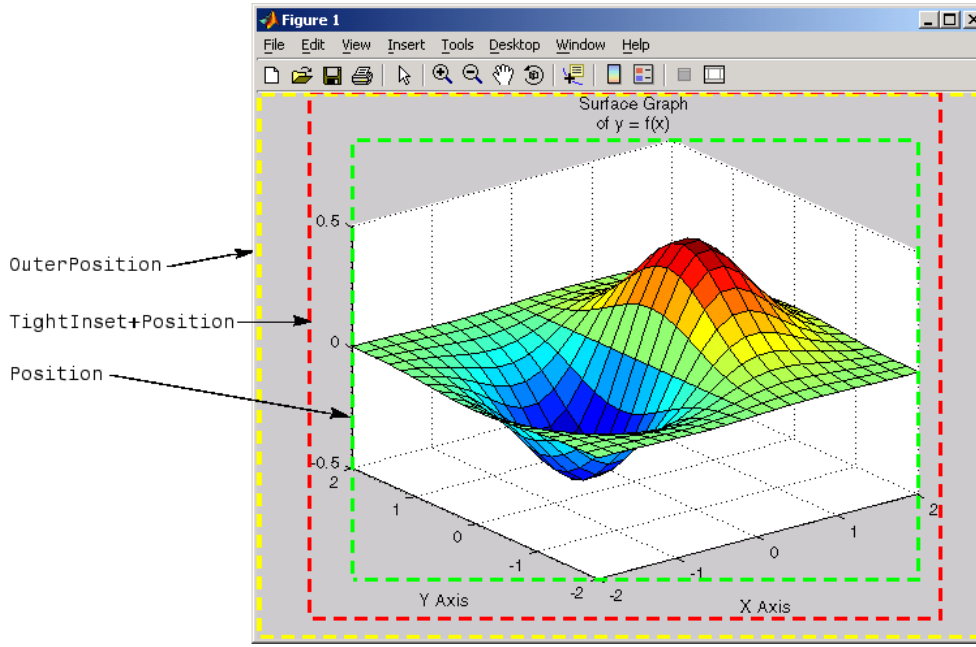
ActivePositionProperty = OuterPosition



ActivePositionProperty = Position



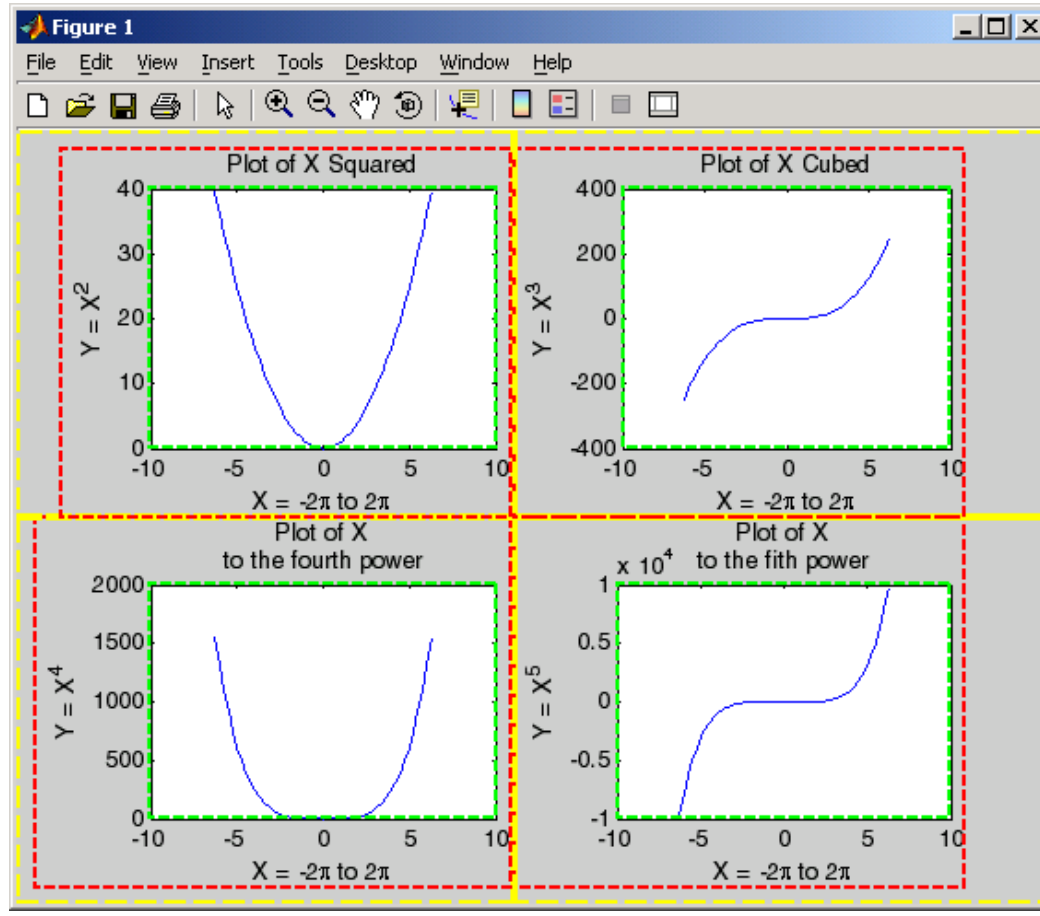
The following picture shows how these properties apply to 3-D graphs.



Axes Resizing in Subplots

Using the `OuterPosition` property as the `ActivePositionProperty` is an effective way to prevent titles and labels from being overwritten when there are multiple axes in a figure.

The following picture illustrates how MATLAB resizes the axes to accommodate the multiline titles on the lower two axes.



The default 3-D view is azimuth = -37.5°, elevation = 30°.

Multiple Axes per Figure

In this section...

Introduction

The `subplot` function creates multiple axes in one figure by computing values for `Position` that produce the specified number of axes.

The `subplot` function is useful for laying out a number of graphs equally spaced in the figure. However, overlapping axes can create some other useful effects. The following sections provide examples.

Placing Text Outside the Axes

MATLAB always displays text objects within an axes. If you want to create a graph and provide a description of the information alongside the graph, you must create another axes to position the text. If you create an axes that is the same size as the figure and then create a smaller axes to draw the graph, you can then display text anywhere independently of the graph.

For example, define two axes.

```
h = axes('Position',[0 0 1 1],'Visible','off');
axes('Position',[.25 .1 .7 .8])
```

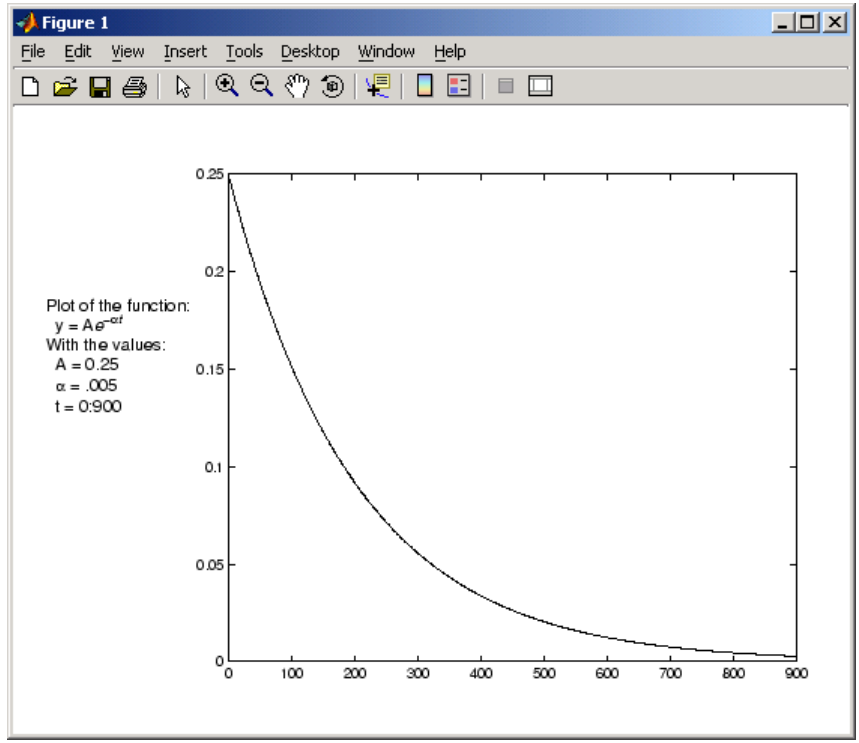
Because the axes units are normalized to the figure, specifying the `Position` as `[0 0 1 1]` creates an axes that encompasses the entire window.

Now plot some data in the current axes. The last axes created is the current axes, so MATLAB directs graphics output there.

```
t = 0:900;
plot(t,0.25*exp(-0.005*t))
```

Define the text and display it in the full-window axes.

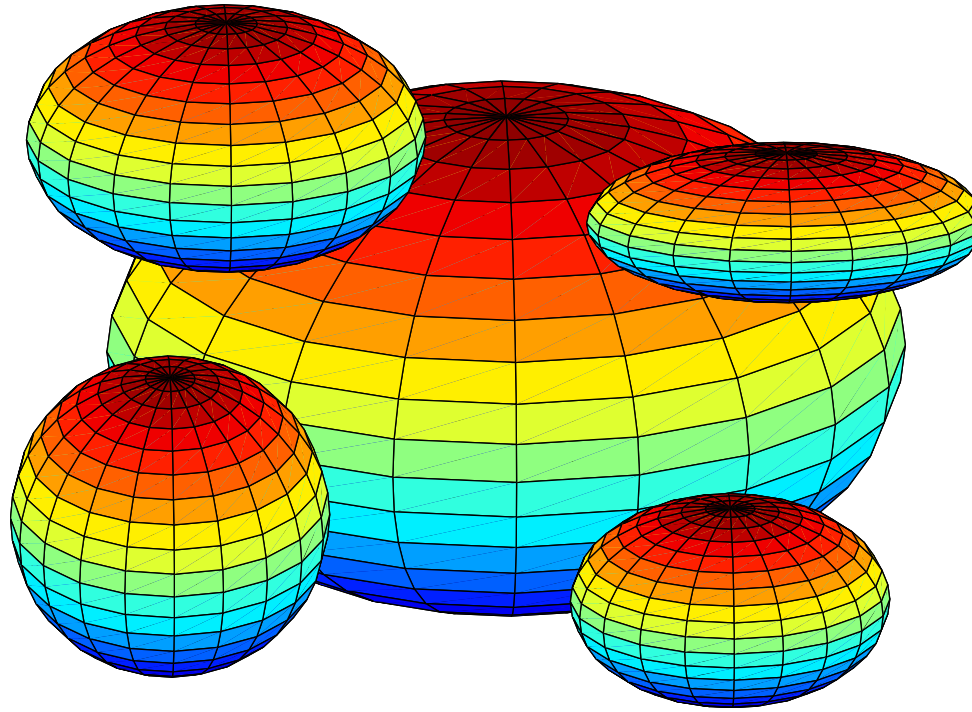
```
str(1) = {'Plot of the function:'};
str(2) = {' y = A{\ite}^{-\alpha{\itt}}'};
str(3) = {'With the values:'};
str(3) = {' A = 0.25'};
str(4) = {' \alpha = .005'};
str(5) = {' t = 0:900'};
set(gcf,'CurrentAxes',h)
text(.025,.6,str,'FontSize',12)
```



Multiple Axes for Different Scaling

You can create multiple axes to display graphics objects with different scaling without changing the data that defines these objects (which would be required to display them in a single axes).

```
h(1) = axes('Position',[0 0 1 1]);
sphere
h(2) = axes('Position',[0 0 .4 .6]);
sphere
h(3) = axes('Position',[0 .5 .5 .5]);
sphere
h(4) = axes('Position',[.5 0 .4 .4]);
sphere
h(5) = axes('Position',[.5 .5 .5 .3]);
sphere
set(h,'Visible','off')
```



Each sphere is defined by the same data. However, because the parent axes occupy regions of different size and location, the spheres appear to be different sizes and shapes.

Individual Axis Control

In this section...

Properties Controlling Axis Limits

MATLAB automatically determines axis limits, tick mark placement, and tick mark labels whenever you create a graph. However, you can specify these values manually by setting the appropriate property.

When you specify a value for a property controlled by a mode (e.g., the `XLim` property has an associated `XLimMode` property), MATLAB sets the mode to manual, enabling you to override automatic specification. Because the default values for these mode properties are automatic, calling high-level functions such as `plot` or `surf` resets these modes to `auto`.

This section discusses the following properties.

Property	Purpose
`XLim,YLim,ZLim`	Sets the axis range

`XLimMode,`
`YLimMode,`
`ZLimMode`
	Specifies whether axis limits are determined automatically by MATLAB or specified manually by the user

`XTick,`
`YTick,`
`ZTick`
	Sets the location of the tick marks along the axis

Property	Purpose
`XTickMode`, `YTickMode`, `ZTickMode`	Specifies whether tick mark locations are determined automatically by MATLAB or specified manually by the user
`XTickLabel`, `YTickLabel`, `ZTickLabel`	Specifies the labels for the axis tick marks
`XTickLabelMode` `YTickLabelMode` `ZTickLabelMode`	Specifies whether tick mark labels are determined automatically by MATLAB or specified manually by the user
`XDir,YDir,ZDir`	Sets the direction of increasing axis values

Setting Axis Limits

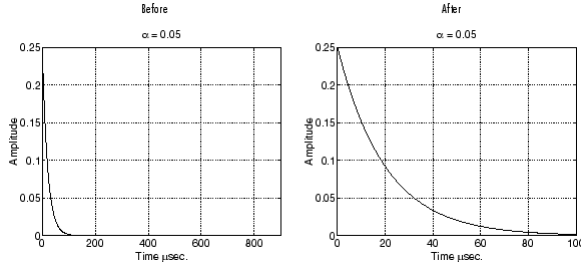
MATLAB determines the limits automatically for each axis based on the range of the data. You can override the selected limits by specifying the `XLim`, `YLim`, or `ZLim` property. For example, consider a plot of the function $Ae^{-\alpha t}$ evaluated with A = 0.25, α = 0.05, and t = 0 to 900.

```
t = 0:900;
plot(t,0.25*exp(-0.05*t))
```

The plot on the left shows the results. MATLAB selects axis limits that encompass the range of data in both x and y. However, because the plot contains little information beyond t = 100, changing the x-axis limits improves the usefulness of the plot. If the handle of the axes is `axes_handle`, then the following statement,

```
set(axes_handle,'XLim',[0 100])
```

creates the plot on the right.



You can use the `axis` command to set limits on the current axes only.

Semiautomatic Limits

You can specify either the minimum or maximum value for an axis limit and allow the other limit to autorange. Do this by setting an explicit value for the manual limit and `Inf` for the automatic limit. For example, the statement

```
set(axes_handle,'XLim',[0 Inf])
```

sets the `XLimMode` property to `auto` and allows MATLAB to determine the maximum value for `XLim`. Similarly, the statement

```
set(axes_handle,'XLim',[-Inf 800])
```

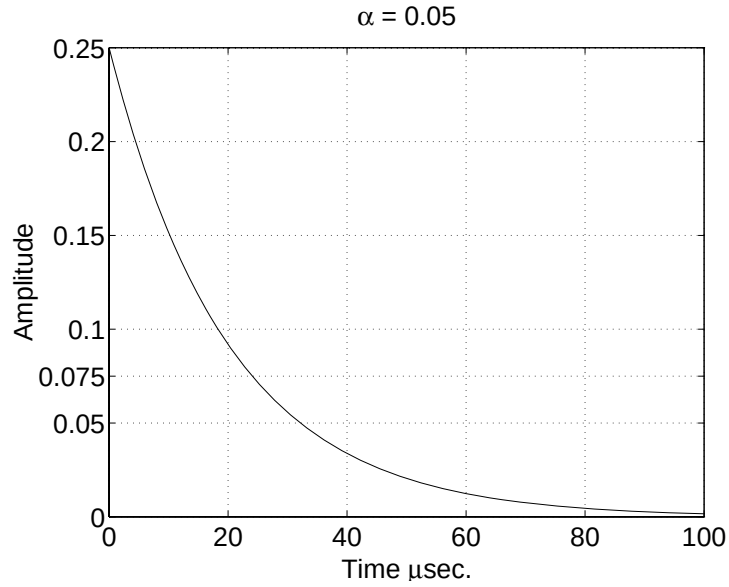
sets the `XLimMode` property to `auto` and allows MATLAB to determine the minimum value for `XLim`.

Setting Tick Mark Locations

MATLAB selects the tick mark location based on the data range to produce equally spaced ticks (for linear graphs). You can specify alternative locations for the tick marks by setting the `XTick`, `YTick`, and `ZTick` properties.

For example, if the value 0.075 is of interest for the amplitude of the function $Ae^{-\alpha t}$, specify tick marks to include that value.

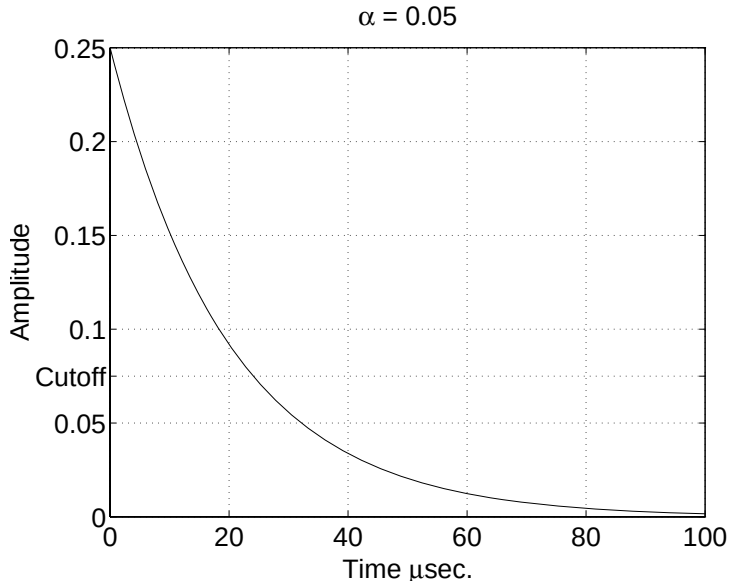
```
set(gca,'YTick',[0 0.05 0.075 0.1 0.15 0.2 0.25])
```



You can change tick labeling from numbers to strings using the `XTickLabel`, `YTickLabel`, and `ZTickLabel` properties.

For example, to label the *y*-axis value of 0.075 with the string `Cutoff`, you can specify all *y*-axis labels as a string, separating each label with the "|" character.

```
set(gca,'YTickLabel','0|0.05|Cutoff|0.1|0.15|0.2|0.25')
```



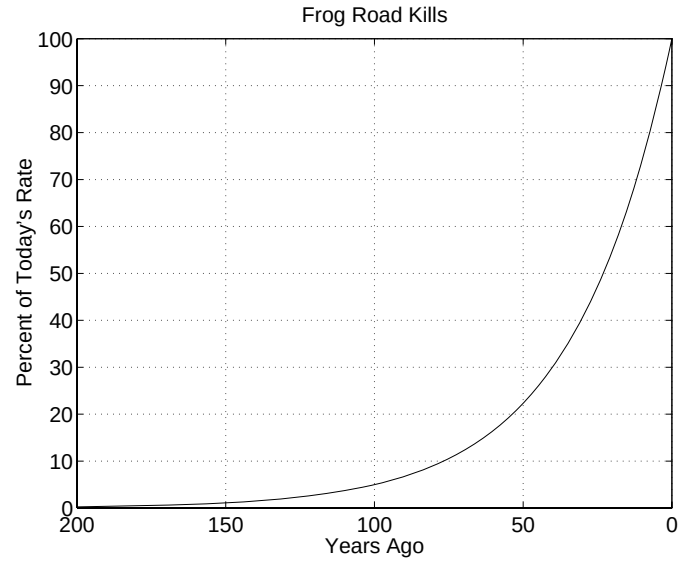
Changing Axis Direction

The `XDir`, `YDir`, and `ZDir` properties control the direction of increasing values on the respective axis. In the default 2-D view, the *x*-axis values increase from left to right and the *y*-axis values increase from bottom to top. The *z*-axis points out of the screen.

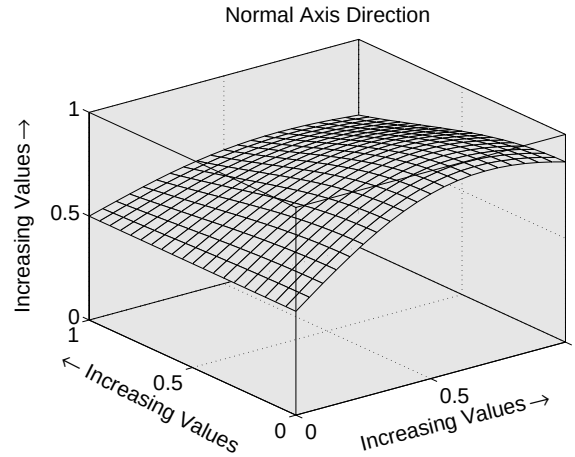
You can change the direction of increasing values by setting the associated property to `reverse`. For example, setting `XDir` to reverse,

```
set(gca,'XDir','reverse')
```

produces a plot whose *x*-axis decreases from left to right.



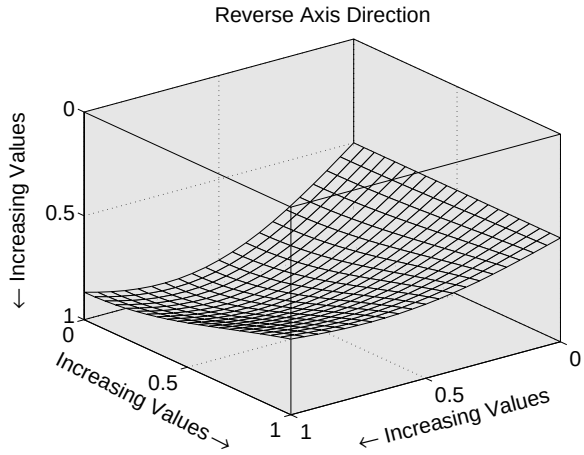
In the 3-D view, the *y*-axis increases from front to back and the *z*-axis increases from bottom to top.



Setting the *x*-, *y*-, and *z*-directions to reverse,

```
set(gca,'XDir','rev','YDir','rev','ZDir','rev')
```

yields



Using Multiple X- and Y-Axes

In this section...

Introduction

The `XAxisLocation` and `YAxisLocation` properties specify on which side of the graph to place the *x*- and *y*-axes. You can create graphs with two different *x*-axes and *y*-axes by superimposing two axes objects and using `XAxisLocation` and `YAxisLocation` to position each axis on a different side of the graph. This technique is useful to plot different sets of data with different scaling in the same graph.

Example — Double Axis Graphs

This example creates a graph to display two separate sets of data using the bottom and left sides as the *x*- and *y*-axis for one, and the top and right sides as the *x*- and *y*-axis for the other.

Suppose you have two sets of data having different *x*- and *y*-ranges:

```
x1 = [0:.1:40];
y1 = 4.*cos(x1)./(x1+2);
x2 = [1:.2:20];
y2 = x2.^2./x2.^3;
```

Using low-level `line` and `axes` routines allows you to superimpose objects easily. Plot the first data, making the color of the line and the corresponding *x*- and *y*-axis the same to more easily associate them.

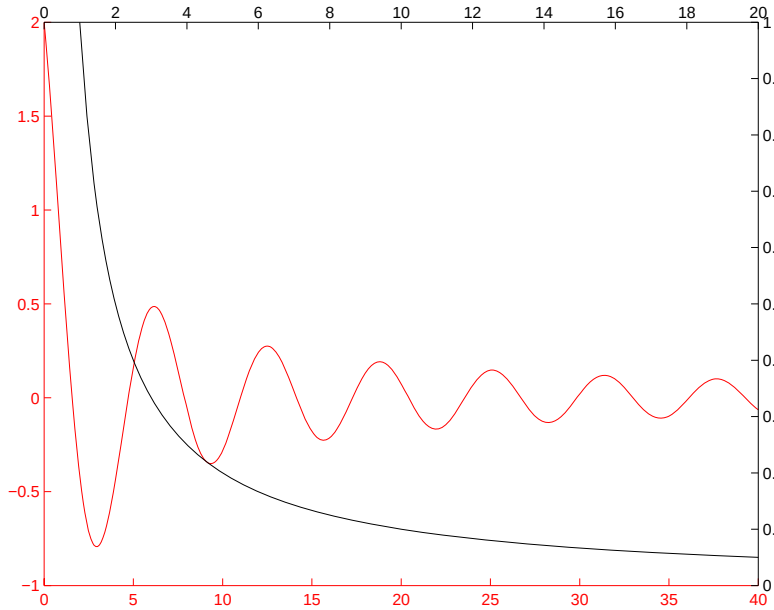
```
hl1 = line(x1,y1,'Color','r');
ax1 = gca;
set(ax1,'XColor','r','YColor','r')
```

Next, create another axes at the same location as the first, placing the *x*-axis on top and the *y*-axis on the right. Set the axes `Color` to `none` to allow the first axes to be visible and color code the *x*- and *y*-axis to match the data.

```
ax2 = axes('Position',get(ax1,'Position'),...
           'XAxisLocation','top',...
           'YAxisLocation','right',...
           'Color','none',...
           'XColor','k','YColor','k');
```

Draw the second set of data in the same color as the *x*- and *y*-axis.

```
hl2 = line(x2,y2,'Color','k','Parent',ax2);
```



Creating Coincident Grids

Since the two axes are completely independent, MATLAB determines tick mark locations according to the data plotted in each. It is unlikely the gridlines will coincide. This produces a somewhat confusing looking graph, even though the two grids are drawn in different colors. However, if you manually specify tick mark locations, you can make the grids coincide.

The key is to specify the same number of tick marks along corresponding axis lines (it is also necessary for both axes to be the same size). The following graph of the same data uses six tick marks per axis, equally spaced within the original limits. To calculate the tick mark locations, obtain the limits of each axis and calculate an increment.

```
xlimits = get(ax1,'XLim');
ylimits = get(ax1,'YLim');
xinc = (xlimits(2)-xlimits(1))/5;
yinc = (ylimits(2)-ylimits(1))/5;
```

Now set the tick mark locations.

```
set(ax1,'XTick',[xlimits(1):xinc:xlimits(2)],...
        'YTick',[ylimits(1):yinc:ylimits(2)])
```

Perform this calculation and set the axis limits for both axes. The resulting graph is visually simpler, even though the *y*-axis on the left has rather odd tick mark values.

Automatic-Mode Properties

While object creation routines that create axes children do not explicitly change axes properties, some axes properties are under automatic control when their associated mode property is set to `auto` (which is the default). The following table lists the automatic-mode properties.

Mode Property	What It Controls
`CameraPositionMode`	Positioning of the viewpoint
`CameraTargetMode`	Positioning of the camera target in the axes
`CameraUpVectorMode`	The direction of "up" in 2-D and 3-D views
`CameraViewAngleMode`	The size of the projected scene and stretch-to-fit behavior
`CLimMode`	Mapping of data values to colors
`DataAspectRatioMode`	Relative scaling of data units along x-, y-, and z-axes and stretch-to-fit behavior
`PlotBoxAspectRatioMode`	Relative scaling of plot box along x-, y-, and z-axes and stretch-to-fit behavior
`TickDirMode`	Direction of axis tick marks (in for 2-D, out for 3-D)

`XLimMode`
`YLimMode`
`ZLimMode`
	Limits of the respective x, y, and z axes

`XTickMode`
`YTickMode`
`ZTickMode`
	Tick mark spacing along the respective x-, y-, and z-axes

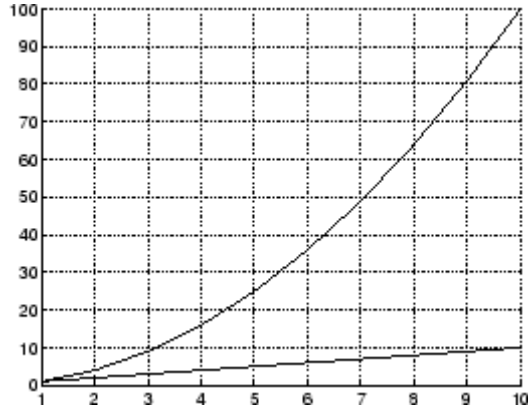
`XTickLabelMode`
`ZTickLabelMode`
`YTickLabelMode`
	Tick mark labels along the respective x-, y-, and z-axes

For example, if all property values are set to their defaults and you enter these statements,

```
line(1:10,1:10)
```

```
line(1:10,[1:10].^2)
```

the second `line` statement causes the `YLim` property to change from `[0 10]` to `[0 100]`.



This is because `YLimMode` is `auto`, which always causes MATLAB to recompute the axis limits.

If you set the value controlled by an automatic-mode property, MATLAB sets the mode to `manual` and does not automatically recompute the value.

For example, in the statements

```
line(1:10,1:10)
set(gca,'XLim',[1 10],'YLim',[1 20])
line(1:10,[1:10].^2)
```

the `set` statement sets the *x*- and *y*-axis limits *and* changes the `XLimMode` and `YLimMode` properties to `manual`. The second `line` statement now draws a line that is clipped to the axis limits `[1 12]` instead of causing the axes to recompute its limits.

Colors Controlled by Axes

In this section...

Introduction

Axes properties specify the color of the axis lines, tick marks, labels, and the background. Properties also control the colors of the lines drawn by plotting routines and how image, patch, and surface objects obtain colors from the figure colormap.

The axes properties discussed in this section are listed in the following table.

Property	Characteristic it Controls
`Color`	Axes background color
`XColor`, `YColor`, `ZColor`	Color of the axis lines, tick marks, gridlines, and labels
`Title`	Title text object handles
`XLabel`, `YLabel`, `Zlabel`	Axis label text object handles
`CLim`	Controls mapping of graphic object `CData` to the figure colormap
`CLimMode`	Automatic or manual control of `CLim` property
`ColorOrder`	Line color autocycle order
`LineStyleOrder`	Line styles autocycle order (not a color, but related to `ColorOrder`)

Specifying Axes Colors

The default axes background color is set up by the `colordef` command, which is called in your startup file. However, you can easily define your own color scheme.

Changing the Color Scheme

Suppose you want an axes to use a “black-on-white” color scheme. First, change the background to white and the axis lines, grid, tick marks, and tick mark labels to black.

```
set(gca,'Color','w',...
        'XColor','k',...
        'YColor','k',...
        'ZColor','k')
```

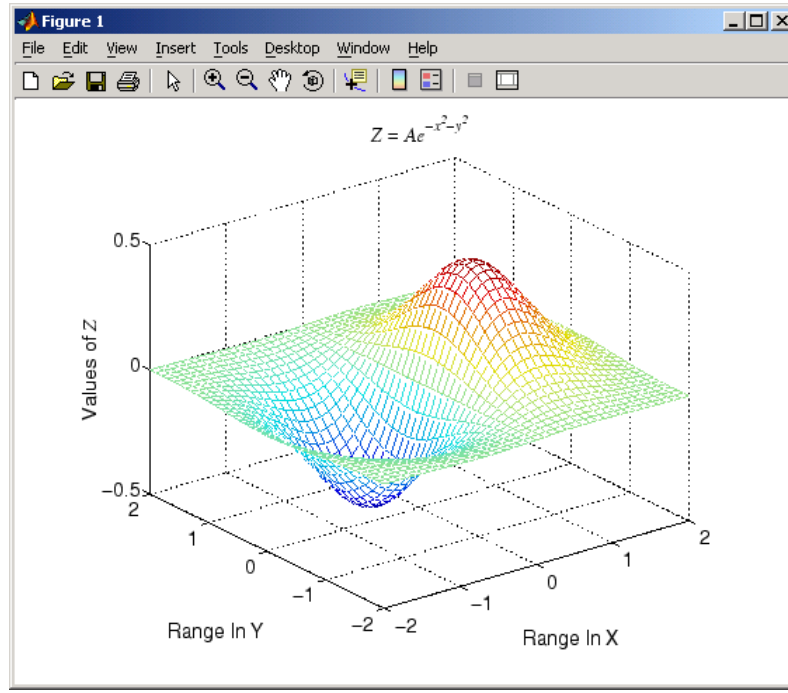
Next, change the color of the text objects used for the title and axis labels.

```
set(get(gca,'Title'),'Color','k')
set(get(gca,'XLabel'),'Color','k')
set(get(gca,'YLabel'),'Color','k')
set(get(gca,'ZLabel'),'Color','k')
```

Changing the figure background color to white completes the new color scheme.

```
set(gcf,'Color','w')
```

When you are done, a figure containing a mesh plot looks like the following figure.



You can define default values for the appropriate properties and put these definitions in your `startup.m` file. Titles and axis labels are text objects, so you must set a default color for all text objects, which is a good idea anyway because the default text color of white is not visible on the white background. Lines created with the low-level `line` function (but not the plotting routines) also have a default color of white, so you should change the default line color as well.

To set default values on the root level, use

```
set(0,'DefaultFigureColor','w'
      'DefaultAxesColor','w',...
      'DefaultAxesXColor','k',...
      'DefaultAxesYColor','k',...
      'DefaultAxesZColor','k',...
      'DefaultTextColor','k',...
      'DefaultLineColor','k')
```

MATLAB colors other axes children (i.e., image, patch, and surface objects) according to the values of their `CData` properties and the figure colormap.

Axes Color Limits — the CLim Property

In this section...

Introduction

Many 3-D plotting functions produce graphs that use color as another data dimension. For example, surface plots map surface height to color. The color limits control the limits of the color dimension in a way analogous to setting axis limits.

The axes `CLim` property controls the mapping of image, patch, and surface `CData` to the figure colormap. `CLim` is a two-element vector `[cmin cmax]` specifying the `CData` value to map to the first color in the colormap (`cmin`) and the `CData` value to map to the last color in the colormap (`cmax`). Data values in between are linearly transformed from the second to the penultimate color, using the expression

```
colormap_index = fix((CData-cmin)/(cmax-cmin)*cm_length)+1
```

`cm_length` is the length of the colormap. When the axes `CLimMode` property is `auto`, MATLAB sets `CLim` to the range of the `CData` of all graphics objects within the axes. However, you can set `CLim` to span any range of values. This enables individual axes within a single figure to use different portions of the figure's colormap. You can create colormaps with different regions, each used by a different axes.

See the `caxis` command for more information on color limits.

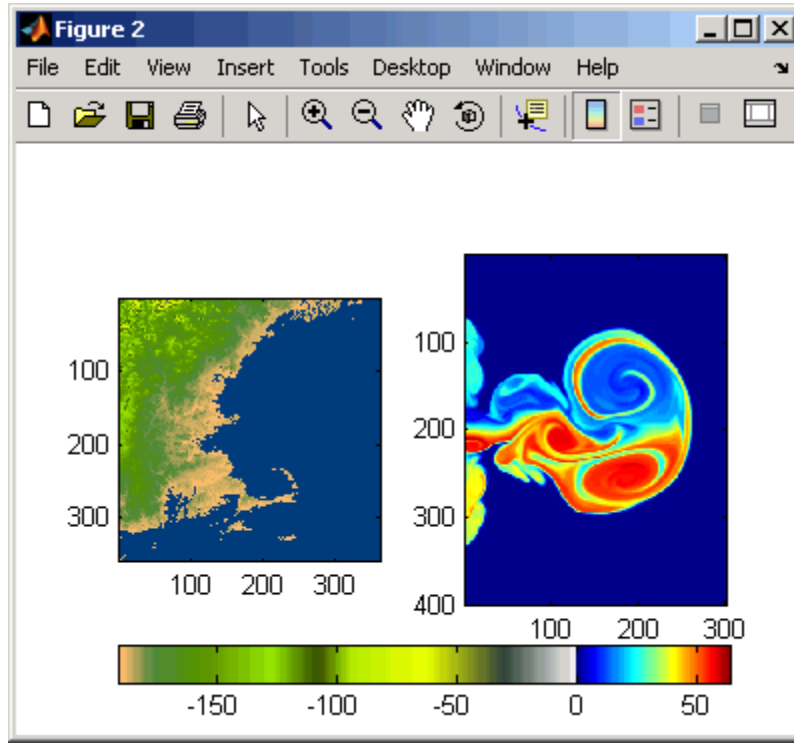
See "Introduction" on page 10-36 for an example that calculates color limits.

Simulating Multiple Colormaps in a Figure

Suppose you want to display two different images in the same figure. Images typically have their own colormaps, but you can specify only one colormap per figure. The solution is to concatenate the two colormaps and then setting the `CLim` property of each axes so that the two images map into different portions of the colormap.

Note Colormap Size Limit. On Windows platforms, the maximum length of the figure colormap is 256 colors (i.e., 256–by-3).

This example displays two images in one figure and maps the data in each image to the appropriate sections of the colormap, which has been created by concatenating the two colormaps together. The `colorbar` below the two images shows the entire colormap.



Complete Example Code

If you are using the MATLAB Help browser, you can:

- Run example
- Open the M-file in the editor

Calculating Color Limits

The key to this example is calculating values for `CLim` that cause each surface to use the section of the colormap containing the appropriate colors.

To calculate the new values for `CLim`, you need to know

- The total length of the colormap (`CmLength`)

- The beginning colormap slot to use for each axes (`BeginSlot`)
- The ending colormap slot to use for each axes (`EndSlot`)
- The minimum and maximum `CData` values of the graphic objects contained in the axes. That is, the values of the axes `CLim` property determined by MATLAB when `CLimMode` is `auto` (`CDmin` and `CDmax`).

First, define subplot regions and plot the surfaces.

```
im1 = load('cape.mat');
im2 = load('flujet.mat');
ax1 = subplot(1,2,1);
imagesc(im1.X)
axis(ax1,'image')
ax2 = subplot(1,2,2);
imagesc(im2.X)
axis(ax2,'image')
```

Concatenate two colormaps and install the new colormap.

```
colormap([im1.map;im2.map])
```

Obtain the data you need to calculate new values for `CLim`.

```
CmLength   = length(colormap);   % Colormap length
BeginSlot1 = 1;                  % Beginning slot
EndSlot1   = length(im1.map);    % Ending slot
BeginSlot2 = EndSlot1 + 1;
EndSlot2   = CmLength;
CLim1      = get(ax1,'CLim');  % CLim values for each axis
CLim2      = get(ax2,'CLim');
```

Defining a Function to Calculate CLim Values

Computing new values for `CLim` involves determining the portion of the colormap you want each axes to use relative to the total colormap size and scaling its `Clim` range accordingly. You can define a MATLAB function to do this.

```
function CLim = newclim(BeginSlot,EndSlot,CDmin,CDmax,CmLength)
   %     Convert slot number and range
```

```
    %     to percent of colormap
    PBeginSlot    = (BeginSlot - 1) / (CmLength - 1);
    PEndSlot      = (EndSlot - 1) / (CmLength - 1);
    PCmRange      = PEndSlot - PBeginSlot;
    %     Determine range and min and max
    %     of new CLim values
    DataRange     = CDmax - CDmin;
    ClimRange     = DataRange / PCmRange;
    NewCmin       = CDmin - (PBeginSlot * ClimRange);
    NewCmax       = CDmax + (1 - PEndSlot) * ClimRange;
    CLim          = [NewCmin,NewCmax];
end
```

The input arguments are identified in the bulleted list above. The function first computes the percentage of the total colormap you want to use for a particular axes (`PCmRange`) and then computes the `CLim` range required to use that portion of the colormap given the `CData` range in the axes. Finally, it determines the minimum and maximum values required for the calculated `CLim` range and returns these values. These values are the color limits for the given axes.

Using the Function

Use the `newclim` function to set the `CLim` values of each axes. The statement

```
set(ax1,'CLim',newclim(BeginSlot1,EndSlot1,CLim1(1),CLim1(2),CmLength))
```

sets the `CLim` values for the first axes so the surface uses color slots 65 to 120. The lit surface uses the lower 64 slots. You need to reset its `CLim` values as well.

```
set(ax2,'CLim',newclim(BeginSlot2,EndSlot2,CLim2(1),CLim2(2),CmLength))
```

How the Function Works

MATLAB enables you to specify any values for the axes `CLim` property, even if these values do not correspond to the `CData` of the graphics objects displayed in the axes. The minimum `CLim` value is always mapped to the first color in the colormap and the maximum `CLim` value is always mapped to the last color in the colormap, whether or not there are really any `CData` values corresponding to these colors. Therefore, if you specify values for `CLim` that

extend beyond the object's actual `CData` minimum or maximum, MATLAB colors the object with only a subset of the colormap.

The `newclim` function computes values for `CLim` that map the graphics object's actual `CData` values to the beginning and ending colormap slots that you specify. It does this by defining a "virtual" graphics object having the computed `CLim` values.

Defining the Color of Lines for Plotting

In this section...

Introduction

The axes `ColorOrder` property determines the color of the individual lines drawn by the `plot` and `plot3` functions. For multiline graphs, these functions cycle through the colors defined by `ColorOrder`, repeating the cycle when they reach the end of the list.

The `colordef` command defines various color order schemes for different background colors. `colordef` is typically called in the `matlabrc` file, which is executed during MATLAB startup.

Defining Your Own ColorOrder

You can redefine `ColorOrder` to be any *m*-by-3 matrix of RGB values, where *m* is the number of colors. However, high-level functions like `plot` and `plot3` reset most axes properties (including `ColorOrder`) to the defaults each time you call them. To use your own `ColorOrder` definition you must do one of the following three things:

- Define a default `ColorOrder` on the figure or root level
- Change the axes `NextPlot` property to `add` or `replacechildren`
- Use the informal form of the `line` function, which obeys the `ColorOrder` but does not clear the axes or reset properties

Changing the Default ColorOrder

You can define a new `ColorOrder` that MATLAB uses within a particular figure, for all axes within any figures created during the MATLAB session, or as a user-defined default that MATLAB always uses.

To change the ColorOrder for all plots in the current figure, set a default in that figure. For example, to set ColorOrder to the colors red, green, and blue, use the statement

```
set(gcf,'DefaultAxesColorOrder',[1 0 0;0 1 0;0 0 1])
```

To define a new ColorOrder that MATLAB uses for all plotting during your entire MATLAB session, set a default on the root level so axes created in any figure use your defaults.

```
set(0,'DefaultAxesColorOrder',[1 0 0;0 1 0;0 0 1])
```

To define a new ColorOrder that MATLAB always uses, place the previous statement in your startup.m file.

Setting the NextPlot Property

The axes NextPlot property determines how high-level graphics functions draw into an existing axes. You can use this property to prevent plot and plot3 from resetting the ColorOrder property each time you call them, but still clear the axes of any existing plots.

By default, NextPlot is set to replace, which is equivalent to a cla reset command (i.e., delete all axes children and reset all properties, except Position, to their defaults). If you set NextPlot to replacechildren,

```
set(gca,'NextPlot','replacechildren')
```

MATLAB deletes the axes children, but does not reset axes properties. This is equivalent to a cla command without the reset.

After setting NextPlot to replacechildren, you can redefine the ColorOrder property and call plot and plot3 without affecting the ColorOrder.

Setting NextPlot to add is the equivalent of issuing the hold on command. This setting prevents MATLAB from resetting the ColorOrder property, but it does not clear the axes children with each call to a plotting function.

Using the line Function

The behavior of the `line` function depends on its calling syntax. When you use the informal form (which does not include any explicit property definitions),

```
line(x,y,z)
```

`line` obeys the `ColorOrder` property, but does not clear the axes with each invocation or change the view to 3-D (as `plot3` does). However, `line` can be useful for creating your own plotting functions where you do not want the automatic behavior of `plot` or `plot3`, but you do want multiline graphs to use a particular `ColorOrder`.

Line Styles Used for Plotting — LineStyleOrder

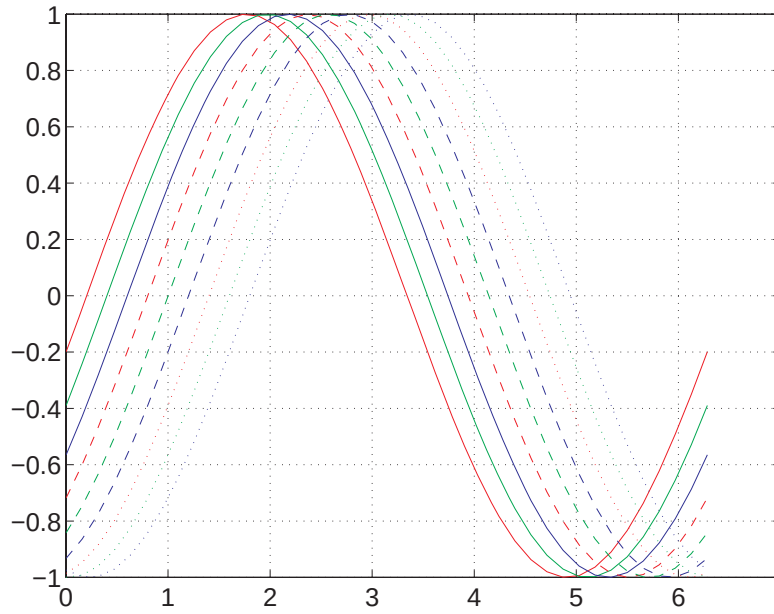
The axes `LineStyleOrder` property is analogous to the `ColorOrder` property. It specifies the line styles to use for multiline plots created with the `plot` and `plot3` functions. MATLAB increments the line style only after using all of the colors in the `ColorOrder` property. It then uses all the colors again with the second line style, and so on.

For example, define a default `ColoOrder` of red, green, and blue and a default `LineStyleOrder` of solid, dashed, and dotted lines.

```
set(0,'DefaultAxesColorOrder',[1 0 0;0 1 0;0 0 1],...
      'DefaultAxesLineStyleOrder','-|--|:')
```

Then plot some multiline data.

```
t = 0:pi/20:2*pi;
a = ones(length(t),9);
for i = 1:9
    a(:,i) = sin(t-i/5)';
end
plot(t,a)
```



MATLAB cycles through all colors for each line style.

MAT-File Format

Introduction

This document describes the internal format of MATLAB® Level 4 and Level 5 MAT-files. Level 4 MAT-files are compatible with versions of MATLAB up to Version 4. Level 5 MAT-files are compatible with MATLAB Versions 5 and up. You can read and write Level 4 MAT-files with the later versions of MATLAB, but when writing a MAT-file under these circumstances, you need to specify a switch in the `save` or `matOpen` command line to tell MATLAB that the MAT-file is at Level 4.

A MAT-file stores data in binary (not human-readable) form. In MATLAB, you create MAT-files using the `save` function, which writes the arrays currently in memory to a file as a continuous byte stream. By convention, this file has the filename extension `.mat`; thus the name MAT-file. The `load` function reads the arrays from a MAT-file into the MATLAB workspace.

Most MATLAB users do not need to know the internal format of a MAT-file. Even users who must read and write MAT-files from C and Fortran programs do not need to know the MAT-file format if they use the MAT-file interface. This interface shields users from dependence on the details of the MAT-file format.

Note See "Importing and Exporting Data" in the MATLAB External Interfaces documentation for information on the MAT-file interface. See "C [or Fortran] MAT-File Functions" in the MATLAB External Interfaces Reference documentation for information on the functions available with this interface.

However, if you need to read or write MAT-files on a system that does not support the MAT-file interface, you must write your own read and write routines. The MAT-file interface is only available for platforms on which MATLAB is supported. This document provides the details about the MAT-file format you will need to read and write MAT-files on these systems.

Note Whenever possible, The MathWorks strongly advises you to use the MAT-file interface functions to read and write MAT-files. Any code you write that depends on the MAT-file format may need to be rewritten when the format changes in future releases.

MAT-File Formats

This document describes both Level 5 and Level 4 MAT-file formats. The Level 5 MAT-file format supports all the array types supported in MATLAB versions 5 and up, including multidimensional numeric arrays, character arrays, sparse arrays, cell arrays, structures, and objects. “Level 5 MAT-File Format” on page 1-4 describes this format.

The Level 4 MAT-file format is a simpler format but it only supports two-dimensional matrices and character strings. “Level 4 MAT-File Format” on page 1-36 describes this format.

Level 5 MAT-File Format

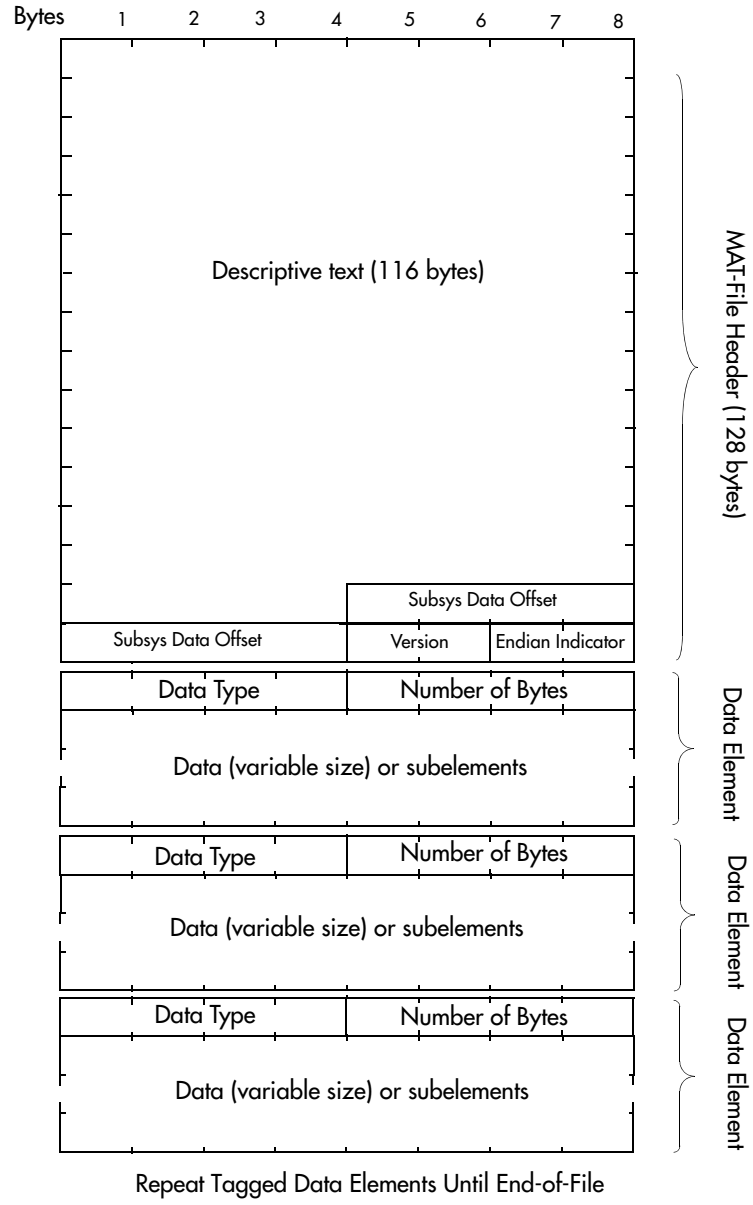
Level 5 MAT-files are made up of a 128-byte *header* followed by one or more *data elements*. Each data element is composed of an 8-byte *tag* followed by the data in the element. The tag specifies the number of bytes in the data element and how these bytes should be interpreted; that is, should the bytes be read as 16-bit values, 32-bit values, floating point values or some other data type.

By using tags, the Level 5 MAT-file format provides quick access to individual data elements within a MAT-file. You can move through a MAT-file by finding a tag and then skipping ahead the specified number of bytes until the next tag.

"MATLAB Level 5 MAT-File Format" on page 1-5 graphically illustrates this MAT-file format. The sections that follow provide more details about these MAT-file elements.

This section covers the following topics:

Figure 1-1: MATLAB Level 5 MAT-File Format



MAT-File Header Format

Level 5 MAT-files begin with a 128-byte header made up of a 124 byte text field and two, 16-bit flag fields.

This section covers the following topics:

Header Text Field

The first 116 bytes of the header can contain text data in human-readable form. This text typically provides information that describes how the MAT-file was created. For example, MAT-files created by MATLAB include the following information in their headers:

- Level of the MAT-file (value equals `1` for Level 5)
- Platform on which the file was created
- Date and time the file was created

You can view the text in a MAT-file header using the `cat` command on UNIX systems, or the `type` command on a PC. The output displays the text in this part of the header. (The display of the header is followed by unreadable characters representing the binary data in the file.)

```
cat my_matfile.mat
MATLAB 5.0 MAT-file, Platform: SOL2, Created on: Thu Nov 13
10:10:27 1997
```

Note When creating a MAT-file, you *must* write data in the first four bytes of this header. MATLAB uses these bytes to determine if a MAT-file uses a Level 5 format or a Level 4 format. If any of these bytes contain a zero, MATLAB will incorrectly assume the file is a Level 4 MAT-file.

Header Subsystem Data Offset Field

Bytes 117 through 124 of the header contain an offset to subsystem-specific data in the MAT-file. All zeros or all spaces in this field indicate that there is no subsystem-specific data stored in the file.

Header Flag Fields

The last four bytes in the header are divided into two, 16-bit flag fields (`int16`).

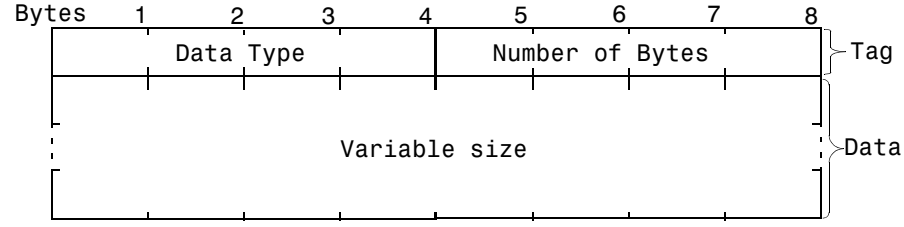
Field	Value
Version	When creating a MAT-file, set this field to `0x0100`.
Endian Indicator	Contains the two characters, `M` and `I`, written to the MAT-file in this order, as a 16-bit value. If, when read from the MAT-file as a 16-bit value, the characters appear in reversed order (`IM` rather than `MI`), it indicates that the program reading the MAT-file must perform byte-swapping to interpret the data in the MAT-file correctly.

Note Programs that create MAT-files always write data in their native machine format. Programs that read MAT-files are responsible for byte-swapping.

Data Element Format

Each data element begins with an 8-byte tag followed immediately by the data in the element. Figure 1-2 shows this format. (MATLAB also supports a compressed data element format. See page 1-10 for more information.)

Figure 1-2: MAT-File Data Element Format



This section covers the following topics:

The Tag Field

The 8-byte data element tag is composed of two, 32-bit fields:

- Data Type
- Number of Bytes

Data Type. The Data Type field specifies how the data in the element should be interpreted, that is, its size and format. The MAT-file format supports many data types including signed and unsigned, 8-bit, 16-bit, 32-bit, and 64-bit data types, a special data type that represents MATLAB arrays, Unicode encoded character data, and data stored in compressed format. Table 1-1 lists all these data types with the values used to specify them. The table also includes

symbols that are used to represent these data types in the examples in this document.

Table 1-1: MAT-File Data Types

Value	Symbol	MAT-File Data Type
1	`miINT8`	8 bit, signed
2	`miUINT8`	8 bit, unsigned
3	`miINT16`	16-bit, signed
4	`miUINT16`	16-bit, unsigned
5	`miINT32`	32-bit, signed
6	`miUINT32`	32-bit, unsigned
7	`miSINGLE`	IEEE 754 single format
8	`--`	Reserved
9	`miDOUBLE`	IEEE 754 double format
10	`--`	Reserved
11	`--`	Reserved
12	`miINT64`	64-bit, signed
13	`miUINT64`	64-bit, unsigned
14	`miMATRIX`	MATLAB array
15	`miCOMPRESSED`	Compressed Data
16	`miUTF8`	Unicode UTF-8 Encoded Character Data
17	`miUTF16`	Unicode UTF-16 Encoded Character Data
18	`miUTF32`	Unicode UTF-32 Encoded Character Data

The `UTF-16` and `UTF-32` encodings are in the byte order specified by the Endian Indicator (See “Header Flag Fields” on page 1-7). UTF-8 is byte order neutral.

For character data that is not Unicode encoded, the Data Type part of the Tag field should be set to `miUINT16`.

For more information about the `miMATRIX` data type, see "Level 5 MATLAB Array Data Element Formats" on page 1-14.

Number of Bytes. The Number of Bytes field is a 32-bit value that specifies the number of bytes of data in the element. This value does not include the eight bytes of the data element's tag.

If Data Type is `miCOMPRESSED`, then the Number of Bytes field contains the compressed MATLAB array size in bytes. (See "Data Compression" on page 1-12.)

The Data Field

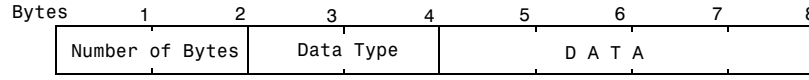
The data immediately follows the tag. All data that is uncompressed must be aligned on 64-bit boundaries. When writing a MAT-file, if the amount of data in a data element falls short of a 64-bit boundary, you must add bytes of padding to make sure the tag of the next data element falls on a 64-bit boundary. Likewise, when reading data from a MAT-file, be sure to account for these padding bytes.

Note For data elements representing MATLAB arrays, (type `miMATRIX`), the value of the Number of Bytes field includes padding bytes in the total. For all other MAT-file data types, the value of the Number of Bytes field does *not* include padding bytes.

Small Data Element Format

If a data element takes up only one to four bytes, MATLAB saves storage space by storing the data in an 8-byte format. In this format, the Data Type and Number of Bytes fields are stored as 16-bit values, freeing four bytes in the tag in which to store the data. Figure 4 illustrates this format.

Figure 1-3: Small Data Element Format

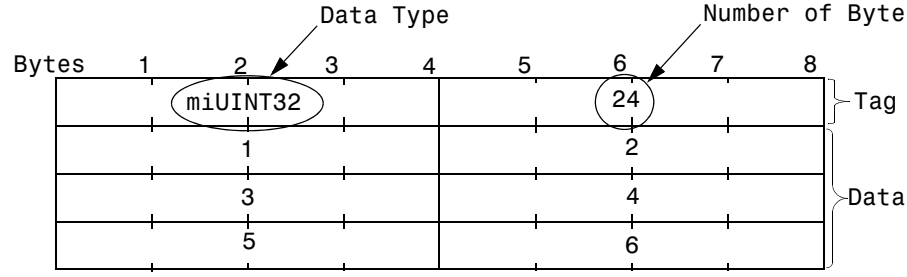


Note When reading a MAT-file, you can tell if you are processing a small data element by comparing the value of the first two bytes of the tag with the value zero (0). If these two bytes are not zero, the tag uses the small data element format. When writing to a MAT-file, use of the small data element format is optional.

Example Data Element

Figure 1-4 illustrates a data element representing an array of six 32-bit, unsigned integers: 1, 2, 3, 4, 5, 6. In the figure, the Data Type field contains the value from Table 1-1 that specifies unsigned, 32-bit integers (`miUINT32`). The Number of Bytes field in the data element tag contains the number of data values multiplied by the number of bytes used to represent each value. Note that this value does not include the eight bytes in the data element tag.

Figure 1-4: Example MAT-File Data Element



Data Compression

MATLAB compresses the data it saves to a MAT-file using buffered in-memory gzip compression. It compresses MATLAB variables transparently as they are written out to disk. This technique uses less memory than systems that compress an entire variable at once before writing it out to disk. Also, no temporary files are required in order to read or write compressed data.

Because it compresses each variable individually, MATLAB can read a compressed MAT-file like any other MAT-file. No code changes are required at either the C or M level to read a compressed MAT-file.

MATLAB compresses data for MAT-files (file I/O) only, not for sequential streams. The reason for this is that the size of the compressed variable is known only after it is compressed, but it must be written in the tag at the beginning of the variable. In a file it is possible to seek back and write the size, while in a stream this cannot be done.

MAT-files containing compressed variables are non-platform specific like any MAT-file, and such a file saved on any MATLAB supported platform can be loaded on any other supported platform.

To decompress the contents of a compressed variable in a MAT-file, you can use the `uncompress` function from the freeware `zlib-1.1.4` library available at the `gzip` web site, `http://www.gzip.org/zlib/`. Once a MATLAB array has been decompressed, you can ignore the `miCOMPRESSED` tag and process the data normally, as if it had not been compressed.

Note To disable data compression when writing to MAT-files, see "Saving and Loading MAT-files" in the "Data Import and Export" chapter of the MATLAB Programming documentation.

Storing Compressed Data

MATLAB stores compressed data in gzip-compressed MATLAB arrays. Each compressed variable is stored complete with its tags and data field in the same format as uncompressed variables, as described in "Data Element Format" on page 1-8. The difference is that the entire variable is compressed into a data buffer, and this buffer is preceded by an 8-byte tag named `miCOMPRESSED`. The tag contains the length of the compressed buffer.

Each variable in a MAT-file has a 56-byte header. Even if the data is stored in the header itself, as can be the case for variables containing 1 to 4 bytes of data, no variable in a MAT-file can be less than 56 bytes. Thus, regardless of how random the data in a variable may be, it is unlikely (but not impossible) that a compressed variable will take more space than its uncompressed counterpart. This is because the 56-byte header always compresses to a smaller size. Note that compression works best on nonrandom data. The more random the data, the less it will compress.

Level 5 MATLAB Array Data Element Formats

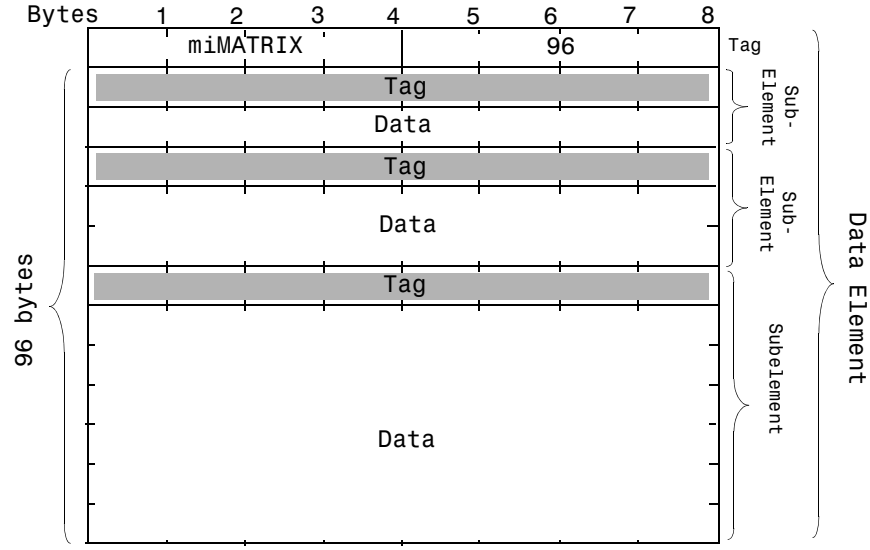
The MAT-file data type `miMATRIX` (`14`) is used to represent all types of MATLAB arrays, including:

- Numeric arrays
- Character arrays
- Sparse arrays
- Cell arrays
- Structures
- Objects

The `miMATRIX` data type is a compound data type. MAT-file data elements of this type are composed of multiple *subelements*. The subelements can be of any other MAT-file data type, including other `miMATRIX` data types.

Figure 1-5 shows a `miMATRIX` data element composed of three subelements. Note how each subelement is a data element with its own tag. The value of the Number of Bytes field (`96` in the figure) in the data element tag includes all the subelements.

Figure 1-5: MATLAB Array Data Element with Subelements



Each `miMATRIX` data element representing the different types of MATLAB arrays each has a specific set of subelements. Some of these subelements are common to all MATLAB arrays. Others subelements are unique to a particular type of array. The following sections detail the subelements for each MATLAB array type.

Numeric Array and Character Array Data Element Formats

A MAT-file data element representing a MATLAB numeric array or character array is composed of four subelements and one optional subelement. Table 1-2 lists the subelements in the order in which they appear in the data element. The table also includes the values of the Data Type and Number of Bytes fields you would use in the tag of each subelement. For an example, see “Examples of Numeric Array Data Elements” on page 1-19.

Table 1-2: Numeric and Character Array Subelements with Tag Data

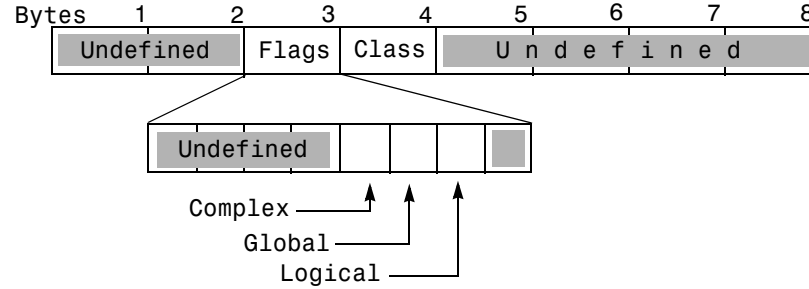
Subelement	Data Type	Number of Bytes
Array Flags	`miUINT32`	`2*size-of-Data-Type (8 bytes)`
Dimensions Array	`miINT32`	`number-of-dimensions*size-of-Data-Type` (To learn how to determine the number of dimensions, see “Dimensions Array Subelement” on page 1-17.)
Array Name	`miINT8`	`number-of-characters*size-of-Data-Type`
Real part (`pr`)	Any of the numeric data types.	`number-of-values*size-of-Data-Type`
Imaginary part (`pi`) (Optional)	Any of the numeric data types.	`number-of-values*size-of-Data-Type`

Array Flags Subelement

This subelement identifies the MATLAB array type (class) represented by the data element and provides other information about the array. The Array Flags subelement is common to all array types.

Figure 1-6 illustrates the format of the Array Flags subelement. (For sparse matrices, bytes 5 through 8 are used to store the maximum number of nonzero elements in the matrix. See “Sparse Array Data Element Format” on page 1-22 for more information.)

Figure 1-6: Array Flags Format



Flags. This field contains three, single-bit flags that indicate whether the numeric data is complex, global, or logical. If the complex bit is set, the data element includes an imaginary part (`pi`). If the global bit is set, MATLAB loads the data element as a global variable in the base workspace. If the logical bit is set, it indicates the array is used for logical indexing.

Class. This field contains a value that identifies the MATLAB array type (class) represented by the data element. Table 1-3 lists the MATLAB array types with the values you use to specify them. The table also includes symbols that are used to represent the MATLAB array type in the examples in this document.

Note The value of the Class field identifies the MATLAB data type. The value of the Data Type field in the data element tag identifies the data type used to store the data *in the MAT-file*. The MAT-file data types are listed in Table 1-1. The value of the Class and the Data Type fields do not need to be the same; for more information, see “Automatic Compression of Numeric Data” on page 1-19.

Table 1-3: MATLAB Array Types (Classes)

MATLAB Array Type (Class)	Value	Symbol
Cell array	1	mxCELL_CLASS
Structure	2	mxSTRUCT_CLASS
Object	3	mxOBJECT_CLASS
Character array	4	mxCHAR_CLASS
Sparse array	5	mxSPARSE_CLASS
Double precision array	6	mxDOUBLE_CLASS
Single precision array	7	mxSINGLE_CLASS
8-bit, signed integer	8	mxINT8_CLASS
8-bit, unsigned integer	9	mxUINT8_CLASS
16-bit, signed integer	10	mxINT16_CLASS
16-bit, unsigned integer	11	mxUINT16_CLASS
32-bit, signed integer	12	mxINT32_CLASS
32-bit unsigned, integer	13	mxUINT32_CLASS

For numeric arrays, Class can contain any of the numeric array types: mxDOUBLE_CLASS, mxSINGLE_CLASS, mxINT8_CLASS, mxUINT8_CLASS, mxINT16_CLASS, mxUINT16_CLASS, mxINT32_CLASS, or mxUINT32_CLASS.

For character arrays, Class contains mxCHAR_CLASS.

Dimensions Array Subelement

This subelement specifies the size of each dimension of an *n*-dimensional array in an *n*-sized array of 32-bit values (miINT32). All numeric arrays have at least two dimensions. The Dimensions Array subelement is common to all MATLAB array types.

For example, if a data element represents a 2-by-3-by-2 MATLAB array, the Dimensions Array subelement would contain three values: `2`, `3`, and `2`.

Note To calculate the number of dimensions in an array, divide the value stored in the Number of Bytes field in the Dimensions Array subelement tag by `4`, the number of bytes in the data type (`miINT32`) used in the subelement.

Array Name Subelement

This subelement specifies the name assigned to the array, as an array of signed, 8-bit values (`miINT8`). This subelement is common to all array types.

Real Part (pr) Subelement

This subelement contains the numeric data in the MATLAB array. If the array contains complex numbers (the complex bit in the Array Flags is set), this is the real part of the number.

The data type of the values can be any of the numeric data types listed in Table 1-1, MAT-File Data Types, on page 1-9.

For character data that is not Unicode encoded, the Data Type part of the Tag field should be set to `miUINT16`.

Imaginary Part (pi) Subelement

This subelement contains the imaginary part of the numeric data in the MATLAB array. This subelement is only present if one or more of the numeric values in the MATLAB array is a complex number (if the complex bit is set in Array Flags). The data type of the values can be any of the numeric data types listed in Table 1-1, MAT-File Data Types, on page 1-9.

Note When reading a MAT-file, check the value of the Data Type field in the tag of Real Part and Imaginary Part subelements to identify the data type used to store data. Also note that MATLAB reads and writes these values in column-major order.

Automatic Compression of Numeric Data

MATLAB stores the numeric data in an array in double precision format. When MATLAB writes a numeric (or sparse) array to a MAT-file, it uses the smallest possible data type to store the data, both the real and imaginary parts.

For example, if MATLAB determines that the data stored in double precision format can actually be stored in an 8-bit format, it will use an 8-bit data type to store it in a MAT-file. Note, however, that if any of the numeric values in the array requires a 64-bit representation, MATLAB stores all of the data in a 64-bit data type. See "Compressed Data Element" on page 1-21 for an example.

When you create a MAT-file, compressing data is optional.

Note When MATLAB uses a smaller data type to store data in a MAT-file, the value of the Class field in the Array Flags subelement identifies the original MATLAB data type.

Examples of Numeric Array Data Elements

This section uses examples to illustrate both the compressed and uncompressed numeric array data element formats.

Uncompressed Data Element. Figure 1-7 shows how this 2-by-2 numeric array, `my_array`, is represented in a MAT-file.

```
my_array = [ 1.1+1.1i 2 ; 3 4 ]

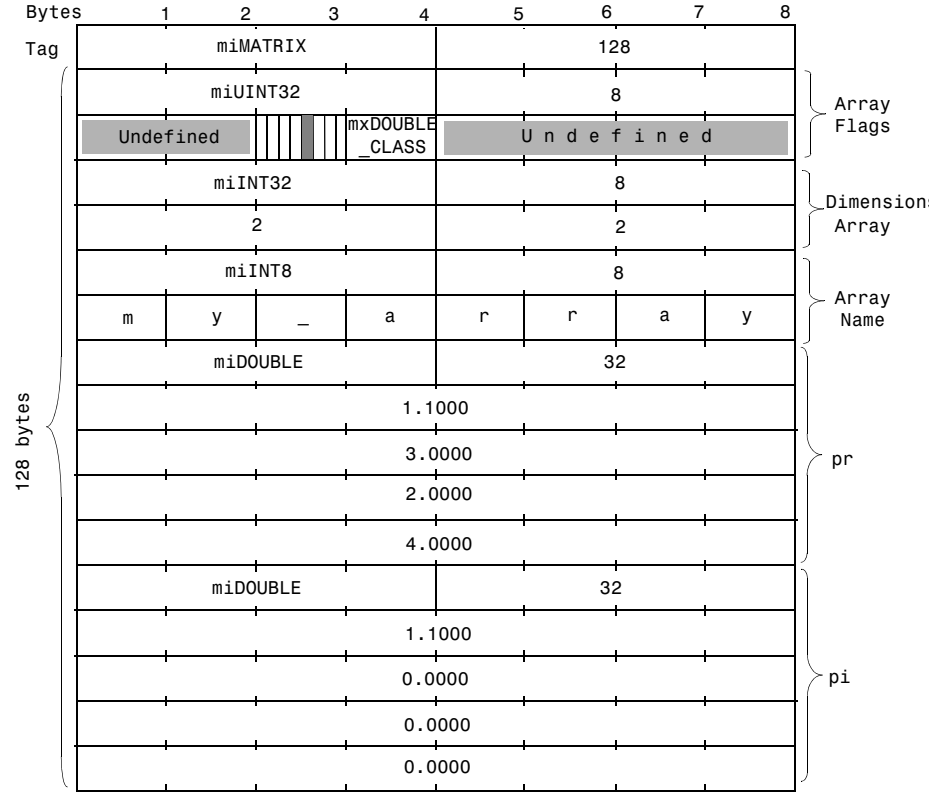
my_array =

     1.1000 + 1.1000i     2.0000
     3.0000               4.0000
```

In the figure, note:

- The data element includes five subelements. Because one of the numeric values in the array is a complex number, the complex bit flag in the Array Flags subelement is set and the Imaginary Part (`pi`) subelement is included.
- The value of the Number of Bytes field in the data element tag includes all the subelements, but not the eight bytes of the tag itself.

Figure 1-7: Example Numeric Array MAT-File Data Element



Compressed Data Element. Figure 1-8 shows how the three-dimensional numeric array in this example, `arr`, is represented in a MAT-file when compression is used to conserve storage space.

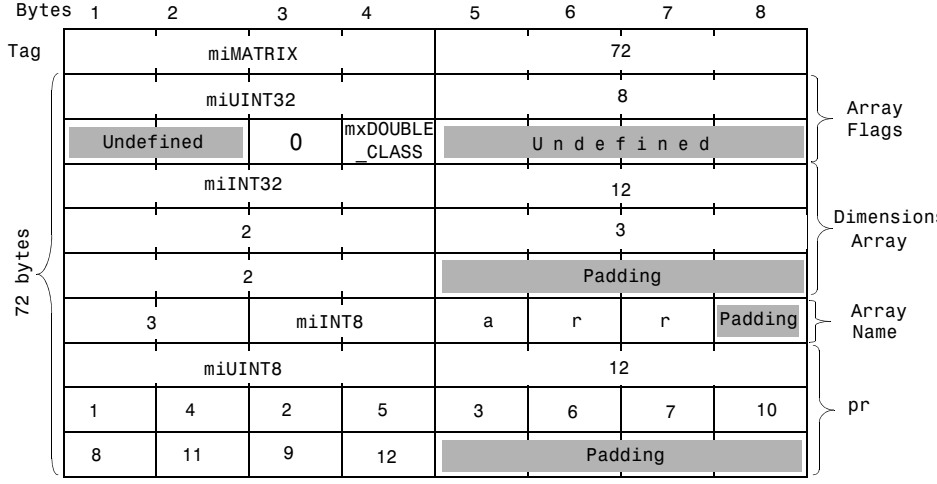
```
A = [ 1 2 3 ; 4 5 6 ];
B = [ 7 8 9 ; 10 11 12];
arr = cat(3,A,B)
arr(:,:,1) =
     1     2     3
     4     5     6

arr(:,:,2) =
     7     8     9
    10    11    12
```

In the figure, note:

- The Array Name subelement uses the compressed data element format.
- The numeric data in the array, stored in double precision format in MATLAB, is stored as 8-bit, unsigned values in the `pr` subelement. The Class field in the Array Flags subelement identifies the original MATLAB data type.

Figure 1-8: Example Numeric Array MAT-file Data Element (Compressed)



Sparse Array Data Element Format

A MAT-file data element representing a MATLAB sparse array is composed of six subelements and one optional subelement. Table 1-4 lists the subelements in the order in which they appear in the data element. The table lists the values of the Data Type and Number of Bytes fields of the tag for each subelement.

Table 1-4: Sparse Array Subelements with Tag Data

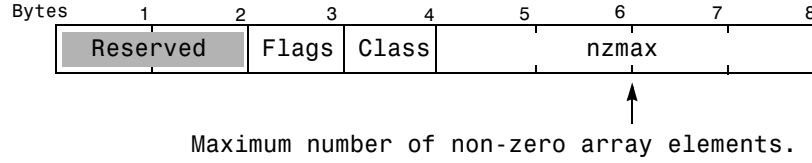
Subelement	Data Type	Number of Bytes
Array Flags	`miUINT32`	`2*size-of-Data-Type (8 bytes)`
Dimensions Array	`miINT32`	`number-of-dimensions*size-of-Data-Type` where `number-of-dimensions` can be 0, 1 or 2.
Array Name	`miINT8`	`number-of-characters*size-of-Data-Type`
Row Index (`ir`)	`miINT32`	`nzmax*size-of-Data-Type` (The `nzmax` value is stored in Array Flags.)
Column Index (`jc`)	`miINT32`	`(N+1)*sizeof(int32)` where `N` is the second element of the Dimensions array subelement.
Real part (`pr`)	Any numeric data type	`number-of-nonzero-values*size-of-Data-Type`
Imaginary part (`pi`) (Optional)	Any numeric data type	`number-of-nonzero-values*size-of-Data-Type`

Array Flags Subelement

This subelement identifies the MATLAB array type (class) represented by the data element and provides other information about the array. The Array Flags subelement is common to all array types.

Figure 1-9 shows the Array Flags format. For sparse arrays, this value also contains the maximum number of non-zero elements in the array (`nzmax`).

Figure 1-9: Array Flags Format for Sparse Arrays



Flag. For more information, see "Flags" on page 1-16.

Class. This field contains a value that identifies the MATLAB data type represented by the data element. For sparse arrays, Class contains the value `5` (`mxSPARSE_CLASS`). See "Class" on page 1-16 for more information.

Dimensions Array Subelement

This subelement specifies the size of each dimension of the array. This subelement is common to all array types. For more information, see "Dimensions Array Subelement" on page 1-17.

Note that MATLAB only supports two-dimensional sparse arrays.

Array Name Subelement

This subelement specifies the name assigned to the array. This subelement is common to all array types. For more information, see "Array Name Subelement" on page 1-18.

Row Index for Non-zero Values (ir) Subelement

This subelement specifies the row indices of the non-zero elements in the real part (`pr`) of the matrix data and the imaginary part (`pi`) of the matrix data, if present. This subelement is a series of 32-bit (`miINT32`) values.

Column Index for Non-Zero Values (jc) Subelement

This subelement contains column index information as a series of 32-bit (`miINT32`) values. For more information about what this subelement contains, see the *MATLAB Application Program Interface Guide*.

Real Part (pr) Subelement

This subelement contains the numeric data in the MATLAB array. If the array contains complex numbers (the complex bit in the Array Flags is set), this is the real part of the number.

Because MATLAB uses data compression to save storage space, the data type of the values can be any of the numeric data types listed in Table 1-1, MAT-File Data Types, on page 1-9. For more information, see "Automatic Compression of Numeric Data" on page 1-19.

Imaginary Part (pi) Subelement

This subelement contains the imaginary data in the array, if one or more of the numeric values in the MATLAB array is a complex number (if the complex bit is set in Array Flags).

Because MATLAB uses data compression to save storage space, the data type of the values can be any of the numeric data types listed in Table 1-1, MAT-File Data Types, on page 1-9. For more information, see "Automatic Compression of Numeric Data" on page 1-19.

Note You must check the value of the Data Type field in the tag of Real Part and Imaginary Part subelements to identify the type of the data. Also note that MATLAB reads and writes these values in column-major order.

Example Sparse Array

Figure 1-10 illustrates the MAT-file data element format of this 3-by-3 sparse matrix:

```
a = [ 1 2 3 ];
S = sparse(a,a,a+.5)

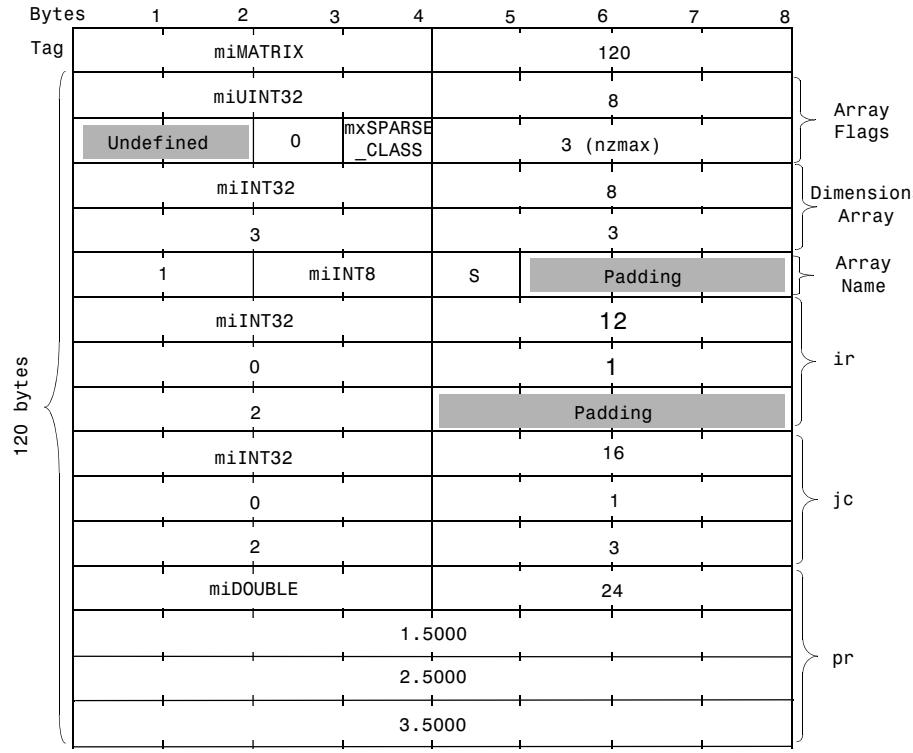
S =

   (1,1)        1.5000
   (2,2)        2.5000
   (3,3)        3.5000
```

In the figure, note:

- The data element contains six subelements.
- The value of the Number of Bytes field in the data element tag includes all the subelements, but not the eight bytes of the tag itself.
- Bytes 5 through 8 of the Array Flags subelement contain the maximum number of non-zero elements (`nzmax`) in the sparse array.
- The Array Name subelement uses the compressed data element format.

Figure 1-10: Example Sparse Array MAT-file Data Element



Cell Array Data Element Format

A MAT-file data element representing a MATLAB cell array is composed of four subelements. Table 1-5 lists the subelements in the order in which they appear in the data element. The table lists the values of the Data Type and Number of Bytes fields of the tag for each subelement.

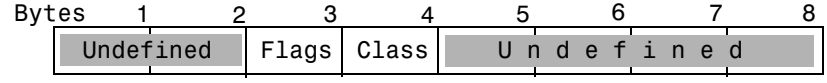
Table 1-5: Cell Array Subelements with Tag Data

Subelement	Data Type	Number of Bytes
Array Flags	`miUINT32`	`2*size-of-Data-Type (8 bytes)`
Dimensions Array	`miINT32`	`number-of-dimensions*size-of-Data-Type`
Array Name	`miINT8`	`number-of-characters*size-of-Data-Type`
Cells	Each cell is written in place as an `miMATRIX` element.	

Array Flags Subelement

This subelement identifies the MATLAB array type (class) represented by the data element and provides other information about the array. Figure 1-11 shows the Array Flags format. The Array Flags subelement is common to all array types.

Figure 1-11: Array Flags Format



Flags. See “Flags” on page 1-16 for more information.

Class. This field contains a value that identifies the MATLAB data type represented by the data element. For cell arrays, Class contains the value `1` (`mxCELL_CLASS`). For more information, see “Class” on page 1-16.

Dimensions Array Subelement

This subelement specifies the size of each dimension of the array. This subelement is common to all array types. For more information, see “Dimensions Array Subelement” on page 1-17.

Array Name Subelement

This subelement specifies the name assigned to the array. This subelement is common to all array types. For more information, see “Array Name Subelement” on page 1-18.

Cells Subelement

This subelement contains the value stored in a cell. These values are MATLAB arrays, represented using the `miMATRIX` format specific to the array type: numeric array, sparse array, structure, object or other cell array. See the appropriate section in this document for details about the MAT-file representation of a each of these array types. Cells are written in column-major order.

Example Cell Array

Figure 1-12 illustrates the MAT-file data element format of this cell array:

```
A = [ 1 2 3 ; 4 5 6 ]
A =
     1     2     3
     4     5     6

B = [ 7 8 9 ; 10 11 12 ]
B =
     7     8     9
    10    11    12

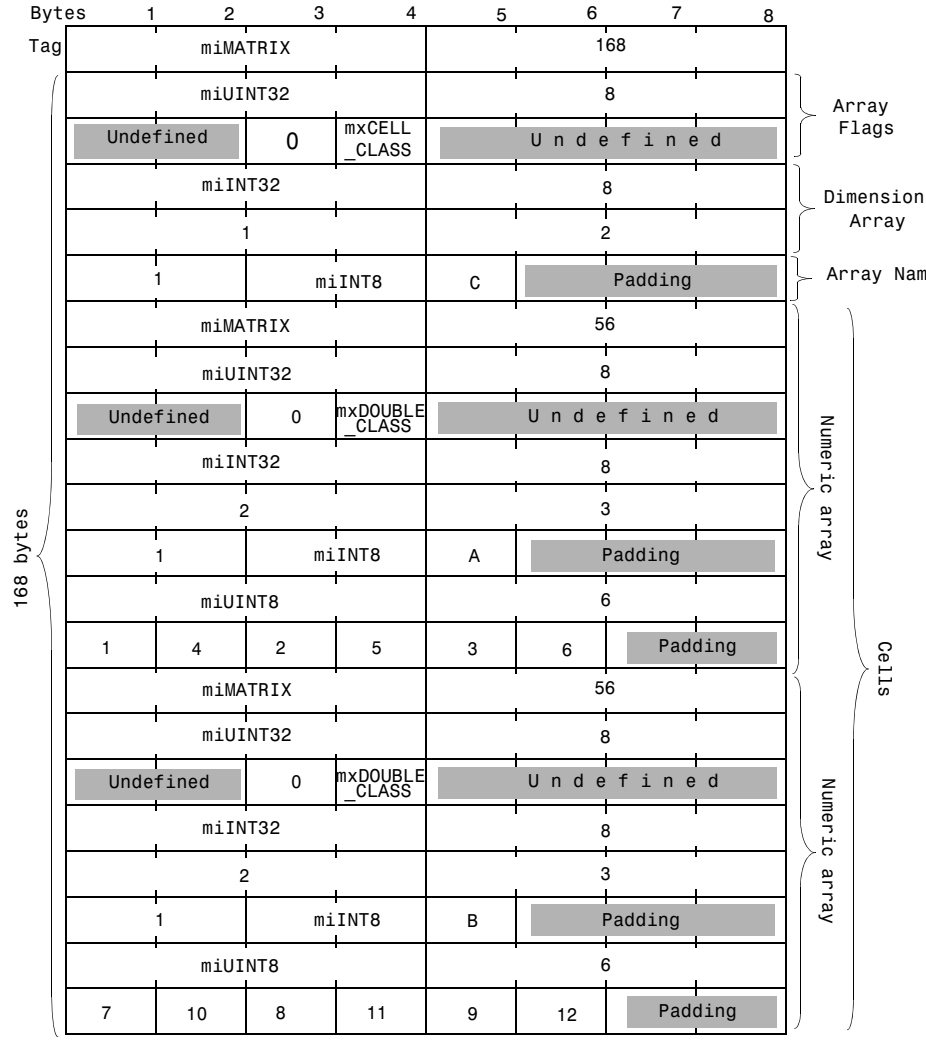
C = { A, B }
C =
   [2x3 double]     [2x3 double]
```

In the figure, note:

- The data element contains five subelements, the three common subelements; Array Flags, Dimensions and Array Name; and two cell subelements.
- The value of the Number of Bytes field in the data element tag includes all the subelements, but not the eight bytes of the tag itself.
- Each cell subelement is an `miMATRIX` type. In the example, each cell contains a numeric array. For more information about the format of these elements,

see “Numeric Array and Character Array Data Element Formats” on page 1-15.

Figure 1-12: Example Cell Array Data Element



Structure MAT-File Data Element Format

A MAT-file data element representing a MATLAB structure is composed of six subelements. Table 1-6 lists the subelements in the order in which they appear in the data element. The table lists the values of the Data Type and Number of Bytes fields of the tag for each subelement.

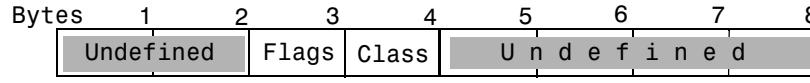
Table 1-6: Structure Subelements with Tag Data

Subelements	Data Type	Number of Bytes
Array Flags	`miUINT32`	`2*size-of-Data-Type (8 bytes)`
Dimensions Array	`miINT32`	`number-of-dimensions*size-of-Data-Type`
Array Name	`miINT8`	`number-of-characters*size-of-Data-Type`
Field Name Length	`miINT32`	`size-of-Data-Type (4 bytes)`
Field Names	`miINT8`	`number-of-fields*Field-Name-Length`
Fields	Each field is written in place as an array. Fields are written in column order.	

Array Flags Subelement

This subelement identifies the MATLAB array type (class) represented by the data element and provides other information about the array. Figure 1-13 shows the Array Flags format. The Array Flags subelement is common to all array types.

Figure 1-13: Array Flags Format



Flags. See “Flags” on page 1-16 for more information.

Class. This field contains a value that identifies the MATLAB data type represented by the data element. For structures, Class contains the value 2 (`mxSTRUCT_CLASS`). For more information, see “Class” on page 1-16.

Dimensions Array Subelement

This subelements Specifies the size of each dimension of the array. This subelement is common to all array types. For more information, see “Dimensions Array Subelement” on page 1-17.

Array Name Subelement

This subelement specifies the name assigned to the structure. This subelement is common to all array types. For more information, see “Array Name Subelement” on page 1-18.

Field Name Length Subelement

This subelement specifies the maximum length of a Field Name. MATLAB sets this limit to 32 (31 characters and a `NULL` terminator). In a MAT-file created by MATLAB, this subelement always uses the compressed data element format.

Field Names Subelement

This subelement specifies the name of each field in the structure as a series of 8-bit (`miINT8`) character arrays. The value of the Field Name Length subelement determines the length of each field name array (32 bytes). Field names must be `NULL`-terminated.

Fields Subelement

This subelement contains the value stored in a field. These values are MATLAB arrays, represented using the `miMATRIX` format specific to the array type: numeric array, sparse array, cell, object or other structure. See the appropriate section of this document for details about the MAT-file format of each of these array type. MATLAB reads and writes these fields in column-major order.

