Introduction

What Is MATLAB?

In this section...

Overview of MATLAB

MATLAB is a high-performance language for technical computing. It integrates computation, visualization, and programming in an easy-to-use environment where problems and solutions are expressed in familiar mathematical notation. Typical uses include

- Math and computation
- Algorithm development
- Data acquisition
- Modeling, simulation, and prototyping
- Data analysis, exploration, and visualization
- Scientific and engineering graphics
- Application development, including graphical user interface building

MATLAB is an interactive system whose basic data element is an array that does not require dimensioning. This allows you to solve many technical computing problems, especially those with matrix and vector formulations, in a fraction of the time it would take to write a program in a scalar noninteractive language such as C or Fortran.

The name MATLAB stands for *matrix laboratory*. MATLAB was originally written to provide easy access to matrix software developed by the LINPACK and EISPACK projects. Today, MATLAB engines incorporate the LAPACK and BLAS libraries, embedding the state of the art in software for matrix computation.

MATLAB has evolved over a period of years with input from many users. In university environments, it is the standard instructional tool for introductory

and advanced courses in mathematics, engineering, and science. In industry, MATLAB is the tool of choice for high-productivity research, development, and analysis.

MATLAB features a family of add-on application-specific solutions called *toolboxes*. Very important to most users of MATLAB, toolboxes allow you to *learn* and *apply* specialized technology. Toolboxes are comprehensive collections of MATLAB functions (M-files) that extend the MATLAB environment to solve particular classes of problems. Areas in which toolboxes are available include signal processing, control systems, neural networks, fuzzy logic, wavelets, simulation, and many others.

The MATLAB System

The MATLAB system consists of these main parts:

Desktop Tools and Development Environment

This is the set of tools and facilities that help you use MATLAB functions and files. Many of these tools are graphical user interfaces. It includes the MATLAB desktop and Command Window, a command history, an editor and debugger, a code analyzer and other reports, and browsers for viewing help, the workspace, files, and the search path.

The MATLAB Mathematical Function Library

This is a vast collection of computational algorithms ranging from elementary functions, like sum, sine, cosine, and complex arithmetic, to more sophisticated functions like matrix inverse, matrix eigenvalues, Bessel functions, and fast Fourier transforms.

The MATLAB Language

This is a high-level matrix/array language with control flow statements, functions, data structures, input/output, and object-oriented programming features. It allows both “programming in the small” to rapidly create quick and dirty throw-away programs, and “programming in the large” to create large and complex application programs.

Graphics

MATLAB has extensive facilities for displaying vectors and matrices as graphs, as well as annotating and printing these graphs. It includes high-level functions for two-dimensional and three-dimensional data visualization, image processing, animation, and presentation graphics. It also includes low-level functions that allow you to fully customize the appearance of graphics as well as to build complete graphical user interfaces on your MATLAB applications.

MATLAB External Interfaces

This is a library that allows you to write C and Fortran programs that interact with MATLAB. It includes facilities for calling routines from MATLAB (dynamic linking), calling MATLAB as a computational engine, and for reading and writing MAT-files.

MATLAB Documentation

MATLAB provides extensive documentation, in both printable and HTML format, to help you learn about and use all of its features. If you are a new user, start with this Getting Started book. It covers all the primary MATLAB features at a high level, including many examples.

To view the online documentation, select **MATLAB Help** from the **Help** menu in MATLAB. Online help appears in the Help browser, providing task-oriented and reference information about MATLAB features. For more information about using the Help browser, including typographical conventions used in the documentation, see “Help” on page 7-8.

The MATLAB documentation is organized into these main topics:

- Desktop Tools and Development Environment — Startup and shutdown, the desktop, and other tools that help you use MATLAB
- Mathematics — Mathematical operations
- Data Analysis — Data analysis, including data fitting, Fourier analysis, and time-series tools
- Programming — The MATLAB language and how to develop MATLAB applications
- Graphics — Tools and techniques for plotting, graph annotation, printing, and programming with Handle Graphics®
- 3-D Visualization — Visualizing surface and volume data, transparency, and viewing and lighting techniques
- Creating Graphical User Interfaces — GUI-building tools and how to write callback functions
- External Interfaces — MEX-files, the MATLAB engine, and interfacing to Java, COM, and the serial port

MATLAB also includes reference documentation for all MATLAB functions:

- “Functions — By Category” — Lists all MATLAB functions grouped into categories
- Handle Graphics Property Browser — Provides easy access to descriptions of graphics object properties
- C and Fortran API Reference — Covers those functions used by the MATLAB external interfaces, providing information on syntax in the calling language, description, arguments, return values, and examples

The MATLAB online documentation also includes

- Examples — An index of examples included in the documentation
- Release Notes — New features, compatibility considerations, and bug reports
- Printable Documentation — PDF versions of the documentation suitable for printing

In addition to the documentation, you can access demos from the Help browser by clicking the **Demos** tab. Run demos to learn about key functionality of MathWorks products and tools.

Starting and Quitting MATLAB

In this section...

Starting MATLAB

On Windows platforms, start MATLAB by double-clicking the MATLAB shortcut icon on your Windows desktop.

On UNIX platforms, start MATLAB by typing `matlab` at the operating system prompt.

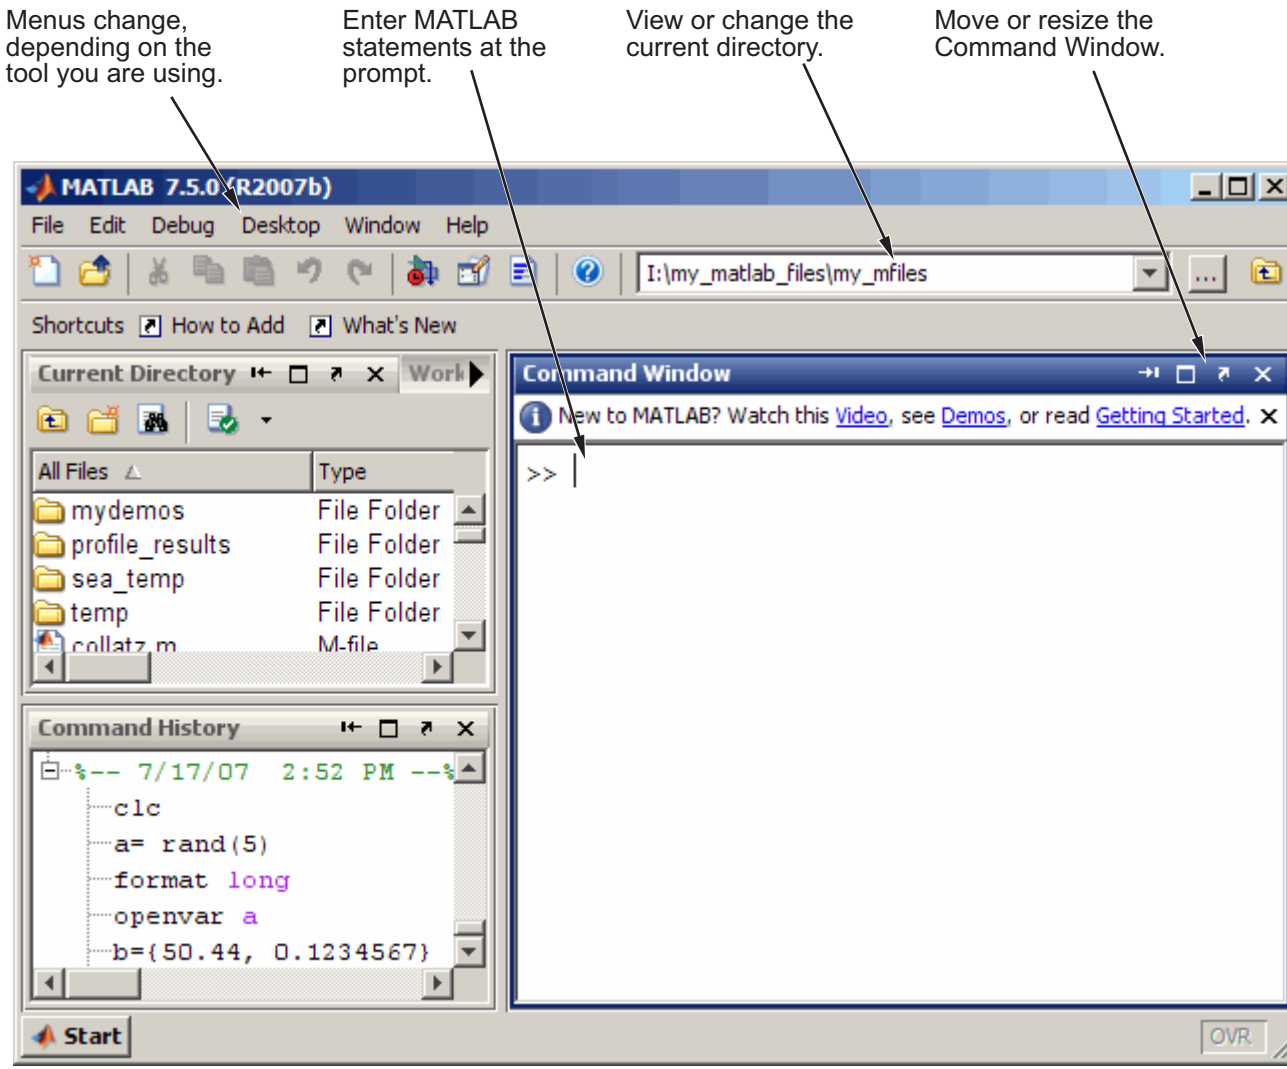
You can customize MATLAB startup. For example, you can change the directory in which MATLAB starts or automatically execute MATLAB statements in a script file named `startup.m`.