Example

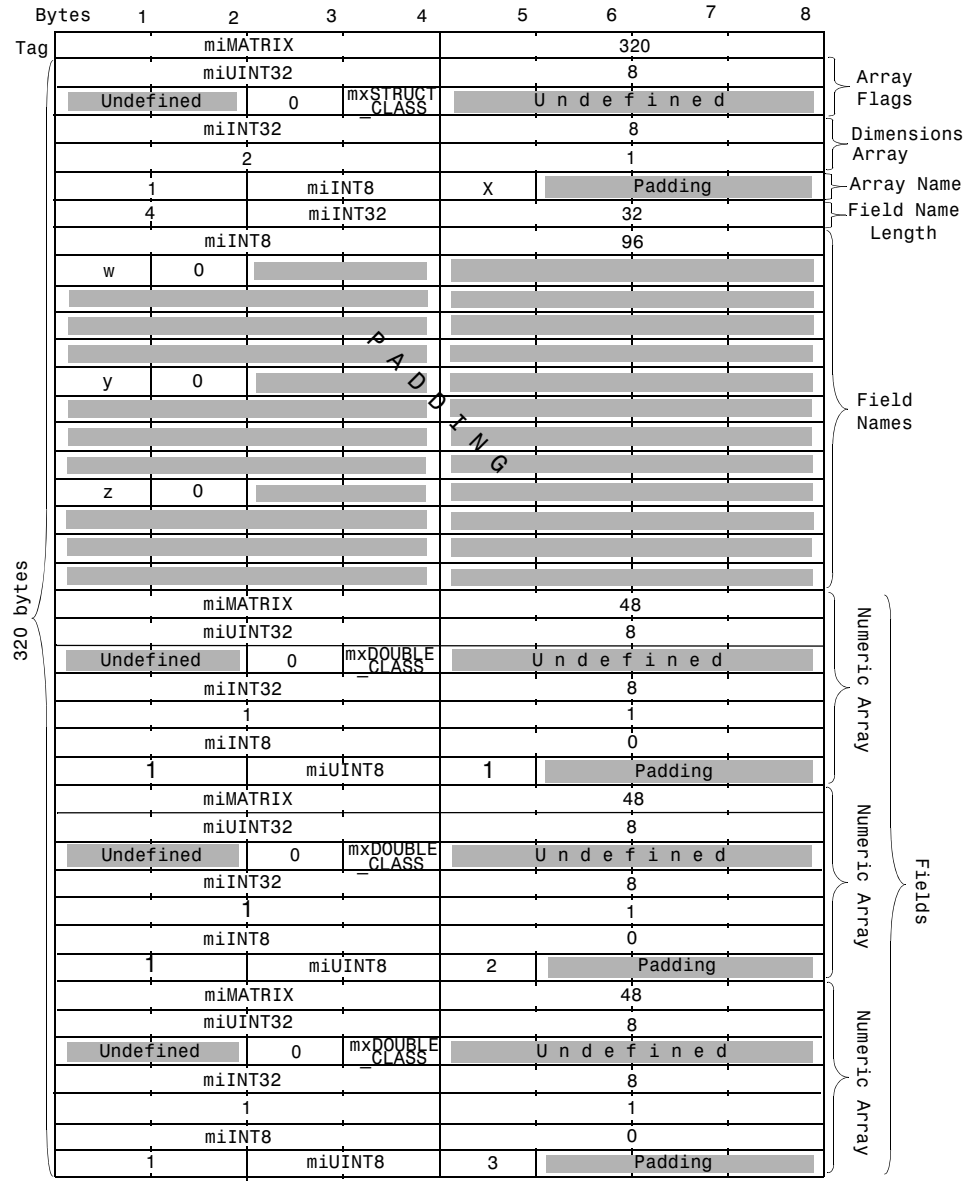
Figure 1-14 illustrates the MAT-file data element format for this MATLAB structure:

```
X.w = [1];
X.y = [2];
X.z = [3];
X
   X =
      w: 1
      y: 2
      z: 3
```

In the figure, note:

- The data element contains eight subelements: the three common subelements (Array Flags, Dimensions and Array Name) and five structure-specific subelements (Field Name Length, Field Names, and three Field subelements).
- The value of the Number of Bytes field in the data element tag includes all the subelements, but not the eight bytes of the tag itself.
- The Field Names subelement allocates 32 bytes of storage for each field name. A `NULL` terminator indicates the end of each field name.
- Each Field subelement is an `miMATRIX` data type. In the example, each field contains a numeric array. For more information about the format of these elements, see “Numeric Array and Character Array Data Element Formats” on page 1-15.
- Each of the numeric arrays contain zero-length Array Name subelements. The Field Names subelement contains the names of the numeric arrays.

Figure 1-14: Example Structure MAT-File Data Element



MATLAB Object MAT-File Data Element Format

A MAT-file data element representing a MATLAB object is composed of seven subelements. Table 1-7 lists the subelements in the order in which they appear in the data element. An object data element has the same subelements as a structure with the addition of the Class Name subelement.The table lists the values of the Data Type and Number of Bytes fields of the tag for each subelement.

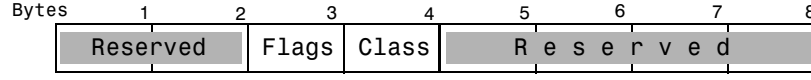
Table 1-7: MATLAB Object Subelements with Tag Data

Subelement	Data Type	Number of Bytes
Array Flags	`miUINT32`	`2*size-of-Data-Type (8 bytes)`
Dimensions Array	`miINT32`	`number-of-dimensions*size-of-Data-Type`
Array Name	`miINT8`	`number-of-characters*size-of-Data-Type`
Class Name	`miINT8`	`number-of-characters*size-of-Data-Type`
Field Name Length	`miINT32`	`size-of-Data-Type (4 bytes)`
Field Names	`miINT8`	`number-of-fields*Field-Name-Length`
Fields	Each field is written in place as an array.	

Array Flags Subelement

This subelement identifies the MATLAB array type (class) represented by the data element and provides other information about the array. Figure 1-15 shows the Array Flags format. The Array Flags subelement is common to all array types.

Figure 1-15: Array Flags Format



Flags. See “Flags” on page 1-16 for more information.

Class. This field contains a value that identifies the MATLAB data type represented by the data element. For objects, the Class byte has the value 3 (`mxOBJECT_CLASS`). For more information, see "Class" on page 1-16.

Dimensions Array Subelement

This subelement specifies the size of each dimension of the array. This subelement is common to all array types. For more information, see "Dimensions Array Subelement" on page 1-17.

Array Name Subelement

This subelement specifies the name assigned to the array. This subelement is common to all array types. For more information, see "Array Name Subelement" on page 1-18.

Class Name Subelement

This subelement specifies the name assigned to the object class. This subelement is an array of 8-bit characters (`miINT8`).

Field Name Length Subelement

This subelement specifies the maximum length of a Field Name. See "Field Name Length Subelement" on page 1-30 for more information.

Field Names Subelement

This subelement specifies the name of each field in the structure. See "Field Names Subelement" on page 1-30 for more information.

Fields Subelement

This subelement contains the value stored in a field. See "Fields Subelement" on page 1-30 for more information.

Example

Figure 1-16 illustrates how the MATLAB object in this example is represented in a MAT-file.

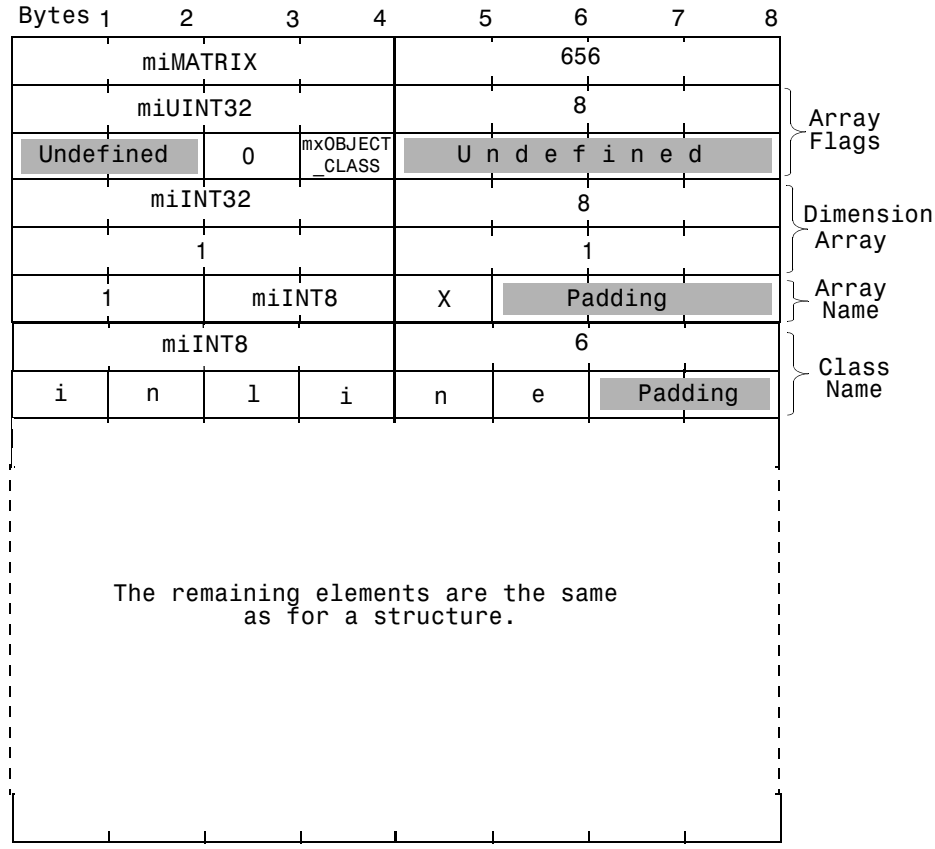
```
X = inline(`t^2');
```

The figure only shows the first four subelements of the object. For an example that shows the remaining subelements, see "Example" on page 1-31.

In the figure, note:

- The Array Flag Class byte is set to `mxOBJECT_CLASS`.
- The data element includes the Class Name subelement.

Figure 1-16: Example Object MAT-file Data Element



Level 4 MAT-File Format

Note This section is taken from the MATLAB V4.2 *External Interface Guide*, which is no longer available in printed form.

This section presents the internal structure of Level 4 MAT-files. This information is provided to enable users to read and write MAT-files on machines for which the MAT-file access routine library is not available. It is not needed when using the MAT-file subroutine library to read and write MAT-files, and we strongly advise that you do use the External Interface Library if it is available for all of the machines that you are working with.

A MAT-file may contain one or more matrices. The matrices are written sequentially on disk, with the bytes forming a continuous stream. Each matrix starts with a fixed-length 20-byte header that contains information describing certain attributes of the Matrix. The 20-byte header consists of five long (4-byte) integers:

Table 1-8: Level 4 MAT-File Matrix Header Format

Field	Description	
type	The `type` flag contains an integer whose decimal digits encode storage information. If the integer is represented as `MOPT` where `M` is the thousands digit, `O` is the hundreds digit, `P` is the tens digit, and `T` is the ones digit, then:	
	`M` indicates the numeric format of binary numbers on the machine that wrote the file. Use this table to determine the number to use for your machine:	
	0	IEEE Little Endian (PC, 386, 486, DEC Risc)
	1	IEEE Big Endian (Macintosh, SPARC, Apollo,SGI, HP 9000/300, other Motorola)
	2	VAX D-float
	3	VAX G-float
	4	Cray

Table 1-8: Level 4 MAT-File Matrix Header Format (Continued)

	`O` is always 0 (zero) and is reserved for future use.	
	`P` indicates which format the data is stored in according to the following table:	
	0	double-precision (64-bit) floating point numbers
	1	single-precision (32-bit) floating point numbers
	2	32-bit signed integers
	3	16-bit signed integers
	4	16-bit unsigned integers
	5	8-bit unsigned integers
	The precision used by the `save` command depends on the size and type of each matrix. Matrices with any noninteger entries and matrices with 10,000 or fewer elements are saved in floating point formats requiring 8 bytes per real element. Matrices with all integer entries and more than 10,000 elements are saved in the following formats, requiring fewer bytes per element.	
	Element range	Bytes per element
	[0:255]	1
	[0:65535]	2
	[-32767:32767]	2
	[-2^31+1:2^31-1]	4
	other	8
	`T` indicates the matrix type according to the following table:	
	0	Numeric (Full) matrix
	1	Text matrix
	2	Sparse matrix
	Note that the elements of a text matrix are stored as floating point numbers between 0 and 255 representing ASCII-encoded characters.	

Table 1-8: Level 4 MAT-File Matrix Header Format (Continued)

mrows	The row dimension contains an integer with the number of rows in the matrix.
`ncols`	The column dimension contains an integer with the number of columns in the matrix.
imagf	The imaginary flag is an integer whose value is either 0 or 1. If 1, then the matrix has an imaginary part. If 0, there is only real data.
namlen	The name length contains an integer with 1 plus the length of the matrix name.

Immediately following the fixed length header is the data whose length is dependent on the variables in the fixed length header:

Table 1-9: Level 4 MAT-File Matrix Data Format

Field	Description
name	The matrix name consists of `namlen` ASCII bytes, the last one of which must be a `null` character (`'\0'`).
real	Real part of the matrix consists of `mrows` * `ncols` numbers in the format specified by the `P` element of the type flag. The data is stored column-wise such that the second column follows the first column, etc.
imag	Imaginary part of the matrix, if any. If the imaginary flag `imagf` is nonzero, the imaginary part of a matrix is placed here. It is stored in the same manner as the real data.

This structure is repeated for each matrix stored in the file.

The following C language code demonstrates how to write a single matrix to disk in Level 1.0 MAT-file format.

```
#include <stdio.h>

main() {
typedef struct {
   long type;
   long mrows;
   long ncols;
   long imagf;
```

```
   long namelen;
   } Fmatrix;

char *pname;
double *pr;
double *pi;
Fmatrix x;
int mn;
FILE *fp;

double real_data = 1.0;
double imag_data = 2.0;

fp = fopen("mymatfile.mat", "wb");
if (fp != NULL) {
   pname = "x";
   x.type = 1000;
   x.mrows = 1;
   x.ncols = 1;
   x.imagf = 1;
   x.namelen = 2;

   pr = &real_data;
   pi = &imag_data;

   fwrite(&x, sizeof(Fmatrix), 1, fp);
   fwrite(pname, sizeof(char), x.namelen, fp);

   mn = x.mrows *x.ncols;
   fwrite(pr, sizeof(double), mn, fp);

   if(x.imagf)
      fwrite(pi, sizeof(double), mn, fp);
   }

else
   printf("File could not be opened.\n");

fclose(fp);
}
```

Again, we strongly advise against using this approach, and recommend that you instead use the MAT-file access routines provided in the External Interface Library. You will need to write your own C code as shown above only if you do not have the MAT-file access routines for the particular platform on which you need to read and write MAT-files.

Matrices and Linear Algebra

Function Summary

The linear algebra functions are located in the MATLAB `matfun` directory.

There are three columns in this table, but only four entries in the first column. The entries in the first column divide the functions into the categories of matrix analysis, linear equations, eigenvalues and singular values, and matrix functions.

Function Summary

Category	Function	Description
Matrix analysis	`norm`	Matrix or vector norm
	`normest`	Estimate the matrix 2-norm
	`rank`	Matrix rank
	`det`	Determinant
	`trace`	Sum of diagonal elements
	`null`	Null space
	`orth`	Orthogonalization
	`rref`	Reduced row echelon form
	`subspace`	Angle between two subspaces

Function Summary (Continued)

Category	Function	Description
Linear equations	\ and /	Linear equation solution
	inv	Matrix inverse
	cond	Condition number for inversion.
	condest	1-norm condition number estimate
	chol	Cholesky factorization
	cholinc	Incomplete Cholesky factorization
	linsolve	Solve a system of linear equations
	lu	LU factorization
	ilu	Incomplete LU factorization
	luinc	Incomplete LU factorization
	qr	Orthogonal-triangular decomposition
	lsqnonneg	Nonnegative least-squares
	pinv	Pseudoinverse
	lscov	Least squares with known covariance

Function Summary (Continued)

Category	Function	Description
Eigenvalues and singular values	`eig`	Eigenvalues and eigenvectors
	`svd`	Singular value decomposition
	`eigs`	A few eigenvalues
	`svds`	A few singular values
	`poly`	Characteristic polynomial
	`polyeig`	Polynomial eigenvalue problem
	`condeig`	Condition number for eigenvalues
	`hess`	Hessenberg form
	`qz`	QZ factorization

Matrices in MATLAB

In this section...

Creating Matrices

Informally, the terms matrix and array are often used interchangeably. More precisely, a matrix is a two-dimensional rectangular array of real or complex numbers that represents a linear transformation. The linear algebraic operations defined on matrices have found applications in a wide variety of technical fields. (The optional Symbolic Math Toolbox extends the capabilities of MATLAB to operations on various types of nonnumeric matrices.)

MATLAB has dozens of functions that create different kinds of matrices. Two of them can be used to create a pair of 3-by-3 example matrices for use throughout this chapter. The first example is symmetric:

```
A = pascal(3)

A =
       1     1     1
       1     2     3
       1     3     6
```

The second example is not symmetric:

```
B = magic(3)

B =
```

```
     8     1     6
     3     5     7
     4     9     2
```

Another example is a 3-by-2 rectangular matrix of random integers:

```
C = fix(10*rand(3,2))

C =
     9     4
     2     8
     6     7
```

A column vector is an *m*-by-1 matrix, a row vector is a 1-by-*n* matrix and a scalar is a 1-by-1 matrix. The statements

```
u = [3; 1; 4]

v = [2 0 -1]

s = 7
```

produce a column vector, a row vector, and a scalar:

```
u =
     3
     1
     4

v =
     2     0    -1

s =
     7
```

For more information about creating and working with matrices, see “Data Structures” in the MATLAB Programming documentation.

Adding and Subtracting Matrices

Addition and subtraction of matrices is defined just as it is for arrays, element-by-element. Adding `A` to `B` and then subtracting `A` from the result recovers `B`:

```
A = pascal(3);
B = magic(3);
X = A + B

X =
       9     2     7
       4     7    10
       5    12     8

Y = X - A

Y =
       8     1     6
       3     5     7
       4     9     2
```

Addition and subtraction require both matrices to have the same dimension, or one of them be a scalar. If the dimensions are incompatible, an error results:

```
C = fix(10*rand(3,2))
X = A + C
Error using ==> +
Matrix dimensions must agree.

w = v + s

w =
       9     7     6
```

Vector Products and Transpose

A row vector and a column vector of the same length can be multiplied in either order. The result is either a scalar, the *inner* product, or a matrix, the outer product:

```
u = [3; 1; 4];
```

```
v = [2 0 -1];
x = v*u

x =
       2

X = u*v

X =
       6     0     -3
       2     0     -1
       8     0     -4
```

For real matrices, the *transpose* operation interchanges a_{ij} and a_{ji}. MATLAB uses the apostrophe operator (`'`) to perform a complex conjugate transpose, and the dot-apostrophe operator (`.'`) to transpose without conjugation. For matrices containing all real elements, the two operators return the same result.

The example matrix `A` is *symmetric*, so `A'` is equal to `A`. But `B` is not symmetric:

```
B = magic(3);
X = B'

X =
       8     3     4
       1     5     9
       6     7     2
```

Transposition turns a row vector into a column vector:

```
x = v'

x =
       2
       0
      -1
```

If `x` and `y` are both real column vectors, the product `x*y` is not defined, but the two products

```
x'*y
```

and

```
y'*x
```

are the same scalar. This quantity is used so frequently, it has three different names: *inner* product, *scalar* product, or *dot* product.

For a complex vector or matrix, `z`, the quantity `z'` not only transposes the vector or matrix, but also converts each complex element to its complex conjugate. That is, the sign of the imaginary part of each complex element is changed. So if

```
z = [1+2i 7-3i 3+4i; 6-2i 9i 4+7i]
z =
   1.0000 + 2.0000i   7.0000 - 3.0000i   3.0000 + 4.0000i
   6.0000 - 2.0000i        0 + 9.0000i   4.0000 + 7.0000i
```

then

```
z'
ans =
   1.0000 - 2.0000i   6.0000 + 2.0000i
   7.0000 + 3.0000i        0 - 9.0000i
   3.0000 - 4.0000i   4.0000 - 7.0000i
```

The unconjugated complex transpose, where the complex part of each element retains its sign, is denoted by `z.'`:

```
z.'
ans =
   1.0000 + 2.0000i   6.0000 - 2.0000i
   7.0000 - 3.0000i        0 + 9.0000i
   3.0000 + 4.0000i   4.0000 + 7.0000i
```

For complex vectors, the two scalar products `x'*y` and `y'*x` are complex conjugates of each other and the scalar product `x'*x` of a complex vector with itself is real.

Multiplying Matrices

Multiplication of matrices is defined in a way that reflects composition of the underlying linear transformations and allows compact representation of systems of simultaneous linear equations. The matrix product $C = AB$ is defined when the column dimension of A is equal to the row dimension of B, or when one of them is a scalar. If A is m-by-p and B is p-by-n, their product C is m-by-n. The product can actually be defined using MATLAB `for` loops, `colon` notation, and vector dot products:

```
A = pascal(3);
B = magic(3);
m = 3; n = 3;
for i = 1:m
     for j = 1:n
        C(i,j) = A(i,:)*B(:,j);
     end
end
```

MATLAB uses a single asterisk to denote matrix multiplication. The next two examples illustrate the fact that matrix multiplication is not commutative; AB is usually not equal to BA:

```
X = A*B

X =
      15    15    15
      26    38    26
      41    70    39

Y = B*A

Y =
      15    28    47
      15    34    60
      15    28    43
```

A matrix can be multiplied on the right by a column vector and on the left by a row vector:

```
u = [3; 1; 4];
```

```
x = A*u

x =
       8
      17
      30

v = [2 0 -1];
y = v*B

y =
      12    -7    10
```

Rectangular matrix multiplications must satisfy the dimension compatibility conditions:

```
C = fix(10*rand(3,2));
X = A*C

X =
      17    19
      31    41
      51    70

Y = C*A

Error using ==> *
Inner matrix dimensions must agree.
```

Anything can be multiplied by a scalar:

```
s = 7;
w = s*v

w =
      14     0    -7
```

The Identity Matrix

Generally accepted mathematical notation uses the capital letter I to denote identity matrices, matrices of various sizes with ones on the main diagonal

and zeros elsewhere. These matrices have the property that $AI = A$ and $IA = A$ whenever the dimensions are compatible. The original version of MATLAB could not use I for this purpose because it did not distinguish between uppercase and lowercase letters and i already served double duty as a subscript and as the complex unit. So an English language pun was introduced. The function

```
eye(m,n)
```

returns an *m*-by-*n* rectangular identity matrix and `eye(n)` returns an *n*-by-*n* square identity matrix.

The Kronecker Tensor Product

The Kronecker product, `kron(X,Y)`, of two matrices is the larger matrix formed from all possible products of the elements of `X` with those of `Y`. If `X` is *m*-by-*n* and `Y` is *p*-by-*q*, then `kron(X,Y)` is *mp*-by-*nq*. The elements are arranged in the following order:

```
[X(1,1)*Y  X(1,2)*Y  . . .  X(1,n)*Y
                     . . .
 X(m,1)*Y  X(m,2)*Y  . . .  X(m,n)*Y]
```

The Kronecker product is often used with matrices of zeros and ones to build up repeated copies of small matrices. For example, if `X` is the 2-by-2 matrix

```
X =
       1     2
       3     4
```

and `I = eye(2,2)` is the 2-by-2 identity matrix, then the two matrices

```
kron(X,I)
```

and

```
kron(I,X)
```

are

```
       1     0     2     0
       0     1     0     2
```

```
     3     0     4     0
     0     3     0     4
```

and

```
     1     2     0     0
     3     4     0     0
     0     0     1     2
     0     0     3     4
```

Vector and Matrix Norms

The p-norm of a vector x

$$\|x\|_p = \left(\sum |x_i|^p\right)^{1/p}$$

is computed by `norm(x,p)`. This is defined by any value of $p > 1$, but the most common values of p are 1, 2, and ∞. The default value is $p = 2$, which corresponds to *Euclidean length*:

```
v = [2 0 -1];
[norm(v,1) norm(v) norm(v,inf)]

ans =
      3.0000    2.2361    2.0000
```

The p-norm of a matrix A,

$$\|A\|_p = \max_x \frac{\|Ax\|_p}{\|x\|_p}$$

can be computed for $p = 1$, 2, and ∞ by `norm(A,p)`. Again, the default value is $p = 2$:

```
C = fix(10*rand(3,2));
[norm(C,1) norm(C) norm(C,inf)]

ans =
     19.0000   14.8015   13.0000
```

Solving Linear Systems of Equations

In this section...

Computational Considerations

One of the most important problems in technical computing is the solution of simultaneous linear equations. In matrix notation, this problem can be stated as follows.

Given two matrices A and B, does there exist a unique matrix X so that AX = B or XA = B?

It is instructive to consider a 1-by-1 example.

Does the equation

$$7x = 21$$

have a unique solution?

The answer, of course, is yes. The equation has the unique solution $x = 3$. The solution is easily obtained by division:

$$x = 21/7 = 3$$

The solution is *not* ordinarily obtained by computing the inverse of 7, that is $7^{-1} = 0.142857...$, and then multiplying 7^{-1} by 21. This would be more work and, if 7^{-1} is represented to a finite number of digits, less accurate. Similar considerations apply to sets of linear equations with more than one unknown; MATLAB solves such equations without computing the inverse of the matrix.

Although it is not standard mathematical notation, MATLAB uses the division terminology familiar in the scalar case to describe the solution of a general system of simultaneous equations. The two division symbols, *slash*, /, and *backslash*, \, are used for the two situations where the unknown matrix appears on the left or right of the coefficient matrix:

`X = A\B`	Denotes the solution to the matrix equation $AX = B$.
`X = B/A`	Denotes the solution to the matrix equation $XA = B$.

You can think of "dividing" both sides of the equation $AX = B$ or $XA = B$ by A. The coefficient matrix `A` is always in the "denominator."

The dimension compatibility conditions for `X = A\B` require the two matrices `A` and `B` to have the same number of rows. The solution `X` then has the same number of columns as `B` and its row dimension is equal to the column dimension of `A`. For `X = B/A`, the roles of rows and columns are interchanged.

In practice, linear equations of the form $AX = B$ occur more frequently than those of the form $XA = B$. Consequently, backslash is used far more frequently than slash. The remainder of this section concentrates on the backslash operator; the corresponding properties of the slash operator can be inferred from the identity

```
(B/A)' = (A'\B')
```

The coefficient matrix `A` need not be square. If `A` is m-by-n, there are three cases:

m = n	Square system. Seek an exact solution.
m > n	Overdetermined system. Find a least squares solution.
m < n	Underdetermined system. Find a basic solution with at most m nonzero components.

The backslash operator employs different algorithms to handle different kinds of coefficient matrices. The various cases, which are diagnosed automatically by examining the coefficient matrix, include

- Permutations of triangular matrices
- Symmetric, positive definite matrices
- Square, nonsingular matrices
- Rectangular, overdetermined systems
- Rectangular, underdetermined systems

General Solution

The general solution to a system of linear equations $AX = b$ describes all possible solutions. You can find the general solution by

1. Solving the corresponding homogeneous system $AX = 0$. Do this using the `null` command, by typing `null(A)`. This returns a basis for the solution space to $AX = 0$. Any solution is a linear combination of basis vectors.
2. Finding a particular solution to the non-homogeneous system $AX = b$.

You can then write any solution to $AX = b$ as the sum of the particular solution to $AX = b$, from step 2, plus a linear combination of the basis vectors from step 1.

The rest of this section describes how to use MATLAB to find a particular solution to $AX = b$, as in step 2.

Square Systems

The most common situation involves a square coefficient matrix `A` and a single right-hand side column vector `b`.

Nonsingular Coefficient Matrix

If the matrix `A` is nonsingular, the solution, `x = A\b`, is then the same size as `b`. For example,

```
A = pascal(3);
```

```
u = [3; 1; 4];
x = A\u

x =
      10
     -12
       5
```

It can be confirmed that `A*x` is exactly equal to `u`.

If `A` and `B` are square and the same size, then `X = A\B` is also that size:

```
B = magic(3);
X = A\B

X =
      19    -3    -1
     -17     4    13
       6     0    -6
```

It can be confirmed that `A*X` is exactly equal to `B`.

Both of these examples have exact, integer solutions. This is because the coefficient matrix was chosen to be `pascal(3)`, which has a determinant equal to one. A later section considers the effects of roundoff error inherent in more realistic computations.

Singular Coefficient Matrix

A square matrix A is singular if it does not have linearly independent columns. If A is singular, the solution to $AX = B$ either does not exist, or is not unique. The backslash operator, `A\B`, issues a warning if `A` is nearly singular and raises an error condition if it detects exact singularity.

If A is singular and $AX = b$ has a solution, you can find a particular solution that is not unique, by typing

```
P = pinv(A)*b
```

`P` is a pseudoinverse of A. If $AX = b$ does not have an exact solution, `pinv(A)` returns a least-squares solution.

For example,

```
A = [ 1     3     7
     -1     4     4
      1    10    18 ]
```

is singular, as you can verify by typing

```
det(A)

ans =
     0
```

Note For information about using `pinv` to solve systems with rectangular coefficient matrices, see "Pseudoinverses" on page 1-27.

Exact Solutions. For `b =[5;2;12]`, the equation $AX = b$ has an exact solution, given by

```
pinv(A)*b

ans =
    0.3850
   -0.1103
    0.7066
```

You can verify that `pinv(A)*b` is an exact solution by typing

```
A*pinv(A)*b

ans =
    5.0000
    2.0000
   12.0000
```

Least Squares Solutions. On the other hand, if `b = [3;6;0]`, then $AX = b$ does not have an exact solution. In this case, `pinv(A)*b` returns a least squares solution. If you type

```
A*pinv(A)*b

ans =
   -1.0000
    4.0000
    2.0000
```

you do not get back the original vector `b`.

You can determine whether $AX = b$ has an exact solution by finding the row reduced echelon form of the augmented matrix `[A b]`. To do so for this example, enter

```
rref([A b])
ans =
    1.0000         0    2.2857         0
         0    1.0000    1.5714         0
         0         0         0    1.0000
```

Since the bottom row contains all zeros except for the last entry, the equation does not have a solution. In this case, `pinv(A)` returns a least-squares solution.

Overdetermined Systems

Overdetermined systems of simultaneous linear equations are often encountered in various kinds of curve fitting to experimental data. Here is a hypothetical example. A quantity y is measured at several different values of time, t, to produce the following observations:

t	y
0.0	0.82
0.3	0.72
0.8	0.63

t	y
1.1	0.60
1.6	0.55
2.3	0.50

Enter the data into MATLAB with the statements

```
t = [0 .3 .8 1.1 1.6 2.3]';
y = [.82 .72 .63 .60 .55 .50]';
```

Try modeling the data with a decaying exponential function:

$$y(t) = c_1 + c_2 e^{-t}$$

The preceding equation says that the vector y should be approximated by a linear combination of two other vectors, one the constant vector containing all ones and the other the vector with components e^{-t}. The unknown coefficients, c_1 and c_2, can be computed by doing a least squares fit, which minimizes the sum of the squares of the deviations of the data from the model. There are six equations in two unknowns, represented by the 6-by-2 matrix:

```
E = [ones(size(t)) exp(-t)]

E =
      1.0000    1.0000
      1.0000    0.7408
      1.0000    0.4493
      1.0000    0.3329
      1.0000    0.2019
      1.0000    0.1003
```

Use the backslash operator to get the least squares solution:

```
c = E\y

c =
      0.4760
```

```
    0.3413
```

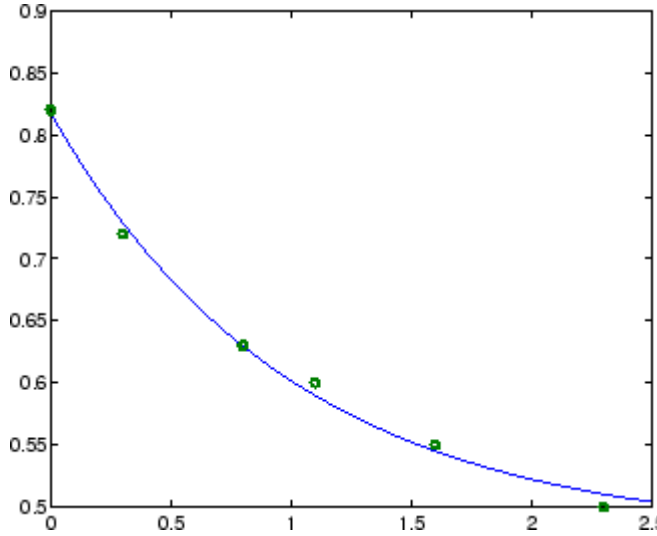
In other words, the least squares fit to the data is

$$y(t) = 0.4760 + 0.3413\ e^{-t}$$

The following statements evaluate the model at regularly spaced increments in t, and then plot the result, together with the original data:

```
T = (0:0.1:2.5)';
Y = [ones(size(T)) exp(-T)]*c;
plot(T,Y,'-',t,y,'o')
```

You can see that `E*c` is not exactly equal to `y`, but that the difference might well be less than measurement errors in the original data.



A rectangular matrix A is *rank deficient* if it does not have linearly independent columns. If A is rank deficient, the least squares solution to $AX = B$ is not unique. The backslash operator, `A\B`, issues a warning if `A` is rank deficient and produces a least squares solution that has at most `rank(A)` nonzeros.

Underdetermined Systems

Underdetermined linear systems involve more unknowns than equations. The solution to such underdetermined systems is not unique. The matrix left division operation in MATLAB finds a basic solution, which has at most `m` nonzero components.

Here is a small, random example:

```
R = [6 8 7 3; 3 5 4 1]
R =
     6     8     7     3
     3     5     4     1

rand('state', 0);
b = fix(10*rand(2,1))
b =
       9
       2
```

The linear system $Rx = b$ involves two equations in four unknowns. Since the coefficient matrix contains small integers, it is appropriate to use the `format` command to display the solution in *rational* format. The particular solution is obtained with

```
format rat
p = R\b
p =
       0
      -3/7
       0
      29/7
```

One of the nonzero components is `p(2)` because `R(:,2)` is the column of `R` with largest norm. The other nonzero component is `p(4)` because `R(:,4)` dominates after `R(:,2)` is eliminated.

The complete solution to the underdetermined system can be characterized by adding an arbitrary vector from the null space, which can be found using the `null` function with an option requesting a “rational” basis:

```
Z = null(R,'r')
Z =
      -1/2           -7/6
      -1/2            1/2
       1              0
       0              1
```

It can be confirmed that `R*Z` is zero and that any vector `x` where

```
x = p + Z*q
```

for an arbitrary vector `q` satisfies `R*x = b`.

Inverses and Determinants

In this section...

Overview

If A is square and nonsingular, the equations $AX = I$ and $XA = I$ have the same solution, X. This solution is called the inverse of A, is denoted by A^{-1}, and is computed by the function `inv`. The *determinant* of a matrix is useful in theoretical considerations and some types of symbolic computation, but its scaling and roundoff error properties make it far less satisfactory for numeric computation. Nevertheless, the function `det` computes the determinant of a square matrix:

```
A = pascal(3)

A =
       1     1     1
       1     2     3
       1     3     6
d = det(A)
X = inv(A)

d =
       1

X =
       3    -3     1
      -3     5    -2
       1    -2     1
```

Again, because `A` is symmetric, has integer elements, and has determinant equal to one, so does its inverse. On the other hand,

```
B = magic(3)

B =
```

```
       8     1     6
       3     5     7
       4     9     2
d = det(B)
X = inv(B)

d =
     -360

X =
      0.1472   -0.1444    0.0639
     -0.0611    0.0222    0.1056
     -0.0194    0.1889   -0.1028
```

Closer examination of the elements of `X`, or use of `format rat`, would reveal that they are integers divided by 360.

If `A` is square and nonsingular, then without roundoff error, `X = inv(A)*B` would theoretically be the same as `X = A\B` and `Y = B*inv(A)` would theoretically be the same as `Y = B/A`. But the computations involving the backslash and slash operators are preferable because they require less computer time, less memory, and have better error detection properties.

Pseudoinverses

Rectangular matrices do not have inverses or determinants. At least one of the equations $AX = I$ and $XA = I$ does not have a solution. A partial replacement for the inverse is provided by the *Moore-Penrose pseudoinverse*, which is computed by the `pinv` function:

```
format short
rand('state', 0);
C = fix(10*rand(3,2));
X = pinv(C)

X =
    0.1159   -0.0729    0.0171
   -0.0534    0.1152    0.0418
```

The matrix

```
Q = X*C

Q =
    1.0000    0.0000
    0.0000    1.0000
```

is the 2-by-2 identity, but the matrix

```
P = C*X

P =
    0.8293   -0.1958    0.3213
   -0.1958    0.7754    0.3685
    0.3213    0.3685    0.3952
```

is not the 3-by-3 identity. However, `P` acts like an identity on a portion of the space in the sense that `P` is symmetric, `P*C` is equal to `C` and `X*P` is equal to `X`.

Solving a Rank-Deficient System

If `A` is m-by-n with $m > n$ and full rank n, then each of the three statements

```
x = A\b
x = pinv(A)*b
x = inv(A'*A)*A'*b
```

theoretically computes the same least squares solution `x`, although the backslash operator does it faster.

However, if `A` does not have full rank, the solution to the least squares problem is not unique. There are many vectors `x` that minimize

```
norm(A*x -b)
```

The solution computed by `x = A\b` is a basic solution; it has at most r nonzero components, where r is the rank of `A`. The solution computed by `x = pinv(A)*b` is the minimal norm solution because it minimizes `norm(x)`. An attempt to compute a solution with `x = inv(A'*A)*A'*b` fails because `A'*A` is singular.

Here is an example that illustrates the various solutions:

```
A = [ 1  2  3
      4  5  6
      7  8  9
     10 11 12 ]
```

does not have full rank. Its second column is the average of the first and third columns. If

```
b = A(:,2)
```

is the second column, then an obvious solution to `A*x = b` is `x = [0 1 0]'`. But none of the approaches computes that `x`. The backslash operator gives

```
x = A\b

Warning: Rank deficient, rank = 2.

x =
      0.5000
      0
      0.5000
```

This solution has two nonzero components. The pseudoinverse approach gives

```
y = pinv(A)*b

y =
      0.3333
      0.3333
      0.3333
```

There is no warning about rank deficiency. But `norm(y) = 0.5774` is less than `norm(x) = 0.7071`. Finally

```
z = inv(A'*A)*A'*b
```

fails completely:

```
Warning: Matrix is singular to working precision.

z =
```

```
Inf
Inf
Inf
```

Cholesky, LU, and QR Factorizations

In this section...

About Matrix Factorizations

All three of these factorizations make use of *triangular* matrices where all the elements either above or below the diagonal are zero. Systems of linear equations involving triangular matrices are easily and quickly solved using either *forward* or *back substitution*.

Cholesky Factorization

The Cholesky factorization expresses a symmetric matrix as the product of a triangular matrix and its transpose

$$A = R'R$$

where R is an upper triangular matrix.

Not all symmetric matrices can be factored in this way; the matrices that have such a factorization are said to be positive definite. This implies that all the diagonal elements of A are positive and that the offdiagonal elements are "not too big." The Pascal matrices provide an interesting example. Throughout this chapter, the example matrix `A` has been the 3-by-3 Pascal matrix. Temporarily switch to the 6-by-6:

```
A = pascal(6)

A =
     1     1     1     1     1     1
     1     2     3     4     5     6
     1     3     6    10    15    21
     1     4    10    20    35    56
```

```
     1     5    15    35    70   126
     1     6    21    56   126   252
```

The elements of `A` are binomial coefficients. Each element is the sum of its north and west neighbors. The Cholesky factorization is

```
R = chol(A)

R =
     1     1     1     1     1     1
     0     1     2     3     4     5
     0     0     1     3     6    10
     0     0     0     1     4    10
     0     0     0     0     1     5
     0     0     0     0     0     1
```

The elements are again binomial coefficients. The fact that `R'*R` is equal to `A` demonstrates an identity involving sums of products of binomial coefficients.

Note The Cholesky factorization also applies to complex matrices. Any complex matrix which has a Cholesky factorization satisfies $A' = A$ and is said to be *Hermitian positive definite*.

The Cholesky factorization allows the linear system

$$Ax = b$$

to be replaced by

$$R'Rx = b$$

Because the backslash operator recognizes triangular systems, this can be solved in MATLAB quickly with

```
x = R\(R'\b)
```

If `A` is n-by-n, the computational complexity of `chol(A)` is $O(n^3)$, but the complexity of the subsequent backslash solutions is only $O(n^2)$.

LU Factorization

LU factorization, or Gaussian elimination, expresses any square matrix A as the product of a permutation of a lower triangular matrix and an upper triangular matrix

$$A = LU$$

where L is a permutation of a lower triangular matrix with ones on its diagonal and U is an upper triangular matrix.

The permutations are necessary for both theoretical and computational reasons. The matrix

$$\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

cannot be expressed as the product of triangular matrices without interchanging its two rows. Although the matrix

$$\begin{bmatrix} \varepsilon & 1 \\ 1 & 0 \end{bmatrix}$$

can be expressed as the product of triangular matrices, when ε is small the elements in the factors are large and magnify errors, so even though the permutations are not strictly necessary, they are desirable. Partial pivoting ensures that the elements of L are bounded by one in magnitude and that the elements of U are not much larger than those of A.

For example

```
[L,U] = lu(B)

L =
    1.0000         0         0
    0.3750    0.5441    1.0000
    0.5000    1.0000         0

U =
    8.0000    1.0000    6.0000
```

```
     0    8.5000   -1.0000
     0         0    5.2941
```

The LU factorization of `A` allows the linear system

```
A*x = b
```

to be solved quickly with

```
x = U\(L\b)
```

Determinants and inverses are computed from the LU factorization using

```
det(A) = det(L)*det(U)
```

and

```
inv(A) = inv(U)*inv(L)
```

You can also compute the determinants using det(A) = `prod(diag(U))`, though the signs of the determinants may be reversed.

QR Factorization

An *orthogonal* matrix, or a matrix with orthonormal columns, is a real matrix whose columns all have unit length and are perpendicular to each other. If Q is orthogonal, then

$$Q'Q = 1$$

The simplest orthogonal matrices are two-dimensional coordinate rotations:

$$\begin{bmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{bmatrix}$$

For complex matrices, the corresponding term is *unitary*. Orthogonal and unitary matrices are desirable for numerical computation because they preserve length, preserve angles, and do not magnify errors.

The orthogonal, or QR, factorization expresses any rectangular matrix as the product of an orthogonal or unitary matrix and an upper triangular matrix. A column permutation may also be involved:

$$A = QR$$

or

$$AP = QR$$

where Q is orthogonal or unitary, R is upper triangular, and P is a permutation.

There are four variants of the QR factorization—full or economy size, and with or without column permutation.

Overdetermined linear systems involve a rectangular matrix with more rows than columns, that is m-by-n with $m > n$. The *full* size QR factorization produces a square, m-by-m orthogonal Q and a rectangular m-by-n upper triangular R:

```
[Q,R] = qr(C)

Q =
   -0.8182    0.3999   -0.4131
   -0.1818   -0.8616   -0.4739
   -0.5455   -0.3126    0.7777

R =
  -11.0000   -8.5455
         0   -7.4817
         0         0
```

In many cases, the last m - n columns of Q are not needed because they are multiplied by the zeros in the bottom portion of R. So the *economy* size QR factorization produces a rectangular, m-by-$n$$Q$ with orthonormal columns and a square n-by-n upper triangular R. For the 3-by-2 example, this is not much of a saving, but for larger, highly rectangular matrices, the savings in both time and memory can be quite important:

```
[Q,R] = qr(C,0)

Q =
    -0.8182    0.3999
    -0.1818   -0.8616
    -0.5455   -0.3126

R =
   -11.0000   -8.5455
          0   -7.4817
```

In contrast to the LU factorization, the QR factorization does not require any pivoting or permutations. But an optional column permutation, triggered by the presence of a third output argument, is useful for detecting singularity or rank deficiency. At each step of the factorization, the column of the remaining unfactored matrix with largest norm is used as the basis for that step. This ensures that the diagonal elements of R occur in decreasing order and that any linear dependence among the columns is almost certainly be revealed by examining these elements. For the small example given here, the second column of `C` has a larger norm than the first, so the two columns are exchanged:

```
[Q,R,P] = qr(C)

Q =
    -0.3522    0.8398   -0.4131
    -0.7044   -0.5285   -0.4739
    -0.6163    0.1241    0.7777

R =
   -11.3578   -8.2762
          0    7.2460
          0         0

P =
     0     1
     1     0
```

When the economy size and column permutations are combined, the third output argument is a permutation vector, rather than a permutation matrix:

```
[Q,R,p] = qr(C,0)

Q =
    -0.3522    0.8398
    -0.7044   -0.5285
    -0.6163    0.1241

R =
   -11.3578   -8.2762
          0    7.2460

p =
     2     1
```

The QR factorization transforms an overdetermined linear system into an equivalent triangular system. The expression

```
norm(A*x - b)
```

is equal to

```
norm(Q*R*x - b)
```

Multiplication by orthogonal matrices preserves the Euclidean norm, so this expression is also equal to

```
norm(R*x - y)
```

where `y = Q'*b`. Since the last m-n rows of R are zero, this expression breaks into two pieces:

```
norm(R(1:n,1:n)*x - y(1:n))
```

and

```
norm(y(n+1:m))
```

When `A` has full rank, it is possible to solve for `x` so that the first of these expressions is zero. Then the second expression gives the norm of the residual.

When A does not have full rank, the triangular structure of R makes it possible to find a basic solution to the least squares problem.

Matrix Powers and Exponentials

In this section...

Positive Integer Powers

If `A` is a square matrix and `p` is a positive integer, then `A^p` effectively multiplies `A` by itself `p-1` times. For example,

```
A = [1 1 1;1 2 3;1 3 6]

A =

     1     1     1
     1     2     3
     1     3     6

X = A^2

X =
     3     6    10
     6    14    25
    10    25    46
```

Inverse and Fractional Powers

If `A` is square and nonsingular, then `A^(-p)` effectively multiplies `inv(A)` by itself `p-1` times:

```
Y = A^(-3)

Y =

  145.0000 -207.0000   81.0000
```

```
  -207.0000  298.0000 -117.0000
    81.0000 -117.0000   46.0000
```

Fractional powers, like `A^(2/3)`, are also permitted; the results depend upon the distribution of the eigenvalues of the matrix.

Element-by-Element Powers

The `.^` operator produces element-by-element powers. For example,

```
X = A.^2

A =
     1     1     1
     1     4     9
     1     9    36
```

Exponentials

The function

```
sqrtm(A)
```

computes `A^(1/2)` by a more accurate algorithm. The `m` in `sqrtm` distinguishes this function from `sqrt(A)` which, like `A.^(1/2)`, does its job element-by-element.

A system of linear, constant coefficient, ordinary differential equations can be written

$$dx/dt = Ax$$

where $x = x(t)$ is a vector of functions of t and A is a matrix independent of t. The solution can be expressed in terms of the matrix exponential,

$$x(t) = e^{tA}x(0)$$

The function

```
expm(A)
```

computes the matrix exponential. An example is provided by the 3-by-3 coefficient matrix

```
A =
     0    -6    -1
     6     2   -16
    -5    20   -10
```

and the initial condition, $x(0)$

```
x0 =
     1
     1
     1
```

The matrix exponential is used to compute the solution, $x(t)$, to the differential equation at 101 points on the interval $0 \le t \le 1$ with

```
X = [];
for t = 0:.01:1
   X = [X expm(t*A)*x0];
end
```

A three-dimensional phase plane plot obtained with

```
plot3(X(1,:),X(2,:),X(3,:),'-o')
```

shows the solution spiraling in towards the origin. This behavior is related to the eigenvalues of the coefficient matrix, which are discussed in the next section.

Eigenvalues

In this section...

Eigenvalue Decomposition

An *eigenvalue* and *eigenvector* of a square matrix A are a scalar λ and a nonzero vector v that satisfy

$$Av = \lambda v$$

With the eigenvalues on the diagonal of a diagonal matrix Λ and the corresponding eigenvectors forming the columns of a matrix V, you have

$$AV = V\Lambda$$

If V is nonsingular, this becomes the eigenvalue decomposition

$$A = V\Lambda V^{-1}$$

A good example is provided by the coefficient matrix of the ordinary differential equation in the previous section:

```
A =
     0     -6     -1
     6      2    -16
    -5     20    -10
```

The statement

```
lambda = eig(A)
```

produces a column vector containing the eigenvalues. For this matrix, the eigenvalues are complex:

```
lambda =
     -3.0710
     -2.4645+17.6008i
     -2.4645-17.6008i
```

The real part of each of the eigenvalues is negative, so $e^{\lambda t}$ approaches zero as t increases. The nonzero imaginary part of two of the eigenvalues, $\pm\omega$, contributes the oscillatory component, $\sin(\omega t)$, to the solution of the differential equation.

With two output arguments, `eig` computes the eigenvectors and stores the eigenvalues in a diagonal matrix:

```
[V,D] = eig(A)

V =
  -0.8326         0.2003 - 0.1394i   0.2003 + 0.1394i
  -0.3553        -0.2110 - 0.6447i  -0.2110 + 0.6447i
  -0.4248        -0.6930            -0.6930

D =
  -3.0710                  0                  0
        0           -2.4645+17.6008i         0
        0                  0           -2.4645-17.6008i
```

The first eigenvector is real and the other two vectors are complex conjugates of each other. All three vectors are normalized to have Euclidean length, `norm(v,2)`, equal to one.

The matrix `V*D*inv(V)`, which can be written more succinctly as `V*D/V`, is within roundoff error of `A`. And, `inv(V)*A*V`, or `V\A*V`, is within roundoff error of `D`.

Defective Matrices

Some matrices do not have an eigenvector decomposition. These matrices are defective, or not diagonalizable. For example,

```
A = [ 6    12    19
     -9   -20   -33
```

```
        4     9    15 ]
```

For this matrix

```
[V,D] = eig(A)
```

produces

```
V =

   -0.4741   -0.4082   -0.4082
    0.8127    0.8165    0.8165
   -0.3386   -0.4082   -0.4082

D =

   -1.0000         0         0
         0    1.0000         0
         0         0    1.0000
```

There is a double eigenvalue at $\lambda = 1$. The second and third columns of `V` are the same. For this matrix, a full set of linearly independent eigenvectors does not exist.

The optional Symbolic Math Toolbox extends the capabilities of MATLAB by connecting to Maple, a powerful computer algebra system. One of the functions provided by the toolbox computes the Jordan Canonical Form. This is appropriate for matrices like the example given here, which is 3-by-3 and has exactly known, integer elements:

```
[X,J] = jordan(A)

X =
   -1.7500    1.5000    2.7500
    3.0000   -3.0000   -3.0000
   -1.2500    1.5000    1.2500

J =
    -1     0     0
     0     1     1
```

```
     0     0     1
```

The Jordan Canonical Form is an important theoretical concept, but it is not a reliable computational tool for larger matrices, or for matrices whose elements are subject to roundoff errors and other uncertainties.

Schur Decomposition in MATLAB Matrix Computations

The MATLAB advanced matrix computations do not require eigenvalue decompositions. They are based, instead, on the Schur decomposition

$$A = U S U^T$$

where U is an orthogonal matrix and S is a block upper triangular matrix with 1-by-1 and 2-by-2 blocks on the diagonal. The eigenvalues are revealed by the diagonal elements and blocks of S, while the columns of U provide a basis with much better numerical properties than a set of eigenvectors. The Schur decomposition of this defective example is

```
[U,S] = schur(A)

U =
   -0.4741    0.6648    0.5774
    0.8127    0.0782    0.5774
   -0.3386   -0.7430    0.5774

S =
   -1.0000   20.7846  -44.6948
         0    1.0000   -0.6096
         0         0    1.0000
```

The double eigenvalue is contained in the lower 2-by-2 block of `S`.

Note If `A` is complex, `schur` returns the complex Schur form, which is upper triangular with the eigenvalues of `A` on the diagonal.

Singular Value Decomposition

A *singular value* and corresponding singular vectors of a rectangular matrix A are a scalar σ and a pair of vectors u and v that satisfy

$$Av = \sigma u$$
$$A^T u = \sigma v$$

With the singular values on the diagonal of a diagonal matrix Σ and the corresponding singular vectors forming the columns of two orthogonal matrices U and V, you have

$$AV = U\Sigma$$
$$A^T U = V\Sigma$$

Since U and V are orthogonal, this becomes the singular value decomposition

$$A = U\Sigma V^T$$

The full singular value decomposition of an m-by-n matrix involves an m-by-m U, an m-by-n Σ, and an n-by-n V. In other words, U and V are both square and Σ is the same size as A. If A has many more rows than columns, the resulting U can be quite large, but most of its columns are multiplied by zeros in Σ. In this situation, the *economy* sized decomposition saves both time and storage by producing an m-by-n U, an n-by-n Σ and the same V.

The eigenvalue decomposition is the appropriate tool for analyzing a matrix when it represents a mapping from a vector space into itself, as it does for an ordinary differential equation. On the other hand, the singular value decomposition is the appropriate tool for analyzing a mapping from one vector space into another vector space, possibly with a different dimension. Most systems of simultaneous linear equations fall into this second category.

If A is square, symmetric, and positive definite, then its eigenvalue and singular value decompositions are the same. But, as A departs from symmetry and positive definiteness, the difference between the two decompositions increases. In particular, the singular value decomposition of a real matrix is always real, but the eigenvalue decomposition of a real, nonsymmetric matrix might be complex.

For the example matrix

```
A =
     9     4
     6     8
     2     7
```

the full singular value decomposition is

```
[U,S,V] = svd(A)
U =
    -0.6105    0.7174    0.3355
    -0.6646   -0.2336   -0.7098
    -0.4308   -0.6563    0.6194
S =
   14.9359         0
         0    5.1883
         0         0
V =
    -0.6925    0.7214
    -0.7214   -0.6925
```

You can verify that `U*S*V'` is equal to `A` to within roundoff error. For this small problem, the economy size decomposition is only slightly smaller:

```
[U,S,V] = svd(A,0)
U =
    -0.6105    0.7174
    -0.6646   -0.2336
    -0.4308   -0.6563
S =
   14.9359         0
         0    5.1883
V =
    -0.6925    0.7214
    -0.7214   -0.6925
```

Again, `U*S*V'` is equal to `A` to within roundoff error.

2

Polynomials and Interpolation

Polynomials

In this section...

Polynomial Function Summary

MATLAB provides functions for standard polynomial operations, such as polynomial roots, evaluation, and differentiation. In addition, there are functions for more advanced applications, such as curve fitting and partial fraction expansion.

The polynomial functions reside in the MATLAB `polyfun` directory.

Polynomial Function Summary

Function	Description
`conv`	Multiply polynomials
`deconv`	Divide polynomials
`poly`	Polynomial with specified roots
`polyder`	Polynomial derivative
`polyfit`	Polynomial curve fitting
`polyval`	Polynomial evaluation

Polynomial Function Summary (Continued)

Function	Description
`polyvalm`	Matrix polynomial evaluation
`residue`	Partial-fraction expansion (residues)
`roots`	Find polynomial roots

Symbolic Math Toolbox contains additional specialized support for polynomial operations.

Representing Polynomials

MATLAB represents polynomials as row vectors containing coefficients ordered by descending powers. For example, consider the equation

$$p(x) = x^3 - 2x - 5$$

This is the celebrated example Wallis used when he first represented Newton's method to the French Academy. To enter this polynomial into MATLAB, use

```
p = [1 0 -2 -5];
```

Polynomial Roots

The `roots` function calculates the roots of a polynomial:

```
r = roots(p)

r =
      2.0946
     -1.0473 +      1.1359i
     -1.0473 -      1.1359i
```

By convention, MATLAB stores roots in column vectors. The function `poly` returns to the polynomial coefficients:

```
p2 = poly(r)

p2 =
```

```
    1    8.8818e-16    -2    -5
```

`poly` and `roots` are inverse functions, up to ordering, scaling, and roundoff error.

Characteristic Polynomials

The `poly` function also computes the coefficients of the characteristic polynomial of a matrix:

```
A = [1.2 3 -0.9; 5 1.75 6; 9 0 1];
poly(A)

ans =
    1.0000    -3.9500    -1.8500  -163.2750
```

The roots of this polynomial, computed with `roots`, are the *characteristic roots*, or eigenvalues, of the matrix `A`. (Use `eig` to compute the eigenvalues of a matrix directly.)

Polynomial Evaluation

The `polyval` function evaluates a polynomial at a specified value. To evaluate `p` at $s = 5$, use

```
polyval(p,5)

ans =
   110
```

It is also possible to evaluate a polynomial in a matrix sense. In this case $p(s) = x^3 - 2x - 5$ becomes $p(X) = X^3 - 2X - 5I$, where X is a square matrix and I is the identity matrix. For example, create a square matrix `X` and evaluate the polynomial `p` at `X`:

```
X = [2 4 5; -1 0 3; 7 1 5];
Y = polyvalm(p,X)

Y =
   377   179   439
```

```
   111    81   136
   490   253   639
```

Convolution and Deconvolution

Polynomial multiplication and division correspond to the operations convolution and deconvolution. The functions `conv` and `deconv` implement these operations.

Consider the polynomials $a(s) = s^2 + 2s + 3$ and $b(s) = 4s^2 + 5s + 6$. To compute their product,

```
a = [1 2 3]; b = [4 5 6];
c = conv(a,b)

c =
     4    13    28    27    18
```

Use deconvolution to divide $a(s)$ back out of the product:

```
[q,r] = deconv(c,a)

q =
     4     5     6

r =
     0     0     0     0     0
```

Polynomial Derivatives

The `polyder` function computes the derivative of any polynomial. To obtain the derivative of the polynomial `p = [1 0 -2 -5]`,

```
q = polyder(p)

q =
     3     0    -2
```

`polyder` also computes the derivative of the product or quotient of two polynomials. For example, create two polynomials `a` and `b`:

```
a = [1 3 5];
b = [2 4 6];
```

Calculate the derivative of the product `a*b` by calling `polyder` with a single output argument:

```
c = polyder(a,b)

c =
     8    30    56    38
```

Calculate the derivative of the quotient `a/b` by calling `polyder` with two output arguments:

```
[q,d] = polyder(a,b)

q =
    -2    -8    -2

d =
     4    16    40    48    36
```

`q/d` is the result of the operation.

Polynomial Curve Fitting

`polyfit` finds the coefficients of a polynomial that fits a set of data in a least-squares sense:

```
p = polyfit(x,y,n)
```

`x` and `y` are vectors containing the *x* and *y* data to be fitted, and `n` is the degree of the polynomial to return. For example, consider the *x*-*y* test data

```
x = [1 2 3 4 5]; y = [5.5 43.1 128 290.7 498.4];
```

A third degree polynomial that approximately fits the data is

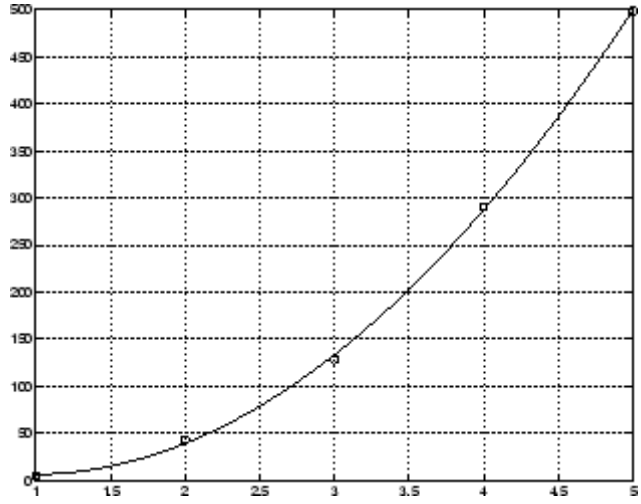
```
p = polyfit(x,y,3)

p =
```

```
    -0.1917   31.5821  -60.3262   35.3400
```

Compute the values of the `polyfit` estimate over a finer range, and plot the estimate over the real data values for comparison:

```
x2 = 1:.1:5;
y2 = polyval(p,x2);
plot(x,y,'o',x2,y2)
grid on
```



To use these functions in an application example, see “Linear Regression Analysis” in MATLAB Data Analysis.

Partial Fraction Expansion

`residue` finds the partial fraction expansion of the ratio of two polynomials. This is particularly useful for applications that represent systems in transfer function form. For polynomials b and a, if there are no multiple roots,

$$\frac{b(s)}{a(s)} = \frac{r_1}{s-p_1} + \frac{r_2}{s-p_2} + \ldots + \frac{r_n}{s-p_n} + k_s$$

where *r* is a column vector of residues, *p* is a column vector of pole locations, and *k* is a row vector of direct terms. Consider the transfer function

$$\frac{-4s+8}{s^2+6s+8}$$

```
b = [-4 8];
a = [1 6 8];
[r,p,k] = residue(b,a)

r =
   -12
     8

p =
    -4
    -2

k =
     []
```

Given three input arguments (`r`, `p`, and `k`), `residue` converts back to polynomial form:

```
[b2,a2] = residue(r,p,k)

b2 =
    -4     8
a2 =
     1     6     8
```

Interpolation

In this section...

Interpolation Function Summary

MATLAB provides a number of interpolation techniques that let you balance the smoothness of the data fit with speed of execution and memory usage.

The interpolation functions reside in the MATLAB `polyfun` directory.

Interpolation Function Summary

Function	Description
`griddata`	Data gridding and surface fitting
`griddata3`	Data gridding and hypersurface fitting for three-dimensional data
`griddatan`	Data gridding and hypersurface fitting (dimension >= 3)
`interp1`	One-dimensional interpolation (table lookup)
`interp2`	Two-dimensional interpolation (table lookup)
`interp3`	Three-dimensional interpolation (table lookup)

Interpolation Function Summary (Continued)

Function	Description
`interpft`	One-dimensional interpolation using FFT method
`interpn`	N-dimensional interpolation (table lookup)
`mkpp`	Make a piecewise polynomial
`pchip`	Piecewise Cubic Hermite Interpolating Polynomial (PCHIP)
`ppval`	Piecewise polynomial evaluation
`spline`	Cubic spline data interpolation
`unmkpp`	Piecewise polynomial details

One-Dimensional Interpolation

There are two kinds of one-dimensional interpolation in MATLAB:

- "Polynomial Interpolation" on page 2-10
- "FFT-Based Interpolation" on page 2-12

Polynomial Interpolation

The function `interp1` performs one-dimensional interpolation, an important operation for data analysis and curve fitting. This function uses polynomial techniques, fitting the supplied data with polynomial functions between data points and evaluating the appropriate function at the desired interpolation points. Its most general form is

```
yi = interp1(x,y,xi,method)
```

`y` is a vector containing the values of a function, and `x` is a vector of the same length containing the points for which the values in `y` are given. `xi` is a vector containing the points at which to interpolate. *`method`* is an optional string specifying an interpolation method:

- *Nearest neighbor interpolation* (`method = 'nearest'`). This method sets the value of an interpolated point to the value of the nearest existing data point.
- *Linear interpolation* (`method = 'linear'`). This method fits a different linear function between each pair of existing data points, and returns the value of the relevant function at the points specified by `xi`. This is the default method for the `interp1` function.
- *Cubic spline interpolation* (`method = 'spline'`). This method fits a different cubic function between each pair of existing data points, and uses the `spline` function to perform cubic spline interpolation at the data points.
- *Cubic interpolation* (`method = 'pchip'` or `'cubic'`). These methods are identical. They use the `pchip` function to perform piecewise cubic Hermite interpolation within the vectors `x` and `y`. These methods preserve monotonicity and the shape of the data.

If any element of `xi` is outside the interval spanned by `x`, the specified interpolation method is used for extrapolation. Alternatively, `yi = interp1(x,Y,xi,method,extrapval)` replaces extrapolated values with `extrapval`. `NaN` is often used for `extrapval`.

All methods work with nonuniformly spaced data.

Speed, Memory, and Smoothness Considerations. When choosing an interpolation method, keep in mind that some require more memory or longer computation time than others. However, you may need to trade off these resources to achieve the desired smoothness in the result:

- Nearest neighbor interpolation is the fastest method. However, it provides the worst results in terms of smoothness.
- Linear interpolation uses more memory than the nearest neighbor method, and requires slightly more execution time. Unlike nearest neighbor interpolation its results are continuous, but the slope changes at the vertex points.
- Cubic spline interpolation has the longest relative execution time, although it requires less memory than cubic interpolation. It produces the smoothest results of all the interpolation methods. You may obtain unexpected results,

however, if your input data is nonuniform and some points are much closer together than others.

- Cubic interpolation requires more memory and execution time than either the nearest neighbor or linear methods. However, both the interpolated data and its derivative are continuous.

The relative performance of each method holds true even for interpolation of two-dimensional or multidimensional data. For a graphical comparison of interpolation methods, see the section "Comparing Interpolation Methods" on page 2-13.

FFT-Based Interpolation

The function `interpft` performs one-dimensional interpolation using an FFT-based method. This method calculates the Fourier transform of a vector that contains the values of a periodic function. It then calculates the inverse Fourier transform using more points. Its form is

```
y = interpft(x,n)
```

`x` is a vector containing the values of a periodic function, sampled at equally spaced points. `n` is the number of equally spaced points to return.

Two-Dimensional Interpolation

The function `interp2` performs two-dimensional interpolation, an important operation for image processing and data visualization. Its most general form is

```
ZI = interp2(X,Y,Z,XI,YI,method)
```

`Z` is a rectangular array containing the values of a two-dimensional function, and `X` and `Y` are arrays of the same size containing the points for which the values in `Z` are given. `XI` and `YI` are matrices containing the points at which to interpolate the data. `method` is an optional string specifying an interpolation method.

There are three different interpolation methods for two-dimensional data:

- *Nearest neighbor interpolation* (`method = 'nearest'`). This method fits a piecewise constant surface through the data values. The value of an interpolated point is the value of the nearest point.
- *Bilinear interpolation* (`method = 'linear'`). This method fits a bilinear surface through existing data points. The value of an interpolated point is a combination of the values of the four closest points. This method is piecewise bilinear, and is faster and less memory-intensive than bicubic interpolation.
- *Bicubic interpolation* (`method = 'cubic'`). This method fits a bicubic surface through existing data points. The value of an interpolated point is a combination of the values of the sixteen closest points. This method is piecewise bicubic, and produces a much smoother surface than bilinear interpolation. This can be a key advantage for applications like image processing. Use bicubic interpolation when the interpolated data and its derivative must be continuous.

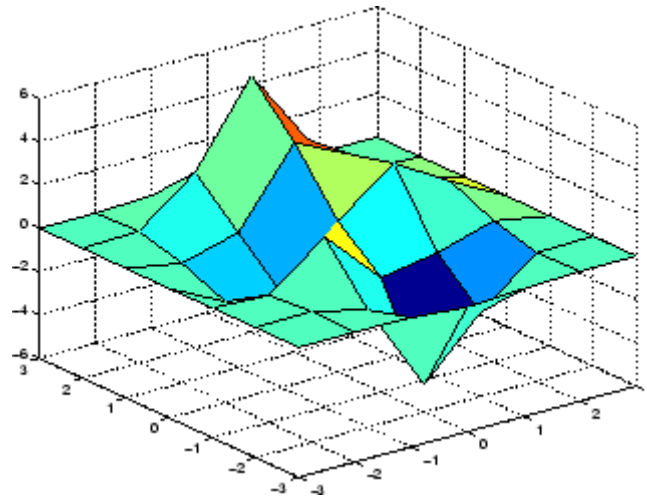
All of these methods require that `X` and `Y` be monotonic, that is, either always increasing or always decreasing from point to point. You should prepare these matrices using the `meshgrid` function, or else be sure that the "pattern" of the points emulates the output of `meshgrid`. In addition, each method automatically maps the input to an equally spaced domain before interpolating. If `X` and `Y` are already equally spaced, you can speed execution time by prepending an asterisk to the `method` string, for example, `'*cubic'`.

Comparing Interpolation Methods

This example compares two-dimensional interpolation methods on a 7-by-7 matrix of data:

1. Generate the peaks function at low resolution:

```
[x,y] = meshgrid(-3:1:3);
z = peaks(x,y);
surf(x,y,z)
```



2 Generate a finer mesh for interpolation:

```
[xi,yi] = meshgrid(-3:0.25:3);
```

3 Interpolate using nearest neighbor interpolation:

```
zi1 = interp2(x,y,z,xi,yi,'nearest');
```

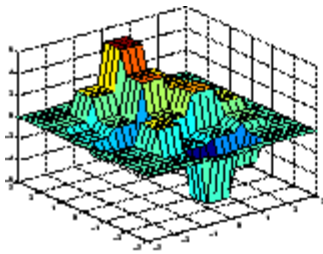
4 Interpolate using bilinear interpolation:

```
zi2 = interp2(x,y,z,xi,yi,'bilinear');
```

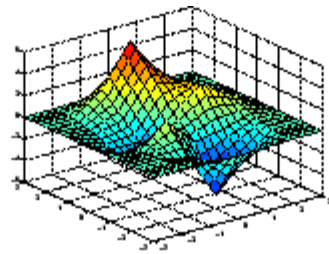
5 Interpolate using bicubic interpolation:

```
zi3 = interp2(x,y,z,xi,yi,'bicubic');
```

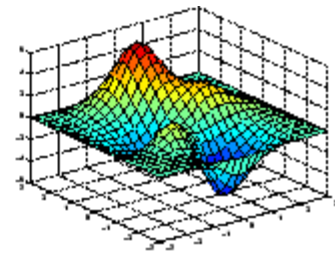
6 Compare the surface plots for the different interpolation methods.



```
surf(xi,yi,zi1)
% nearest
```

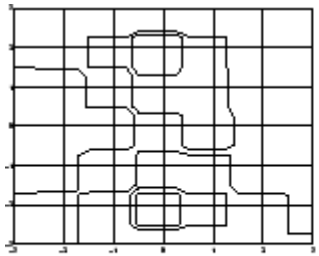


```
surf(xi,yi,zi2)
% bilinear
```

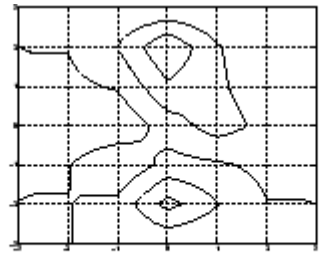


```
surf(xi,yi,zi3)
% bicubic
```

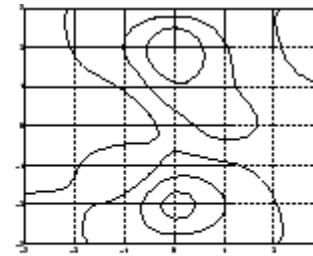
7 Compare the contour plots for the different interpolation methods.



```
contour(xi,yi,zi1)
% nearest
```



```
contour(xi,yi,zi2)
% bilinear
```



```
contour(xi,yi,zi3)
% bicubic
```

Notice that the bicubic method, in particular, produces smoother contours. This is not always the primary concern, however. For some applications, such as medical image processing, a method like nearest neighbor may be preferred because it doesn't generate any "new" data values.

Interpolation and Multidimensional Arrays

Several interpolation functions operate specifically on multidimensional data.

Interpolation Functions for Multidimensional Data

Function	Description
`interp3`	Three-dimensional data interpolation
`interpn`	Multidimensional data interpolation
`ndgrid`	Multidimensional data gridding (`elmat` directory)

This section discusses

Interpolation of Three-Dimensional Data

The function `interp3` performs three-dimensional interpolation, finding interpolated values between points of a three-dimensional set of samples `V`. You must specify a set of known data points:

- `X`, `Y`, and `Z` matrices specify the points for which values of `V` are given.
- A matrix `V` contains values corresponding to the points in `X`, `Y`, and `Z`.

The most general form for `interp3` is

```
VI = interp3(X,Y,Z,V,XI,YI,ZI,method)
```

`XI`, `YI`, and `ZI` are the points at which `interp3` interpolates values of `V`. For out-of-range values, `interp3` returns `NaN`.

There are three different interpolation methods for three-dimensional data:

- *Nearest neighbor interpolation* (`method = 'nearest'`). This method chooses the value of the nearest point.
- *Trilinear interpolation* (`method = 'linear'`). This method uses piecewise linear interpolation based on the values of the nearest eight points.

- *Tricubic interpolation* (`method = 'cubic'`). This method uses piecewise cubic interpolation based on the values of the nearest sixty-four points.

All of these methods require that `X`, `Y`, and `Z` be *monotonic*, that is, either always increasing or always decreasing in a particular direction. In addition, you should prepare these matrices using the `meshgrid` function, or else be sure that the "pattern" of the points emulates the output of `meshgrid`.

Each method automatically maps the input to an equally spaced domain before interpolating. If `x` is already equally spaced, you can speed execution time by prepending an asterisk to the `method` string, for example, `'*cubic'`.

Interpolation of Higher Dimensional Data

The function `interpn` performs multidimensional interpolation, finding interpolated values between points of a multidimensional set of samples `V`. The most general form for `interpn` is

```
VI = interpn(X1,X2,X3...,V,Y1,Y2,Y3,...,method)
```

`1`, `2`, `3`, `...` are matrices that specify the points for which values of `V` are given. `V` is a matrix that contains the values corresponding to these points. `1`, `2`, `3`, `...` are the points for which `interpn` returns interpolated values of `V`. For out-of-range values, `interpn` returns `NaN`.

`Y1`, `Y2`, `Y3`, `...` must be either arrays of the same size, or vectors. If they are vectors of different sizes, `interpn` passes them to `ndgrid` and then uses the resulting arrays.

There are three different interpolation methods for multidimensional data:

- *Nearest neighbor interpolation* (`method = 'nearest'`). This method chooses the value of the nearest point.
- *Linear interpolation* (`method = 'linear'`). This method uses piecewise linear interpolation based on the values of the nearest two points in each dimension.
- *Cubic interpolation* (`method = 'cubic'`). This method uses piecewise cubic interpolation based on the values of the nearest four points in each dimension.

All of these methods require that `X1`, `X2`,`X3` be monotonic. In addition, you should prepare these matrices using the `ndgrid` function, or else be sure that the "pattern" of the points emulates the output of `ndgrid`.

Each method automatically maps the input to an equally spaced domain before interpolating. If `X` is already equally spaced, you can speed execution time by prepending an asterisk to the `method` string; for example, `'*cubic'`.

Multidimensional Data Gridding

The `ndgrid` function generates arrays of data for multidimensional function evaluation and interpolation. `ndgrid` transforms the domain specified by a series of input vectors into a series of output arrays. The `i`th dimension of these output arrays are copies of the elements of input vector x_i.

The syntax for `ndgrid` is

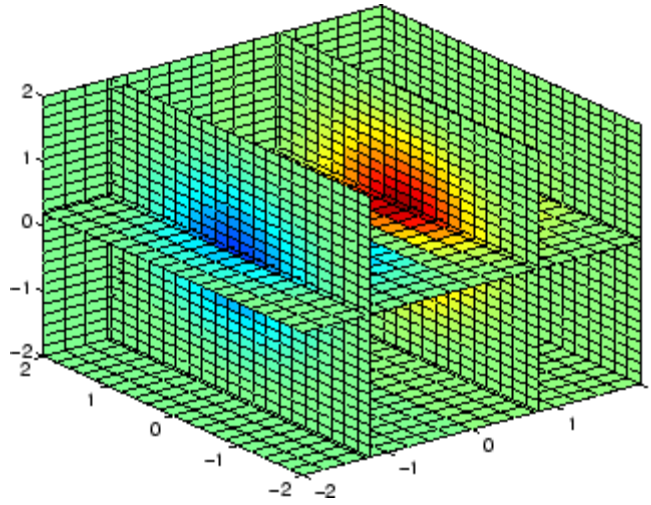
```
[X1,X2,X3,...] = ndgrid(x1,x2,x3,...)
```

For example, assume that you want to evaluate a function of three variables over a given range. Consider the function

$$z = x_2 e^{(-x_1^2 - x_2^2 - x_3^2)}$$

for $-2\pi \le x_1 \le 0$, $2\pi \le x_2 \le 4\pi$, and $0 \le x_3 \le 2\pi$. To evaluate and plot this function,

```
x1 = -2:0.2:2;
x2 = -2:0.25:2;
x3 = -2:0.16:2;
[X1,X2,X3] = ndgrid(x1,x2,x3);
z = X2.*exp(-X1.^2 -X2.^2 -X3.^2);
slice(X2,X1,X3,z,[-1.2 0.8 2],2,[-2 0.2])
```



Triangulation and Interpolation of Scattered Data

MATLAB provides routines that aid in the analysis of closest-point problems and geometric analysis.

Functions for Analysis of Closest-Point Problems and Geometric Analysis

Function	Description
`convhull`	Convex hull
`delaunay`	Delaunay triangulation
`delaunay3`	3-D Delaunay tessellation
`dsearch`	Nearest point search of Delaunay triangulation
`inpolygon`	True for points inside polygonal region
`polyarea`	Area of polygon
`rectint`	Area of intersection for two or more rectangles

Functions for Analysis of Closest-Point Problems and Geometric Analysis (Continued)

Function	Description
`tsearch`	Closest triangle search
`voronoi`	Voronoi diagram

This section applies the following techniques to the `seamount` data set supplied with MATLAB:

- "Convex Hulls" on page 2-20
- "Delaunay Triangulation" on page 2-21
- "Voronoi Diagrams" on page 2-26

See also "Tessellation and Interpolation of Scattered Data in Higher Dimensions" on page 2-27.

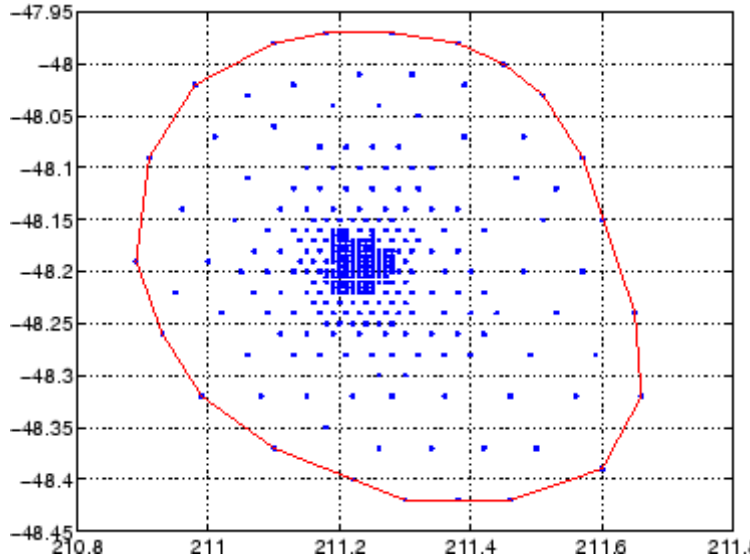
Note Examples in this section use the MATLAB `seamount` data set. Seamounts are underwater mountains. They are valuable sources of information about marine geology. The `seamount` data set represents the surface, in 1984, of the seamount designated LR148.8W located at 48.2°S, 148.8°W on the Louisville Ridge in the South Pacific. For more information about the data and its use, see Parker [2]. The `seamount` data set provides longitude (`x`), latitude (`y`) and depth-in-feet (`z`) data for 294 points on the seamount LR148.8W.

Convex Hulls

The `convhull` function returns the indices of the points in a data set that comprise the convex hull for the set. Use the `plot` function to plot the output of `convhull`.

This example loads the `seamount` data and plots the longitudinal (`x`) and latitudinal (`y`) data as a scatter plot. It then generates the convex hull and uses `plot` to plot the convex hull:

```
load seamount
plot(x,y,'.','markersize',10)
k = convhull(x,y);
hold on, plot(x(k),y(k),'-r'), hold off
grid on
```



Delaunay Triangulation

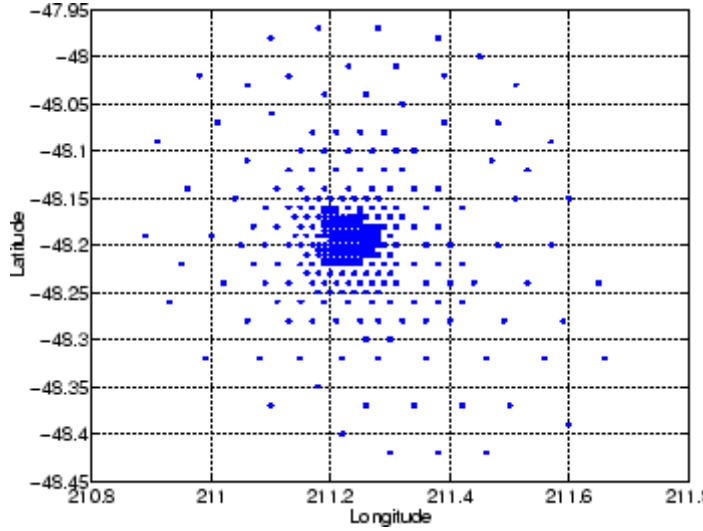
Given a set of coplanar data points, *Delaunay triangulation* is a set of lines connecting each point to its natural neighbors. The `delaunay` function returns a Delaunay triangulation as a set of triangles having the property that, for each triangle, the unique circle circumscribed about the triangle contains no data points.

You can use `triplot` to print the resulting triangles in two-dimensional space. You can also add data for a third dimension to the output of `delaunay` and plot the result as a surface with `trisurf`, or as a mesh with `trimesh`.

Plotting a Delaunay Triangulation. To try `delaunay`, load the `seamount` data set and view the longitude (`x`) and latitude (`y`) data as a scatter plot:

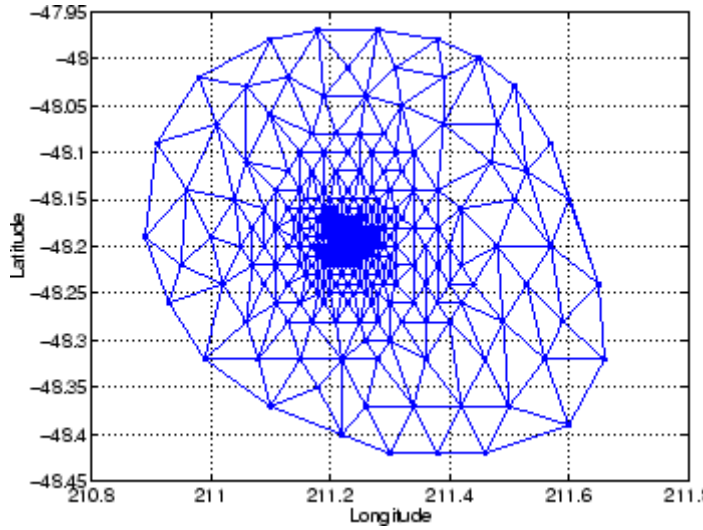
```
load seamount
```

```
plot(x,y,'.','markersize',12)
xlabel('Longitude'), ylabel('Latitude')
grid on
```



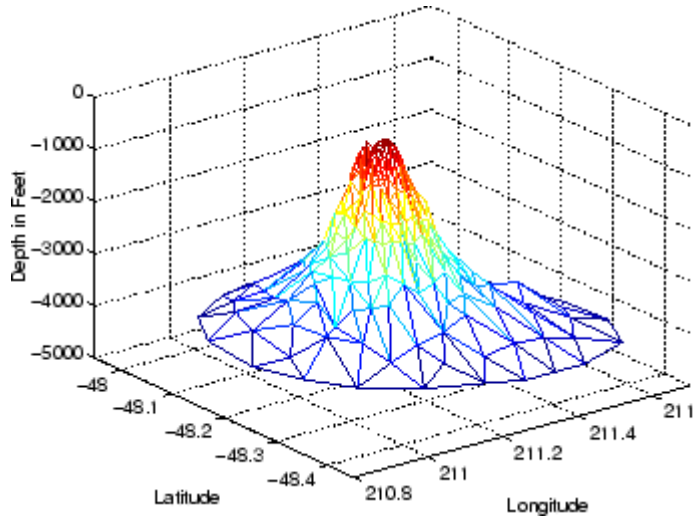
Apply Delaunay triangulation and use `triplot` to overplot the resulting triangles on the scatter plot:

```
tri = delaunay(x,y);
hold on, triplot(tri,x,y), hold off
```



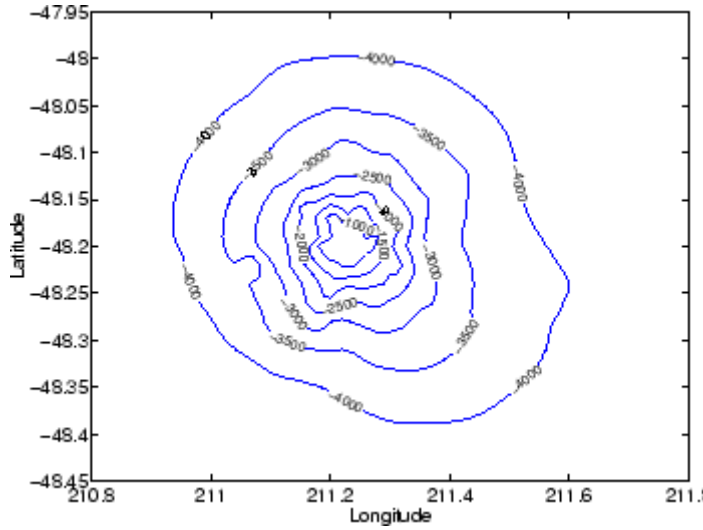
Mesh and Surface Plots. Add the depth data (`z`) from `seamount`, to the Delaunay triangulation, and use `trimesh` to produce a mesh in three-dimensional space. Similarly, you can use `trisurf` to produce a surface:

```
figure
hidden on
trimesh(tri,x,y,z)
grid on
xlabel('Longitude'); ylabel('Latitude'); zlabel('Depth in Feet')
```



Contour Plots. This code uses `meshgrid`, `griddata`, and `contour` to produce a contour plot of the `seamount` data:

```
figure
[xi,yi] = meshgrid(210.8:.01:211.8,-48.5:.01:-47.9);
zi = griddata(x,y,z,xi,yi,'cubic');
[c,h] = contour(xi,yi,zi,'b-');
clabel(c,h)
xlabel('Longitude'), ylabel('Latitude')
```



The arguments for `meshgrid` encompass the largest and smallest `x` and `y` values in the original `seamount` data. To obtain these values, use `min(x)`, `max(x)`, `min(y)`, and `max(y)`.

Closest-Point Searches. You can search through the Delaunay triangulation data with two functions:

- `dsearch` finds the indices of the `(x,y)` points in a Delaunay triangulation closest to the points you specify. This code searches for the point closest to (211.32, -48.35) in the triangulation of the `seamount` data.

```
xi = 211.32; yi = -48.35;
p = dsearch(x,y,tri,xi,yi);
[x(p), y(p)]

ans =
    211.3400   -48.3700
```

- `tsearch` finds the indices into the `delaunay` output that specify the enclosing triangles of the points you specify. This example uses the index of the enclosing triangle for the point (211.32, -48.35) to obtain the coordinates of the vertices of the triangle:

```
xi = 211.32; yi = -48.35;
t = tsearch(x,y,tri,xi,yi);
r = tri(t,:);
A = [x(r) y(r)]

A =
  211.2800  -48.3200
  211.3400  -48.3700
  211.3000  -48.3000
```

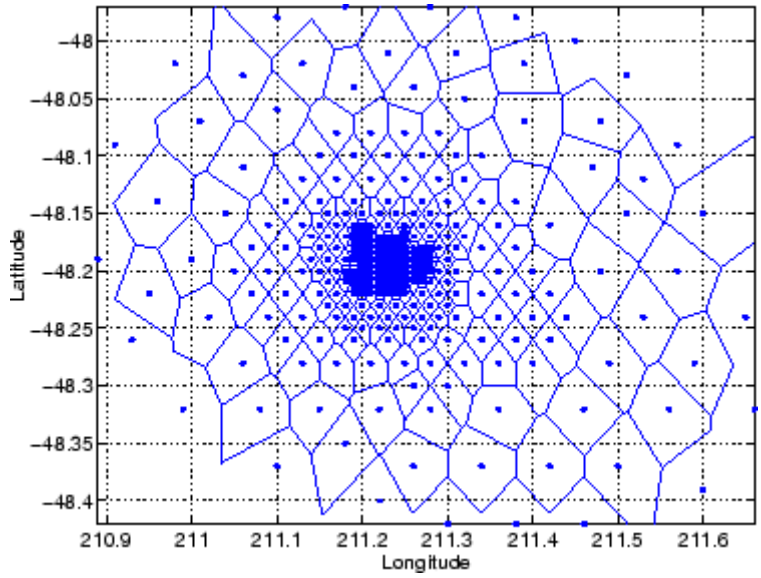
Voronoi Diagrams

Voronoi diagrams are a closest-point plotting technique related to Delaunay triangulation.

For each point in a set of coplanar points, you can draw a polygon that encloses all the intermediate points that are closer to that point than to any other point in the set. Such a polygon is called a *Voronoi polygon*, and the set of all Voronoi polygons for a given point set is called a *Voronoi diagram*.

The `voronoi` function can plot the cells of the Voronoi diagram, or return the vertices of the edges of the diagram. This example loads the `seamount` data, then uses the `voronoi` function to produce the Voronoi diagram for the longitudinal (`x`) and latitudinal (`y`) dimensions. Note that `voronoi` plots only the bounded cells of the Voronoi diagram:

```
load seamount
voronoi(x,y)
grid on
xlabel('Longitude'), ylabel('Latitude')
```



Note See the `voronoi` function for an example that uses the vertices of the edges to plot a Voronoi diagram.

Tessellation and Interpolation of Scattered Data in Higher Dimensions

Many applications in science, engineering, statistics, and mathematics require structures like convex hulls, Voronoi diagrams, and Delaunay tessellations. Using Qhull [1], MATLAB functions enable you to geometrically analyze data sets in any dimension.

Functions for Multidimensional Geometrical Analysis

Function	Description
`convhulln`	N-dimensional convex hull
`delaunayn`	N-dimensional Delaunay tessellation
`dsearchn`	N-dimensional nearest point search

Functions for Multidimensional Geometrical Analysis (Continued)

Function	Description
griddatan	N-dimensional data gridding and hypersurface fitting
tsearchn	N-dimensional closest simplex search
voronoin	N-dimensional Voronoi diagrams

This section demonstrates these geometric analysis techniques:

Convex Hulls

The convex hull of a data set in n-dimensional space is defined as the smallest convex region that contains the data set.

Computing a Convex Hull. The `convhulln` function returns the indices of the points in a data set that comprise the facets of the convex hull for the set. For example, suppose `X` is an 8-by-3 matrix that consists of the 8 vertices of a cube. The convex hull of `X` then consists of 12 facets:

```
d = [-1 1];
[x,y,z] = meshgrid(d,d,d);
X = [x(:),y(:),z(:)];       % 8 corner points of a cube
C = convhulln(X)

C =
     4     2     1
     3     4     1
     7     3     1
     5     7     1
     7     4     3
     4     7     8
     2     6     1
```

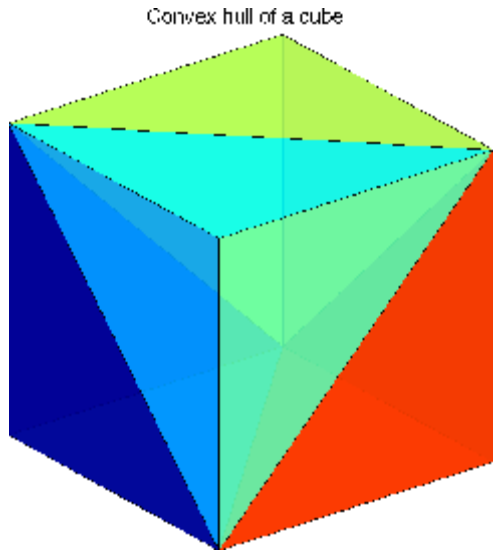
```
     6     5     1
     4     6     2
     6     4     8
     6     7     5
     7     6     8
```

Because the data is three-dimensional, the facets that make up the convex hull are triangles. The 12 rows of `C` represent 12 triangles. The elements of C are indices of points in `X`. For example, the first row, 3 1 5, means that the first triangle has `X(3,:)`, `X(1,:)`, and `X(5,:)` as its vertices.