For More Information See "Starting MATLAB on Windows Platforms" and "Starting MATLAB on UNIX Platforms" in the Desktop Tools and Development Environment documentation.

MATLAB Desktop

When you start MATLAB, the MATLAB desktop appears, containing tools (graphical user interfaces) for managing files, variables, and applications associated with MATLAB.

The following illustration shows the default desktop. You can customize the arrangement of tools and documents to suit your needs. For more information about the desktop tools, see Chapter 7, "Desktop Tools and Development Environment".



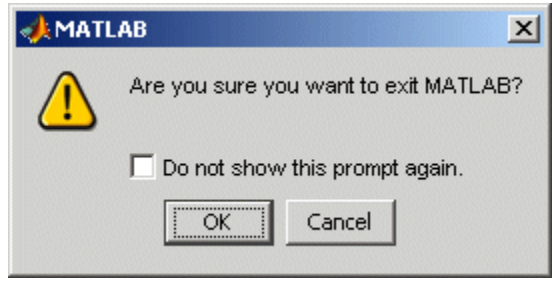
Quitting MATLAB

To end your MATLAB session, select **File > Exit MATLAB** in the desktop, or type `quit` in the Command Window. You can run a script file named

`finish.m` each time MATLAB quits that, for example, executes functions to save the workspace.

Confirm Quitting

MATLAB can display a confirmation dialog box before quitting. To set this option, select **File > Preferences > General > Confirmation Dialogs**, and select the check box for **Confirm before exiting MATLAB**.



For More Information See “Quitting MATLAB” in the Desktop Tools and Development Environment documentation.