For three-dimensional convex hulls, you can use `trisurf` to plot the output. However, using `patch` to plot the output gives you more control over the color of the facets. Note that you cannot plot `convhulln` output for `n > 3`.

This code plots the convex hull by drawing the triangles as three-dimensional patches:

```
figure, hold on
d = [1 2 3 1];      % Index into C column.
for i = 1:size(C,1) % Draw each triangle.
    j= C(i,d);      % Get the ith C to make a patch.
    h(i)=patch(X(j,1),X(j,2),X(j,3),i,'FaceAlpha',0.9);
end                 % 'FaceAlpha' is used to make it transparent.
hold off
view(3), axis equal, axis off
camorbit(90,-5);    % To view it from another angle
title('Convex hull of a cube')
```



Delaunay Tessellations

A Delaunay tessellation is a set of simplices with the property that, for each simplex, the unique sphere circumscribed about the simplex contains no data points. In two-dimensional space, a simplex is a triangle. In three-dimensional space, a simplex is a tetrahedron.

Computing a Delaunay Tessellation. The `delaunayn` function returns the indices of the points in a data set that comprise the simplices of an n-dimensional Delaunay tessellation of the data set.

This example uses the same `X` as in the convex hull example, i.e., the 8 corner points of a cube, with the addition of a center point:

```
d = [-1 1];
[x,y,z] = meshgrid(d,d,d);
X = [x(:),y(:),z(:)];   % 8 corner points of a cube
X(9,:) = [0 0 0];       % Add center to the vertex list.
T = delaunayn(X)      % Generate Delaunay tessellation.

T =
     4     3     9     1
```

```
     4     9     2     1
     7     9     3     1
     7     5     9     1
     7     9     4     3
     7     8     4     9
     6     2     9     1
     6     9     5     1
     6     4     9     2
     6     4     8     9
     6     9     7     5
     6     8     7     9
```

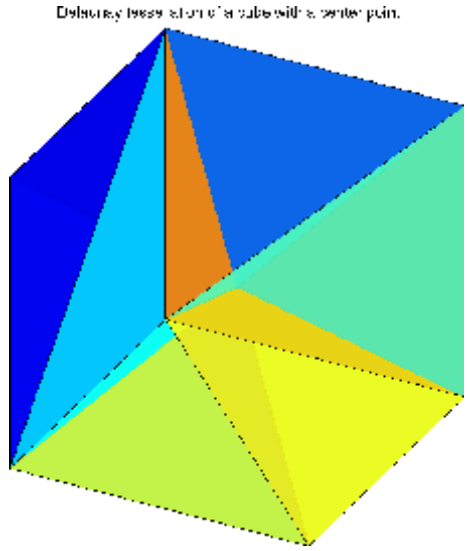
The 12 rows of `T` represent the 12 simplices, in this case irregular tetrahedrons, that partition the cube. Each row represents one tetrahedron, and the row elements are indices of points in `X`.

For three-dimensional tessellations, you can use `tetramesh` to plot the output. However, using `patch` to plot the output gives you more control over the color of the facets. Note that you cannot plot `delaunayn` output for `n > 3`.

This code plots the tessellation `T` by drawing the tetrahedrons using three-dimensional patches:

```
figure, hold on
d = [1 1 1 2; 2 2 3 3; 3 4 4 4];  % Index into T
for i = 1:size(T,1)      % Draw each tetrahedron.
   y = T(i,d);           % Get the ith T to make a patch.
   x1 = reshape(X(y,1),3,4);
   x2 = reshape(X(y,2),3,4);
   x3 = reshape(X(y,3),3,4);
   h(i)=patch(x1,x2,x3,(1:4)*i,'FaceAlpha',0.9);
end
hold off
view(3), axis equal
axis off
camorbit(65,120)         % To view it from another angle
title('Delaunay tessellation of a cube with a center point')
```

You can use `cameramenu` to rotate the figure in any direction.



Voronoi Diagrams

Given m data points in n-dimensional space, a *Voronoi diagram* is the partition of n-dimensional space into m polyhedral regions, one region for each data point. Such a region is called a *Voronoi cell*. A Voronoi cell satisfies the condition that it contains all points that are closer to its data point than any other data point in the set.

Computing a Voronoi Diagram. The `voronoin` function returns two outputs:

- `V` is an m-by-n matrix of m points in n-space. Each row of `V` represents a Voronoi vertex.
- `C` is a cell array of vectors. Each vector in the cell array `C` represents a Voronoi cell. The vector contains indices of the points in `V` that are the vertices of the Voronoi cell. Each Voronoi cell may have a different number of points.

Because a Voronoi cell can be unbounded, the first row of `V` is a point at infinity. Then any unbounded Voronoi cell in `C` includes the point at infinity, i.e., the first point in `V`.

This example uses the same `X` as in the Delaunay example, i.e., the 8 corner points of a cube and its center. Random noise is added to make the cube less regular. The resulting Voronoi diagram has 9 Voronoi cells:

```
d = [-1 1];
[x,y,z] = meshgrid(d,d,d);
X = [x(:),y(:),z(:)];      % 8 corner points of a cube
X(9,:) = [0 0 0];          % Add center to the vertex list.

rand('twister', 5489);     % Initialize the random number generator.
X = X+0.01*rand(size(X));  % Make the cube less regular.

[V,C] = voronoin(X)

V =
       Inf       Inf       Inf
    0.0029   -1.4858    0.0079
    0.1702   -0.0719  193.1848
    0.0018    0.0089    1.5064
    0.0067    0.0040    1.5064
    0.0060    2.9397    0.0073
    0.0033    1.5095    0.0119
    0.0117    1.5095    0.0035
   -1.4873    0.0055    0.0107
   -1.6607    0.0051    0.0100
   -1.4873    0.0050    0.0101
    0.0054   -1.4858    0.0054
    4.6864   -0.0017    0.0080
    1.5105    0.0107    0.0022
    1.5105    0.0025    0.0104
    0.0108    0.0120   -1.4850
    0.0032    0.0070   -3.1326
    0.0043    0.0056   -1.4849

C =
    [1x7  double]
    [1x10 double]
    [1x8  double]
    [1x7  double]
    [1x8  double]
```

```
    [1x7  double]
    [1x7  double]
    [1x10 double]
    [1x12 double]
```

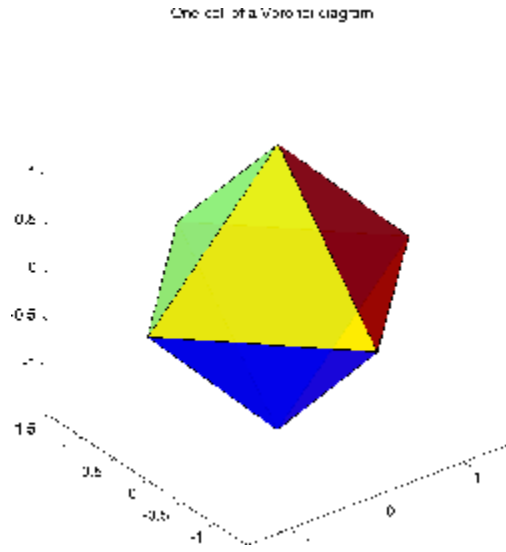
In this example, `V` is a 13-by-3 matrix, the 13 rows are the coordinates of the 13 Voronoi vertices. The first row of `V` is a point at infinity. `C` is a 9-by-1 cell array, where each cell in the array contains an index vector into `V` corresponding to one of the 9 Voronoi cells. For example, the 9th cell of the Voronoi diagram is

```
C{9} = 2   4   5   7   8   9  11  12  14  15  16  18
```

If any index in a cell of the cell array is `1`, then the corresponding Voronoi cell contains the first point in `V`, a point at infinity. This means the Voronoi cell is unbounded.

To view a *bounded* Voronoi cell, i.e., one that does not contain a point at infinity, use the `convhulln` function to compute the vertices of the facets that make up the Voronoi cell. Then use `patch` and other plot functions to generate the figure. For example, this code plots the Voronoi cell defined by the 9th cell in `C`:

```
X = V(C{9},:);       % View 9th Voronoi cell.
K = convhulln(X);
figure
hold on
d = [1 2 3 1];       % Index into K
for i = 1:size(K,1)
   j = K(i,d);
   h(i)=patch(X(j,1),X(j,2),X(j,3),i,'FaceAlpha',0.9);
end
hold off
view(3)
axis equal
title('One cell of a Voronoi diagram')
```



Interpolating N-Dimensional Data

Use the `griddatan` function to interpolate multidimensional data, particularly scattered data. `griddatan` uses the `delaunayn` function to tessellate the data, and then interpolates based on the tessellation.

Suppose you want to visualize a function that you have evaluated at a set of `n` scattered points. In this example, `X` is an `n`-by-3 matrix of points, each row containing the `(x,y,z)` coordinates for one of the points. The vector `v` contains the `n` function values at these points. The function for this example is the squared distance from the origin, `v = x.^2 + y.^2 + z.^2`.

Start by generating `n = 5000` points at random in three-dimensional space, and computing the value of a function on those points:

```
n = 5000;
X = 2*rand(n,3)-1;
v = sum(X.^2,2);
```

The next step is to use interpolation to compute function values over a grid. Use `meshgrid` to create the grid, and `griddatan` to do the interpolation:

```
delta = 0.05;
```

```
d = -1:delta:1;
[x0,y0,z0] = meshgrid(d,d,d);
X0 = [x0(:), y0(:), z0(:)];
v0 = griddatan(X,v,X0);
v0 = reshape(v0, size(x0));
```

Then use `isosurface` and related functions to visualize the surface that consists of the `(x,y,z)` values for which the function takes a constant value. You could pick any value, but the example uses the value 0.6. Since the function is the squared distance from the origin, the surface at a constant value is a sphere:

```
p = patch(isosurface(x0,y0,z0,v0,0.6));
isonormals(x0,y0,z0,v0,p);
set(p,'FaceColor','red','EdgeColor','none');
view(3);
camlight;
lighting phong
axis equal
title('Interpolated sphere from scattered data')
```

Note A smaller `delta` produces a smoother sphere, but increases the compute time.

Fast Fourier Transform (FFT)

The fast Fourier transform (FFT) is an efficient algorithm for computing the discrete Fourier transform (DFT) of a sequence; it is not a separate transform. It is particularly useful in areas such as signal and image processing, where its uses range from filtering, convolution, and frequency analysis to power spectrum estimation.

Introduction

In this section...

Finding an FFT

For length N input sequence x, the DFT is a length N vector, X. `fft` and `ifft` implement the relationships

$$X(k) = \sum_{n=1}^{N} x(n) e^{-j2\pi(k-1)\left(\frac{n-1}{N}\right)} \qquad 1 \le k \le N$$

$$x(n) = \frac{1}{N} \sum_{k=1}^{N} X(k) e^{j2\pi(k-1)\left(\frac{n-1}{N}\right)} \qquad 1 \le n \le N$$

Note Since the first element of a MATLAB vector has an index 1, the summations in the equations above are from 1 to N. These produce identical results as traditional Fourier equations with summations from 0 to N-1.

If $x(n)$ is real, you can rewrite the above equation in terms of a summation of sine and cosine functions with real coefficients:

$$x(n) = \frac{1}{N} \sum_{k=1}^{N} a(k) \cos\left(\frac{2\pi(k-1)(n-1)}{N}\right) + b(k) \sin\left(\frac{2\pi(k-1)(n-1)}{N}\right)$$

where

$$a(k) = \mathrm{real}(X(k)),\ b(k) = -\mathrm{imag}(X(k)),\ 1 \le n \le N$$

The FFT of a column vector x

```
x = [4 3 7 -9 1 0 0 0]' ;
```

is found with

```
y = fft(x)
```

which results in

```
y =
6.0000
11.4853 - 2.7574i
-2.0000 -12.0000i
-5.4853 +11.2426i
18.0000
-5.4853 -11.2426i
-2.0000 +12.0000i
11.4853 + 2.7574i
```

Notice that although the sequence `x` is real, `y` is complex. The first component of the transformed data is the constant contribution and the fifth element corresponds to the Nyquist frequency. The last three values of `y` correspond to negative frequencies and, for the real sequence `x`, they are complex conjugates of three components in the first half of `y`.

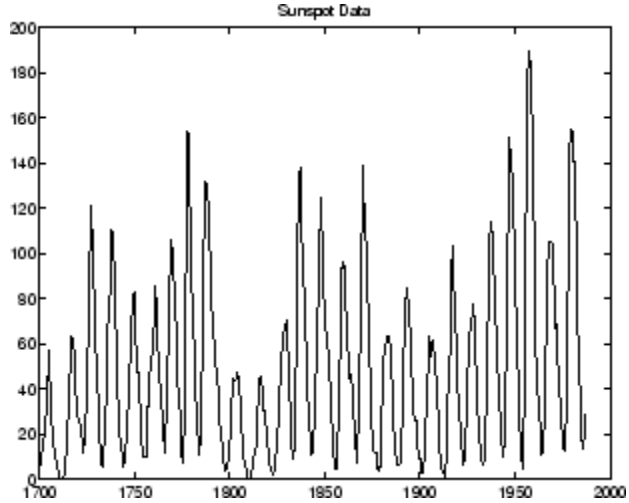
Example: Using FFT to Calculate Sunspot Periodicity

Suppose, you want to analyze the variations in sunspot activity over the last 300 years. You are probably aware that sunspot activity is cyclical, reaching a maximum about every 11 years. This example confirms that.

Astronomers have tabulated a quantity called the Wolfer number for almost 300 years. This quantity measures both number and size of sunspots.

Load and plot the sunspot data:

```
load sunspot.dat
year = sunspot(:,1);
wolfer = sunspot(:,2);
plot(year,wolfer)
title('Sunspot Data')
```

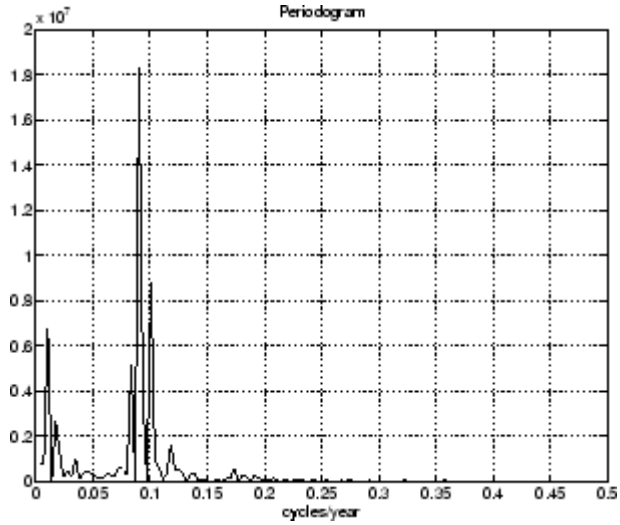


Now take the FFT of the sunspot data:

```
Y = fft(wolfer);
```

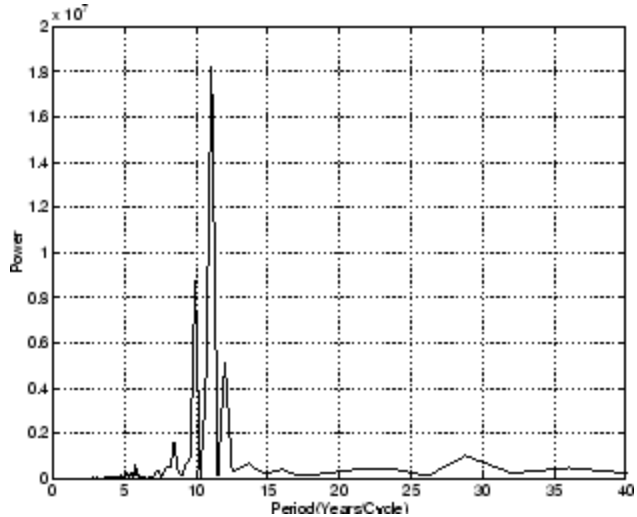
The result of this transform is the complex vector, `Y`. The magnitude of `Y` squared is called the *power* and a plot of power versus frequency is a *periodogram*. Remove the first component of `Y`, which is simply the sum of the data, and plot the results:

```
N = length(Y);
Y(1) = [];
power = abs(Y(1:N/2)).^2;
nyquist = 1/2;
freq = (1:N/2)/(N/2)*nyquist;
plot(freq,power), grid on
xlabel('cycles/year')
title('Periodogram')
```



The scale in cycles/year is somewhat inconvenient. You can plot in years/cycle and estimate what one cycle is. For convenience, plot the power versus period (where `period = 1./freq`) from 0 to 40 years/cycle:

```
period = 1./freq;
plot(period,power), axis([0 40 0 2e7]), grid on
ylabel('Power')
xlabel('Period(Years/Cycle)')
```



In order to determine the cycle more precisely,

```
[mp,index] = max(power);
period(index)

ans =
      11.0769
```

Magnitude and Phase of Transformed Data

Important information about a transformed sequence includes its magnitude and phase. The MATLAB functions `abs` and `angle` calculate this information.

To try this, create a time vector `t`, and use this vector to create a sequence `x` consisting of two sinusoids at different frequencies:

```
t = 0:1/100:10-1/100;
x = sin(2*pi*15*t) + sin(2*pi*40*t);
```

Now use the `fft` function to compute the DFT of the sequence. The code below calculates the magnitude and phase of the transformed sequence. It uses the `abs` function to obtain the magnitude of the data, the `angle` function to obtain the phase information, and `unwrap` to remove phase jumps greater than `pi` to their `2*pi` complement:

```
y = fft(x);
m = abs(y);
p = unwrap(angle(y));
```

Now create a frequency vector for the *x*-axis and plot the magnitude and phase:

```
f = (0:length(y)-1)'*100/length(y);
subplot(2,1,1), plot(f,m),
ylabel('Abs. Magnitude'), grid on
subplot(2,1,2), plot(f,p*180/pi)
ylabel('Phase [Degrees]'), grid on
xlabel('Frequency [Hertz]')
```

The magnitude plot is perfectly symmetrical about the Nyquist frequency of 50 hertz. The useful information in the signal is found in the range 0 to 50 hertz.

FFT Length Versus Speed

You can add a second argument to `fft` to specify a number of points `n` for the transform:

```
y = fft(x,n)
```

With this syntax, `fft` pads `x` with zeros if it is shorter than `n`, or truncates it if it is longer than `n`. If you do not specify `n`, `fft` defaults to the length of the input sequence.

The execution time for `fft` depends on the length of the transform. It is fastest for powers of two. It is almost as fast for lengths that have only small prime factors. It is typically several times slower for lengths that are prime or which have large prime factors.

The inverse FFT function `ifft` also accepts a transform length argument.

For practical application of the FFT, “Signal Processing Toolbox” includes numerous functions for spectral analysis.

Function Summary

MATLAB provides a collection of functions for computing and working with Fourier transforms.

FFT Function Summary

Function	Description
`fft`	Discrete Fourier transform
`fft2`	Two-dimensional discrete Fourier transform
`fftn`	N-dimensional discrete Fourier transform
`ifft`	Inverse discrete Fourier transform
`ifft2`	Two-dimensional inverse discrete Fourier transform
`ifftn`	N-dimensional inverse discrete Fourier transform
`abs`	Magnitude
`angle`	Phase angle
`unwrap`	Unwrap phase angle in radians
`fftshift`	Move zeroth lag to center of spectrum
`cplxpair`	Sort numbers into complex conjugate pairs
`nextpow2`	Next higher power of two

4

Function Functions

See the Chapter 5, “Differential Equations” and Chapter 6, “Sparse Matrices” chapters for information about the use of other function functions.

For information about function handles, see the `function_handle` (@), `func2str`, and `str2func` reference pages, and the “Function Handles” section of .

Function Summary

Function functions are functions that call other functions as input arguments. An example of a function function is `fplot`, which plots the graphs of functions. You can call the function `fplot` with the syntax

```
fplot(@fun, [-pi pi])
```

where the input argument `@fun` is a handle to the function you want to plot. The function `fun` is referred to as the *called* function.

The function functions are located in the MATLAB `funfun` directory.

This table provides a brief description of the functions discussed in this chapter. Related functions are grouped by category.

This is a three column by eight row table. The entries in the first column span several rows. The first entry, Plotting, has only one function, `fplot`. The second entry, Optimization and zero finding, covers the functions `fminbnd`, `fminsearch`, and `fzero`. The third entry, numerical integration, covers the functions `quad`, `quad1`, `dblquad`, and `triplequad`.

Function Summary

Category	Function	Description
Plotting	`fplot`	Plot function
Optimization and zero finding	`fminbnd`	Minimize function of one variable with bound constraints
	`fminsearch`	Minimize function of several variables
	`fzero`	Find zero of function of one variable

Function Summary (Continued)

Category	Function	Description
Numerical integration	`quad`	Numerically evaluate integral, adaptive Simpson quadrature
	`quadl`	Numerically evaluate integral, adaptive Lobatto quadrature
	`quadv`	Vectorized quadrature
	`dblquad`	Numerically evaluate double integral
	`triplequad`	Numerically evaluate triple integral

Representing Functions in MATLAB

In this section...

MATLAB Functions

MATLAB can represent mathematical functions by expressing them as MATLAB functions in M-files or as "Anonymous Functions" in . For example, consider the function

$$f(x) = \frac{1}{(x-0.3)^2 + 0.01} + \frac{1}{(x-0.9)^2 + 0.04} - 6$$

This function can be used as input to any of the function functions.

You can find the function above in the M-file named `humps.m`.

```
function y = humps(x)
y = 1./((x - 0.3).^2 + 0.01) + 1./((x - 0.9).^2 + 0.04) - 6;
```

To evaluate the function `humps` at 2.0, use `@` to obtain a function handle for `humps`, and then use the function handle in the same way you would use a function name to call the function:

```
fh = @humps;
fh(2.0)

ans =
   -4.8552
```

Anonymous Functions

A second way to represent a mathematical function at the command line is by creating an anonymous function from a string expression. For example, you can create an anonymous function of the `humps` function. The value returned, `fh`, is a function handle:

```
fh = @(x)1./((x-0.3).^2 + 0.01) + 1./((x-0.9).^2 + 0.04)-6;
```

You can then evaluate `fh` at `2.0` in the same way that you can with a function handle for a MATLAB function:

```
fh(2.0)
ans =
   -4.8552
```

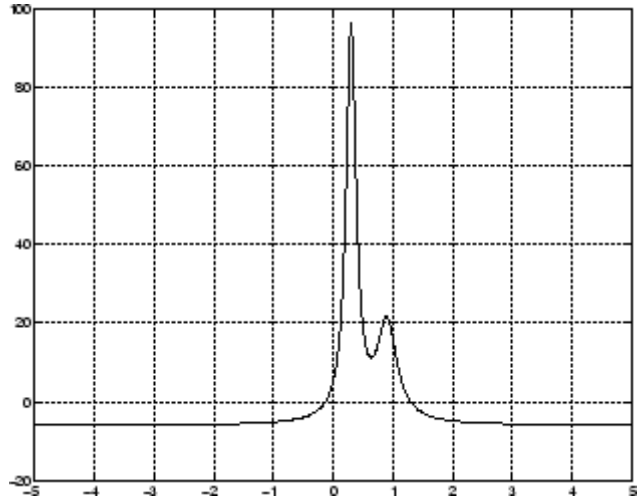
You can also create anonymous functions of more than one argument. The following function has two input arguments `x` and `y`.

```
fh = @(x,y)y*sin(x)+x*cos(y);
fh(pi,2*pi)
ans =
    3.1416
```

Plotting Mathematical Functions

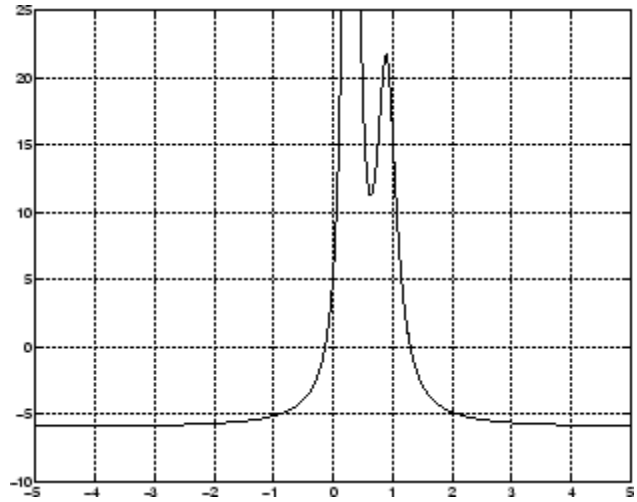
The `fplot` function plots a mathematical function between a given set of axes limits. You can control the *x*-axis limits only, or both the *x*- and *y*-axis limits. For example, to plot the `humps` function over the *x*-axis range `[-5 5]`, use

```
fplot(@humps,[-5 5])
grid on
```



You can zoom in on the function by selecting *y*-axis limits of `-10` and `25`, using

```
fplot(@humps,[-5 5 -10 25])
grid on
```



You can also pass the function handle for an anonymous function for `fplot` to graph, as in

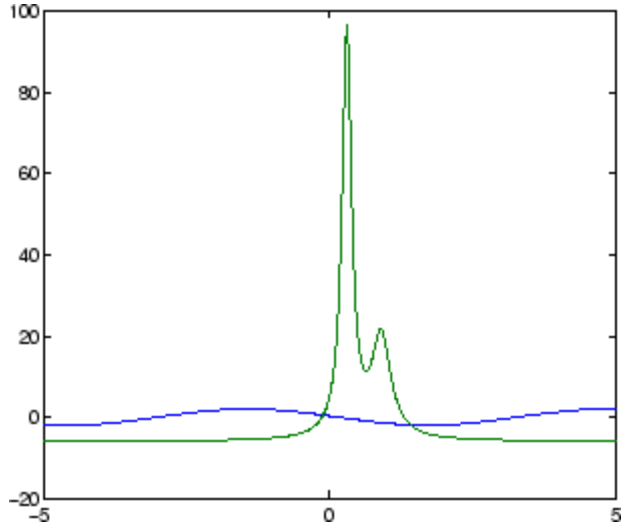
```
fplot(@(x)2*sin(x+3),[-1 1]);
```

You can plot more than one function on the same graph with one call to `fplot`. If you use this with a function, then the function must take a column vector `x` and return a matrix where each column corresponds to each function, evaluated at each value of `x`.

If you pass an anonymous function consisting of several functions to `fplot`, the anonymous function also must return a matrix where each column corresponds to each function evaluated at each value of `x`, as in

```
fplot(@(x)[2*sin(x+3), humps(x)],[-5 5])
```

which plots the first and second functions on the same graph.



Note that the anonymous function

```
fh = @(x)[2*sin(x+3), humps(x)];
```

evaluates to a matrix of two columns, one for each function, when `x` is a column vector.

```
fh([1;2;3])
```

returns

```
    -1.5136   16.0000
    -1.9178   -4.8552
    -0.5588   -5.6383
```

Minimizing Functions and Finding Zeros

In this section...

MATLAB Optimization Functions

The MATLAB optimization functions are:

`fminbnd`	Minimize a function of one variable on a fixed interval
`fminsearch`	Minimize a function of several variables
`fzero`	Find zero of a function of one variable
`lsqnonneg`	Linear least squares with nonnegativity constraints
`optimget`	Get optimization options structure parameter values
`optimset`	Create or edit optimization options parameter structure

For more optimization capabilities, see the *Optimization Toolbox User's Guide*.

Minimizing Functions of One Variable

Given a mathematical function of a single variable coded in an M-file, you can use the `fminbnd` function to find a local minimizer of the function in a given interval. For example, to find a minimum of the `humps` function in the range (0.3, 1), use

```
x = fminbnd(@humps,0.3,1)
```

which returns

```
x =
    0.6370
```

You can ask for a tabular display of output by passing a fourth argument created by the `optimset` command to `fminbnd`

```
x = fminbnd(@humps,0.3,1,optimset('Display','iter'))
```

which gives the output

```
Func-count     x          f(x)         Procedure
    3       0.567376      12.9098        initial
    4       0.732624      13.7746        golden
    5       0.465248      25.1714        golden
    6       0.644416      11.2693        parabolic
    7         0.6413      11.2583        parabolic
    8       0.637618      11.2529        parabolic
    9       0.636985      11.2528        parabolic
   10       0.637019      11.2528        parabolic
   11       0.637052      11.2528        parabolic

Optimization terminated:
 the current x satisfies the termination criteria using
OPTIONS.TolX of 1.000000e-004

x =

    0.6370
```

This shows the current value of `x` and the function value at `f(x)` each time a function evaluation occurs. For `fminbnd`, one function evaluation corresponds to one iteration of the algorithm. The last column shows what procedure is being used at each iteration, either a golden section search or a parabolic interpolation.

Minimizing Functions of Several Variables

The `fminsearch` function is similar to `fminbnd` except that it handles functions of many variables, and you specify a starting vector x_0 rather than a starting interval. `fminsearch` attempts to return a vector x that is a local minimizer of the mathematical function near this starting vector.

To try `fminsearch`, create a function `three_var` of three variables, `x`, `y`, and `z`.

```
function b = three_var(v)
x = v(1);
y = v(2);
z = v(3);
b = x.^2 + 2.5*sin(y) - z^2*x^2*y^2;
```

Now find a minimum for this function using `x = -0.6`, `y = -1.2`, and `z = 0.135` as the starting values.

```
v = [-0.6 -1.2 0.135];
a = fminsearch(@three_var,v)

a =
    0.0000   -1.5708    0.1803
```

Fitting a Curve to Data

This section gives an example that shows how to fit an exponential function of the form $Ae^{-\lambda t}$ to some data. The example uses the function `fminsearch` to minimize the sum of squares of errors between the data and an exponential function $Ae^{-\lambda t}$ for varying parameters A and λ. This section covers the following topics.

• "Plotting the Results" on page 4-13

Creating an M-file for the Example

To run the example, first create an M-file that

- Accepts vectors corresponding to the *x*- and *y*-coordinates of the data
- Returns the parameters of the exponential function that best fits the data

To do so, copy and paste the following code into an M-file and save it as `fitcurvedemo` in a directory on the MATLAB path.

```
function [estimates, model] = fitcurvedemo(xdata, ydata)
% Call fminsearch with a random starting point.
start_point = rand(1, 2);
model = @expfun;
estimates = fminsearch(model, start_point);
% expfun accepts curve parameters as inputs, and outputs sse,
% the sum of squares error for A * exp(-lambda * xdata) - ydata,
% and the FittedCurve. FMINSEARCH only needs sse, but we want to
% plot the FittedCurve at the end.
    function [sse, FittedCurve] = expfun(params)
        A = params(1);
        lambda = params(2);
        FittedCurve = A .* exp(-lambda * xdata);
        ErrorVector = FittedCurve - ydata;
        sse = sum(ErrorVector .^ 2);
    end
end
```

The M-file calls the function `fminsearch`, which find parameters `A` and `lambda` that minimize the sum of squares of the differences between the data and the exponential function `A*exp(-lambda*t)`. The nested function `expfun` computes the sum of squares.

Running the Example

To run the example, first create some random data to fit. The following commands create random data that is approximately exponential with parameters `A = 40` and `lambda = .5`.

```
xdata = (0:.1:10)';
ydata = 40 * exp(-.5 * xdata) + randn(size(xdata));
```

To fit an exponential function to the data, enter

```
[estimates, model] = fitcurvedemo(xdata,ydata)
```

This returns estimates for the parameters `A` and `lambda`,

```
estimates =

   40.1334    0.5025
```

and a function handle, `model`, to the function that computes the exponential function `A*exp(-lambda*t)`.

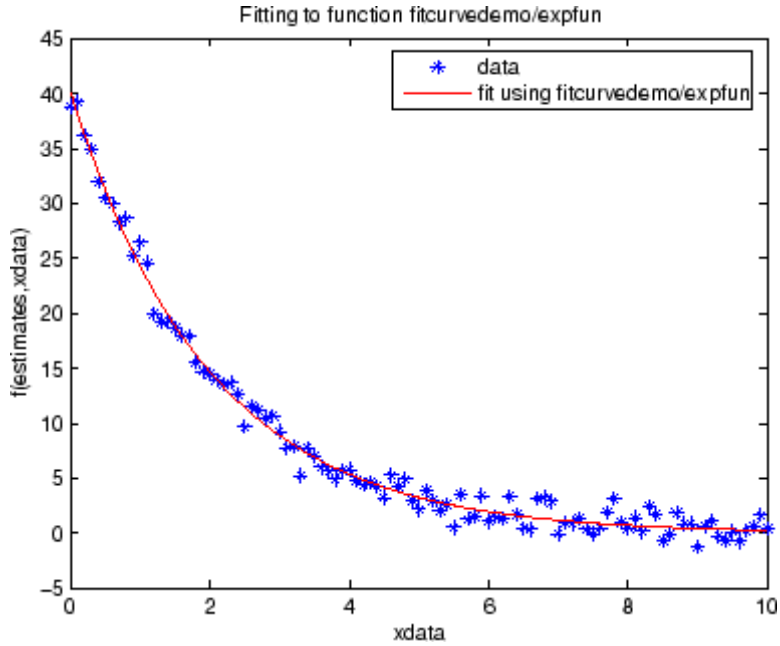
Plotting the Results

To plot the fit and the data, enter the following commands.

```
plot(xdata, ydata, '*')
hold on
[sse, FittedCurve] = model(estimates);
plot(xdata, FittedCurve, 'r')

xlabel('xdata')
ylabel('f(estimates,xdata)')
title(['Fitting to function ', func2str(model)]);
legend('data', ['fit using ', func2str(model)])
hold off
```

The resulting plot displays the data points and the exponential fit.



Setting Minimization Options

You can specify control options that set some minimization parameters using an `options` structure that you create using the function `optimset`. You then pass `options` as an input to the optimization function, for example, by calling `fminbnd` with the syntax

```
x = fminbnd(fun,x1,x2,options)
```

or `fminsearch` with the syntax

```
x = fminsearch(fun,x0,options)
```

Use `optimset` to set the values of the `options` structure. For example, to set the `'Display'` option to `'iter'`, in order to display output from the algorithm at each iteration, enter

```
options = optimset('Display','iter');
```

`fminbnd` and `fminsearch` use only the `options` parameters shown in the following table.

`options.Display`	A flag that determines if intermediate steps in the minimization appear on the screen. If set to `'iter'`, intermediate steps are displayed; if set to `'off'`, no intermediate solutions are displayed, if set to `final`, displays just the final output.
`options.TolX`	The termination tolerance for x. Its default value is `1.e-4`.
`options.TolFun`	The termination tolerance for the function value. The default value is `1.e-4`. This parameter is used by `fminsearch`, but not `fminbnd`.
`options.MaxIter`	Maximum number of iterations allowed.
`options.MaxFunEvals`	The maximum number of function evaluations allowed. The default value is `500` for `fminbnd` and `200*length(x0)` for `fminsearch`.

The number of function evaluations, the number of iterations, and the algorithm are returned in the structure `output` when you provide `fminbnd` or `fminsearch` with a fourth output argument, as in

```
[x,fval,exitflag,output] = fminbnd(@humps,0.3,1);
```

or

```
[x,fval,exitflag,output] = fminsearch(@three_var,v);
```

Output Functions

An *output function* is a function that an optimization function calls at each iteration of its algorithm. Typically, you might use an output function to generate graphical output, record the history of the data the algorithm generates, or halt the algorithm based on the data at the current iteration. You can create an output function as an M-file function, a subfunction, or a nested function.

You can use the `OutputFcn` option with the following MATLAB optimization functions:

- `fminbnd`
- `fminsearch`
- `fzero`

This section covers the following topics:

Creating and Using an Output Function

The following is a simple example of an output function that plots the points generated by an optimization function.

```
function stop = outfun(x, optimValues, state)
stop = false;
hold on;
plot(x(1),x(2),'.');
drawnow
```

You can use this output function to plot the points generated by `fminsearch` in solving the optimization problem

$$\underset{x}{\text{minimize}}\ f(x) = e^{x_1}(4x_1^2 + 2x_2^2 + 4x_1x_2 + 2x_2 + 1)$$

To do so,

1. Create an M-file containing the preceding code and save it as `outfun.m` in a directory on the MATLAB path.
2. Enter the command

```
options = optimset('OutputFcn', @outfun);
```

to set the value of the `Outputfcn` field of the `options` structure to a function handle to `outfun`.

3 Enter the following commands:

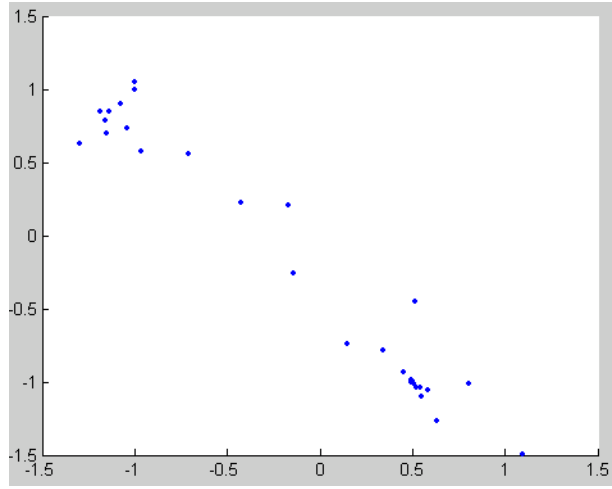
```
hold on
objfun=@(x) exp(x(1))*(4*x(1)^2+2*x(2)^2+x(1)*x(2)+2*x(2));
[x fval] = fminsearch(objfun, [-1 1], options)
hold off
```

This returns the solution

```
x =
    0.1290   -0.5323

fval =
   -0.5689
```

and displays the following plot of the points generated by `fminsearch`:



Structure of the Output Function

The function definition line of the output function has the following form:

```
stop = outfun(x, optimValues, state)
```

where

- `stop` is a flag that is `true` or `false` depending on whether the optimization routine should quit or continue. See "Stop Flag" on page 4-22.
- `x` is the point computed by the algorithm at the current iteration.
- `optimValues` is a structure containing data from the current iteration. "Fields in optimValues" on page 4-20 describes the structure in detail.
- `state` is the current state of the algorithm. "States of the Algorithm" on page 4-21 lists the possible values.

The optimization function passes the values of the input arguments to `outfun` at each iteration.

Example of a Nested Output Function

The example in "Creating and Using an Output Function" on page 4-16 does not require the output function to preserve data from one iteration to the next. When this is the case, you can write the output function as an M-file and call the optimization function directly from the command line. However, if you want your output function to record data from one iteration to the next, you should write a single M-file that does the following:

- Contains the output function as a nested function—see "Nested Functions" in the MATLAB Programming documentation for more information.
- Calls the optimization function.

In the following example, the M-file also contains the objective function as a subfunction, although you could also write the objective function as a separate M-file or as an anonymous function.

Since the nested function has access to variables in the M-file function that contains it, this method enables the output function to preserve variables from one iteration to the next.

The following example uses an output function to record the points generated by `fminsearch` in solving the optimization problem

$$\underset{x}{\text{minimize}}\ f(x) = e^{x_1}(4x_1^2 + 2x_2^2 + 4x_1x_2 + 2x_2 + 1)$$

and returns the sequence of points as a matrix called `history`.

To run the example, do the following steps:

1 Open a new M-file in the MATLAB editor.

2 Copy and paste the following code into the M-file.

```
function [x fval history] = myproblem(x0)
    history = [];
    options = optimset('OutputFcn', @myoutput);
    [x fval] = fminsearch(@objfun, x0,options);

    function stop = myoutput(x,optimvalues,state);
        stop = false;
        if state == 'iter'
          history = [history; x];
        end
    end

    function z = objfun(x)
      z = exp(x(1))*(4*x(1)^2+2*x(2)^2+x(1)*x(2)+2*x(2));
    end
end
```

3 Save the file as `myproblem.m` in a directory on the MATLAB path.

4 At the MATLAB prompt, enter

```
[x fval history] = myproblem([-1 1])
```

The function `fminsearch` returns `x`, the optimal point, and `fval`, the value of the objective function at x.

```
x =

    0.1290   -0.5323
```

```
fval =

   -0.5689
```

In addition, the output function `myoutput` returns the matrix `history`, which contains the points generated by the algorithm at each iteration, to the MATLAB workspace. The first four rows of `history` are

```
history(1:4,:) =

   -1.0000    1.0000
   -1.0000    1.0000
   -1.0750    0.9000
   -1.0125    0.8500
```

The final row of points is the same as the optimal point, `x`.

```
history(end,:)

ans =

    0.1290   -0.5323

objfun(history(end,:))

ans =

   -0.5689
```

Fields in optimValues

The following table lists the fields of the `optimValues` structure that are provided by all three optimization functions, `fminbnd`, `fminsearch`, and `fzero`. The function `fzero` also provides additional fields that are described in its reference page.

The “Command-Line Display Headings” column of the table lists the headings, corresponding to the `optimValues` fields that are displayed at the command line when you set the `Display` parameter of `options` to `'iter'`.

optimValues Field (optimValues.field)	Description	Command-Line Display Heading
`funcount`	Cumulative number of function evaluations	`Func-count`
`fval`	Function value at current point	`min f(x)`
`iteration`	Iteration number — starts at `0`	`Iteration`
`procedure`	Procedure messages	`Procedure`

States of the Algorithm

The following table lists the possible values for `state`:

State	Description
`'init'`	The algorithm is in the initial state before the first iteration.
`'interrupt'`	The algorithm is performing an iteration. In this state, the output function can interrupt the current iteration of the optimization. You might want the output function to do this to improve the efficiency of the computations. When state is set to `'interrupt'`, the values of `x` and `optimValues` are the same as at the last call to the output function, in which `state` is set to `'iter'`.
`'iter'`	The algorithm is at the end of an iteration.
`'done'`	The algorithm is in the final state after the last iteration.

The following code illustrates how the output function might use the value of `state` to decide which tasks to perform at the current iteration.

```
switch state
    case 'init'
          % Setup for plots or guis
```

```
    case 'iter'
          % Make updates to plot or guis as needed.
    case 'interrupt'
          % Check conditions to see whether optimization
          % should quit.
        case 'done'
          % Cleanup of plots, guis, or final plot
otherwise
end
```

Stop Flag

The output argument `stop` is a flag that is `true` or `false`. The flag tells the optimization function whether the optimization should quit or continue. The following examples show typical ways to use the `stop` flag.

Stopping an Optimization Based on Data in optimValues. The output function can stop an optimization at any iteration based on the current data in `optimValues`. For example, the following code sets `stop` to `true` if the objective function value is less than `5`:

```
function stop = myoutput(x, optimValues, state)
stop = false;
% Check if objective function is less than 5.
if optimValues.fval < 5
    stop = true;
end
```

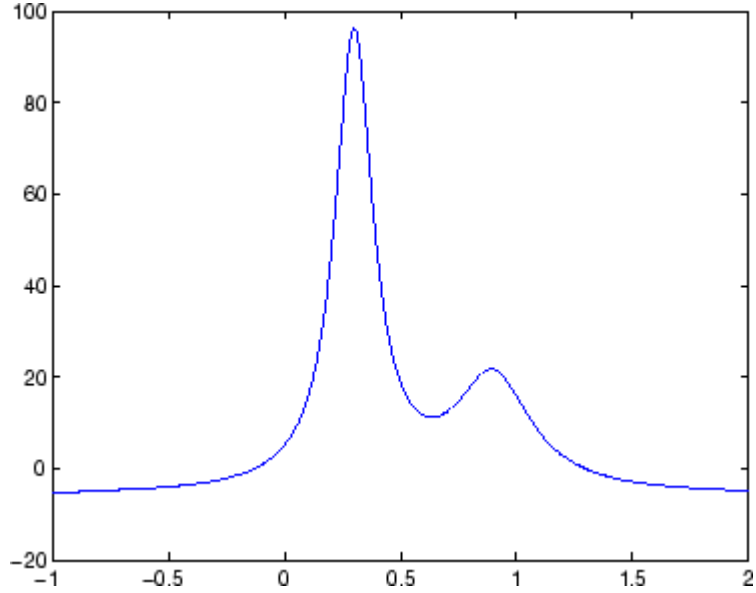
Stopping an Optimization Based on GUI Input. If you design a GUI to perform optimizations, you can make the output function stop an optimization when a user clicks a **Stop** button on the GUI. The following code shows how to do this, assuming that the **Stop** button callback stores the value `true` in the `optimstop` field of a `handles` structure called `hObject` stored in `appdata`.

```
function stop = myoutput(x, optimValues, state)
stop = false;
% Check if user has requested to stop the optimization.
stop = getappdata(hObject,'optimstop');
```

Finding Zeros of Functions

The `fzero` function attempts to find a zero of one equation with one variable. You can call this function with either a one-element starting point or a two-element vector that designates a starting interval. If you give `fzero` a starting point `x0`, `fzero` first searches for an interval around this point where the function changes sign. If the interval is found, `fzero` returns a value near where the function changes sign. If no such interval is found, `fzero` returns `NaN`. Alternatively, if you know two points where the function value differs in sign, you can specify this starting interval using a two-element vector; `fzero` is guaranteed to narrow down the interval and return a value near a sign change.

The following sections contain two examples that illustrate how to find a zero of a function using a starting interval and a starting point. The examples use the function `humps`, which is provided with MATLAB. The following figure shows the graph of `humps`.



Using a Starting Interval

The graph of humps indicates that the function is negative at x = -1 and positive at x = 1. You can confirm this by calculating humps at these two points.

```
humps(1)

ans =
    16

humps(-1)

ans =
   -5.1378
```

Consequently, you can use [-1 1] as a starting interval for fzero.

The iterative algorithm for fzero finds smaller and smaller subintervals of [-1 1]. For each subinterval, the sign of humps differs at the two endpoints. As the endpoints of the subintervals get closer and closer, they converge to zero for humps.

To show the progress of fzero at each iteration, set the Display option to iter using the function optimset.

```
options = optimset('Display','iter');
```

Then call fzero as follows:

```
a = fzero(@humps,[-1 1],options)
```

This returns the following iterative output:

```
a = fzero(@humps,[-1 1],options)

 Func-count    x          f(x)             Procedure
    2              -1      -5.13779        initial
    3       -0.513876      -4.02235        interpolation
    4       -0.513876      -4.02235        bisection
    5       -0.473635      -3.83767        interpolation
    6       -0.115287      0.414441        bisection
```

```
     7       -0.115287      0.414441        interpolation
     8       -0.132562    -0.0226907        interpolation
     9       -0.131666    -0.0011492        interpolation
    10       -0.131618  1.88371e-007        interpolation
    11       -0.131618  -2.7935e-011        interpolation
    12       -0.131618  8.88178e-016        interpolation
    13       -0.131618  8.88178e-016        interpolation

Zero found in the interval [-1, 1]

a =

   -0.1316
```

Each value `x` represents the best endpoint so far. The `Procedure` column tells you whether each step of the algorithm uses bisection or interpolation.

You can verify that the function value at `a` is close to zero by entering

```
humps(a)

ans =

  8.8818e-016
```

Using a Starting Point

Suppose you do not know two points at which the function values of `humps` differ in sign. In that case, you can choose a scalar `x0` as the starting point for `fzero`. `fzero` first searches for an interval around this point on which the function changes sign. If `fzero` finds such an interval, it proceeds with the algorithm described in the previous section. If no such interval is found, `fzero` returns `NaN`.

For example, if you set the starting point to `-0.2`, the `Display` option to `Iter`, and call `fzero` by

```
a = fzero(@humps,-0.2,options)
```

`fzero` returns the following output:

```
Search for an interval around -0.2 containing a sign change:
 Func-count    a          f(a)             b          f(b)        Procedure
     1            -0.2      -1.35385          -0.2      -1.35385   initial interval
     3       -0.194343      -1.26077     -0.205657      -1.44411   search
     5          -0.192      -1.22137        -0.208       -1.4807   search
     7       -0.188686      -1.16477     -0.211314      -1.53167   search
     9          -0.184      -1.08293        -0.216      -1.60224   search
    11       -0.177373     -0.963455     -0.222627      -1.69911   search
    13          -0.168     -0.786636        -0.232      -1.83055   search
    15       -0.154745      -0.51962     -0.245255      -2.00602   search
    17          -0.136     -0.104165        -0.264      -2.23521   search
    18        -0.10949      0.572246        -0.264      -2.23521   search

Search for a zero in the interval [-0.10949, -0.264]:
 Func-count    x          f(x)             Procedure
    18        -0.10949      0.572246        initial
    19       -0.140984     -0.219277        interpolation
    20       -0.132259    -0.0154224        interpolation
    21       -0.131617  3.40729e-005        interpolation
    22       -0.131618 -6.79505e-008        interpolation
    23       -0.131618 -2.98428e-013        interpolation
    24       -0.131618  8.88178e-016        interpolation
    25       -0.131618  8.88178e-016        interpolation

Zero found in the interval [-0.10949, -0.264]

a =

   -0.1316
```

The endpoints of the current subinterval at each iteration are listed under the headings `a` and `b`, while the corresponding values of `humps` at the endpoints are listed under `f(a)` and `f(b)`, respectively.

Note The endpoints `a` and `b` are not listed in any specific order: `a` can be greater than `b` or less than `b`.

For the first nine steps, the sign of `humps` is negative at both endpoints of the current subinterval, which is shown in the output. At the tenth step, the sign of `humps` is positive at the endpoint, `-0.10949`, but negative at the endpoint, `-0.264`. From this point on, the algorithm continues to narrow down the interval `[-0.10949 -0.264]`, as described in the previous section, until it reaches the value `-0.1316`.

Tips

Optimization problems may take many iterations to converge. Most optimization problems benefit from good starting guesses. Providing good starting guesses improves the execution efficiency and may help locate the global minimum instead of a local minimum.

Sophisticated problems are best solved by an evolutionary approach, whereby a problem with a smaller number of independent variables is solved first. Solutions from lower order problems can generally be used as starting points for higher order problems by using an appropriate mapping.

The use of simpler cost functions and less stringent termination criteria in the early stages of an optimization problem can also reduce computation time. Such an approach often produces superior results by avoiding local minima.

Troubleshooting

Here is a list of typical problems and recommendations for dealing with them.

Problem	Recommendation
The solution found by `fminbnd` or `fminsearch` does not appear to be a global minimum.	There is no guarantee that you have a global minimum unless your problem is continuous and has only one minimum. Starting the optimization from a number of different starting points (or intervals in the case of `fminbnd`) may help to locate the global minimum or verify that there is only one minimum. Use different methods, where possible, to verify results.

Problem	Recommendation
Sometimes an optimization problem has values of `x` for which it is impossible to evaluate `f`.	Modify your function to include a penalty function to give a large positive value to `f` when infeasibility is encountered.
The minimization routine appears to enter an infinite loop or returns a solution that is not a minimum (or not a zero in the case of `fzero`).	Your objective function (`fun`) may be returning `NaN` or complex values. The optimization routines expect only real numbers to be returned. Any other values may cause unexpected results. To determine whether this is the case, set `options = optimset('FunValCheck', 'on')` and call the optimization function with `options` as an input argument. This displays an error when the objective function returns `NaN` or complex values.

Numerical Integration (Quadrature)

In this section...

The area beneath a section of a function $F(x)$ can be determined by numerically integrating $F(x)$, a process referred to as *quadrature*. The MATLAB quadrature functions are:

`quad`	Use adaptive Simpson quadrature
`quadl`	Use adaptive Lobatto quadrature
`quadgk`	Use adaptive Gauss-Kronrod quadrature
`quadv`	Vectorized quadrature
`dblquad`	Numerically evaluate double integral
`triplequad`	Numerically evaluate triple integral

To integrate the function defined by `humps.m` from `0` to `1`, use

```
q = quad(@humps,0,1)

q =
    29.8583
```

Both `quad` and `quadl` operate recursively. If either method detects a possible singularity, it prints a warning.

You can include a fourth argument for `quad` or `quadl` that specifies an absolute error tolerance for the integration. If a nonzero fifth argument is passed to `quad` or `quadl`, the function evaluations are traced.

Two examples illustrate use of these functions:

- Computing the length of a curve
- Double integration

Example: Computing the Length of a Curve

You can use `quad` or `quadl` to compute the length of a curve. Consider the curve parameterized by the equations

$$x(t) = \sin(2t), \qquad y(t) = \cos(t), \qquad z(t) = t$$

where $t \in [0, 3\pi]$.

A three-dimensional plot of this curve is

```
t = 0:0.1:3*pi;
plot3(sin(2*t),cos(t),t)
```

The arc length formula says the length of the curve is the integral of the norm of the derivatives of the parameterized equations

$$\int_0^{3\pi} \sqrt{4\cos(2t)^2 + \sin(t)^2 + 1}\ dt$$

The function `hcurve` computes the integrand

```
function f = hcurve(t)
f = sqrt(4*cos(2*t).^2 + sin(t).^2 + 1);
```

Integrate this function with a call to `quad`

```
len = quad(@hcurve,0,3*pi)

len =
   1.7222e+01
```

The length of this curve is about 17.2.

Example: Double Integration

Consider the numerical solution of

$$\int_{ymin}^{ymax} \int_{xmin}^{xmax} f(x,y)\ dxdy$$

For this example $f(x,y) = y\sin(x) + x\cos(y)$. The first step is to build the function to be evaluated. The function must be capable of returning a vector output when given a vector input. You must also consider which variable is in the inner integral, and which goes in the outer integral. In this example, the inner variable is *x* and the outer variable is *y* (the order in the integral is *dxdy*). In this case, the `integrand` function is

```
function out = integrnd(x,y)
out = y*sin(x) + x*cos(y);
```

To perform the integration, two functions are available in the `funfun` directory. The first, `dblquad`, is called directly from the command line. This M-file evaluates the outer loop using `quad`. At each iteration, `quad` calls the second helper function that evaluates the inner loop.

To evaluate the double integral, use

```
result = dblquad(@integrnd,xmin,xmax,ymin,ymax);
```

The first argument is a string with the name of the `integrand` function. The second to fifth arguments are

`xmin`	Lower limit of inner integral
`xmax`	Upper limit of the inner integral
`ymin`	Lower limit of outer integral
`ymax`	Upper limit of the outer integral

Here is a numeric example that illustrates the use of `dblquad`.

```
xmin = pi;
xmax = 2*pi;
ymin = 0;
ymax = pi;
result = dblquad(@integrnd,xmin,xmax,ymin,ymax)
```

The result is -9.8698.

By default, `dblquad` calls `quad`. To integrate the previous example using `quadl` (with the default values for the tolerance argument), use

```
result = dblquad(@integrnd,xmin,xmax,ymin,ymax,[],@quadl);
```

Alternatively, you can pass any user-defined quadrature function name to `dblquad` as long as the quadrature function has the same calling and return arguments as `quad`.

Parameterizing Functions Called by Function Functions

In this section...

Providing Parameter Values Using Nested Functions

One way to provide parameters to the polynomial is to write a single M-file that

- Accepts the additional parameters as inputs
- Invokes the function function
- Contains the function called by the function function as a nested function

The following example illustrates how to find a zero of the cubic polynomial $x^3 + bx + c$, for different values of the coefficients `b` and `c`, using this method. To do so, write an M-file with the following code.

```
function y = findzero(b, c, x0)

options = optimset('Display', 'off'); % Turn off Display
y = fzero(@poly, x0, options);

 function y = poly(x) % Compute the polynomial.
 y = x^3 + b*x + c;
 end
end
```

The main function, `findzero`, does two things:

- Invokes the function `fzero` to find a zero of the polynomial
- Computes the polynomial in a nested function, `poly`, which is called by `fzero`

You can call `findzero` with any values of the coefficients `b` and `c`, which are seen by `poly` because it is a nested function.

As an example, to find a zero of the polynomial with `b = 2` and `c = 3.5`, using the starting point `x0 = 0`, call `findzero` as follows.

```
x = findzero(2, 3.5, 0)
```

This returns the zero

```
x =

    -1.0945
```

Providing Parameter Values to Anonymous Functions

Suppose you have already written a standalone M-file for the function `poly` containing the following code, which computes the polynomial for any coefficients `b` and `c`,

```
function y = poly(x, b, c) % Compute the polynomial.
y = x^3 + b*x + c;
```

You then want to find a zero for the coefficient values `b = 2` and `c = 3.5`. You cannot simply apply `fzero` to `poly`, which has three input arguments, because `fzero` only accepts functions with a single input argument. As an alternative to rewriting `poly` as a nested function, as described in "Providing Parameter Values Using Nested Functions" on page 4-33, you can pass `poly` to `fzero` as a function handle to an anonymous function that has the form `@(x) poly(x, b, c)`. The function handle has just one input argument `x`, so `fzero` accepts it.

```
b = 2;
c = 3.5;
x = fzero(@(x) poly(x, b, c), 0)
```

This returns the zero

```
x =

    -1.0945
```

"Anonymous Functions" on page 4-4 explains how to create anonymous functions.

If you later decide to find a zero for different values of `b` and `c`, you must redefine the anonymous function using the new values. For example,

```
b = 4;
c = -1;
fzero(@(x) poly(x, b, c), 0)

ans =

    0.2463
```

For more complicated objective functions, it is usually preferable to write the function as a nested function, as described in “Providing Parameter Values Using Nested Functions” on page 4-33.

Differential Equations

Note In function tables, commonly used functions are listed first, followed by more advanced functions. The same is true of property tables.

Initial Value Problems for ODEs and DAEs

In this section...

ODE Function Summary

ODE Initial Value Problem Solvers

The following table lists the initial value problem solvers, the kind of problem you can solve with each solver, and the method each solver uses.

Solver	Solves These Kinds of Problems	Method
`ode45`	Nonstiff differential equations	Runge-Kutta
`ode23`	Nonstiff differential equations	Runge-Kutta
`ode113`	Nonstiff differential equations	Adams
`ode15s`	Stiff differential equations and DAEs	NDFs (BDFs)
`ode23s`	Stiff differential equations	Rosenbrock

Solver	Solves These Kinds of Problems	Method
`ode23t`	Moderately stiff differential equations and DAEs	Trapezoidal rule
`ode23tb`	Stiff differential equations	TR-BDF2
`ode15i`	Fully implicit differential equations	BDFs

ODE Solution Evaluation and Extension

You can use the following functions to evaluate and extend solutions to ODEs.

Function	Description
`deval`	Evaluate the numerical solution using the output of ODE solvers.
`odextend`	Extend the solution of an initial value problem for an ODE

ODE Solvers Properties Handling

An options structure contains named properties whose values are passed to ODE solvers, and which affect problem solution. Use these functions to create, alter, or access an options structure.

Function	Description
`odeset`	Create or alter options structure for input to ODE solver.
`odeget`	Extract properties from options structure created with `odeset`.

ODE Solver Output Functions

If an output function is specified, the solver calls the specified function after every successful integration step. You can use `odeset` to specify one of these

sample functions as the OutputFcn property, or you can modify them to create your own functions.

Function	Description
`odeplot`	Time-series plot
`odephas2`	Two-dimensional phase plane plot
`odephas3`	Three-dimensional phase plane plot
`odeprint`	Print to command window

Introduction to Initial Value ODE Problems

What Is an Ordinary Differential Equation?

The ODE solvers are designed to handle *ordinary differential equations*. An ordinary differential equation contains one or more derivatives of a dependent variable y with respect to a single independent variable t, usually referred to as *time*. The derivative of y with respect to t is denoted as y', the second derivative as y'', and so on. Often $y(t)$ is a vector, having elements $y_1, y_2, \cdots, y_n$.

Types of Problems Handled by the ODE Solvers

The ODE solvers handle the following types of first-order ODEs:

- Explicit ODEs of the form $y' = f(t, y)$

- Linearly implicit ODEs of the form $M(t,y)\cdot y' = f(t,y)$, where $M(t,y)$ is a matrix
- Fully implicit ODEs of the form $f(t,y,y') = 0$ (`ode15i` only)

Using Initial Conditions to Specify the Solution of Interest

Generally there are many functions $y(t)$ that satisfy a given ODE, and additional information is necessary to specify the solution of interest. In an *initial value problem,* the solution of interest satisfies a specific *initial condition*, that is, y is equal to y_0 at a given initial time t_0. An initial value problem for an ODE is then

$$\begin{aligned} y' &= f(t,y) \\ y(t_0) &= y_0 \end{aligned} \qquad \textbf{(5-1)}$$

If the function $f(t,y)$ is sufficiently smooth, this problem has one and only one solution. Generally there is no analytic expression for the solution, so it is necessary to approximate $y(t)$ by numerical means, such as using one of the ODE solvers.

Working with Higher Order ODEs

The ODE solvers accept only first-order differential equations. However, ODEs often involve a number of dependent variables, as well as derivatives of order higher than one. To use the ODE solvers, you must rewrite such equations as an equivalent system of first-order differential equations of the form

$$y' = f(t,y)$$

You can write any ordinary differential equation

$$y^{(n)} = f(t, y, y', \ldots, y^{(n-1)})$$

as a system of first-order equations by making the substitutions

$$y_1 = y, \quad y_2 = y', \quad \ldots, \quad y_n = y^{(n-1)}$$

The result is an equivalent system of n first-order ODEs.

$$
\begin{aligned}
y_1' &= y_2 \\
y_2' &= y_3 \\
&\vdots \\
y_n' &= f(t, y_1, y_2, \ldots, y_n)
\end{aligned}
$$

"Example: Solving an IVP ODE (van der Pol Equation, Nonstiff)" on page 5-11 rewrites the second-order van der Pol equation

$$y_1'' - \mu(1 - y_1^2)\, y_1' + y_1 = 0$$

as a system of first-order ODEs.

Solvers for Explicit and Linearly Implicit ODEs

This section describes the ODE solver functions for explicit or linearly implicit ODEs, as described in "Types of Problems Handled by the ODE Solvers" on page 5-5. The solver functions implement numerical integration methods for solving initial value problems for ODEs. Beginning at the initial time with initial conditions, they step through the time interval, computing a solution at each time step. If the solution for a time step satisfies the solver's error tolerance criteria, it is a successful step. Otherwise, it is a failed attempt; the solver shrinks the step size and tries again.

Mass Matrix and DAE Properties, in the reference page for `odeset`, explains how to set options to solve more general linearly implicit problems.

The function `ode15i`, which solves implicit ODEs, is described in "Solver for Fully Implicit ODEs" on page 5-17.

Solvers for Nonstiff Problems

There are three solvers designed for nonstiff problems:

`ode45`	Based on an explicit Runge-Kutta (4,5) formula, the Dormand-Prince pair. It is a *one-step* solver – in computing $y(t_n)$, it needs only the solution at the immediately preceding time point, $y(t_{n-1})$. In general, `ode45` is the best function to apply as a "first try" for most problems.
`ode23`	Based on an explicit Runge-Kutta (2,3) pair of Bogacki and Shampine. It may be more efficient than `ode45` at crude tolerances and in the presence of mild stiffness. Like `ode45`, `ode23` is a one-step solver.
`ode113`	Variable order Adams-Bashforth-Moulton PECE solver. It may be more efficient than `ode45` at stringent tolerances and when the ODE function is particularly expensive to evaluate. `ode113` is a *multistep* solver—it normally needs the solutions at several preceding time points to compute the current solution.

Solvers for Stiff Problems

Not all difficult problems are stiff, but all stiff problems are difficult for solvers not specifically designed for them. Solvers for stiff problems can be used exactly like the other solvers. However, you can often significantly improve the efficiency of these solvers by providing them with additional information about the problem. (See "Changing ODE Integration Properties" on page 5-19.)

There are four solvers designed for stiff problems:

`ode15s`	Variable-order solver based on the numerical differentiation formulas (NDFs). Optionally it uses the backward differentiation formulas, BDFs (also known as Gear's method). Like `ode113`, `ode15s` is a multistep solver. If you suspect that a problem is stiff or if `ode45` failed or was very inefficient, try `ode15s`.
`ode23s`	Based on a modified Rosenbrock formula of order 2. Because it is a one-step solver, it may be more efficient than `ode15s` at crude tolerances. It can solve some kinds of stiff problems for which `ode15s` is not effective.
`ode23t`	An implementation of the trapezoidal rule using a "free" interpolant. Use this solver if the problem is only moderately stiff and you need a solution without numerical damping.
`ode23tb`	An implementation of TR-BDF2, an implicit Runge-Kutta formula with a first stage that is a trapezoidal rule step and a second stage that is a backward differentiation formula of order 2. Like `ode23s`, this solver may be more efficient than `ode15s` at crude tolerances.

Basic ODE Solver Syntax

All of the ODE solver functions, except for `ode15i`, share a syntax that makes it easy to try any of the different numerical methods, if it is not apparent which is the most appropriate. To apply a different method to the same problem, simply change the ODE solver function name. The simplest syntax, common to all the solver functions, is

```
[t,y] = solver(odefun,tspan,y0,options)
```

where *`solver`* is one of the ODE solver functions listed previously.

The basic input arguments are

`odefun`	Handle to a function that evaluates the system of ODEs. The function has the form `dydt = odefun(t,y)` where `t` is a scalar, and `dydt` and `y` are column vectors. See "Function Handles" in the MATLAB Programming documentation for more information.
`tspan`	Vector specifying the interval of integration. The solver imposes the initial conditions at `tspan(1)`, and integrates from `tspan(1)` to `tspan(end)`.
`y0`	Vector of initial conditions for the problem See also "Introduction to Initial Value ODE Problems" on page 5-5.
`options`	Structure of optional parameters that change the default integration properties. "Changing ODE Integration Properties" on page 5-19 tells you how to create the structure and describes the properties you can specify.

The output arguments contain the solution approximated at discrete points:

`t`	Column vector of time points
`y`	Solution array. Each row in `y` corresponds to the solution at a time returned in the corresponding row of `t`.

See the reference page for the ODE solvers for more information about these arguments.

Note See "Evaluating the Solution at Specific Points" on page 5-76 for more information about solver syntax where a continuous solution is returned.

Examples: Solving Explicit ODE Problems

This section uses the van der Pol equation

$$y_1'' - \mu(1 - y_1^2)y_1' + y_1 = 0$$

to describe the process for solving initial value ODE problems using the ODE solvers.

- "Example: Solving an IVP ODE (van der Pol Equation, Nonstiff)" on page 5-11 describes each step of the process. Because the van der Pol equation is a second-order equation, the example must first rewrite it as a system of first order equations.
- "Example: The van der Pol Equation, μ = 1000 (Stiff)" on page 5-14 demonstrates the solution of a stiff problem.
- "Evaluating the Solution at Specific Points" on page 5-16 tells you how to evaluate the solution at specific points.

Note See "Basic ODE Solver Syntax" on page 5-9 for more information.

Example: Solving an IVP ODE (van der Pol Equation, Nonstiff)

This example explains and illustrates the steps you need to solve an initial value ODE problem:

1 **Rewrite the problem as a system of first-order ODEs.** Rewrite the van der Pol equation (second-order)

$$y_1'' - \mu(1 - y_1^2)y_1' + y_1 = 0$$

where $\mu > 0$ is a scalar parameter, by making the substitution $y'_1 = y_2$. The resulting system of first-order ODEs is

$$y'_1 = y_2$$
$$y'_2 = \mu(1 - y_1^2)y_2 - y_1$$

See “Working with Higher Order ODEs” on page 5-6 for more information.

2 **Code the system of first-order ODEs.** Once you represent the equation as a system of first-order ODEs, you can code it as a function that an ODE solver can use. The function must be of the form

```
dydt = odefun(t,y)
```

Although `t` and `y` must be the function's two arguments, the function does not need to use them. The output `dydt`, a column vector, is the derivative of `y`.

The code below represents the van der Pol system in the function, `vdp1`. The `vdp1` function assumes that $\mu = 1$. The variables y_1 and y_2 are the entries `y(1)` and `y(2)` of a two-element vector.

```
function dydt = vdp1(t,y)
dydt = [y(2); (1-y(1)^2)*y(2)-y(1)];
```

Note that, although `vdp1` must accept the arguments `t` and `y`, it does not use `t` in its computations.

3 **Apply a solver to the problem.**

Decide which solver you want to use to solve the problem. Then call the solver and pass it the function you created to describe the first-order system of ODEs, the time interval on which you want to solve the problem, and an initial condition vector. See “Examples: Solving Explicit ODE Problems” on page 5-11 and the `@` for descriptions of the ODE solvers.

For the van der Pol system, you can use `ode45` on time interval `[0 20]` with initial values `y(1) = 2` and `y(2) = 0`.

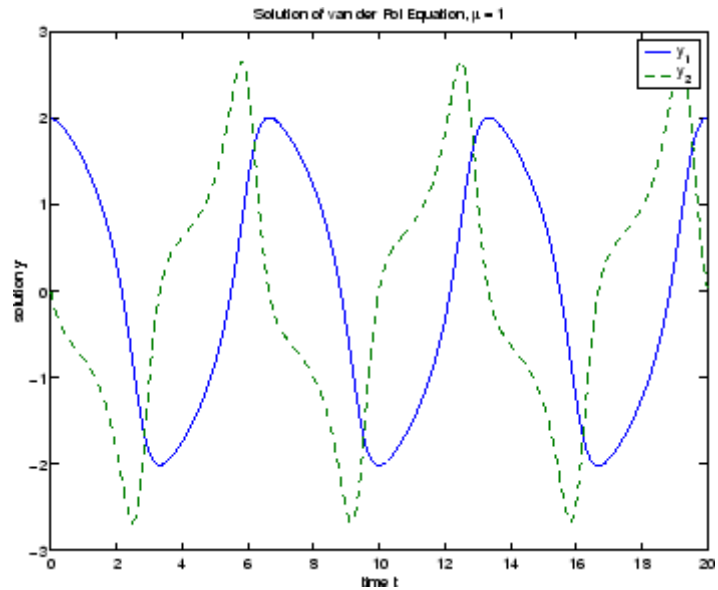
```
[t,y] = ode45(@vdp1,[0 20],[2; 0]);
```

This example uses `@` to pass `vdp1` as a function handle to `ode45`. The resulting output is a column vector of time points `t` and a solution array `y`. Each row in `y` corresponds to a time returned in the corresponding row of `t`. The first column of `y` corresponds to y_1, and the second column to y_2.

Note For information on function handles, see the `function_handle` (@), `func2str`, and `str2func` reference pages, and the "Function Handles" section of in the MATLAB documentation.

4 **View the solver output.** You can simply use the `plot` command to view the solver output.

```
plot(t,y(:,1),'-',t,y(:,2),'--')
title('Solution of van der Pol Equation, \mu = 1');
xlabel('time t');
ylabel('solution y');
legend('y_1','y_2')
```



As an alternative, you can use a solver output function to process the output. The solver calls the function specified in the integration property `OutputFcn` after each successful time step. Use `odeset` to set `OutputFcn` to the desired function. See Solver Output Properties, in the reference page for `odeset`, for more information about `OutputFcn`.

Example: The van der Pol Equation, μ = 1000 (Stiff)

This example presents a stiff problem. For a stiff problem, solutions can change on a time scale that is very short compared to the interval of integration, but the solution of interest changes on a much longer time scale. Methods not designed for stiff problems are ineffective on intervals where the solution changes slowly because they use time steps small enough to resolve the fastest possible change.

When μ is increased to 1000, the solution to the van der Pol equation changes dramatically and exhibits oscillation on a much longer time scale. Approximating the solution of the initial value problem becomes a more difficult task. Because this particular problem is stiff, a solver intended for nonstiff problems, such as `ode45`, is too inefficient to be practical. A solver such as `ode15s` is intended for such stiff problems.

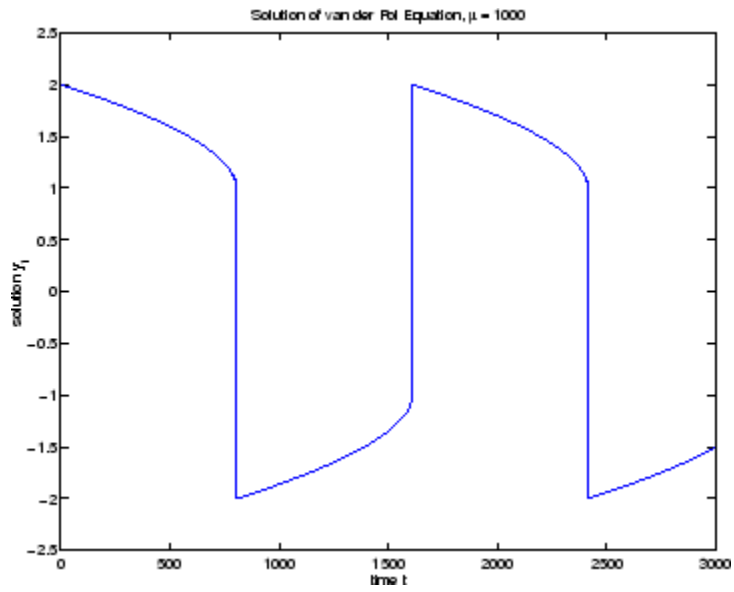
The `vdp1000` function evaluates the van der Pol system from the previous example, but with μ = 1000.

```
function dydt = vdp1000(t,y)
dydt = [y(2); 1000*(1-y(1)^2)*y(2)-y(1)];
```

Note This example hardcodes μ in the ODE function. The `vdpode` example solves the same problem, but passes a user-specified μ as a parameter to the ODE function.

Now use the `ode15s` function to solve the problem with the initial condition vector of `[2; 0]`, but a time interval of `[0 3000]`. For scaling reasons, plot just the first component of `y(t)`.

```
[t,y] = ode15s(@vdp1000,[0 3000],[2; 0]);
plot(t,y(:,1),'-');
title('Solution of van der Pol Equation, \mu = 1000');
xlabel('time t');
ylabel('solution y_1');
```



Note For detailed instructions for solving an initial value ODE problem, see "Example: Solving an IVP ODE (van der Pol Equation, Nonstiff)" on page 5-11.

Parameterizing an ODE Function

The preceding sections showed how to solve the van der Pol equation for two different values of the parameter μ. In those examples, the values μ = 1 and μ=1000 are hard-coded in the ODE functions. If you are solving an ODE for several different parameter values, it might be more convenient to include the parameter in the ODE function and assign a value to the parameter each time you run the ODE solver. This section explains how to do this for the van der Pol equation.

One way to provide parameter values to the ODE function is to write an M-file that

- Accepts the parameters as inputs.

- Contains ODE function as a nested function, internally using the input parameters.
- Calls the ODE solver.

The following code illustrates this:

```
function [t,y] = solve_vdp(mu)
tspan = [0 max(20, 3*mu)];
y0 = [2; 0];

% Call the ODE solver ode15s.
[t,y] = ode15s(@vdp,tspan,y0);

    % Define the ODE function as nested function,
    % using the parameter mu.
    function dydt = vdp(t,y)
    dydt = [y(2); mu*(1-y(1)^2)*y(2)-y(1)];
    end
end
```

Because the ODE function `vdp` is a nested function, the value of the parameter `mu` is available to it.

To run the M-file for `mu = 1`, as in "Example: Solving an IVP ODE (van der Pol Equation, Nonstiff)" on page 5-11, enter

```
[t,y] = solve_vdp(1);
```

To run the code for μ = 1000, as in "Example: The van der Pol Equation, μ = 1000 (Stiff)" on page 5-14, enter

```
[t,y] = solve_vdp(1000);
```

See the `vdpode` code for a complete example based on these functions.

Evaluating the Solution at Specific Points

The numerical methods implemented in the ODE solvers produce a continuous solution over the interval of integration `[`a, b`]`. You can evaluate the approximate solution, $S(x)$, at any point in `[`a, b`]` using the function `deval`

and the structure `sol` returned by the solver. For example, if you solve the problem described in "Example: Solving an IVP ODE (van der Pol Equation, Nonstiff)" on page 5-11 by calling `ode45` with a single output argument `sol`,

```
sol = ode45(@vdp1,[0 20],[2; 0]);
```

`ode45` returns the solution as a structure. You can then evaluate the approximate solution at points in the vector `xint = 1:5` as follows:

```
xint = 1:5;
Sxint = deval(sol,xint)

Sxint =

    1.5081    0.3235   -1.8686   -1.7407   -0.8344
   -0.7803   -1.8320   -1.0220    0.6260    1.3095
```

The `deval` function is vectorized. For a vector `xint`, the `i`th column of `Sxint` approximates the solution $y(\text{xint(i)})$.

Solver for Fully Implicit ODEs

The solver `ode15i` solves fully implicit differential equations of the form

$$f(t, y, y') = 0$$

using the variable order BDF method. The basic syntax for `ode15i` is

```
[t,y] = ode15i(odefun,tspan,y0,yp0,options)
```

The input arguments are

`odefun`	A function that evaluates the left side of the differential equation of the form $f(t, y, y') = 0$.
`tspan`	A vector specifying the interval of integration, `[t0,tf]`. To obtain solutions at specific times (all increasing or all decreasing), use `tspan = [t0,t1,...,tf]`.

`y0, yp0`	Vectors of initial conditions for $y(t_0)$ and $y'(t_0)$, respectively. The specified values must be consistent; that is, they must satisfy `f(t0,y0,yp0) = 0`. "Example: Solving a Fully Implicit ODE Problem" on page 5-18 shows how to use the function `decic` to compute consistent initial conditions.
`options`	Optional integration argument created using the `odeset` function. See the `odeset` reference page for details.

The output arguments contain the solution approximated at discrete points:

`t`	Column vector of time points
`y`	Solution array. Each row in `y` corresponds to the solution at a time returned in the corresponding row of `t`.

See the `ode15i` reference page for more information about these arguments.

Note See "Evaluating the Solution at Specific Points" on page 5-76 for more information about solver syntax where a continuous solution is returned.

Example: Solving a Fully Implicit ODE Problem

The following example shows how to use the function `ode15i` to solve the implicit ODE problem defined by Weissinger's equation

$$ty^2(y')^3 - y^3(y')^2 + t(t^2+1)y' - t^2y = 0$$

with the initial value $y(1) = \sqrt{3/2}$. The exact solution of the ODE is

$$y(t) = \sqrt{t^2 + 0.5}$$

The example uses the function `weissinger`, which is provided with MATLAB, to compute the left-hand side of the equation.

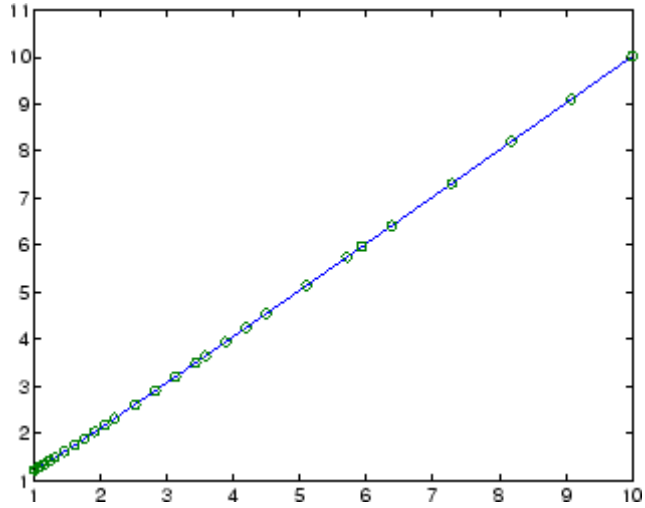
Before calling `ode15i`, the example uses a helper function `decic` to compute a consistent initial value for $y'(t_0)$. In the following call, the given initial

value $y(1) = \sqrt{3/2}$ is held fixed and a guess of 0 is specified for $y'(1)$. See the reference page for `decic` for more information.

```
t0 = 1;
y0 = sqrt(3/2);
yp0 = 0;
[y0,yp0] = decic(@weissinger,t0,y0,1,yp0,0);
```

You can now call `ode15i` to solve the ODE and then plot the numerical solution against the analytical solution with the following commands.

```
[t,y] = ode15i(@weissinger,[1 10],y0,yp0);
ytrue = sqrt(t.^2 + 0.5);
plot(t,y,t,ytrue,'o');
```



Changing ODE Integration Properties

The default integration properties in the ODE solvers are selected to handle common problems. In some cases, you can improve ODE solver performance by overriding these defaults. You do this by supplying the solvers with an `options` structure that specifies one or more property values.

For example, to change the value of the relative error tolerance of the solver from the default value of `1e-3` to `1e-4`,

1 Create an options structure using the function `odeset` by entering

```
options = odeset('RelTol', 1e-4);
```

2 Pass the `options` structure to the solver as follows:

- For all solvers except `ode15i`, use the syntax

```
[t,y] = solver(odefun,tspan,y0,options)
```

- For `ode15i`, use the syntax

```
[t,y] = ode15i(odefun,tspan,y0,yp0,options)
```

For an example that uses the `options` structure, see "Example: Stiff Problem (van der Pol Equation)" on page 5-22. For a complete description of the available options, see the reference page for `odeset`.

Examples: Applying the ODE Initial Value Problem Solvers

Running the Examples

This section contains several examples that illustrate the kinds of problems you can solve. For each example, there is a corresponding M-file, included in MATLAB. You can

- View the M-file code in an editor by entering `edit` followed by the name of the M-file at the MATLAB prompt. For example, to view the code for the simple nonstiff problem example, enter

  ```
  edit rigidode
  ```

  Alternatively, if you are reading this in the MATLAB Help Browser, you can click the name of the M-file in the list below.

- Run the example by entering the name of the M-file at the MATLAB prompt.

Example: Simple Nonstiff Problem

`rigidode` illustrates the solution of a standard test problem proposed by Krogh for solvers intended for nonstiff problems [8].

The ODEs are the Euler equations of a rigid body without external forces.

$$y_1' = y_2 y_3$$

$$y_2' = -y_1 y_3$$

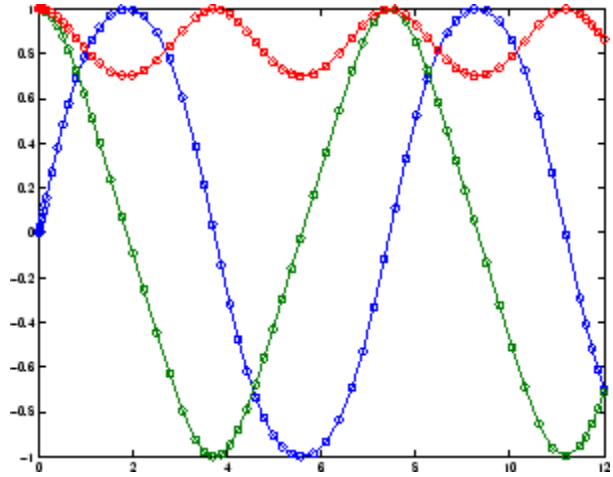
$$y_3' = -0.51 y_1 y_2$$

For your convenience, the entire problem is defined and solved in a single M-file. The differential equations are coded as a subfunction `f`. Because the example calls the `ode45` solver without output arguments, the solver uses the default output function `odeplot` to plot the solution components.

To run this example, click on the example name, or type `rigidode` at the command line.

```
function rigidode
%RIGIDODE  Euler equations of a rigid body without external forces
tspan = [0 12];
y0 = [0; 1; 1];

% Solve the problem using ode45
ode45(@f,tspan,y0);
% --------------------------------------------------------------
function dydt = f(t,y)
dydt = [ y(2)*y(3)
        -y(1)*y(3)
        -0.51*y(1)*y(2) ];
```



Example: Stiff Problem (van der Pol Equation)

`vdpode` illustrates the solution of the van der Pol problem described in "Example: The van der Pol Equation, μ = 1000 (Stiff)" on page 5-14. The differential equations

$$y_1' = y_2$$

$$y_2' = \mu(1 - y_1^2)y_2 - y_1$$

involve a constant parameter μ.

As μ increases, the problem becomes more stiff, and the period of oscillation becomes larger. When μ is 1000 the equation is in relaxation oscillation and the problem is very stiff. The limit cycle has portions where the solution components change slowly and the problem is quite stiff, alternating with regions of very sharp change where it is not stiff (quasi-discontinuities).

By default, the solvers in the ODE suite that are intended for stiff problems approximate Jacobian matrices numerically. However, this example provides a nested function `J(t,y)` to evaluate the Jacobian matrix $\partial f/\partial y$ analytically at `(t,y)` for μ = `MU`. The use of an analytic Jacobian can improve the reliability and efficiency of integration.

To run this example, click on the example name, or type `vdpode` at the command line. From the command line, you can specify a value of μ as an argument to `vdpode`. The default is mu μ = 1000.

```
function vdpode(MU)
%VDPODE  Parameterizable van der Pol equation (stiff for large MU)
if nargin < 1
  MU = 1000;     % default
end

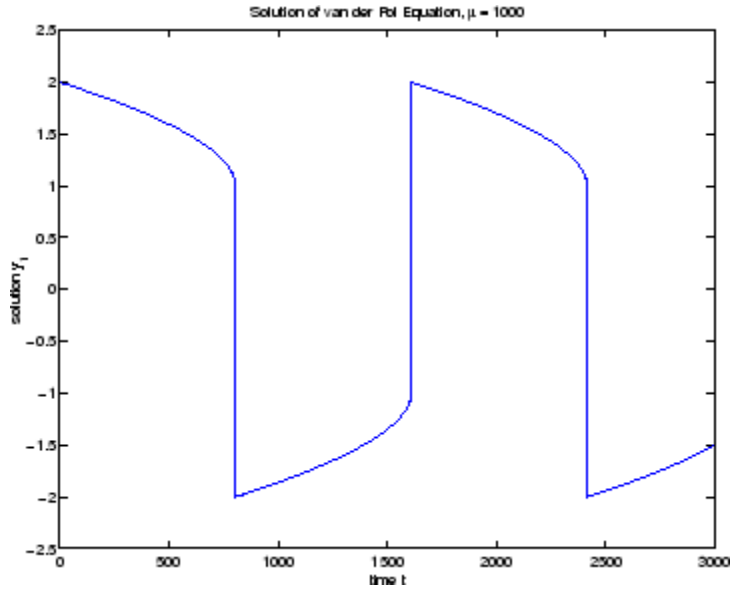
tspan = [0; max(20,3*MU)];              % Several periods
y0 = [2; 0];
options = odeset('Jacobian',@J);

[t,y] = ode15s(@f,tspan,y0,options);

plot(t,y(:,1));
title(['Solution of van der Pol Equation, \mu = ' num2str(MU)]);
xlabel('time t');
ylabel('solution y_1');

axis([tspan(1) tspan(end) -2.5 2.5]);
---------------------------------------------------------------
function dydt = f(t,y)
dydt = [            y(2)
         MU*(1-y(1)^2)*y(2)-y(1) ];
```

```
end   % End nested function f
--------------------------------------------------------------------
function dfdy = J(t,y)
dfdy = [         0                   1
         -2*MU*y(1)*y(2)-1    MU*(1-y(1)^2) ];
end   % End nested function J
end
```



Example: Finite Element Discretization

`fem1ode` illustrates the solution of ODEs that result from a finite element discretization of a partial differential equation. The value of `N` in the call `fem1ode(N)` controls the discretization, and the resulting system consists of `N` equations. By default, `N` is 19.

This example involves a mass matrix. The system of ODEs comes from a method of lines solution of the partial differential equation

$$e^{-t}\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2}$$

with initial condition $u(0,x) = \sin(x)$ and boundary conditions $u(t,0) = u(t,\pi) = 0$. An integer N is chosen, h is defined as $\pi/(N+1)$, and the solution of the partial differential equation is approximated at $x_k = kh$ for k = 0, 1, ..., N+1 by

$$u(t,x_k) = \sum_{k=1}^{N} c_k(t)\phi_k(x)$$

Here $\phi_k(x)$ is a piecewise linear function that is 1 at x_k and 0 at all the other x_j. A Galerkin discretization leads to the system of ODEs

$$M(t)c' = Jc \quad \text{where} \quad c(t) = \begin{bmatrix} c_1(t) \\ \\ c_N(t) \end{bmatrix}$$

and the tridiagonal matrices $M(t)$ and J are given by

$$M_{ij} = \begin{cases} 2h/3 \exp(-t) & \text{if } i = j \\ h/6 \exp(-t) & \text{if } i = j \pm 1 \\ 0 & \text{otherwise} \end{cases}$$

and

$$J_{ij} = \begin{cases} -2/h & \text{if } i = j \\ 1/h & \text{if } i = j \pm 1 \\ 0 & \text{otherwise} \end{cases}$$

The initial values $c(0)$ are taken from the initial condition for the partial differential equation. The problem is solved on the time interval $[0, \pi]$.

In the `fem1ode` example, the properties

```
options = odeset('Mass',@mass,'MStateDep','none','Jacobian',J)
```

indicate that the problem is of the form $M(t)y' = Jy$. The nested function `mass(t)` evaluates the time-dependent mass matrix $M(t)$ and `J` is the constant Jacobian.

To run this example, click on the example name, or type `fem1ode` at the command line. From the command line, you can specify a value of N as an argument to `fem1ode`. The default is $N = 19$.

```
function fem1ode(N)
%FEM1ODE  Stiff problem with a time-dependent mass matrix

if nargin < 1
  N = 19;
end
h = pi/(N+1);
y0 = sin(h*(1:N)');
tspan = [0; pi];

% The Jacobian is constant.
e = repmat(1/h,N,1);    %  e=[(1/h) ... (1/h)];
d = repmat(-2/h,N,1);   %  d=[(-2/h) ... (-2/h)];
% J is shared with the derivative function.
J = spdiags([e d e], -1:1, N, N);

d = repmat(h/6,N,1);
% M is shared with the mass matrix function.
M = spdiags([d 4*d d], -1:1, N, N);

options = odeset('Mass',@mass,'MStateDep','none', ...
                 'Jacobian',J);

[t,y] = ode15s(@f,tspan,y0,options);

figure;
surf((1:N)/(N+1),t,y);
set(gca,'ZLim',[0 1]);
view(142.5,30);
title(['Finite element problem with time-dependent mass ' ...
       'matrix, solved by ODE15S']);
xlabel('space ( x/\pi )');
ylabel('time');
zlabel('solution');
%-------------------------------------------------------------

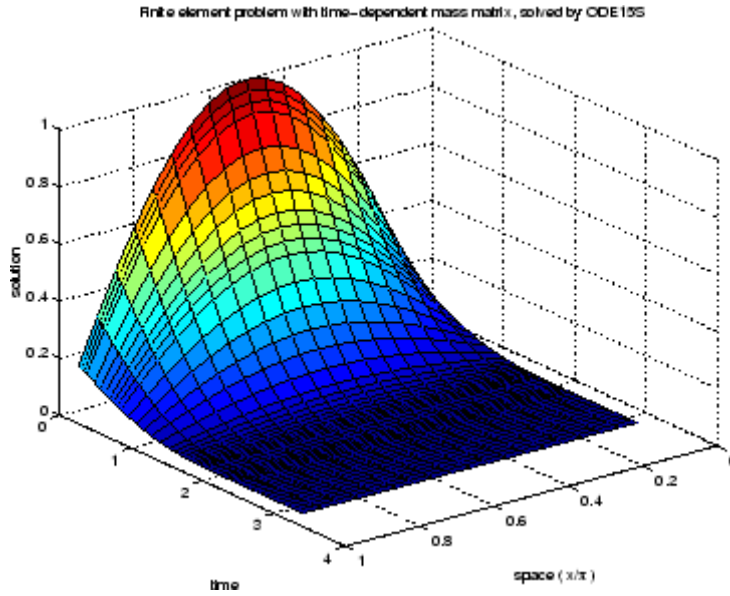
```

```
function yp = f(t,y)
% Derivative function.
   yp = J*y;    % Constant Jacobian is provided by outer function
end             % End nested function f
%-------------------------------------------------------------
-
function Mt = mass(t)
% Mass matrix function.
   Mt = exp(-t)*M;    % M is provided by outer function
end                   % End nested function mass
%-------------------------------------------------------------
-
end
```



Example: Large, Stiff, Sparse Problem

`brussode` illustrates the solution of a (potentially) large stiff sparse problem. The problem is the classic “Brusselator“ system [3] that models diffusion in a chemical reaction

$$u_i' = 1 + u_i^2 v_i - 4u_i + \alpha(N+1)^2(u_{i-1} - 2u_i + u_{i+1})$$
$$v_i' = 3u_i - u_i^2 v_i + \alpha(N+1)^2(v_{i-1} - 2v_i + v_{i+1})$$

and is solved on the time interval `[0,10]` with $\alpha = 1/50$ and

$$\left.\begin{aligned} u_i(0) &= 1 + \sin(2\pi x_i) \\ v_i(0) &= 3 \end{aligned}\right\} \quad \text{with } x_i = i/(N+1), \text{ for } i = 1, \ldots, N$$

There are $2N$ equations in the system, but the Jacobian is banded with a constant width 5 if the equations are ordered as $u_1, v_1, u_2, v_2, \cdots$

In the call `brussode(N)`, where `N` corresponds to N, the parameter `N` ≥ 2 specifies the number of grid points. The resulting system consists of `2N` equations. By default, `N` is `20`. The problem becomes increasingly stiff and the Jacobian increasingly sparse as `N` increases.

The nested function `f(t,y)` returns the derivatives vector for the Brusselator problem. The subfunction `jpattern(N)` returns a sparse matrix of `1`s and `0`s showing the locations of nonzeros in the Jacobian $\partial f/\partial y$. The example assigns this matrix to the property `JPattern`, and the solver uses the sparsity pattern to generate the Jacobian numerically as a sparse matrix. Providing a sparsity pattern can significantly reduce the number of function evaluations required to generate the Jacobian and can accelerate integration.

For the Brusselator problem, if the sparsity pattern is not supplied, `2N` evaluations of the function are needed to compute the `2N`-by-`2N` Jacobian matrix. If the sparsity pattern is supplied, only four evaluations are needed, regardless of the value of `N`.

To run this example, click on the example name, or type `brussode` at the command line. From the command line, you can specify a value of N as an argument to `brussode`. The default is $N = 20$.

```
function brussode(N)
%BRUSSODE  Stiff problem modeling a chemical reaction

if nargin < 1
  N = 20;
```

```
end

tspan = [0; 10];
y0 = [1+sin((2*pi/(N+1))*(1:N));
repmat(3,1,N)];

options = odeset('Vectorized','on','JPattern',jpattern(N));

[t,y] = ode15s(@f,tspan,y0,options);

u = y(:,1:2:end);
x = (1:N)/(N+1);
surf(x,t,u);
view(-40,30);
xlabel('space');
ylabel('time');
zlabel('solution u');
title(['The Brusselator for N = ' num2str(N)]);
% ------------------------------------------------------------
function dydt = f(t,y)
c = 0.02 * (N+1)^2;
dydt = zeros(2*N,size(y,2));      % preallocate dy/dt
% Evaluate the two components of the function at one edge of
% the grid (with edge conditions).
i = 1;
dydt(i,:) = 1 + y(i+1,:).*y(i,:).^2 - 4*y(i,:) + ...
            c*(1-2*y(i,:)+y(i+2,:));
dydt(i+1,:) = 3*y(i,:) - y(i+1,:).*y(i,:).^2 + ...
              c*(3-2*y(i+1,:)+y(i+3,:));

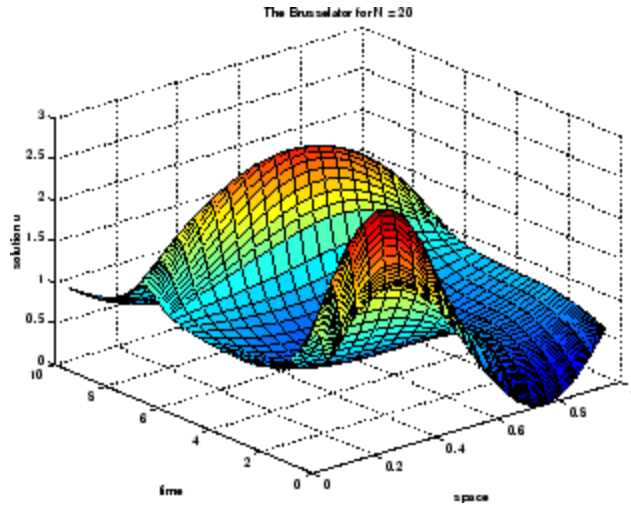
S = spdiags(B,-2:2,2*N,2*N);
end;
```



Example: Simple Event Location

`ballode` models the motion of a bouncing ball. This example illustrates the event location capabilities of the ODE solvers.

The equations for the bouncing ball are

$$y_1' = y_2$$
$$y_2' = -9.8$$

In this example, the event function is coded in a subfunction `events`

```
[value,isterminal,direction] = events(t,y)
```

which returns

- A value of the event function
- The information whether or not the integration should stop when `value = 0` (`isterminal = 1` or `0`, respectively)
- The desired directionality of the zero crossings:

`-1`	Detect zero crossings in the negative direction only
`0`	Detect all zero crossings
`1`	Detect zero crossings in the positive direction only

The length of `value`, `isterminal`, and `direction` is the same as the number of event functions. The `i`th element of each vector, corresponds to the `i`th event function. For an example of more advanced event location, see `orbitode` (“Example: Advanced Event Location” on page 5-33).

In `ballode`, setting the `Events` property to `@events` causes the solver to stop the integration (`isterminal = 1`) when the ball hits the ground (the height `y(1)` is `0`) during its fall (`direction = -1`). The example then restarts the integration with initial conditions corresponding to a ball that bounced.

To run this example, click on the example name, or type `ballode` at the command line.

```
function ballode
%BALLODE  Run a demo of a bouncing ball.

tstart = 0;
tfinal = 30;
y0 = [0; 20];
refine = 4;
options = odeset('Events',@events,'OutputFcn', @odeplot,...
                 'OutputSel',1,'Refine',refine);
```

```
set(gca,'xlim',[0 30],'ylim',[0 25]);
box on
hold on;

tout = tstart;
yout = y0.';
teout = [];
yeout = [];
ieout = [];
for i = 1:10
  % Solve until the first terminal event.
  [t,y,te,ye,ie] = ode23(@f,[tstart tfinal],y0,options);
  if ~ishold
    hold on
  end
  % Accumulate output.
  nt = length(t);
  tout = [tout; t(2:nt)];
  yout = [yout; y(2:nt,:)];
  teout = [teout; te];    % Events at tstart are never reported.
  yeout = [yeout; ye];
  ieout = [ieout; ie];

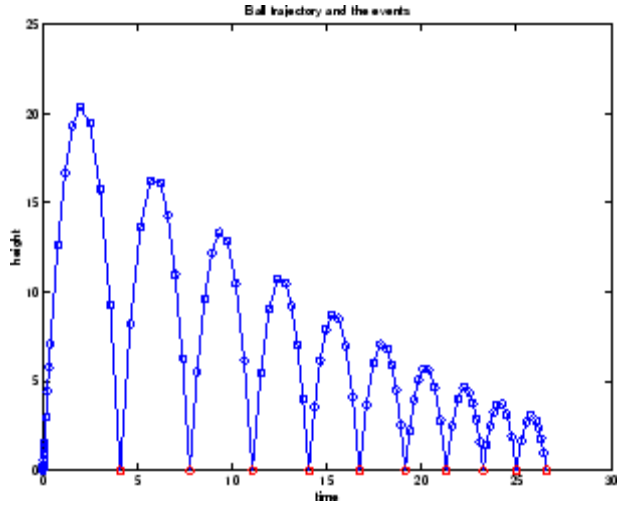
  ud = get(gcf,'UserData');
  if ud.stop
    break;
  end

  % Set the new initial conditions, with .9 attenuation.
  y0(1) = 0;
  y0(2) = -.9*y(nt,2);

  % A good guess of a valid first time step is the length of
  % the last valid time step, so use it for faster computation.
  options = odeset(options,'InitialStep',t(nt)-t(nt-refine),...
                           'MaxStep',t(nt)-t(1));
  tstart = t(nt);
end

plot(teout,yeout(:,1),'ro')
```

```
xlabel('time');
ylabel('height');
title('Ball trajectory and the events');
hold off
odeplot([],[],'done');
% --------------------------------------------------------------------
function dydt = f(t,y)
dydt = [y(2); -9.8];
% --------------------------------------------------------------------
function [value,isterminal,direction] = events(t,y)
% Locate the time when height passes through zero in a
% decreasing direction and stop integration.
value = y(1);     % Detect height = 0
isterminal = 1;   % Stop the integration
direction = -1;   % Negative direction only
```



Example: Advanced Event Location

`orbitode` illustrates the solution of a standard test problem for those solvers that are intended for nonstiff problems. It traces the path of a spaceship traveling around the moon and returning to the earth (Shampine and Gordon [8], p. 246).

The `orbitode` problem is a system of the following four equations shown:

$$y_1' = y_3$$

$$y_2' = y_4$$

$$y_3' = 2y_4 + y_1 - \frac{\mu^*(y_1+\mu)}{r_1^3} - \frac{\mu(y_1-\mu^*)}{r_2^3}$$

$$y_4' = -2y_3 + y_2 - \frac{\mu^* y_2}{r_1^3} - \frac{\mu y_2}{r_2^3}$$

where

$$\mu = 1/82.45$$

$$\mu^* = 1-\mu$$

$$r_1 = \sqrt{(y_1+\mu)^2 + y_2^2}$$

$$r_2 = \sqrt{(y_1-\mu^*)^2 + y_2^2}$$

The first two solution components are coordinates of the body of infinitesimal mass, so plotting one against the other gives the orbit of the body. The initial conditions have been chosen to make the orbit periodic. The value of μ corresponds to a spaceship traveling around the moon and the earth. Moderately stringent tolerances are necessary to reproduce the qualitative behavior of the orbit. Suitable values are `1e-5` for `RelTol` and `1e-4` for `AbsTol`.

The nested `events` function includes event functions that locate the point of maximum distance from the starting point and the time the spaceship returns to the starting point. Note that the events are located accurately, even though the step sizes used by the integrator are *not* determined by the location of the events. In this example, the ability to specify the direction of the zero crossing is critical. Both the point of return to the initial point and the point of maximum distance have the same event function value, and the direction of the crossing is used to distinguish them.

To run this example, click on the example name, or type `orbitode` at the command line. The example uses the output function `odephas2` to produce

the two-dimensional phase plane plot and let you to see the progress of the integration.

```
function orbitode
%ORBITODE  Restricted three-body problem

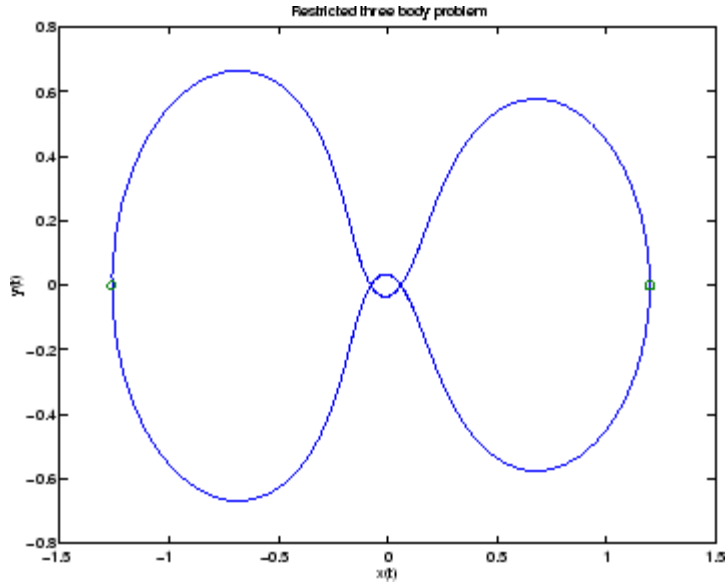
mu = 1 / 82.45;
mustar = 1 - mu;
y0 = [1.2; 0; 0; -1.04935750983031990726];
tspan = [0 7];

options = odeset('RelTol',1e-5,'AbsTol',1e-4,...
                 'OutputFcn',@odephas2,'Events',@events);

[t,y,te,ye,ie] = ode45(@f,tspan,y0,options);

plot(y(:,1),y(:,2),ye(:,1),ye(:,2),'o');
title ('Restricted three body problem')
ylabel ('y(t)')
xlabel ('x(t)')
% ------------------------------------------------------------
function dydt = f(t,y)
r13 = ((y(1) + mu)^2 + y(2)^2) ^ 1.5;
r23 = ((y(1) - mustar)^2 + y(2)^2) ^ 1.5;
dydt = [ y(3)
         y(4)
         2*y(4) + y(1) - mustar*((y(1)+mu)/r13) - ...
                         mu*((y(1)-mustar)/r23)
        -2*y(3) + y(2) - mustar*(y(2)/r13) - mu*(y(2)/r23) ];
end   % End nested function f
% ------------------------------------------------------------
function [value,isterminal,direction] = events(t,y)
% Locate the time when the object returns closest to the
% initial point y0 and starts to move away, and stop integration.
% Also locate the time when the object is farthest from the
% initial point y0 and starts to move closer.
%
% The current distance of the body is
%
%   DSQ = (y(1)-y0(1))^2 + (y(2)-y0(2))^2
```

```
%       = <y(1:2)-y0(1:2),y(1:2)-y0(1:2)>
%
% A local minimum of DSQ occurs when d/dt DSQ crosses zero
% heading in the positive direction.  We can compute d(DSQ)/dt as
%
%  d(DSQ)/dt = 2*(y(1:2)-y0(1:2))'*dy(1:2)/dt = ...
%                 2*(y(1:2)-y0(1:2))'*y(3:4)
%
dDSQdt = 2 * ((y(1:2)-y0(1:2))' * y(3:4));
value = [dDSQdt; dDSQdt];
isterminal = [1; 0];            % Stop at local minimum
direction = [1; -1];            % [local minimum, local maximum]
end   % End nested function events
end
```



Example: Differential-Algebraic Problem

`hb1dae` reformulates the `hb1ode` example as a *differential-algebraic equation* (DAE) problem. The Robertson problem coded in `hb1ode` is a classic test problem for codes that solve stiff ODEs.

$$y_1' = -0.04y_1 + 10^4 y_2 y_3$$

$$y_2' = 0.04y_1 - 10^4 y_2 y_3 - 3 \cdot 10^7 y_2^2$$

$$y_3' = 3 \cdot 10^7 y_2^2$$

Note The Robertson problem appears as an example in the prolog to LSODI [4].

In `hb1ode`, the problem is solved with initial conditions $y_1(0) = 1$, $y_2(0) = 0$, $y_3(0) = 0$ to steady state. These differential equations satisfy a linear conservation law that is used to reformulate the problem as the DAE

$$y_1' = -0.04y_1 + 10^4 y_2 y_3$$

$$y_2' = 0.04y_1 - 10^4 y_2 y_3 - 3 \cdot 10^7 y_2^2$$

$$0 = y_1 + y_2 + y_3 - 1$$

These equations do not have a solution for $y(0)$ with components that do not sum to 1. The problem has the form of $My' = f(t, y)$ with

$$M = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}$$

M is singular, but `hb1dae` does not inform the solver of this. The solver must recognize that the problem is a DAE, not an ODE. Similarly, although consistent initial conditions are obvious, the example uses an inconsistent value $y_3(0) = 10^{-3}$ to illustrate computation of consistent initial conditions.

To run this example, click on the example name, or type `hb1dae` at the command line. Note that `hb1dae`

- Imposes a much smaller absolute error tolerance on y_2 than on the other components. This is because y_2 is much smaller than the other components and its major change takes place in a relatively short time.
- Specifies additional points at which the solution is computed to more clearly show the behavior of y_2.
- Multiplies y_2 by 10^4 to make y_2 visible when plotting it with the rest of the solution.
- Uses a logarithmic scale to plot the solution on the long time interval.

```
function hb1dae
%HB1DAE  Stiff differential-algebraic equation (DAE)

% A constant, singular mass matrix
M = [1 0 0
     0 1 0
     0 0 0];

% Use an inconsistent initial condition to test initialization.
y0 = [1; 0; 1e-3];
tspan = [0 4*logspace(-6,6)];

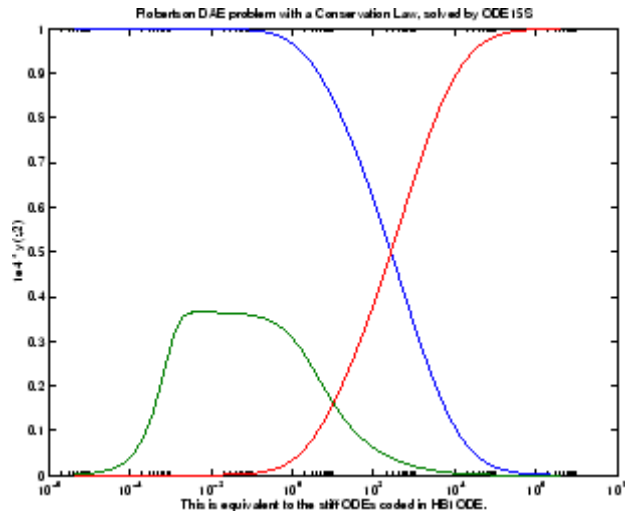
% Use the LSODI example tolerances. The 'MassSingular' property
% is left at its default 'maybe' to test the automatic detection
% of a DAE.
options = odeset('Mass',M,'RelTol',1e-4,...
                 'AbsTol',[1e-6 1e-10 1e-6],'Vectorized','on');

[t,y] = ode15s(@f,tspan,y0,options);

y(:,2) = 1e4*y(:,2);

semilogx(t,y);
ylabel('1e4 * y(:,2)');
title(['Robertson DAE problem with a Conservation Law, '...
       'solved by ODE15S']);
xlabel('This is equivalent to the stiff ODEs coded in HB1ODE.');
% --------------------------------------------------------------
function out = f(t,y)
out = [ -0.04*y(1,:) + 1e4*y(2,:).*y(3,:)
```

```
    0.04*y(1,:) - 1e4*y(2,:).*y(3,:) - 3e7*y(2,:).^2
    y(1,:) + y(2,:) + y(3,:) - 1 ];
```



Example: Computing Nonnegative Solutions

If certain components of the solution must be nonnegative, use `odeset` to set the `NonNegative` property for the indices of these components.

Note This option is not available for `ode23s`, `ode15i`, or for implicit solvers (`ode15s`, `ode23t`, `ode23tb`) applied to problems where there is a mass matrix.

Imposing nonnegativity is not always a trivial task. We suggest that you use this option only when necessary, for example in instances in which the application of a solution or integration will fail otherwise.

Consider the following initial value problem solved on the interval `[0, 40]`:

```
y' = - |y|, y(0) = 1
```

The solution of this problem decays to zero. If a solver produces a negative approximate solution, it begins to track the solution of the ODE through this

value, the solution goes off to minus infinity, and the computation fails. Using the `NonNegative` property prevents this from happening.

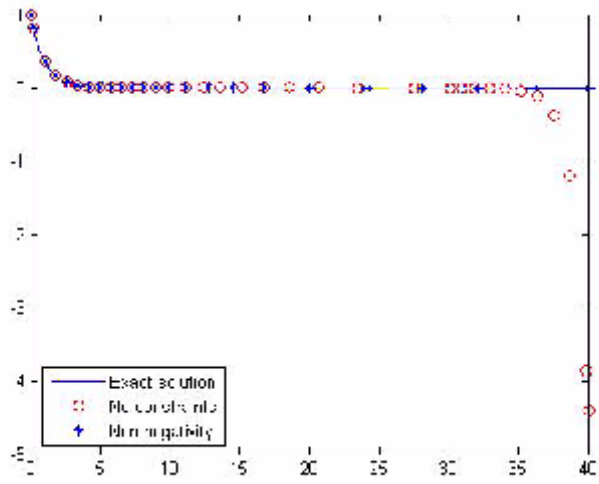
In this example, the first call to `ode45` uses the defaults for the solver parameters:

```
ode = @(t,y) -abs(y);
[t0,y0] = ode45(ode,[0, 40], 1);
```

The second uses options to impose nonnegativity conditions:

```
options = odeset('NonNegative',1);
[t1,y1] = ode45(ode,[0, 40], 1, options);
```

This plot compares the numerical solution to the exact solution.



Here is a more complete view of the code used to obtain this plot:

```
ode = @(t,y) -abs(y);
options = odeset('Refine',1);
[t0,y0] = ode45(ode,[0, 40], 1,options);
options = odeset(options,'NonNegative',1);
```

```
[t1,y1] = ode45(ode,[0, 40], 1, options);
t = linspace(0,40,1000);
y = exp(-t);
plot(t,y,'b-',t0,y0,'ro',t1,y1,'b*');
legend('Exact solution','No constraints','Nonnegativity', ...
       'Location','SouthWest')
```

The MATLAB kneeode Demo. The MATLAB `kneeode` demo solves the "knee problem" by imposing a nonnegativity constraint on the numerical solution. The initial value problem is

$$\epsilon y' = (1-x)y - y^2, \quad y(0) = 1$$

For $0 < \epsilon < 1$, the solution of this problem approaches null isoclines $y = 1 - x$ and $y = 0$ for $x < 1$ and $x > 1$, respectively. The numerical solution, when computed with default tolerances, follows the $y = 1 - x$ isocline for the whole interval of integration. Imposing nonnegativity constraints results in the correct solution.

Here is the code that makes up the `kneeode` demo:

```
function kneeode
%KNEEODE  The "knee problem" with Nonnegativity constraints.

% Problem parameter
epsilon = 1e-6;

y0 = 1;
xspan = [0, 2];

% Solve without imposing constraints
options = [];
[x1,y1] = ode15s(@odefcn,xspan,y0,options);

% Impose nonnegativity constraint
options = odeset('NonNegative',1);
[x2,y2] = ode15s(@odefcn,xspan,y0,options);

figure
plot(x1,y1,'b.-',x2,y2,'g-')
```

```
axis([0,2,-1,1]);
title('The "knee problem"');
legend('No constraints','nonnegativity')
xlabel('x');
ylabel('solution y')

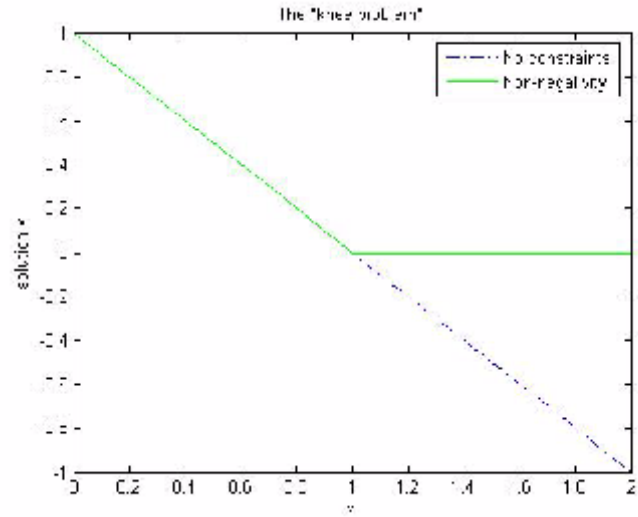
   function yp = odefcn(x,y)
      yp = ((1 - x)*y - y^2)/epsilon;
   end
end  % kneeode
```

The derivative function is defined within nested function `odefcn`. The value of epsilon used in `odefcn` is obtained from the outer function:

```
function yp = odefcn(x,y)
yp = ((1 - x)*y - y^2)/epsilon;
end
```

The demo solves the problem using the `ode15s` function, first with the default options, and then by imposing a nonnegativity constraint. To run the demo, type `kneeode` at the MATLAB command prompt.

Here is the output plot. The plot confirms correct solution behavior after imposing constraints.



Summary of Code Examples

The following table lists the M-files for all the ODE initial value problem examples. Click the example name to see the code in an editor. Type the example name at the command line to run it.

Note The Differential Equations Examples browser enables you to view the code for the ODE examples and DAE examples. You can also run the examples from the browser. Click these links to invoke the browser, or type `odeexamples('ode')` or `odeexamples('dae')` at the command line.

Example	Description
`amp1dae`	Stiff DAE — electrical circuit
`ballode`	Simple event location — bouncing ball
`batonode`	ODE with time- and state-dependent mass matrix — motion of a baton
`brussode`	Stiff large problem — diffusion in a chemical reaction (the Brusselator)

Example	Description
`burgersode`	ODE with strongly state-dependent mass matrix — Burgers' equation solved using a moving mesh technique
`fem1ode`	Stiff problem with a time-dependent mass matrix — finite element method
`fem2ode`	Stiff problem with a constant mass matrix — finite element method
`hb1ode`	Stiff ODE problem solved on a very long interval — Robertson chemical reaction
`hb1dae`	Robertson problem — stiff, linearly implicit DAE from a conservation law
`ihb1dae`	Robertson problem — stiff, fully implicit DAE
`iburgersode`	Burgers' equation solved as implicit ODE system
`kneeode`	The "knee problem" with nonnegativity constraints
`orbitode`	Advanced event location — restricted three body problem
`rigidode`	Nonstiff problem — Euler equations of a rigid body without external forces
`vdpode`	Parameterizable van der Pol equation (stiff for large μ)

Questions and Answers, and Troubleshooting

This section contains a number of tables that answer questions about the use and operation of the ODE solvers:

- Solving Different Kinds of Problems on page 5-49
- Troubleshooting on page 5-51

General ODE Solver Questions

Question	Answer
How do the ODE solvers differ from `quad` or `quadl`?	`quad` and `quadl` solve problems of the form $y' = f(t)$. The ODE solvers handle more general problems $y' = f(t, y)$, linearly implicit problems that involve a mass matrix $M(t, y)\, y' = f(t, y)$, and fully implicit problems $f(t, y, y') = 0$.
Can I solve ODE systems in which there are more equations than unknowns, or vice versa?	No.

Problem Size, Memory Use, and Computation Speed

Question	Answer
How large a problem can I solve with the ODE suite?	The primary constraints are memory and time. At each time step, the solvers for nonstiff problems allocate vectors of length `n`, where `n` is the number of equations in the system. The solvers for stiff problems but also allocate an `n`-by-`n` Jacobian matrix. For these solvers it may be advantageous to use the sparse option. If the problem is nonstiff, or if you are using the sparse option, it may be possible to solve a problem with thousands of unknowns. In this case, however, storage of the result can be problematic. Try asking the solver to evaluate the solution at specific points only, or call the solver with no output arguments and use an output function to monitor the solution.

Problem Size, Memory Use, and Computation Speed (Continued)

Question	Answer
I'm solving a very large system, but only care about a couple of the components of `y`. Is there any way to avoid storing all of the elements?	Yes. The user-installable output function capability is designed specifically for this purpose. When you call the solver with no output arguments, the solver does not allocate storage to hold the entire solution history. Instead, the solver calls `OutputFcn(t,y,flag)` at each time step. To keep the history of specific elements, write an output function that stores or plots only the elements you care about.
What is the startup cost of the integration and how can I reduce it?	The biggest startup cost occurs as the solver attempts to find a step size appropriate to the scale of the problem. If you happen to know an appropriate step size, use the `InitialStep` property. For example, if you repeatedly call the integrator in an event location loop, the last step that was taken before the event is probably on scale for the next integration. See `ballode` for an example.

Time Steps for Integration

Question	Answer
The first step size that the integrator takes is too large, and it misses important behavior.	You can specify the first step size with the `InitialStep` property. The integrator tries this value, then reduces it if necessary.
Can I integrate with fixed step sizes?	No.

Error Tolerance and Other Options

Question	Answer
How do I choose `RelTol` and `AbsTol`?	`RelTol`, the relative accuracy tolerance, controls the number of correct digits in the answer. `AbsTol`, the absolute error tolerance, controls the difference between the answer and the solution. At each step, the error `e` in component `i` of the solution satisfies `|e(i)| ≤max(RelTol*abs(y(i)),AbsTol(i))` Roughly speaking, this means that you want `RelTol` correct digits in all solution components except those smaller than thresholds `AbsTol(i)`. Even if you are not interested in a component `y(i)` when it is small, you may have to specify `AbsTol(i)` small enough to get some correct digits in `y(i)` so that you can accurately compute more interesting components.

Error Tolerance and Other Options (Continued)

Question	Answer
I want answers that are correct to the precision of the computer. Why can't I simply set `RelTol` to `eps`?	You can get close to machine precision, but not that close. The solvers do not allow `RelTol` near `eps` because they try to approximate a continuous function. At tolerances comparable to `eps`, the machine arithmetic causes all functions to look discontinuous.
How do I tell the solver that I don't care about getting an accurate answer for one of the solution components?	You can increase the absolute error tolerance corresponding to this solution component. If the tolerance is bigger than the component, this specifies no correct digits for the component. The solver may have to get some correct digits in this component to compute other components accurately, but it generally handles this automatically.

Solving Different Kinds of Problems

Question	Answer
Can the solvers handle partial differential equations (PDEs) that have been discretized by the method of lines?	Yes, because the discretization produces a system of ODEs. Depending on the discretization, you might have a form involving mass matrices – the ODE solvers provide for this. Often the system is stiff. This is to be expected when the PDE is parabolic and when there are phenomena that happen on very different time scales such as a chemical reaction in a fluid flow. In such cases, use one of the four solvers: `ode15s`, `ode23s`, `ode23t`, `ode23tb`. If there are many equations, set the `JPattern` property. This might make the difference between success and failure due to the computation being too expensive. For an example that uses `JPattern`, see "Example: Large, Stiff, Sparse Problem" on page 5-27. When the system is not stiff, or not very stiff, `ode23` or `ode45` is more efficient than `ode15s`, `ode23s`, `ode23t`, or `ode23tb`. Parabolic-elliptic partial differential equations in 1-D can be solved directly with the MATLAB PDE solver, `pdepe`. For more information, see "Partial Differential Equations" on page 5-93.
Can I solve differential-algebraic equation (DAE) systems?	Yes. The solvers `ode15s` and `ode23t` can solve some DAEs of the form $M(t,y)y' = f(t,y)$ where $M(t,y)$ is singular. The DAEs must be of index 1. `ode15i` can solve fully implicit DAEs of index 1, $f(t,y,y') = 0$. For examples, see `amp1dae`, `hb1dae`, or `ihb1dae`.

Solving Different Kinds of Problems (Continued)

Question	Answer
Can I integrate a set of sampled data?	Not directly. You have to represent the data as a function by interpolation or some other scheme for fitting data. The smoothness of this function is critical. A piecewise polynomial fit like a spline can look smooth to the eye, but rough to a solver; the solver takes small steps where the derivatives of the fit have jumps. Either use a smooth function to represent the data or use one of the lower order solvers (`ode23`, `ode23s`, `ode23t`, `ode23tb`) that is less sensitive to this.
What do I do when I have the final and not the initial value?	All the solvers of the ODE suite allow you to solve backwards or forwards in time. The syntax for the solvers is `[t,y] = ode45(odefun,[t0 tf],y0);`and the syntax accepts `t0 > tf`.

Troubleshooting

Question	Answer
The solution doesn't look like what I expected.	If you're right about its appearance, you need to reduce the error tolerances from their default values. A smaller relative error tolerance is needed to compute accurately the solution of problems integrated over "long" intervals, as well as solutions of problems that are moderately unstable. You should check whether there are solution components that stay smaller than their absolute error tolerance for some time. If so, you are not asking for any correct digits in these components. This may be acceptable for these components, but failing to compute them accurately may degrade the accuracy of other components that depend on them.
My plots aren't smooth enough.	Increase the value of `Refine` from its default of `4` in `ode45` and `1` in the other solvers. The bigger the value of `Refine`, the more output points. Execution speed is not affected much by the value of `Refine`.
I'm plotting the solution as it is computed and it looks fine, but the code gets stuck at some point.	First verify that the ODE function is smooth near the point where the code gets stuck. If it isn't, the solver must take small steps to deal with this. It may help to break `tspan` into pieces on which the ODE function is smooth. If the function is smooth and the code is taking extremely small steps, you are probably trying to solve a stiff problem with a solver not intended for this purpose. Switch to `ode15s`, `ode23s`, `ode23t`, or `ode23tb`.

Troubleshooting (Continued)

Question	Answer
My integration proceeds very slowly, using too many time steps.	First, check that your `tspan` is not too long. Remember that the solver uses as many time points as necessary to produce a smooth solution. If the ODE function changes on a time scale that is very short compared to the `tspan`, the solver uses a lot of time steps. Long-time integration is a hard problem. Break `tspan` into smaller pieces. If the ODE function does not change noticeably on the `tspan` interval, it could be that your problem is stiff. Try using `ode15s`, `ode23s`, `ode23t`, or `ode23tb`. Finally, make sure that the ODE function is written in an efficient way. The solvers evaluate the derivatives in the ODE function many times. The cost of numerical integration depends critically on the expense of evaluating the ODE function. Rather than recompute complicated constant parameters at each evaluation, store them in globals or calculate them once and pass them to nested functions.
I know that the solution undergoes a radical change at time t where `t0 ≤ t ≤ tf` but the integrator steps past without "seeing" it.	If you know there is a sharp change at time `t`, it might help to break the `tspan` interval into two pieces, `[t0 t]` and `[t tf]`, and call the integrator twice. If the differential equation has periodic coefficients or solution, you might restrict the maximum step size to the length of the period so the integrator won't step over periods.

Initial Value Problems for DDEs

In this section...

DDE Function Summary

DDE Initial Value Problem Solvers

Solver	Description
`dde23`	Solve initial value problems for delay differential equations with constant delays.
`ddesd`	Solve initial value problems for delay differential equations with general delays.

DDE Helper Functions

Function	Description
`deval`	Evaluate the numerical solution using the output of `dde23` or `ddesd`.

DDE Solver Properties Handling

Use these functions to create, alter, or access an options structure. An options structure contains named properties, the values of which are passed to `dde23` or `ddesd`, thus affecting the solution of the problem.

Function	Description
ddeset	Create/alter the DDE options structure.
ddeget	Extract properties from options structure created with ddeset.

DDE Initial Value Problem Examples

These examples illustrate the kind of problems you can solve using dde23 or ddesd. Click the example name to see the code in an editor. Type the example name at the command line to run it.

Note The Differential Equations Examples browser enables you to view the code for the DDE examples, and also run them. Click the link to invoke the browser, or type odeexamples('dde') at the command line.

The first two of these examples demonstrate ways that you can use the dde23 solver. The last example demonstrates the ddesd solver.

Example	Description
ddex1	Straightforward example
ddex2	Cardiovascular model with discontinuities
ddex3	Problem involving state-dependent delays

Additional examples are provided by "Tutorial on Solving DDEs with DDE23," available at http://www.mathworks.com/dde_tutorial.

Introduction to Initial Value DDE Problems

The DDE dde23 solver can solve systems of ordinary differential equations, such as

$$y'(t) = f(t, y(t), y(t-\tau_1), \ldots, y(t-\tau_k))$$

where t is the independent variable, y is the dependent variable, and y' represents (derivative of y with respect to t)dy/dt. The delays (lags) $\tau_1, \ldots, \tau_k$ are positive constants. The solver `ddesd` allows delays that depend on t and y.

Using a History to Specify the Solution of Interest

In an *initial value problem*, you seek the solution on an interval $[t_0, t_f]$ with $t_0 < t_f$. The DDE shows that $y'(t)$ depends on values of the solution at times prior to t. In particular, $y'(t_0)$ depends on $y(t_0 - \tau_1), \ldots, y(t_0 - \tau_k)$. Because of this, a solution on $[t_0, t_f]$ depends on its values for $t \le t_0$, i.e., its *history* $S(t)$.

Propagation of Discontinuities with DDE Solvers

Generally, the solution $y(t)$ of an IVP for a system of DDEs has a jump in its first derivative at the initial point t_0 because the first derivative of the history function does not satisfy the DDE there. A discontinuity in any derivative propagates into the future at spacings of $\tau_1, \tau_2, \ldots, \tau_k$ when the delays are constant, and in a more complicated way when they are not. For the DDEs solved by `dde23` and `ddesd`, the solution becomes smoother as the integration proceeds.

DDE Solvers

This section describes:

The basic syntax for the two solvers is shown in the function reference pages for `dde23` and `ddesd`.

DDE Solver dde23

The function `dde23` solves initial value problems for DDEs with constant delays. It integrates a system of first-order differential equations

$$y'(t) = f(t, y(t), y(t - \tau_1), \ldots, y(t - \tau_k))$$

on the interval $[t_0, t_f]$, with $t_0 < t_f$ and given history $y(t) = S(t)$ for $t \le t_0$.

dde23 produces a solution that is continuous on $[t_0, t_f]$. You can use the function deval and the output of dde23 to evaluate the solution at specific points on the interval of integration.

dde23 tracks low-order discontinuities and integrates the differential equations with the explicit Runge-Kutta (2,3) pair and interpolant used by ode23. The Runge-Kutta formulas are implicit for step sizes longer than the delays. When the solution is smooth enough that steps this big are justified, the implicit formulas are evaluated by a predictor-corrector iteration.

DDE Solver ddesd

The function ddesd solves initial value problems for DDEs with general delays. It integrates a system of first-order differential equations

$$y'(t) = f(t, y(t), y(d(1)), \ldots, y(d(k)))$$

on the interval $[t_0, t_f]$, with $t_0 < t_f$, where delays $d(j)$ can depend on both t and $y(t)$. Use the function deval and the output of ddesd to evaluate the solution at specific points on the interval of integration.

ddesd integrates with the classic four-stage, fourth-order explicit Runge-Kutta method, and controls the size of the residual of a natural interpolant. It uses iteration to take steps that are longer than the delays. For further details, see "Solving ODEs and DDEs with Residual Control," L.F. *Shampine, Applied Numerical Mathematics*, 52 (2005), pp 113-127.

Solving DDE Problems

This section uses examples to describe

- Using dde23 and ddesd to solve initial value problems for DDEs
- Evaluating the solution at specific points

Example: A Straightforward Problem

This example illustrates the straightforward formulation, computation, and display of the solution of a system of DDEs with constant delays. The history is constant, which is often the case. The differential equations are

$$y_1'(t) = y_1(t-1)$$
$$y_2'(t) = y_1(t-1) + y_2(t-0.2)$$
$$y_3'(t) = y_2(t)$$

The example solves the equations on [0,5] with history

$$y_1(t) = 1$$
$$y_2(t) = 1$$
$$y_3(t) = 1$$

for $t \le 0$.

Note The demo `ddex1` contains the complete code for this example. To see the code in an editor, click the example name, or type `edit ddex1` at the command line. To run the example type `ddex1` at the command line.

---

1 **Rewrite the problem as a first-order system.** To use `dde23`, you must rewrite the equations as an equivalent system of first-order differential equations. Do this just as you would when solving IVPs and BVPs for ODEs (see "Examples: Solving Explicit ODE Problems" on page 5-11). However, this example needs no such preparation because it already has the form of a first-order system of equations.

2 **Identify the lags.** The delays (lags) $\tau_1, \ldots, \tau_k$ are supplied to `dde23` as a vector. For the example we could use

```
lags = [1,0.2];
```

In coding the differential equations, τ_j = `lags(j)`.

3 **Code the system of first-order DDEs.** Once you represent the equations as a first-order system, and specify lags, you can code the equations as a function that `dde23` can use.

This code represents the system in the function, `ddex1de`.

```
function dydt = ddex1de(t,y,Z)
ylag1 = Z(:,1);
ylag2 = Z(:,2);
dydt = [ylag1(1)
        ylag1(1) + ylag2(2)
        y(2)               ];
```

4 **Code the history function.** The history function for this example is

```
function S = ddex1hist(t)
S = ones(3,1);
```

5 **Apply the DDE solver.** The example now calls `dde23` with the functions `ddex1de` and `ddex1hist`.

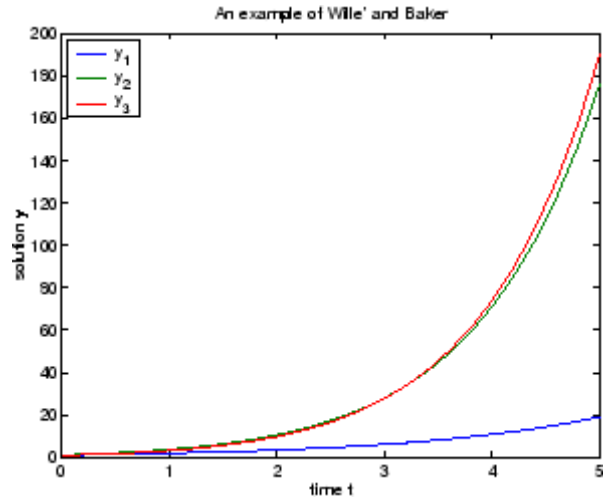
```
sol = dde23(@ddex1de,lags,@ddex1hist,[0,5]);
```

Here the example supplies the interval of integration [0,5] directly. Because the history is constant, we could also call `dde23` by

```
sol = dde23(@ddex1de,lags,ones(3,1),[0,5]);
```

6 **View the results.** Complete the example by displaying the results. `dde23` returns the mesh it selects and the solution there as fields in the solution structure `sol`. Often, these provide a smooth graph.

```
plot(sol.x,sol.y);
title('An example of Wille'' and Baker');
xlabel('time t');
ylabel('solution y');
legend('y_1','y_2','y_3',2)
```



Evaluating the Solution at Specific Points

The method implemented in `dde23` produces a continuous solution over the whole interval of integration $[t_0, t_f]$. You can evaluate the approximate solution, $S(t)$, at any point in $[t_0, t_f]$ using the helper function `deval` and the structure `sol` returned by `dde23`.

```
Sint = deval(sol,tint)
```

The `deval` function is vectorized. For a vector `tint`, the `i`th column of `Sint` approximates the solution $y(\text{tint(i)})$.

Using the output `sol` from the previous example, this code evaluates the numerical solution at 100 equally spaced points in the interval [0,5] and plots the result.

```
tint = linspace(0,5);
Sint = deval(sol,tint);
plot(tint,Sint);
```

Discontinuities

`dde23` performs better if it is informed of discontinuities in the history and at known locations. Discontinuities may be specified by event functions. There

is a property with which you can specify a solution that is different from the value given by the history function.

Discontinuity	Property	Comments
At the initial value $t = t_0$	`InitialY`	Generally the initial value $y(t_0)$ is the value $S(t_0)$ returned by the history function, which is to say that the solution is continuous at the initial point. However, if this is not the case, supply a different initial value using the `InitialY` property.
In the history, i.e., the solution at $t < t_0$, or in the equation coefficients for $t > t_0$	`Jumps`	Provide the known locations t of the discontinuities in a vector as the value of the `Jumps` property. Applies only to `dde23`.
State-dependent	`Events`	`dde23` and `ddesd` use the events function you supply to locate these discontinuities. When the solver finds such a discontinuity, restart the integration to continue. Specify the solution structure for the current integration as the history for the new integration. The solver extends each element of the solution structure after each restart so that the final structure provides the solution for the whole interval of integration. If the new problem involves a change in the solution, use the `InitialY` property to specify the initial value for the new integration.

Example: Cardiovascular Model

This example solves a cardiovascular model due to J. T. Ottesen [6]. The equations are integrated over the interval [0,1000]. The situation of interest is when the peripheral pressure R is reduced exponentially from its value of 1.05 to 0.84 beginning at t = 600.

This is a problem with one delay, a constant history, and three differential equations with fourteen physical parameters. It has a discontinuity in a low order derivative at `t = 600`.

Note The demo `ddex2` contains the complete code for this example. To see the code in an editor, click the example name, or type `edit ddex2` at the command line. To run the example type `ddex2` at the command line.

In `ddex2`, the fourteen physical parameters are set as fields in a structure `p` that is shared with nested functions. The function `ddex2de` for evaluating the equations begins with

```
function dydt = ddex2de(t,y,Z)
if t <= 600
   p.R = 1.05;
else
   p.R = 0.21 * exp(600-t) + 0.84;
end
.
.
.
```

Solve Using the Jumps Property. The peripheral pressure R is a continuous function of t, but it does not have a continuous derivative at `t = 600`. The example uses the `Jumps` property to inform `dde23` about the location of this discontinuity.

```
opts = ddeset('Jumps',600);
```

After defining the delay `tau` and the constant `history`, the call is

```
sol = dde23(@ddex2de,tau,history,[0, 1000],opts);
```

The demo `ddex2` plots only the third component, the heart rate, which shows a sharp change at `t = 600`.

Solve by Restarting. The example could have solved this problem by breaking it into two pieces

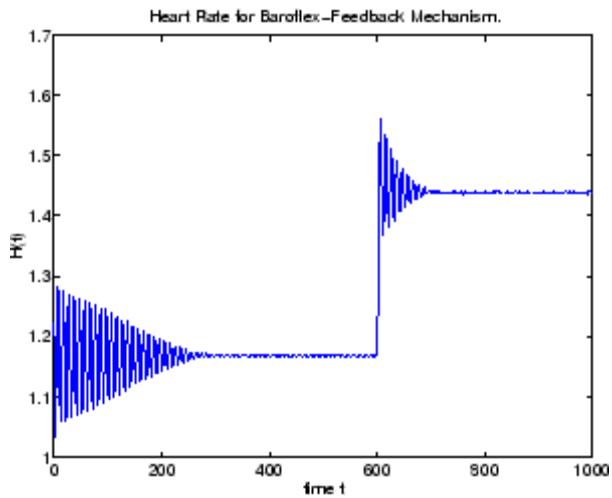
```
sol = dde23(@ddex2de,tau,history,[0, 600]);
sol = dde23(@ddex2de,tau,sol,[600, 1000]);
```

The solution structure `sol` on the interval `[0,600]` serves as history for restarting the integration at `t = 600`. In the second call, `dde23` extends `sol` so that on return the solution is available on the whole interval `[0,1000]`. That is, after this second return,

```
Sint = deval(sol,[300,900]);
```

evaluates the solution obtained in the first integration at `t = 300`, and the solution obtained in the second integration at `t = 900`.

When discontinuities occur in low order derivatives at points known in advance, it is better to use the `Jumps` property. This is not an option with `ddesd`, which handles discontinuities in a different way. When you use event functions to locate such discontinuities, you must restart the integration at discontinuities.



Changing DDE Integration Properties

The default integration properties in the DDE solver `dde23` are selected to handle common problems. In some cases, you can improve solver performance by overriding these defaults. You do this by supplying `dde23` with an `options` structure that specifies one or more property values.

For example, to change the relative error tolerance of `dde23` from the default value of `1e-3` to `1e-4`,

1 Create an options structure using the function `ddeset` by entering

```
options = ddeset('RelTol', 1e-4);
```

2 Pass the `options` structure to `dde23` as follows:

```
sol = dde23(ddefun,lags,history,tspan,options)
```

For a complete description of the available options, see the reference page for `ddeset`.

Example of a State-Dependent Delay

This example solves a system of two DDEs with state-dependent delay that was used as a test problem by W.H. Enright and H. Hayashi [10] because it has an analytical solution. The differential equations are

$$y'_1(t) = y_2(t)$$
$$y'_2(t) = -y_2(e^{(1-y_2(t))}) \times y_2(t)^2 \times e^{(1-y_2(t))}$$

The analytical solution

$$y_1(t) = \log(t)$$
$$y_2(t) = 1/t$$

is used as the history for $t \le 0.1$ and the equations are solved on `[0.1, 5]`. The only thing different about solving this example is that it must be solved with `ddesd` rather than `dde23`. This is because the first factor in the second equation has the form $y_2(d(y))$ with a delay that depends on the second component of the solution. The delay is provided to `ddesd` with a function like

```
function d = ddex3delay(t,y)
% State dependent delay function for DDEX3
d = exp(1 - y(2));
```

Note The demo `ddex3` contains the complete code for this example. To see the code in an editor, click the example name, or type `edit ddex3` at the command line. To run the example type `ddex3` at the command line.

Boundary Value Problems for ODEs

In this section...

BVP Function Summary

ODE Boundary Value Problem Solver

Solver	Description
`bvp4c`	Solve boundary value problems for ordinary differential equations.

BVP Helper Functions

Function	Description
`bvpinit`	Form the initial guess for `bvp4c`.
`deval`	Evaluate the numerical solution using the output of `bvp4c`.

BVP Solver Properties Handling

An options structure contains named properties whose values are passed to `bvp4c`, and which affect problem solution. Use these functions to create, alter, or access an options structure.

Function	Description
`bvpset`	Create/alter the BVP options structure.
`bvpget`	Extract properties from options structure created with `bvpset`.

ODE Boundary Value Problem Examples

These examples illustrate the kind of problems you can solve using the BVP solver. Click the example name to see the code in an editor. Type the example name at the command line to run it.

Note The Differential Equations Examples browser enables you to view the code for the BVP examples, and also run them. Click on the link to invoke the browser, or type `odeexamples('bvp')` at the command line.

Example	Description
`emdenbvp`	Emden's equation, a singular BVP
`fsbvp`	Falkner-Skan BVP on an infinite interval
`mat4bvp`	Fourth eigenfunction of Mathieu's equation
`shockbvp`	Solution with a shock layer near x = 0
`twobvp`	BVP with exactly two solutions
`threebvp`	Three-point boundary value problem

Additional examples are provided by "Tutorial on Solving BVPs with BVP4C," available at `http://www.mathworks.com/bvp_tutorial`.

Introduction to Boundary Value ODE Problems

The BVP solver is designed to handle systems of ordinary differential equations

$$y' = f(x, y)$$

where x is the independent variable, y is the dependent variable, and y' represents the derivative of y with respect to x dy/dx.

See “What Is an Ordinary Differential Equation?” on page 5-5 for general information about ODEs.

Using Boundary Conditions to Specify the Solution of Interest

In a *boundary value problem,* the solution of interest satisfies certain boundary conditions. These conditions specify a relationship between the values of the solution at more than one x. In its basic syntax, `bvp4c` is designed to solve two-point BVPs, i.e., problems where the solution sought on an interval $[a, b]$ must satisfy the boundary conditions

$$g(y(a), y(b)) = 0$$

Unlike initial value problems, a boundary value problem may not have a solution, may have a finite number of solutions, or may have infinitely many solutions. As an integral part of the process of solving a BVP, you need to provide a guess for the required solution. The quality of this guess can be critical for the solver performance and even for a successful computation.

There may be other difficulties when solving BVPs, such as problems imposed on infinite intervals or problems that involve singular coefficients. Often BVPs involve unknown parameters p that have to be determined as part of solving the problem

$$y' = f(x, y, p)$$
$$g(y(a), y(b), p) = 0$$

In this case, the boundary conditions must suffice to determine the value of p.

Boundary Value Problem Solver

The BVP Solver

The function `bvp4c` solves two-point boundary value problems for ordinary differential equations (ODEs). It integrates a system of first-order ordinary differential equations

$$y' = f(x, y)$$

on the interval $[a, b]$, subject to general two-point boundary conditions

$$bc(y(a), y(b)) = 0$$

It can also accommodate other types of BVP problems, such as those that have any of the following:

- Unknown parameters
- Singularities in the solutions
- Multipoint conditions

In this case, the number of boundary conditions must be sufficient to determine the solution and the unknown parameters. For more information, see “Finding Unknown Parameters” on page 5-75.

`bvp4c` produces a solution that is continuous on $[a, b]$ and has a continuous first derivative there. You can use the function `deval` and the output of `bvp4c` to evaluate the solution at specific points on the interval of integration.

`bvp4c` is a finite difference code that implements the 3-stage Lobatto IIIa formula. This is a collocation formula and the collocation polynomial provides a C^1-continuous solution that is fourth-order accurate uniformly in the interval of integration. Mesh selection and error control are based on the residual of the continuous solution.

The collocation technique uses a mesh of points to divide the interval of integration into subintervals. The solver determines a numerical solution by solving a global system of algebraic equations resulting from the boundary conditions, and the collocation conditions imposed on all the subintervals. The solver then estimates the error of the numerical solution on each subinterval. If the solution does not satisfy the tolerance criteria, the solver adapts the mesh and repeats the process. The user *must* provide the points of the initial mesh as well as an initial approximation of the solution at the mesh points.

BVP Solver Basic Syntax

The basic syntax of the BVP solver is

```
sol = bvp4c(odefun,bcfun,solinit)
```

The input arguments are

`odefun` — Handle to a function that evaluates the differential equations. It has the basic form

```
dydx = odefun(x,y)
```

where `x` is a scalar, and `dydx` and `y` are column vectors. See "Function Handles" in the MATLAB Programming documentation for more information. `odefun` can also accept a vector of unknown parameters and a variable number of known parameters, (see "BVP Solver Options" on page 5-70).

`bcfun` — Handle to a function that evaluates the residual in the boundary conditions. It has the basic form

```
res = bcfun(ya,yb)
```

where `ya` and `yb` are column vectors representing `y(a)` and `y(b)`, and `res` is a column vector of the residual in satisfying the boundary conditions. `bcfun` can also accept a vector of unknown parameters and a variable number of known parameters, (see "BVP Solver Options" on page 5-70).

`solinit` — Structure with fields `x` and `y`:

`x`	Ordered nodes of the initial mesh. Boundary conditions are imposed at a = `solinit.x(1)` and b = `solinit.x(end)`.
`y`	Initial guess for the solution with `solinit.y(:,i)` a guess for the solution at the node `solinit.x(i)`.

The structure can have any name, but the fields must be named `x` and `y`. It can also contain a vector that provides an initial guess for unknown parameters. You can form `solinit` with the helper function `bvpinit`. See the `bvpinit` reference page for details.

The output argument `sol` is a structure created by the solver. In the basic case the structure has fields `x`, `y`, `yp`, and `solver`.

`sol.x`	Nodes of the mesh selected by `bvp4c`
`sol.y`	Approximation to $y(x)$ at the mesh points of `sol.x`
`sol.yp`	Approximation to $y'(x)$ at the mesh points of `sol.x`
`sol.solver`	`'bvp4c'`

The structure `sol` returned by `bvp4c` contains an additional field if the problem involves unknown parameters:

`sol.parameters`	Value of unknown parameters, if present, found by the solver.

The function `deval` uses the output structure `sol` to evaluate the numerical solution at any point from `[a,b]`. For information about using `deval`, see “Evaluating the Solution at Specific Points” on page 5-59.

BVP Solver Options

For more advanced applications, you can specify solver options by passing an input argument `options`.

`options`	Structure of optional parameters that change the default integration properties. This is the fourth input argument. `sol = bvp4c(odefun,bcfun,solinit,options)` You can create the structure options using the function `bvpset`. The `bvpset` reference page describes the properties you can specify.

Changing BVP Integration Properties

The default integration properties in the BVP solver `bvp4c` are selected to handle common problems. In some cases, you can improve solver performance by overriding these defaults. You do this by supplying `bvp4c` with an `options` structure that specifies one or more property values.

For example, to change the value of the relative error tolerance of `bvp4c` from the default value of `1e-3` to `1e-4`,

1 Create an options structure using the function `bvpset` by entering

```
options = bvpset('RelTol', 1e-4);
```

2 Pass the `options` structure to `bvp4c` as follows:

```
sol = bvp4c(odefun,bcfun,solinit,options)
```

For a complete description of the available options, see the reference page for `bvpset`.

Note For other ways to improve solver efficiency, check “Using Continuation to Make a Good Initial Guess” on page 5-76 and the tutorial, “Solving Boundary Value Problems for Ordinary Differential Equations in MATLAB with bvp4c,” available at `http://www.mathworks.com/bvp_tutorial`.

Solving BVP Problems

Example: Mathieu's Equation

This example determines the fourth eigenvalue of Mathieu's Equation. It illustrates how to write second-order differential equations as a system of two first-order ODEs and how to use `bvp4c` to determine an unknown parameter λ.

The task is to compute the fourth ($q = 5$) eigenvalue lambdaλ of Mathieu's equation

$$y'' + (\lambda - 2q\cos 2x)y = 0$$

Because the unknown parameter λ is present, this second-order differential equation is subject to *three* boundary conditions

$$y(0) = 1$$
$$y'(0) = 0$$
$$y'(\pi) = 0$$

Note The demo `mat4bvp` contains the complete code for this example. The demo uses nested functions to place all functions required by `bvp4c` in a single M-file. To run this example type `mat4bvp` at the command line. See "BVP Solver Basic Syntax" on page 5-69 for more information.

---

1 **Rewrite the problem as a first-order system.** To use `bvp4c`, you must rewrite the equations as an equivalent system of first-order differential equations. Using a substitution $y_1 = y$ and $y_2 = y'$, the differential equation is written as a system of two first-order equations

$$y_1' = y_2$$
$$y_2' = -(\lambda - 2q\cos 2x)y_1$$

Note that the differential equations depend on the unknown parameter λ. The boundary conditions become

$$y_1(0) - 1 = 0$$
$$y_2(0) = 0$$
$$y_2(\pi) = 0$$

2 Code the system of first-order ODEs. Once you represent the equation as a first-order system, you can code it as a function that `bvp4c` can use. Because there is an unknown parameter, the function must be of the form

```
dydx = odefun(x,y,parameters)
```

The following code represents the system in the function, `mat4ode`. Variable `q` is shared with the outer function:

```
function dydx = mat4ode(x,y,lambda)
dydx = [ y(2)
         -(lambda - 2*q*cos(2*x))*y(1) ];
end   % End nested function mat4ode
```

See “Finding Unknown Parameters” on page 5-75 for more information about using unknown parameters with `bvp4c`.

3 Code the boundary conditions function. You must also code the boundary conditions in a function. Because there is an unknown parameter, the function must be of the form

```
res = bcfun(ya,yb,parameters)
```

The code below represents the boundary conditions in the function, `mat4bc`.

```
function res = mat4bc(ya,yb,lambda)
res = [  ya(2)
         yb(2)
        ya(1)-1 ];
```

4 **Create an initial guess.** To form the guess structure `solinit` with `bvpinit`, you need to provide initial guesses for both the solution and the unknown parameter.

The function `mat4init` provides an initial guess for the solution. `mat4init` uses $y = \cos 4x$ because this function satisfies the boundary conditions and has the correct qualitative behavior (the correct number of sign changes).

```
function yinit = mat4init(x)
yinit = [  cos(4*x)
          -4*sin(4*x) ];
```

In the call to `bvpinit`, the third argument, `lambda`, provides an initial guess for the unknown parameter λ.

```
lambda = 15;
solinit = bvpinit(linspace(0,pi,10),@mat4init,lambda);
```

This example uses `@` to pass `mat4init` as a function handle to `bvpinit`.

Note See the `function_handle` (`@`), `func2str`, and `str2func` reference pages, and the "Function Handles" section of MATLAB Programming in the MATLAB documentation for information about function handles.

---

5 **Apply the BVP solver.** The `mat4bvp` example calls `bvp4c` with the functions `mat4ode` and `mat4bc` and the structure `solinit` created with `bvpinit`.

```
sol = bvp4c(@mat4ode,@mat4bc,solinit);
```

6 **View the results.** Complete the example by displaying the results:

a Print the value of the unknown parameter λ found by `bvp4c`.

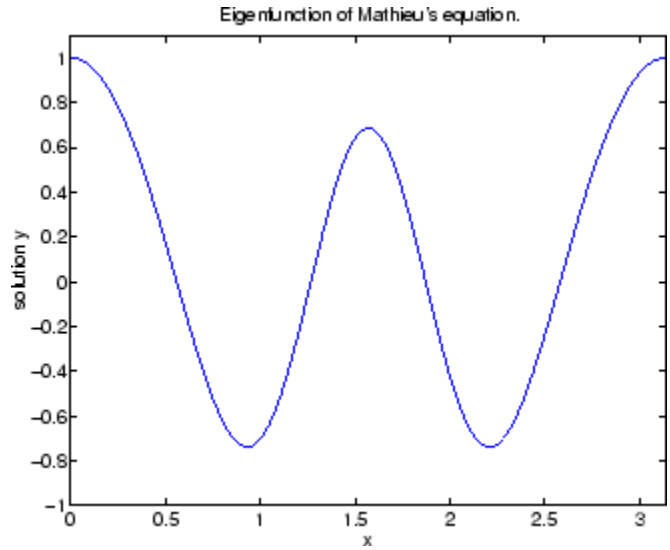
```
fprintf('The fourth eigenvalue is approximately %7.3f.\n',...
        sol.parameters)
```

b Use `deval` to evaluate the numerical solution at 100 equally spaced points in the interval $[0, \pi]$, and plot its first component. This component approximates $y(x)$.

```
xint = linspace(0,pi);
Sxint = deval(sol,xint);
plot(xint,Sxint(1,:))
axis([0 pi -1 1.1])
title('Eigenfunction of Mathieu''s equation.')
xlabel('x')
ylabel('solution y')
```

See “Evaluating the Solution at Specific Points” on page 5-76 for information about using `deval`.

The following plot shows the eigenfunction associated with the final eigenvalue λ = 17.097.



Finding Unknown Parameters

The `bvp4c` solver can find unknown parameters p for problems of the form

$$y' = f(x, y, p)$$
$$bc(y(a), y(b), p) = 0$$

You must provide `bvp4c` an initial guess for any unknown parameters in the vector `solinit.parameters`. When you call `bvpinit` to create the structure `solinit`, specify the initial guess as a vector in the additional argument `parameters`.

```
solinit = bvpinit(x,v,parameters)
```

The `bvp4c` function arguments `odefun` and `bcfun` must each have a third argument.

```
dydx = odefun(x,y,parameters)
res = bcfun(ya,yb,parameters)
```

While solving the differential equations, `bvp4c` adjusts the value of unknown parameters to satisfy the boundary conditions. The solver returns the final values of these unknown parameters in `sol.parameters`. See "Example: Mathieu's Equation" on page 5-72.

Evaluating the Solution at Specific Points

The collocation method implemented in `bvp4c` produces a C^1-continuous solution over the whole interval of integration $[a, b]$. You can evaluate the approximate solution, $S(x)$, at any point in $[a, b]$ using the helper function `deval` and the structure `sol` returned by `bvp4c`.

```
Sxint = deval(sol,xint)
```

The `deval` function is vectorized. For a vector `xint`, the `i`th column of `Sxint` approximates the solution $y(\text{xint(i)})$.

Using Continuation to Make a Good Initial Guess

To solve a boundary value problem, you need to provide an initial guess for the solution. The quality of your initial guess can be critical to the solver performance, and to being able to solve the problem at all. However, coming up with a sufficiently good guess can be the most challenging part of solving a boundary value problem. Certainly, you should apply the knowledge of the problem's physical origin. Often a problem can be solved as a sequence

of relatively simpler problems, i.e., a continuation. This section provides examples that illustrate how to use continuation to:

- Solve a difficult BVP
- Verify a solution's consistent behavior

Example: Using Continuation to Solve a Difficult BVP

This example solves the differential equation

$$\varepsilon y'' + xy' = \varepsilon\pi^2\cos(\pi x) - \pi x\sin(\pi x)$$

for $\varepsilon = 10^{-4}$, on the interval [-1 1], with boundary conditions $y(-1) = -2$ and $y(1) = 0$. For $0 < \varepsilon < 1$, the solution has a transition layer at $x = 0$. Because of this rapid change in the solution for small values of ε, the problem becomes difficult to solve numerically.

The example solves the problem as a sequence of relatively simpler problems, i.e., a continuation. The solution of one problem is used as the initial guess for solving the next problem.

Note The demo `shockbvp` contains the complete code for this example. The demo uses nested functions to place all required functions in a single M-file. To run this example type `shockbvp` at the command line. See "BVP Solver Basic Syntax" on page 5-69 and "Solving BVP Problems" on page 5-72 for more information.

Note This problem appears in [1] to illustrate the mesh selection capability of a well established BVP code COLSYS.

---

1 **Code the ODE and boundary condition functions.** Code the differential equation and the boundary conditions as functions that `bvp4c` can use:

The code below represents the differential equation and the boundary conditions in the functions `shockODE` and `shockBC`. Note that `shockODE` is vectorized to improve solver performance. The additional parameter ε is represented by `e` and is shared with the outer function.

```
function dydx = shockODE(x,y)
pix = pi*x;
dydx = [  y(2,:)
         -x/e.*y(2,:) - pi^2*cos(pix) - pix/e.*sin(pix) ];
end %   End nested function shockODE

function res = shockBC(ya,yb)
res = [ ya(1)+2
        yb(1)   ];
end %   End nested function shockBC
```

2 **Provide analytical partial derivatives.** For this problem, the solver benefits from using analytical partial derivatives. The code below represents the derivatives in functions `shockJac` and `shockBCJac`.

```
function jac = shockJac(x,y)
jac = [ 0   1
        0 -x/e ];
end %   End nested function shockJac

function [dBCdya,dBCdyb] = shockBCJac(ya,yb)
dBCdya = [ 1 0
           0 0 ];
dBCdyb = [ 0 0
           1 0 ];
end %   End nested function shockBCJac
```

shockJac shares `e` with the outer function.

Tell `bvp4c` to use these functions to evaluate the partial derivatives by setting the options FJacobian and BCJacobian. Also set `'Vectorized'` to `'on'` to indicate that the differential equation function `shockODE` is vectorized.

```
options = bvpset('FJacobian',@shockJac,...
                 'BCJacobian',@shockBCJac,...
```

```
                    'Vectorized','on');
```

3 **Create an initial guess.** You must provide `bvp4c` with a guess structure that contains an initial mesh and a guess for values of the solution at the mesh points. A constant guess of $y(x) \equiv 1$ and $y'(x) \equiv 0$, and a mesh of five equally spaced points on [-1 1] suffice to solve the problem for $\varepsilon = 10^{-2}$. Use `bvpinit` to form the guess structure.

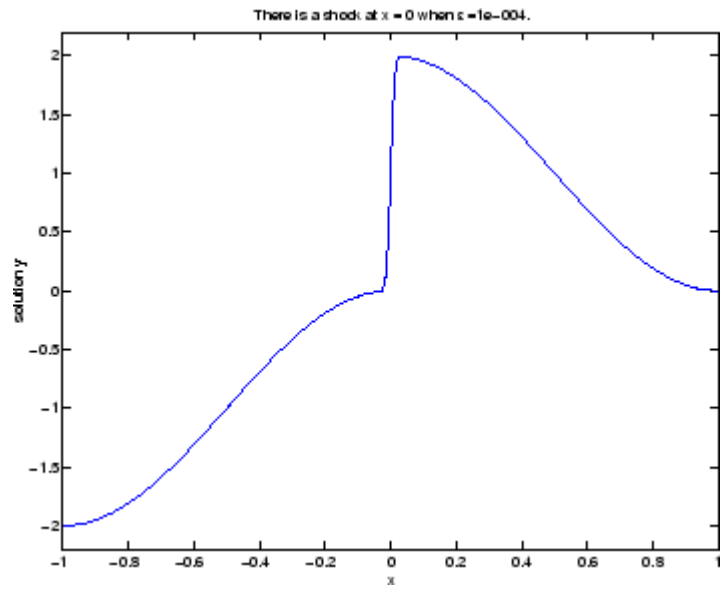
```
sol = bvpinit([-1 -0.5 0 0.5 1],[1 0]);
```

4 **Use continuation to solve the problem.** To obtain the solution for the parameter $\varepsilon = 10^{-4}$, the example uses continuation by solving a sequence of problems for $\varepsilon = 10^{-2}, 10^{-3}, 10^{-4}$. The solver `bvp4c` does not perform continuation automatically, but the code's user interface has been designed to make continuation easy. The code uses the output `sol` that `bvp4c` produces for one value of `e` as the guess in the next iteration.

```
e = 0.1;
for i=2:4
    e = e/10;
    sol = bvp4c(@shockODE,@shockBC,sol,options);
end
```

5 **View the results.** Complete the example by displaying the final solution

```
plot(sol.x,sol.y(1,:))
axis([-1 1 -2.2 2.2])
title(['There is a shock at x = 0 when \epsilon = '...
      sprintf('%.e',e) '.'])
xlabel('x')
ylabel('solution y')
```



Example: Using Continuation to Verify a Solution's Consistent Behavior

Falkner-Skan BVPs arise from similarity solutions of viscous, incompressible, laminar flow over a flat plate. An example is

$$f''' + ff'' + \beta(1 - (f')^2) = 0$$

for $\beta = 0.5$ on the interval $[0, \infty)$ with boundary conditions $f(0) = 0$, $f'(0) = 0$, and $f'(\infty) = 1$.

The BVP cannot be solved on an infinite interval, and it would be impractical to solve it for even a very large finite interval. So, the example tries to solve a sequence of problems posed on increasingly larger intervals to verify the solution's consistent behavior as the boundary approaches ∞.

The example imposes the infinite boundary condition at a finite point called `infinity`. The example then uses continuation in this end point to get convergence for increasingly larger values of `infinity`. It uses `bvpinit` to extrapolate the solution `sol` for one value of `infinity` as an initial guess

for the new value of `infinity`. The plot of each successive solution is superimposed over those of previous solutions so they can easily be compared for consistency.

Note The demo `fsbvp` contains the complete code for this example. The demo uses nested functions to place all required functions in a single M-file. To run this example type `fsbvp` at the command line. See "BVP Solver Basic Syntax" on page 5-69 and "Solving BVP Problems" on page 5-72 for more information.

---

1 **Code the ODE and boundary condition functions.** Code the differential equation and the boundary conditions as functions that `bvp4c` can use. The problem parameter `beta` is shared with the outer function.

```
function dfdeta = fsode(eta,f)
dfdeta = [ f(2)
           f(3)
          -f(1)*f(3) - beta*(1 - f(2)^2) ];
end %   End nested function fsode

function res = fsbc(f0,finf)
res = [f0(1)
       f0(2)
       finf(2) - 1];
end %   End nested function fsbc
```

2 **Create an initial guess.** You must provide `bvp4c` with a guess structure that contains an initial mesh and a guess for values of the solution at the mesh points. A crude mesh of five points and a constant guess that satisfies the boundary conditions are good enough to get convergence when `infinity = 3`.

```
infinity = 3;
maxinfinity = 6;

solinit = bvpinit(linspace(0,infinity,5),[0 0 1]);
```

3 Solve on the initial interval. The example obtains the solution for `infinity = 3`. It then prints the computed value of $f''(0)$ for comparison with the value reported by Cebeci and Keller [2]:

```
sol = bvp4c(@fsode,@fsbc,solinit);
eta = sol.x;
f = sol.y;

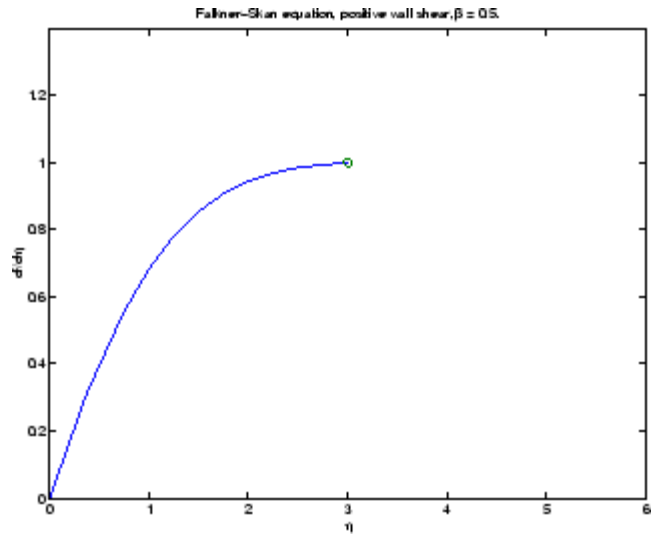
fprintf('\n');
fprintf('Cebeci & Keller report that f''''(0) = 0.92768.\n')
fprintf('Value computed using infinity = %g is %7.5f.\n', ...
         infinity,f(3,1))
```

The example prints

```
Cebeci & Keller report that f''(0) = 0.92768.
Value computed using infinity = 3 is 0.92915.
```

4 Setup the figure and plot the initial solution.

```
figure
plot(eta,f(2,:),eta(end),f(2,end),'o');
axis([0 maxinfinity 0 1.4]);
title('Falkner-Skan equation, positive wall shear, \beta = 0.5.')
xlabel('\eta')
ylabel('df/d\eta')
hold on
drawnow
shg
```



5 **Use continuation to solve the problem and plot subsequent solutions.** The example then solves the problem for `infinity = 4, 5, 6`. It uses `bvpinit` to extrapolate the solution `sol` for one value of `infinity` as an initial guess for the next value of `infinity`. For each iteration, the example prints the computed value of $f''(0)$ and superimposes a plot of the solution in the existing figure.

```
for Bnew = infinity+1:maxinfinity

  solinit = bvpinit(sol,[0 Bnew]); % Extend solution to Bnew.
  sol = bvp4c(@fsode,@fsbc,solinit);
  eta = sol.x;
  f = sol.y;

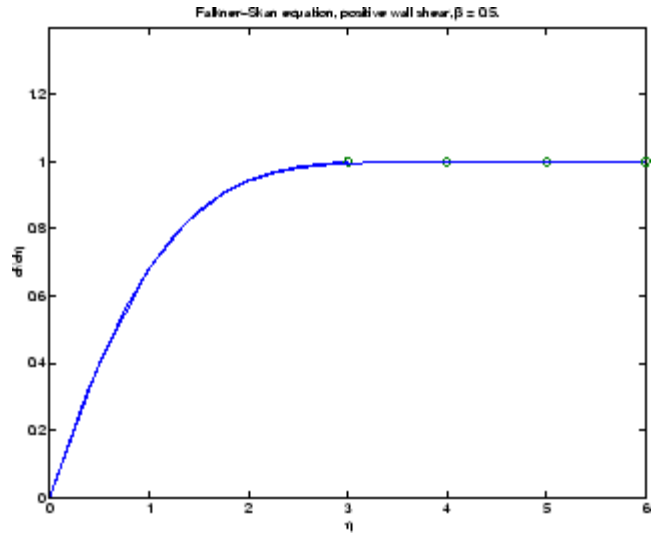
  fprintf('Value computed using infinity = %g is %7.5f.\n', ...
           Bnew,f(3,1))
  plot(eta,f(2,:),eta(end),f(2,end),'o');
  drawnow

end
hold off
```

The example prints

```
Value computed using infinity = 4 is 0.92774.
Value computed using infinity = 5 is 0.92770.
Value computed using infinity = 6 is 0.92770.
```

Note that the values approach 0.92768 as reported by Cebeci and Keller. The superimposed plots confirm the consistency of the solution's behavior.



Solving Singular BVPs

The function `bvp4c` solves a class of singular BVPs of the form

$$y' = \frac{1}{x}Sy + f(x, y)$$
$$0 = g(y(0), y(b)) \qquad \textbf{(5-2)}$$

It can also accommodate unknown parameters for problems of the form

$$y' = \frac{1}{x}Sy + f(x, y, p)$$
$$0 = g(y(0), y(b), p)$$

Singular problems must be posed on an interval $[0, b]$ with $b > 0$. Use `bvpset` to pass the constant matrix S to `bvp4c` as the value of the `'SingularTerm'` integration property. Boundary conditions at $x = 0$ must be consistent with the necessary condition for a smooth solution, $Sy(0) = 0$. An initial guess should also satisfy this necessary condition.

When you solve a singular BVP using

```
sol = bvp4c(@odefun,@bcfun,solinit,options)
```

`bvp4c` requires that your function `odefun(x,y)` return only the value of the $f(x, y)$ term in Equation 5-2.

Example: Solving a BVP That Has a Singular Term

Emden's equation arises in modeling a spherical body of gas. The PDE of the model is reduced by symmetry to the ODE

$$y'' + \frac{2}{x}y' + y^5 = 0$$

on an interval $[0, 1]$. The coefficient $2/x$ is singular at $x = 0$, but symmetry implies the boundary condition $y'(0) = 0$. With this boundary condition, the term

$$\frac{2}{x}y'(0)$$

is well-defined as x approaches 0. For the boundary condition $y(1) = \sqrt{3}/2$, this BVP has the analytical solution

$$y(x) = \left(1 + \frac{x^2}{3}\right)^{-1/2}$$

Note The demo `emdenbvp` contains the complete code for this example. The demo uses subfunctions to place all required functions in a single M-file. To run this example type `emdenbvp` at the command line. See "BVP Solver Basic Syntax" on page 5-69 and "Solving BVP Problems" on page 5-72 for more information.

---

1 **Rewrite the problem as a first-order system and identify the singular term.** Using a substitution $y_1 = y$ and $y_2 = y'$, write the differential equation as a system of two first-order equations

$$y_1' = y_2$$
$$y_2' = -\frac{2}{x}y_2 - y_1^5$$

The boundary conditions become

$$y_2(0) = 0$$
$$y_1(1) = \sqrt{3}/2$$

Writing the ODE system in a vector-matrix form

$$\begin{bmatrix} y_1' \\ y_2' \end{bmatrix} = \frac{1}{x}\begin{bmatrix} 0 & 0 \\ 0 & -2 \end{bmatrix}\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} + \begin{bmatrix} y_2 \\ -y_1^5 \end{bmatrix}$$

the terms of Equation 5-2 are identified as

$$S = \begin{bmatrix} 0 & 0 \\ 0 & -2 \end{bmatrix}$$

and

$$f(x,y) = \begin{bmatrix} y_2 \\ -y_1^5 \end{bmatrix}$$

2 **Code the ODE and boundary condition functions.** Code the differential equation and the boundary conditions as functions that `bvp4c` can use.

```
function dydx = emdenode(x,y)
dydx = [  y(2)
         -y(1)^5 ];
function res = emdenbc(ya,yb)
```

```
res = [ ya(2)
        yb(1) - sqrt(3)/2 ];
```

3 Setup integration properties. Use the matrix as the value of the `'SingularTerm'` integration property.

```
S = [0,0;0,-2];
options = bvpset('SingularTerm',S);
```

4 Create an initial guess. This example starts with a mesh of five points and a constant guess for the solution.

$$y_1(x) \equiv \sqrt{3}/2$$

$$y_2(x) \equiv 0$$

Use `bvpinit` to form the guess structure

```
guess = [sqrt(3)/2;0];
solinit = bvpinit(linspace(0,1,5),guess);
```

5 Solve the problem. Use the standard `bvp4c` syntax to solve the problem.

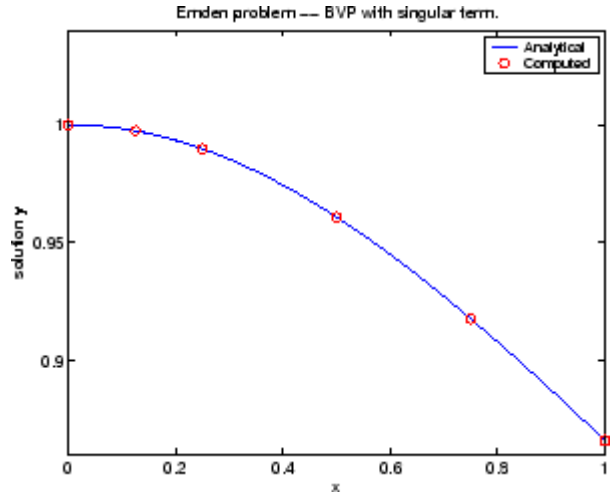
```
sol = bvp4c(@emdenode,@emdenbc,solinit,options);
```

6 View the results. This problem has an analytical solution

$$y(x) = \left(1 + \frac{x^2}{3}\right)^{-1/2}$$

The example evaluates the analytical solution at 100 equally spaced points and plots it along with the numerical solution computed using `bvp4c`.

```
x = linspace(0,1);
truy = 1 ./ sqrt(1 + (x.^2)/3);
plot(x,truy,sol.x,sol.y(1,:),'ro');
title('Emden problem -- BVP with singular term.')
legend('Analytical','Computed');
xlabel('x');
ylabel('solution y');
```



Solving Multipoint BVPs

In multipoint boundary value problems, the solution of interest satisfies conditions at points inside the interval of integration. The `bvp4c` function is useful in solving such problems.

The following example shows how the multipoint capability in `bvp4c` can improve efficiency when you are solving a nonsmooth problem. The following equations are solved on $0 \le x \le \lambda$ for constant parameters `n`, κ, $\lambda > 1$, and $\eta = \lambda^2/(n \times \kappa^2)$. These are subject to boundary conditions `v(0) = 0` and $C(\lambda) = 1$:

```
v' = (C - 1)/n
C' = (v * C - min(x,1))/η
```

The term `min(x,1)` is not smooth at `xc = 1`, and this can affect the solver's efficiency. By introducing an interface point at `xc = 1`, smooth solutions can be obtained on `[0,1]` and `[1,λ]`. To get a continuous solution over the entire interval `[0,λ]`, the example imposes matching conditions at the interface.

Note The demo `threebvp` contains the complete code for this example and solves the problem for λ = 2, n = 0.05, and several values of κ. The demo uses nested functions to place all functions required by `bvp4c` in a single M-file and to communicate problem parameters efficiently. To run this example, type `threebvp` at the MATLAB command prompt.

The demo takes you through the following steps:

1 **Determine the interfaces and divide the interval of integration into regions.** Introducing an interface point at `xc = 1` divides the problem into two regions in which the solutions remain smooth. The differential equations for the two regions are

Region 1: $0 \le x \le 1$

```
v' = (C - 1)/n
C' = (v * C - x)/η
```

Region 2: $1 \le x \le \lambda$

```
v' = (C - 1)/n
C' = (v * C - 1)/η
```

Note that the interface `xc = 1` is included in both regions. At `xc = 1`, `bvp4c` produces a *left* and *right* solution. These solutions are denoted as `v(1-)`, `C(1-)` and `v(1+)`, `C(1+)` respectively.

2 **Determine the boundary conditions.** Solving two first-order differential equations in two regions requires imposing four boundary conditions. Two of these conditions come from the original formulation; the others enforce the continuity of the solution across the interface `xc = 1`:

```
v(0) = 0
C(λ) - 1 = 0
v(1-) - v(1+) = 0
C(1-) - C(1+) = 0
```

Here, `v(1-)`, `C(1-)` and `v(1+)`, `C(1+)` denote the left and right solution at the interface.

3 **Code the derivative function.** In the derivative function, `y(1)` corresponds to `v(x)`, and `y(2)` corresponds to `C(x)`. The additional input argument `region` identifies the region in which the derivative is evaluated. `bvp4c` enumerates regions from left to right, starting with 1. Note that the problem parameters `n` and η are shared with the outer function:

```
function dydx = f(x,y,region)
   dydx = zeros(2,1);
   dydx(1) = (y(2) - 1)/n;

   % The definition of C'(x) depends on the region.
   switch region
      case 1                                % x in [0 1]
         dydx(2) = (y(1)*y(2) - x)/η;
      case 2                                % x in [1 λ]
         dydx(2) = (y(1)*y(2) - 1)/η;
    end
end               % End nested function f
```

4 **Code the boundary conditions function.** For multipoint BVPs, the arguments of the boundary conditions function, `YL` and `YR`, become matrices. In particular, the `k`th column `YL(:,k)` represents the solution at the left boundary of the `k`th region. Similarly, `YR(:,k)` represents the solution at the right boundary of the `k`th region.

In the example, `y(0)` is approximated by `YL(:,1)`, while `y(`λ`)` is approximated by `YR(:,end)`. Continuity of the solution at the internal interface requires that `YR(:,1) = YL(:,2)`. Nested function `bc` computes the residual in the boundary conditions:

```
function res = bc(YL,YR)
   res = [YL(1,1)               % v(0) = 0
          YR(1,1) - YL(1,2)     % Continuity of v(x) at x=1
          YR(2,1) - YL(2,2)     % Continuity of C(x) at x=1
          YR(2,end) - 1];       % C(λ) = 1
end                             % End nested function bc
```

5 **Create an initial guess.** For multipoint BVPs, when creating an initial guess using `bvpinit`, use double entries in `xinit` for the interface point `xc`. This example uses a constant guess `yinit = [1;1]`:

```
xc = 1;
xinit = [0, 0.25, 0.5, 0.75, xc, xc, 1.25, 1.5, 1.75, 2];
solinit = bvpinit(xinit,yinit)
```

For multipoint BVPs, you can use different guesses in different regions. To do that, you specify the initial guess for `y` as a function using the following syntax:

```
solinit = bvpinit(xinit,@yinitfcn)
```

The initial guess function must have the following general form:

```
function y = yinitfcn(x,region)
   switch region
   case 1            % x in [0, 1]
      y = [1;1];     % initial guess for y(x) 0≤x≤1
   case 2 % x in [1, λ]
      y = [1;1];     % initial guess for y(x), 1≤x≤λ
end
```

6 **Apply the solver.** The `bvp4c` function uses the same syntax for multipoint BVPs as it does for two-point BVPs:

```
sol = bvp4c(@f,@bc,solinit);
```

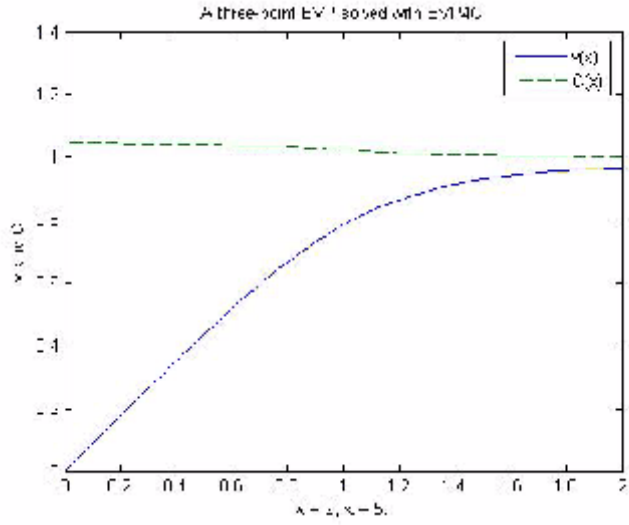
The mesh points returned in `sol.x` are adapted to the solution behavior, but the mesh still includes a double entry for the interface point `xc = 1`. Corresponding columns of `sol.y` represent the left and right solution at `xc`.

7 **View the results.** Using `deval`, the solution can be evaluated at any point in the interval of integration.

Note that, with the left and right values computed at the interface, the solution is not uniquely defined at `xc = 1`. When evaluating the solution exactly at the interface, `deval` issues a warning and returns the average of the left and right solution values. Call `deval` at `xc-eps(xc)` and `xc+eps(xc)` to get the limit values at `xc`.

The example plots the solution approximated at the mesh points selected by the solver:

```
plot(sol.x,sol.y(1,:),sol.x,sol.y(2,:),'--')
legend('v(x)','C(x)')
title('A three-point BVP solved with BVP4C')
xlabel(['\lambda = ',num2str(lambda), ...
        ', \kappa = ',num2str(kappa),'.'])
ylabel('v and C')
```



Partial Differential Equations

PDE Function Summary

MATLAB PDE Solver

This is the MATLAB PDE solver.

PDE Initial-Boundary Value Problem Solver	Description
`pdepe`	Solve initial-boundary value problems for systems of parabolic and elliptic PDEs in one space variable and time.

PDE Helper Function

PDE Helper Function	Description
`pdeval`	Evaluate the numerical solution of a PDE using the output of `pdepe`.

PDE Examples

These examples illustrate some problems you can solve using the MATLAB PDE solver. Click the example name to see the code in an editor. Type the example name at the command line to run it.

Note The Differential Equations Examples browser enables you to view the code for the PDE examples, and also run them. Click the link to invoke the browser, or type `odeexamples('pde')` at the command line.

Example	Description
`pdex1`	Simple PDE that illustrates the straightforward formulation, computation, and plotting of the solution
`pdex2`	Problem that involves discontinuities
`pdex3`	Problem that requires computing values of the partial derivative
`pdex4`	System of two PDEs whose solution has boundary layers at both ends of the interval and changes rapidly for small t
`pdex5`	System of PDEs with step functions as initial conditions

Introduction to PDE Problems

`pdepe` solves systems of parabolic and elliptic PDEs in one spatial variable x and time t, of the form

$$c\left(x,t,u,\frac{\partial u}{\partial x}\right)\frac{\partial u}{\partial t} = x^{-m}\frac{\partial}{\partial x}\left(x^m f\left(x,t,u,\frac{\partial u}{\partial x}\right)\right) + s\left(x,t,u,\frac{\partial u}{\partial x}\right) \qquad \textbf{(5-3)}$$

The PDEs hold for $t_0 \le t \le t_f$ and $a \le x \le b$. The interval [a,b][a, b] must be finite. m can be 0, 1, or 2, corresponding to slab, cylindrical, or spherical symmetry, respectively. If $m > 0$, then $a \ge 0$ must also hold.

In Equation 5-3, $f(x,t,u,\partial u/\partial x)$ is a flux term and $s(x,t,u,\partial u/\partial x)$ is a source term. The flux term must depend on $\partial u/\partial x$. The coupling of the partial

derivatives with respect to time is restricted to multiplication by a diagonal matrix $c(x,t,u,\partial u/\partial x)$. The diagonal elements of this matrix are either identically zero or positive. An element that is identically zero corresponds to an elliptic equation and otherwise to a parabolic equation. There must be at least one parabolic equation. An element of c that corresponds to a parabolic equation can vanish at isolated values of x if they are mesh points. Discontinuities in c and/or s due to material interfaces are permitted provided that a mesh point is placed at each interface.

At the initial time $t = t_0$, for all xx the solution components satisfy initial conditions of the form

$$u(x,t_0) = u_0(x) \tag{5-4}$$

At the boundary $x = a$ or $x = b$, for all t the solution components satisfy a boundary condition of the form

$$p(x,t,u) + q(x,t)f\left(x,t,u,\frac{\partial u}{\partial x}\right) = 0 \tag{5-5}$$

$q(x,t)$ is a diagonal matrix with elements that are either identically zero or never zero. Note that the boundary conditions are expressed in terms of the f rather than partial derivative of u with respect to x$\partial u/\partial x$. Also, of the two coefficients, only p can depend on u.