2

Matrices and Arrays

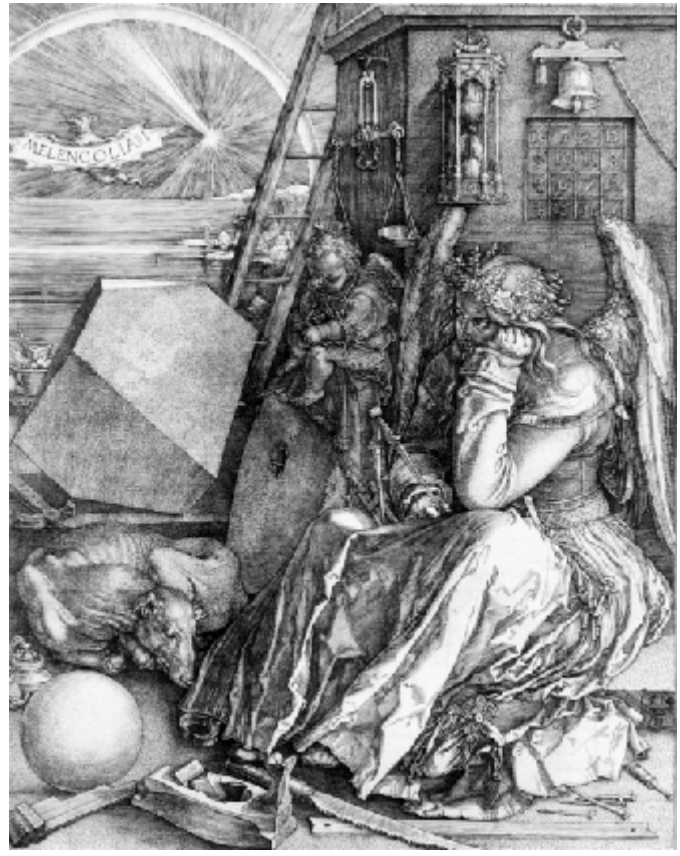
You can watch the Getting Started with MATLAB video demo for an overview of the major functionality.

Matrices and Magic Squares

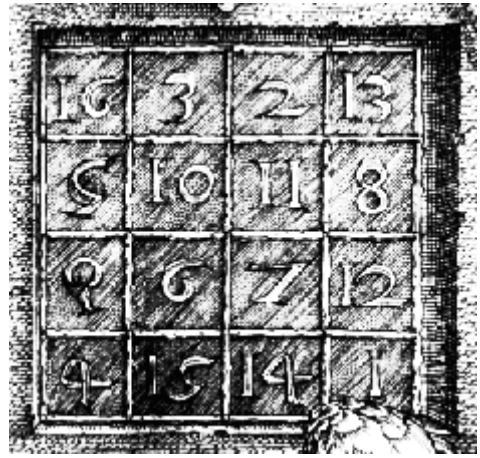
In this section...

About Matrices

In MATLAB, a matrix is a rectangular array of numbers. Special meaning is sometimes attached to 1-by-1 matrices, which are scalars, and to matrices with only one row or column, which are vectors. MATLAB has other ways of storing both numeric and nonnumeric data, but in the beginning, it is usually best to think of everything as a matrix. The operations in MATLAB are designed to be as natural as possible. Where other programming languages work with numbers one at a time, MATLAB allows you to work with entire matrices quickly and easily. A good example matrix, used throughout this book, appears in the Renaissance engraving Melencolia I by the German artist and amateur mathematician Albrecht Dürer.



This image is filled with mathematical symbolism, and if you look carefully, you will see a matrix in the upper right corner. This matrix is known as a magic square and was believed by many in Dürer's time to have genuinely magical properties. It does turn out to have some fascinating characteristics worth exploring.



Entering Matrices

The best way for you to get started with MATLAB is to learn how to handle matrices. Start MATLAB and follow along with each example.

You can enter matrices into MATLAB in several different ways:

- Enter an explicit list of elements.
- Load matrices from external data files.
- Generate matrices using built-in functions.
- Create matrices with your own functions in M-files.

Start by entering Dürer's matrix as a list of its elements. You only have to follow a few basic conventions:

- Separate the elements of a row with blanks or commas.
- Use a semicolon, `;` , to indicate the end of each row.
- Surround the entire list of elements with square brackets, `[ ]`.

To enter Dürer's matrix, simply type in the Command Window

```
A = [16 3 2 13; 5 10 11 8; 9 6 7 12; 4 15 14 1]
```

MATLAB displays the matrix you just entered:

```
A =
    16     3     2    13
     5    10    11     8
     9     6     7    12
     4    15    14     1
```

This matrix matches the numbers in the engraving. Once you have entered the matrix, it is automatically remembered in the MATLAB workspace. You can refer to it simply as `A`. Now that you have `A` in the workspace, take a look at what makes it so interesting. Why is it magic?

sum, transpose, and diag

You are probably already aware that the special properties of a magic square have to do with the various ways of summing its elements. If you take the sum along any row or column, or along either of the two main diagonals, you will always get the same number. Let us verify that using MATLAB. The first statement to try is

```
sum(A)
```

MATLAB replies with

```
ans =
    34    34    34    34
```

When you do not specify an output variable, MATLAB uses the variable `ans`, short for *answer*, to store the results of a calculation. You have computed a row vector containing the sums of the columns of `A`. Sure enough, each of the columns has the same sum, the *magic* sum, 34.