MATLAB Partial Differential Equation Solver

The PDE Solver

The MATLAB PDE solver, `pdepe`, solves initial-boundary value problems for systems of parabolic and elliptic PDEs in the one space variable x and time t. There must be at least one parabolic equation in the system.

The pdepe solver converts the PDEs to ODEs using a second-order accurate spatial discretization based on a fixed set of nodes specified by the user. The discretization method is described in [9]. The time integration is done with ode15s. The pdepe solver exploits the capabilities of ode15s for solving the differential-algebraic equations that arise when Equation 5-3 contains elliptic equations, and for handling Jacobians with a specified sparsity pattern. ode15s changes both the time step and the formula dynamically.

After discretization, elliptic equations give rise to algebraic equations. If the elements of the initial conditions vector that correspond to elliptic equations are not "consistent" with the discretization, pdepe tries to adjust them before beginning the time integration. For this reason, the solution returned for the initial time may have a discretization error comparable to that at any other time. If the mesh is sufficiently fine, pdepe can find consistent initial conditions close to the given ones. If pdepe displays a message that it has difficulty finding consistent initial conditions, try refining the mesh. No adjustment is necessary for elements of the initial conditions vector that correspond to parabolic equations.

PDE Solver Basic Syntax

The basic syntax of the solver is

```
sol = pdepe(m,pdefun,icfun,bcfun,xmesh,tspan)
```

Note Correspondences given are to terms used in "Introduction to PDE Problems" on page 5-94.

The input arguments are

`m` — Specifies the symmetry of the problem. `m` can be `0` = slab, `1` = cylindrical, or `2` = spherical. It corresponds to m in Equation 5-3.

`pdefun` — Function that defines the components of the PDE. It computes the terms c, f, and s in Equation 5-3, and has the form

```
[c,f,s] = pdefun(x,t,u,dudx)
```

where `x` and `t` are scalars, and `u` and `dudx` are vectors that approximate the solution u and its partial derivative with respect to x. `c`, `f`, and `s` are column vectors. `c` stores the diagonal elements of the matrix c.

`icfun` — Function that evaluates the initial conditions. It has the form

```
u = icfun(x)
```

When called with an argument `x`, `icfun` evaluates and returns the initial values of the solution components at `x` in the column vector `u`.

`bcfun` — Function that evaluates the terms p and q of the boundary conditions. It has the form

```
[pl,ql,pr,qr] = bcfun(xl,ul,xr,ur,t)
```

where `ul` is the approximate solution at the left boundary $xl = a$ and `ur` is the approximate solution at the right boundary$xr = b$. `pl` and `ql` are column vectors corresponding to p and the diagonal of q evaluated at `xl`. Similarly, `pr` and `qr` correspond to `xr`. When $m > 0$ and $a = 0$, boundedness of the solution near $x = 0$ requires that the f vanish at $a = 0$. `pdepe` imposes this boundary condition automatically and it ignores values returned in `pl` and `ql`.

`xmesh` — Vector [x0, x1, ..., xn] specifying the points at which a numerical solution is requested for every value in `tspan`. `x0` and `xn` correspond to a and b, respectively.

Second-order approximation to the solution is made on the mesh specified in `xmesh`. Generally, it is best to use closely spaced mesh points where the solution changes rapidly. `pdepe` does *not* select the mesh in x automatically. You must provide an appropriate fixed mesh in `xmesh`. The cost depends strongly on the length of `xmesh`. When $m > 0$, it is not necessary to use a fine mesh near $x = 0$ to account for the coordinate singularity.

The elements of `xmesh` must satisfy `x0 < x1 < ... < xn`. The length of `xmesh` must be ≥ 3.

`tspan` — Vector [t0, t1, ..., tf] specifying the points at which a solution is requested for every value in `xmesh`. `t0` and `tf` correspond to t_0 and t_f, respectively.

`pdepe` performs the time integration with an ODE solver that selects both the time step and formula dynamically. The solutions at the points specified in `tspan` are obtained using the natural continuous extension of the integration formulas. The elements of `tspan` merely specify where you want answers and the cost depends weakly on the length of `tspan`.

The elements of `tspan` must satisfy `t0 < t1 < ... < tf`. The length of `tspan` must be ≥ 3.

The output argument `sol` is a three-dimensional array, such that

- `sol(:,:,k)` approximates component `k` of the solution u.
- `sol(i,:,k)` approximates component `k` of the solution at time `tspan(i)` and mesh points `xmesh(:)`.
- `sol(i,j,k)` approximates component `k` of the solution at time `tspan(i)` and the mesh point `xmesh(j)`.

Additional PDE Solver Arguments

For more advanced applications, you can also specify as input arguments solver options and additional parameters that are passed to the PDE functions.

`options` Structure of optional parameters that change the default integration properties. This is the seventh input argument.

```
sol = pdepe(m,pdefun,icfun,bcfun,...
            xmesh,tspan,options)
```

See “Changing PDE Integration Properties” on page 5-104 for more information.

Solving PDE Problems

Example: A Single PDE

This example illustrates the straightforward formulation, solution, and plotting of the solution of a single PDE

$$\pi^2 \frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2}$$

This equation holds on an interval $0 \le x \le 1$ for times t ≥ 0. At $t = 0$, the solution satisfies the initial condition

$$u(x,0) = \sin \pi x$$

At $x = 0$ and $x = 1$, the solution satisfies the boundary conditions

$$u(0,t) = 0$$

$$\pi e^{-t} + \frac{\partial u}{\partial x}(1,t) = 0$$

Note The demo `pdex1` contains the complete code for this example. The demo uses subfunctions to place all functions it requires in a single M-file. To run the demo type `pdex1` at the command line. See "PDE Solver Basic Syntax" on page 5-96 for more information.

1 Rewrite the PDE. Write the PDE in the form

$$c\left(x,t,u,\frac{\partial u}{\partial x}\right)\frac{\partial u}{\partial t} = x^{-m}\frac{\partial}{\partial x}\left(x^{m} f\left(x,t,u,\frac{\partial u}{\partial x}\right)\right) + s\left(x,t,u,\frac{\partial u}{\partial x}\right)$$

This is the form shown in Equation 5-3 and expected by `pdepe`. See "Introduction to PDE Problems" on page 5-94 for more information. For this example, the resulting equation is

$$\pi^2\frac{\partial u}{\partial t} = x^{0}\frac{\partial}{\partial x}\left(x^{0}\frac{\partial u}{\partial x}\right) + 0$$

with parameter $m = 0$ and the terms

$$c\left(x,t,u,\frac{\partial u}{\partial x}\right) = \pi^2$$

$$f\left(x,t,u,\frac{\partial u}{\partial x}\right) = \frac{\partial u}{\partial x}$$

$$s\left(x,t,u,\frac{\partial u}{\partial x}\right) = 0$$

2 Code the PDE. Once you rewrite the PDE in the form shown above (Equation 5-3) and identify the terms, you can code the PDE in a function that `pdepe` can use. The function must be of the form

```
[c,f,s] = pdefun(x,t,u,dudx)
```

where `c`, `f`, and `s` correspond to the c, f, and s terms. The code below computes `c`, `f`, and `s` for the example problem.

```
function [c,f,s] = pdex1pde(x,t,u,DuDx)
c = pi^2;
```

```
f = DuDx;
s = 0;
```

3 **Code the initial conditions function.** You must code the initial conditions in a function of the form

```
u = icfun(x)
```

The code below represents the initial conditions in the function `pdex1ic`.

```
function u0 = pdex1ic(x)
u0 = sin(pi*x);
```

4 **Code the boundary conditions function.** You must also code the boundary conditions in a function of the form

```
[pl,ql,pr,qr] = bcfun(xl,ul,xr,ur,t)
```

The boundary conditions, written in the same form as Equation 5-5, are

$$u(0,t) + 0 \cdot \frac{\partial u}{\partial x}(0,t) = 0 \qquad \text{at } x = 0$$

and

$$\pi e^{-t} + 1 \cdot \frac{\partial u}{\partial x}(1,t) = 0 \qquad \text{at } x = 1$$

The code below evaluates the components $p(x,t,u)$ and $q(x,t)$ of the boundary conditions in the function `pdex1bc`.

```
function [pl,ql,pr,qr] = pdex1bc(xl,ul,xr,ur,t)
pl = ul;
ql = 0;
pr = pi * exp(-t);
qr = 1;
```

In the function `pdex1bc`, `pl` and `ql` correspond to the left boundary conditions ($x = 0$), and `pr` and `qr` correspond to the right boundary condition $x = 1$.

5 **Select mesh points for the solution.** Before you use the MATLAB PDE solver, you need to specify the mesh points (t, x) at which you want `pdepe` to evaluate the solution. Specify the points as vectors `t` and `x`.

The vectors `t` and `x` play different roles in the solver (see "MATLAB Partial Differential Equation Solver" on page 5-95). In particular, the cost and the accuracy of the solution depend strongly on the length of the vector `x`. However, the computation is much less sensitive to the values in the vector `t`.

This example requests the solution on the mesh produced by 20 equally spaced points from the spatial interval [0,1] and five values of `t` from the time interval [0,2].

```
x = linspace(0,1,20);
t = linspace(0,2,5);
```

6 **Apply the PDE solver.** The example calls `pdepe` with `m = 0`, the functions `pdex1pde`, `pdex1ic`, and `pdex1bc`, and the mesh defined by `x` and `t` at which `pdepe` is to evaluate the solution. The `pdepe` function returns the numerical solution in a three-dimensional array `sol`, where `sol(i,j,k)` approximates the `k`th component of the solution, u_k, evaluated at `t(i)` and `x(j)`.

```
m = 0;
sol = pdepe(m,@pdex1pde,@pdex1ic,@pdex1bc,x,t);
```

This example uses `@` to pass `pdex1pde`, `pdex1ic`, and `pdex1bc` as function handles to `pdepe`.

Note See the `function_handle` (@), `func2str`, and `str2func` reference pages, and the `@` section of MATLAB Programming for information about function handles.

---

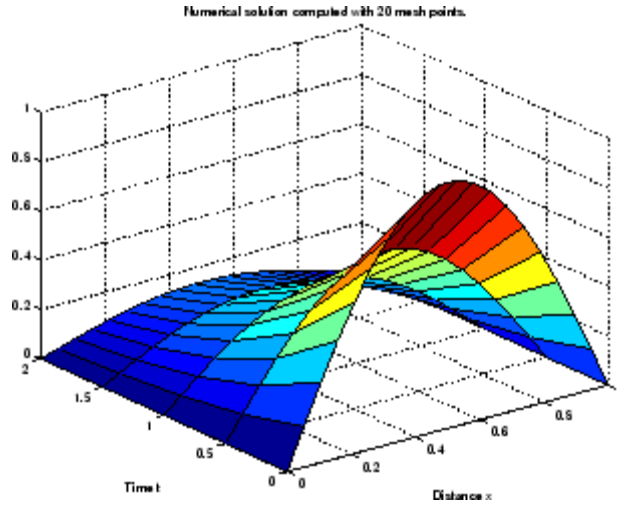
7 **View the results.** Complete the example by displaying the results:

a Extract and display the first solution component. In this example, the solution u has only one component, but for illustrative purposes, the

example “extracts” it from the three-dimensional array. The surface plot shows the behavior of the solution.

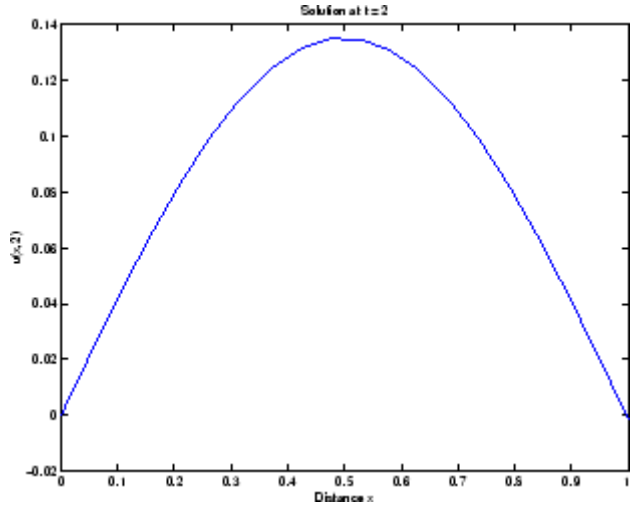
```
u = sol(:,:,1);

surf(x,t,u)
title('Numerical solution computed with 20 mesh points')
xlabel('Distance x')
ylabel('Time t')
```



b Display a solution profile at t_f, the final value of t. In this example, t_f = t = 2. See “Evaluating the Solution at Specific Points” on page 5-104 for more information.

```
figure
plot(x,u(end,:))
title('Solution at t = 2')
xlabel('Distance x')
ylabel('u(x,2)')
```



Evaluating the Solution at Specific Points

After obtaining and plotting the solution above, you might be interested in a solution profile for a particular value of `t`, or the time changes of the solution at a particular point `x`. The `k`th column `u(:,k)` (of the solution extracted in step 7) contains the time history of the solution at `x(k)`. The `j`th row `u(j,:)` contains the solution profile at `t(j)`.

Using the vectors `x` and `u(j,:)`, and the helper function `pdeval`, you can evaluate the solution `u` and its derivative $\partial u/\partial x$ at any set of points `xout`

```
[uout,DuoutDx] = pdeval(m,x,u(j,:),xout)
```

The example `pdex3` uses `pdeval` to evaluate the derivative of the solution at `xout = 0`. See `pdeval` for details.

Changing PDE Integration Properties

The default integration properties in the MATLAB PDE solver are selected to handle common problems. In some cases, you can improve solver performance by overriding these defaults. You do this by supplying `pdepe` with one or more property values in an options structure.

```
sol = pdepe(m,pdefun,icfun,bcfun,xmesh,tspan,options)
```

Use `odeset` to create the options structure. Only those options of the underlying ODE solver shown in the following table are available for `pdepe`. The defaults obtained by leaving off the input argument `options` are generally satisfactory. "Changing ODE Integration Properties" on page 5-19 tells you how to create the structure and describes the properties.

PDE Property Categories

Properties Category	Property Name
Error control	`RelTol`, `AbsTol`, `NormControl`
Step-size	`InitialStep`, `MaxStep`

Example: Electrodynamics Problem

This example illustrates the solution of a system of partial differential equations. The problem is taken from electrodynamics. It has boundary layers at both ends of the interval, and the solution changes rapidly for small t.

The PDEs are

$$\frac{\partial u_1}{\partial t} = 0.024\,\frac{\partial^2 u_1}{\partial x^2} - F(u_1 - u_2)$$

$$\frac{\partial u_2}{\partial t} = 0.170\,\frac{\partial^2 u_2}{\partial x^2} + F(u_1 - u_2)$$

where $F(y) = \exp(5.73y) - \exp(-11.46y)$. The equations hold on an interval 0 less than or equal to x less than or equal to $10 \le x \le 1$ for times $t \ge 0$.

The solution u satisfies the initial conditions

$$u_1(x, 0) \equiv 1$$

$$u_2(x, 0) \equiv 0$$

and boundary conditions

$$\frac{\partial u_1}{\partial x}(0,t) \equiv 0$$
$$u_2(0,t) \equiv 0$$
$$u_1(1,t) \equiv 1$$
$$\frac{\partial u_2}{\partial x}(1,t) \equiv 0$$

Note The demo `pdex4` contains the complete code for this example. The demo uses subfunctions to place all required functions in a single M-file. To run this example type `pdex4` at the command line. See "PDE Solver Basic Syntax" on page 5-96 and "Solving PDE Problems" on page 5-99 for more information.

---

1 **Rewrite the PDE.** In the form expected by `pdepe`, the equations are

$$\begin{bmatrix}1\\1\end{bmatrix} .* \frac{\partial}{\partial t}\begin{bmatrix}u_1\\u_2\end{bmatrix} = \frac{\partial}{\partial x}\begin{bmatrix}0.024(\partial u_1/\partial x)\\0.170(\partial u_2/\partial x)\end{bmatrix} + \begin{bmatrix}-F(u_1-u_2)\\F(u_1-u_2)\end{bmatrix}$$

The boundary conditions on the partial derivatives of u have to be written in terms of the flux. In the form expected by `pdepe`, the left boundary condition is

$$\begin{bmatrix}0\\u_2\end{bmatrix} + \begin{bmatrix}1\\0\end{bmatrix} .* \begin{bmatrix}0.024(\partial u_1/\partial x)\\0.170(\partial u_2/\partial x)\end{bmatrix} = \begin{bmatrix}0\\0\end{bmatrix}$$

and the right boundary condition is

$$\begin{bmatrix}u_1-1\\0\end{bmatrix} + \begin{bmatrix}0\\1\end{bmatrix} .* \begin{bmatrix}0.024(\partial u_1/\partial x)\\0.170(\partial u_2/\partial x)\end{bmatrix} = \begin{bmatrix}0\\0\end{bmatrix}$$

2 **Code the PDE.** After you rewrite the PDE in the form shown above, you can code it as a function that `pdepe` can use. The function must be of the form

```
[c,f,s] = pdefun(x,t,u,dudx)
```

where `c`, `f`, and `s` correspond to the c, f, and s terms in Equation 5-3.

```
function [c,f,s] = pdex4pde(x,t,u,DuDx)
c = [1; 1];
f = [0.024; 0.17] .* DuDx;
y = u(1) - u(2);
F = exp(5.73*y)-exp(-11.47*y);
s = [-F; F];
```

3 **Code the initial conditions function.** The initial conditions function must be of the form

```
u = icfun(x)
```

The code below represents the initial conditions in the function `pdex4ic`.

```
function u0 = pdex4ic(x);
u0 = [1; 0];
```

4 **Code the boundary conditions function.** The boundary conditions functions must be of the form

```
[pl,ql,pr,qr] = bcfun(xl,ul,xr,ur,t)
```

The code below evaluates the components $p(x,t,u)$ and $q(x,t)$ (Equation 5-5) of the boundary conditions in the function `pdex4bc`.

```
function [pl,ql,pr,qr] = pdex4bc(xl,ul,xr,ur,t)
pl = [0; ul(2)];
ql = [1; 0];
pr = [ur(1)-1; 0];
qr = [0; 1];
```

5 **Select mesh points for the solution.** The solution changes rapidly for small t. The program selects the step size in time to resolve this sharp change, but to see this behavior in the plots, output times must be selected accordingly. There are boundary layers in the solution at both ends of [0,1], so mesh points must be placed there to resolve these sharp changes.

Often some experimentation is needed to select the mesh that reveals the behavior of the solution.

```
x = [0 0.005 0.01 0.05 0.1 0.2 0.5 0.7 0.9 0.95 0.99 0.995 1];
t = [0 0.005 0.01 0.05 0.1 0.5 1 1.5 2];
```

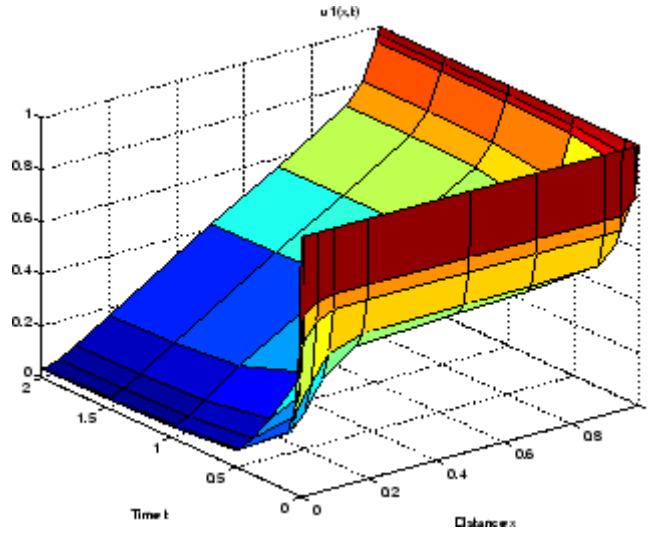
6 **Apply the PDE solver.** The example calls `pdepe` with `m = 0`, the functions `pdex4pde`, `pdex4ic`, and `pdex4bc`, and the mesh defined by `x` and `t` at which `pdepe` is to evaluate the solution. The `pdepe` function returns the numerical solution in a three-dimensional array `sol`, where `sol(i,j,k)` approximates the `k`th component of the solution, u_k, evaluated at `t(i)` and `x(j)`.

```
m = 0;
sol = pdepe(m,@pdex4pde,@pdex4ic,@pdex4bc,x,t);
```

7 **View the results.** The surface plots show the behavior of the solution components.

```
u1 = sol(:,:,1);
u2 = sol(:,:,2);

figure
surf(x,t,u1)
title('u1(x,t)')
xlabel('Distance x')
ylabel('Time t')
```



```
figure
surf(x,t,u2)
title('u2(x,t)')
xlabel('Distance x')
ylabel('Time t')
```

Sparse Matrices

Function Summary

In this section...

Categories of Functions That Support Sparse Matrices

Sparse matrix functions are located in the MATLAB `sparfun` directory. These functions fall into the following categories:

Elementary Sparse Matrices

Function	Description
`speye`	Sparse identity matrix
`sprand`	Sparse uniformly distributed random matrix
`sprandn`	Sparse normally distributed random matrix
`sprandsym`	Sparse random symmetric matrix
`spdiags`	Sparse matrix formed from diagonals

Full to Sparse Conversion

Function	Description
sparse	Create sparse matrix
full	Convert sparse matrix to full matrix
find	Find indices of nonzero elements
spconvert	Import from sparse matrix external format

Working with Sparse Matrices

Function	Description
nnz	Number of nonzero matrix elements
nonzeros	Nonzero matrix elements
nzmax	Amount of storage allocated for nonzero matrix elements
spones	Replace nonzero sparse matrix elements with ones
spalloc	Allocate space for sparse matrix
issparse	True for sparse matrix
spfun	Apply function to nonzero matrix elements
spy	Visualize sparsity pattern

Graph Theory

Function	Description
gplot	Plot graph, as in “graph theory”
etree	Elimination tree
etreeplot	Plot elimination tree
treelayout	Lay out tree or forest
treeplot	Plot picture of tree

Reordering Algorithms

Function	Description
`colamd`	Column approximate minimum degree permutation
`symamd`	Symmetric approximate minimum degree permutation
`symrcm`	Symmetric reverse Cuthill-McKee permutation
`colperm`	Column permutation
`randperm`	Random permutation
`dmperm`	Dulmage-Mendelsohn permutation

Linear Algebra

Function	Description
`eigs`	A few eigenvalues
`svds`	A few singular values
`luinc`	Incomplete LU factorization
`ilu`	Incomplete LU factorization
`cholinc`	Incomplete Cholesky factorization
`normest`	Estimate the matrix 2-norm
`condest`	1-norm condition number estimate
`sprank`	Structural rank

Linear Equations (Iterative Methods)

Function	Description
`bicg`	Biconjugate gradients method
`bicgstab`	Biconjugate gradients stabilized method
`cgs`	Conjugate gradients squared method

Function	Description
gmres	Generalized minimum residual method
lsqr	LSQR method
minres	Minimum residual method
pcg	Preconditioned conjugate gradients method
qmr	Quasi-minimal residual method
symmlq	Symmetric LQ method

Other Miscellaneous Functions

Function	Description
spaugment	Form least squares augmented system
spparms	Set parameters for sparse matrix routines
symbfact	Symbolic factorization analysis

Categories of Functions That Do Not Support Sparse Matrices

- "Histogram Plotting Functions" on page 6-9

These built-in functions do not accept sparse matrices as input. M-file functions that depend on these built-ins will also not work with sparse matrices.

Elementary Matrices and Arrays

Function	Description
`rand`	Uniformly distributed pseudorandom numbers

Elementary Math Functions

Complex Functions.

Function	Description
`complex`	Construct complex data from real and imaginary components

Real Array Exponential Functions.

Function	Description
`reallog`	Natural logarithm for nonnegative real arrays
`realpow`	Array power for real-only output
`realsqrt`	Square root for nonnegative real arrays

Bit-wise Functions

Function	Description
`bitand`	Bitwise AND
`bitcmp`	Bitwise complement
`bitget`	Bit at specified position
`bitmax`	Maximum double-precision floating-point integer

Function	Description
bitor	Bitwise OR
bitset	Set bit at specified position
bitshift	Shift bits specified number of places
bitxor	Bitwise XOR

Eigenvalue and Singular Value Functions

Function	Description
hess	Hessenberg form of matrix
ordeig	Eigenvalues of quasitriangular matrices
ordqz	Reorder eigenvalues in QZ factorization
ordschur	Reorder eigenvalues in Schur factorization
schur	Schur decomposition
svd	Singular value decomposition

Matrix Analysis Functions

Function	Description
cond	Condition number with respect to inversion
null	Null space
orth	Range space of matrix
rcond	Matrix reciprocal condition number estimate

Factorization Functions

Function	Description
`cholupdate`	Rank 1 update to Cholesky factorization
`gsvd`	Generalized singular value decomposition
`qz`	QZ factorization for generalized eigenvalues

Linear Equation Functions

Function	Description
`linsolve`	Solve linear system of equations
`lsqnonneg`	Solve nonnegative least-squares constraints problem
`pinv`	Moore-Penrose pseudoinverse of matrix

Specialized Math Functions

Function	Description
`airy`	Airy functions
`besselh`	Bessel function of third kind (Hankel function)
`besseli`	Modified Bessel function of first kind
`besselj`	Bessel function of first kind
`besselk`	Modified Bessel function of second kind
`bessely`	Bessel function of second kind
`erfc`	Error function
`erf`	Error function
`erfcx`	Error function
`gamma`	Gamma function

Function	Description
gammaln	Gamma function
psi	Psi (polygamma) function

Filtering and Convolution Functions

Function	Description
conv2	2-D convolution
convn	N-D convolution
filter	1-D digital filter
filter2	2-D digital filter

Fourier Transform Functions

Function	Description
fft	Discrete Fourier transform
fftn	N-D discrete Fourier transform
ifft	Inverse discrete Fourier transform
ifftn	N-D inverse discrete Fourier transform

Histogram Plotting Functions

Function	Description
histc	Histogram count

Sparse-Supported Replacement Functions

These functions do not accept sparse inputs, but you can use other functions in their place.

Function	Replacement Function Supporting Sparse Inputs
`cond`	Use `condest` instead.
`eig`	Syntax `d = eig(S)` accepts a sparse symmetric matrix `S`. Otherwise, use `eigs` in place of `eig`.
`norm(S,2)`	Use `normest` for the 2-norm of a sparse matrix `S`.
`svd`	Use `svds` instead.

Reducing Memory and Efficiency with Sparse Matrices

In this section...

Storing Sparse Matrices

Using sparse matrices to store data that contains a large number of zero-valued elements can both save a significant amount of memory and also speed up the processing of that data. `sparse` is an attribute that you can assign to any two-dimensional MATLAB matrix that is composed of `double` or `logical` elements.

The `sparse` attribute allows MATLAB to:

- Store only the nonzero elements of the matrix, together with their indices.
- Reduce computation time by eliminating operations on zero elements.

For full matrices, MATLAB stores internally every matrix element. Zero-valued elements require the same amount of storage space as any other matrix element. For sparse matrices, however, MATLAB stores only the nonzero elements and their indices. For large matrices with a high percentage of zero-valued elements, this scheme significantly reduces the amount of memory required for data storage.

Comparing Storage for Sparse and Full Matrices

The `whos` command provides high-level information about matrix storage, including size and storage class. For example, this `whos` listing shows information about sparse and full versions of the same matrix.

```
M_full = magic(1100);          % Create 1100-by-1100 matrix.
M_full(M_full > 50) = 0;       % Set elements >50 to zero.
M_sparse = sparse(M_full);     % Create sparse matrix of same.

whos
  Name           Size              Bytes  Class

  M_full      1100x1100          9680000  double array
  M_sparse    1100x1100             5004  double array (sparse)

Grand total is 1210050 elements using 9685004 bytes
```

Notice that the number of bytes used is fewer in the sparse case, because zero-valued elements are not stored.

Creating and Importing Sparse Matrices

In this section...

Creating Sparse Matrices

MATLAB never creates sparse matrices automatically. Instead, you must determine if a matrix contains a large enough percentage of zeros to benefit from sparse techniques.

The *density* of a matrix is the number of nonzero elements divided by the total number of matrix elements. For matrix `M`, this would be

```
nnz(M) / prod(size(M));
```

Matrices with very low density are often good candidates for use of the sparse format.

Converting Full to Sparse

You can convert a full matrix to sparse storage using the `sparse` function with a single argument.

```
S = sparse(A)
```

For example:

```
A = [ 0   0   0   5
      0   2   0   0
      1   3   0   0
      0   0   4   0];
```

```
S = sparse(A)
```

produces

```
S =

   (3,1)        1
   (2,2)        2
   (3,2)        3
   (4,3)        4
   (1,4)        5
```

The printed output lists the nonzero elements of `S`, together with their row and column indices. The elements are sorted by columns, reflecting the internal data structure.

You can convert a sparse matrix to full storage using the `full` function, provided the matrix order is not too large. For example `A = full(S)` reverses the example conversion.

Converting a full matrix to sparse storage is not the most frequent way of generating sparse matrices. If the order of a matrix is small enough that full storage is possible, then conversion to sparse storage rarely offers significant savings.

Creating Sparse Matrices Directly

You can create a sparse matrix from a list of nonzero elements using the `sparse` function with five arguments.

```
S = sparse(i,j,s,m,n)
```

`i` and `j` are vectors of row and column indices, respectively, for the nonzero elements of the matrix. `s` is a vector of nonzero values whose indices are specified by the corresponding `(i,j)` pairs. `m` is the row dimension for the resulting matrix, and `n` is the column dimension.

The matrix `S` of the previous example can be generated directly with

```
S = sparse([3 2 3 4 1],[1 2 2 3 4],[1 2 3 4 5],4,4)
```

```
S =

   (3,1)        1
   (2,2)        2
   (3,2)        3
   (4,3)        4
   (1,4)        5
```

The `sparse` command has a number of alternate forms. The example above uses a form that sets the maximum number of nonzero elements in the matrix to `length(s)`. If desired, you can append a sixth argument that specifies a larger maximum, allowing you to add nonzero elements later without reallocating the sparse matrix.

Example: Generating a Second Difference Operator

The matrix representation of the second difference operator is a good example of a sparse matrix. It is a tridiagonal matrix with -2s on the diagonal and 1s on the super- and subdiagonal. There are many ways to generate it—here's one possibility.

```
D = sparse(1:n,1:n,-2*ones(1,n),n,n);
E = sparse(2:n,1:n-1,ones(1,n-1),n,n);
S = E+D+E'
```

For `n = 5`, MATLAB responds with

```
S =

   (1,1)       -2
   (2,1)        1
   (1,2)        1
   (2,2)       -2
   (3,2)        1
   (2,3)        1
   (3,3)       -2
   (4,3)        1
   (3,4)        1
   (4,4)       -2
   (5,4)        1
   (4,5)        1
```

```
   (5,5)        -2
```

Now `F = full(S)` displays the corresponding full matrix.

```
F = full(S)

F =

    -2     1     0     0     0
     1    -2     1     0     0
     0     1    -2     1     0
     0     0     1    -2     1
     0     0     0     1    -2
```

Creating Sparse Matrices from Their Diagonal Elements

Creating sparse matrices based on their diagonal elements is a common operation, so the function `spdiags` handles this task. Its syntax is

```
S = spdiags(B,d,m,n)
```

To create an output matrix `S` of size *m*-by-*n* with elements on `p` diagonals:

- `B` is a matrix of size `min(`*m*`,`*n*`)`-by-*p*. The columns of `B` are the values to populate the diagonals of `S`.
- `d` is a vector of length `p` whose integer elements specify which diagonals of `S` to populate.

That is, the elements in column `j` of `B` fill the diagonal specified by element `j` of `d`.

Note If a column of `B` is longer than the diagonal it's replacing, super-diagonals are taken from the lower part of the column of `B`, and sub-diagonals are taken from the upper part of the column of `B`.

As an example, consider the matrix `B` and the vector `d`.

```
B = [ 41    11     0
      52    22     0
      63    33    13
      74    44    24 ];

d = [-3
      0
      2];
```

Use these matrices to create a 7-by-4 sparse matrix `A`:

```
A = spdiags(B,d,7,4)

A =

   (1,1)        11
   (4,1)        41
   (2,2)        22
   (5,2)        52
   (1,3)        13
   (3,3)        33
   (6,3)        63
   (2,4)        24
   (4,4)        44
   (7,4)        74
```

In its full form, `A` looks like this:

```
full(A)

ans =

    11     0    13     0
     0    22     0    24
     0     0    33     0
    41     0     0    44
     0    52     0     0
     0     0    63     0
     0     0     0    74
```

`spdiags` can also extract diagonal elements from a sparse matrix, or replace matrix diagonal elements with new values. Type `help spdiags` for details.

Importing Sparse Matrices from Outside MATLAB

You can import sparse matrices from computations outside MATLAB. Use the `spconvert` function in conjunction with the `load` command to import text files containing lists of indices and nonzero elements. For example, consider a three-column text file `T.dat` whose first column is a list of row indices, second column is a list of column indices, and third column is a list of nonzero values. These statements load `T.dat` into MATLAB and convert it into a sparse matrix `S`:

```
load T.dat
S = spconvert(T)
```

The `save` and `load` commands can also process sparse matrices stored as binary data in MAT-files.

Viewing Sparse Matrices

In this section...

Obtaining Information About Nonzero Elements

There are several commands that provide high-level information about the nonzero elements of a sparse matrix:

- `nnz` returns the number of nonzero elements in a sparse matrix.
- `nonzeros` returns a column vector containing all the nonzero elements of a sparse matrix.
- `nzmax` returns the amount of storage space allocated for the nonzero entries of a sparse matrix.

To try some of these, load the supplied sparse matrix `west0479`, one of the Harwell-Boeing collection.

```
load west0479
whos
  Name           Size          Bytes  Class

  west0479     479x479         24576  sparse array
```

This matrix models an eight-stage chemical distillation column.

Try these commands.

```
nnz(west0479)

ans =
1887

format short e
```

```
west0479

west0479 =

  (25,1)      1.0000e+00
  (31,1)     -3.7648e-02
  (87,1)     -3.4424e-01
  (26,2)      1.0000e+00
  (31,2)     -2.4523e-02
  (88,2)     -3.7371e-01
  (27,3)      1.0000e+00
  (31,3)     -3.6613e-02
  (89,3)     -8.3694e-01
  (28,4)      1.3000e+02
    .
    .
    .

nonzeros(west0479);
    ans =

   1.0000e+00
  -3.7648e-02
  -3.4424e-01
   1.0000e+00
  -2.4523e-02
  -3.7371e-01
   1.0000e+00
  -3.6613e-02
  -8.3694e-01
   1.3000e+02
    .
    .
    .
```

Note Use **Ctrl+C** to stop the `nonzeros` listing at any time.

Note that initially `nnz` has the same value as `nzmax` by default. That is, the number of nonzero elements is equivalent to the number of storage locations allocated for nonzeros. However, MATLAB does not dynamically release memory if you zero out additional array elements. Changing the value of some matrix elements to zero changes the value of `nnz`, but not that of `nzmax`.

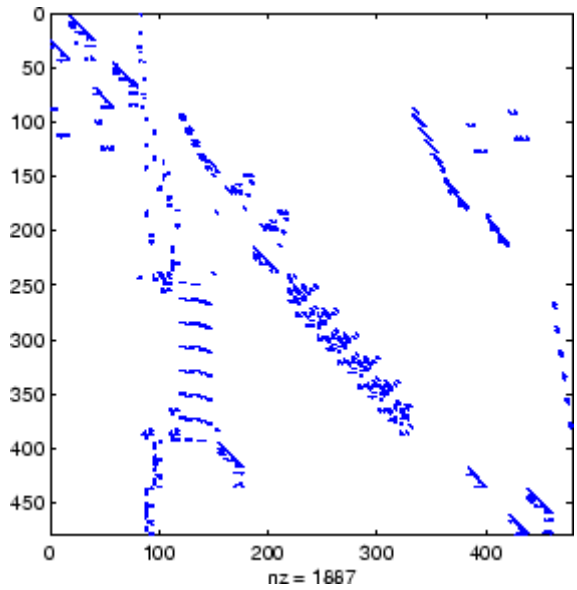
However, you can add as many nonzero elements to the matrix as desired. You are not constrained by the original value of `nzmax`.

Viewing Sparse Matrices Graphically

It is often useful to use a graphical format to view the distribution of the nonzero elements within a sparse matrix. The MATLAB `spy` function produces a template view of the sparsity structure, where each point on the graph represents the location of a nonzero array element.

For example:

```
spy(west0479)
```



Finding Indices and Values of Sparse Matrices

For any matrix, full or sparse, the `find` function returns the indices and values of nonzero elements. Its syntax is

```
[i,j,s] = find(S)
```

`find` returns the row indices of nonzero values in vector `i`, the column indices in vector `j`, and the nonzero values themselves in the vector `s`. The example below uses `find` to locate the indices and values of the nonzeros in a sparse matrix. The `sparse` function uses the `find` output, together with the size of the matrix, to recreate the matrix.

```
[i,j,s] = find(S)
[m,n] = size(S)
S = sparse(i,j,s,m,n)
```

Operating on Sparse Matrices

In this section...

Considering Computational Complexity and Standard Mathematical Operations

Computational Complexity

The computational complexity of sparse operations is proportional to `nnz`, the number of nonzero elements in the matrix. Computational complexity also depends linearly on the row size `m` and column size `n` of the matrix, but is independent of the product `m*n`, the total number of zero and nonzero elements.

The complexity of fairly complicated operations, such as the solution of sparse linear equations, involves factors like ordering and fill-in, which are discussed in the previous section. In general, however, the computer time required for a sparse matrix operation is proportional to the number of arithmetic operations on nonzero quantities.

Operating Principals for Sparse Matrices

Sparse matrices propagate through computations according to these rules:

- Functions that accept a matrix and return a scalar or constant-size vector always produce output in full storage format. For example, the `size` function always returns a full vector, whether its input is full or sparse.

- Functions that accept scalars or vectors and return matrices, such as `zeros`, `ones`, `rand`, and `eye`, always return full results. This is necessary to avoid introducing sparsity unexpectedly. The sparse analog of `zeros(m,n)` is simply `sparse(m,n)`. The sparse analogs of `rand` and `eye` are `sprand` and `speye`, respectively. There is no sparse analog for the function `ones`.
- Unary functions that accept a matrix and return a matrix or vector preserve the storage class of the operand. If `S` is a sparse matrix, then `chol(S)` is also a sparse matrix, and `diag(S)` is a sparse vector. Columnwise functions such as `max` and `sum` also return sparse vectors, even though these vectors can be entirely nonzero. Important exceptions to this rule are the `sparse` and `full` functions.
- Binary operators yield sparse results if both operands are sparse, and full results if both are full. For mixed operands, the result is full unless the operation preserves sparsity. If `S` is sparse and `F` is full, then `S+F`, `S*F`, and `F\S` are full, while `S.*F` and `S&F` are sparse. In some cases, the result might be sparse even though the matrix has few zero elements.
- Matrix concatenation using either the `cat` function or square brackets produces sparse results for mixed operands.
- Submatrix indexing on the right side of an assignment preserves the storage format of the operand unless the result is a scalar. `T = S(i,j)` produces a sparse result if `S` is sparse and either `i` or `j` is a vector. It produces a full scalar if both `i` and `j` are scalars. Submatrix indexing on the left, as in `T(i,j) = S`, does not change the storage format of the matrix on the left.

Performing Permutations and Reordering

- "Reordering for Sparsity" on page 6-26
- "Reordering to Reduce Bandwidth" on page 6-26
- "Approximate Minimum Degree Ordering" on page 6-26

A permutation of the rows and columns of a sparse matrix `S` can be represented in two ways:

- A permutation matrix `P` acts on the rows of `S` as `P*S` or on the columns as `S*P'`.

- A permutation vector `p`, which is a full vector containing a permutation of `1:n`, acts on the rows of `S` as `S(p,:)`, or on the columns as `S(:,p)`.

For example, the statements

```
p = [1 3 4 2 5]
I = eye(5,5);
P = I(p,:);
e = ones(4,1);
S = diag(11:11:55) + diag(e,1) + diag(e,-1)
```

produce:

```
p =

     1     3     4     2     5

P =

     1     0     0     0     0
     0     0     1     0     0
     0     0     0     1     0
     0     1     0     0     0
     0     0     0     0     1

S =

    11     1     0     0     0
     1    22     1     0     0
     0     1    33     1     0
     0     0     1    44     1
     0     0     0     1    55
```

You can now try some permutations using the permutation vector `p` and the permutation matrix `P`. For example, the statements `S(p,:)` and `P*S` produce

```
ans =

    11     1     0     0     0
     0     1    33     1     0
     0     0     1    44     1
```

```
     1    22     1     0     0
     0     0     0     1    55
```

Similarly, `S(:,p)` and `S*P'` produce

```
ans =

    11     0     0     1     0
     1     1     0    22     0
     0    33     1     1     0
     0     1    44     0     1
     0     0     1     0    55
```

If `P` is a sparse matrix, then both representations use storage proportional to `n` and you can apply either to `S` in time proportional to `nnz(S)`. The vector representation is slightly more compact and efficient, so the various sparse matrix permutation routines all return full row vectors with the exception of the pivoting permutation in LU (triangular) factorization, which returns a matrix compatible with the full LU factorization.

To convert between the two representations, let `I = speye(n)` be an identity matrix of the appropriate size. Then,

```
P = I(p,:)
P' = I(:,p)
p = (1:n)*P'
p = (P*(1:n)')'
```

The inverse of `P` is simply `R = P'`. You can compute the inverse of `p` with `r(p) = 1:n`.

```
r(p) = 1:5

r =

     1     4     2     3     5
```

Reordering for Sparsity

Reordering the columns of a matrix can often make its LU or QR factors sparser. Reordering the rows and columns can often make its Cholesky factors sparser. The simplest such reordering is to sort the columns by nonzero count. This is sometimes a good reordering for matrices with very irregular structures, especially if there is great variation in the nonzero counts of rows or columns.

The function `p = colperm(S)` computes this column-count permutation. The `colperm` M-file has only a single line.

```
[ignore,p] = sort(sum(spones(S)));
```

This line performs these steps:

1. The inner call to `spones` creates a sparse matrix with ones at the location of every nonzero element in `S`.
2. The `sum` function sums down the columns of the matrix, producing a vector that contains the count of nonzeros in each column.
3. `full` converts this vector to full storage format.
4. `sort` sorts the values in ascending order. The second output argument from `sort` is the permutation that sorts this vector.

Reordering to Reduce Bandwidth

The reverse Cuthill-McKee ordering is intended to reduce the profile or bandwidth of the matrix. It is not guaranteed to find the smallest possible bandwidth, but it usually does. The function `symrcm(A)` actually operates on the nonzero structure of the symmetric matrix `A + A'`, but the result is also useful for asymmetric matrices. This ordering is useful for matrices that come from one-dimensional problems or problems that are in some sense “long and thin.”

Approximate Minimum Degree Ordering

The degree of a node in a graph is the number of connections to that node. This is the same as the number of off-diagonal nonzero elements in the corresponding row of the adjacency matrix. The approximate minimum

degree algorithm generates an ordering based on how these degrees are altered during Gaussian elimination or Cholesky factorization. It is a complicated and powerful algorithm that usually leads to sparser factors than most other orderings, including column count and reverse Cuthill-McKee. Because the keeping track of the degree of each node is very time-consuming, the approximate minimum degree algorithm uses an approximation to the degree, rather than the exact degree.

The following MATLAB functions implement the approximate minimum degree algorithm:

- `symamd` — Use with symmetric matrices.
- `colamd` — Use with nonsymmetric matrices and symmetric matrices of the form `A*A'` or `A'*A`.

See "Reordering and Factorization" on page 6-29 for an example using `symamd`.

You can change various parameters associated with details of the algorithms using the `spparms` function.

For details on the algorithms used by `colamd` and `symamd`, see [5]. The approximate degree the algorithms use is based on [1].

Factorizing

This section discusses four important factorization techniques for sparse matrices:

LU Factorization

If `S` is a sparse matrix, the following command returns three sparse matrices `L`, `U`, and `P` such that `P*S = L*U`.

```
[L,U,P] = lu(S)
```

`lu` obtains the factors by Gaussian elimination with partial pivoting. The permutation matrix `P` has only `n` nonzero elements. As with dense matrices, the statement `[L,U] = lu(S)` returns a permuted unit lower triangular matrix and an upper triangular matrix whose product is `S`. By itself, `lu(S)` returns `L` and `U` in a single matrix without the pivot information.

The three-output syntax

```
[L,U,P] = lu(S)
```

selects `P` via numerical partial pivoting, but does not pivot to improve sparsity in the `LU` factors. On the other hand, the four-output syntax

```
[L,U,P,Q]=lu(S)
```

selects `P` via threshold partial pivoting, and selects `P` and `Q` to improve sparsity in the `LU` factors.

You can control pivoting in sparse matrices using

```
lu(S,thresh)
```

where `thresh` is a pivot threshold in [0,1]. Pivoting occurs when the diagonal entry in a column has magnitude less than `thresh` times the magnitude of any sub-diagonal entry in that column. `thresh = 0` forces diagonal pivoting. `thresh = 1` is the default. (The default for `thresh` is `0.1` for the four-output syntax).

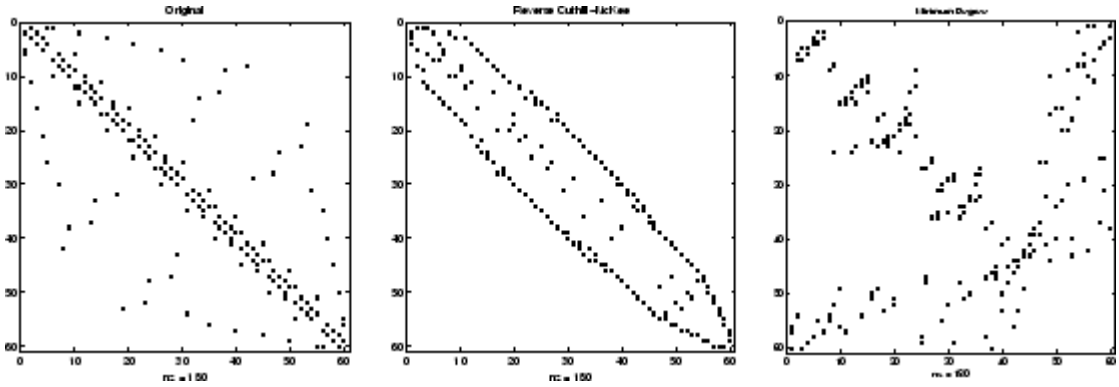
When you call `lu` with three or less outputs, MATLAB automatically allocates the memory necessary to hold the sparse `L` and `U` factors during the factorization. Except for the four-output syntax, MATLAB does not use any symbolic LU prefactorization to determine the memory requirements and set up the data structures in advance.

Reordering and Factorization. If you obtain a good column permutation `p` that reduces fill-in, perhaps from `symrcm` or `colamd`, then computing `lu(S(:,p))` takes less time and storage than computing `lu(S)`. Two permutations are the symmetric reverse Cuthill-McKee ordering and the symmetric approximate minimum degree ordering.

```
r = symrcm(B);
m = symamd(B);
```

The three spy plots produced by the lines below show the three adjacency matrices of the Bucky Ball graph with these three different numberings. The local, pentagon-based structure of the original numbering is not evident in the other three.

```
spy(B)
spy(B(r,r))
spy(B(m,m))
```



The reverse Cuthill-McKee ordering, `r`, reduces the bandwidth and concentrates all the nonzero elements near the diagonal. The approximate minimum degree ordering, `m`, produces a fractal-like structure with large blocks of zeros.

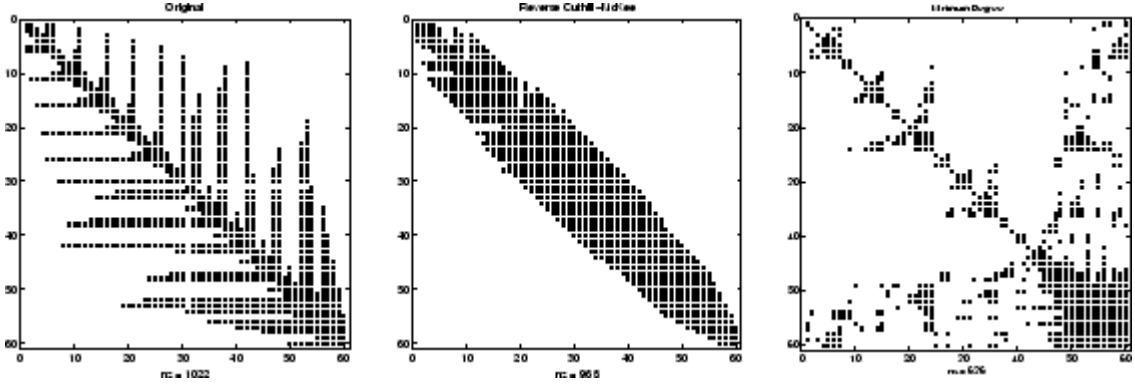
To see the fill-in generated in the LU factorization of the Bucky ball, use `speye(n,n)`, the sparse identity matrix, to insert -3s on the diagonal of `B`.

```
B = B - 3*speye(n,n);
```

Since each row sum is now zero, this new `B` is actually singular, but it is still instructive to compute its LU factorization. When called with only one output argument, `lu` returns the two triangular factors, `L` and `U`, in a single sparse matrix. The number of nonzeros in that matrix is a measure of the time and storage required to solve linear systems involving `B`. Here are the nonzero counts for the three permutations being considered.

Original	`lu(B)`	1022
Reverse Cuthill-McKee	`lu(B(r,r))`	968
Approximate minimum degree	`lu(B(m,m))`	636

Even though this is a small example, the results are typical. The original numbering scheme leads to the most fill-in. The fill-in for the reverse Cuthill-McKee ordering is concentrated within the band, but it is almost as extensive as the first two orderings. For the approximate minimum degree ordering, the relatively large blocks of zeros are preserved during the elimination and the amount of fill-in is significantly less than that generated by the other orderings. The `spy` plots below reflect the characteristics of each reordering.



Cholesky Factorization

If `S` is a symmetric (or Hermitian), positive definite, sparse matrix, the statement below returns a sparse, upper triangular matrix `R` so that `R'*R = S`.

```
R = chol(S)
```

`chol` does not automatically pivot for sparsity, but you can compute approximate minimum degree and profile limiting permutations for use with `chol(S(p,p))`.

Since the Cholesky algorithm does not use pivoting for sparsity and does not require pivoting for numerical stability, `chol` does a quick calculation of the amount of memory required and allocates all the memory at the start of the factorization. You can use `symbfact`, which uses the same algorithm as `chol`, to calculate how much memory is allocated.

QR Factorization

MATLAB computes the complete QR factorization of a sparse matrix `S` with

```
[Q,R] = qr(S)
```

but this is usually impractical. The orthogonal matrix `Q` often fails to have a high proportion of zero elements. A more practical alternative, sometimes known as "the Q-less QR factorization," is available.

With one sparse input argument and one output argument

```
R = qr(S)
```

returns just the upper triangular portion of the QR factorization. The matrix `R` provides a Cholesky factorization for the matrix associated with the normal equations:

```
R'*R = S'*S
```

However, the loss of numerical information inherent in the computation of `S'*S` is avoided.

With two input arguments having the same number of rows, and two output arguments, the statement

```
[C,R] = qr(S,B)
```

applies the orthogonal transformations to `B`, producing `C = Q'*B` without computing `Q`.

The Q-less QR factorization allows the solution of sparse least squares problems

$$\text{minimize}\|Ax - b\|$$

with two steps

```
[c,R] = qr(A,b)
x = R\c
```

If `A` is sparse, but not square, MATLAB uses these steps for the linear equation solving backslash operator:

```
x = A\b
```

Or, you can do the factorization yourself and examine `R` for rank deficiency.

It is also possible to solve a sequence of least squares linear systems with different right-hand sides, `b`, that are not necessarily known when `R = qr(A)` is computed. The approach solves the “semi-normal equations”

```
R'*R*x = A'*b
```

with

```
x = R\(R'\(A'*b))
```

and then employs one step of iterative refinement to reduce roundoff error:

```
r = b - A*x
e = R\(R'\(A'*r))
x = x + e
```

Incomplete Factorizations

The `luinc`, `ilu`, and `cholinc` functions provide approximate, *incomplete* factorizations, which are useful as preconditioners for sparse iterative methods.

The `luinc` function produces two different kinds of incomplete LU (ILU) factorizations, one involving a drop tolerance and one involving fill-in level. The `ilu` function produces three incomplete LU factorizations, the ILU with level 0 fill-in (ILU(0)), the Crout version of ILU (ILUC), and the ILU with threshold and pivoting (ILUTP).

For example:

```
A = gallery('neumann', 1600) + speye(1600);
nnz(A)
ans =
        7840

nnz(lu(A))
ans =
      126478
```

shows that `A` has 7840 zeros, and its complete LU factorization has 126478 nonzeros:

```
nnz(luinc(A,'0'))
ans =
        7840

setup.type = 'nofill';
nnz(ilu(A,setup))
ans =
        7840

nnz(luinc(A,1e-6))
ans =
       51541

setup.type = 'ilutp';
setup.droptol = 1e-6;
```

```
nnz(luinc(A,setup))
ans =
       51541
```

These calculations, with both the `luinc` and `ilu` functions, show that with level 0 fill-in it has 7840 zeros, and with a drop tolerance of `1e-6` it has 51541 nonzeros. See the `luinc` and `ilu` reference pages for more options and details.

The `cholinc` function provides drop tolerance and level 0 fill-in Cholesky factorizations of symmetric, positive definite sparse matrices. See the `cholinc` reference page for more information.

Solving Simultaneous Linear Equations

- "Direct Methods" on page 6-34
- "Iterative Methods" on page 6-35

There are two different classes of methods for solving systems of simultaneous linear equations:

- *Direct methods* are usually variants of Gaussian elimination. These methods involve the individual matrix elements directly, through matrix factorizations such as LU or Cholesky factorization. MATLAB implements direct methods through the matrix division operators / and \, which you can use to solve linear systems.
- *Iterative methods* produce only an approximate solution after a finite number of steps. These methods involve the coefficient matrix only indirectly, through a matrix-vector product or an abstract linear operator. Iterative methods are usually applied only to sparse matrices.

Direct Methods

Direct methods are usually faster and more generally applicable than indirect methods, if there is enough storage available to carry them out. Iterative methods are usually applicable to restricted cases of equations and depend upon properties like diagonal dominance or the existence of an underlying differential operator. Direct methods are implemented in the core of MATLAB and are made as efficient as possible for general classes of matrices. Iterative

methods are usually implemented in MATLAB M-files and can make use of the direct solution of subproblems or preconditioners.

Using a Different Preordering. If `A` is not diagonal, banded, triangular, or a permutation of a triangular matrix, backslash (`\`) reorders the indices of `A` to reduce the amount of fill-in—that is, the number of nonzero entries that are added to the sparse factorization matrices. The new ordering, called a *preordering*, is performed before the factorization of `A`. In some cases, you might be able to provide a better preordering than the one used by the backslash algorithm.

To use a different preordering, first turn off both of the automatic preorderings that backslash might perform by default, using the function `spparms` as follows:

```
spparms('autoamd',0);
spparms('autommd',0);
```

Now, assuming you have created a permutation vector `p` that specifies a preordering of the indices of `A`, apply backslash to the matrix `A(:,p)`, whose columns are the columns of `A`, permuted according to the vector `p`.

```
x = A (:,p) \ b;
x(p) = x;
spparms('autoamd',1);
spparms('autommd',1);
```

The commands `spparms('autoamd',1)` and `spparms('autommd',1)` turns the automatic preordering back on, in case you use `A\b` later without specifying an appropriate preordering.

Iterative Methods

Nine functions are available that implement iterative methods for sparse systems of simultaneous linear systems.

Functions for Iterative Methods for Sparse Systems

Function	Method
`bicg`	Biconjugate gradient
`bicgstab`	Biconjugate gradient stabilized
`cgs`	Conjugate gradient squared
`gmres`	Generalized minimum residual
`lsqr`	Least squares
`minres`	Minimum residual
`pcg`	Preconditioned conjugate gradient
`qmr`	Quasiminimal residual
`symmlq`	Symmetric LQ

These methods are designed to solve $Ax = b$ or $\min\|b - Ax\|$. For the Preconditioned Conjugate Gradient method, `pcg`, A must be a symmetric, positive definite matrix. `minres` and `symmlq` can be used on symmetric indefinite matrices. For `lsqr`, the matrix need not be square. The other five can handle nonsymmetric, square matrices.

All nine methods can make use of preconditioners. The linear system

$$Ax = b$$

is replaced by the equivalent system

$$M^{-1}Ax = M^{-1}b$$

The preconditioner M is chosen to accelerate convergence of the iterative method. In many cases, the preconditioners occur naturally in the mathematical model. A partial differential equation with variable coefficients can be approximated by one with constant coefficients, for example. Incomplete matrix factorizations can be used in the absence of natural preconditioners.

The five-point finite difference approximation to Laplace's equation on a square, two-dimensional domain provides an example. The following statements use the preconditioned conjugate gradient method preconditioner M = R'*R, where R is the incomplete Cholesky factor of A.

```
A = delsq(numgrid('S',50));
b = ones(size(A,1),1);
tol = 1.e-3;
maxit = 10;
R = cholinc(A,tol);
[x,flag,err,iter,res] = pcg(A,b,tol,maxit,R',R);
```

Only four iterations are required to achieve the prescribed accuracy.

Background information on these iterative methods and incomplete factorizations is available in [2] and [7].

Solving Eigenvalues and Singular Values

Two functions are available that compute a few specified eigenvalues or singular values. `svds` is based on `eigs` that uses ARPACK [6].

Functions to Compute a Few Eigenvalues or Singular Values

Function	Description
`eigs`	Few eigenvalues
`svds`	Few singular values

These functions are most frequently used with sparse matrices, but they can be used with full matrices or even with linear operators defined by M-files.

The statement

```
[V,lambda] = eigs(A,k,sigma)
```

finds the `k` eigenvalues and corresponding eigenvectors of the matrix `A` that are nearest the "shift" `sigma`. If `sigma` is omitted, the eigenvalues largest in magnitude are found. If `sigma` is zero, the eigenvalues smallest in magnitude

are found. A second matrix, B, can be included for the generalized eigenvalue problem:

$$Av = \lambda Bv$$

The statement

```
[U,S,V] = svds(A,k)
```

finds the k largest singular values of A and

```
[U,S,V] = svds(A,k,0)
```

finds the k smallest singular values.

For example, the statements

```
L = numgrid('L',65);
A = delsq(L);
```

set up the five-point Laplacian difference operator on a 65-by-65 grid in an L-shaped, two-dimensional domain. The statements

```
size(A)
nnz(A)
```

show that A is a matrix of order 2945 with 14,473 nonzero elements.

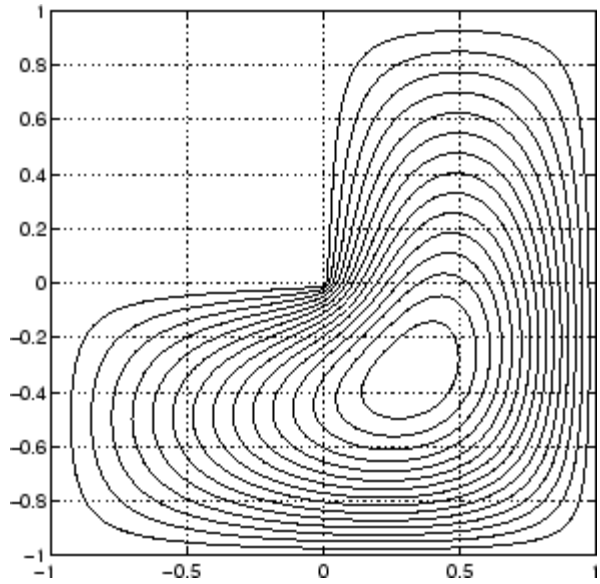
The statement

```
[v,d] = eigs(A,1,0);
```

computes the smallest eigenvalue and eigenvector. Finally,

```
L(L>0) = full(v(L(L>0)));
x = -1:1/32:1;
contour(x,x,L,15)
axis square
```

distributes the components of the eigenvector over the appropriate grid points and produces a contour plot of the result.



The numerical techniques used in `eigs` and `svds` are described in [6].

Identifying Performance Limitations

This section describes some limitations of the sparse matrix storage format and their impact on matrix creation, manipulation, and operations.

Creating Sparse Matrices

The best way to create a sparse matrix is to use the `sparse` function. If you do not have prior knowledge of the nonzero indices or their values, it is much more efficient to create the vectors containing these values, and then create the sparse matrix.

Preallocating the memory for a sparse matrix and filling it in an elementwise manner causes a significant amount of overhead in indexing into the sparse array:

```
S1 = spalloc(1000,1000,100000);
tic;
for n = 1:100000
    i = ceil(1000*rand(1,1));
    j = ceil(1000*rand(1,1));
    S1(i,j) = rand(1,1);
end
toc

Elapsed time is 26.281000 seconds.
```

Whereas constructing the vectors of indices and values eliminates the need to index into the sparse array, and thus is significantly faster:

```
i = ceil(1000*rand(100000,1));
j = ceil(1000*rand(100000,1));
v = zeros(size(i));
for n = 1:100000
    v(n) = rand(1,1);
end

tic;
S2 = sparse(i,j,v,1000,1000);
toc

Elapsed time is 0.078000 seconds.
```

Manipulating Sparse Matrices

Because sparse matrices are stored in a column-major format, accessing the matrix by columns is more efficient than by rows. Compare the time required for adding rows of a matrix 1000 times

```
S = sparse(10000,10000,1);
tic;
for n = 1:1000
   A = S(100,:) + S(200,:);
end;
toc
```

```
Elapsed time is 1.208162 seconds.
```

versus the time required for adding columns

```
S = sparse(10000,10000,1);
tic;
for n = 1:1000
   B = S(:,100) + S(:,200);
end;
toc

Elapsed time is 0.088747 seconds.
```

When possible, you can transpose the matrix, perform operations on the columns, and then retranspose the result:

```
S = sparse(10000,10000,1);
tic;
for n = 1:1000
   A = S(100,:)' + S(200,:)';
   A = A';
end;
toc

Elapsed time is 0.597142 seconds.
```

The time required to transpose the matrix is negligible. Note that the sparse matrix memory requirements could prevent you from transposing a sparse matrix having a large number of rows. This might occur even when the number of nonzero values is small.

Using linear indexing to access or assign an element in a large sparse matrix will fail if the linear index exceeds `intmax`. To access an element whose linear index is greater than `intmax`, use array indexing:

```
S = spalloc(216^2, 216^2, 2)
S(1) = 1
S(end) = 1
S(216^2,216^2) = 1
```

The Test Matrix Toolbox for MATLAB (Version 3.0)

Nicholas J. Higham*

September 22, 1995

Abstract

We describe version 3.0 of the Test Matrix Toolbox for MATLAB 4.2. The toolbox contains a collection of test matrices, routines for visualizing matrices, routines for direct search optimization, and miscellaneous routines that provide useful additions to MATLAB's existing set of functions. There are 58 parametrized test matrices, which are mostly square, dense, nonrandom, and of arbitrary dimension. The test matrices include ones with known inverses or known eigenvalues; ill-conditioned or rank deficient matrices; and symmetric, positive definite, orthogonal, defective, involutary, and totally positive matrices. The visualization routines display surface plots of a matrix and its (pseudo-) inverse, the field of values, Gershgorin disks, and two- and three-dimensional views of pseudospectra. The direct search optimization routines implement the alternating directions method, the multidirectional search method and the Nelder–Mead simplex method. We explain the need for collections of test matrices and summarize the features of the collection in the toolbox. We give examples of the use of the toolbox and explain some of the interesting properties of the Frank matrix and magic square matrices. The leading comment lines from all the toolbox routines are listed.

Key words. test matrix, MATLAB, pseudospectrum, visualization, Frank matrix, magic square matrix, random matrix, direct search optimization.

AMS subject classifications. primary 65F05

Contents

1 Distribution

If you wish to distribute the toolbox please give exact copies of it, not selected routines.

2 Installation

The Test Matrix Toolbox is available by anonymous ftp from The MathWorks with URL

```
ftp://ftp.mathworks.com/pub/contrib/linalg/testmatrix
```

This document is `testmatrix.ps` in the same location. The MathWorks ftp server provides information on how to download a complete directory as one file.

The toolbox is also available from the URL

```
ftp://ftp.ma.man.ac.uk/pub/higham/testmatrix.tar.Z
```

This document is `narep276.ps.Z` in the same location. To install the toolbox from this location, download the tar file (in binary mode) into a `testmatrix` directory (`matlab/testmatrix` is recommended). Then uncompress the tar file and untar it:

```
uncompress testmatrix.tar.Z
tar xvf testmatrix
```

To try the toolbox from within MATLAB, change to the `testmatrix` directory and run the demonstration script by typing `tmtdemo`. For serious use it is best to put the `testmatrix` directory on the MATLAB path *before* the `matlab/toolbox` entries—this is because several toolbox routines have the same name as MATLAB routines and are intended to replace them (namely, `compan`, `cond`, `hadamard`, `hilb`, and `pascal`).

This document describes version 3.0 of the toolbox, dated September 19, 1995.

3 Release History

The first release of this toolbox (version 1.0, July 4 1989) was described in a technical report [19]. The collection was subsequently published as ACM Algorithm 694 [21]. Prior to the current version, version 3.0, the most recent release was version 2.0 (November 14 1993) [24]. Version 2.0 incorporated many additions and improvements over version 1.3 and took full advantage of the features of MATLAB 4.

The major changes in version 3.0 are as follows.

- New routines: `cgs` (classical Gram–Schmidt), `mgs` (modified Gram–Schmidt), `gj` (Gauss–Jordan elimination), `diagpiv` (diagonal pivoting factorization with partial pivoting for a symmetric matrix); `adsmax`, `mdsmax` and `nmsmax` for direct search optimization.
- Bug in `eigsens` corrected. Minor bugs in other routines corrected.

Version 3.0 of the toolbox was developed in conjunction with the book *Accuracy and Stability of Numerical Algorithms* [26]. The book contains a chapter *A Gallery of Test Matrices* which has sections

- The Hilbert and Cauchy Matrices
- Random Matrices
- "Randsvd" Matrices
- The Pascal Matrix
- Tridiagonal Toeplitz Matrices
- Companion Matrices
- Notes and References
- LAPACK
- Problems

Users of the toolbox should consult [26] for further information not contained in this document.

4 Quick Reference Tables

This section contains quick reference tables for the Test Matrix Toolbox. All the M-files in the toolbox are listed by category, with a short description. More detailed documentation is given in Section 10, or can be obtained on-line by typing `help M-file_name`.

Demonstration	
`tmtdemo`	Demonstration of Test Matrix Toolbox.

Test Matrices, A–K	
`augment`	Augmented system matrix.
`cauchy`	Cauchy matrix.
`chebspec`	Chebyshev spectral differentiation matrix.
`chebvand`	Vandermonde-like matrix for the Chebyshev polynomials.
`chow`	Chow matrix—a singular Toeplitz lower Hessenberg matrix.
`circul`	Circulant matrix.
`clement`	Clement matrix—tridiagonal with zero diagonal entries.
`compan`	Companion matrix.
`condex`	"Counterexamples" to matrix condition number estimators.
`cycol`	Matrix whose columns repeat cyclically.
`dingdong`	Dingdong matrix—a symmetric Hankel matrix.
`dorr`	Dorr matrix—diagonally dominant, ill conditioned, tridiagonal.
`dramadah`	A $(0,1)$ matrix whose inverse has large integer entries.
`fiedler`	Fiedler matrix—symmetric.
`forsythe`	Forsythe matrix—a perturbed Jordan block.
`frank`	Frank matrix—ill conditioned eigenvalues.
`gallery`	Famous, and not so famous, test matrices.
`gearm`	Gear matrix.
`gfpp`	Matrix giving maximal growth factor for Gaussian elimination with partial pivoting.
`grcar`	Grcar matrix—a Toeplitz matrix with sensitive eigenvalues.
`hadamard`	Hadamard matrix.
`hanowa`	A matrix whose eigenvalues lie on a vertical line in the complex plane.
`hilb`	Hilbert matrix.
`invhess`	Inverse of an upper Hessenberg matrix.
`invol`	An involutory matrix.
`ipjfact`	A Hankel matrix with factorial elements.
`jordbloc`	Jordan block.
`kahan`	Kahan matrix—upper trapezoidal.
`kms`	Kac–Murdock–Szegö Toeplitz matrix.
`krylov`	Krylov matrix.

Test Matrices, L–Z	
`lauchli`	Lauchli matrix—rectangular.
`lehmer`	Lehmer matrix—symmetric positive definite.
`lesp`	A tridiagonal matrix with real, sensitive eigenvalues.
`lotkin`	Lotkin matrix.
`makejcf`	A matrix with given Jordan canonical form.
`minij`	Symmetric positive definite matrix $\min(i,j)$.
`moler`	Moler matrix—symmetric positive definite.
`neumann`	Singular matrix from the discrete Neumann problem (sparse).
`ohess`	Random, orthogonal upper Hessenberg matrix.
`orthog`	Orthogonal and nearly orthogonal matrices.
`parter`	Parter matrix—a Toeplitz matrix with singular values near π.
`pascal`	Pascal matrix.
`pdtoep`	Symmetric positive definite Toeplitz matrix.
`pei`	Pei matrix.
`pentoep`	Pentadiagonal Toeplitz matrix (sparse).
`poisson`	Block tridiagonal matrix from Poisson's equation (sparse).
`prolate`	Prolate matrix—symmetric, ill-conditioned Toeplitz matrix.
`rando`	Random matrix with elements -1, 0 or 1.
`randsvd`	Random matrix with pre-assigned singular values.
`redheff`	A (0,1) matrix of Redheffer associated with the Riemann hypothesis.
`riemann`	A matrix associated with the Riemann hypothesis.
`rschur`	An upper quasi-triangular matrix.
`smoke`	Smoke matrix—complex, with a "smoke ring" pseudospectrum.
`tridiag`	Tridiagonal matrix (sparse).
`triw`	Upper triangular matrix discussed by Wilkinson and others.
`vand`	Vandermonde matrix.
`wathen`	Wathen matrix—a finite element matrix (sparse, random entries).
`wilk`	Various specific matrices devised/discussed by Wilkinson.

Visualization	
`fv`	Field of values (or numerical range).
`gersh`	Gershgorin disks.
`ps`	Dot plot of a pseudospectrum.
`pscont`	Contours and colour pictures of pseudospectra.
`see`	Pictures of a matrix and its (pseudo-) inverse.

Decompositions and Factorizations	
`cgs`	Classical Gram–Schmidt QR factorization.
`cholp`	Cholesky factorization with pivoting of a positive semidefinite matrix.
`cod`	Complete orthogonal decomposition.
`diagpiv`	Diagonal pivoting factorization with partial pivoting.
`ge`	Gaussian elimination without pivoting.
`gecp`	Gaussian elimination with complete pivoting.
`gj`	Gauss–Jordan elimination to solve $Ax = b$.
`mgs`	Modified Gram–Schmidt QR factorization.
`poldec`	Polar decomposition.
`signm`	Matrix sign decomposition.

Direct Search Optimization	
`adsmax`	Alternating directions direct search method.
`mdsmax`	Multidirectional search method for direct search optimization.
`mmsmax`	Nelder–Mead simplex method for direct search optimization.

Miscellaneous	
`bandred`	Band reduction by two-sided unitary transformations.
`chop`	Round matrix elements.
`comp`	Comparison matrices.
`cond`	Matrix condition number in 1, 2, Frobenius, or ∞-norm.
`cpltaxes`	Determine suitable `axis` for plot of complex vector.
`dual`	Dual vector with respect to Hölder p-norm.
`eigsens`	Eigenvalue condition numbers.
`house`	Householder matrix.
`matrix`	Test Matrix Toolbox information and matrix access by number.
`matsignt`	Matrix sign function of a triangular matrix.
`pnorm`	Estimate of matrix p-norm ($1 \leq p \leq \infty$).
`qmult`	Pre-multiply by random orthogonal matrix.
`rq`	Rayleigh quotient.
`seqa`	Additive sequence.
`seqcheb`	Sequence of points related to Chebyshev polynomials.
`seqm`	Multiplicative sequence.
`show`	Display signs of matrix elements.
`skewpart`	Skew-symmetric (skew-Hermitian) part.
`sparsify`	Randomly sets matrix elements to zero.
`sub`	Principal submatrix.
`symmpart`	Symmetric (Hermitian) part.
`trap2tri`	Unitary reduction of trapezoidal matrix to triangular form.

5 Test Matrices

Numerical experiments are an indispensable part of research in numerical analysis. We do them for several reasons:

- To gain insight and understanding into an algorithm that is only partially understood theoretically.
- To verify the correctness of a theoretical analysis and to see if the analysis completely explains the practical behaviour.
- To compare rival methods with regard to accuracy, speed, reliability, and so on.
- To tune parameters in algorithms and codes, and to test heuristics.

One of the difficulties in designing experiments is finding good test problems—ones that reveal extremes of behaviour, cover a wide range of difficulty, are representative of practical problems, and (ideally) have known solutions. In many areas of numerical analysis good test problems have been identified, and several collections of such problems have been published. For example, collections are available in the areas of nonlinear optimization [33], linear programming [13], [31], ordinary differential equations [10], and partial differential equations [34].

Probably the most prolific devisers of test problems have been workers in matrix computations. Indeed, in the 1950s and 1960s it was common for a whole paper to be devoted to a particular test matrix: typically its inverse or eigenvalues would be obtained in closed form. An early survey of test matrices was given by Rutishauser [36]; most of the matrices he discusses come from continued fractions or moment problems. Two well-known books present collections of test matrices. Gregory and Karney [15] deal exclusively with the topic, while Westlake [43] gives an appendix of test matrices. In the 24 years since these books appeared several interesting matrices have been discovered (and in fact both books omit some worthy test matrices that were known at the time).

The Test Matrix Toolbox contains an up-to-date, well documented and readily accessible collection of test matrices. The matrices are given in the form of self-documenting MATLAB M-files. For some of the matrices we give mathematical formulas for the matrix elements in comment lines; in other cases the formulas can be reconstructed from the MATLAB code. We do not give exhaustive descriptions of matrix properties, or proofs of these properties; instead, in the comment lines we list a few key properties and give references where further details can be found.

With a few exceptions each of the 58 matrices satisfies the following requirements:

- It is a square matrix with one or more variable parameters, one of which is the dimension. Thus it is actually a parametrized family of matrices of arbitrary dimension.
- It is dense.
- It has some property that makes it of interest as a test matrix.

The first criterion is enforced because it is often desirable to explore the behaviour of a numerical method as parameters such as the matrix dimension vary. The third criterion is somewhat subjective, and the matrices presented here represent the author's personal choice. Note that we have omitted plausible matrices that we thought not "sufficiently different" from others in the collection. Although all but two of our test matrices are usually real, those with an arbitrary parameter can be made complex by choosing a non-real value for the parameter.

As well as their obvious application to research in matrix computations we hope that the matrices presented here will be useful for constructing test problems in other areas, such as optimization (see, for example, [3]) and ordinary differential equations.

We mention some other collections of test matrices that complement ours. The Harwell-Boeing collection of sparse matrices, largely drawn from practical problems, is presented by Duff, Grimes and Lewis [8], [9]. Bai [2] is building a collection of test matrices for the large-scale nonsymmetric eigenvalue problem. Zielke [46] gives various parametrized rectangular matrices of fixed dimension with known generalized inverses. Demmel and McKenney [7] present a suite of Fortran 77 codes for generating random square and rectangular matrices with prescribed singular values, eigenvalues, band structure, and other properties. This suite is part of the testing code for LAPACK [1]. Our focus is primarily on non-random matrices but we include a class of random matrices `randsvd` that has some of the features of the Demmel and McKenney test set.

Where possible, we have chosen the names of the test matrices eponymously, since it is easier to remember, for example, "the Kahan matrix", than "Example 3.8". For portability reasons we restrict all M-file names in the toolbox to eight characters (since this is the limit in the MSDOS operating system, under which the Microsoft Windows version of MATLAB runs). We have written a routine `matrix` that accesses the matrices by number rather than by name; this makes it easy to run experiments on the whole collection of matrices (with parameters other than the matrix dimension set to their default values.)

The matrices described here can be modified in various ways while still retaining some or all of their interesting properties. Among the many ways of constructing new test matrices from old are:

- Similarity transformations $A \leftarrow X^{-1}AX$.
- Unitary transformations $A \leftarrow UAV$, where $U^*U = V^*V = I$.
- Kronecker products $A \leftarrow A \otimes B$ or $B \otimes A$ (for which MATLAB has a routine `kron`).
- Powers $A \leftarrow A^k$.

For a discussion of these techniques, and others, see [15, Chapter 2]. Techniques for obtaining a triangular, orthogonal, or symmetric positive definite matrix that is related to a given matrix include

- Bandwidth reduction using unitary transformations (see toolbox routine `bandred`).
- LU, Cholesky, QR and polar decompositions (see `lu`, `chol`, `qr` and, from the toolbox, `cholp`, `ge`, `gecp` and `poldec`.)

See [14] for details of these techniques.

Another way to generate a new matrix is to perturb an existing one. One approach is to add a random perturbation. Another is to round the matrix elements to a certain number of binary places; this can be done using the toolbox routine `chop`.

Our programming style is as follows. Each M-file `foo` begins with comment lines that are displayed when the user types `help foo`. The first comment line, the H1 line, is a self-contained statement of the purpose of the routine; the H1 lines are searched and displayed by MATLAB's `lookfor` command (e.g., `lookfor toeplitz`). Any further comments and references follow a blank line and so are not displayed by `help`. As far as possible, every routine sets default values for any arguments that are not specified. In particular, for most test matrix routines `testmat`, `A = testmat(n)` is a valid way to generate an $n \times n$ matrix. In general we have strived for

conciseness, modularity, speed, and minimal use of temporary storage in our MATLAB codes. Hence, where possible, we used matrix or vector constructs instead of `for` loops and have used calls to existing M-files.

Some of those matrices that are banded with a small bandwidth are given the sparse storage format, to allow large matrices to be generated. The `full` function can be used to convert to non-sparse storage (e.g., `A = full(tridiag(32))`). We check for errors in parameters in some, but not all, cases. A few of the test matrix routines do not properly handle the dimension $n = 1$ (for example, they halt with an error, or return an empty matrix). We decided not to add extra code for this case, since the routines are unlikely to be called with $n = 1$.

Tables 5.1 and 5.2 provide a summary of the properties of the test matrices. The column headings have the following meanings:

Inverse: the inverse of the matrix is known explicitly.

Ill-cond: the matrix is ill-conditioned for some values of the parameters.

Rank: the matrix is rank-deficient for some values of the parameters (we exclude "trivial" examples such as `vand`, which is singular if its vector argument contains repeated points). Note that there are some matrices that are mathematically rank-deficient but behave as ill-conditioned full rank matrices in the presence of rounding errors; these are listed only as rank-deficient (for example, `chebspec`).

Symm: the matrix is symmetric for some values of the parameters.

Pos Def: the matrix is symmetric positive definite for some values of the parameters.

Orth: the matrix is orthogonal, or a diagonal scaling of an orthogonal matrix, for some values of the parameters.

Eig: something is known about the eigensystem (or the singular values), ranging from bounds or qualitative knowledge of the eigenvalues to explicit formulas for some or all eigenvalues and eigenvectors.

We summarise further interesting properties possessed by some of the matrices. Recall that A is a *Hankel matrix* if the anti-diagonals are constant ($a_{ij} = r_{i+j}$), *idempotent* if $A^2 = A$, *normal* if $A^*A = AA^*$ (or, equivalently, A is unitarily diagonalizable), *nilpotent* if $A^k = 0$ for some k, *involutary* if $A^2 = I$, *totally positive (nonnegative)* if the determinant of every submatrix is positive (nonnegative), and a *Toeplitz matrix* if the diagonals are constant ($a_{ij} = r_{j-i}$). A totally positive matrix has distinct, real and positive eigenvalues and its ith eigenvector (corresponding to the ith largest eigenvalue) has exactly $i - 1$ sign changes [12, Theorem 13, p. 105]; this property is important in testing regularization algorithms [16], [17]. See [28] for further details of these matrix properties.

defective: `chebspec, gallery, gear, jordbloc, triw`

inverse of a tridiagonal matrix: `kms, lehmer, minij`

triangular: `dramadah, jordbloc, kahan, pascal, triw`

Finally, we note that several of the test matrices are related to those supplied with MATLAB. The functions `hadamard` and `pascal` were in the first release of the toolbox and were subsequently included by The MathWorks in the MATLAB distribution. The toolbox version of `hadamard` is the same as the one in MATLAB 4.2 except for the addition of an H1 line, whereas the toolbox version of `pascal` contains more informative comment lines than the MATLAB 4.2 version and produces a different `pascal(n,2)` matrix[3] (but one that is still a cube root of the identity). The toolbox routine `compan` is more versatile than the MATLAB 4.2 version. Similarly, the toolbox routine `vand` is more versatile than MATLAB 4.2's `vander`. The toolbox version of `hilb` is coded differently and contains more informative comments than the one in MATLAB 4.2. The toolbox routine `augment` is similar to MATLAB 4.2's `spaugment`, but produces a non-sparse matrix instead of a sparse one. The toolbox function `cond` supports the 1, 2, ∞ and Frobenius norms, whereas MATLAB 4.2's `cond` supports only the 2-norm.

6 Visualization

The toolbox contains five routines for visualizing matrices. The routines can give insight into the properties of a matrix that is not easy to obtain by looking at the numerical entries. They also provide an easy way to generate pretty pictures!

The routine `see` displays a figure with four subplots (strictly speaking four "axes", in MATLAB terminology) in the format

`mesh(A)`	`mesh(pinv(A))`
`semilogy(svd(A))`	`fv(A)`

An example for the `chebvand` matrix is given in Figure 6.1. MATLAB's `mesh` command plots a three-dimensional, coloured, wire-frame surface, by regarding the entries of a matrix as specifying heights above a plane. We use `axis('ij')`, so that the coordinate system for the plot matches the (i, j) matrix element numbering. `pinv(A)` is the Moore–Penrose pseudo-inverse A^+ of A, which is the usual inverse when A is square and nonsingular. `semilogy(svd(A))` plots the singular values of A (ordered in decreasing size) on a logarithmic scale; the singular values are denoted by circles, which are joined by a solid line to emphasise the shape of the distribution. From Figure 6.1 we can see that `chebvand(8)` has a 2-norm condition number of about 10^5 and that the largest elements of its inverse are in the lower triangle. For a sparse MATLAB matrix, `see` simply displays a `spy` plot, which shows the sparsity pattern of the matrix. The user could,

[1] `cauchy(x,y)` is totally positive if $0 < x_1 < \cdots < x_n$ and $0 < y_1 < \cdots < y_n$ [39, p. 295].

[2] `vand(p)` is totally positive if the p_i satisfy $0 < p_1 < \cdots < p_n$ [12, p. 99].

[3] The new `pascal(n,2)` is generated by a call to `rot90` and is "reverse upper triangular" instead of "reverse lower triangular" as in the MATLAB 4.2 version.

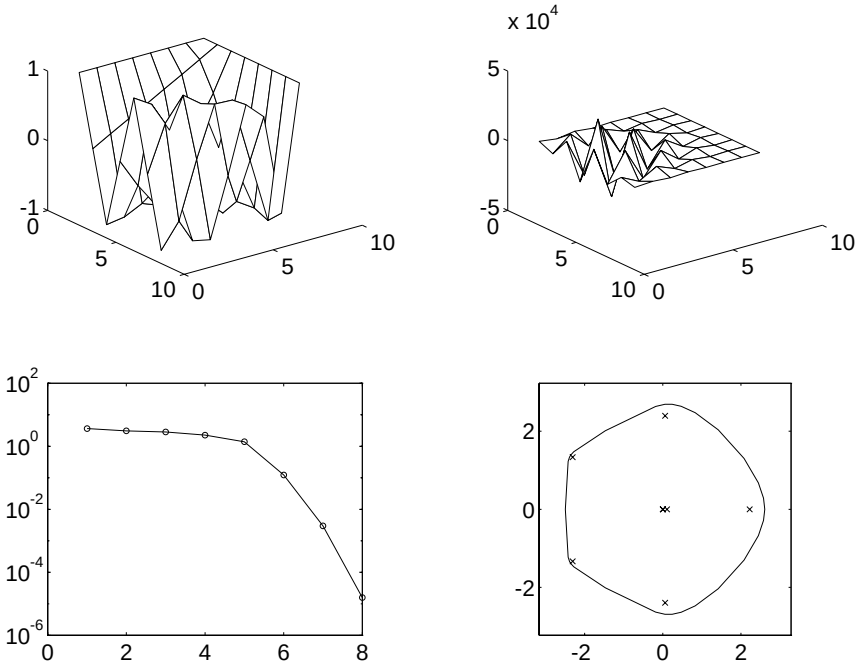

Figure 6.1: `see(chebvand(8))`.

of course, try `see(full(A))` for a sparse matrix, but for large dimensions the storage and time required would be prohibitive. Figure 6.2 displays the result of applying `see` to the Wathen matrix—a symmetric positive definite sparse matrix that comes from a finite element problem.

The routine `fv` plots the field of values of a square matrix $A \in \mathbf{C}^{n\times n}$ (also called the numerical range), which is the set of all Rayleigh quotients,

$$\left\{ \frac{x^*Ax}{x^*x} : 0 \neq x \in \mathbf{C}^n \right\};$$

the eigenvalues of A are plotted as crosses. The field of values is a convex set that contains the eigenvalues. It is the convex hull of the eigenvalues when A is a normal matrix. If A is Hermitian, the field of values is just a segment of the real line. For non-Hermitian A the field of values is usually two-dimensional and its shape and size gives some feel for the behaviour of the matrix. Trefethen [41] notes that the field of values is the largest reasonable answer to the question "Where in $\mathbf{C}$ does a matrix A 'live'?" and the spectrum is the smallest reasonable answer.

Some examples of field of values plots are given in Figure 6.3. The `circul` matrix is normal, hence its field of values is the convex hull of the eigenvalues. For an example of how the field of values gives insight into the problem of finding a nearest normal matrix see [35]. An excellent reference for the theory of the field of values is [29, Chapter 1].

The routine `gersh` plots the Gershgorin disks for an $A \in \mathbf{C}^{n\times n}$, which are the n disks

$$D_i = \{ z \in \mathbf{C} : |z - a_{ii}| \leq \sum_{\substack{j=1 \\ j\neq i}}^{n} |a_{ij}| \}$$

in the complex plane. Gershgorin's theorem tells us that the eigenvalues of A lie in the union of the disks, and an extension of the theorem states that if k disks form a connected region that is isolated from the other disks, then there are precisely k eigenvalues in this region. Thus the size of the disks gives a feel for how nearly diagonal A is, and their locations give information

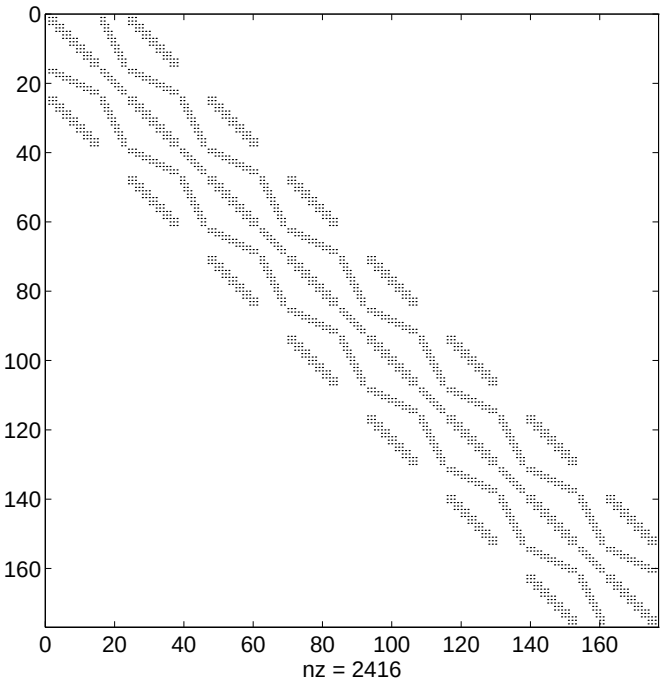

Figure 6.2: `see(wathen(7,7))`.

on where the eigenvalues lie in the complex plane. Four examples of Gershgorin disk plots are given in Figure 6.4; Gershgorin's theorem provides nontrivial information only for the third matrix, `ipjfact(8,1)`.

The last two routines, `ps` and `pscont`, are concerned with pseudospectra. The ϵ-pseudospectrum of a matrix $A \in \mathbf{C}^{n\times n}$ is defined, for a given $\epsilon > 0$, to be the set

$$\Lambda_\epsilon(A) = \{\, z : z \text{ is an eigenvalue of } A + E \text{ for some } E \text{ with } \|E\|_2 \le \epsilon \,\}.$$

In other words, it is the set of all complex numbers that are eigenvalues of $A + E$ for some perturbation E of 2-norm at most ϵ. For a normal matrix A the ϵ-pseudospectrum is the union of the balls of radius ϵ around the eigenvalues of A. For nonnormal matrices the ϵ-pseudospectrum can take a wide variety of shapes and sizes, depending on the matrix and how nonnormal it is. Pseudospectra play an important role in many numerical problems. For full details see the work of Trefethen—in particular, [40] and [41].

The routine `ps` plots an approximation to the ϵ-pseudospectrum $\Lambda_\epsilon(A)$, which it obtains by computing the eigenvalues of a given number of random perturbations of A. The eigenvalues are plotted as crosses and the pseudo-eigenvalues as dots. Arguments to `ps` control the number and type of perturbations. Figure 6.5 gives four examples of 10^{-3}-pseudospectra, all of which involve the pentadiagonal Toeplitz matrix `pentoep`.

Another characterization of $\Lambda_\epsilon(A)$, in terms of the resolvent $(zI - A)^{-1}$, is

$$\Lambda_\epsilon(A) = \{\, z : \|(zI - A)^{-1}\|_2 \ge \epsilon^{-1} \,\}.$$

An alternative way of viewing the pseudospectrum is to plot the function

$$f(z) = \|(zI - A)^{-1}\|_2^{-1} = \sigma_{\min}(zI - A)$$

over the complex plane, where $\sigma_{\min}$ denotes the smallest singular value [41]. The routine `pscont` plots $\log_{10} f(z)^{-1}$ and offers several ways to view the surface: by its contour lines alone, or as

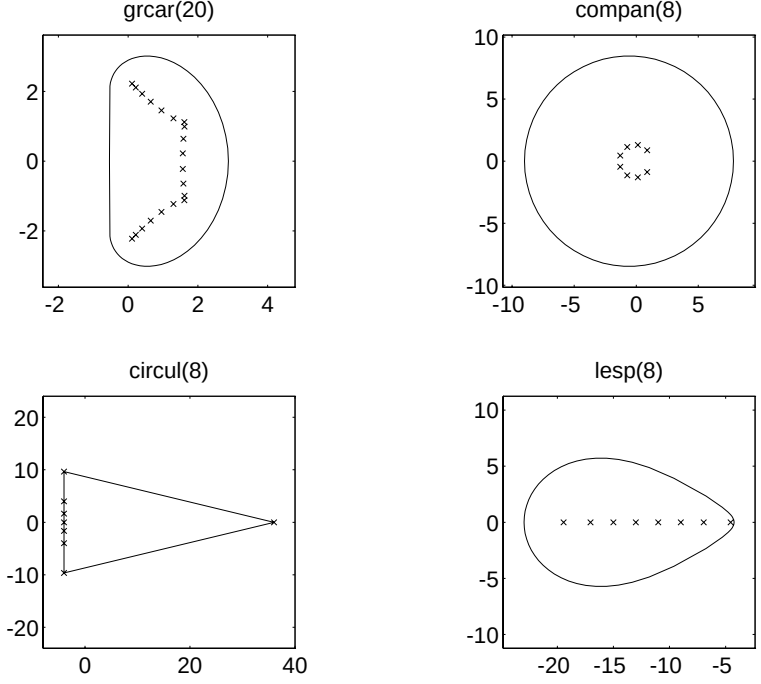

Figure 6.3: Fields of values (`fv`).

a coloured surface plot in two or three dimensions, with or without contour lines. (The two-dimensional plot is the view from directly above the surface.) Two different `pscont` views of the pseudospectra of the triangular matrix `triw(11)` are given in Figures 6.6 and 6.7. Since all the eigenvalues of this matrix are equal to 1, there is a single point where the resolvent is unbounded in norm—this is the "bottomless pit" in the pictures. The spike in Figure 6.7 should be infinitely deep; since `pscont` evaluates $f(z)$ on a finite grid, the spike has a finite depth dependent on the grid spacing. Also because of the grid spacing chosen, the contours are a little jagged. Various aspects of the plots can be changed from the MATLAB command line upon return from `pscont`; for example, the colour map (`colormap`), the shading (`shading`), and the viewing angle (`view`). For Figure 6.6 we set `shading interp` and `colormap copper`.

Both pseudospectrum routines are computationally intensive, so the defaults for the arguments are chosen to produce a result in a reasonable time (under 20 seconds on a SPARC-2 processor or equivalent); for plots that reveal reasonable detail it is usually necessary to override the defaults.

7 Direct Search Optimization

The toolbox contains three multivariate direct search maximization routines `mdsmax`, `adsmax` and `nmsmax`, together with a demonstration function `fdemo` on which to try them. The routines are competitors to `fmins`, which is supplied with MATLAB (but `fmins` minimizes rather than maximizes). `nmsmax` is actually a modified version of `fmins` with the same interface as `mdsmax` and `adsmax`.

`mdsmax`, `adsmax` and `nmsmax` are direct search methods (as is `fmins`), that is, they attempt to maximize a real function f of a vector argument x using function values only. `mdsmax` uses the multidirectional search method, `adsmax` uses the method of alternating directions, and `nmsmax` uses the Nelder–Mead simplex method. In general, `mdsmax` and `nmsmax` can be expected to perform better than `adsmax` since they use a more sophisticated method.

These routines were developed during the work described in [23].

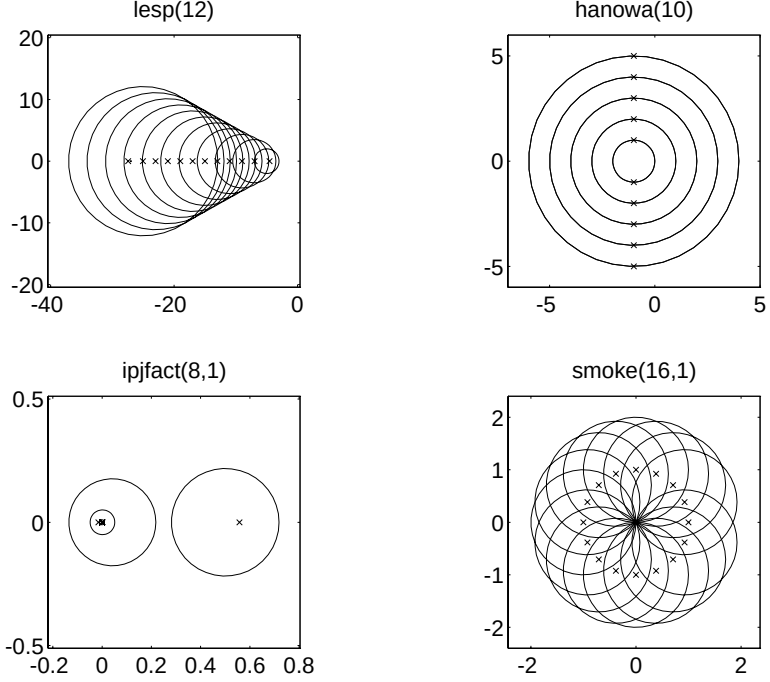

Figure 6.4: Gershgorin disks (`gersh`).

Note: These routines, like `fmins`, are not competitive with more sophisticated methods such as (quasi-)Newton methods when applied to smooth problems. They are at their best when applied to non-smooth problems such as the one in the example below.

The routines are fully documented in their leading comment lines, but it is appropriate to add here a few comments about the format of the output and the use of the `savit` argument.

`mdsmax` produces output to the screen (this can be suppressed by setting the input argument `stopit(5) = 0`). The output is illustrated by

```
Iter. 10,  inner =  2,  size = -4,  nf = 401,  f = 4.7183e+001  (51.0%)
```

The means that on the tenth iteration, two inner iterations were required, and at the end of the iteration the simplex edges were 2^{-4} times the length of those of the initial simplex. Further, `nf` is the total number of function evaluations so far, `f` is the current highest function value, and the percentage increase in function value over the tenth iteration is 51%.

The output produced by `adsmax` is similar to that of `mdsmax` and is illustrated by the following extract from the start of the second outer iteration:

```
Iter  2  (nf = 146)
Comp. =  1,  steps = 12,  f = 1.5607e+000  (0.4%)
```

`Comp` denotes the component of x being varied on the current stage and steps is the number of steps in the crude line search for this stage.

The output from `nmsmax` is also similar to that from `mdsmax`, but only iterations on which an increase in the function value is achieved are reported.

In all three routines, if a non-empty fourth input argument string `savit` is present then at the end of each iteration the following "snapshot" is written to the file specified by `savit`: the largest function value found so far, `fmax`, the point at which it is achieved, `x`, and the total number of function evaluations, `nf`. This option enables the user to abort an optimization, load and examine `x`, `fmax` and nf using MATLAB's `load` command, and then possibly restart the optimization at `x`.

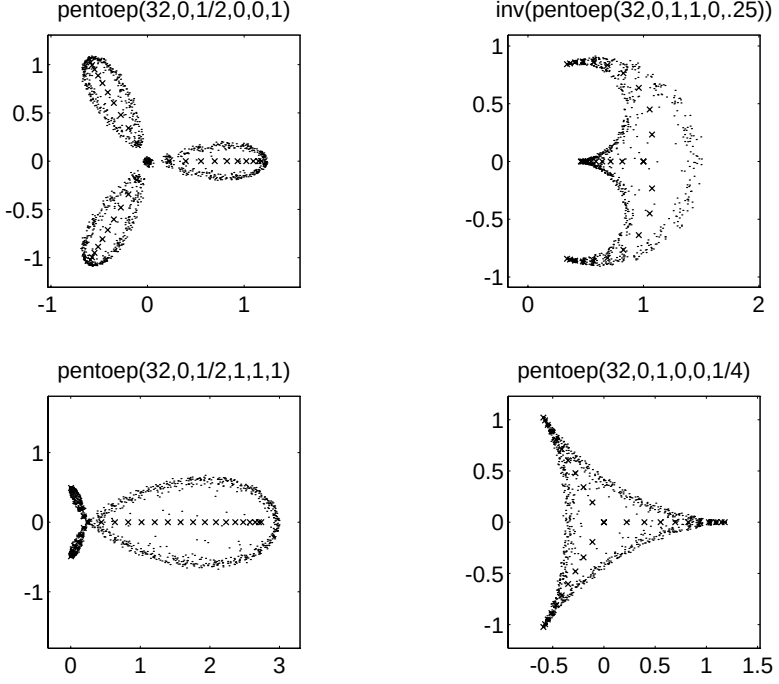

Figure 6.5: Pseudospectra (`ps`).

One further point worth mentioning is that `mdsmax`, `adsmax` and `nmsmax` always call the function `f` to be maximized with an argument of the same dimensions (or shape) as the starting value `x0`. Similarly, the output argument `x` and the variable `x` in `savit` saves have the same shape as `x0`. This feature is very convenient when `f` is a function of a matrix, as in the example below.

To facilitate a quick test of the routines the toolbox includes a function `fdemo`, which takes a square matrix argument `A` and evaluates the ratio of `rcond(A)` to the exact 1-norm condition number of the matrix `A`. (`rcond` is MATLAB's built-in condition estimator.) Making `fdemo` large corresponds to finding a matrix where `rcond` returns a poor condition number estimate.

Here is an extract from output produced by MATLAB 4.2b on a 486DX PC; similar output should be obtained on other machines (a machine that uses IEEE arithmetic will probably produce identical results). In this example MDSMAX rapidly achieves a function value of over 100, but ADSMAX and NMSMAX make only slow progress and terminate when the default convergence tests are satisfied.

```
>> A = hilb(5);  % Starting matrix.
>> B = mdsmax('fdemo', A);

f(x0) = 1.3596e+000
Iter.  1,  inner =  0,  size =  0,  nf =  26,  f = 1.3648e+000  (0.4%)
Iter.  2,  inner =  1,  size =  1,  nf =  76,  f = 1.4493e+000  (6.2%)
Iter.  3,  inner =  1,  size =  1,  nf = 126,  f = 1.4954e+000  (3.2%)
Iter.  4,  inner =  1,  size =  2,  nf = 176,  f = 1.5935e+000  (6.6%)
Iter.  5,  inner =  1,  size =  2,  nf = 226,  f = 1.7589e+000  (10.4%)
Iter.  6,  inner =  1,  size =  2,  nf = 276,  f = 3.7883e+000  (115.4%)
Iter.  7,  inner =  1,  size =  3,  nf = 326,  f = 3.1601e+001  (734.2%)
Iter.  8,  inner =  1,  size =  4,  nf = 376,  f = 5.3514e+001  (69.3%)
Iter.  9,  inner =  2,  size =  3,  nf = 476,  f = 5.3888e+001  (0.7%)
```

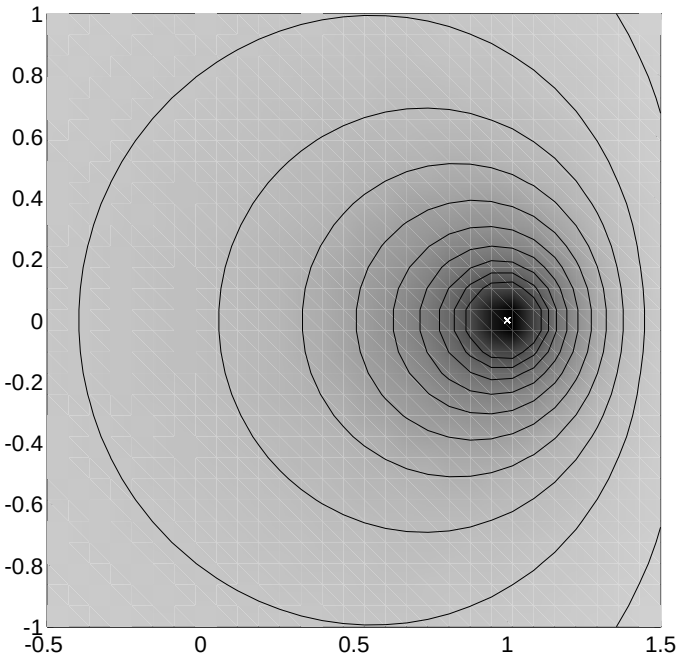

Figure 6.6: `pscont(triw(11), 0, 30, [-0.5 1.5 -1 1])`.

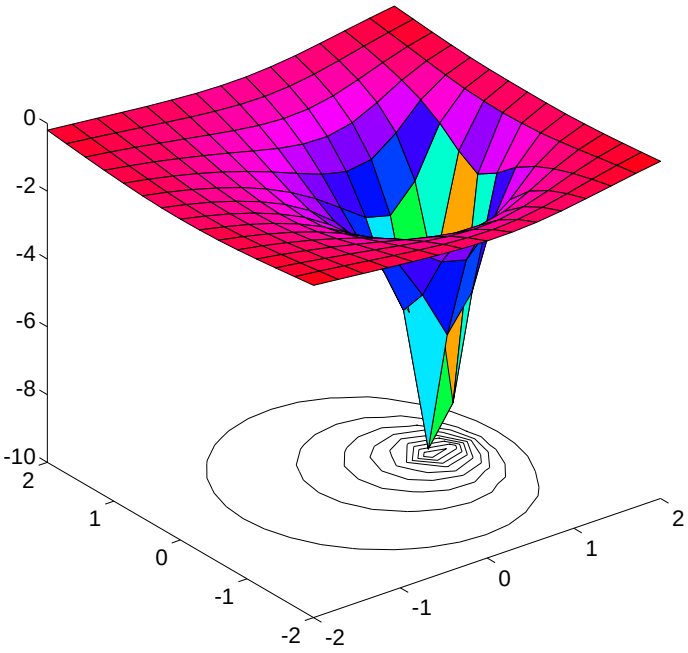

Figure 6.7: `pscont(triw(11), 2, 15, [-2 2 -2 2])`.

```
Iter. 10,  inner =  1,  size =  3,  nf = 526,  f = 9.9432e+001  (84.5%)

8 Miscellaneous Routines

In addition to the test matrices and visualization routines, the Test Matrix Toolbox provides several routines that can be used to manipulate matrices or compute matrix functions or decompositions.

The decomposition functions offered are as follows.

• `cgs` and `mgs` apply the classical and modified Gram–Schmidt methods, respectively, to a matrix $A \in \mathbf{C}^{m\times n}$ of full rank n, to produce the factorization $A = QR$, where $Q \in \mathbf{C}^{m\times n}$ has orthonormal columns and $R \in \mathbf{C}^{n\times n}$ is upper triangular. The methods are identical in exact arithmetic but produce different results in the presence of rounding errors [26].

• `cholp` computes the Cholesky factorization with pivoting $\Pi^T A \Pi = R^* R$ of a Hermitian positive semi-definite matrix $A \in \mathbf{C}^{n\times n}$. Here, R is upper triangular with nonnegative diagonal elements and Π is a permutation matrix chosen to permute the largest diagonal element to the pivot position at each stage of the reduction (see [14, Section 4.2.9]). For the usual Cholesky factorization, as computed by `chol`, Π is the identity. Whereas `chol` can break down when presented with a Hermitian positive semi-definite matrix that is singular, `cholp` will always succeed.

• `cod` computes the complete orthogonal decomposition of a rank r matrix $A \in \mathbf{C}^{m\times n}$,

$$A = U \begin{bmatrix} R & 0 \\ 0 & 0 \end{bmatrix} V,$$

where $R \in \mathbf{C}^{r\times r}$ is upper triangular and $U \in \mathbf{C}^{m\times m}$ and $V \in \mathbf{C}^{n\times n}$ are unitary. The criterion used to define the numerical rank is a simple one based on the diagonal elements of the upper triangular matrix from the QR factorization with column pivoting. The complete orthogonal decomposition is an important tool in rank-deficient least squares problems [14, Sec. 5.5.2], [37].

• `diagpiv` implements the diagonal pivoting factorization with partial pivoting of a symmetric matrix A. It produces the factorization $PAP^T = LDL^T$, where P is a permutation, L is unit lower triangular, and D is block diagonal with 1×1 and 2×2 diagonal blocks. The Bunch–Kaufman partial pivoting strategy is used [4].

• `ge` implements Gaussian elimination without pivoting. This routine is similar to `lu`, except that no row interchanges are done. Thus the routine computes, if possible, the LU factorization

$A = LU$ of $A \in \mathbf{C}^{n\times n}$. The routine is of pedagogical interest, but also of practical interest because there are certain classes of $Ax = b$ problem where a more accurate solution is obtained from LU factorization when there are no row or column interchanges [20], [26].

• `gecp` implements Gaussian elimination with complete pivoting. Thus it computes the factorization $PAQ = LU$ of $A \in \mathbf{C}^{n\times n}$, where P and Q are permutation matrices and L and U are lower and upper triangular, respectively. At the kth stage of the reduction of A to triangular form, row and column interchanges are used to bring the element of largest absolute value in the active submatrix to the pivot position (k,k) [14, Sec. 3.4.8].

• `gj` implements Gauss–Jordan elimination for solving a nonsingular linear system $Ax = b$.

• `poldec` computes the polar decomposition $A = UH \in \mathbf{C}^{m\times n}$, where $H \in \mathbf{C}^{n\times n}$ is Hermitian positive semi-definite and $U \in \mathbf{C}^{m\times n}$ has orthonormal columns or rows, according as $m \geq n$ or $m \leq n$. The polar decomposition is a generalization of the polar representation $z = re^{i\theta}$ for complex numbers. The factor U has the property that when $m \geq n$ it is the nearest matrix with orthonormal columns to A for both the 2-norm and the Frobenius norm:

$$\|A - U\| = \min\{\, \|A - Q\| : Q^*Q = I,\ Q \in \mathbf{C}^{m\times n} \,\}.$$

For more details see [18] or [28].

• `signm` computes the matrix sign decomposition $A = SN \in \mathbf{C}^{n\times n}$, where $S = \mathrm{sign}(A)$ is the matrix sign function [25]. If A has the Jordan canonical form

$$A = XJX^{-1} = X \begin{bmatrix} J_1 & 0 \\ 0 & J_2 \end{bmatrix} X^{-1},$$

where the eigenvalues of J_1 lie in the open left half-plane and those of J_2 lie in the open right half-plane, then

$$\mathrm{sign}(A) = X \begin{bmatrix} -I & 0 \\ 0 & I \end{bmatrix} X^{-1}.$$

(The sign function is not defined if A has any pure imaginary eigenvalues). The matrix sign function has several applications and is the subject of much recent research; see [25] for details and further references. Since $\mathrm{sign}(A)^2 = I$, `signm` provides one way to generate involutary matrices.

The toolbox contains further miscellaneous routines, including the following ones.

`bandred`: bandwidth reduction by unitary transformation (called by `randsvd`).

`comp`: forms comparison matrices.

`cond`: generalizes the `cond` function supplied with MATLAB 4.0 to work with the 1, ∞ and Frobenius norms (for square matrices) as well as the 2-norm.

`qmult`: Premultiplies a matrix by a random real orthogonal matrix from the Haar distribution (called by `randsvd`).

`seqa`, `seqm`: form additive or multiplicative sequences.

`sparsify`: randomly sets elements of a matrix to zero.

`pnorm`: estimates the p-norm of a matrix for $1 \leq p \leq \infty$ (MATLAB's `norm` works only for $p = 1, 2, \infty$, `'fro'`).

`eigsens`: evaluates the Wilkinson condition numbers for the eigenvalues of a matrix.

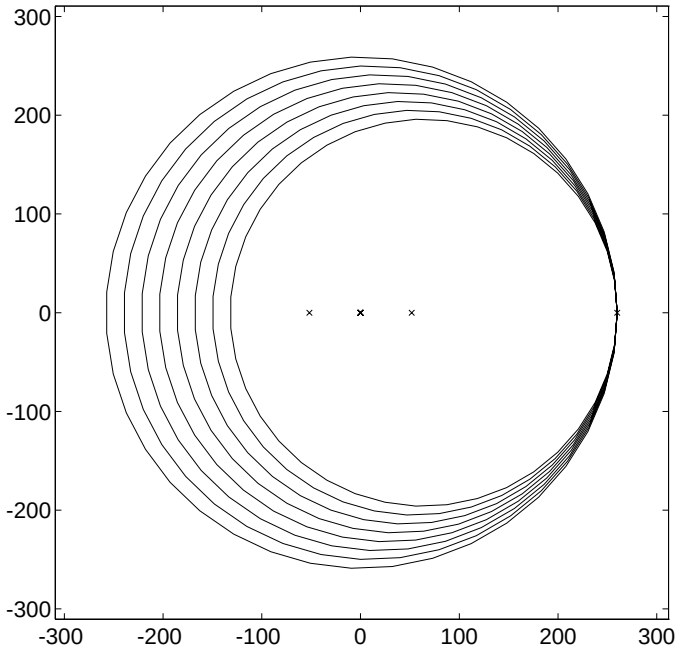

Figure 9.1: Gershgorin disks for `magic(8)`.

9 Examples

In this section we give examples of the use of the toolbox and explain some of the interesting properties of magic squares and the Frank matrix.

9.1 Magic Squares

In the winter 1993 MathWorks Newsletter, Moler described some of the fascinating properties of magic squares, as embodied in MATLAB's `magic` function [32]. Some further properties can be illustrated with the aid of the toolbox. Recall that a magic square is an $n \times n$ matrix containing the integers from 1 to n^2 whose row and column sums are all the same. Let μ_n denote the magic sum of `magic(n)` (thus, $\mu_n = n(n^2+1)/2$).

Moler pointed out that the largest singular value of `A = magic(n)` (namely `max(svd(A))`) is μ_n, but left the proof as an exercise. The largest singular value of A is its 2-norm, so the problem is to prove that $\|A\|_2 = \mu_n$. This leads naturally to the question of what is the p-norm of a magic square, for any p between 1 and ∞. The Hölder p-norm of an $m \times n$ matrix A is defined by

$$\|A\|_p = \max_{x \neq 0} \frac{\|Ax\|_p}{\|x\|_p}, \tag{9.1}$$

where $p \geq 1$ and $\|x\|_p = (\sum_{i=1}^{n} |x_i|^p)^{1/p}$. We can investigate the p-norm of a magic square using the toolbox function `pnorm`, which computes an *estimate* of $\|A\|_p$ using a generalization of the power method.

```
for p = [1 1.5 2 exp(1) pi 10 inf]
    fprintf(' %9.4f    %9.4f\n', p, pnorm(magic(10),p))
end
    1.0000     505.0000
    1.5000     504.9968
    2.0000     504.9968
```

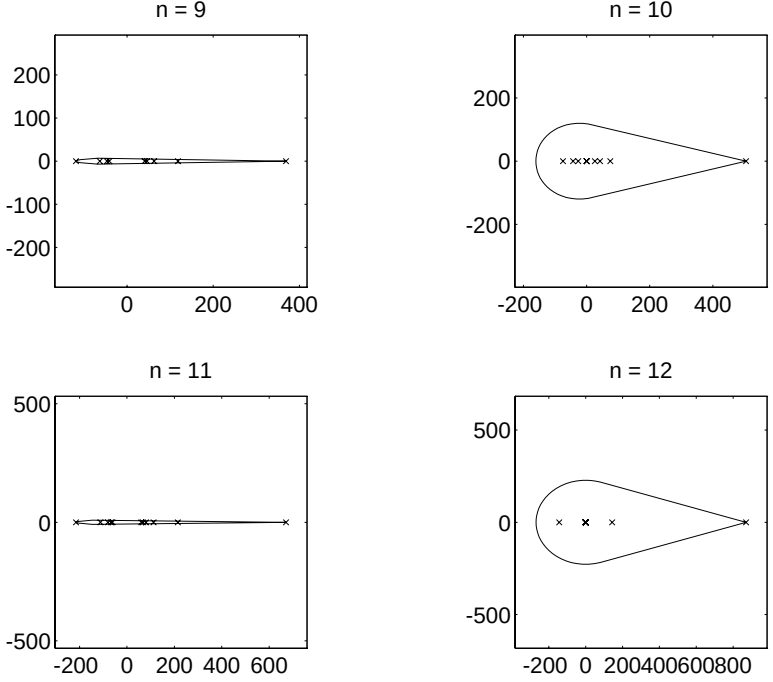

Figure 9.2: Field of values for `magic(n)`.

```
    2.7183      504.9971
    3.1416      504.9997
   10.0000      504.9988
       Inf      505.0000
```

All the p-norms in this example are very close to $\mu_{10} = 505$. Since the default convergence tolerance for `pnorm` is 10^{-4}, the exact p-norms could all be 505, as far as we can tell from the estimates. In fact, $\|A\|_p \equiv \mu_n$ for all $1 \leq p \leq \infty$. The proof relies on the convexity of the p-norm, which yields the inequality (see, [22], for example)

$$\|A\|_p \leq \|A\|_1^{1/p} \|A\|_\infty^{1-1/p}.$$

(This inequality is well-known for $p = 2$.) For a magic square, $\|A\|_1 = \|A\|_\infty = \mu_n$, so the inequality gives $\|A\|_p \leq \mu_n$. But by taking x in (9.1) to be the vector of all ones, we see that $\|A\|_p \geq \mu_n$, and so it follows that $\|A\|_p = \mu_n$. This result is actually a special case of an apparently little-known 1962 result of Stoer and Witzgall, which says that the norm of a doubly stochastic matrix is 1 for any norm subordinate to a permutation-invariant absolute vector norm [38].

To estimate the eigenvalues of `magic(n)` we can apply Gershgorin's theorem. Unfortunately, the results are not very informative because the Gershgorin disks are all approximately the same, as is clear from the structure of the matrix; see Figure 9.1.

In his article, Moler pointed out that the function `magic` uses different algorithms for odd n, even n divisible by 4, and even n not divisible by 4. He gave four `mesh` plots to illustrate the difference. Another approach is to look at the fields of values—see Figure 9.2. The plot for $n = 10$ reflects the fact that `magic(n)` has rank $n/2 + 2$ when n is even and not divisible by 4—there are only 6 eigenvalues away from the origin (`magic(10)` is diagonalizable). For n divisible by 4 the rank is only 3.

9.2 The Frank Matrix

A famous test matrix for eigensolvers is the $n \times n$ upper Hessenberg matrix F_n introduced by Frank in 1958 [11], illustrated for $n = 8$ by

```
F = frank(8)

F =

     8     7     6     5     4     3     2     1
     7     7     6     5     4     3     2     1
     0     6     6     5     4     3     2     1
     0     0     5     5     4     3     2     1
     0     0     0     4     4     3     2     1
     0     0     0     0     3     3     2     1
     0     0     0     0     0     2     2     1
     0     0     0     0     0     0     1     1
```

In evaluating three eigenvalue algorithms Frank found that this matrix "gives our selected procedures difficulties", and that "accuracy was lost in the smaller roots". The difficulties encountered by Frank's codes were shown by Wilkinson [44, Section 8], [45, pp. 92–93] to be caused by the inherent sensitivity of the eigenvalues to perturbations in the matrix.

The Frank matrix is interesting to analyze using MATLAB. The toolbox function `eigsens` evaluates the Wilkinson eigenvalue condition numbers, which are the reciprocals of the cosines of the angles between the left and right eigenvectors:

```
F = frank(10);
[V, D, s] = eigsens(F); d = diag(D); [x, k] = sort(d);
[d(k) s(k)]  % Eigenvalue followed by its condition number.
ans =

  3.9100e-002  1.4082e+005
  6.7743e-002  2.5897e+005
  1.2426e-001  1.4103e+005
  2.5692e-001  2.4028e+004
  6.1859e-001  1.1837e+003
  1.6166e+000  3.1920e+001
  3.8922e+000  2.2871e+000
  8.0476e+000  1.8287e+000
  1.4762e+001  3.0303e+000
  2.5575e+001  2.3393e+000
```

The output shows that the condition numbers grow, almost monotonically, as the eigenvalues decrease in size—in other words, the smallest eigenvalues are the most sensitive to perturbations in the matrix. The varying eigenvalue sensitivities can also be seen from pseudospectral plots. Figure 9.3 shows the 0.1-pseudospectrum, which shows that perturbations to F_{10} of 2-norm at most 0.1 have the greatest effect on the smallest eigenvalues. Another view is provided by Figure 9.4, for which we set `colormap hot`.

Further insight into the eigenvalues of F_n can be obtained by looking at its characteristic polynomial:

```
poly(F)
```

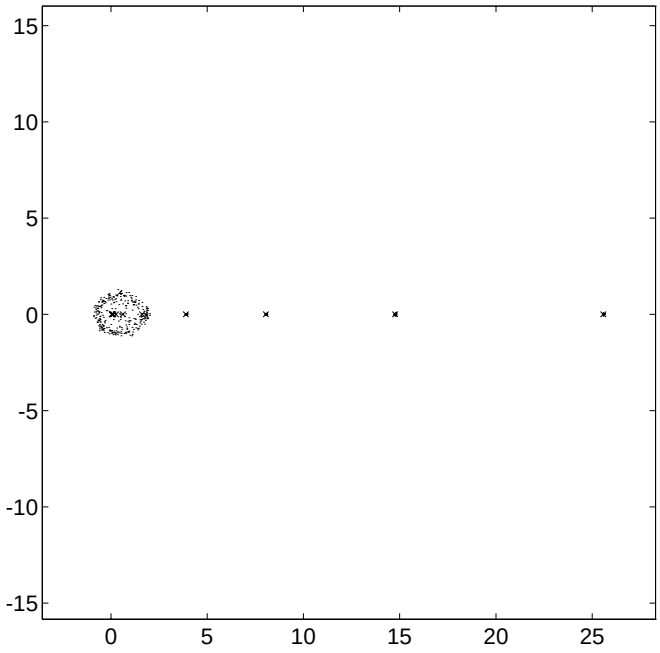

Figure 9.3: `ps(frank(10), 50, 1e-1, 0, 1)`.

```
ans =

  1.0e+004 *

  Columns 1 through 7

    0.0001   -0.0055    0.1035   -0.8310    2.9505   -4.5297    2.9505

  Columns 8 through 11

   -0.8310    0.1035   -0.0055    0.0001
```

The coefficients seem to be palindromic! As a check we use the function `charpoly` from MATLAB 4's Maple Symbolic Toolbox [5] to compute the characteristic polynomial exactly:

```
charpoly(F)

ans =

1-55*x+1035*x^2-8310*x^3+29505*x^4-45297*x^5+29505*x^6-8310*x^7+1035*x^8-55*x^9+x^10
```

Any matrix whose characteristic polynomial π_n has a palindromic coefficient vector has eigenvalues occurring in reciprocal pairs, since $\pi_n(\lambda) = \lambda^n \pi_n(1/\lambda)$. In particular, it has determinant 1, and 1 is an eigenvalue when n is odd. We can check the determinant property numerically:

```
F = frank(20); [det(F) det(F')]

ans =
```

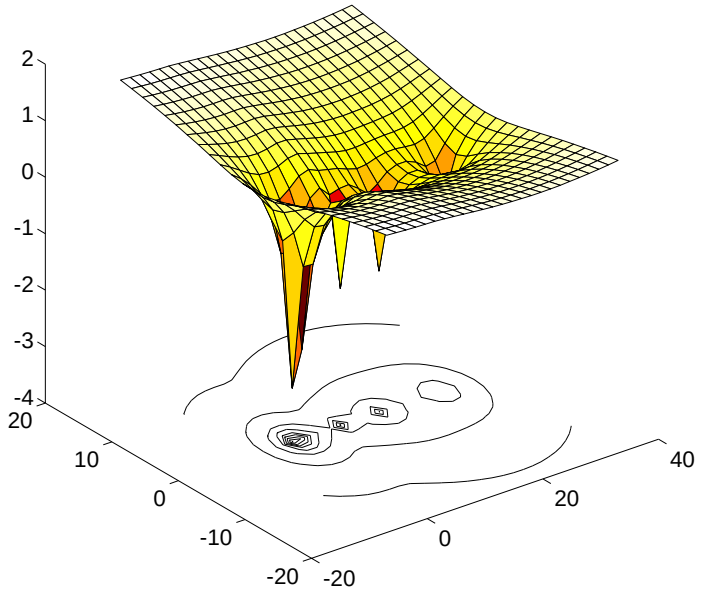

Figure 9.4: `pscont(frank(10), 2, 25, [-7 33 -20 20])`.

```
     1   -14

F = frank(25); [det(F) det(F')]

ans =

            1   -48886168
```

Since $\det(A) = \det(A^T)$ for any matrix A, the output is mathematically incorrect. The reason is that rounding errors influence MATLAB's evaluation of $\det(F_n^T)$ much more than its evaluation of $\det(F_n)$; an illuminating discussion of this phenomenon is given by Frank [11] and Wilkinson [44, Section 8], [45, pp. 92–93]. The extreme sensitivity of $\det(F_n)$ to perturbations in F_n is easy to see: if we change the $(1,n)$ element from 1 to $1+\epsilon$, then $\det(F_n)$ changes from 1 to $1 + (-1)^n(n-1)!\epsilon$.

The inverse of F_n is lower Hessenberg. This can be seen using the following representation of F_n noted by Rutishauser [36, Sec. 9]:

$$F_n = PC_nP,$$

where P is the identity with the order of its columns reversed (`I = eye(n); P = I(:, n:-1:1)` in MATLAB notation) and

$$C_n = \begin{bmatrix} 1 & & & & \\ -1 & 1 & & & \\ & -1 & 1 & & \\ & & \ddots & \ddots & \\ & & & -1 & 1 \end{bmatrix}^{-1} \begin{bmatrix} 1 & 1 & & & \\ & 1 & 2 & & \\ & & 1 & \ddots & \\ & & & \ddots & n-1 \\ & & & & 1 \end{bmatrix}.$$

(By manipulating the identity $\det(F_n - \lambda I) = \det(C_n - \lambda I)$ the reciprocal pair property of the eigenvalues can be proved; cf. [42].) As an illustration, here is the exact inverse as returned

by the Maple Symbolic Toolbox (the MATLAB function `inv` produces nonzero, but tiny, upper triangular elements because of rounding errors):

```
inverse(frank(8))

ans =

[    1,    -1,    0,    0,   0,  0,  0,  0]
[   -7,     8,   -1,    0,   0,  0,  0,  0]
[   42,   -48,    7,   -1,   0,  0,  0,  0]
[ -210,   240,  -35,    6,  -1,  0,  0,  0]

In his 1958 paper, Frank commented

> "At the moment, the largest matrices resolved on the [Univac] 1103A are two 20-order matrices, one real symmetric and one complex. In both cases computing time was approximately one hour, and 6–8 places of accuracy were obtained."

The complete eigensystem of a complex 20×20 matrix A is found in under a second by the MATLAB command `eig(A)` on the workstation used for the examples reported here! This improvement over Frank's timing is attributable not only to hardware advances but also to an algorithmic breakthrough: `eig` uses the QR algorithm, which was not available to Frank.

9.3 Numerical Linear Algebra

The Test Matrix Toolbox M-files embody some well-known and other not so well-known results from numerical linear algebra.

The function `gfpp` generates $n \times n$ matrices that produce the maximum growth of 2^{n-1} for Gaussian elimination with partial pivoting; these include Wilkinson's classic example [45, p. 212]

```
gfpp(7)

ans =

     1     0     0     0     0     0     1
    -1     1     0     0     0     0     1
    -1    -1     1     0     0     0     1
    -1    -1    -1     1     0     0     1
    -1    -1    -1    -1     1     0     1
    -1    -1    -1    -1    -1     1     1
    -1    -1    -1    -1    -1    -1     1
```

as well as all members of the "2^{n-1} class" described by Higham and Higham [27]. The following extract uses the toolbox routine `gecp` to evaluate the growth factor for complete pivoting on the Wilkinson matrix.

```
n = 20; A = gfpp(n);
[L, U] = lu(A);    % Partial pivoting.
[max(max(abs(U))) / max(max(abs(A)))  2^(n-1)] % Approximation to growth factor.

ans =

      524288      524288

% Complete pivoting using toolbox routine GECP.
[L, U, P, Q, rho] = gecp(A); rho

rho =

     2
```

As the output shows, complete pivoting is perfectly stable for these matrices. However, several of the matrices produced by `orthog` yield relatively large growth for complete pivoting: growth of order $n/2$ for real data, or n for a particular complex matrix [27].

```
n = 50;
for k = [-2 -1 1 2 3]
    A = orthog(n, k);
    [L, U, P, Q, rho] = gecp(A);
    fprintf(' %g\n', rho)
end
 25.3116
 24.7028
 25.6214
 25.3296
 50

A = hadamard(64);
[L, U, P, Q, rho] = gecp(A); rho

rho =

    64
```

It is easy to show that complete pivoting suffers growth of at least n for an $n \times n$ Hadamard matrix. However, Hadamard matrices do not exist for all n.

The MATLAB function `rcond` computes an upper bound for $\kappa_1(A)^{-1} = (\|A\|_1\|A^{-1}\|_1)^{-1}$ using the LINPACK condition estimation algorithm. Although this algorithm is very reliable in general, parametrized matrices are known for which it can perform arbitrarily badly [6]. Here are two examples, from the toolbox routine `condex`. The underestimation ratio is approximately the same in both examples, but the second is probably the more serious because `rcond` does not detect any ill-conditioning whatsoever.

```
A = condex(4, 1, 1e8);  format short e
% True         estimate     true/estimate
[cond(A,1)  1/rcond(A)  cond(A,1)*rcond(A)]

ans =
```

```
  8.0000e+016   5.6000e+008   1.4286e+008

A = condex(3, 2, 1e8);
[cond(A,1)   1/rcond(A)   cond(A,1)*rcond(A)]

ans =

  6.0000e+008   7.5000e+000   8.0000e+007
```

The QR decomposition with column pivoting of $A \in \mathbf{C}^{m\times n}$ $(m \geq n)$ is a decomposition $A\Pi = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$ where Π is a permutation matrix chosen according to a certain pivoting strategy, Q is orthogonal, and R is upper triangular [14, Section 5.4.1]. This decomposition is often used to estimate the rank of A; in particular, $|r_{nn}|$ provides an upper bound for the smallest singular value $\sigma_{\min}(A)$ of A that is usually at most a factor of 10 too big. Kahan [30] designed a matrix for which $|r_{nn}|$ can be approximately 2^{n-1} times bigger than $\sigma_{\min}(A)$, and which thus shows the fallibility of the QR decomposition with column pivoting for revealing rank. The toolbox function `kahan` generates Kahan's matrix:

```
n = 25;
A = kahan(n, 0.6);
[Q, R, Pi] = qr(A);
norm(Pi-eye(n),1), R(n,n)/min(svd(A))

ans =

     0

ans =

  1.0638e+006
```

Kahan's matrix $A(\theta)$ is upper triangular and is designed so that Π is the identity in the QR decomposition with column pivoting. In practice, rounding errors can cause Π to differ from the identity for the Kahan matrix, thus nullifying the example (the test on $\Pi - I$ in the above example confirms that Π is indeed the identity here). The toolbox routine adds a small perturbation to the diagonal elements of $A(\theta)$ so that $\Pi = I$ for a range of choices of n and θ. If we set the perturbation in the above example to zero, this is what happens:

```
A = kahan(n, 0.6, 0);  % Third parameter is the diagonal perturbation.
[Q, R, Pi] = qr(A);
norm(Pi-eye(n),1), R(n,n)/min(svd(A))

ans =

     2

ans =

    1.1953
```

The toolbox contains two matrices, one a Toeplitz matrix and the other a Hankel matrix, whose eigenvalues or singular values are related to π:

```
A = parter(10); format long
e = svd(A); [e  e-pi]

ans =

   3.14159265358968  -0.00000000000011

```

Finally, here is an example of the use of the function `matrix` to access the test matrices sequentially, by number. The following piece of code steps through all the square matrices of arbitrary dimension, setting A to each 10×10 matrix in turn (any matrix parameters are at their default values). It evaluates the 2-norm condition number and the ratio $\mu(A) = \max_i |\lambda_i(A)| / \min_i |\lambda_i(A)|$ of the largest to smallest eigenvalue in absolute value.

```
c = []; e = [];
j = 1;
for i=1:matrix(0)
    A = full(matrix(i, 10));
    if norm(skewpart(A),1)  % If not Hermitian...
       c1 = cond(A);
       eg = eig(A);
       e1 = max(abs(eg)) / min(abs(eg));
       % Filter out extremely ill-conditioned matrices.
```

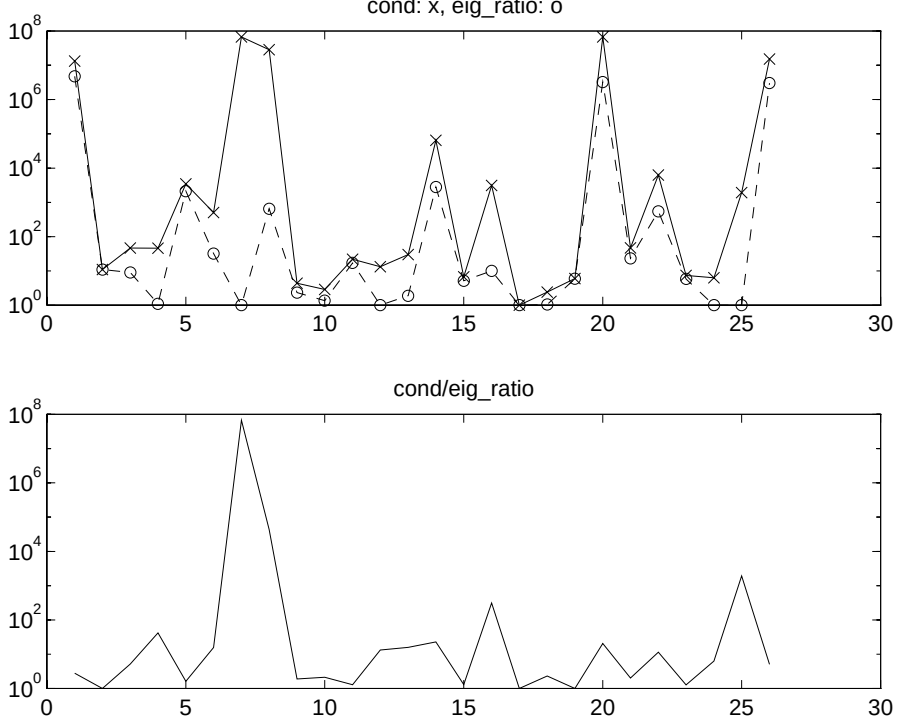

Figure 9.5: Comparison of condition number with extremal eigenvalue ratio.

```
        if c1 <= 1e10, c(j) = c1; e(j) = e1; j = j + 1; end
    end
end
```

As is well known, $\kappa_2(A)$ can be arbitrarily larger than $\mu(A)$. The plots in Figure 9.5, produced from the vectors `c` and `e` from the above code, confirm that $\kappa_2(A)/\mu(A)$ can be large.

10 M-File Leading Comment Lines

The demonstration file `tmtdemo` is not listed here.

```
function [x, fmax, nf] = adsmax(f, x, stopit, savit, P)
%ADSMAX  Alternating directions direct search method.
%        [x, fmax, nf] = ADSMAX(f, x0, STOPIT, SAVIT, P) attempts to
%        maximize the function specified by the string f, using the starting
%        vector x0.  The alternating directions direct search method is used.
%        Output arguments:
%               x    = vector yielding largest function value found,
%               fmax = function value at x,
%               nf   = number of function evaluations.
%        The iteration is terminated when either
%               - the relative increase in function value between successive
%                 iterations is <= STOPIT(1) (default 1e-3),
%               - STOPIT(2) function evaluations have been performed
%                 (default inf, i.e., no limit), or
%               - a function value equals or exceeds STOPIT(3)
%                 (default inf, i.e., no test on function values).
%        Progress of the iteration is not shown if STOPIT(5) = 0 (default 1).
%        If a non-empty fourth parameter string SAVIT is present, then
%        'SAVE SAVIT x fmax nf' is executed after each inner iteration.
%        By default, the search directions are the co-ordinate directions.
%        The columns of a fifth parameter matrix P specify alternative search
%        directions (P = EYE is the default).
%        NB: x0 can be a matrix.  In the output argument, in SAVIT saves,
%            and in function calls, x has the same shape as x0.

%          companion form systems, Math. Control Signals Systems, 1 (1988),
%          pp. 239-256. (Gives explicit formulas for the singular values of
%          COMPAN(P).)
```

```
function y = cond(A, p)
%COND   Matrix condition number in 1, 2, Frobenius, or infinity norm.
%       For p = 1, 2, 'fro', inf,  COND(A,p) = NORM(A,p) * NORM(INV(A),p).
%       If p is omitted then p = 2 is used.
%       A may be a rectangular matrix if p = 2; in this case COND(A)
%       is the ratio of the largest singular value of A to the smallest
%       (and hence is infinite if A is rank deficient).
```

```
function A = condex(n, k, theta)
%CONDEX   'Counterexamples' to matrix condition number estimators.
%         CONDEX(N, K, THETA) is a 'counterexample' matrix to a condition
%         estimator.  It has order N and scalar parameter THETA (default 100).
%         If N is not equal to the 'natural' size of the matrix then
%         the matrix is padded out with an identity matrix to order N.
%         The matrix, its natural size, and the estimator to which it applies
%         are specified by K (default K = 4) as follows:
%             K = 1:   4-by-4,     LINPACK (RCOND)
%             K = 2:   3-by-3,     LINPACK (RCOND)
%             K = 3:   arbitrary,  LINPACK (RCOND) (independent of THETA)
%             K = 4:   N >= 4,     SONEST (Higham 1988)
%         (Note that in practice the K = 4 matrix is not usually a
%          counterexample because of the rounding errors in forming it.)

```

```
function x = cpltaxes(z)
%CPLTAXES   Determine suitable AXIS for plot of complex vector.
%           X = CPLTAXES(Z), where Z is a complex vector,
%           determines a 4-vector X such that AXIS(X) sets axes for a plot
%           of Z that has axes of equal length and leaves a reasonable amount
%           of space around the edge of the plot.

%           Called by FV, GERSH, PS and PSCONT.
```

```
function A = cycol(n, k)
%CYCOL   Matrix whose columns repeat cyclically.
%        A = CYCOL([M N], K) is an M-by-N matrix of the form A = B(1:M,1:N)
%        where B = [C C C...] and C = RANDN(M, K).  Thus A's columns repeat
%        cyclically, and A has rank at most K.   K need not divide N.
%        K defaults to ROUND(N/4).
%        CYCOL(N, K), where N is a scalar, is the same as CYCOL([N N], K).
%
%        This type of matrix can lead to underflow problems for Gaussian
%        elimination: see NA Digest Volume 89, Issue 3 (January 22, 1989).
```

```
function [L, D, P, rho] = diagpiv(A)
%DIAGPIV     Diagonal pivoting factorization with partial pivoting.
%            Given a symmetric matrix A,
%            [L, D, P, rho] = diagpiv(A) computes a permutation P,
%            a unit lower triangular L, and a block diagonal D
%            with 1x1 and 2x2 diagonal blocks, such that
%            P*A*P' = L*D*L'.
%            The Bunch-Kaufman partial pivoting strategy is used.
%            Rho is the growth factor.

```

```
function [c, d, e] = dorr(n, theta)
%DORR  Dorr matrix - diagonally dominant, ill conditioned, tridiagonal.
%      [C, D, E] = DORR(N, THETA) returns the vectors defining a row diagonally
%      dominant, tridiagonal M-matrix that is ill conditioned for small
%      values of the parameter THETA >= 0.
%      If only one output parameter is supplied then
%      C = FULL(TRIDIAG(C,D,E)), i.e., the matrix iself is returned.
%      The columns of INV(C) vary greatly in norm.  THETA defaults to 0.01.
%      The amount of diagonal dominance is given by (ignoring rounding errors):
%            COMP(C)*ONES(N,1) = THETA*(N+1)^2 * [1 0 0 ... 0 1]'.

%      Reference:
%      F.W. Dorr, An example of ill-conditioning in the numerical
%      solution of singular perturbation problems, Math. Comp., 25 (1971),
%      pp. 271-283.
```

```
function A = dramadah(n, k)
%DRAMADAH  A (0,1) matrix whose inverse has large integer entries.
%          An anti-Hadamard matrix A is a matrix with elements 0 or 1 for
%          which MU(A) := NORM(INV(A),'FRO') is maximal.
%          A = DRAMADAH(N, K) is an N-by-N (0,1) matrix for which MU(A) is
%          relatively large, although not necessarily maximal.
%          Available types (the default is K = 1):
%          K = 1: A is Toeplitz, with ABS(DET(A)) = 1, and MU(A) > c(1.75)^N,
%                 where c is a constant.
%          K = 2: A is upper triangular and Toeplitz.
%          The inverses of both types have integer entries.
%
%          Another interesting (0,1) matrix:
%          K = 3: A has maximal determinant among (0,1) lower Hessenberg
%          matrices: det(A) = the n'th Fibonacci number.  A is Toeplitz.
%          The eigenvalues have an interesting distribution in the complex
%          plane.

%          References:
%          R.L. Graham and N.J.A. Sloane, Anti-Hadamard matrices,

%          L. Ching, The maximum determinant of an nxn lower Hessenberg
%             (0,1) matrix, Linear Algebra and Appl., 183 (1993), pp. 147-153.
```

```
function y = dual(x, p)
%DUAL    Dual vector with respect to Holder p-norm.
%        Y = DUAL(X, p), where 1 <= p <= inf, is a vector of unit q-norm
%        that is dual to X with respect to the p-norm, that is,
%        norm(Y, q) = 1 where 1/p + 1/q = 1 and there is
%        equality in the Holder inequality: X'*Y = norm(X, p)*norm(Y, q).
%        Special case: DUAL(X), where X >= 1 is a scalar, returns Y such
%                      that 1/X + 1/Y = 1.

%        Called by PNORM.
```

```
function [X, D, s] = eigsens(A)
%EIGSENS   Eigenvalue condition numbers.
%          EIGSENS(A) is a vector of condition numbers for the eigenvalues
%          of A (reciprocals of the Wilkinson s(lambda) numbers).
%          These condition numbers are the reciprocals of the cosines of the
%          angles between the left and right eigenvectors.
%          [V, D, s] = EIGSENS(A) is equivalent to
%                      [V, D] = EIG(A); s = EIGSENS(A);

%          Reference:
%          G.H. Golub and C.F. Van Loan, Matrix Computations, Second
%          Edition, Johns Hopkins University Press, Baltimore, Maryland,
%          1989, sec. 7.2.2.
```

```
function f = fdemo(A)
%FDEMO   Demonstration function for direct search maximizers.
%        FDEMO(A) is the reciprocal of the underestimation ratio for RCOND
%        applied to the square matrix A.
%        Demonstration function for ADSMAX, MDSMAX and NMSMAX.
```

```
function A = fiedler(c)
%FIEDLER  Fiedler matrix - symmetric.
%         A = FIEDLER(C), where C is an n-vector, is the n-by-n symmetric
%         matrix with elements ABS(C(i)-C(j)).
%         Special case: if C is a scalar, then A = FIEDLER(1:C)
%                       (i.e. A(i,j) = ABS(i-j)).
%         Properties:
%           FIEDLER(N) has a dominant positive eigenvalue and all the other
%                      eigenvalues are negative (Szego, 1936).
%           Explicit formulas for INV(A) and DET(A) are given by Todd (1977)
%           and attributed to Fiedler.  These indicate that INV(A) is
%           tridiagonal except for nonzero (1,n) and (n,1) elements.
%           [I think these formulas are valid only if the elements of
%           C are in increasing or decreasing order---NJH.]

```

```
function A = forsythe(n, alpha, lambda)
%FORSYTHE  Forsythe matrix - a perturbed Jordan block.
%          FORSYTHE(N, ALPHA, LAMBDA) is the N-by-N matrix equal to
%          JORDBLOC(N, LAMBDA) except it has an ALPHA in the (N,1) position.
%          It has the characteristic polynomial
%                  DET(A-t*EYE) = (LAMBDA-t)^N - (-1)^N ALPHA.
%          ALPHA defaults to SQRT(EPS) and LAMBDA to 0.
```

```
function F = frank(n, k)
%FRANK   Frank matrix---ill conditioned eigenvalues.
%        F = FRANK(N, K) is the Frank matrix of order N.  It is upper
%        Hessenberg with determinant 1.  K = 0 is the default; if K = 1 the
%        elements are reflected about the anti-diagonal (1,N)--(N,1).
%        F has all positive eigenvalues and they occur in reciprocal pairs
%        (so that 1 is an eigenvalue if N is odd).
%        The eigenvalues of F may be obtained in terms of the zeros of the
%        Hermite polynomials.
%        The FLOOR(N/2) smallest eigenvalues of F are ill conditioned,
%        the more so for bigger N.

%        DET(FRANK(N)') comes out far from 1 for large N---see Frank (1958)
%        and Wilkinson (1960) for discussions.
%
%        This version incorporates improvements suggested by W. Kahan.

```

```
function [f, e] = fv(B, nk, thmax, noplot)
%FV     Field of values (or numerical range).
%       FV(A, NK, THMAX) evaluates and plots the field of values of the
%       NK largest leading principal submatrices of A, using THMAX
%       equally spaced angles in the complex plane.
%       The defaults are NK = 1 and THMAX = 16.
%       (For a 'publication quality' picture, set THMAX higher, say 32.)
%       The eigenvalues of A are displayed as 'x'.
%       Alternative usage: [F, E] = FV(A, NK, THMAX, 1) suppresses the
%       plot and returns the field of values plot data in F, with A's
%       eigenvalues in E.   Note that NORM(F,INF) approximates the
%       numerical radius,
%                 max {abs(z): z is in the field of values of A}.

%       Theory:
%       Field of values FV(A) = set of all Rayleigh quotients. FV(A) is a
%       convex set containing the eigenvalues of A.  When A is normal FV(A) is
%       the convex hull of the eigenvalues of A (but not vice versa).
%               z = x'Ax/(x'x),  z' = x'A'x/(x'x)
%               => REAL(z) = x'Hx/(x'x),   H = (A+A')/2
%       so      MIN(EIG(H)) <= REAL(z) <= MAX(EIG(H))
%       with equality for x = corresponding eigenvectors of H.  For these x,
%       RQ(A,x) is on the boundary of FV(A).

```
function [L, U, P, Q, rho] = gecp(A)
%GECP   Gaussian elimination with complete pivoting.
%       [L, U, P, Q, RHO] = GECP(A) computes the factorization P*A*Q = L*U,
%       where L is unit lower triangular, U is upper triangular,
%       and P and Q are permutation matrices.  RHO is the growth factor.
%       By itself, GECP(A) returns the final reduced matrix from the
%       elimination containing both L and U.
```

```
function  [G, e] = gersh(A, noplot)
%GERSH    Gershgorin disks.
%         GERSH(A) draws the Gershgorin disks for the matrix A.
%         The eigenvalues are plotted as crosses 'x'.
%         Alternative usage: [G, E] = GERSH(A, 1) suppresses the plot
%         and returns the data in G, with A's eigenvalues in E.
%
%         Try GERSH(LESP(N)) and GERSH(SMOKE(N,1)).
```

```
function A = gfpp(T, c)
%GFPP   Matrix giving maximal growth factor for Gaussian elim. with pivoting.
%       GFPP(T) is a matrix of order N for which Gaussian elimination
%       with partial pivoting yields a growth factor 2^(N-1).
%       T is an arbitrary nonsingular upper triangular matrix of order N-1.
%       GFPP(T, C) sets all the multipliers to C  (0 <= C <= 1)
%       and gives growth factor (1+C)^(N-1).
%       GFPP(N, C) (a special case) is the same as GFPP(EYE(N-1), C) and
%       generates the well-known example of Wilkinson.

%       Reference:
%       N.J. Higham and D.J. Higham, Large growth factors in
%       Gaussian elimination with pivoting, SIAM J. Matrix Analysis and
%       Appl., 10 (1989), pp. 155-164.
```

```
function x = gj(A, b, piv)
%GJ        Gauss-Jordan elimination to solve Ax = b.
%          x = GJ(A, b, PIV) solves Ax = b by Gauss-Jordan elimination,
%          where A is a square, nonsingular matrix.
%          PIV determines the form of pivoting:
%              PIV = 0:           no pivoting,
%              PIV = 1 (default): partial pivoting.
```

```
function G = grcar(n, k)
%GRCAR     Grcar matrix - a Toeplitz matrix with sensitive eigenvalues.
%          GRCAR(N, K) is an N-by-N matrix with -1s on the
%          subdiagonal, 1s on the diagonal, and K superdiagonals of 1s.
%          The default is K = 3.  The eigenvalues of this matrix form an
%          interesting pattern in the complex plane (try PS(GRCAR(32))).

```

```
function J = jordbloc(n, lambda)
%JORDBLOC  Jordan block.
%          JORDBLOC(N, LAMBDA) is the N-by-N Jordan block with eigenvalue
%          LAMBDA.  LAMBDA = 1 is the default.
```

```
function U = kahan(n, theta, pert)
%KAHAN  Kahan matrix - upper trapezoidal.
%       KAHAN(N, THETA) is an upper trapezoidal matrix
%       that has some interesting properties regarding estimation of
%       condition and rank.
%       The matrix is N-by-N unless N is a 2-vector, in which case it
%       is N(1)-by-N(2).
%       The parameter THETA defaults to 1.2.
%       The useful range of THETA is 0 < THETA < PI.
%
%       To ensure that the QR factorization with column pivoting does not
%       interchange columns in the presence of rounding errors, the diagonal
%       is perturbed by PERT*EPS*diag( [N:-1:1] ).
%       The default is PERT = 25, which ensures no interchanges for KAHAN(N)
%       up to at least N = 90 in IEEE arithmetic.
%       KAHAN(N, THETA, PERT) uses the given value of PERT.

%       The inverse of KAHAN(N, THETA) is known explicitly: see
%       Higham (1987, p. 588), for example.
%       The diagonal perturbation was suggested by Christian Bischof.

```

```
function A = makejcf(n, e, m, X)
%MAKEJCF   A matrix with given Jordan canonical form.
%          MAKEJCF(N, E, M) is a matrix having the Jordan canonical form
%          whose i'th Jordan block is of dimension M(i) with eigenvalue E(i),
%          and where N = SUM(M).
%          Defaults: E = 1:N, M = ONES(SIZE(E)) with M(1) so that SUM(M) = N.
%          The matrix is constructed by applying a random similarity
%          transformation to the Jordan form.
%          Alternatively, the matrix used in the similarity transformation
%          can be specified as a fifth parameter.
```

```
%          In particular, MAKEJCF(N, E, M, EYE(N)) returns the Jordan form
%          itself.
%          NB: The JCF is very sensitive to rounding errors.
```

```
function A = matrix(k, n)
%MATRIX    Test Matrix Toolbox information and matrix access by number.
%          MATRIX(K, N) is the N-by-N instance of the matrix number K in
%          the Test Matrix Toolbox (including some of the matrices provided
%          with MATLAB), with all other parameters set to their default.
%          N.B. Only those matrices which take an arbitrary dimension N
%               are included (thus GALLERY is omitted, for example).
%          MATRIX(K) is a string containing the name of the K'th matrix.
%          MATRIX(0) is the number of matrices, i.e. the upper limit for K.
%          Thus to set A to each N-by-N test matrix in turn use a loop like
%                for k=1:matrix(0)
%                    A = matrix(k, N);
%                    Aname = matrix(k);   % The name of the matrix
%                end
%          MATRIX(-1) returns the version number and date of the toolbox.
%          MATRIX with no arguments lists the names of the M-files in the
%          collection.

%             MATLAB, ACM Trans. Math. Soft., 17 (1991), pp. 289-305.
%
%          Matrices omitted are: gallery, hadamard, hanowa, lauchli,
%          neumann, wathen, wilk.
%          Matrices provided with MATLAB that are included here: invhilb,
%          magic.
```

```
function S = matsignt(T)
%MATSIGNT    Matrix sign function of a triangular matrix.
%            S = MATSIGN(T) computes the matrix sign function S of the
%            upper triangular matrix T using a recurrence.

%            Adapted from FUNM.  Called by SIGNM.
```

```
function [x, fmax, nf] = mdsmax(fun, x, stopit, savit)
%MDSMAX  Multidirectional search method for direct search optimization.
%        [x, fmax, nf] = MDSMAX(fun, x0, STOPIT, SAVIT) attempts to
%        maximize the function specified by the string fun, using the
%        starting vector x0.  The method of multidirectional search is used.
%        Output arguments:
%               x    = vector yielding largest function value found,
```

```
%               fmax = function value at x,
%               nf   = number of function evaluations.
%       The iteration is terminated when either
%               - the relative size of the simplex is <= STOPIT(1)
%                 (default 1e-3),
%               - STOPIT(2) function evaluations have been performed
%                 (default inf, i.e., no limit), or
%               - a function value equals or exceeds STOPIT(3)
%                 (default inf, i.e., no test on function values).
%       The form of the initial simplex is determined by STOPIT(4):
%          STOPIT(4) = 0: regular simplex (sides of equal length, the default)
%          STOPIT(4) = 1: right-angled simplex.
%       Progress of the iteration is not shown if STOPIT(5) = 0 (default 1).
%       If a non-empty fourth parameter string SAVIT is present, then
%       'SAVE SAVIT x fmax nf' is executed after each inner iteration.
%       NB: x0 can be a matrix.  In the output argument, in SAVIT saves,
%           and in function calls, x has the same shape as x0.

%         NPTS defaults to a SIZE(A)-dependent value.
%         The limits are AX(1) and AX(2) on the x-axis and
%                        AX(3) and AX(4) on the y-axis.
%         If AX is omitted, suitable limits are guessed based on the
%         eigenvalues of A.
%         The eigenvalues of A are plotted as crosses 'x'.
%         K determines the type of plot:
%             K = 0 (default) PCOLOR and CONTOUR
%             K = 1           PCOLOR only
%             K = 2           SURFC (SURF and CONTOUR)
%             K = 3           SURF only
%             K = 4           CONTOUR only
%         The contours levels are specified by the vector LEVELS, which
%         defaults to -10:-1 (recall we are plotting log10 of the data).
%         Thus, by default, the contour lines trace out the boundaries of
%         the epsilon pseudospectra for epsilon = 1e-10, ..., 1e-1.
%         [X, Y, Z, NPTS] = PSCONT(A, ...) returns the plot data X, Y, Z
%         and the value of NPTS used.
%
%         After calling this function you may want to change the
%         color map (e.g., type COLORMAP HOT - see HELP COLOR) and the
%         shading (e.g., type SHADING INTERP - see HELP INTERP).
%         For an explanation of the term 'pseudospectra' see PS.M.
%         When A is real and the grid is symmetric about the x-axis, this
%         routine exploits symmetry to halve the computational work.

%         Colour pseduospectral pictures of this type are referred to as
%         'spectral portraits' by Godunov, Kostin, and colleagues.

```

```
function A = rando(n, k)
%RANDO   Random matrix with elements -1, 0 or 1.
%        A = RANDO(N, K) is a random N-by-N matrix with elements from
%        one of the following discrete distributions (default K = 1):
%          K = 1:  A(i,j) =  0 or 1    with equal probability,
%          K = 2:  A(i,j) = -1 or 1    with equal probability,
%          K = 3:  A(i,j) = -1, 0 or 1 with equal probability.
%        N may be a 2-vector, in which case the matrix is N(1)-by-N(2).
```

```
function A = randsvd(n, kappa, mode, kl, ku)
%RANDSVD  Random matrix with pre-assigned singular values.
%      RANDSVD(N, KAPPA, MODE, KL, KU) is a (banded) random matrix of order N
%      with COND(A) = KAPPA and singular values from the distribution MODE.
%      N may be a 2-vector, in which case the matrix is N(1)-by-N(2).
%      Available types:
%             MODE = 1:   one large singular value,
%             MODE = 2:   one small singular value,
%             MODE = 3:   geometrically distributed singular values,
%             MODE = 4:   arithmetically distributed singular values,
%             MODE = 5:   random singular values with unif. dist. logarithm.
%      If omitted, MODE defaults to 3, and KAPPA defaults to SQRT(1/EPS).
%      If MODE < 0 then the effect is as for ABS(MODE) except that in the
%      original matrix of singular values the order of the diagonal entries
%      is reversed: small to large instead of large to small.
%      KL and KU are the lower and upper bandwidths respectively; if they
%      are omitted a full matrix is produced.
%      If only KL is present, KU defaults to KL.
%      Special case: if KAPPA < 0 then a random full symmetric positive
```

```
%                   definite matrix is produced with COND(A) = -KAPPA and
%                   eigenvalues distributed according to MODE.
%                   KL and KU, if present, are ignored.

%         USA, 1996; sec. 26.3.
```

```
function A = redheff(n)
%REDHEFF    A (0,1) matrix of Redheffer associated with the Riemann hypothesis.
%           A = REDHEFF(N) is an N-by-N matrix of 0s and 1s defined by
%               A(i,j) = 1 if j = 1 or if i divides j,
%               A(i,j) = 0 otherwise.
%           It has N - FLOOR(LOG2(N)) - 1 eigenvalues equal to 1,
%           a real eigenvalue (the spectral radius) approximately SQRT(N),
%           a negative eigenvalue approximately -SQRT(N),
%           and the remaining eigenvalues are provably ``small''.
%           Barrett and Jarvis (1992) conjecture that
%             ``the small eigenvalues all lie inside the unit circle
%               ABS(Z) = 1'',
%           and a proof of this conjecture, together with a proof that some
%           eigenvalue tends to zero as N tends to infinity, would yield
%           a new proof of the prime number theorem.
%           The Riemann hypothesis is true if and only if
%           DET(A) = O( N^(1/2+epsilon) ) for every epsilon > 0
%                                           (`!' denotes factorial).
%           See also RIEMANN.

```
function see(A, k)
%SEE    Pictures of a matrix and its (pseudo-) inverse.
%       SEE(A) displays MESH(A), MESH(PINV(A)), SEMILOGY(SVD(A),'o'),
%       and (if A is square) FV(A) in four subplot windows.
%       SEE(A, 1) plots an approximation to the pseudospectrum in the
%       third window instead of the singular values.
%       SEE(A, -1) plots only the eigenvalues in the fourth window,
%       which is much quicker than plotting the field of values.
%       If A is complex, only real parts are used for the mesh plots.
%       If A is sparse, just SPY(A) is shown.
```

```
function y = seqa(a, b, n)
%SEQA   Additive sequence.
%       Y = SEQA(A, B, N) produces a row vector comprising N equally
%       spaced numbers starting at A and finishing at B.
%       If N is omitted then 10 points are generated.
```

```
function x = seqcheb(n, k)
%SEQCHEB   Sequence of points related to Chebyshev polynomials.
%          X = SEQCHEB(N, K) produces a row vector of length N.
%          There are two choices:
%              K = 1:  zeros of T_N,          (the default)
%              K = 2:  extrema of T_{N-1},
%          where T_k is the Chebsyhev polynomial of degree k.
```

```
function y = seqm(a, b, n)
%SEQM   Multiplicative sequence.
%       Y = SEQM(A, B, N) produces a row vector comprising N
%       logarithmically equally spaced numbers, starting at A ~= 0
%       and finishing at B ~= 0.
%       If A*B < 0 and N > 2 then complex results are produced.
%       If N is omitted then 10 points are generated.
```

```
function show(x)
%SHOW   Display signs of matrix elements.
%       SHOW(X) displays X in 'FORMAT +' form, that is,
%       with '+', '-' and  blank representing positive, negative
%       and zero elements respectively.
```

```
function [S, N] = signm(A)
%SIGNM   Matrix sign decomposition.
%        [S, N] = SIGNM(A) is the matrix sign decomposition A = S*N,
%        computed via the Schur decomposition.
%        S is the matrix sign function, sign(A).

%        Reference:
%        N.J. Higham, The matrix sign decomposition and its relation to the
%        polar decomposition, Linear Algebra and Appl., 212/213:3-20, 1994.
```

```
function S = skewpart(A)
%SKEWPART  Skew-symmetric (skew-Hermitian) part.
%          SKEWPART(A) is the skew-symmetric (skew-Hermitian) part of A,
%          (A - A')/2.
%          It is the nearest skew-symmetric (skew-Hermitian) matrix to A in
%          both the 2- and the Frobenius norms.
```

```
function A = smoke(n, k)
%SMOKE     Smoke matrix - complex, with a 'smoke ring' pseudospectrum.
%          SMOKE(N) is an N-by-N matrix with 1s on the
%          superdiagonal, 1 in the (N,1) position, and powers of
%          roots of unity along the diagonal.
%          SMOKE(N, 1) is the same except for a zero (N,1) element.
%          The eigenvalues of SMOKE(N, 1) are the N'th roots of unity;
```

```
%          those of SMOKE(N) are the N'th roots of unity times 2^(1/N).
%
%          Try PS(SMOKE(32)).  For SMOKE(N, 1) the pseudospectrum looks
%          like a sausage folded back on itself.
%          GERSH(SMOKE(N, 1)) is interesting.

```

Acknowledgements

In preparing the earlier test matrix collections I benefited from the helpful suggestions of people too numerous to mention. While working on version 2.0 of the toolbox I received valuable advice from Cleve Moler and Nick Trefethen, and Per Christian Hansen offered helpful comments on a draft version of the manual accompanying version 2.0.

October 25, 1995

Abstract

This report provides an introductory overview of the numerical solution of large scale algebraic eigenvalue problems. The main focus is on a class of methods called Krylov subspace projection methods. The Lanczos method is the premier member of this class and the Arnoldi method is a generalization to the nonsymmetric case. A recently developed and very promising variant of the Arnoldi/Lanczos scheme called the Implicitly Restarted Arnoldi Method is presented here in detail. This method is highlighted because of its suitability as a basis for software development. It may be viewed as a truncated form of the implicitly shifted QR-algorithm that is appropriate for very large problems. Based on this technique, a public domain software package called ARPACK has been developed in Fortran 77 for finding a few eigenvalues and eigenvectors of large scale symmetric, nonsymmetric, standard or generalized problems. This package has performed well on workstations, parallel-vector supercomputers, distributed memory parallel systems and clusters of workstations. The important features of this package are presented along with a discussion some applications and performance indicators.

1 Introduction

Eigenvalues and eigenfunctions of linear operators are important to many areas of applied mathematics. The ability to approximate these quantities numerically is becoming increasingly important in a wide variety of applications. This increasing demand has fueled interest in the development of new methods and software for the numerical solution of large scale algebraic eigenvalue problems. In turn, the existence of these new methods and software, along with the dramatically increased computational capabilities now available, has enabled the solution of problems that would not have even been posed five or ten years ago. Until very recently, software for large scale nonsymmetric problems was virtually non-existent. Fortunately, the situation is improving rapidly.

The purpose of this article is to provide an overview of the numerical solution of large scale algebraic eigenvalue problems. The focus will be on a class of methods called Krylov subspace projection methods. The well known Lanczos method is the premier member of this class. The Arnoldi method generalizes the Lanczos method to the non-symmetric case. A recently developed variant of the Arnoldi/Lanczos scheme called the Implicitly Restarted Arnoldi Method [44] is presented here in some depth. This method is highlighted because of its suitability as a basis for software development.

The discussion begins with a brief synopsis of the theory and the basic iterations suitable for large scale problems to motivate the introduction of Krylov subspaces. Then the Lanczos/Arnoldi factorization is introduced along with a discussion of its important approximation properties. Spectral transformations are presented as a means to improve these approximation properties and to enhance convergence of the basic methods. Restarting is introduced as a way to overcome intractable storage and computational requirements in the

original Arnoldi method. Implicit restarting is a new sophisticated variant of restarting. This new technique may be viewed as a truncated form of the powerful implicitly shifted QR technique that is suitable for large scale problems. Implicit restarting provides a means to approximate a few eigenvalues with user specified properties in space proportional to nk where k is the number of eigenvalues sought.

Generalized eigenvalue problems are discussed in some detail. They arise naturally in PDE applications and they have a number of subtleties with respect to numerically stable implementation of spectral transformations.

Software issues and considerations for implementation on vector and parallel computers are introduced in the later sections. Implicit restarting has provided a means to develop very robust and efficient software for a wide variety of large scale eigen-problems. A public domain software package called ARPACK has been developed in Fortran 77. This package has performed well on workstations, parallel-vector supercomputers, distributed memory parallel systems and clusters of workstations. The features of this package along with some applications and performance indicators occupy the final section of this paper.

2 Eigenvalues, Power Iterations, and Spectral Transformations

A brief discussion of the mathematical structure of the eigenvalue problem is necessary to fix notation and introduce ideas that lead to an understanding of the behavior, strengths and limitations of the algorithms. In this discussion, the real and complex number fields are denoted by $\mathbf{R}$ and $\mathbf{C}$ respectively. The standard n-dimensional real and complex vectors are denoted by $\mathbf{R}^n$ and $\mathbf{C}^n$ and the symbols $\mathbf{R}^{m\times n}$ and $\mathbf{C}^{m\times n}$ will denote the real and complex matrices m rows and n columns. Scalars are denoted by lower case Greek letters, vectors are denoted by lower case Latin letters and matrices by capital Latin letters. The transpose of a matrix A is denoted by A^T and the conjugate-transpose by A^H. The symbol, $\|\cdot\|$ will denote the Euclidean or 2-norm of a vector. The standard basis of $\mathbf{C}^n$ is denoted by the set $\{e_j\}_{j=1}^n$.

The set of numbers $\sigma(A) \equiv \{\lambda \in \mathbf{C} : rank(A-\lambda I) < n)\}$ is called the *spectrum* of A. The elements of this discrete set are the *eigenvalues* of A and they may be characterized as the n roots of the *characteristic polynomial* $p_A(\lambda) \equiv det(\lambda I - A)$. Corresponding to each distinct eigenvalue $\lambda \in \sigma(A)$ is at least one nonzero vector x such that $Ax = x\lambda$. This vector is called a *right eigenvector* of A corresponding to the eigenvalue λ. The pair (x, λ) is called an *eigenpair*. A nonzero vector y such that $y^H A = \lambda y^H$ is called a *left eigenvector*. The multiplicity $n_a(\lambda)$ of λ as a root of the characteristic polynomial is the *algebraic* multiplicity and the dimension $n_g(\lambda)$ of $Null(\lambda I - A)$ is the *geometric* multiplicity of λ. A matrix is *defective* if $n_g(\lambda) < n_a(\lambda)$ and otherwise A is *non-defective*. The eigenvalue λ is *simple* if $n_a(\lambda) = 1$.

A subspace $\mathcal{S}$ of $\mathbf{C}^{n\times n}$ is called an *invariant subspace* of A if $A\mathcal{S} \subset \mathcal{S}$. It is straightforward to show if $A \in \mathbf{C}^{n\times n}$, $X \in \mathbf{C}^{n\times k}$ and $B \in \mathbf{C}^{k\times k}$ satisfy

$$AX = XB, \tag{1}$$

then $\mathcal{S} \equiv \mathrm{R}ange(X)$ is an invariant subspace of A. Moreover, if X has full column rank k then the columns of X form a basis for this subspace and $\sigma(B) \subset \sigma(A)$. If $k = n$ then $\sigma(B) = \sigma(A)$ and A is said to be *similar* to B under the *similarity transformation* X. A is *diagonalizable* if it is similar to a diagonal matrix and this property is equivalent to A being non-defective.

An extremely important theorem to the study of numerical algorithms for eigenproblems is the Schur decomposition. It states that every square matrix is *unitarily similar* to an upper triangular matrix. In other words, for any linear operator on $\mathbf{C}^n$, there is a unitary basis in which the operator has an upper triangular matrix representation.

Theorem 2.1 *(Schur Decomposition). Let $A \in \mathbf{C}^{n\times n}$. Then there is a unitary matrix Q and an upper triangular matrix R such that*

$$AQ = QR. \tag{2}$$

The diagonal elements of R are the eigenvalues of A.

From the Schur decomposition, the fundamental structure of Hermitian and normal matrices is easily exposed:

Lemma 2.2 *A matrix $A \in \mathbf{C}^{n\times n}$ is normal ($AA^H = A^HA$) if and only if $A = Q\Lambda Q^H$ with $Q \in \mathbf{C}^{n\times n}$ unitary and $\Lambda \in \mathbf{C}^{n\times n}$ diagonal. A matrix $A \in \mathbf{C}^{n\times n}$ is Hermitian ($A = A^H$) if and only if $A = Q\Lambda Q^H$ with $Q \in \mathbf{C}^{n\times n}$ unitary and $\Lambda \in \mathbf{R}^{n\times n}$ diagonal. In either case, the diagonal entries of Λ are the eigenvalues of A and the columns of Q are the corresponding eigenvectors.*

The proof follows easily through substitution of the Schur decomposition in place of A in each of the defining relationships. The columns of Q are called Schur vectors in general and these are eigenvectors of A if and only if A is normal.

For purposes of algorithmic development this structure is fundamental. In fact, the well known Implicitly Shifted QR-Algorithm [16] is designed to produce a sequence of unitary similarity transformations Q_j that iteratively reduce A to upper triangular form. This algorithm begins with an initial unitary similarity transformation V of A to the condensed form $AV = VH$ where H is upper Hessenberg (tridiagonal in case $A = A^H$). Then the following iteration is performed:

Algorithm 1: Implicitly Shifted QR-iteration

Input: (A, V, H) with $AV = VH, V^HV = I$, H upper Hessenberg;

For $j = 1, 2, 3, \ldots$ until *convergence*,

(a1.1) Select a shift $\mu \leftarrow \mu_j$

(a1.2) Factor $[Q, R] = \mathrm{qr}(H - \mu I)$;

(a1.3) $H \leftarrow Q^HHQ$; $V \leftarrow VQ$;

End_For

where Q is unitary and R is upper triangular (i.e. the QR factorization of $H - \mu I$). It is easy to see that H is unitarily similar to A throughout the course of this iteration. The

iteration is continued until the subdiagonal elements of H converge to zero, i.e. until a Schur decomposition has been (approximately) obtained. In the standard implicitly shifted QR-iteration, the unitary matrix Q is never actually formed. it is computed indirectly as a product of 2×2 Givens or 3×3 Householder transformations through a "bulge chase" process. The elegant details of an efficient and stable implementation would be too much of a digression here. They may be found in [18]. The convergence behavior of this iteration is fascinating. The columns of V converge to Schur vectors at various rates. These rates are fundamentally linked to the simple power method and its rapidly convergent variant, inverse iteration (see [51]).

Despite the extremely fast rate of convergence and the efficient use of storage, the implicitly shifted QR method is not suitable for large scale problems and it has proved to be extremely difficult to parallelize. Large scale problems are typically sparse or structured so that a matrix-vector product $w \leftarrow Av$ may be computed with time and storage proportional to n rather than n^2 . A method based upon full similarity transformations quickly destroys this structure. Storage and operation counts become order n^2. Hence, there is considerable motivation for methods that only require matrix-vector products with the original A.

2.1 SINGLE VECTOR POWER ITERATIONS

Probably the oldest algorithm for approximating eigenvalues and corresponding eigenvectors of a matrix is the power method. This method is an important tool in its own right when conditions are appropriate. It is very simple and only requires matrix-vector products along with two vectors of storage. In addition to its role as an algorithm, the method is central to the development, understanding, and convergence analysis of all of the iterative methods discussed here.

Algorithm 2: The Power Method

Input: (A, v_o)

Put $v = v_o / \|v_o\|_\infty$;

For $j = 1, 2, 3, \ldots$ until $convergence$,

(a2.1) $w \leftarrow Av$;

(a2.2) $\lambda = \frac{v^H w}{v^H v}$;

(a2.3) $i =$ i_max (w);

(a2.4) $v \leftarrow v/(e_i^T w)$;

End_For

At Step (a2.3), i is the index of the element of w with largest absolute value. It is easily seen that the contents of v after k-steps of this iteration will be the vector

$$v_k = (\frac{1}{e_i^T A^k v_o}) A^k v_o = (\frac{\rho_k}{e_i^T A^k v_o})(\frac{1}{\rho_k} A^k v_o)$$

for any nonzero scalar ρ_k. In particular, this iteration may be analyzed as if the vectors had been scaled by $\rho_k = \lambda_1^k$ at each step, with λ_1 an eigenvalue of A with largest magnitude.

If A is diagonalizable with eigenpairs $\{(x_j, \lambda_j), 1 \leq j \leq n\}$ and v_o has the expansion $v_o = \sum_{j=1}^{n} x_j \gamma_j$ in this basis then

$$\frac{1}{\lambda_1^k} A^k v_o = \frac{1}{\lambda_1^k} \sum_{j=1}^{n} A^k x_j \gamma_j = \sum_{j=1}^{n} x_j (\lambda_j / \lambda_1)^k \gamma_j. \tag{3}$$

If λ_1 is a simple eigenvalue then

$$\left(\frac{\lambda_j}{\lambda_1} \right)^k \to 0, \quad 2 \leq j \leq n.$$

It follows that $v_k \to x_1 / (e_i^T x_1)$, where $i =$ i_max (x_1), at a linear rate with a convergence factor of $|\frac{\lambda_2}{\lambda_1}|$.

While the power method is useful, it has two obvious drawbacks. Convergence may be arbitrarily slow or may not happen at all. Only one eigenvalue and corresponding vector can be found.

2.2 SPECTRAL TRANSFORMATIONS

The basic power iteration may be modified to overcome these difficulties. The most fundamental modification is to employ a *spectral transformation*. Spectral transformations are generally based upon the following:

Let $A \in \mathbf{C}^{n \times n}$ have an eigenvalue λ with corresponding eigenvector x.

1. Let $p(\tau) = \gamma_0 + \gamma_1 \tau + \gamma_2 \tau^2 + \ldots + \gamma_k \tau^k$. Then $p(\lambda)$ is an eigenvalue of the matrix $p(A) = \gamma_0 I + \gamma_1 A + \gamma_2 A^2 + \ldots + \gamma_k A^k$ with corresponding eigenvector x (i.e. $p(A)x = x p(\lambda)$).

2. If $r(\tau) = \frac{p(\tau)}{q(\tau)}$ where p and q are polynomials with $q(A)$ nonsingular, define $r(A) = [q(A)]^{-1} p(A)$. Then $r(\lambda)$ is an eigenvalue of $r(A)$ with corresponding eigenvector x.

It is often possible to construct a polynomial or rational function $\phi(\tau)$ such that

$$|\phi(\lambda_i)| \ll |\phi(\lambda_j)| \quad \text{for} \quad 1 \leq j \leq n, \quad j \neq i,$$

where λ_i is an eigenvalue of particular interest. This is called a spectral transformation since the eigenvectors of the transformed matrix $\phi(A)$ remain the same, but the corresponding eigenvalues λ_j are transformed to $\phi(\lambda_j)$. Applying the power method with $\phi(A)$ in place of A will then produce the eigenvector $q \equiv x_i$ corresponding to λ_i at a linear a convergence rate with a convergence factor of $|\frac{\phi(\lambda_j)}{\phi(\lambda_i)}| << 1$. Once the eigenvector has been found, the eigenvalue $\lambda \equiv \lambda_i$ may be calculated directly from a Rayleigh quotient $\lambda = q^H A q / q^H q$.

2.3 INVERSE ITERATION

Spectral transformation can lead to dramatic enhancement of the convergence of the power method. Polynomial transformations may be applied using only matrix-vector products.

Rational transformations require the solution of linear systems with the transformed matrix as the coefficient matrix. The simplest rational transformation turns out to be very powerful and is almost exclusively used for this purpose. If $\mu \notin \sigma(A)$ then $A - \mu I$ is invertible and $\sigma([A - \mu I]^{-1}) = \{1/(\lambda - \mu) : \lambda \in \sigma(A)\}$. This transformation is very successful since eigenvalues near the shift μ are transformed to extremal eigenvalues which are well separated from the other ones while the original extremal eigenvalues are transformed near the origin. Hence under this transformation the eigenvector q corresponding to the eigenvalue of A that is closest to μ may be readily found and the corresponding eigenvalue may obtained either through the formula $\lambda = \theta + 1/\mu$, where θ is the eigenvalue of the transformed matrix, or it may be calculated directly from a Rayleigh quotient.

Algorithm 3: The Inverse Power Method

Input: $(A, v_o, \mu\ )$

Put $v = v_o / \|v_o\|_\infty$;

For $j = 1, 2, 3, ...$ until $convergence$,

(a3.1) Solve $(A - \mu I)w = v$;

(a3.2) $\lambda = \mu + \frac{v^H w}{w^H w}$;

(a3.3) $i =$ i_max (w);

(a3.4) $v \leftarrow v/(e_i^T w)$;

End_For

Observe that the formula for λ at Step (a3.2) is equivalent to forming $\lambda = (w^H A w)/(w^H w)$ so an additional matrix vector product is not necessary to obtain the Rayleigh quotient estimate. The analysis of convergence remains entirely in tact. This iteration converges linearly with the convergence factor

$$\frac{|\lambda_1 - \mu|}{|\lambda_2 - \mu|}$$

where the eigenvalues of A have been re-indexed so that $|\lambda_1 - \mu| < |\lambda_2 - \mu| \leq |\lambda_3 - \mu| \leq ... \leq |\lambda_n - \mu|$. Hence, the convergence becomes faster as μ gets closer to λ_1.

This result is encouraging but still leaves us wondering how to select the shift μ to be close to the unknown eigenvalue we are trying to compute. In many applications the choice is apparent from the requirements of the problem. It is also possible to change the shift at each iteration at the expense of a new matrix factorization at each step. An obvious choice would be to replace the shift with the current Rayleigh quotient estimate. This method, called Rayleigh Quotient Iteration, has very impressive convergence rates indeed. Rayleigh Quotient Iteration converges at a quadratic rate in general and at a cubic rate on Hermitian problems. For a more detailed discussion of the eigenvalue problem and basic algorithms see [52, 46, 18].

3 Krylov Subspaces and Projection Methods

Although the rate of convergence can be improved to an acceptable level through spectral transformations, power iterations are only able to find one eigenvector at a time. If more vectors are sought, then various deflation techniques (such as orthogonalizing against previously converged eigenvectors) and shift strategies must be introduced. One alternative is to introduce a block form of the simple power method which is often called subspace iteration. This important class of algorithms has been developed and investigated in [46]. Several software efforts have been based upon this approach [3, 47, 12]. However, there is another class of algorithms called Krylov subspace projection methods that are based upon the intricate structure of the sequence of vectors naturally produced by the power method.

An examination of the behavior of the power sequence as exposed in equation (3) hints that the successive vectors produced by a power iteration may contain considerable information along eigenvector directions corresponding to eigenvalues other than the one with largest magnitude. The expansion coefficients of the vectors in the power sequence evolve in a very structured way. Therefore, linear combinations of the these vectors might well be devised to expose additional eigenvectors. A single vector power iteration simply ignores this additional information, but more sophisticated techniques may be employed to extract it.

If one hopes to obtain additional information through various linear combinations of the power sequence, it is natural to formally consider the *Krylov* subspace

$$\mathcal{K}_k(A, v_1) = \text{Span } \{v_1, Av_1, A^2v_1, \ldots, A^{k-1}v_1\}$$

and to attempt to formulate the best possible approximations to eigenvectors from this subspace.

It is reasonable to construct approximate eigenpairs from this subspace by imposing a Galerkin condition: A vector $x \in \mathcal{K}_k(A, v_1)$ is called a *Ritz vector* with corresponding *Ritz value* θ if the Galerkin condition

$$< w, Ax - x\theta >= 0 \ , \quad \text{for all} \quad w \in \mathcal{K}_k(A, v_1)$$

is satisfied. There are some immediate consequences of this definition: Let W be a matrix whose columns form an orthonormal basis for $\mathcal{K}_k \equiv \mathcal{K}_k(A, v_1)$. Let $\mathcal{P} = WW^H$ denote the related orthogonal projector onto $\mathcal{K}_k$ and define $\hat{A} \equiv \mathcal{P}A\mathcal{P} = WBW^H$ where $B \equiv W^HAW$. It can be shown that

Lemma 3.1 *For the quantities defined above:*

1. (x, θ) *is a Ritz-pair if and only if* $x = Wy$ *with* $By = y\theta$.
2. $\|(I - \mathcal{P})AW\| = \|(A - \hat{A})W\| \leq \|(A - M)W\|$
   for all $M \in \mathbf{C}^{n\times n}$ *such that* $M\mathcal{K}_k \subset \mathcal{K}_k$.
3. *The Ritz-pairs* (x, θ) *and the minimum value* $\|(I - \mathcal{P})AW\|$ *are independent of the choice of orthonormal basis* W.

Item (1) follows immediately from the Galerkin condition since it implies that $0 = W^H(AWy -$

$Wy\theta) = By - y\theta$. Item (2) is easily shown using invariance of $\|\cdot\|$ under unitary transformations. Item (3) follows from the fact that V is an orthonormal basis for $\mathcal{K}_k$ if and only if $V = WQ$ for some $k \times k$ unitary matrix Q. With this change of basis $\hat{A} = VHV^H$, where $H = V^H AV = Q^H BQ$. Since H is unitarily similar to B, the Ritz-values remain the same and the Ritz-vectors are of the form $x = Wy = V\hat{y}$ where $\hat{y} = Q^H y$.

These facts are actually valid for any k dimensional subspace $\mathcal{S}$ in place of $\mathcal{K}_k$. The following properties are consequences of the fact that every $w \in \mathcal{K}_k$ is of the form $w = \phi(A)v_1$ for some polynomial ϕ of degree less than k.

Lemma 3.2 *For the quantities defined above:*

1. *If q is a polynomial of degree less than k then*

   $$q(A)v_1 = q(\hat{A})v_1 = Wq(B)z_1$$

   where $v_1 = Wz_1$, and if degree of q is k then

   $$\mathcal{P}q(A)v_1 = q(\hat{A})v_1.$$

2. *If $\hat{p}(\lambda) \equiv det(\lambda I - B)$ is the characteristic polynomial of B then $\hat{p}(\hat{A}) = 0$ and $\|\hat{p}(A)v_1\| \leq \|q(A)v_1\|$ for all monic polynomials of degree k.*

3. *If y is any vector in $\mathbf{C}^k$ then $AWy - WBy = \gamma\hat{p}(A)v_1$ for some scalar γ.*

4. *If (x, θ) is any Ritz-pair for A with respect to $\mathcal{K}_k$ then*

   $$Ax - x\theta = \gamma\hat{p}(A)v_1$$

   for some scalar γ.

This discussion follows the treatment given by Saad in [40] and in his earlier papers. While these facts may seem esoteric, they have important algorithmic consequences. First, it should be noted that $\mathcal{K}_k$ is an invariant subspace for A if and only if $v_1 = Vy$, where $AV = VR$ with $V^H V = I_k$ and R is $k \times k$ upper triangular. Also, $\mathcal{K}_k$ is an invariant subspace for A if $v_1 = Xy$, where $X \in \mathbf{C}^{n\times k}$ and $AX = X\Lambda$ with Λ diagonal . This follows from items (2) and (3) since there is a k degree monic polynomial q such that $q(R) = 0$ and hence $\|\hat{p}(A)v_1\| \leq \|q(A)v_1\| = \|Vq(R)y\| = 0$ (A similar argument holds when $v_1 = Xy$).