How about the row sums? MATLAB has a preference for working with the columns of a matrix, so one way to get the row sums is to transpose the matrix, compute the column sums of the transpose, and then transpose the result. For an additional way that avoids the double transpose use the dimension argument for the `sum` function.

MATLAB has two transpose operators. The apostrophe operator (e.g., `A'`) performs a complex conjugate transposition. It flips a matrix about its main

diagonal, and also changes the sign of the imaginary component of any complex elements of the matrix. The dot-apostrophe operator (e.g., `A.'`), transposes without affecting the sign of complex elements. For matrices containing all real elements, the two operators return the same result.

So

```
A'
```

produces

```
ans =
    16     5     9     4
     3    10     6    15
     2    11     7    14
    13     8    12     1
```

and

```
sum(A')'
```

produces a column vector containing the row sums

```
ans =
    34
    34
    34
    34
```

The sum of the elements on the main diagonal is obtained with the `sum` and the `diag` functions:

```
diag(A)
```

produces

```
ans =
    16
    10
     7
     1
```

and

```
sum(diag(A))
```

produces

```
ans =
    34
```

The other diagonal, the so-called *antidiagonal,* is not so important mathematically, so MATLAB does not have a ready-made function for it. But a function originally intended for use in graphics, `fliplr`, flips a matrix from left to right:

```
sum(diag(fliplr(A)))
ans =
    34
```

You have verified that the matrix in Dürer's engraving is indeed a magic square and, in the process, have sampled a few MATLAB matrix operations. The following sections continue to use this matrix to illustrate additional MATLAB capabilities.

Subscripts

The element in row `i` and column `j` of `A` is denoted by `A(i,j)`. For example, `A(4,2)` is the number in the fourth row and second column. For our magic square, `A(4,2)` is `15`. So to compute the sum of the elements in the fourth column of `A`, type

```
A(1,4) + A(2,4) + A(3,4) + A(4,4)
```

This produces

```
ans =
     34
```

but is not the most elegant way of summing a single column.

It is also possible to refer to the elements of a matrix with a single subscript, `A(k)`. This is the usual way of referencing row and column vectors. But it can also apply to a fully two-dimensional matrix, in which case the array is

regarded as one long column vector formed from the columns of the original matrix. So, for our magic square, `A(8)` is another way of referring to the value `15` stored in `A(4,2)`.

If you try to use the value of an element outside of the matrix, it is an error:

```
t = A(4,5)
Index exceeds matrix dimensions.
```

On the other hand, if you store a value in an element outside of the matrix, the size increases to accommodate the newcomer:

```
X = A;
X(4,5) = 17

X =
    16     3     2    13     0
     5    10    11     8     0
     9     6     7    12     0
     4    15    14     1    17
```

The Colon Operator

The colon, `:`, is one of the most important MATLAB operators. It occurs in several different forms. The expression

```
1:10
```

is a row vector containing the integers from 1 to 10:

```
1     2     3     4     5     6     7     8     9    10
```

To obtain nonunit spacing, specify an increment. For example,

```
100:-7:50
```

is

```
100    93    86    79    72    65    58    51
```

and

```
0:pi/4:pi
```

is

```
0    0.7854    1.5708    2.3562    3.1416
```

Subscript expressions involving colons refer to portions of a matrix:

```
A(1:k,j)
```

is the first `k` elements of the `j`th column of `A`. So

```
sum(A(1:4,4))
```

computes the sum of the fourth column. But there is a better way. The colon by itself refers to *all* the elements in a row or column of a matrix and the keyword `end` refers to the *last* row or column. So

```
sum(A(:,end))
```

computes the sum of the elements in the last column of `A`:

```
ans =
     34
```