Secondly, there is some algorithmic motivation to seek a convenient orthonormal basis $V = WQ$ that will provide a means to successively construct these basis vectors. It is possible to construct a $k \times k$ unitary Q using standard Householder transformations such that $v_1 = Ve_1$ and $H = Q^H BQ$ is upper Hessenberg with non-negative subdiagonal elements. It is also possible to show using item (3) that in this basis,

$$AV = VH + fe_k^T, \quad \text{where} \quad f = \gamma\hat{p}(A)v_1$$

and $V^H f = 0$ follows from the Galerkin condition.

The first observation shows that if it is possible to obtain a v_1 as a linear combination of k eigenvectors of A then $f = 0$ and V is an orthonormal basis for an invariant subspace of A and that the Ritz values $\sigma(H) \subset \sigma(A)$ and corresponding Ritz vectors are eigenpairs for A. The second observation leads to the Lanczos/Arnoldi process [23, 1].

4 The Arnoldi Factorization

Definition : If $A \in \mathbf{C}^{n\times n}$ then a relation of the form

$$AV_k = V_k H_k + f_k e_k^T$$

where $V_k \in \mathbf{C}^{n\times k}$ has orthonormal columns, $V_k^H f_k = 0$ and $H_k \in \mathbf{C}^{k\times k}$ is upper Hessenberg with non-negative subdiagonal elements is called a $k-$*step Arnoldi Factorization* of A. If A is Hermitian then H_k is real, symmetric and tridiagonal and the relation is called a $k-$*step Lanczos Factorization* of A. The columns of V_k are referred to as the *Arnoldi vectors* or *Lanczos vectors* respectively.

The development of this factorization has been purely through the consequences of the orthogonal projection imposed by the Galerkin conditions. A more straightforward but less illuminating derivation is to simply truncate the reduction of A to Hessenberg form that precedes the implicitly shifted QR-iteration by equating the first k columns on both sides of the complete reduction $AV = VH$. An alternative way to write this factorization is

$$AV_k = (V_k, v_{k+1}) \begin{pmatrix} H_k \\ \beta_k e_k^T \end{pmatrix} \quad \text{where} \quad \beta_k = \|f_k\| \quad \text{and} \quad v_{k+1} = \frac{1}{\beta_k} f_k \ .$$

This factorization may be used to obtain approximate solutions to a linear system $Ax = b$ if $b = v_1\beta_o$ and this underlies the GMRES method [41]. However, the purpose here is to investigate the use of this factorization to obtain approximate eigenvalues and eigenvectors. The discussion of the previous section implies that Ritz pairs satisfying the Galerkin condition are immediately available from the eigenpairs of the small projected matrix H.

If $H_k y = y\theta$ then the vector $x = V_k y$ satisfies

$$\|Ax - x\theta\| = \|(AV_k - V_k H_k)y\| = |\beta_k e_k^T y|.$$

The number $|\beta_k e_k^T y|$ is called the *Ritz estimate* for this the Ritz pair (x, θ) as an approximate eigenpair for A. Observe that if (x, θ) is a Ritz pair then

$$\theta = y^H H_k y = (V_k y)^H A (V_k y) = x^H A x$$

is a Rayleigh Quotient (assuming $\|y\| = 1$) and the associated Rayleigh Quotient residual $r(x) = Ax - x\theta$ satisfies

$$\|r(x)\| = |\beta_k e_k^T y|.$$

When A is Hermitian, this relation may be used to provide computable rigorous bounds on the accuracy of the eigenvalues of H as approximations to eigenvalues of A (see [34]). When A is non-Hermitian the possibility of non-normality precludes such bounds and one can only say that the RQ-residual is small if $|\beta_k e_k^T y|$ is small. However, in either case, if

$f_k = 0$ these the Ritz pairs become exact eigenpairs of A.

This factorization may be advanced one step at the cost of a (sparse) matrix-vector product involving A and two dense matrix vector products involving V_k^T and V_k.

The explicit steps needed to form a k-Step Arnoldi Factorization are:

Algorithm 4: The k-Step Arnoldi Factorization

Input: (A, v)

Put $v_1 = v/\|v\|$; $w = Av_1$;$\alpha_1 = v_1^H w$;

Put $f_1 \leftarrow w - v_1\alpha_1$; $V \leftarrow (v_1)$; $H \leftarrow (\alpha_1)$;

For $j = 1, 2, 3, ...$k-1,

(a4.1) $\beta_j = \|f_j\|$; $v_{j+1} \leftarrow f_j/\beta_j$;

(a4.2) $V_{j+1} \leftarrow (V_j, v_{j+1})$; $\hat{H}_j \leftarrow \begin{pmatrix} H_j \\ \beta_j e_j^T \end{pmatrix}$;

(a4.3) $z \leftarrow Av_{j+1}$;

(a4.4) $h \leftarrow V_{j+1}^T z$; $f_{j+1} \leftarrow z - V_{j+1}h$;

(a4.5) $H_{j+1} \leftarrow (\hat{H}_j, h)$;

End_For

In exact arithmetic, the columns of V form an orthonormal basis for the Krylov subspace and H is the orthogonal projection of A onto this space. In finite precision arithmetic, care must be taken to assure that the computed vectors are orthogonal to working precision. The method proposed by Daniel, Gragg, Kaufman and Stewart (DGKS) in [9] provides an excellent way to construct a vector f_{j+1} that is numerically orthogonal to V_{j+1}. It amounts to computing a correction

$$s = V_{j+1}^T f_{j+1}; \quad f_{j+1} \leftarrow f_{j+1} - V_{j+1}s; \quad h \leftarrow h + s;$$

just after Step (a4.4) if necessary. A simple test can be devised to avoid this DGKS correction if it is not needed.

The dense matrix-vector products at Step (a4.4) and also the correction may be accomplished using Level 2 BLAS. This is quite important for performance on vector, and parallel-vector supercomputers. The BLAS operation _GEMV is easily parallelized and vectorized and has a much better ratio of floating point computation to data movement [10, 11]. The Modified Gram-Schmidt Process (MGS) is often used in the construction of Arnoldi factorizations. However, MGS will definitely not produce numerically orthogonal basis vectors in practice. Moreover, MGS cannot be formulated in terms of Level 2 BLAS unless all of the vectors to be orthogonalized are known in advance and this is not the case in the Arnoldi process. For these reasons, classical Gram-Schmidt orthogonalization with the DGKS correction step is highly recommended.

The information obtained through this process is completely determined by the choice of the starting vector. Eigen-information of interest may not appear until k gets very large.

In this case it becomes intractable to maintain numerical orthogonality of the basis vectors V_k. Moreover, extensive storage will be required and repeatedly finding the eigensystem of H will become prohibitive at a cost of $\mathcal{O}(k^3)$ flops.

Failure to maintain orthogonality leads to several numerical difficulties. In a certain sense, the computation (or approximation) of the projection indicated at Step (a4.4) in a way that overcomes these difficulties has been the main source of research activity in these Krylov subspace projection methods. The computational difficulty stems from the fact that $\|f_k\| = 0$ if and only if the columns of V_k span an invariant subspace of A. When V_k "nearly" spans such a subspace $\|f_k\|$ will be small. Typically, in this situation, a loss of significant digits will take place at Step (a4.4) through numerical cancellation unless special care is taken (i.e. use of the DGKS correction).

It is desirable for $\|f_k\|$ to become small because this indicates that the eigenvalues of H are accurate approximations to the eigenvalues of A. However, this "convergence" will indicate a probable loss of numerical orthogonality in V. Moreover, if subsequent Arnoldi vectors are not forced to be orthogonal to the converged ones then components along these directions re-enter the basis via round-off effects and quickly cause a spurious copy of the previously computed eigenvalue to appear repeatedly in the spectrum of the projected matrix H. The identification of this phenomenon in the symmetric case and the first rigorous numerical treatment is due to Paige [31]. There have been several approaches to overcome this problem in the symmetric case. They include: (1) complete re-orthogonalization, which may be accomplished through maintaining V in product Householder form [50, 17] or through the Modified Gram-Schmidt processes with re-orthogonalization [9]. (2) Selective re-orthogonalization, which has been proposed by Parlett and has been heavily researched by him and his students. Most notably, the theses and subsequent papers and computer codes of Scott and of Simon have developed this idea [34, 33, 43]. (3) No re-orthogonalization, which has been developed by Cullum and her colleagues. This last option introduces the almost certain possibility of introducing spurious eigenvalues. Various techniques have been developed to detect and deal with the presence of spurious eigenvalues [6, 8].

The appearance of spurious eigenvalues may be avoided through complete orthogonalization of the Arnoldi (or Lanczos) vectors using the DGKS correction. Computational cost has been cited as the reason for not employing this option . However, the cost will be reasonable if one is able to fix k at a modest size and then update the starting vector $v_1 = V_k e_1$ while repeatedly doing k-Arnoldi steps. This approach was introduced in [21] and developed further by [7] for the symmetric case. Saad [38, 39, 40] has developed explicit restarting for the nonsymmetric case. Restarting has proven to have important consequences for the development of numerical software based upon Arnoldi's method and this will be explored in the following section.

5 Restarting the Arnoldi Method

An unfortunate aspect of the Lanczos/Arnoldi process is that one cannot know in advance how many steps will be required before eigenvalues of interest are well approximated by Ritz

values. This is particularly true when the problem has a wide range of eigenvalues but the eigenvalues of interest are clustered. For example, in computational chemistry, problems are usually symmetric and positive definite and there is a wide range of eigenvalues varying over many orders of magnitude. Only the smallest eigenvalues are physically interesting and they are typically clustered at the low end of the spectrum. Shift and invert is usually not an option because of fill in from the factorizations. Without a spectral transformation, many Lanczos steps are required to obtain the smallest eigenvalues. In order to recover eigenvectors, one is obliged to store all of the Lanczos basis vectors (usually on a peripheral device) and to solve very large tridiagonal eigenvalue subproblems at each step. In the Arnoldi process that is used in the non-Hermitian case, not only do the basis vectors have to be stored, but the cost of the Hessenberg eigenvalue subproblem is $\mathcal{O}(k^3)$ at the k-th step.

5.1 EXPLICIT RESTARTING

An alternative has been proposed by Saad based upon the polynomial acceleration scheme developed by Manteuffel [28] for the iterative solution of linear systems. Saad [39] proposed to restart the iteration with a vector that has been preconditioned so that it is more nearly in a k-dimensional invariant subspace of interest. This preconditioning takes the form of a polynomial applied to the starting vector that is constructed to damp unwanted components from the eigenvector expansion. The resulting algorithm takes the form:

Algorithm 5: An Explicitly Restarted Arnoldi Method

Input: (A, v)

Put $v_1 = v/\|v\|$;

For $j = 1, 2, 3, \ldots$ until *convergence*

(a5.1) Compute an m-step Arnoldi factorization

$AV_m = V_m H_m + f_m e_m^T$ with $V_m e_1 = v_1$;

(a5.2) Compute $\sigma(H_m)$ and corresponding Ritz estimates

and halt if desired eigenvalues are well approximated.

(a5.3) Construct a polynomial ψ based upon $\sigma(H_m)$ to damp unwanted components.

(a5.4) $v_1 \leftarrow \psi(A)v_1$; $v_1 \leftarrow v_1/\|v_1\|$;

End_For

The construction of the polynomial at Step (a5.3) may be guided by *a priori* information about the spectrum of A or solely by information gleaned from $\sigma(H_m)$. A typical scheme is to sort the spectrum of H_m into two disjoint sets Ω_w and Ω_u, with $\sigma(H_m) = \Omega_w \cup \Omega_u$. The Ritz values in the set Ω_w are to be regarded as approximations to the "wanted" eigenvalues of A and an open convex set $\mathcal{C}_u$ containing Ω_u with $\Omega_w \cap \mathcal{C}_u = \emptyset$ is to be regarded as a region that approximately encloses the "unwanted" portion of the spectrum of A. The polynomial ψ is then constructed to be as small in magnitude as possible on $\mathcal{C}_u$ when normalized, for example, to take the value 1 at an element of Ω_w closest to $\partial\mathcal{C}_u$. Chebyshev polynomials

are appropriate when $\mathcal{C}_u$ is taken to be an ellipse and this was the original proposal of Saad when he adapted the Manteuffel idea to eigenvalue calculations. Another possibility explored by Saad has been to take $\mathcal{C}_u$ to be the convex hull of Ω_u and to construct the polynomial ψ that best approximates 0 on this set in the least squares sense. Both of these are based upon well known theory of polynomial approximation. The problem of constructing an optimal ellipse for this problem has been studied by Chatelin and Ho. The reader is referred to [5] for details of constructing these polynomials.

The reasoning behind this type of algorithm is that that if v_1 is a linear combination of precisely k eigenvectors of A then Arnoldi factorization terminates in k steps (i.e. $f_k = 0$). The columns of V_k will form an orthonormal basis for the invariant subspace spanned by those eigenvectors, and the Ritz values $\sigma(H_k)$ will be the corresponding eigenvalues of A. The update of the starting vector v_1 is designed to enhance the components of this vector in the directions of the wanted eigenvectors and damp its components in the unwanted directions. This effect is achieved at Step (a5.4) since

$$v_1 = \sum_{j=1}^{n} x_j \gamma_j \Rightarrow \psi(A)v_1 = \sum_{j=1}^{n} x_j \psi(\lambda_j)\gamma_j.$$

If the same polynomial were applied each time, then after M iterations, the j-th original expansion coefficient would be essentially attenuated by a factor

$$\left(\frac{\psi(\lambda_j)}{\psi(\lambda_1)}\right)^M ,$$

where the eigenvalues have been ordered according decreasing values $|\psi(\lambda_j))|$. The eigenvalues inside the region $\mathcal{C}_u$ become less and less significant as the iteration proceeds. Hence, the wanted eigenvalues are approximated increasingly well as the iteration proceeds.

Another restarting strategy proposed by Saad is to replace the starting vector with a linear combination of Ritz vectors corresponding to wanted Ritz values. If the eigenvalues and corresponding vectors are re-indexed so that the first k are wanted and $(\hat{x}_j, \theta_j)$ is the the Ritz pair approximating the eigenpair (x_j, λ_j) then

$$v_1^+ \leftarrow \sum_{j=1}^{k} \hat{x}_j \gamma_j \tag{4}$$

is taken as the new starting vector. Again, the motivation here is that the Arnoldi residual f_k would vanish if these k Ritz vectors were actually eigenvectors of A and the Ritz vectors are the best available approximations to these eigenvectors. A heuristic choice for the coefficients γ_j has also been suggested by Saad [38]. It is to weight the j-th Ritz vector with the value of its Ritz estimate and then normalize so that the new starting vector has norm 1. This has the effect of favoring the Ritz vectors that have least converged. Additional aspects of explicit restarting are developed thoroughly in Chapter VII of [40]. In any case, this restarting mechanism is actually polynomial restarting in disguise. Since $\hat{x}_j \in \mathcal{K}_m(A, v_1)$ implies $\hat{x}_j = \phi_j(A)v_1$ for some polynomial ϕ_j the formula for v_1^+ in (4) is

of the form

$$v_1^+ \leftarrow \phi(A)v_1 \equiv \sum_{j=1}^{k} \gamma_j \phi_j(A)v_1. \tag{5}$$

The technique just described is referred to as explicit (polynomial) restarting. When Chebyshev polynomials are used it is called an Arnoldi-Chebyshev method. The cost in terms of matrix-vector products $w \leftarrow Av$ is $M*(m+deg(\psi))$ for M major iterations. The cost of the arithmetic in the Arnoldi factorization is $M*(2n*m^2+O(m^3))$ Flops (floating point operations). Tradeoffs must be made in terms of cost of the Arnoldi factorization vs. cost of the matrix-vector products Av and also in terms of storage $(nm+O(m^2))$.

5.2 IMPLICIT RESTARTING

There is another approach to restarting that offers a more efficient and numerically stable formulation. This approach called *implicit restarting* is a technique for combining the implicitly shifted QR mechanism with a k-step Arnoldi or Lanczos factorization to obtain a truncated form of the implicitly shifted QR-iteration. The numerical difficulties and storage problems normally associated with Arnoldi and Lanczos processes are avoided. The algorithm is capable of computing a few (k) eigenvalues with user specified features such as largest real part or largest magnitude using $2nk+O(k^2)$storage. No auxiliary storage is required. The computed Schur basis vectors for the desired k-dimensional eigen-space are numerically orthogonal to working precision. This method is well suited to the development of mathematical software and this will be discussed in Section 7.

Implicit restarting provides a means to extract interesting information from very large Krylov subspaces while avoiding the storage and numerical difficulties associated with the standard approach. It does this by continually compressing the interesting information into a fixed size k-dimensional subspace. This is accomplished through the implicitly shifted QR mechanism. An Arnoldi factorization of length $m = k+p$

$$AV_m = V_m H_m + f_m e_m^T, \tag{6}$$

is compressed to a factorization of length k that retains the eigen-information of interest. This is accomplished using QR steps to apply p shifts implicitly. The first stage of this shift process results in

$$AV_m^+ = V_m^+ H_m^+ + f_m e_m^T Q, \tag{7}$$

where $V_m^+ = V_m Q$, $H_m^+ = Q^T H_m Q$, and $Q = Q_1 Q_2 \cdots Q_p$, with Q_j the orthogonal matrix associated with the shift μ_j. It may be shown that the first $k-1$ entries of the vector $e_m^T Q$ are zero (i.e. $e_m^T Q = (\sigma e_k^T, \hat{q}^T)$). Equating the first k columns on both sides yields an updated $k-$step Arnoldi factorization

$$AV_k^+ = V_k^+ H_k^+ + f_k^+ e_k^T, \tag{8}$$

with an updated residual of the form $f_k^+ = V_{k+p}^+ e_{k+1}\hat{\beta}_k + f_{k+p}\sigma$. Using this as a starting point it is possible to apply p additional steps of the Arnoldi process to return to the original m-step form.

Each of these shift cycles results in the implicit application of a polynomial in A of degree p to the starting vector.

$$v_1 \leftarrow \psi(A)v_1 \quad \text{with} \quad \psi(\lambda) = \prod_1^p (\lambda - \mu_j).$$

The roots of this polynomial are the shifts used in the QR process and these may be selected to filter unwanted information from the starting vector and hence from the Arnoldi factorization. Full details may be found in [44]. The basic iteration is given here in Algorithm 6 and the diagrams in Figures 1-3 describe how this iteration proceeds schematically. In Algorithm 6 and in the discussion below, the notation $M_{(1:n,1:k)}$ denotes the leading $n \times k$ submatrix of M.

Algorithm 6: An Implicitly Restarted Arnoldi Method

Input: (A, V, H, f) with $AV_m = V_m H_m + f_m e_m^T$, an m-Step Arnoldi Factorization;

For $\ell = 1, 2, 3, \ldots$ until *convergence*

(a6.2) Compute $\sigma(H_m)$ and select set of p shifts $\mu_1, \mu_2, \ldots \mu_p$
based upon $\sigma(H_m)$ or perhaps other information;

(a6.3) $q^T \leftarrow e_m^T$;

(a6.4) For $j = 1, 2, \ldots, p$,
Factor $[Q_j, R_j] = \mathrm{qr}(H_m - \mu_j I)$;
$H_m \leftarrow Q_j^H H_m Q_j$; $V_m \leftarrow V_m Q_j$;
$q \leftarrow q^H Q_j$;
End_For

(a6.5) $f_k \leftarrow v_{k+1}\hat{\beta}_k + f_m \sigma_k$; $V_k \leftarrow V_{m(1:n,1:k)}$; $H_k \leftarrow H_{m(1:k,1:k)}$;

(a6.6) Beginning with the k-step Arnoldi factorization
$AV_k = V_k H_k + f_k e_k^T$,
apply p additional steps of the Arnoldi process
to obtain a new m-step Arnoldi factorization
$AV_m = V_m H_m + f_m e_m^T$.

End_For

The diagrams in Figures 1-3 indicate how this iteration proceeds schematically.

Observe that if $m = n$ then $f = 0$ and this iteration is precisely the same as the Implicitly Shifted QR iteration. Even for $m < n$, the first k columns of V and the Hessenberg submatrix $H_{(1:k,1:k)}$ are mathematically equivalent to the matrices that would appear in the full Implicitly Shifted QR iteration using the same shifts μ_j. In this sense, the Implicitly Restarted Arnoldi method may be viewed as a truncation of the Implicitly Shifted QR iteration. The fundamental difference is that the standard Implicitly Shifted QR iteration selects shifts to drive subdiagonal elements of H to zero from the bottom up while the shift selection in the Implicitly Restarted Arnoldi method is made to drive subdiagonal

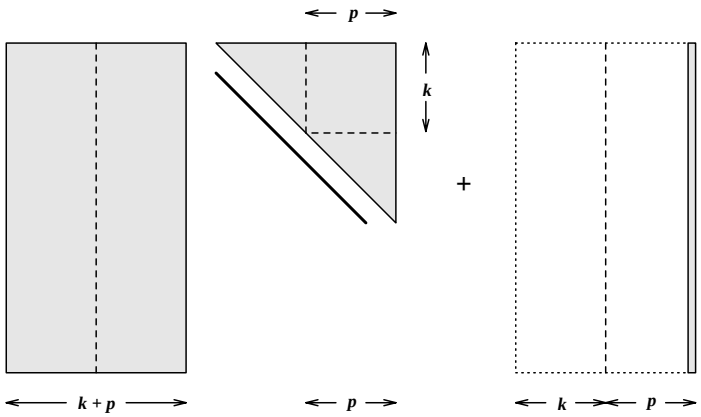

Figure 1: Representation of $V_{k+p}H_{k+p} + f_{k+p}e_{k+p}^T$. Shaded regions denote nonzeros.

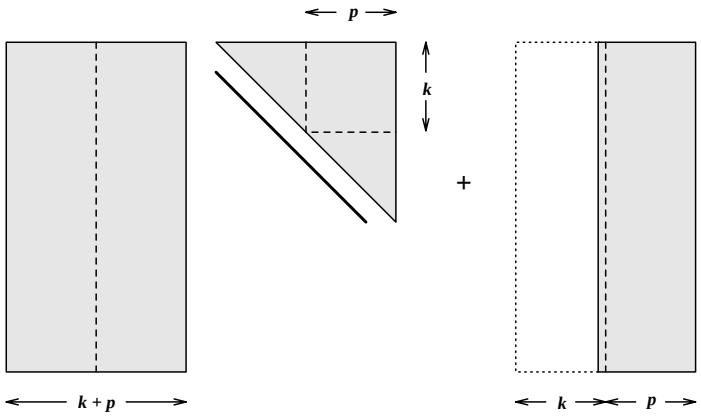

Figure 2: $V_{k+p}QQ^TH_{k+p}Q + f_{k+p}e_{k+p}^TQ$ after p implicitly shifted QR steps.

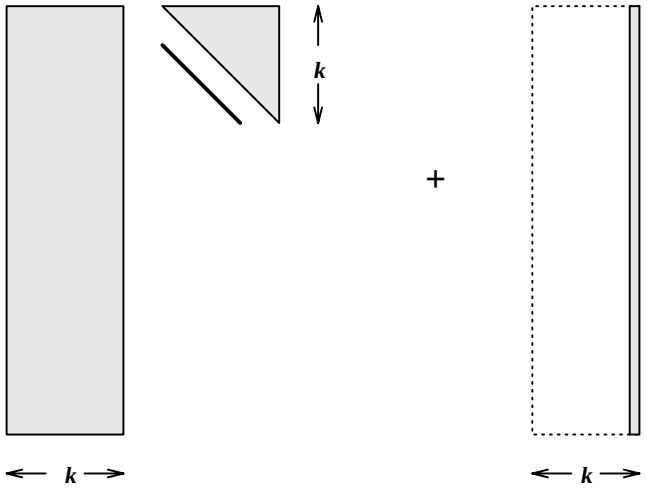

Figure 3: Leading k columns $V_kH_k + f_ke_k^T$ form a length k Arnoldi factorization after discarding the last p columns.

elements of H to zero from the top down. Important implementation details concerning the deflation (setting to zero) of subdiagonal elements of H and the purging of unwanted but converged Ritz values are beyond the scope of this discussion. However, these details are extremely important to the success of this iteration in difficult cases. Complete details of these numerical refinements may be found in [26, 24]

The above iteration can be used to apply any known polynomial restart. If the roots of the polynomial are not known there is an alternative implementation that only requires one to compute $q_1 = \psi(H)e_1$ where ψ is the desired degree p polynomial. A sequence of Householder transformations may developed to form a unitary matrix Q such that $Qe_1 = q_1$ and $H \leftarrow Q^H H Q$ is upper Hessenberg. The details which follow standard developments for the Implicitly Shifted QR iteration will be omitted here.

A shift selection strategy that has proved successful in practice is called the "Exact Shift Strategy". In this strategy, one computes $\sigma(H)$ and sorts this into two disjoint sets Ω_w and Ω_u. The k Ritz values in the set Ω_w are regarded as approximations to the "wanted" eigenvalues of A , and the p Ritz values in the set Ω_u are taken as the shifts μ_j. An interesting consequence (in exact arithmetic) is that after Step (a6.4) above, the spectrum of H_k in Step (a6.5) is $\sigma(H_k) = \Omega_w$ and the updated starting vector v_1 is a particular linear combination of the k Ritz vectors associated with these Ritz values. In other words, the implicit restarting scheme with exact shifts provides a specific selection of the coefficients γ_j in the formula (4) and this implicit scheme costs p rather than the $k+p$ matrix-vector products the explicit scheme would require. Thus the exact shift strategy can be viewed both as a means to damp unwanted components from the starting vector and also as directly forcing the starting vector to be a linear combination of wanted eigenvectors. The exact shift strategy has two additional interesting theoretical properties.

Lemma 5.1 *If H is unreduced and diagonalizable then:*

1. *The polynomial ϕ in (5) satisfies $\phi(\lambda) = \psi(\lambda)\rho(\lambda)$, where ψ is the exact shift polynomial and ρ is some polynomial of degree at most $k-1$.*

2. *The updated Krylov subspace generated by the new starting vector satisfies*
   $\mathcal{K}_m(A, v_1^+) = Span\{\hat{x}_1, \hat{x}_2, \cdots, \hat{x}_k, A\hat{x}_j, A^2\hat{x}_j, \cdots, A^p\hat{x}_j\}$
   for $j = 1, 2, \cdots, k$.

The first property $\phi(\lambda) = \psi(\lambda)\rho(\lambda)$ indicates that the linear combination selected by the exact shift scheme is somehow minimal while the second property indicates that each of the subspaces $\mathcal{K}_p(A, \hat{x}_j) \subset \mathcal{K}_m(A, v_1^+)$ so that each sequence of "wanted" Ritz vectors is represented equally in the updated subspace. The first property was established in [24] along with an extensive analysis of the numerical properties of implicit restarting. The surprising second property was established by Morgan in [30] along with some compelling numerical results indicating superior performance of implicit over explicit restarting.

6 The Generalized Eigenvalue Problem

A typical source of large scale eigenproblems is through a discrete form of a continuous problem. The resulting finite dimensional problems become large due to accuracy requirements and spatial dimensionality. Typically this takes the form

$$\begin{aligned} \mathcal{L}u &= u\lambda \text{ in } \Omega, \\ u &\text{ satisfies } \mathcal{B} \text{ on } \partial\Omega, \end{aligned} \tag{9}$$

where $\mathcal{L}$ is some linear differential operator. A number of techniques may be used to discretize $\mathcal{L}$. The finite element method provides an elegant discretization. If $\mathcal{W}$ is a space of functions in which the solution to (9) may be found and $\mathcal{W}_n \subset \mathcal{W}$ is an n-dimensional subspace with basis functions $\{\phi_j\}$ then an approximate solution u_n is expanded in the form

$$u_n = \sum_{j=1}^{n} \phi_j \xi_j.$$

A variational or a Galerkin principle is applied depending on whether or not $\mathcal{L}$ is self-adjoint, leading to a weak form of (9)

$$\mathcal{A}(v,u) = \lambda < v, u >, \tag{10}$$

where $\mathcal{A}(v,u)$ is a bilinear form. Substituting the expanded form of $u = u_n$ and requiring (10) to hold for each trial function $v = \phi_i$ gives a set of algebraic equations

$$\mathcal{A}(\phi_i, \sum_{j=1}^{n} \phi_j \xi_j) = \lambda < \phi_i, \sum_{j=1}^{n} \phi_j \xi_j >,$$

where $< \cdot, \cdot >$ is an inner product in $\mathcal{W}_n$. This leads to the following systems of equations

$$\sum_{j=1}^{n} \mathcal{A}(\phi_i, \phi_j)\xi_j = \lambda \sum_{j=1}^{n} < \phi_i, \phi_j > \xi_j, \tag{11}$$

for $1 \le i \le n$. We may rewrite (11) and obtain the matrix equation

$$Ax = \lambda M x,$$

where

$$A_{i,j} = \mathcal{A}(\phi_i, \phi_j), \quad M_{i,j} =< \phi_i, \phi_j >, \quad x^T = [\xi_1, \ldots, \xi_n]^T,$$

for $1 \le i, j \le n$. Typically the basis functions are chosen so that few entries in a row of A or M are nonzero. In structures problems A is called the "stiffness" matrix and M is called the "mass" matrix. In chemistry and physics M is often referred to as the "overlap" matrix. A nice feature of this approach to discretization is that boundary conditions are naturally incorporated into the discrete problem. Moreover, in the self-adjoint case, the Rayleigh principle is preserved from the continuous to the discrete problem. In particular, since Ritz values are Rayleigh quotients, this assures the smallest Ritz value is greater than the smallest eigenvalue of the original problem.

Thus, it is natural for large scale eigenproblems to arise as generalized rather than standard problems. If $\mathcal{L}$ is self-adjoint the discrete problems are symmetric or Hermitian and if not the matrix A is nonsymmetric but the matrix M is symmetric and at least positive

semi-definite. There are a number of ways to convert the generalized problem to standard form. There is always motivation to preserve symmetry when it is present.

If M is positive definite then factor $M = LL^T$ and the eigenvalues of $\hat{A} \equiv L^{-1}AL^{-T}$ are the eigenvalues of (A, M) and the eigenvectors are obtained by solving $L^T x = \hat{x}$ where $\hat{x}$ is an eigenvector of $\hat{A}$. This standard transformation is fine if one wants the eigenvalues of largest magnitude and it preserves symmetry if A is symmetric. However, when M is ill-conditioned this can be a dangerous transformation leading to numerical difficulties. Since a matrix factorization will have to be done anyway, one may as well formulate a spectral transformation.

6.1 STRUCTURE OF THE SPECTRAL TRANSFORMATION

A convenient way to provide a spectral transformation is to note that

$$Ax = \lambda Mx \iff (A - \mu M)x = (\lambda - \mu)Mx$$

Thus

$$(A - \mu M)^{-1}Mx = x\theta, \quad \text{where} \quad \theta = \frac{1}{\lambda - \mu}.$$

If A is symmetric then one can maintain symmetry in the Arnoldi/Lanczos process by taking the inner product to be

$$< x, y >= x^T My.$$

It is easy to verify that the operator $(A - \mu M)^{-1}M$ is symmetric with respect to this inner product if A is symmetric. In the Arnoldi/Lanczos process the matrix-vector product $w \leftarrow Av$ is replaced by $w \leftarrow (A - \mu M)^{-1}Mv$ and the step $h \leftarrow V^T f$ is replaced by $h \leftarrow V^T(Mf)$. If A is symmetric then the matrix H is symmetric and tridiagonal. Moreover, this process is well defined even when M is singular and this can have important consequences even if A is nonsymmetric. We shall refer to this process as the M-Arnoldi process.

If M is singular then the operator $S \equiv (A - \mu M)^{-1}M$ has a non-trivial null space and the bilinear function $< x, y >= x^T My$ is a semi-inner product and $\|x\|_M \equiv < x, y >^{1/2}$ is a semi-norm. Since $(A - \mu M)$ is assumed to be nonsingular, $\mathcal{N} \equiv Null(S) = Null(M)$. Vectors in $\mathcal{N}$ are generalized eigenvectors corresponding to *infinite* eigenvalues. Typically, one is only interested in the finite eigenvalues of (A, M) and these will correspond to the non-zero eigenvalues of S. The invariant subspace corresponding to these non-zero eigenvalues is easily corrupted by components of vectors from $\mathcal{N}$ during the Arnoldi process. However, using the M-Arnoldi process with some refinements can provide a solution.

In order to better understand the situation, it is convenient to note that since M is positive semi-definite, there is an orthogonal matrix Q such that

$$M = Q \begin{bmatrix} D & 0 \\ 0 & 0 \end{bmatrix} Q^T$$

where D is a positive definite diagonal matrix of order n, say. Thus

$$\hat{S} \equiv Q^T S Q = \begin{bmatrix} S_1 & 0 \\ S_2 & 0 \end{bmatrix},$$

where S_1 is a square matrix of order n and S_2 is an $m \times n$ matrix with the original A, M being of order $m+n$. Observe now that a non-zero eigenvalue λ of $\hat{S}$ satisfies $\hat{S}x = x\lambda$, i.e.

$$\begin{bmatrix} S_1 x_1 \\ S_2 x_1 \end{bmatrix} = \begin{bmatrix} x_1 \lambda \\ x_2 \lambda \end{bmatrix}$$

so that $x_2 = \frac{1}{\lambda} S_2 x_1$ must hold. Note also that for any eigenvector $x^H = (x_1^H, x_2^H)$, the leading vector x_1 must be an eigenvector of S_1. Since $\hat{S}$ is block triangular, $\sigma(\hat{S}) = \sigma(S_1) \cup \sigma(0_m)$. Assuming S_2 has full rank, it follows that if S_1 has a zero eigenvalue then there is no corresponding eigenvector (since $S_2 x_1 = 0$ would be implied). Thus if zero is an eigenvalue of S_1 with algebraic multiplicity m_o then zero is an eigenvalue of $\hat{S}$ of algebraic multiplicity $m + m_o$ and with geometric multiplicity m. Of course, since, S is similar to $\hat{S}$ all of these statements hold for S as well.

6.2 EIGENVECTOR/NULL-SPACE PURIFICATION

With these observations in hand, it is possible to see the virtue of using M-Arnoldi on S. After k-steps of M-Arnoldi,

$$SV = VH + fe_k^T \quad \text{with} \quad V^T M V = I_k, V^T M f = 0.$$

Introducing the similarity transformation Q gives

$$\hat{S}\hat{V} = \hat{V}H + \hat{f}e_k^T \quad \text{with} \quad \hat{V}^T Q^T M Q \hat{V} = I_k, V^T Q^T M Q \hat{f} = 0,$$

where $\hat{V} = Q^T V$ and $\hat{f} = Q^T f$. Partitioning $\hat{V}^T = (V_1^T V_2^T)$ and $\hat{f}^T = (f_1^T, f_2^T)$ consistent with the blocking of $\hat{S}$ gives

$$S_1 V_1 = V_1 H + f_1 e_k^T \quad \text{with} \quad V_1^T D V_1 = I_k, V_1^T D f_1 = 0.$$

Moreover, the side condition $S_2 V_1 = V_2 H + f_2 e_k^T$ holds, so that in exact arithmetic a zero eigenvalue should not appear as a converged Ritz value of H. This argument shows that M-Arnoldi on S is at the same time doing D-Arnoldi on S_1 while avoiding convergence to zero eigenvalues.

Round-off error due to finite precision arithmetic will cloud the situation, as usual. It is clear that the goal is to prevent components in $\mathcal{N}$ from corrupting the vectors V Thus to begin, the starting vector v_1 should be of the form $v_1 = Sv$. If a final approximate eigenvector x has components in $\mathcal{N}$ they may be purged by replacing $x \leftarrow Sx$ and then normalizing. To see the effect of this, note that if $x = Q \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$

$$Sx = Q \begin{bmatrix} S_1 x_1 \\ S_2 x_1 \end{bmatrix}$$

and all components in $\mathcal{N}$ which are of the form $Q \begin{bmatrix} 0 \\ p \end{bmatrix}$ will have been purged. This final application of S may be done implicitly in two ways. One is to note that if $x = Vy$ with $Hy = y\theta$ then $Sx = VHy + fe_k^T y = x\theta + fe_k^T y$ and this is the correction suggested by [32]. Another recent suggestion due to Meerbergen and Spence is to use implicit restarting with a zero shift [29]. Recall that implicit restarting with ℓ zero shifts is equivalent to starting the M-Arnoldi process with a starting vector of $S^\ell v_1$ and all the resulting Ritz vectors will be multiplied by S^ℓ as well. After applying the implicit shifts to H, the leading submatrix of order $k - \ell$ will provide the updated Ritz values. No additional explicit matrix-vector products with S are required.

The ability to apply ℓ zero shifts (i.e. to multiply by S^ℓ implicitly) is very important when S_1 has zero eigenvalues. If $S_1 x_1 = 0$ then

$$\begin{bmatrix} S_1 & 0 \\ S_2 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} 0 \\ S_2 x_1 \end{bmatrix} \in \mathcal{N}.$$

Thus to completely eradicate components from $\mathcal{N}$ one must multiply by S^ℓ where ℓ is equal to the dimension of the largest Jordan block corresponding to a zero eigenvalue of S_1.

Spectral transformations were studied extensively by Ericsson and Ruhe [14] and the first eigenvector purification strategy was developed in [32]. Shift and invert techniques play an essential role in the block Lanczos code developed by Grimes, Lewis, and Simon. The many nuances of this technique in practical applications is discussed thoroughly in [19]. The development presented here and the eigenvector purification through implicit restarting is due to Meerbergen and Spence [29].

6.3 AN EXAMPLE

This discussion is illustrated with the following example.

$$A = \begin{bmatrix} K & C \\ C^T & 0 \end{bmatrix} \quad \text{and} \quad M = \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix},$$

with A an order 225 matrix approximation to a convection-diffusion operator and C a structured random matrix. This example was chosen because it has the block structure of a typical steady-state Navier-Stokes linear stability analysis (see [29]). The following MATLAB code was used to generate the example:

```
rand('seed',0);
n = 225;m=100;
K = lapc(n,100);
C = [rand(m,m) ; zeros(n-m,m)];
M = [eye(n) zeros(n,m) ; zeros(m,n) zeros(m,m)];
A = [K C ; C' zeros(m,m)];
mu = 7.0;
S = (A - mu*M)\M;
```

$\|P_{\mathcal{N}}V\|$	$\|P_{\mathcal{N}}V^+\|$	$\|P_{\mathcal{G}}V\|$	$\|P_{\mathcal{G}}V^+\|$
3.70	1.48(-11)	1.32(-11)	2.85(-12)

Table 1: Projection of V onto $\mathcal{N}$ and $\mathcal{G}$

j	$\|Ax_j - Mx_j\lambda_j\|$	$\|(Ax_j - Mx_j\lambda_j)^+\|$
1	1.50(-03)	9.93(-06)
2	1.11(-02)	6.77(-05)

Table 2: Residuals before and after purging components from $\mathcal{N}$ and $\mathcal{G}$

The matrices `K, C, M, A` correspond to the matrices in the equations above. The funcion `lapc` computes a finite difference approximation to $\Delta u + \rho u_x$ on a 15×15 regular grid in the unit square with $\rho = 100$. Any matrix pencil (A, M) with this block structure (assuming C full rank and $A - \mu * M$ nonsingular) will produce an S of the form

$$S = \begin{bmatrix} 0 & 0 & 0 \\ 0 & S_{22} & 0 \\ S_{31} & S_{32} & 0 \end{bmatrix},$$

with S_{22} nonsingular and order $n - m$. From the above discussion one may conclude that S has an eigenvalue 0 with algebraic multiplicity $2m$ and geometric multiplicity m. There are three important subspaces associated with S. They are $\mathcal{N}$, $\mathcal{G}$ and $\mathcal{R}$ and these spaces satisfy

$$S\mathcal{N} = \{0\} \quad , \quad S\mathcal{G} \subset \mathcal{N} \quad , \quad S\mathcal{R} \subset \mathcal{R}.$$

All of $\mathbf{C}^n$ may be represented as a direct sum of these three spaces. The (oblique) projectors associated with these spaces shall be denoted by $P_{\mathcal{N}}$, $P_{\mathcal{G}}$, and $P_{\mathcal{R}}$ respectively. Explicit formulas are:

$$P_{\mathcal{N}} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & -S_{32}S_{22}^{-1} & I \end{bmatrix} \quad P_{\mathcal{G}} = \begin{bmatrix} I & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad P_{\mathcal{R}} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & S_{22} & \\ S_{31} & S_{32} & 0 \end{bmatrix}$$

The following table shows the norms of the projections of the basis vectors V onto the spaces $\mathcal{N}$ and $\mathcal{G}$ where V was computed with 20 steps of M-Arnoldi starting with a vector $v_1 = Sv$ (v a vector with all entries equal to 1) . The norms of the projections are taken before and after purging by applying two zero shifts using implicit restarting. The + symbol denotes the updated basis after purging.

The next table shows the residual norms for the two approximate eigenvalues that are closest to the shift μ before and after purging.

Clearly, there is considerable merit to doing this purging. This generalizes the purging proposed by [32] and seems to be quite promising. Further testing is needed but some form of this process is essential to the construction of numerical software to implement shift-invert strategies.

7 SOFTWARE, PERFORMANCE, and PARALLEL COMPUTATION

The Implicitly Restarted Arnoldi Method has been implemented and a package of Fortran 77 subroutines has been developed. This software, called ARPACK [27], provides several features which are not present in other codes based upon a single-vector Arnoldi process. One of the most important features from the software standpoint is the reverse communication interface. This feature provides a convenient way to interface with application codes without imposing a structure on the users matrix or the way a matrix-vector product is accomplished. In the parallel setting, this reverse communication interface enables efficient memory and communication management for massively parallel MIMD and SIMD machines. The important features of ARPACK are:

- A reverse communication interface.
- Ability to return k eigenvalues which satisfy a user specified criterion such as largest real part, largest absolute value, largest algebraic value (symmetric case), etc.
- A fixed pre-determined storage requirement suffices throughout the computation. Usually this is $n*O(2k)+O(k^2)$ where k is the number of eigenvalues to be computed and n is the order of the matrix. No auxiliary storage or interaction with such devices is required during the course of the computation.
- Eigenvectors may be computed on request. The Arnoldi basis of dimension k is always computed. The Arnoldi basis consists of vectors which are numerically orthogonal to working accuracy. Computed eigenvectors of symmetric matrices are also numerically orthogonal.
- The numerical accuracy of the computed eigenvalues and vectors is user specified. Residual tolerances may be set to the level of working precision. At working precision, the accuracy of the computed eigenvalues and vectors is consistent with the accuracy expected of a dense method such as the implicitly shifted QR iteration.
- Multiple eigenvalues offer no theoretical or computational difficulty other than additional matrix-vector products required to expose the multiple instances. This is made possible through the implementation of deflation techniques similar to those employed to make the implicitly shifted QR-algorithm robust and practical. A block method is not required and hence one does not need to "guess" the correct blocksize that would be needed to capture multiple eigenvalues.

7.1 REVERSE COMMUNICATION INTERFACE

As mentioned above, the reverse communication interface is one of the most important aspects of the design of ARPACK. In the serial code, a typical usage of this interface is illustrated with the following example:

```
10  continue
    call snaupd (ido, bmat, n, which,...,V,...,lworkl, info)
```

```
if (ido .eq. newprod) then
   call matvec ('A', n, workd(ipntr(1)), workd(ipntr(2)))
else
   return
endif
go to 10
```

As usual, with reverse communication, control is returned to the calling program when interaction with the matrix A is required. The action requested of the calling program is to simply perform the action indicated by the reverse communication parameter `ido` (in this case multiply the vector held in the array `workd` beginning at location `ipntr(1)` and put the result in the array `workd` beginning at location `ipntr(2)`). Note that call to the subroutine `matvec` in this code segment is simply meant to indicate that this matrix-vector operation is taking place. The user is free to use any available mechanism or subroutine to accomplish this task. In particular, no specific data structure is imposed and indeed, no explicit representation of the matrix is even required. One only needs to supply the action of the matrix on the specified vector.

There are several reasons for supplying this interface. It is more convenient to use with large application codes. The alternative is to put the user supplied matrix-vector product in a subroutine with a pre-specified calling sequence. This may be quite cumbersome and is especially so in those cases where the action of the matrix on a vector is known only through a lengthy computation that doesn't involve the matrix A explicitly. Typically, if the matrix-vector product must be provided in the form of a subroutine with a fixed calling sequence, then named `common` or some other means must be used to pass data to the routine. This is incompatible with efficient memory management for massively parallel MIMD and SIMD machines.

This has been implemented on a number of parallel machines including the CRAY-C90, Thinking Machines CM-200 and CM-5, Intel Delta, and CRAY T3D. Parallel performance on the C90 is obtained through the BLAS operations without any modification to the serial code. SIMD performance on the CM-200 is also relatively straightforward. All of the BLAS operations were expressed using Fortran 90 array constructs and hence were automatically compiled for execution on the SIMD array instead of the frontend. Operations on the projected matrix H were not encoded with these array constructs and hence were automatically scheduled for the frontend. The only additional complication was to define the data layouts of the V array and the work arrays for efficient execution. In the distributed memory implementations, the reverse communication interface provided a natural way to parallelize the ARPACK codes internally without imposing a fixed parallel decomposition on the user supplied matrix-vector product.

7.2 DATA DISTRIBUTION AND GLOBAL OPERATIONS

The parallelization strategy for distributed memory machines consists of providing the user with an Single Program Multiple Data (SPMD) template. The array V is blocked and distributed across the processors. The projected matrix H is replicated. The SPMD

program looks essentially like the serial code except that the local block `Vloc` is passed in place of V. The work space is partitioned consistently with the partition of V and each section of the work space is distributed to the node processors. Thus the SPMD parallel code looks very similar to that of the serial code. Assuming a parallel version of the subroutine matvec, an example of the application of the distributed interface is illustrated as the follows:

```
10  continue
    call snaupd (ido, bmat, nloc, which, ...,
   *                      Vloc , ... lworkl, info)
    if (ido .eq. newprod) then
       call matvec ('A', nloc,workd(ipntr(1)), workd(ipntr(2)))
    else
       return
    endif
    go to 10
```

Where, `nloc` is the number of rows in the block `Vloc` of V that has been assigned to this node process.

Typically, the blocking of V is commensurate with the parallel decomposition of the matrix A as well as with the configuration of the distributed memory and interconnection network. Logically, the V matrix be partitioned by blocks

$$V^T = ({V^{(1)}}^T, {V^{(2)}}^T, ..., {V^{(nproc)}}^T)$$

with one block per processor and with H replicated on each processor.

The explicit steps of the process responsible for the j block are:

1. $\beta_k = gnorm(f_k^{(*)})$; $v_{k+1}^{(j)} \leftarrow f_k^{(j)}/\beta$;
2. $V_{k+1}^{(j)} \leftarrow (V_k, v_{k+1})^{(j)}$; $\hat{H}_k \leftarrow \begin{pmatrix} H_k \\ \beta_k e_k^T \end{pmatrix}$.
3. $z \leftarrow (Aloc)v_{k+1}$;
4. $h^{(j)} \leftarrow {V_k^{(j)}}^T z$; $h \leftarrow gsum(h^{(*)})$ $f_{k+1} \leftarrow z - V_{k+1}h$;
5. $H_{k+1} \leftarrow (\hat{H}_k, h)$;

Note that the function $gnorm$ at Step 1 is meant to represent the global reduction operation of computing the norm of the distributed vector f_k from the norms of the local segments $f_k^{(j)}$ and the function $gsum$ at Step 4 is meant to represent the global sum of the local vectors $h^{(j)}$ so that the quantity $h = \sum_{j=1}^{nproc} h^{(j)}$ is available to each process on completion. These are the only two communication points within this algorithm. The remainder is perfectly parallel. Additional communication will typically occur at Step 3. Here the operation $(Aloc)v$ is meant to indicate that the user supplied matrix-vector product is able to compute the local segment of the matrix-vector product Av that is consistent with the

partition of V. Ideally, this would only involve nearest neighbor communication among the processes.

Since H is replicated on each processor, the parallelization of the implicit restart mechanism described by Algorithm(6) remains untouched. The only difference is that the local block $V^{(j)}$ is in place of the full matrix V. All operations on the matrix H are replicated on each processor. Thus there is no communication overhead but there is a "serial bottleneck" here due to the redundant work. If k is small relative to n this bottleneck is insignificant. However, it becomes a very important latency issue as k grows and will prevent scalabilty if k grows with n as the problem size increases.

The main benefit of this approach is that the changes to the serial version of ARPACK are very minimal. Since the change of dimension from matrix order n to its local distributed blocksize `nloc` is invoked through the calling sequence of the subroutine `snaupd`, there is no essential change to the code. Only six routines were effected in a minimal way. These routines either required a change in norm calculation for distributed vectors (Step 1) or for the distributed dense matrix-vector product (Step 4). Since the vectors are distributed, norms had to be done via partial (scaled) dot products for the local vector segments and then a global sum operation was used to complete the sum of the squared norms of these segments on all processors. More specifically, the commands are changed from

```
   rnorm = sdot (n, resid, 1, workd, 1)
   rnorm = sqrt(abs(rnorm))
```

to

```
   rnorm0 = sdot (n, resid, 1, workd, 1)
   call gssum(rnorm0,1,tmp)
   rnorm0 = sqrt(abs(rnorm0))
   rnorm  = rnorm0
```

Similarly, the computation of the matrix-vector product operation $h \leftarrow V^T w$ requires a change from

```
   call sgemv ('T', n, j, one, v, ldv, workd(ipj), 1,
  *            zero, h(1,j), 1)
```

to

```
   call sgemv ('T', n, j, one, v, ldv, workd(ipj), 1,
  *            zero, h(1,j), 1)
   call gssum(h(1,j),j,h(1,j+1))
```

so the global sum operation `gssum` was sufficient to implement all of the global operations.

7.3 DISTRIBUTED MEMORY PARALLEL PERFORMANCE

To get an idea of the potential performance of ARPACK on distributed memory machines some examples have been run on the Intel Touchstone DELTA. The examples involved have been designed to test the performance of the software, the matrix structure and the

Touchstone DELTA machine architecture, and the speedup behavior of the software on DELTA.

The user's implementation of the matrix-vector product $w \leftarrow Av$ can have considerable effect upon the parallel performance. Moreover, there is a fundamental difficulty in testing how the performance scales as the problem size increases. The difficulty is that the problem often becomes increasingly difficult to solve as the size increases due to clustering of eigenvalues. The tests reported here attempt to isolate and measure the performance of the parallelization of the ARPACK routines independently of the matrix-vector product.

In order to isolate the performance of the ARPACK routines from the performance of the user's matrix-vector product and also to isolate effects of a changing problem characteristics as the size increases, a test was comprised of replicating the same matrix repeatedly to obtain a block diagonal matrix. Each diagonal block corresponded to a corresponding block of the partitioned and distributed matrix V. This is, of course, a completely contrived situation that allows the workload to increase linearly with the number of processors. Since the each diagonal block of the matrix is identical the algorithm should behave as if $nproc$ identical problems are being solved simultaneously as long as the initial distributed segments of v_1 are generated the same. Thus, the only things that could prevent ideal speedup are the communication involved in the global operations and the "serial bottleneck" associated with the replicated operations on the projected matrix H. If neither of these were present then one would expect the execution time to remain constant as the problem size and the number of processors increase.

In this first example, each diagonal block is of order 3,000 which is identical to the vector segment size on each node. The matrix-vector product operation $z^{(j)} \leftarrow (Aloc)v_{k+1}^{(j)}$ is executed locally on each node processor upon the distributed vector segments $v_{k+1}^{(j)}$, and there is no communication among processors involved in this operation. As described above, the problem size in increased linearly with the the number of processors by adjoining an additional identical diagonal block to the A matrix for each additional processor. The global sum operation `gssum` is essentially a ring algorithm and thus has a linear dependence with respect to the number of nodes. Since the diagonal blocks are identical, the replicated operations on H should remain the same as the problem size increases and hence linear speed up is expected, i.e. as the problem size increases the execution time should remain constant. This ideal speedup is very nearly achieved as is clearly reflected in Table 3.

The second example is obtained from the similar numerical model of the eigenproblem of the Laplacian operator defined on the unit square with square with Dirichlet boundary conditions on three sides and a Neuman boundary condition on the fourth side. This leads to a mildly nonsymmetric matrix with the same 5-diagonal structure as the standard 2-D discrete Laplacian on a 5 point stencil. The unit square $\{(x, y)|0 \leq x, y \leq 1\}$ was discretized with x-direction mesh size and y-direction mesh size $1/(n+1)$ and $1/(m+1)$, respectively. Thus the matrix A is block tridiagonal and of order $N = nm$. The order of each diagonal block is n, and the number of diagonal blocks is m.

A natural way to carry out the matrix-vector product operation $w \leftarrow Av$ is described as the follows. A standard domain decomposition partitioning of the unit square into sub-

Problem size	Number of nodes	Total Time (s)
3000*1	1	22.96
3000*2	2	23.22
3000*4	4	23.98
3000*8	8	24.08
3000*16	16	24.39
3000*32	32	24.95
3000*64	64	25.50
3000*128	128	27.13
3000*256	256	28.65

Table 3: Parallel ARPACK test on DELTA, matrix order 3,000 on each node

Problem size	Number of nodes	Total Time (s)
2500*1	1	19.63
2500*2	2	20.71
2500*4	4	21.97
2500*8	8	22.47
2500*16	16	22.50
2500*32	32	23.13
2500*64	64	23.68
2500*128	128	24.78
2500*256	256	28.16

Table 4: Parallel ARPACK test on DELTA, matrix order 2,500 on each node

rectangles leads to a parallel matrix-vector product that only exchanges boundary data across the boundaries of the sub-domains and hence only needs nearest neighbor connections. The subdomains are naturally chosen so that the blocking of the matrix is commensurate with the blocking and distribution of the V array. The reverse communication interface allows the user supplied matrix-vector product to take advantage of the matrix structure. Simple send and receive operations using the native Intel *isend* and *irecv* were used to carry out the nearest neighbor communication operation.

The results of these tests are given in Table 4 and demonstrate nearly the same speedup as to Table 3. The relatively minor communication to receive boundary data from nearest neighbors effected the speedup properties somewhat.

The final example shows how dramatically an inefficient matrix-vector product operation $w \leftarrow Av$ and also how problem size can effect performance. A naive way to perform the matrix-vector product would be to collect the segments of the vector v from all nodes before the operation, and then distribute the segments of the result vector w to each node after the operation. The performance of this scheme is shown in Table 5. No advantage of the matrix structure was taken in computing the matrix-vector product. The matrix size was fixed at

Nodes	Time (s)	Iters.	Ave. $\frac{Time}{Iter}$	$\frac{OP*x\ Time}{Total\ Time}$
1	1809.07	173	10.46	0.84 %
2	1073.36	189	5.679	1.48 %
4	732.72	213	3.440	2.65 %
8	449.95	225	2.000	5.24 %
16	201.27	192	1.048	8.90 %
32	114.98	154	0.747	13.3 %
64	161.24	260	0.620	18.0 %
128	128.28	210	0.611	25.9 %

Table 5: Parallel ARPACK test run, matrix order 3,200

n = 3,200. The parallel ARPACK software was then used to compute the eigenvalues and eigenvectors. A residual tolerance of (10^{-8}) was imposed.

Table 5 shows the total time and the number of iterations required to solve this fixed problem with a different number of processors. The number of iterations varied with different processor configurations and this was attributed to different initial random vectors being generated as the number of processors changed. However, the corresponding result eigenvalues and eigenvectors are identical for all of the runs.

The speedup caused by increasing the number of processors can be observed by checking the average run time per iterate for each individual test. The third column in Table 5, demonstrates deteriorated speedup after the number of processors exceeds 32. Column four shows that the reason for this deterioration lies with the inefficient matrix-vector product.

7.4 GENERAL APPLICATIONS OF ARPACK

ARPACK has been used in a variety of challenging applications, and has proven to be useful both in symmetric and nonsymmetric problems. It is of particular interest when there is no opportunity to factor the matrix and employ a "shift and invert" form of spectral transformation,

$$\hat{A} \leftarrow (A - \sigma I)^{-1} \ . \tag{12}$$

Existing codes often rely upon this transformation to enhance convergence. Extreme eigenvalues $\{\mu\}$ of the matrix $\hat{A}$ are found very rapidly with the Arnoldi/Lanczos process and the corresponding eigenvalues $\{\lambda\}$ of the original matrix A are recovered from the relation $\lambda = 1/\mu + \sigma$. Implementation of this transformation generally requires a matrix factorization. In many important applications this is not possible due to storage requirements and computational costs. The implicit restarting technique used in ARPACK is often successful without this spectral transformation.

One of the most important classes of application arise in computational fluid dynamics. Here the matrices are obtained through discretization of the Navier-Stokes equations. A typical application involves linear stability analysis of steady state solutions. Here one lin-

earizes the nonlinear equation about a steady state and studies the stability of this state through the examination of the spectrum. Usually this amounts to determining if the eigenvalues of the discrete operator lie in the left halfplane. Typically these are parametrically dependent problems and the analysis consists of determining phenomena such as simple bifurcation, Hopf bifurcation (an imaginary complex pair of eigenvalues cross the imaginary axis), turbulence, and vortex shedding as this parameter is varied. ARPACK is well suited to this setting as it is able to track a specified set of eigenvalues while they vary as functions of the parameter. Our software has been used to find the leading eigenvalues in a Couette-Taylor wavy vortex instability problem involving matrices of order 4000. One interesting facet of this application is that the matrices are not available explicitly and are logically dense. The particular discretization provides efficient matrix-vector products through Fourier transform. Details may be found in [13].

Very large symmetric generalized eigenproblems arise in structural analysis. One example that we have worked with at Cray Research through the courtesy of Ford Motor Company involves an automobile engine model constructed from 3D solid elements. Here the interest is in a set of modes to allow solution of a forced frequency response problem $(K - \lambda M)x = f(t)$, where $f(t)$ is a cyclic forcing function which is used to simulate expanding gas loads in the engine cylinder as well as bearing loads from the piston connecting rods. This model has over 250,000 degrees of freedom. The smallest eigenvalues are of interest and the ARPACK code appears to be very competitive with the best commercially available codes on problems of this size. For details see [45].

The Singular Value Decomposition (SVD) may also be computed using ARPACK and the SVD has a many large scale applications. Two SVD applications occur in computational biology. The first of these is the 3-D image reconstruction of biological macromolecules from 2-D projections obtained through electron micrographs. The second is an application to molecular dynamical simulation of the motions of proteins. The SVD may be used to compress the data required to represent the simulation and more importantly to provide an analytical tool to help in understanding the function of the protean. See [35] for further details of the molecular dynamics application. The underlying algorithm for reconstructing 3-D image reconstruction of biological macromolecules from 2-D projections [48] is based upon the statistical technique of principal component analysis [49]. In this algorithm, a singular value decomposition (SVD) of the data set is performed to extract the largest singular vectors which are then used in a classification procedure. Our initial effort has been to replace the existing algorithm for computing the SVD with ARPACK which has increased the speed of the analysis by a factor of 7 on an Iris workstation. The accuracy of the results were also increased dramatically. Details are reported in [15].

Computational chemistry provides a rich source of problems. ARPACK is being used in two applications currently and holds promise for a variety of challenging problems in this area. We are collaborating with researchers at Ohio State on large scale three-dimensional reactive scattering problems. The governing equation is the Schroedinger equation and the computational technique for studying the physical phenomena relies upon repeated eigenanalysis of a Hamiltonian operator consisting of a Laplacian operator discretized in spherical co-ordinates plus a surface potential. The discrete operator has a tensor product

structure from the discrete Laplacian plus a diagonal matrix from the potential. The resulting matrix has a block structure consisting of $m \times m$ blocks of order n . The diagonal blocks are dense and the off diagonal blocks are scalar multiples of the order n identity matrix. It is virtually impossible to factor this matrix directly because the factors are dense in any ordering. We are using a distributed memory parallel version of ARPACK together with some preconditioning ideas to solve these problems on distributed memory machines. Encouraging computational results have been obtained on Cray Y-MP machines and also on the Intel Delta and the CM-5. The code has recently been ported to the CRAY T3D with very promising results. On a matrix of order 12800 computing the smallest eight eigenvalues using a Chebyshev polynomial preconditioner of degree eight the CRAY YMP executed at a rate of 290.66 Mflops while the T3D using the distributed-shared memory model executed at a peak rate of 1412 Mflops (See Table 6). For details about the method and experimental results, see [20], [45].

Nonsymmetric problems also arise in quantum chemistry. Researchers at University of Washington have used the code to investigate the effects of the electric field on InAs/GaSb and GaAs/Al_xGa_{1-x} as quantum wells. ARPACK was used to find highly accurate solutions to these nonsymmetric problems which couldn't be solved by other means. See [25] for details. Researchers at U. Massachusetts have used ARPACK to solve the eignvalue problems arising in their FEM quantum well Kp model for strained layer superlattices [4].

A final example of non-symmetric eigenproblems to be discussed here arises in magneto-hydrodynamics (MHD) involving the study of the interaction of a plasma and a magnetic field. The MHD equations describe the macroscopic behavior of the plasma in the magnetic field. These equations form a system of coupled nonlinear PDE. Linear stability analysis of the linearized MHD equations leads to a complex eigenvalue problem. Researchers at the Institute for Plasma Physics and Utrecht University in the Netherlands have modified the codes in ARPACK to work in complex arithmetic and are using the resulting code to obtain very accurate approximations to the eigenvalues lying on the Alfven curve. The code is not only computes extremely accurate solutions, it does so very efficiently in comparison to other methods that have been tried. See [22] for details.

There are many other applications. It is hoped that the examples that have been briefly discussed here will provide an indication of the versatility of the ARPACK software as well a the wide variety of eigenvalue problems that arise.

8 Conclusions

This paper has attempted to give an overview of the numerical solution of large scale eigenvalue problems. Basic theory and algorithms were introduced to motivate Krylov subspace projection methods. The focus has been on a particular variant, the Implicitly Restarted Arnoldi Method which has been developed into a substantial software package ARPACK.

There are a number of competing methods that have not been discussed here in any detail. Two notable methods that have not been discussed are methods based on the nonsymmetric two-sided Lanczos process and methods based upon subspace iteration. At this point, no single method appears to be viable for all problems. Certainly in the nonsymmetric case there is no "black box" technique and it is questionable that there is one in the symmetric case either. A block method called ABLE based upon two-sided nonsymmetric Lanczos is being developed by Bai, Day and Ye [2]. Software based upon subspace iteration with Chbeychev acceleration has been developed by Duff and Scott [12]. Jennifer Scott has also developed software based upon an explicitly restarted Chebyshev-Arnoldi method [42]. Finally, the Rational Krylov method being developed by Ruhe [36, 37] is very promising for the nonsymmetric problem when a factorization of the matrix is possible.

9 Acknowledgements

The computational results presented in Section 7 are due to Zdenko Tomasic and Dan Hu. I would like to thank Rich Lehoucq for producing Figures 1-3 and for constructive comments and discussions about this work.

SPARSE MATRICES IN MATLAB: DESIGN AND IMPLEMENTATION

JOHN R. GILBERT*, CLEVE MOLER†, AND ROBERT SCHREIBER‡

Dedicated to Gene Golub on the occasion of his 60th birthday.

Abstract. We have extended the matrix computation language and environment MATLAB to include sparse matrix storage and operations. The only change to the outward appearance of the MATLAB language is a pair of commands to create full or sparse matrices. Nearly all the operations of MATLAB now apply equally to full or sparse matrices, without any explicit action by the user. The sparse data structure represents a matrix in space proportional to the number of nonzero entries, and most of the operations compute sparse results in time proportional to the number of arithmetic operations on nonzeros.

Key words. MATLAB, mathematical software, matrix computation, sparse matrix algorithms.

AMS subject classifications. 65–04, 65F05, 65F20, 65F50, 68N15, 68R10.

1. Introduction. MATLAB is an interactive environment and programming language for numeric scientific computation [18]. One of its distinguishing features is the use of matrices as the only data type. In MATLAB, a matrix is a rectangular array of real or complex numbers. All quantities, even loop variables and character strings, are represented as matrices, although matrices with only one row, or one column, or one element are sometimes treated specially.

The part of MATLAB that involves computational linear algebra on dense matrices is based on direct adaptations of subroutines from LINPACK and EISPACK [5, 23]. An $m \times n$ real matrix is stored as a full array of mn floating point numbers. The computational complexity of basic operations such as addition or transposition is proportional to mn. The complexity of more complicated operations such as triangular factorization is proportional to mn^2. This has limited the applicability of MATLAB to problems involving matrices of order a few hundred on contemporary workstations and perhaps a few thousand on contemporary supercomputers.

We have now added sparse matrix storage and operations to MATLAB. This report describes our design and implementation.

Sparse matrices are widely used in scientific computation, especially in large-scale optimization, structural and circuit analysis, computational fluid dynamics, and, generally, the numerical solution of partial differential equations. Several effective Fortran subroutine packages for solving sparse linear systems are available, including SPARSPAK [11], the Yale Sparse Matrix Package [9], and some of the routines in the Harwell Subroutine Library [25].

Our work was facilitated by our knowledge of the techniques used in the Fortran sparse matrix packages, but we have not directly adapted any of their code. MATLAB

TABLE 1
Operations with the 4096 by 4096 discrete Laplacian.

	Sparse	Full
Memory	0.25 megabyte	128 megabytes
Compute Dx	0.2 seconds	30 seconds
Solve $Dx = b$	10 seconds	$>$ 12 hours

is written in C and we wished to take advantage of the data structures and other programming features of C that would not be used in a simple translation of Fortran code. We also wanted to implement the full range of matrix operations that MATLAB provides; the Fortran packages do not generally have routines for simply adding or transposing sparse matrices, for example. And, finally, we wanted to incorporate some recent algorithmic ideas that are not used in the Fortran packages.

J. H. Wilkinson's informal working definition of a sparse matrix was "any matrix with enough zeros that it pays to take advantage of them." So sparsity is an economic issue. By avoiding arithmetic operations on zero elements, sparse matrix algorithms require less computer time. And, perhaps more importantly, by not storing many zero elements, sparse matrix data structures require less computer memory. In a sense, we have not added any new functionality to MATLAB; we've merely made some existing functionality more efficient in terms of both time and storage.

An important descriptive parameter of a sparse matrix S is $\mathrm{nnz}(S)$, the number of nonzero elements in S. Computer storage requirements are proportional to nnz. The computational complexity of simple array operations should also be should be proportional to nnz, and perhaps also depend linearly on m or n, but be independent of the product mn. The complexity of more complicated operations involves such factors as ordering and fill-in, but an objective of a good sparse matrix algorithm should be:

> The time required for a sparse matrix operation should be proportional to number of arithmetic operations on nonzero quantities.

We call this the "time is proportional to flops" rule; it is a fundamental tenet of our design.

With sparse techniques, it is practical to handle matrices involving tens of thousands of nonzero elements on contemporary workstations. As one example, let D be the matrix representation of the discrete 5-point Laplacian on a square 64×64 grid with a nested dissection ordering. This is a 4096×4096 matrix with 20224 nonzeros. Table 1 gives the memory requirements for storing D as a MATLAB sparse matrix and as a traditional Fortran or MATLAB full matrix, as well as the execution time on a Sun SPARCstation-1 workstation for computing a matrix-vector product and solving a linear system of equations by elimination.

Band matrices are special cases of sparse matrices whose nonzero elements all happen to be near the diagonal. It would be somewhat more efficient, in both time and storage, to provide a third data structure and collection of operations for band matrices. We have decided against doing this because of the added complexity, particular in cases involving mixtures of full, sparse and band matrices. We suspect that solving linear systems with matrices which are dense within a narrow band might be twice as fast with band storage as it is with sparse matrix storage, but that linear systems with matrices that are sparse within the band (such as those obtained

from two-dimensional grids) are more efficiently solved with general sparse matrix technology. However, we have not investigated these tradeoffs in any detail.

In this paper, we concentrate on elementary sparse matrix operations, such as addition and multiplication, and on direct methods for solving sparse linear systems of equations. These operations are now included in the "core" of MATLAB. Except for a few short examples, we will not discuss higher level sparse matrix operations, such as iterative methods for linear systems. We intend to implement such operations as interpreted programs in the MATLAB language, so-called "m-files," outside the MATLAB core.

2. The user's view of sparse MATLAB.

2.1. Sparse matrix storage. We wish to emphasize the distinction between a matrix and what we call its *storage class*. A given matrix can conceivably be stored in many different ways—fixed point or floating point, by rows or by columns, real or complex, full or sparse—but all the different ways represent the same matrix. We now have two matrix storage classes in MATLAB, full and sparse.

Two MATLAB variables, `A` and `B`, can have different storage classes but still represent the same matrix. They occupy different amounts of computer memory, but in most other respects they are the same. Their elements are equal, their determinants and their eigenvalues are equal, and so on. The crucial question of which storage class to choose for a given matrix is the topic of Section 2.5.

Even though MATLAB is written in C, it follows its LINPACK and Fortran predecessors and stores full matrices by columns [5, 19]. This organization has been carried over to sparse matrices. A sparse matrix is stored as the concatenation of the sparse vectors representing its columns. Each sparse vector consists of a floating point array of nonzero entries (or two such arrays for complex matrices), together with an integer array of row indices. A second integer array gives the locations in the other arrays of the first element in each column. Consequently, the storage requirement for an $m \times n$ real sparse matrix with nnz nonzero entries is nnz reals and $nnz + n$ integers. On typical machines with 8-byte reals and 4-byte integers, this is $12nnz + 4n$ bytes. Complex matrices use a second array of nnz reals. Notice that m, the number of rows, is almost irrelevant. It is not involved in the storage requirements, nor in the operation counts for most operations. Its primary use is in error checks for subscript ranges. Similar storage schemes, with either row or column orientation, are used in the Fortran sparse packages.

2.2. Converting between full and sparse storage. Initially, we contemplated schemes for automatic conversion between sparse and full storage. There is a MATLAB precedent for such an approach. Matrices are either real or complex and the conversion between the two is automatic. Computations such as square roots and logarithms of negative numbers and eigenvalues of nonsymmetric matrices generate complex results from real data. MATLAB automatically expands the data structure by adding an array for the imaginary parts.

Moreover, several of MATLAB's functions for building matrices produce results that might effectively be stored in the sparse organization. The function `zeros(m,n)`, which generates an $m \times n$ matrix of all zeros, is the most obvious candidate. The functions `eye(n)` and `diag(v)`, which generate the $n \times n$ identity matrix and a diagonal matrix with the entries of vector v on the main diagonal, are also possibilities. Even `tril(A)` and `triu(A)`, which take the lower and upper triangular parts of a matrix A, might be considered. But this short list begins to demonstrate a difficulty—how far

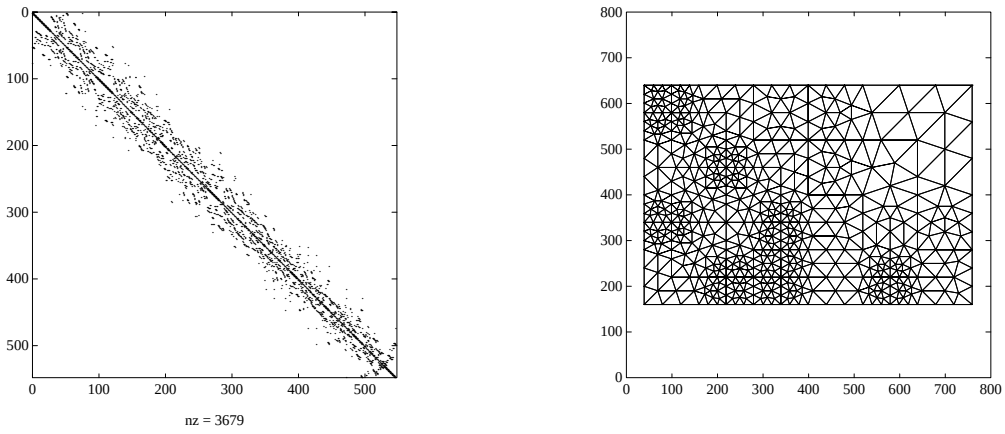

FIG. 1. *The Eppstein mesh as plotted by* `spy(A)` *and* `gplot(A,xy)`.

should "automatic sparsification" be carried? Is there some threshold value of sparsity where the conversion should be done? Should the user provide the value for such a sparsification parameter? We don't know the answers to these questions, so we decided to take another approach, which we have since found to be quite satisfactory.

No sparse matrices are created without some overt direction from the user. Thus, the changes we have made to MATLAB do not affect the user who has no need for sparsity. Operations on full matrices continue to produce full matrices. But once initiated, sparsity propagates. Operations on sparse matrices produce sparse matrices. And an operation on a mixture of sparse and full matrices produces a sparse result unless the operator ordinarily destroys sparsity. (Matrix addition is an example; more on this later.)

There are two new built-in functions, `full` and `sparse`. For any matrix A, `full(A)` returns A stored as a full matrix. If A is already full, then A is returned unchanged. If A is sparse, then zeros are inserted at the appropriate locations to fill out the storage. Conversely, `sparse(A)` removes any zero elements and returns A stored as a sparse matrix, regardless of how sparse A actually is.

2.3. Displaying sparse matrices. Sparse and full matrices print differently. The statement

```
A = [0 0 11; 22 0 0; 0 33 0]
```

produces a conventional MATLAB full matrix that prints as

```
A =
     0     0    11
    22     0     0
     0    33     0
```

The statement `S = sparse(A)` converts A to sparse storage, and prints

```
S =
   (2,1)       22
   (3,2)       33
   (1,3)       11
```

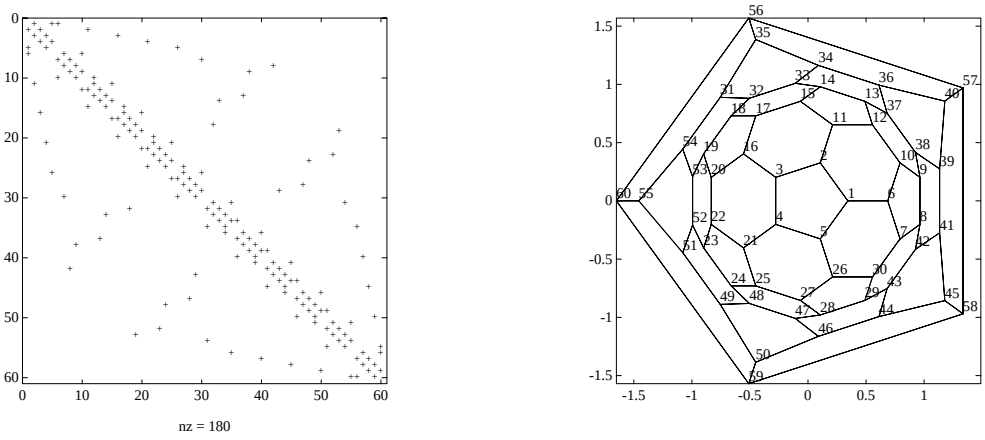

FIG. 2. *The buckyball as rendered by* `spy` *and* `gplot`.

As this illustrates, sparse matrices are printed as a list of their nonzero elements (with indices), in column major order.

The function `nnz(A)` returns the number of nonzero elements of A. It is implemented by scanning full matrices, and by access to the internal data structure for sparse matrices. The function `nzmax(A)` returns the number of storage locations for nonzeros allocated for A.

Graphic visualization of the structure of a sparse matrix is often a useful tool. The function `spy(A)` plots a silhouette of the nonzero structure of A. Figure 1 illustrates such a plot for a matrix that comes from a finite element mesh due to David Eppstein. A picture of the graph of a matrix is another way to visualize its structure. Laying out an arbitrary graph for display is a hard problem that we do not address. However, some sparse matrices (from finite element applications, for example) have spatial coordinates associated with their rows or columns. If xy contains such coordinates for matrix A, the function `gplot(A,xy)` draws its graph. The second plot in Figure 1 shows the graph of the sample matrix, which in this case is just the same as the finite element mesh. Figure 2 is another example: The `spy` plot is the 60×60 adjacency matrix of the graph of a Buckminster Fuller geodesic dome, a soccer ball, and a C_{60} molecule, and the `gplot` shows the graph itself.

Section 3.3.4 describes another function for visualizing the elimination tree of a matrix.

2.4. Creating sparse matrices. Usually one wants to create a sparse matrix directly, without first having a full matrix A and then converting it with `S = sparse(A)`. One way to do this is by simply supplying a list of nonzero entries and their indices. Several alternate forms of `sparse` (with more than one argument) allow this. The most general is

```
S = sparse(i,j,s,m,n,nzmax)
```

Ordinarily, i and j are vectors of integer indices, s is a vector of real or complex entries, and m, n, and $nzmax$ are integer scalars. This call generates an $m \times n$ sparse matrix, having one nonzero for each entry in the vectors i, j, and s, with $S(i(k), j(k)) = s(k)$, and with enough space allocated for S to have $nzmax$ nonzeros. The indices in i and j need not be given in any particular order.

If a pair of indices occurs more than once in i and j, `sparse` adds the corresponding values of s together. Then the sparse matrix S is created with one nonzero for each nonzero in this modified vector s. The argument s and one of the arguments i and j may be scalars, in which case they are expanded so that the first three arguments all have the same length.

There are several simplifications of the full six-argument call to `sparse`.

`S = sparse(i,j,s,m,n)` uses $nzmax = \text{length}(s)$.

`S = sparse(i,j,s)` uses $m = \max(i)$ and $n = \max(j)$.

`S = sparse(m,n)` is the same as `S = sparse([],[],[],m,n)`, where `[]` is MATLAB's empty matrix. It produces the ultimate sparse matrix, an $m \times n$ matrix of all zeros.

Thus for example

```
S = sparse([1 2 3], [3 1 2], [11 22 33])
```

produces the sparse matrix S from the example in Section 2.3, but does not generate any full 3 by 3 matrix during the process.

MATLAB's function `k = find(A)` returns a list of the positions of the nonzeros of A, counting in column-major order. For sparse MATLAB we extended the definition of `find` to extract the nonzero elements together with their indices. For any matrix A, full or sparse, `[i,j,s] = find(A)` returns the indices and values of the nonzeros. (The square bracket notation on the left side of an assignment indicates that the function being called can return more than one value. In this case, `find` returns three values, which are assigned to the three separate variables i, j, and s.) For example, this dissects and then reassembles a sparse matrix:

```
[i,j,s] = find(S);
[m,n] = size(S);
S = sparse(i,j,s,m,n);
```

So does this, if the last row and column have nonzero entries:

```
[i,j,s] = find(S);
S = sparse(i,j,s);
```

Another common way to create a sparse matrix, particularly for finite difference computations, is to give the values of some of its diagonals. Two functions `diags` and `blockdiags` can create sparse matrices with specified diagonal or block diagonal structure.

There are several ways to read and write sparse matrices. The MATLAB `save` and `load` commands, which save the current workspace or load a saved workspace, have been extended to accept sparse matrices and save them efficiently. We have written a Fortran utility routine that converts a file containing a sparse matrix in the Harwell-Boeing format [6] into a file that MATLAB can load.

2.5. The results of sparse operations. What is the result of a MATLAB operation on sparse matrices? This is really two fundamental questions: what is the value of the result, and what is its storage class? In this section we discuss the answers that we settled on for those questions.

A function or subroutine written in MATLAB is called an *m-file*. We want it to be possible to write m-files that produce the same results for sparse and for full inputs. Of course, one could ensure this by converting all inputs to full, but that would defeat the goal of efficiency. A better idea, we decided, is to postulate that

> The value of the result of an operation does not depend on the storage class of the operands, although the storage class of the result may.

The only exception is a function to inquire about the storage class of an object: `issparse(A)` returns 1 if A is sparse, 0 otherwise.

Some intriguing notions were ruled out by our postulate. We thought, for a while, that in cases such as `A ./ S` (which denotes the pointwise quotient of A and S) we ought not to divide by zero where S is zero, since that would not produce anything useful; instead we thought to implement this as if it returned $A(i,j)/S(i,j)$ wherever $S(i,j) \neq 0$, leaving A unchanged elsewhere. All such ideas, however, were dropped in the interest of observing the rule that the result does not depend on storage class.

The second fundamental question is how to determine the storage class of the result of an operation. Our decision here is based on three ideas. First, the storage class of the result of an operation should depend only on the storage classes of the operands, not on their values or sizes. (Reason: it's too risky to make a heuristic decision about when to sparsify a matrix without knowing how it will be used.) Second, sparsity should not be introduced into a computation unless the user explicitly asks for it. (Reason: the full matrix user shouldn't have sparsity appear unexpectedly, because of the performance penalty in doing sparse operations on mostly nonzero matrices.) Third, once a sparse matrix is created, sparsity should propagate through matrix and vector operations, concatenation, and so forth. (Reason: most m-files should be able to do sparse operations for sparse input or full operations for full input without modification.)

Thus full inputs always give full outputs, except for functions like `sparse` whose purpose is to create sparse matrices. Sparse inputs, or mixed sparse and full inputs, follow these rules (where S is sparse and F is full):

- Functions from matrices to scalars or fixed-size vectors, like `size` or `nnz`, always return full results.
- Functions from scalars or fixed-size vectors to matrices, like `zeros`, `ones`, and `eye`, generally return full results. Having `zeros(m,n)` and `eye(m,n)` return full results is necessary to avoid introducing sparsity into a full user's computation; there are also functions `spzeros` and `speye` that return sparse zero and identity matrices.
- The remaining unary functions from matrices to matrices or vectors generally return a result of the same storage class as the operand (the main exceptions are `sparse` and `full`). Thus, `chol(S)` returns a sparse Cholesky factor, and `diag(S)` returns a sparse vector (a sparse $m \times 1$ matrix). The vectors returned by `max(S)`, `sum(S)`, and their relatives (that is, the vectors of column maxima and column sums respectively) are sparse, even though they may well be all nonzero.
- Binary operators yield sparse results if both operands are sparse, and full results if both are full. In the mixed case, the result's storage class depends on the operator. For example, `S + F` and `F \ S` (which solves the linear system $SX = F$) are full; `S .* F` (the pointwise product) and `S & F` are sparse.
- A block matrix formed by concatenating smaller matrices, like

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix},$$

is written as `[A B ; C D]` in MATLAB. If all the inputs are full, the result is full, but a concatenation that contains any sparse matrix is sparse. Submatrix indexing on the right counts as a unary operator; `A = S(i,j)` produces a sparse result (for sparse S) whether i and j are scalars or vectors. Submatrix indexing on the left, as in `A(i,j) = S`, does not change the storage class of the matrix being modified.

These decisions gave us some difficulty. Cases like `~S` and `S >= T`, where the result has many ones when the operands are sparse, made us consider adding more exceptions to the rules. We discussed the possibility of "sparse" matrices in which all the values not explicitly stored would be some scalar (like 1) rather than zero. We rejected these ideas in the interest of simplicity.

3. Implementation. This section describes the algorithms for the sparse operations in MATLAB in some detail. We begin with a discussion of fundamental data structures and design decisions.

3.1. Fundamentals.

3.1.1. Data structure. A most important implementation decision is the choice of a data structure. The internal representation of a sparse matrix must be flexible enough to implement all the MATLAB operations. For simplicity, we ruled out the use of different data structures for different operations. The data structure should be compact, storing only nonzero elements, with a minimum of overhead storage for integers or pointers. Wherever possible, it should support matrix operations in time proportional to flops. Since MATLAB is an interpreted, high-level matrix language, efficiency is more important in matrix arithmetic and matrix-vector operations than in accessing single elements of matrices.

These goals are met by a simple column-oriented scheme that has been widely used in sparse matrix computation. A sparse matrix is a C record structure with the following constituents. The nonzero elements are stored in a one-dimensional array of double-precision reals, in column major order. (If the matrix is complex, the imaginary parts are stored in another such array.) A second array of integers stores the row indices. A third array of $n+1$ integers stores the index into the first two arrays of the leading entry in each of the n columns, and a terminating index whose value is nnz. Thus a real $m \times n$ sparse matrix with nnz nonzeros uses nnz reals and $nnz + n + 1$ integers.

This scheme is not efficient for manipulating matrices one element at a time: access to a single element takes time at least proportional to the logarithm of the length of its column; inserting or removing a nonzero may require extensive data movement. However, element-by-element manipulation is rare in MATLAB (and is expensive even in full MATLAB). Its most common application would be to create a sparse matrix, but this is more efficiently done by building a list $[i, j, s]$ of matrix elements in arbitrary order and then using `sparse(i,j,s)` to create the matrix.

The sparse data structure is allowed to have unused elements after the end of the last column of the matrix. Thus an algorithm that builds up a matrix one column at a time can be implemented efficiently by allocating enough space for all the expected nonzeros at the outset.

3.1.2. Storage allocation. Storage allocation is one of the thorniest parts of building portable systems. MATLAB handles storage allocation for the user, invisibly allocating and deallocating storage as matrices appear, disappear, and change size.

Sometimes the user can gain efficiency by preallocating storage for the result of a computation. One does this in full MATLAB by allocating a matrix of zeros and filling it in incrementally. Similarly, in sparse MATLAB one can preallocate a matrix (using `sparse`) with room for a specified number of nonzeros. Filling in the sparse matrix a column at a time requires no copying or reallocation.

Within MATLAB, simple "allocate" and "free" procedures handle storage allocation. (We will not discuss how MATLAB handles its free storage and interfaces to the operating system to provide these procedures.) There is no provision for doing storage allocation within a single matrix; a matrix is allocated as a single block of storage, and if it must expand beyond that block it is copied into a newly allocated larger block.

MATLAB must allocate space to hold the results of operations. For a full result, MATLAB allocates mn elements at the start of the computation. This strategy could be disastrous for sparse matrices. Thus, sparse MATLAB attempts to make a reasonable choice of how much space to allocate for a sparse result.

Some sparse matrix operations, like Cholesky factorization, can predict in advance the exact amount of storage the result will require. These operations simply allocate a block of the right size before the computation begins. Other operations, like matrix multiplication and LU factorization, have results of unpredictable size. These operations are all implemented by algorithms that compute one column at a time. Such an algorithm first makes a guess at the size of the result. If more space is needed at some point, it allocates a new block that is larger by a constant factor (typically 1.5) than the current block, copies the columns already computed into the new block, and frees the old block.

Most of the other operations compute a simple upper bound on the storage required by the result to decide how much space to allocate—for example, the pointwise product `S .* T` uses the smaller of $\mathrm{nnz}(S)$ and $\mathrm{nnz}(T)$, and `S + T` uses the smaller of $\mathrm{nnz}(S) + \mathrm{nnz}(T)$ and mn.

3.1.3. The sparse accumulator. Many sparse matrix algorithms use a dense working vector to allow random access to the currently "active" column or row of a matrix. The sparse MATLAB implementation formalizes this idea by defining an abstract data type called the sparse accumulator, or SPA. The SPA consists of a dense vector of real (or complex) values, a dense vector of true/false "occupied" flags, and an unordered list of the indices whose occupied flags are true.

The SPA represents a column vector whose "unoccupied" positions are zero and whose "occupied" positions have values (zero or nonzero) specified by the dense real or complex vector. It allows random access to a single element in constant time, as well as sequencing through the occupied positions in constant time per element. Most matrix operations allocate the SPA (with appropriate dimension) at their beginning and free it at their end. Allocating the SPA takes time proportional to its dimension (to turn off all the occupied flags), but subsequent operations take only constant time per nonzero.

In a sense the SPA is a register and an instruction set in an abstract machine architecture for sparse matrix computation. MATLAB manipulates the SPA through some thirty-odd access procedures. About half of these are operations between the SPA and a sparse or dense vector, from a "spaxpy" that implements SPA := SPA+ax (where a is a scalar and x is a column of a sparse matrix) to a "spaeq" that tests elementwise equality. Other routines load and store the SPA, permute it, and access individual elements. The most complicated SPA operation is a depth-first search on

an acyclic graph, which marks as "occupied" a topologically ordered list of reachable vertices; this is used in the sparse triangular solve described in Section 3.4.2.

The SPA simplifies data structure manipulation, because all fill occurs in the SPA; that is, only in the SPA can a zero become nonzero. The "spastore" routine does not store exact zeros, and in fact the sparse matrix data structure never contains any explicit zeros. Almost all real arithmetic operations occur in SPA routines, too, which simplifies MATLAB's tally of flops. (The main exceptions are in certain scalar-matrix operations like `2*A`, which are implemented without the SPA for efficiency.)

3.1.4. Asymptotic complexity analysis. A strong philosophical principle in the sparse MATLAB implementation is that it should be possible to analyze the complexity of the various operations, and that they should be efficient in the asymptotic sense as well as in practice. This section discusses this principle, in terms of both theoretical ideals and engineering compromises.

Ideally all the matrix operations would use time proportional to flops, that is, their running time would be proportional to the number of nonzero real arithmetic operations performed. This goal cannot always be met: for example, `[0 1] + [1 0]` does no nonzero arithmetic. A more accurate statement is that time should be proportional to flops or data size, whichever is larger. Here "data size" means the size of the output and that part of the input that is used nontrivially; for example, in `A*b` only those columns of A corresponding to nonzeros in b participate nontrivially.

This more accurate ideal can be realized in almost all of MATLAB. The exceptions are some operations that do no arithmetic and cannot be implemented in time proportional to data size. The algorithms to compute most of the reordering permutations described in Section 3.3 are efficient in practice but not linear in the worst case. Submatrix indexing is another example: if i and j are vectors of row and column indices, `B = A(i,j)` may examine all the nonzeros in the columns $A(:, j)$, and `B(i,j) = A` can at worst take time linear in the total size of B.

The MATLAB implementation actually violates the "time proportional to flops" philosophy in one systematic way. The list of occupied row indices in the SPA is not maintained in numerical order, but the sparse matrix data structure does require row indices to be ordered. Sorting the row indices when storing the SPA would theoretically imply an extra factor of $O(\log n)$ in the worst-case running times of many of the matrix operations. All our algorithms could avoid this factor—usually by storing the matrix with unordered row indices, then using a linear-time transposition sort to reorder all the rows of the final result at once—but for simplicity of programming we included the sort in "spastore".

The idea that running time should be susceptible to analysis helps the user who writes programs in MATLAB to choose among alternative algorithms, gives guidance in scaling up running times from small examples to larger problems, and, in a general-purpose system like MATLAB, gives some insurance against an unexpected worst-case instance arising in practice. Of course complete *a priori* analysis is impossible—the work in sparse LU factorization depends on numerical pivoting choices, and the efficacy of a heuristic reordering such as minimum degree is unpredictable—but we feel it is worthwhile to stay as close to the principle as we can.

In a technical report [14] we present some experimental evidence that sparse MATLAB operations require time proportional to flops and data size in practice.

3.2. Factorizations. The LU and Cholesky factorizations of a sparse matrix yield sparse results. MATLAB does not yet have a sparse QR factorization. Section 3.6 includes some remarks on sparse eigenvalue computation in MATLAB.

3.2.1. LU **Factorization.** If A is a sparse matrix, `[L,U,P] = lu(A)` returns three sparse matrices such that $PA = LU$, as obtained by Gaussian elimination with partial pivoting. The permutation matrix P uses only $O(n)$ storage in sparse format. As in dense MATLAB, `[L,U] = lu(A)` returns a permuted unit lower triangular and an upper triangular matrix whose product is A.

Since sparse LU must behave like MATLAB's full LU, it does not pivot for sparsity. A user who happens to know a good column permutation Q for sparsity can, of course, ask for `lu(A*Q')`, or `lu(A(:,q))` where q is an integer permutation vector. Section 3.3 describes a few ways to find such a permutation. The matrix division operators \ and / do pivot for sparsity by default; see Section 3.4.

We use a version of the `GPLU` algorithm [15] to compute the LU factorization. This computes one column of L and U at a time by solving a sparse triangular system with the already-finished columns of L. Section 3.4.2 describes the sparse triangular solver that does most of the work. The total time for the factorization is proportional to the number of nonzero arithmetic operations (plus the size of the result), as desired.

The column-oriented data structure for the factors is created as the factorization progresses, never using any more storage for a column than it requires. However, the total size of L or U cannot be predicted in advance. Thus the factorization routine makes an initial guess at the required storage, and expands that storage (by a factor of 1.5) whenever necessary.

3.2.2. Cholesky factorization. As in full MATLAB, `R = chol(A)` returns the upper triangular Cholesky factor of a Hermitian positive definite matrix A. Pivoting for sparsity is not automatic, but minimum degree and profile-limiting permutations can be computed as described in Section 3.3.

Our current implementation of Cholesky factorization emphasizes simplicity and compatibility with the rest of sparse MATLAB; thus it does not use some of the more sophisticated techniques such as the compressed index storage scheme [11, Sec. 5.4.2], or supernodal methods to take advantage of the clique structure of the chordal graph of the factor [2]. It does, however, run in time proportional to arithmetic operations with little overhead for data structure manipulation.

We use a slightly simplified version of an algorithm from the Yale Sparse Matrix Package [9], which is described in detail by George and Liu [11]. We begin with a combinatorial step that determines the number of nonzeros in the Cholesky factor (assuming no exact cancellation) and allocates a large enough block of storage. We then compute the lower triangular factor R^T one column at a time. Unlike YSMP and SPARSPAK, we do not begin with a symbolic factorization; instead, we create the sparse data structure column by column as we compute the factor. The only reason for the initial combinatorial step is to determine how much storage to allocate for the result.

3.3. Permutations. A permutation of the rows or columns of a sparse matrix A can be represented in two ways. A permutation matrix P acts on the rows of A as `P*A` or on the columns as `A*P'`. A permutation vector p, which is a full vector of length n containing a permutation of `1:n`, acts on the rows of A as `A(p,:)` or on the columns as `A(:,p)`. Here p could be either a row vector or a column vector.

Both representations use $O(n)$ storage, and both can be applied to A in time proportional to $\mathrm{nnz}(A)$. The vector representation is slightly more compact and efficient, so the various sparse matrix permutation routines all return vectors—full row vectors, to be precise—with the exception of the pivoting permutation in LU factorization.

Converting between the representations is almost never necessary, but it is simple. If I is a sparse identity matrix of the appropriate size, then P is `I(p,:)` and P^T is `I(:,p)`. Also p is `(P*(1:n)')'` or `(1:n)*P'`. (We leave to the reader the puzzle of using `find` to obtain p from P without doing any arithmetic.) The inverse of P is `P'`; the inverse r of p can be computed by the "vectorized" statement `r(p) = 1:n`.

3.3.1. Permutations for sparsity: Asymmetric matrices. Reordering the columns of a matrix can often make its LU or QR factors sparser. The simplest such reordering is to sort the columns by increasing nonzero count. This is sometimes a good reordering for matrices with very irregular structures, especially if there is great variation in the nonzero counts of rows or columns.

The MATLAB function `p = colperm(A)` computes this column-count permutation. It is implemented as a two-line m-file:

```
[i,j] = find(A);
[ignore,p] = sort(diff(find(diff([0 j' inf]))));
```

The vector j is the column indices of all the nonzeros in A, in column major order. The inner `diff` computes first differences of j to give a vector with ones at the starts of columns and zeros elsewhere; the `find` converts this to a vector of column-start indices; the outer `diff` gives the vector of column lengths; and the second output argument from `sort` is the permutation that sorts this vector.

The symmetric reverse Cuthill-McKee ordering described in Section 3.3.2 can be used for asymmetric matrices as well; the function `symrcm(A)` actually operates on the nonzero structure of $A + A^T$. This is sometimes a good ordering for matrices that come from one-dimensional problems or problems that are in some sense long and thin.

Minimum degree is an ordering that often performs better than `colperm` or `symrcm`. The sparse MATLAB function `p = colmmd(A)` computes a minimum degree ordering for the columns of A. This column ordering is the same as a symmetric minimum degree ordering for the matrix $A^T A$, though we do not actually form $A^T A$ to compute it.

George and Liu [10] survey the extensive development of efficient and effective versions of symmetric minimum degree, most of which is reflected in the symmetric minimum degree codes in SPARSPAK, YSMP, and the Harwell Subroutine Library. The MATLAB version of minimum degree uses many of these ideas, as well as some ideas from a parallel symmetric minimum degree algorithm by Gilbert, Lewis, and Schreiber [13]. We sketch the algorithm briefly to show how these ideas are expressed in the framework of column minimum degree. The reader who is not interested in all the details can skip to Section 3.3.2.

Although most column minimum degree codes for asymmetric matrices are based on a symmetric minimum degree code, our organization is the other way around: MATLAB's symmetric minimum degree code (described in Section 3.3.2) is based on its column minimum degree code. This is because the best way to represent a symmetric matrix (for the purposes of minimum degree) is as a union of cliques, or full submatrices. When we begin with an asymmetric matrix A, we wish to reorder its columns by using a minimum degree order on the symmetric matrix $A^T A$—but each row of A induces a clique in $A^T A$, so we can simply use A itself to represent $A^T A$ instead of forming the product explictly. Speelpenning [24] called such a clique representation of a symmetric graph the "generalized element" representation; George and

Liu [10] call it the "quotient graph model." Ours is the first column minimum degree implementation that we know of whose data structures are based directly on A, and which does not need to spend the time and storage to form the structure of A^TA. The idea for such a code is not new, however—George and Liu [10] suggest it, and our implementation owes a great deal to discussions between the first author and Esmond Ng and Barry Peyton of Oak Ridge National Laboratories.

We simulate symmetric Gaussian elimination on A^TA, using a data structure that represents A as a set of vertices and a set of cliques whose union is the graph of A^TA. Initially, each column of A is a vertex and each row is a clique. Elimination of a vertex j induces fill among all the (so far uneliminated) vertices adjacent to j. This means that all the vertices in cliques containing j become adjacent to one another. Thus all the cliques containing vertex j merge into one clique. In other words, all the rows of A with nonzeros in column j disappear, to be replaced by a single row whose nonzero structure is their union. Even though fill is implicitly being added to A^TA, the data structure for A gets smaller as the rows merge, so no extra storage is required during the elimination.

Minimum degree chooses a vertex of lowest degree (the sparsest remaining column of A^TA, or the column of A having nonzero rows in common with the fewest other columns), eliminates that vertex, and updates the remainder of A by adding fill (i.e. merging rows). This whole process is called a "stage"; after n stages the columns are all eliminated and the permutation is complete. In practice, updating the data structure after each elimination is too slow, so several devices are used to perform many eliminations in a single stage before doing the update for the stage.

First, instead of finding a single minimum-degree vertex, we find an entire "independent set" of minimum-degree vertices with no common nonzero rows. Eliminating one such vertex has no effect on the others, so we can eliminate them all at the same stage and do a single update. George and Liu call this strategy "multiple elimination". (They point out that the resulting permutation may not be a strict minimum degree order, but the difference is generally insignificant.)

Second, we use what George and Liu call "mass elimination": After a vertex j is eliminated, its neighbors in A^TA form a clique (a single row in A). Any of those neighbors whose own neighbors all lie within that same clique will be a candidate for elimination at the next stage. Thus, we may as well eliminate such a neighbor during the same stage as j, immediately after j, delaying the update until afterward. This often saves a tremendous number of stages because of the large cliques that form late in the elimination. (The number of stages is reduced from the height of the elimination tree to approximately the height of the clique tree; for many two-dimensional finite element problems, for example, this reduces the number of stages from about $\sqrt{n}$ to about $\log n$.) Mass elimination is particularly simple to implement in the column data structure: after all rows with nonzeros in column j are merged into one row, the columns to be eliminated with j are those whose only remaining nonzero is in that new row.

Third, we note that any two columns with the same nonzero structure will be eliminated in the same stage by mass elimination. Thus we allow the option of combining such columns into "supernodes" (or, as George and Liu call them, "indistinguishable nodes"). This speeds up the ordering by making the data structure for A smaller. The degree computation must account for the sizes of supernodes, but this turns out to be an advantage for two reasons. The quality of the ordering actually improves slightly if the degree computation does not count neighbors within the same

supernode. (George and Liu observe this phenomenon and call the number of neighbors outside a vertex's supernode its "external degree.") Also, supernodes improve the approximate degree computation described below. Amalgamating columns into supernodes is fairly slow (though it takes time only proportional to the size of A). Supernodes can be amalgamated at every stage, periodically, or never; the current default is every third stage.

Fourth, we note that the structure of A^TA is not changed by dropping any row of A whose nonzero structure is a subset of that of another row. This row reduction speeds up the ordering by making the data structure smaller. More significantly, it allows mass elimination to recognize larger cliques, which decreases the number of stages dramatically. Duff and Reid [8] call this strategy "element absorption." Row reduction takes time proportional to multiplying AA^T in the worst case (though the worst case is rarely realized and the constant of proportionality is very small). By default, we reduce at every third stage; again the user can change this.

Fifth, to achieve larger independent sets and hence fewer stages, we relax the minimum degree requirement and allow elimination of any vertex of degree at most $\alpha d+\beta$, where d is the minimum degree at this stage and α and β are parameters. The choice of threshold can be used to trade off ordering time for quality of the resulting ordering. For problems that are very large, have many right-hand sides, or factor many matrices with the same nonzero structure, ordering time is insignificant and the tightest threshold is appropriate. For one-off problems of moderate size, looser thresholds like $1.5d+2$ or even $2d+10$ may be appropriate. The threshold can be set by the user; its default is $1.2d+1$.

Sixth and last, our code has the option of using an "approximate degree" instead of computing the actual vertex degrees. Recall that a vertex is a column of A, and its degree is the number of other columns with which it shares some nonzero row. Computing all the vertex degrees in A^TA takes time proportional to actually computing A^TA, though the constant is quite small and no extra space is needed. Still, the exact degree computation can be the slowest part of a stage. If column j is a supernode containing $n(j)$ original columns, we define its approximate degree as

$$d(j) = \sum_{a_{ij}\neq 0} (\mathrm{nnz}(A(i,:)) - n(j)).$$

This can be interpreted as the sum of the sizes of the cliques containing j, except that j and the other columns in its supernode are not counted. This is a fairly good approximation in practice; it errs only by overcounting vertices that are members of at least three cliques containing j. George and Liu call such vertices "outmatched nodes," and observe that they tend to be rare in the symmetric algorithm. Computing approximate degrees takes only time proportional to the size of A.

Column minimum degree sometimes performs poorly if the matrix A has a few very dense rows, because then the structure of A^TA consists mostly of the cliques induced by those rows. Thus `colmmd` will withhold from consideration any row containing more than a fixed proportion (by default, 50%) of nonzeros.

All these options for minimum degree are under the user's control, though the casual user of MATLAB never needs to change the defaults. The default settings use approximate degrees, row reduction and supernode amalgamation every third stage, and a degree threshold of $1.2d+1$, and withhold rows that are at least 50% dense.

3.3.2. Permutations for sparsity: Symmetric matrices. Preorderings for Cholesky factorization apply symmetrically to the rows and columns of a symmetric

positive definite matrix. Sparse MATLAB includes two symmetric preordering permutation functions. The `colperm` permutation can also be used as a symmetric ordering, but it is usually not the best choice.

Bandwidth-limiting and profile-limiting orderings are useful for matrices whose structure is "one-dimensional" in a sense that is hard to make precise. The reverse Cuthill-McKee ordering is an effective and inexpensive profile-limiting permutation. MATLAB function `p = symrcm(A)` returns a reverse Cuthill-McKee permutation for symmetric matrix A. The algorithm first finds a "pseudo-peripheral" vertex of the graph of A, then generates a level structure by breadth-first search and orders the vertices by decreasing distance from the pseudo-peripheral vertex. Our implementation is based closely on the SPARSPAK implementation as described in the book by George and Liu [11].

Profile methods like reverse Cuthill-McKee are not the best choice for most large matrices arising from problems with two or more dimensions, or problems without much geometric structure, because such matrices typically do not have reorderings with low profile. The most generally useful symmetric preordering in MATLAB is minimum degree, obtained by the function `p = symmmd(A)`. Our symmetric minimum degree implementation is based on the column minimum degree described in Section 3.3.1. In fact, `symmmd` just creates a nonzero structure K with a column for each column of A and a row for each above-diagonal nonzero in A, such that K^TK has the same nonzero structure as A; it then calls the column minimum degree code on K.

3.3.3. Nonzero diagonals and block triangular form. A square nonsingular matrix A always has a row permutation p such that $A(p,:)$ has nonzeros on its main diagonal. The MATLAB function `p = dmperm(A)` computes such a permutation. With two output arguments, the function `[p,q] = dmperm(A)` gives both row and column permutations that put A into block upper triangular form; that is, $A(p,q)$ has a nonzero main diagonal and a block triangular structure with the largest possible number of blocks. Notice that the permutations p returned by these two calls are likely to be different.

The most common application of block triangular form is to solve a reducible system of linear equations by block back substitution, factoring only the diagonal blocks of the matrix. Figure 9 is an m-file that implements this algorithm. The m-file illustrates the call `[p,q,r] = dmperm(A)`, which returns p and q as before, and also a vector r giving the boundaries of the blocks of the block upper triangular form. To be precise, if there are b blocks in each direction, then r has length $b+1$, and the i-th diagonal block of $A(p,q)$ consists of rows and columns with indices from $r(i)$ through $r(i+1)-1$.

Any matrix, whether square or not, has a form called the "Dulmage-Mendelsohn decomposition" [4, 20], which is the same as ordinary block upper triangular form if the matrix is square and nonsingular. The most general form of the decomposition, for arbitrary rectangular A, is `[p,q,r,s] = dmperm(A)`. The first two outputs are permutations that put $A(p,q)$ into block form. Then r describes the row boundaries of the blocks and s the column boundaries: the i-th diagonal block of $A(p,q)$ has rows $r(i)$ through $r(i+1)-1$ and columns $s(i)$ through $s(i+1)-1$. The first diagonal block may have more columns than rows, the last diagonal block may have more rows than columns, and all the other diagonal blocks are square. The subdiagonal blocks are all zero. The square diagonal blocks have nonzero diagonal elements. All the diagonal blocks are irreducible; for the non-square blocks, this means that they have the "strong Hall property" [4]. This block form can be used to solve least squares

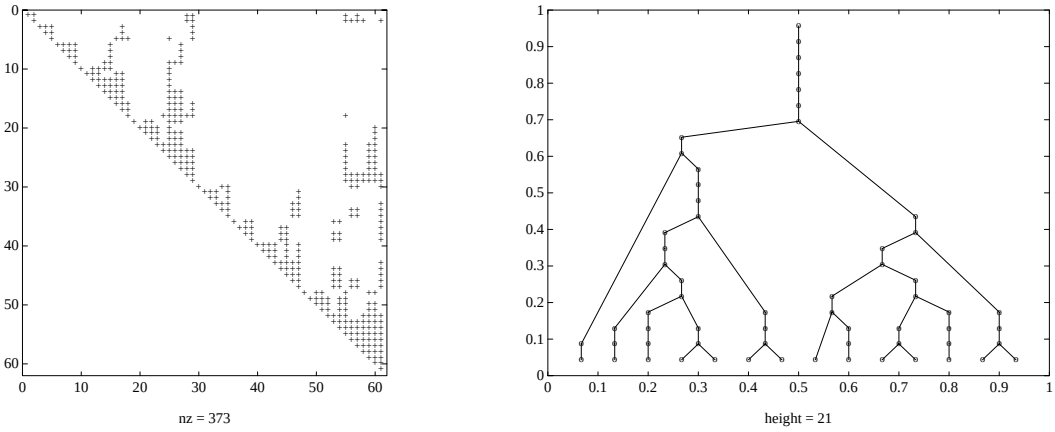

FIG. 3. *The Cholesky factor of a matrix and its elimination tree.*

problems by a method analogous to block back-substitution; see the references for more details.

3.3.4. Elimination trees. The elimination tree [21] of a symmetric positive definite matrix describes the dependences among rows or columns in Cholesky factorization. Liu [16] surveys applications of the elimination tree in sparse factorization. The nodes of the tree are the integers 1 through n, representing the rows of the matrix and of its upper triangular Cholesky factor. The parent of row i is the smallest $j > i$ such that the (i, j) element of the upper triangular Cholesky factor of the matrix is nonzero; if row i of the factor is zero after the diagonal, then i is a root. If the matrix is irreducible then its only root is node n.

Liu describes an algorithm to find the elimination tree without forming the Cholesky factorization, in time almost linear in the size of the matrix. That algorithm is implemented as the MATLAB function `[t,q] = etree(A)`. The resulting tree is represented by a row vector t of parent pointers: $t(i)$ is the parent of node i, or zero if i is a root.

The optional second output q is a permutation vector which gives a postorder permutation of the tree, or of the rows and columns of A. This permutation reorders the tree vertices so that every subtree is numbered consecutively, with the subtree's root last. This is an "equivalent reordering" of A, to use Liu's terminology: the Cholesky factorization of $A(q, q)$ has the same fill, operation count, and elimination tree as that of A. The permutation brings together the "fundamental supernodes" of A, which are full blocks in the Cholesky factor whose structure can be exploited in vectorized or parallel supernodal factorization [2, 17].

The postorder permutation can also be used to lay out the vertices for a picture of the elimination tree. The function `tspy(A)` plots a picture of the elimination tree of A, as shown in Figure 3.

3.4. Matrix division. The usual way to solve systems of linear equations in MATLAB is not by calling `lu` or `chol`, but with the matrix division operators / and \. If A is square, the result of `X = A\B` is the solution to the linear system $AX = B$; if A is not square then a least squares solution is computed. The result of `X = A/B` is the solution to $A = XB$, which is `(B'\A')'`. Full MATLAB computes $A\backslash B$ by LU

factorization with partial pivoting if A is square, or by QR factorization with column pivoting if not.

3.4.1. The sparse linear equation solver. Like full MATLAB, sparse MATLAB uses direct factorization methods to solve linear systems. The philosophy behind this is that iterative linear system solvers are best implemented as MATLAB m-files, which can use the sparse matrix data structures and operations in the core of MATLAB.

If A is sparse, MATLAB chooses among a sparse triangular solve, sparse Cholesky factorization, and sparse LU factorization, with optional preordering by minimum degree in the last two cases. The result returned has the same storage class as B. The outline of sparse $A\backslash B$ is as follows.

- If A is not square, solve the least squares problem.
- Otherwise, if A is triangular, perform a sparse triangular solve for each column of B.
- Otherwise, if A is a permutation of a triangular matrix, permute it and then perform a sparse triangular solve for each column of B.
- Otherwise, if A is Hermitian and has positive real diagonal elements, find a symmetric minimum degree order p and attempt to compute the Cholesky factorization of $A(p,p)$. If successful, finish with two sparse triangular solves for each column of B.
- Otherwise (if A is not Hermitian with positive diagonal or if Cholesky factorization fails), find a column minimum degree order p, compute the LU factorization with partial pivoting of $A(:,p)$, and perform two sparse triangular solves for each column of B.

Section 3.5 describes the sparse least squares method we currently use.

For a square matrix, the four possibilities are tried in order of increasing cost. Thus, the cost of checking alternatives is a small fraction of the total cost. The test for triangular A takes only $O(n)$ time if A is n by n; it just examines the first and last row indices in each column. (Notice that a test for triangularity would take $O(n^2)$ time for a full matrix.) The test for a "morally triangular" matrix, which is a row and column permutation of a nonsingular triangular matrix, takes time proportional to the number of nonzeros in the matrix and is in practice very fast. (A Dulmage-Mendelsohn decomposition would also detect moral triangularity, but would be slower.) These tests mean that, for example, the MATLAB sequence

```
[L,U] = lu(A);
y = L\b;
x = U\y;
```

will use triangular solves for both matrix divisions, since L is morally triangular and U is triangular.

The test for Hermitian positive diagonal is an inexpensive guess at when to use Cholesky factorization. Cholesky is quite a bit faster than LU, both because it does half as many operations and because storage management is simpler. (The time to look at every element of A in the test is insignificant.) Of course it is possible to construct examples in which Cholesky fails only at the last column of the reordered matrix, wasting significant time, but we have not seen this happen in practice.

The function `spparms` can be used to turn the minimum degree preordering off if the user knows how to compute a better preorder for the particular matrix in question.

MATLAB's matrix division does not have a block-triangular preordering built in, unlike (for example) the Harwell `MA28` code. Block triangular preordering and solution can be implemented easily as an m-file using the `dmperm` function; see Section 4.3.

Full MATLAB uses the LINPACK condition estimator and gives a warning if the denominator in matrix division is nearly singular. Sparse MATLAB should do the same, but the current version does not yet implement it.

3.4.2. Sparse triangular systems. The triangular linear system solver, which is also the main step of LU factorization, is based on an algorithm of Gilbert and Peierls [15]. When A is triangular and b is a sparse vector, $x = A\backslash b$ is computed in two steps. First, the nonzero structures of A and b are used (as described below) to make a list of the nonzero indices of x. This list is also the list of columns of A that participate nontrivially in the triangular solution. Second, the actual values of x are computed by using each column on the list to update the sparse accumulator with a "spaxpy" operation (Section 3.1.3). The list is generated in a "topological" order, which is one that guarantees that x_i is computed before column i of A is used in a spaxpy. Increasing order is one topological order of a lower triangular matrix, but any topological order will serve.

It remains to describe how to generate the topologically ordered list of indices efficiently. Consider the directed graph whose vertices are the columns of A, with an edge from j to i if $a_{ij} \neq 0$. (No extra data structure is needed to represent this graph—it is just an interpretation of the standard column data structure for A.) Each nonzero index of b corresponds to a vertex of the graph. The set of nonzero indices of x corresponds to the set of all vertices of b, plus all vertices that can be reached from vertices of b via directed paths in the graph of A. (This is true even if A is not triangular [12].) Any graph-searching algorithm could be used to identify those vertices and find the nonzero indices of x. A depth-first search has the advantage that a topological order for the list can be generated during the search. We add each vertex to the list at the time the depth-first search backtracks from that vertex. This creates the list in the reverse of a topological order; the numerical solution step then processes the list backwards, in topological order.

The reason to use this "reverse postorder" as the topological order is that there seems to be no way to generate the list in increasing or decreasing order, and the time wasted in sorting it would often be more than the number of arithmetic operations. However, the depth-first search examines just once each nonzero of A that participates nontrivially in the solve. Thus generating the list takes time proportional to the number of nonzero arithmetic operations in the numerical solve. This means that LU factorization can run in time proportional to arithmetic operations.

3.5. Least squares and the augmented system. We have not yet written a sparse QR factorization for the core of MATLAB. Instead, linear least squares problems of the form

$$\min \|b - Ax\|$$

are solved via the augmented system of equations

$$\begin{aligned} r + Ax &= b \\ A^T r &= 0. \end{aligned}$$

Introducing a residual scaling parameter α this can be written

$$\begin{pmatrix} \alpha I & A \\ A^T & 0 \end{pmatrix} \begin{pmatrix} r/\alpha \\ x \end{pmatrix} = \begin{pmatrix} b \\ 0 \end{pmatrix}.$$

The augmented matrix, which inherits any sparsity in A, is symmetric, but clearly not positive definite. We ignore the symmetry and solve the linear system with a general sparse LU factorization, although a symmetric, indefinite factorization might be twice as fast.

A recent note by Björck [3] analyzes the choice of the parameter α by bounding the effect of roundoff errors on the error in the computed solution x. The value of α which minimizes the bound involves two quantities, $\|r\|$ and the smallest singular value of A, which are too expensive to compute. Instead, we use an apparently satisfactory substitute,

$$\alpha = \max|a_{ij}|/1000.$$

This approach has been used by several other authors, including Arioli et al. [1], who do use a symmetric factorization and a similar heuristic for choosing α.

It is not clear whether augmented matrices, orthogonal factorizations, or iterative methods are preferable for least squares problems, from either an efficiency or an accuracy point of view. We have chosen the augmented matrix approach because it is competitive with the other approaches, and because we could use exisiting code.

3.6. Eigenvalues of sparse matrices. We expect that most eigenvalue computations involving sparse matrices will be done with iterative methods of Lanczos and Arnoldi type, implemented outside the core of MATLAB as m-files. The most time-consuming portion will be the computation of Ax for sparse A and dense x, which can be done efficiently using our core operations.

However, we do provide one almost-direct technique for computing all the eigenvalues (but not the eigenvectors) of a real symmetric or complex Hermitian sparse matrix. The reverse Cuthill-McKee algorithm is first used to provide a permutation which reduces the bandwidth. Then an algorithm of Schwartz [22] provides a sequence of plane rotations which further reduces the bandwidth to tridiagonal. Finally, the symmetric tridiagonal QR algorithm from dense MATLAB yields all the eigenvalues.

4. Examples. This section gives the flavor of sparse MATLAB by presenting several examples. First, we show the effect of reorderings for sparse factorization by illustrating a Cholesky factorization with several different permutations. Then we give two examples of m-files, which are programs written in the MATLAB language to provide functionality that is not implemented in the "core" of MATLAB. These sample m-files are simplified somewhat for the purposes of presentation. They omit some of the error-checking that would be present in real implementations, and they could be written to contain more flexible options than they do.

4.1. Effect of permutations on Cholesky factors. This sequence of examples illustrates the effect of reorderings on the computation of the Cholesky factorization of one symmetric test matrix. The matrix is $S = WW^T$ where W is the Harwell-Boeing matrix `WEST0479` [6], a model due to Westerberg of an eight-stage chemical distillation column.

There are four figures. Each figure shows two `spy` plots, first a particular symmetric permutation of S and then the Cholesky factor of the permuted matrix. The

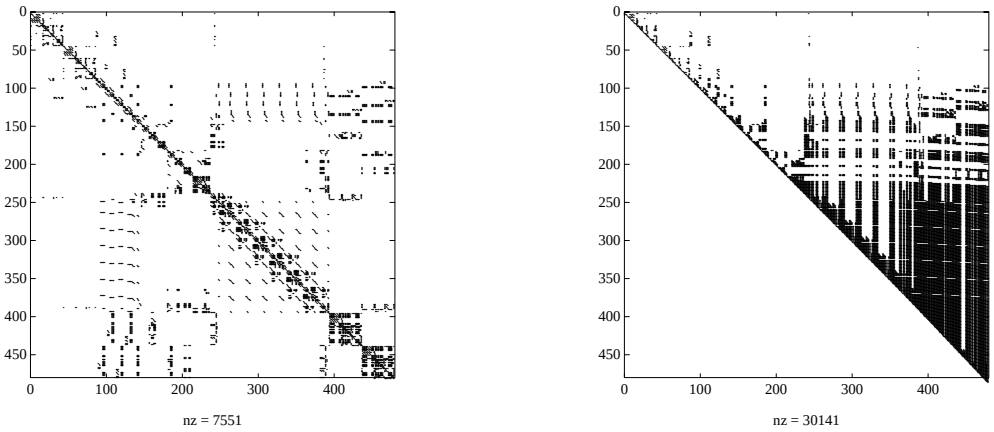

FIG. 4. *The structure of S and its Cholesky factor.*

TABLE 2
Effect of permutations on Cholesky factorization.

	nnz	time
Original order	30141	5.64
Reverse Cuthill-McKee	23866	4.26
Column count	12675	1.91
Minimum degree	12064	1.75

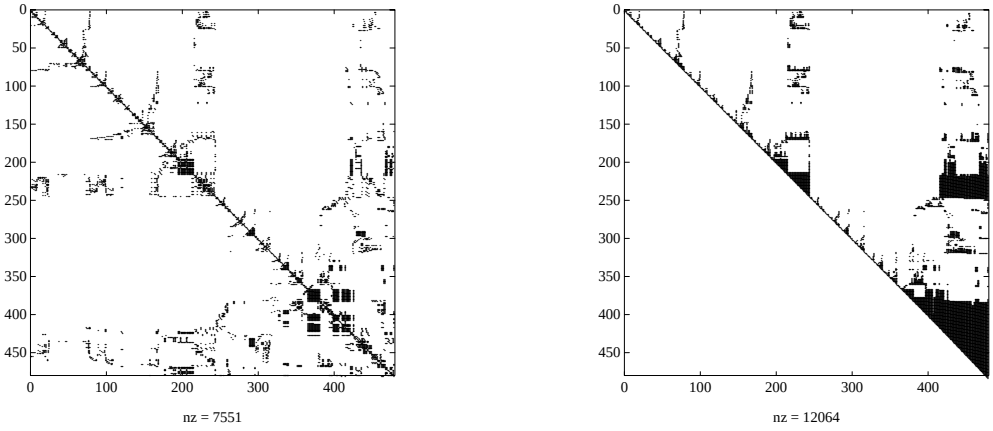

FIG. 7. *Matrix S and its Cholesky factor after minimum degree reordering.*

first figure is the original ordering; the second uses symmetric reverse Cuthill-McKee, `symrcm`; the third uses the column count permutation, `colperm`; the fourth uses symmetric minimum degree, `symmmd`. Each of the `spy` plots shows a matrix profile that is typical for the underlying permutation: Cuthill-McKee shows an envelope; column count shows all the mass in the later rows and columns; and minimum degree shows a recursive pattern curiously similar to divide-and-conquer orderings like nested dissection.

The matrix S is of order 479 and has 7551 nonzeros. Table 2 shows the number of nonzeros and the execution time in seconds (on a Sun SPARCstation-1) required to compute the Cholesky factors for each of the permutations. The behavior of `symrcm` and `symmmd` is typical; both produce significant reductions in nnz and in the execution time. The behavior of `colperm` is less typical; its reductions are not usually this significant.

4.2. The conjugate gradient method. Iterative techniques like the conjugate gradient method are often attractive for solving large sparse systems of linear equations. Figure 8 is an m-file for a conjugate gradient method. The code is somewhat simplified—a real code might use a more complicated criterion for termination, might compute Ap in a subroutine call in case A is not held explicitly, and might provide for preconditioning—but it illustrates an important point. Sparsity is never mentioned explicitly in the code. If the argument A is sparse then `Ap = A*p` will be computed as a sparse operation; if A is full then all the operations will be full.

In contrast with sparse direct methods, most iterative methods operate on matri-

```
function x = cgsolve (A,b,tol)

% Solve A*x = b by the conjugate gradient method.
% Iterate until norm(A*x-b) / norm(b) <= tol.

    x = zeros(size(b));
    r = b;
    rtr = r'*r;
    p = zeros(size(b));
    beta = 0;
    while ( norm(r) > tol * norm(b) )
        p = r + beta * p;
        Ap = A * p;
        alpha = rtr / ( p' * Ap );
        x = x + alpha * p;
        r = r - alpha * Ap;
        rtrold = rtr;
        rtr = r'*r;
        beta = rtr / rtrold;
    end
```

FIG. 8. *Solving $Ax = b$ by conjugate gradients.*

ces and vectors at a high level, typically using the coefficient matrix only in matrix-vector multiplications. This is the reason for our decision not to build an iterative linear solver into the core of MATLAB; such solvers can be more easily and flexibly written as m-files that make use of the basic sparse operations.

4.3. Solving reducible systems. If A is a reducible matrix, the linear system $Ax = b$ can be solved by permuting A to block upper triangular form (with irreducible diagonal blocks) and then performing block back-substitution. Only the diagonal blocks of the permuted matrix need to be factored, saving fill and arithmetic in the above-diagonal blocks. This strategy is incorporated in some existing Fortran sparse matrix packages, most notably Duff and Reid's code `MA28` in the Harwell Subroutine Library [7]. Figure 9 is an implementation as a MATLAB m-file. This function is a good illustration of the use of permutation vectors.

The call `[p,q,r] = dmperm(A)` returns a row permutation p and a column permutation q to put A in block triangular form. The third output argument r is an integer vector describing the boundaries of the blocks: the k-th block of $A(p,q)$ includes indices from $r(k)$ to $r(k+1)-1$. The loop has one iteration for each diagonal block; note that i and j are vectors of indices. The code resembles an ordinary triangular backsolve, but at each iteration the statement `x(j) = A(j,j) \ x(j)` solves for an entire block of x at once by sparse LU decomposition (with column minimum degree ordering) of one of the irreducible diagonal blocks of A.

Again this code is simplified a bit. A real code would merge every sequence of adjacent 1×1 diagonal blocks into a single triangular block, thus reducing the number of iterations of the main loop.

```
function x = dmsolve (A,b)

% Solve A*x = b by permuting A to block
% upper triangular form and then performing
% block back substitution.

    % Permute A to block form.
    [p,q,r] = dmperm(A);
    nblocks = length(r)-1;
    A = A(p,q);
    x = b(p);

    % Block backsolve.
    for k = nblocks : -1 : 1

        % Indices above the k-th block.
        i = 1 : r(k)-1;

        % Indices of the k-th block.
        j = r(k) : r(k+1)-1;

        x(j) = A(j,j) \ x(j);
        x(i) = x(i) - A(i,j) * x(j);

    end;

    % Undo the permutation of x.
    x(q) = x;
```

THE MATLAB ODE SUITE

LAWRENCE F. SHAMPINE* AND MARK W. REICHELT†

Abstract. This paper describes mathematical and software developments for a suite of programs for solving ordinary differential equations in MATLAB.

Key words. ordinary differential equations, stiff systems, BDF, Gear method, Rosenbrock method, non-stiff systems, Runge-Kutta method, Adams method, software

AMS subject classifications. 65L06, 65L05, 65Y99, 34A65

1. Introduction. This paper presents mathematical and software developments that are the basis for a suite of programs for the solution of initial value problems

$$y' = F(t, y)$$

on a time interval $[t_0, t_f]$, given initial values $y(t_0) = y_0$. The solvers for stiff problems allow the more general form

$$M(t)\, y' = f(t, y)$$

with a mass matrix $M(t)$ that is non-singular and (usually) sparse. The programs have been developed for MATLAB [29], a widely used environment for scientific computing. This influenced the choice of methods and how they were implemented.

As in many environments, the typical problem in MATLAB is solved interactively and the results displayed graphically. Generally functions defining the differential equations are not expensive to evaluate. The typical stiff problem is either of modest size or has a highly structured Jacobian. In MATLAB, linear algebra and the built-in array operations are relatively fast, and the language provides for sparse arrays. MATLAB handles storage dynamically and retains copies of arrays.

A new family of formulas for the solution of stiff problems called the numerical differentiation formulas, NDF's, are devised in §2. They are more efficient than the backward differentiation formulas, BDF's, though a couple of the higher order formulas are somewhat less stable. These formulas are conveniently implemented with backward differences. A way of changing step size in this representation is developed that is both compact and efficient in MATLAB. In §3 we devise a new linearly implicit one-step method for solving stiff systems, specifically a modified Rosenbrock method, and also a continuous extension of the method. §4 describes briefly how to modify these methods so as to solve conveniently and efficiently problems involving a mass matrix. In §5, we discuss briefly three methods for non-stiff problems. The two based on explicit Runge-Kutta methods are more efficient than those previously available in MATLAB and have free interpolants.

MATLAB has features, some of which are available in C and FORTRAN 90, that make possible an interesting and powerful user interface. §6 explains how the language was exploited to devise an interface that is unobtrusive, powerful, and extendable. Using the scheme of §7 for the numerical approximation of Jacobians, the design makes it possible for all the codes of the suite to be used in *exactly* the same manner. Options

* Mathematics Department, Southern Methodist University, Dallas, TX 75275. (shampine@na-net.ornl.gov)

† The MathWorks, Inc., 24 Prime Park Way, Natick, MA 01760. (mwr@mathworks.com)

allow users to supply more information that makes the solution of stiff problems more reliable and/or efficient. In particular, it is easy to exploit sparse Jacobians.

Examples in §8 show the relative performance of codes in the suite and the value of some of the options. The availability of the codes is described in §9.

2. Implicit Formulas for Stiff Systems. The BDF's are very popular for solving stiff problems. When the step size is a constant h and backward differences are used, the formula of order k, BDFk, for a step from (t_n, y_n) to (t_{n+1}, y_{n+1}) is

$$\sum_{m=1}^{k} \frac{1}{m} \nabla^m y_{n+1} - hF(t_{n+1}, y_{n+1}) = 0 \tag{1}$$

The algebraic equation for y_{n+1} is solved with a simplified Newton (chord) iteration. The iteration is started with the predicted value

$$y_{n+1}^{(0)} = \sum_{m=0}^{k} \nabla^m y_n \tag{2}$$

The leading term of the BDFk truncation error can be conveniently approximated as

$$\frac{1}{k+1} h^{k+1} y^{(k+1)} \approx \frac{1}{k+1} \nabla^{k+1} y_{n+1}. \tag{3}$$

The typical implementation of a general-purpose BDF code is quasi-constant step size. This means that the formulas used are those for a constant step size and the step size is held constant during an integration unless there is good reason to change it. General-purpose BDF codes also vary the order during an integration.

2.1. The Numerical Differentiation Formulas. Noting that the predictor (2) has a longer memory than (1), Klopfenstein [25] and Reiher [31] considered how to exploit this to obtain better stability. Klopfenstein studied methods of the form

$$\sum_{m=1}^{k} \frac{1}{m} \nabla^m y_{n+1} - hF(t_{n+1}, y_{n+1}) - \kappa\gamma_k \left(y_{n+1} - y_{n+1}^{(0)} \right) = 0 \tag{4}$$

that he called numerical differentiation formulas, NDF's. Here κ is a scalar parameter and the coefficients γ_k are given by $\gamma_k = \sum_{j=1}^{k} \frac{1}{j}$. The role of the term added to BDFk is illuminated by the identity

$$y_{n+1} - y_{n+1}^{(0)} = \nabla^{k+1} y_{n+1}$$

and the approximation (3) to the truncation error of BDFk. It follows easily that for any value of the parameter κ, the method is of order (at least) k and the leading term of its truncation error is

$$\left(\kappa\gamma_k + \frac{1}{k+1} \right) h^{k+1} y^{(k+1)} \tag{5}$$

For orders 3-6, Klopfenstein and Reiher found numerically the κ that maximizes the angle of A(α)-stability. Because BDF2 is already A-stable, Klopfenstein considered how to choose κ so as to reduce the truncation error as much as possible whilst still retaining A-stability. The optimal choice is $\kappa = -1/9$, yielding a truncation error

TABLE 1
The Klopfenstein-Shampine NDF's and their efficiency and A(α)-stability relative to the BDF's.

order	NDF coeff	step ratio	stability angle		percent
k	κ	percent	BDF	NDF	change
1	-0.1850	26%	90°	90°	0%
2	-1/9	26%	90°	90°	0%
3	-0.0823	26%	86°	80°	-7%
4	-0.0415	12%	73°	66°	-10%
5	0	0%	51°	51°	0%

coefficient half that of BDF2. This implies that for sufficiently small step sizes, NDF2 can achieve the same accuracy as BDF2 with a step size about 26% bigger.

The formulas derived by Klopfenstein and Reiher at orders higher than 2 are less successful because the price of improved stability is reduced efficiency. Taking the opposite tack, we sought values of κ that would make the NDF's more accurate than the BDF's and not much less stable. Of course the leading term of the truncation error cannot be made too small, else it would not dominate and the formula would not behave as expected at realistic step sizes. Because Klopfenstein's second order formula optimally improves accuracy while retaining L-stability, it serves as the order 2 method of our NDF family. Correspondingly, we sought to obtain the same improvement in efficiency (26%) at orders 3-5. This comes at the price of reduced stability and we were not willing to reduce the stability angle by more than 10%. The search was carried out numerically. Our choices and the compromises made in balancing efficiency and stability are shown in Table 1. The stability of BDF5 is so poor that we were not willing to reduce it at all.

The first-order formula NDF1 has the form

$$y_{n+1} - y_n - \kappa\,(y_{n+1} - 2y_n + y_{n-1}) = hF(t_{n+1}, y_{n+1})$$

The boundary of the stability region of a linear multistep method consists of those points z for which the characteristic equation $\rho(\theta) - z\sigma(\theta) = 0$ has a root θ of magnitude 1. The root-locus method obtains the boundary as a subset of $z = \rho(\theta)/\sigma(\theta)$ as $\theta = \exp(i\psi)$ ranges over all numbers of magnitude 1. For NDF1 it is found that

$$Re(z) = 1 - (1 - 2\kappa)\cos(\psi) - 2\kappa\cos^2(\psi)$$

and that a sufficient condition for the formula to be A-stable is $1 - 2\kappa \geq 0$. As at other orders, we chose an improvement in efficiency of 26%, leading to $\kappa = -0.1850$.

2.2. Changing the Step Size. Backward differences are very suitable for implementing the NDF's in MATLAB because the basic algorithms can be coded compactly and efficiently. We develop here a way of changing step size that is also well-suited to the language.

When the integration reaches t_n, there are available solution values $y(t_{n-j})$ at $t_{n-j} = t_n - jh$ for $j = 0, 1, ..., k$. The interpolating polynomial is

$$P(t) = y(t_n) + \sum_{j=1}^{k} \nabla^j y(t_n) \frac{1}{j!h^j} \prod_{m=0}^{j-1} (t - t_{n-m})\,.$$

By definition $\nabla^j P(t_n) = \nabla^j y(t_n)$. In this representation the solution is held in the form of the current value $y(t_n)$ and a table of backward differences

$$D = \left[\nabla P(t_n), \nabla^2 P(t_n), ..., \nabla^k P(t_n)\right].$$

Changing to a new step size $h^* \neq h$ amounts to evaluating $P(t)$ at $t^* = t_n - jh^*$ for $j = 0, 1, ..., k$ and then forming

$$D^* = \left[\nabla^* P(t_n), \nabla^{*2} P(t_n), ..., \nabla^{*k} P(t_n)\right].$$

Here the asterisk on the backward difference ∇^* indicates that it is for step size h^*.

Equating the two representations of $P(t)$ leads to the identity

$$\sum_{j=1}^{k} \nabla^{*j} P(t_n) \frac{1}{j! h^{*j}} \prod_{m=0}^{j-1} \left(t - t^*_{n-m}\right) = \sum_{j=1}^{k} \nabla^j P(t_n) \frac{1}{j! h^j} \prod_{m=0}^{j-1} \left(t - t_{n-m}\right).$$

Evaluating this identity at $t = t^*_{n-r}$ for $r = 1, ..., k$ leads to the system of equations

$$\sum_{j=1}^{k} \nabla^{*j} P(t_n) U_{jr} = \sum_{j=1}^{k} \nabla^j P(t_n) R_{jr}$$

which is in matrix terms $D^* U = DR$. The entries of the $k \times k$ matrix U are

$$U_{jr} = \frac{1}{j! h^{*j}} \prod_{m=0}^{j-1} \left(t^*_{n-r} - t^*_{n-m}\right) = \frac{1}{j!} \prod_{m=0}^{j-1} (m - r).$$

Matrix U satisfies $U^2 = I$. This implies that $D^* = D\,(RU)$, the scheme we use for changing the step size. The entries of U are integers that do not depend on h nor on k. In terms of $\rho = h^*/h \neq 1$, the entries of the $k \times k$ matrix R are

$$R_{jr} = \frac{1}{j!} \prod_{m=0}^{j-1} (m - r\rho)$$

R must be formed each time the step size is changed. This is done in a single line of MATLAB code using the cumprod function. Likewise, changing the representation by means of matrix multiplication is done in a single line. Accordingly, in MATLAB this way of changing the step size is both compact and efficient.

2.3. The `ode15s` Program. The code `ode15s` is a quasi-constant step size implementation of the NDF's in terms of backward differences. Options allow integration with the BDF's and integration with a maximum order less than the default of 5.

The identity

$$\sum_{m=1}^{k} \frac{1}{m} \nabla^m y_{n+1} = \gamma_k \left(y_{n+1} - y^{(0)}_{n+1}\right) + \sum_{m=1}^{k} \gamma_m \nabla^m y_n$$

shows that equation (4) is equivalent to

$$(1 - \kappa)\,\gamma_k \left(y_{n+1} - y^{(0)}_{n+1}\right) + \sum_{m=1}^{k} \gamma_m \nabla^m y_n - hF(t_{n+1}, y_{n+1}) = 0.$$

In the simplified Newton iteration, the correction to the current iterate

$$y_{n+1}^{(i+1)} = y_{n+1}^{(i)} + \Delta^{(i)}$$

is obtained by solving

$$\left(I - \frac{h}{(1-\kappa)\,\gamma_k} J\right) \Delta^{(i)} = \frac{h}{(1-\kappa)\,\gamma_k} F(t_{n+1}, y_{n+1}^{(i)}) - \Psi - \left(y_{n+1}^{(i)} - y_{n+1}^{(0)}\right).$$

Here J is an approximation to the Jacobian of $F(t,y)$ and

$$\Psi = \frac{1}{(1-\kappa)\,\gamma_k} \sum_{m=1}^{k} \gamma_m \nabla^m y_n$$

is a quantity that is fixed during the computation of y_{n+1}. Scaling the equation to remove the scalar multiplying J offers some advantages [36]. It is much more accurate to obtain the fundamental quantity $\nabla^{k+1} y_{n+1}$ as the limit of

$$d^{(i)} = y_{n+1}^{(i)} - y_{n+1}^{(0)}$$

computed from

$$\begin{aligned} d^{(i+1)} &= d^{(i)} + \Delta^{(i)} \\ y_{n+1}^{(i+1)} &= y_{n+1}^{(0)} + d^{(i+1)} \end{aligned}$$

Many of the tactics adopted in the code resemble those found in the well-known codes DIFSUB [17], DDRIV2 [24], LSODE [22], and VODE [7]. In particular, local extrapolation is not done. The selection of the initial step size follows Curtis [10] who observes that by forming partial derivatives of $F(t,y)$ at t_0, it is possible to estimate the *optimal* initial step size.

In the context of MATLAB it is natural to retain a copy of the Jacobian matrix. Of the codes cited, only VODE exploits this possibility. It is also natural to form and factor the iteration matrix every time the step size or order is changed. The rate of convergence is monitored [34] and the iteration terminated if it is predicted that convergence will not be achieved in four iterations. Should this happen and the Jacobian not be current, a new Jacobian is formed. Otherwise the step size is reduced.

Our scheme for reusing Jacobians means that when the Jacobian is constant, `ode15s` will normally form a Jacobian just once in the whole integration. Also, the code will form very few Jacobians when applied to a problem that is not stiff. `ode15s` competes rather well with the codes for non-stiff problems because of this and the efficient linear algebra of MATLAB.

3. Linearly Implicit Formulas for Stiff Systems. In this section it is convenient at first to consider differential equations in autonomous form, $y' = F(y)$. Rosenbrock methods have the form

$$y_{n+1} = y_n + h \sum_{i=1}^{s} b_i k_i,$$

where the k_i are obtained for $i = 1, 2, ..., s$ by solving

$$W k_i = F\left(y_n + h \sum_{j=1}^{i-1} a_{ij} k_j\right) + hJ \sum_{j=1}^{i-1} d_{ij} k_j.$$

Here $W = I - hdJ$ and $J = \partial F(y_n)/\partial y$. Such methods are said to be linearly implicit because the computation of y_{n+1} requires the solution of systems of linear equations.

A number of authors have explored formulas of this form with J that only approximate $\partial F(y_n)/\partial y$. A second order formula due to Wolfbrandt [40] is

$$\begin{aligned} Wk_1 &= F\left(y_n\right) \\ Wk_2 &= F\left(y_n + \frac{2}{3}hk_1\right) - \frac{4}{3}hdJk_1 \\ y_{n+1} &= y_n + \frac{h}{4}\left(k_1 + 3k_2\right) \end{aligned}$$

Here the parameter $d = 1/\left(2+\sqrt{2}\right)$. It is characteristic of such W-formulas that the order of the formula does not depend on J. The stability does depend on J, and if $J = \partial F/\partial y$, the formula is L-stable.

One of the attractions of Rosenbrock and W methods is that they are one-step. However, it is not easy to retain this property when estimating the error, and the error estimate of [40] for Wolfbrandt's formula gives it up. Scraton [33] achieved a one-step error estimate without additional evaluations of F by assuming that

$$J = \frac{\partial F}{\partial y}\left(t_n, y_n\right) + hB + O\left(h^2\right)$$

We must assume that $J \approx \partial F/\partial y$ if we are to apply the usual linear stability theory to conclude the good stability that leads us to consider such formulas in the first place. We describe formulas based on Scraton's assumption as modified Rosenbrock formulas. Scraton's error estimate is inefficient for very stiff problems because the companion formula of order 3 is not stable at infinity. Zedan [43], [42] derived a companion that is A-stable and also requires no additional evaluations of F.

3.1. A Modified Rosenbrock Triple. In a step from t_n to t_{n+1} with Wolfbrandt's formula and any of the error estimates cited, F is evaluated only at t_n and $t_n + 2h/3$. It is possible that if a solution component changes sharply somewhere in $(t_n + 2h/3, t_n + h)$, a poor approximation to this component at t_{n+1} will be produced and accepted. Very sharp changes in a solution component are common when solving stiff problems and robust software ought to be able to deal with them. For this reason, many authors attempt to derive pairs that evaluate at both ends of a step.

Wolfbrandt's formula is a member of a family of second order, L-stable W methods [40] that involve two evaluations of F. By making the *first* evaluation of F for the next step the *same as* the *last* of the current step (FSAL), we have at our disposal a function evaluation that is usually "free" because most steps are successful. Exploiting this we derived a pair of formulas that we present in a form that avoids unnecessary matrix multiplications [36]. When advancing a step from (t_n, y_n) to $t_{n+1} = t_n + h$, the modified Rosenbrock pair is

$$\begin{aligned} F_0 &= F\left(t_n, y_n\right) \\ k_1 &= W^{-1}\left(F_0 + hdT\right) \\ F_1 &= F\left(t_n + 0.5h, y_n + 0.5hk_1\right) \\ k_2 &= W^{-1}\left(F_1 - k_1\right) + k_1 \\ y_{n+1} &= y_n + hk_2 \\ F_2 &= F\left(t_{n+1}, y_{n+1}\right) \end{aligned}$$

$$k_3 = W^{-1}\left[F_2 - e_{32}\left(k_2 - F_1\right) - 2\left(k_1 - F_0\right) + hdT\right]$$
$$error \approx \frac{h}{6}\left(k_1 - 2k_2 + k_3\right)$$

Here $W = I - hdJ$ with $d = 1/\left(2+\sqrt{2}\right)$ and $e_{32} = 6+\sqrt{2}$,

$$J \approx \frac{\partial F}{\partial y}\left(t_n, y_n\right) \quad \text{and} \quad T \approx \frac{\partial F}{\partial t}\left(t_n, y_n\right).$$

If the step is a success, the F_2 of the current step is the F_0 of the next. If $J = \partial F/\partial y$, the second order formula is L-stable. Because the pair samples at both ends of the step, it has a chance of recognizing very sharp changes that occur within the span of a step.

On p. 129 of his dissertation, Zedan describes briefly a scheme for interpolating his modified Rosenbrock method. On $[t_n, t_n + h]$ he approximates the solution with the quadratic polynomial interpolating y_n, y_{n+1}, and $F_0 = F\left(t_n, y_n\right)$. Interpolating F_0 can be unsatisfactory when the problem is very stiff. A standard way to obtain a continous extension to a one-step method is to derive a family of formulas, each of which provides an approximation at $t_n + h^*$ for a given $h^* = sh$. For any s, it is easy to derive a formula that has the same form as that of the basic step to t_{n+1}; the trick is to reuse the computations of the basic step as much as possible. In the new formula the matrix $W^* = I - h^*d^*J$, so if we take the parameter $d^* = d/s$, then $W^* = W$. It is easily found that with similar definitions, it is possible to obtain a second order W method for the intermediate value that requires no major computations not already available from the basic step itself. Specifically, it is found that a second order approximation to $y\left(t_n + sh\right)$ is provided by

$$y_{n+s} = y_n + h\left[\frac{s\left(1-s\right)}{1-2d}k_1 + \frac{s\left(s-2d\right)}{1-2d}k_2\right].$$

Though derived as a family of formulas depending on a parameter s, the continuous extension turns out to be a quadratic polynomial in s. It interpolates both y_n and y_{n+1}, hence connects continuously with approximations on adjacent steps. This interpolant behaves better for stiff problems than the one depending on F_0, in essence because of the W^{-1} implicit in the k_i.

3.2. The `ode23s` Program. The code `ode23s` based on the scheme derived here provides an alternative to `ode15s` for the solution of stiff problems. It is especially effective at crude tolerances, when a one-step method has advantages over methods with memory, and when Jacobians have eigenvalues near the imaginary axis. It is a fixed order method of such simple structure that the overhead is low except for the linear algebra, which is relatively fast in MATLAB. The integration is advanced with the lower order formula, so `ode23s` does not do local extrapolation. To achieve the same L-stability in `ode15s`, the maximum order would have to be restricted to 2.

We have considered algorithms along the lines of [11] for recognizing when a new Jacobian is needed and we have also considered tactics like those of [40] and [42] for this purpose. This is promising and we may revisit the matter, but the current version of `ode23s` forms a new Jacobian at every step for several reasons. A formula of order 2 is most appropriate at crude tolerances. At such tolerances solution components often change significantly in the course of a single step, so it is often appropriate to form a new Jacobian. In MATLAB the Jacobian is typically of modest size or sparse and its

evaluation is not very expensive compared with evaluating F. Lastly, evaluating the Jacobian at every step enhances the reliability and robustness of the code.

For non-autonomous problems `ode23s` requires an approximation to $\partial F/\partial t$ in addition to the approximation to $\partial F/\partial y$. For the convenience of the user and to make the use of all the codes the same, we have chosen always to approximate this partial derivative numerically.

4. Stiff Systems of More General Form. A stiff problem $M(t)\,y' = f(t,y)$ with a non-singular mass matrix $M(t)$ can always be solved by transforming the equation to the equivalent form $y' = F(t,y) = M^{-1}(t)\,f(t,y)$. Small modifications to the methods avoid the inconvenience and expense of this transformation.

Because the modified Rosenbrock method was derived for autonomous systems, it is awkward to accomodate matrices M that depend on t. Accordingly, we allow only constant mass matrices in `ode23s`. The modification is derived by applying the method to the transformed equation and then rewriting the computations in terms of M and $f(t,y)$. The first stage k_1 is obtained from

$$W k_1 = (I - hdJ)k_1 = F_0 + hdT$$

Here $F_0 = M^{-1}f(t_0,y_0) = M^{-1}f_0$,

$$J \approx \frac{\partial F}{\partial y} = M^{-1}\frac{\partial f}{\partial y} \quad \text{and} \quad T \approx \frac{\partial F}{\partial t} = M^{-1}\frac{\partial f}{\partial t}.$$

Scaling the equation for k_1 by M leads to

$$\left(M - hd\frac{\partial f}{\partial y}\right) k_1 = f_0 + hd\frac{\partial f}{\partial t}$$

The remaining computations are treated similarly. The usual form of the method is recovered when $M = I$. This modification of the method allows the user to pose the problem in terms of M and $f(t,y)$. It avoids the solution of linear equations that arise when the equation is transformed.

The `ode15s` code allows the mass matrix to depend on t. This causes only one difference in the modification of the methods of this code. The simplified Newton method involves solution of linear systems with the iteration matrix

$$I - \frac{h}{(1-\kappa)\gamma_k}J$$

and right hand sides involving

$$F(t_{n+1}, y_{n+1}^{(i)}) = M^{-1}(t_{n+1})f(t_{n+1}, y_{n+1}^{(i)})$$

Here

$$J \approx \frac{\partial F}{\partial y}\,(t_m, y_m) = M^{-1}(t_m)\frac{\partial f}{\partial y}\,(t_m, y_m)$$

for some $m \le n$. Because M depends on t, it is not possible to remove all the inverses simply by scaling with $M(t_{n+1})$. We approximate the scaled iteration matrix by

$$M(t_m) - \frac{h}{(1-\kappa)\gamma_k}J \quad \text{where} \quad J \approx \frac{\partial f}{\partial y}\,(t_m, y_m)\,.$$

With this approximation, the computations can be written in terms of $M(t)$ and $f(t,y)$. The modified method reduces to the usual one when $M(t) = I$.

5. Explicit Formulas for Non-Stiff Systems. The two explicit Runge-Kutta codes, `ode23` and `ode45`, in previous versions of MATLAB have been replaced by codes with the same names that remedy some deficiencies in design and take advantage of developments in the theory and practice of Runge-Kutta methods. A new code, `ode113`, is a PECE implementation of Adams-Bashforth-Moulton methods.

The new `ode23` is based on the Bogacki-Shampine $(2, 3)$ pair [3] (see also [37]) and the new `ode45` is based on the Dormand-Prince $(4, 5)$ pair [12]. Workers in the field employ a number of quantitative measures for evaluating the quality of a pair of formulas. In the standard measures these pairs are of high quality and significantly more efficient than those used in the earlier codes. Both pairs are FSAL and constructed for local extrapolation.

Because solution components can change substantially in the course of a single step, the values computed at the end of each natural step may not provide adequate resolution of the solution for plotting. This phenomenon is exacerbated when plotting in the phase plane. A good way to deal with this is to form additional values by means of a continuous extension (interpolant). A continuous extension also makes possible event location, a valuable capability in ODE codes. We selected pairs for which continuous extensions were available. In the case of the $(2, 3)$ pair, accurate solution values can be obtained for "free" (no additional evaluations of F) by cubic Hermite interpolation to the values and slopes computed at the ends of the step. Dormand and Prince obtained a number of inexpensive interpolants for their pair in [13]; they communicated to us another interpolant of order 4 that is of high quality and "free". The default in `ode45` is to use this interpolant to compute solution values at four points spaced evenly within the span of each natural step. Figure 1 shows the importance of this development. We return to this issue in §6.

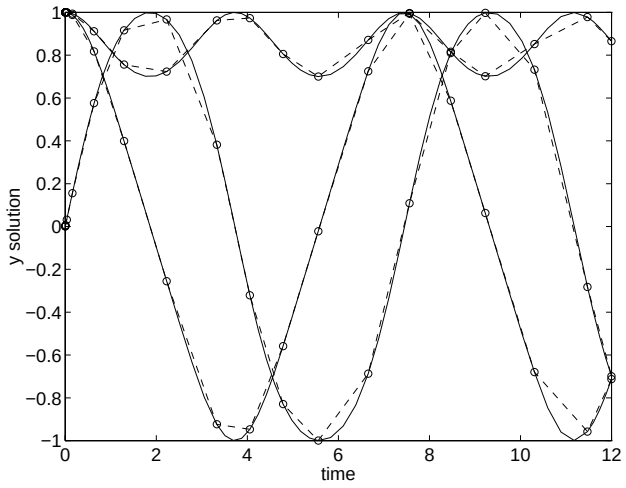

FIG. 1. *The* `rigid` *solution as computed by* `ode45`*. The continuous curves result from the default output of* `ode45`*. The discrete values are the results at the end of each step. The dashed curves show what happens when the new interpolation capability is disabled.*

`ode113` is a descendant of ODE/STEP, INTRP [39]. Though the code differs considerably in detail, its basic algorithms follow closely those of STEP. In particular, it does local extrapolation. The authors of ODE/STEP, INTRP tried to obtain as cheaply and reliably as possible solutions of moderate to high accuracy to problems

involving functions F that are expensive to evaluate. This was accomplished by monitoring the integration very closely and by providing formulas of quite high orders. In the present context the overhead of this monitoring is comparatively expensive. Although more than graphical accuracy is necessary for adequate resolution of solutions of moderately unstable problems, the high order formulas available in `ode113` are not nearly as helpful in the present context as they are in general scientific computation.

6. User Interface. Every author of an ODE code wants to make it as easy as possible to use. At the same time the code must be able to solve typical problems. It is not easy to reconcile these goals. In the MATLAB environment we considered it essential that it be possible to use all the codes in *exactly* the same way. However, we also considered it essential to provide codes for the solution of stiff problems. Methods for stiff problems make use of Jacobians. If a code for solving stiff problems is to "look" like a code for non-stiff problems, it is necessary to approximate these Jacobians inside the code. Unfortunately, it is difficult to do this reliably. Moreover, when it is not inconvenient to supply some information about the structure of the Jacobian, it can be quite advantageous. Indeed, this information is crucial to the solution of "large" systems. Clearly a user interface to a code for stiff problems must allow for the provision of additional information and this without complication when users do not have the additional information or do not think it worth the trouble of supplying. The same is true of other optional information, so a key issue is how to make options unobtrusive. Further, the design must be extendable. Indeed, we have already extended the functionality of our original design three times.

It is possible to use all the codes in the suite in precisely the same manner, so in the examples that follow `ode15s` is generic. An initial value problem can be solved by

```
[t,y] = ode15s('ydot',tspan,y0);
```

The results can then be displayed with the usual plotting tools of MATLAB, e.g., by `plot(t,y)`. Here `ydot` is the name of a function that defines the differential equation. Figure 2 shows an example of the van der Pol equation coded as function `vdpnsode`. The interval of integration is `tspan=[t0,tfinal]` and the initial conditions are `y0`. The code obtains the number of equations by measuring the length of the vector `y0`.

```
function dy = vdpnsode(t,y)
dy = zeros(2,1);          % preallocate column vector dy
dy(1) = y(2);
dy(2) = (1-y(1)^2)*y(2)-y(1);
```

FIG. 2. *The* MATLAB *code for the initial value problem* `vdpnsode`.

The suite exploits the possibility of a variable number of arguments. For instance, the codes monitor several measures of cost, such as the number of steps and the number of Jacobian evaluations, and return them in an optional output argument, viz. `[t,y,stats]`. It also exploits the possibility of empty arrays. For example, it is possible to define the initial value problem in one file. Figure 3 illustrates this for the CHM6 [14] stiff test problem of [28]. With the function coded as shown, if `ode15s` is invoked with empty or missing arguments for `tspan` and `y0`, it will call `chm6ode` with an empty argument for `t` to obtain the information not supplied in the call list.

Returning the independent variable and approximate solution at each step in arrays `[t,y]` is natural in MATLAB because it facilitates plotting and the sizes of

```
function [out1,out2,out3] = chm6ode(t,y)
if isempty(t)             % return default tspan, y0, options
  out1 = [0; 1000];
  out2 = [761; 0; 600; 0.1];
  out3 = odeset('atol',1e-13);
  return;
end
dy = zeros(4,1);          % preallocate column vector dy
K = exp(20.7 - 1500/y(1));
dy(1) = 1.3*(y(3) - y(1)) + 10400*K*y(2);
dy(2) = 1880 * (y(4) - y(2) * (1+K));
dy(3) = 1752 - 269*y(3) + 267*y(1);
dy(4) = 0.1 + 320*y(2) - 321*y(4);
out1 = dy;
```

FIG. 3. *The* MATLAB *code for the initial value problem* `chm6ode`.

output arrays do not have to be specified in advance. The steps chosen by a code tend to cluster where solution components change rapidly, so this design generally results in satisfactory plots. However, this is not always the case, a point made by Polking [30] for the old `ode45` and illustrated by Figure 1 for the new. All the methods implemented in the suite have free interpolants that can be evaluated at additional points to obtain a smooth plot. In our design there is an option `refine` for specifying the number of answers to be computed at points equally spaced in the span of each step. By increasing `refine`, it is always possible to get a smooth plot. The additional output is obtained inexpensively via a continuous extension of the formula.

To deal with output at specific points, we overload the definition of `tspan` and use the length of this vector to dictate how its values are to be interpreted. An input `tspan` with two entries means that output at the natural steps is desired. If `tspan` contains more than two entries, the code is to produce output at the values of the independent variable specified in `tspan` and only these values. Because output is obtained by evaluating a polynomial, the number and placement of specified output points has little effect on the cost of the integration.

It is difficult to accomodate all the possibilities for optional input without complicating the interface to the point that users despair. A traditional approach is to use an options vector. We do this too, but with some innovations. The options vector is optional. When it is employed, the syntax of a call to the solver is

```
[t,y] = ode15s('ydot',tspan,y0,options);
```

The vector `options` is built by means of the function `odeset` that accepts name-value pairs. We make use of keywords and exploit the fact that in MATLAB we can specify values for the options that are of different data types. Indeed, an option can have more than one data type as a value. `odeset` allows options to be set in any order and default values are used for any quantity not explicitly set by the user. A number of things are done to make the interface more convenient, e.g., the name alone instructs `odeset` to assign the value "true" to a Boolean variable.

The most commonly used options are `rtol` and `atol`, tolerances associated with the error control. Specification of the error control is a difficult matter discussed in

[37]. There it is explained how the simplifying assumptions made in the old `ode23` and `ode45` can lead to unsatisfactory results. Polking [30] makes the same point. Unfortunately, there seems to be no way to provide automatically a default control of the error that is completely satisfactory.

In the suite, the local error e_i in y_i is estimated in each step and made to satisfy

$$|e_i| \leq r\,|y_i| + a_i$$

where $r =$ `rtol` and $a_i =$ `atol(i)`. The scalar relative error tolerance `rtol` has a default value of 10^{-3}. The vector of absolute error tolerances `atol` has by default all its values equal to 10^{-6}. If a scalar absolute error tolerance is input, the code understands that the value is to be assigned to all entries of the `atol` vector.

As another example of setting options, suppose that we wish to solve a stiff problem with a constant Jacobian, an absolute error tolerance of 10^{-20} is appropriate for all components, and we wish to impose a maximum step size of 3500 to assure that the code will recognize phenomena occurring on this time scale. This is done by

```
options = odeset('constantJ','atol',1e-20,'hmax',3500);
```

An illuminating example is provided by the `chm6ode` function shown in Figure 3. Its solution is discussed in [27]. Figure 5 is a log-log plot of $y_2(t)$. A fundamental difficulty is that with an initial value of 0, there is no natural measure of scale for $y_2(t)$. It turns out that the component never gets bigger than about 7×10^{-10}, so the default absolute error tolerance of 10^{-6} is inappropriate. After an integration that revealed the general size of this solution component, we solved the problem again with the default relative tolerance of 10^{-3} and an optional absolute error tolerance of 10^{-13}. This is accomplished by `ode15s` in only 139 steps. The step sizes ranged from 5×10^{-14} to 10^2! This is mainly due to $y_2(t)$ changing rapidly on a very short time scale. On plotting the output it is seen that a logarithmic scale in t would be more appropriate. Because all the solution values are provided to users in our design and they are retained in MATLAB, they can be displayed in a more satisfactory way without having to recompute them.

In order that all codes in the suite have the same appearance to the user, the codes intended for stiff problems by default compute internally the necessary partial derivatives by differences. Users are given the option of providing a function for the analytical evaluation of the Jacobian. They are also given the option of specifying that the Jacobian is constant, a special case that leads to significant savings in `ode23s`. The default is to treat the Jacobian as a full matrix. To take advantage of a sparse Jacobian, the code must be informed of the sparsity pattern. The distinction between banded Jacobians and the much more complicated case of general sparse Jacobians that is important in other codes is absent in the new suite. All that a user must do is provide a (sparse) matrix S of zeros and ones that represents the sparsity pattern of the Jacobian. There are a number of ways to create matrix S. If there are `neq` equations, an `neq` $\times$ `neq` sparse matrix of zeros can be created by

```
S = sparse(neq,neq);
```

Then for each equation i in $F(t, y)$, if y_j appears in the equation, the (i, j) entry of S is set to 1, i.e. `S(i,j) = 1`. These quantities can be set in any order. If the Jacobian has a regular structure, it may be possible to define S more compactly. For example, if the Jacobian is banded with bandwidth $2m + 1$, it can be defined in a single line

```
S = spdiags(ones(neq,2m+1),-m:m,neq,neq)
```

After defining the sparsity pattern, the value S is assigned to the option `sparseJ` with `odeset`. No further action is required of the user.

As discussed in §4, the two codes for stiff problems permit a more general form of the differential equation, namely $M(t)\,y' = f(t,y)$, with a mass matrix $M(t)$. In other computing environments a mass matrix raises awkward questions about specification of M and its structure and how its structure relates to that of the Jacobian of $f(t,y)$. In our interface, the codes are informed of the presence of a mass matrix by means of the `mass` option. The value of this option is the name of a function that returns $M(t)$. Or, if the mass matrix is constant, the matrix itself can be provided as the value of the option. The language deals automatically with the structures of the matrices that arise in the specification and solution of the problem [19].

7. Numerical Partial Derivatives. Methods for the solution of stiff problems involve partial derivatives of the function defining the differential equation. The popular codes allow users to provide a routine for evaluating these derivatives analytically. However, this is so much trouble for users and so prone to error that the default is to approximate them internally by numerical differentiation. The new suite follows this approach, using a function `numjac` to compute the numerical approximation.

The scaling difficulties that are possible when approximating partial derivatives by differences are well-known [37]. The `numjac` code implements a scheme of D. E. Salane [32] that takes advantage of experience gained at one step to select good increments for difference quotients at the next step. If it appears that a column might consist mainly of roundoff, the increment is adjusted and the column recomputed.

The solvers invoke `numjac` by

```
[dFdy,fac,g] = numjac('F',t,y,Fty,thresh,fac,vectorized,S,g);
```

where the argument `'F'` is a string naming the function that defines the differential equation and `Fty` is the result of `'F'` evaluated at the current point in the integration `(t,y)`. The vector `thresh` provides a threshold of significance for `y`, i.e. the exact value of a component `y(i)` with magnitude less than `thresh(i)` is not important.

One aspect of the formation of partial derivatives special to the suite is the Boolean option `vectorized`. It is generally easy to code `'F'` so that it can return an array of function values. A vectorized version of the van der Pol example is shown in Figure 4. If `'F'` is coded so that `F(t,[y1 y2 ...])` returns `[F(t,y1) F(t,y2) ...]` and `vectorized` is set true, `numjac` will approximate all columns of the Jacobian with a single call to `'F'`. This avoids the overhead of repeatedly calling the function and it may reduce the cost of the evaluations themselves.

```
function dy = vdpex(t,y)
dy = zeros(size(y));      % preallocate column vector dy
dy(1,:) = y(2,:);
dy(2,:) = 1000*(1 - y(1,:).^2).*y(2,:) - y(1,:);
```

FIG. 4. *The vectorized* MATLAB *code for the* `vdpex` *problem.*

Another special aspect of `numjac` is that it computes sparse Jacobians as well as full ones. The structure of the Jacobian is provided by means of a sparse matrix `S` of

zeros and ones. The first time that a solver calls `numjac`, the function finds groups of columns of `dFdy` that can be approximated with a single call to `'F'`. This is done only once and the grouping is saved in `g`. Two schemes are tried (first-fit and first-fit after reverse column minimum-degree ordering [19]) and the more efficient grouping is adopted. This may not result in an optimal grouping because finding the smallest packing is an NP-complete problem equivalent to K-coloring a graph [9].

The modified Rosenbrock code requires the partial derivative `dFdt` every time it requires `dFdy`. On reaching t, the step size h provides a measure of scale for the approximation of `dFdt` by a forward difference. The computation is so simple that it is done in the solver itself.

8. Examples. The first question a user must ask is, which of the five codes in the suite should I use and which, if any, of the options? By design it is very easy simply to try the most promising codes, but it is useful to have some insight. The method implemented suggests circumstances in which a code might be particularly efficient or not. This section presents some experiments with test problems from classic collections that illustrate the performance of the solvers and the effects of using certain options. We report how much it costs to solve a problem for a given tolerance, usually the default tolerance. This is ordinarily what users of MATLAB want to know. A discussion of some of the issues that arise in comparing solvers is found in [37] where this approach is called the *first measure of efficiency*. Implicit in the use of this measure is the assumption that for routine problems, the codes compared will produce solutions with accuracy at least comparable to the tolerance. No credit is given for producing solutions with much more accuracy than requested. Because the solvers control local errors, the true, or global, error can be sensitive to the method and the details of its implementation. We have tuned the step size selection algorithms so that for a wide range of test problems, consistent global accuracies comparable to the tolerance are delivered by the various solvers applied to the same problem.

From our experience with writing solvers in other computing environments, we believe that our implementations of the methods are comparable in quality to popular codes based on the same or related methods. Naturally we tested this by comparing the new Runge-Kutta codes to the old MATLAB ones. Also, we report here tests showing that the NDF code is comparable to a popular BDF code written in FORTRAN.

The experiments reported here and others we have made suggest that except in special circumstances, `ode45` should be the code tried first. If there is reason to believe the problem to be stiff, or if the problem turns out to be unexpectedly difficult for `ode45`, the `ode15s` code should be tried. When solving stiff problems, it is important to keep in mind the options that improve the efficiency of forming Jacobians.

8.1. Stiff Examples. In MATLAB it is advantageous to vectorize computations whenever possible. Accordingly, all stiff problems were coded to use the `vectorized` option when computing numerical Jacobians. Also, the advantages of the `constantJ` option are so obvious that we used it when solving the stiff problems with constant Jacobians, namely `a2ex`, `a3ex`, `b5ex`, and `hb3ex`.

The `ode15s` code was developed for the NDF's. It is such an easy matter to provide for the BDF's in this code that they were allowed as an option. Some experiments show the consequences of exercising this option. Table 2 gives the number of steps and the real time required for the two choices when applied to a set of 13 stiff problems. For all but one problem the default NDF's result in fewer steps than the BDF's (an average of 10.9% fewer), and for *all* problems, the code is faster when using the NDF's (an average of 8.2% faster).

TABLE 2
Comparison of the NDF's and BDF's in `ode15s`*. Times are measured as seconds on a Sparc2.*

	BDF steps	NDF steps	percent fewer	BDF time	NDF time	percent faster
`a2ex`	118	101	14.4	3.60	3.14	12.8
`a3ex`	134	130	3.0	3.96	3.87	2.4
`b5ex`	1165	936	19.7	32.58	25.95	20.4
`buiex`	57	52	8.8	2.05	1.92	6.4
`chm6ex`	152	139	8.6	4.05	3.63	10.3
`chm7ex`	57	39	31.6	1.82	1.48	18.4
`chm9ex`	910	825	9.3	30.53	29.38	3.8
`d1ex`	67	62	7.5	2.35	2.29	2.5
`gearex`	20	19	5.0	1.12	1.08	3.5
`hb1ex`	197	179	9.1	5.57	5.09	8.5
`hb2ex`	555	577	-4.0	13.49	13.45	0.3
`hb3ex`	766	690	9.9	19.79	17.77	10.2
`vdpex`	708	573	19.1	20.75	19.33	6.9

To verify that the performance of `ode15s` is comparable to that of a modern BDF code, we have compared `ode15s` using the NDF's to DDRIV2 [24] on some relatively difficult problems. DDRIV2 is an easy-to-use driver for a more complex code with an appearance not too different from `ode15s`. It is a quasi-constant step size implementation of the BDF's of orders 1-5 that computes answers at specified points by interpolation. It approximates Jacobians internally by differences with an algorithm related to that of `ode15s`.

It is not possible to compare DDRIV2 and `ode15s` in detail because they cannot be used to solve exactly the same computational problem. For one thing, the error controls are different. DDRIV2 uses a root-mean-square norm to measure the error in a solution component relative to the larger of the magnitude of the component and a threshold. We made the controls roughly equivalent by taking the threshold to be equal to the desired absolute error and dividing the tolerances given to DDRIV2 by the square root of the number of equations. In addition the two codes handle output differently. DDRIV2 provides answers wherever requested, but only at those points. We asked the codes to produce 150 answers equally spaced within the interval of integration. This is inadequate for some of the examples, but asking for more answers could increase the cost in DDRIV2 because it has an internal maximum step size that is twice the distance between output points. Accepting a possible reduction in efficiency in `ode15s`, we used an option to impose the same maximum step size.

Table 3 compares DDRIV2 to `ode15s` using the NDF's. We interpret these comparisons as showing that `ode15s` is an effective code for the solution of stiff problems. DDRIV2 does not save Jacobians and the numerical results indicate that to a degree `ode15s` is trading linear algebra for a smaller number of approximate Jacobians. This is appropriate in MATLAB, but because these examples involve just a few equations, the benefits of reusing Jacobians are masked.

The chemical reaction problem `chm6ex` is given in §6. A plot of one component is displayed in Figure 5. `ode15s` is able to solve the problem effectively using a remarkably small number of Jacobians. Problem `chm9ex` is a scaled version of the Belousov oscillating chemical reaction [14]. A discussion of this problem and plots are

TABLE 3
Comparison of DDRIV2 to `ode15s` *using the NDF's. The table shows the number of successful steps, the number of failed steps, the number of function calls, the number of partial derivative evaluations, the number of LU decompositions, and the number of linear system solutions. Note that the integration parameters of* `ode15s` *were changed from their default values.*

example	code	time steps	failed steps	f evals	$\partial f/\partial y$ evals	LU's	linear solves
`chm6ex`	DDRIV2	218	6	404	33	33	271
	`ode15s`	177	4	224	2	29	213
`chm9ex`	DDRIV2	1073	217	2470	220	220	1802
	`ode15s`	750	227	2366	83	322	2033
`hb2ex`	DDRIV2	1370	162	2675	176	176	2316
	`ode15s`	939	70	1321	4	165	1308
`vdpex`	DDRIV2	871	185	1836	167	167	1497
	`ode15s`	724	197	1965	33	261	1865

found in [1], p. 49 ff. The limit solution is periodic and exhibits regions of very sharp change. We chose the interval $[0, 650]$ so as to include two complete periods and part of another. `ode15s` is trading some linear algebra for a reduction in the number of Jacobians. Because there are only three solution components, reducing the number of Jacobians does not have much effect on the number of function evaluations.

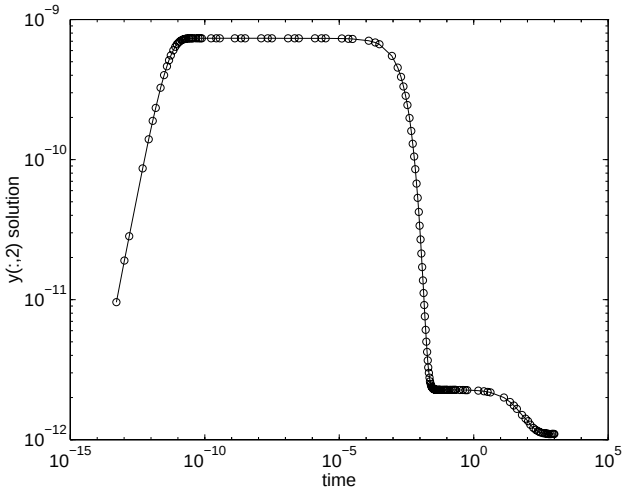

FIG. 5. *A log-log plot of the second component of the solution of* `chm6ex`.

Hindmarsh and Byrne [23] present the non-autonomous problem coded in `hb2ex` that arises in a diurnal kinetics model and they discuss its solution with EPISODE. The scaling of one component is such that an absolute error tolerance of 10^{-20} is needed. The problem is also discussed at length in [24] where it is solved with DDRIV2. As the measures of cost given in Table 3 show, `ode15s` performs quite well in comparison to a good BDF code. For this problem, reuse of Jacobians proved to be quite advantageous. With only two equations, numerical evaluation of a Jacobian is so cheap that the difference in cost cannot be due entirely to saving Jacobians.

Example `vdpex` is the van der Pol equation in relaxation oscillation in the form

specified in [35]. The tradeoffs in the tuning of `ode15s` as compared to DDRIV2 are clear. Because this problem involves only two solution components, forming Jacobians more often would probably have been a bargain in `ode15s`.

Now we compare the modified Rosenbrock code `ode23s` to `ode15s`. Table 4 provides statistics for two stiff problems. Note that `ode15s` was run with both the NDF's and the BDF's. The fact that NDF1 and NDF2 are more efficient than BDF1 and BDF2 is evident for the `b5ex` experiments in which the maximum order was limited.

TABLE 4
Comparison of `ode23s` *to* `ode15s`. *For* `vdpex`, *the relative accuracy was changed from the default of 0.1% to 1%. Times are measured as seconds on a Sparc2.*

example	code	time	time steps	failed steps	f evals	$\partial f/\partial y$ evals	LU's	linear solves
`vdpex`	`ode15s` (BDF)	17.06	525	203	1594	45	266	1458
	`ode15s` (NDF)	15.83	490	179	1514	46	249	1375
	`ode23s`	14.21	302	96	1706	303	398	1194
`b5ex`	`ode15s` (BDF)	32.58	1165	124	2586	1	319	2578
	`ode15s` (NDF)	25.95	936	97	2074	1	263	2066
	`ode23s`	15.38	549	17	1689	1	566	1698

As a first example we solved `vdpex` with a relative accuracy tolerance of 1.0%. At this tolerance `ode23s` was faster than `ode15s`, even though it made many more Jacobian evaluations, and the plot of $y(t)$ in Figure 6 obtained with `ode23s` is notably better than that of `ode15s`. However, when the tolerance is tightened to the default of 0.1%, `ode15s` is faster than `ode23s` and the plot of $y(t)$ is just as good.

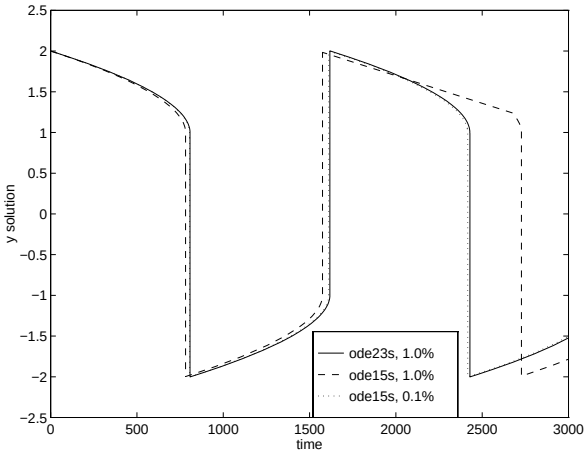

FIG. 6. *The* `vdpex` *solution computed by* `ode23s` *and* `ode15s` *at 1.0% accuracy, and by* `ode15s` *at 0.1% accuracy. The latter indicates that the 1.0% solution by* `ode15s` *is less accurate than* `ode23s`.

Problem `b5ex` [15] has a Jacobian with eigenvalues near the imaginary axis. The popular variable-order BDF codes do not deal with this well. Gaffney [16] compares BDF and other kinds of codes on this and similar problems. `ode15s` recognizes automatically that this problem has a constant Jacobian. For a fair comparison, we used

the option of telling both codes that the Jacobian is constant. We also restricted the maximum order of the NDF's used by `ode15s` to 2, so that both codes would be L-stable. Evidently `ode23s` is to be preferred for the solution of this problem.

Supplying a function for evaluating the Jacobian can be quite advantageous, both with respect to reliability and cost. Table 5 shows the effects of using the `analyticJ` option for some of the most expensive of our examples. Because `ode23s` evaluates the Jacobian at every step, reducing this cost by means of an analytical Jacobian has an important effect on the overall cost. It is much less significant when using `ode15s` because it makes comparatively few evaluations of the Jacobian.

TABLE 5

The solutions of four problems by `ode23s` *and* `ode15s` *showing the effect of using the* `analyticJ` *option to supply a function for evaluation of the Jacobian (time2). The* `brussex` *problem is* 100×100 *and its Jacobian function returns a sparse matrix. Times are measured as seconds on a Sparc2.*

	`ode23s`		`ode15s`	
problem	time	time2	time	time2
`brussex`	80.00	13.82	23.37	9.70
`chm9ex`	47.12	27.32	29.38	25.86
`hb2ex`	140.78	87.29	13.45	13.40
`vdpex`	28.61	16.36	19.33	19.21

Next, we examine the role of Jacobian sparsity. The `brussex` example is the classic "Brusselator" system modelling diffusion in a chemical reaction [21],

$$\begin{aligned} u_i' &= 1 + u_i^2 v_i - 4u_i + \alpha(N+1)^2(u_{i-1} - 2u_i + u_{i+1}) \\ v_i' &= 3u_i - u_i^2 v_i + \alpha(N+1)^2(v_{i-1} - 2v_i + v_{i+1}) \end{aligned}$$

and is solved on the time interval $[0, 10]$ with $\alpha = 1/50$ and

$$\left.\begin{array}{rcl} u_i(0) & = & 1 + \sin(2\pi x_i) \\ v_i(0) & = & 3 \end{array}\right\} \text{with } x_i = i/(N+1) \text{ for } i = 1, \ldots, N$$

There are $2N$ equations in this system, but the Jacobian is banded with a constant width 5, if the equations are ordered as $u_1, v_1, u_2, v_2, \ldots$.

For progressively larger values of N, Table 6 shows the number of steps taken and compares the number of seconds required to solve the `brussex` problem by `ode45`, `ode23s` and `ode15s`. The `ode45` results indicate that the system becomes quite stiff for the larger N. The first columns of the results for `ode23s` and `ode15s` were produced using the default numerical approximation of Jacobians. As the second columns show, the `sparseJ` option makes a tremendous difference. Until N becomes large, `ode15s` is efficient even without the `sparseJ` option because it forms relatively few Jacobians.

The `fem2ex` example involves a mass matrix. The system of ODE's, found in [41], comes from a method of lines solution of the partial differential equation

$$e^{-t}\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2}$$

with initial condition $u(0, x) = \sin(x)$ and boundary conditions $u(t, 0) = u(t, \pi) = 0$. An integer N is chosen, h is defined as $1/(N+1)$, and the solution of the partial differential equation is approximated at $x_k = k\pi h$ for $k = 0, 1, \ldots, N+1$ by

$$u(t, x_k) \approx \sum_{k=1}^{N} c_k(t)\phi_k(x)$$

TABLE 6
The solutions of various size `brussex` *problems by* `ode45`, `ode23s`, `ode23s` *using the* `sparseJ` *option (time2),* `ode15s`, *and* `ode15s` *using the* `sparseJ` *option (time2). Times are measured as seconds on a Sparc2.*

	`ode45`		`ode23s`			`ode15s`		
size	steps	time	steps	time	time2	steps	time	time2
100	629	143.95	59	80.00	15.04	82	23.37	10.36
200	2458	4052.99	59	499.44	24.50	82	104.49	17.78
400	NA	NA	59	3398.47	43.00	85	574.42	32.19
600	NA	NA	59	NA	62.84	85	1703.68	49.21
800	NA	NA	59	NA	83.91	85	NA	63.51
1000	NA	NA	59	NA	105.93	85	NA	80.74

Here $\phi_k(x)$ is a piecewise linear function that is 1 at x_k and 0 at all the other x_j. The Galerkin discretization leads to the system of ODE's

$$A(t)\,c' = R\,c \quad \text{where} \quad c(t) = \begin{bmatrix} c_1(t) \\ \vdots \\ c_N(t) \end{bmatrix}$$

and the tridiagonal matrices $A(t)$ and R are given by

$$A_{ij} = \begin{cases} \exp(-t)2h/3 & \text{if } i = j \\ \exp(-t)h/6 & \text{if } i = j \pm 1 \\ 0 & \text{otherwise} \end{cases} \quad \text{and} \quad R_{ij} = \begin{cases} -2/h & \text{if } i = j \\ 1/h & \text{if } i = j \pm 1 \\ 0 & \text{otherwise} \end{cases}$$

The initial values $c(0)$ are taken from the initial condition for the partial differential equation. The problem is solved on the time interval $[0, \pi]$.

Because the mass matrix A depends on t, this equation cannot be solved directly with `ode23s`. However, scaling by $\exp(t)$ results in an equivalent system with a constant mass matrix that can be solved with both codes. As is typical of the method of lines, the mass matrix is sparse, but in this instance we have followed [41] in taking $N = 9$, which is too small to take advantage of the sparsity. The solution of `fem2ex` is shown in Figure 7 and statistics are presented in Table 7.

TABLE 7
Comparison of `ode23s` *to* `ode15s` *for a problem with a constant mass matrix,* `fem2ex` *with* $N = 9$. *Times are measured as seconds on a Sparc2.*

example	code	time	time steps	failed steps	f evals	$\partial f/\partial y$ evals	LU's	linear solves
`fem2ex`	`ode15s`	4.71	46	14	175	5	21	124
	`ode23s`	5.35	40	1	493	41	41	123

8.2. Non-stiff Examples. In this section we consider four non-stiff examples drawn from the collections [15, 39]. `vdpns` is the van der Pol equation with $\mu = 1$. `rigid` is the Euler equations of a rigid body without external forces as proposed by Krogh. The solution is displayed in Figure 1. `twobody`, D5 of [15], is the two body problem with an elliptical orbit of eccentricity 0.9. `r3body` describes a periodic orbit for a restricted three body problem [39]. Because the problems are non-stiff, they can be solved with all the MATLAB ODE solvers. Table 8 compares the costs of solution.

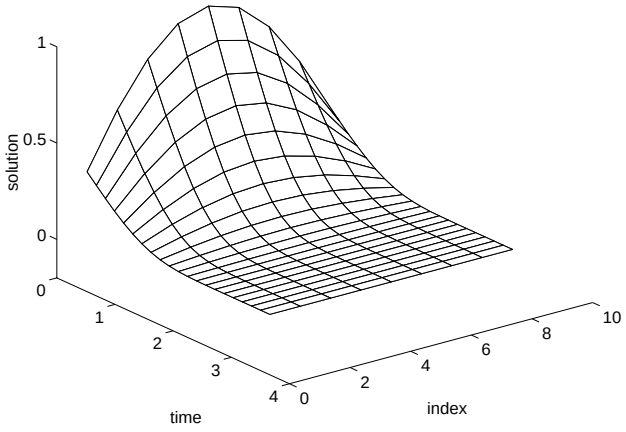

FIG. 7. *The* `fem2ex` *solution with* $N = 9$ *as computed by* `ode15s`.

9. Conclusion. Source code for the solvers and examples may be obtained gratis by ftp on ftp.mathworks.com in the pub/mathworks/toolbox/matlab/funfun directory. The solvers require MATLAB version 4.2 or later.

We have had the pleasure of correspondence and discussions with many experts whose publications and advice have been crucial to a number of aspects of this project. C. B. Moler helped us with just about every aspect. We have had the benefit of advice from a number of leading experts in explicit Runge-Kutta methods, viz. J. Dormand and P. Prince; M. Calvo, L. Randez, and J. Montijano; and P. Sharp and J. Verner. D. Salane provided us with FORTRAN versions of his algorithm for computing numerical partial derivatives along with helpful comments. T. Coleman provided advice about column grouping strategies. I. Gladwell provided advice about mathematical software for ordinary differential equations. H. Zedan provided copies of his publications that were essential to the development of our modified Rosenbrock method. J. Polking's experience teaching the solution of ordinary differential equations using the previous generation of codes in MATLAB influenced the new generation in a number of ways.