Why is the magic sum for a 4-by-4 square equal to 34? If the integers from 1 to 16 are sorted into four groups with equal sums, that sum must be

```
sum(1:16)/4
```

which, of course, is

```
ans =
     34
```

The magic Function

MATLAB actually has a built-in function that creates magic squares of almost any size. Not surprisingly, this function is named `magic`:

```
B = magic(4)
B =
    16     2     3    13
     5    11    10     8
     9     7     6    12
     4    14    15     1
```

This matrix is almost the same as the one in the Dürer engraving and has all the same "magic" properties; the only difference is that the two middle columns are exchanged.

To make this `B` into Dürer's `A`, swap the two middle columns:

```
A = B(:,[1 3 2 4])
```

This says, for each of the rows of matrix `B`, reorder the elements in the order 1, 3, 2, 4. It produces

```
A =
    16     3     2    13
     5    10    11     8
     9     6     7    12
     4    15    14     1
```

Why would Dürer go to the trouble of rearranging the columns when he could have used MATLAB ordering? No doubt he wanted to include the date of the engraving, 1514, at the bottom of his magic square.

Expressions

In this section...

Variables

Like most other programming languages, MATLAB provides mathematical *expressions*, but unlike most programming languages, these expressions involve entire matrices.

MATLAB does not require any type declarations or dimension statements. When MATLAB encounters a new variable name, it automatically creates the variable and allocates the appropriate amount of storage. If the variable already exists, MATLAB changes its contents and, if necessary, allocates new storage. For example,

```
num_students = 25
```

creates a 1-by-1 matrix named `num_students` and stores the value 25 in its single element. To view the matrix assigned to any variable, simply enter the variable name.

Variable names consist of a letter, followed by any number of letters, digits, or underscores. MATLAB is case sensitive; it distinguishes between uppercase and lowercase letters. `A` and `a` are *not* the same variable.

Although variable names can be of any length, MATLAB uses only the first `N` characters of the name, (where `N` is the number returned by the function `namelengthmax`), and ignores the rest. Hence, it is important to make each variable name unique in the first `N` characters to enable MATLAB to distinguish variables.

```
N = namelengthmax
```

```
N =
    63
```

The `genvarname` function can be useful in creating variable names that are both valid and unique.

Numbers

MATLAB uses conventional decimal notation, with an optional decimal point and leading plus or minus sign, for numbers. *Scientific notation* uses the letter `e` to specify a power-of-ten scale factor. *Imaginary numbers* use either `i` or `j` as a suffix. Some examples of legal numbers are

```
3              -99            0.0001
9.6397238      1.60210e-20    6.02252e23
1i             -3.14159j      3e5i
```

All numbers are stored internally using the *long* format specified by the IEEE floating-point standard. Floating-point numbers have a finite *precision* of roughly 16 significant decimal digits and a finite *range* of roughly 10^{-308} to 10^{+308}.

The section "Avoiding Common Problems with Floating-Point Arithmetic" gives a few of the examples showing how IEEE floating-point arithmetic affects computations in MATLAB. For more examples and information, see Technical Note 1108 — Common Problems with Floating-Point Arithmetic.

Operators

Expressions use familiar arithmetic operators and precedence rules.

`+`	Addition
`-`	Subtraction
`*`	Multiplication
`/`	Division
`\`	Left division (described in "Matrices and Linear Algebra" in the MATLAB documentation)
`^`	Power

'	Complex conjugate transpose
( )	Specify evaluation order

Functions

MATLAB provides a large number of standard elementary mathematical functions, including `abs`, `sqrt`, `exp`, and `sin`. Taking the square root or logarithm of a negative number is not an error; the appropriate complex result is produced automatically. MATLAB also provides many more advanced mathematical functions, including Bessel and gamma functions. Most of these functions accept complex arguments. For a list of the elementary mathematical functions, type

```
help elfun
```

For a list of more advanced mathematical and matrix functions, type

```
help specfun
help elmat
```

Some of the functions, like `sqrt` and `sin`, are *built in*. Built-in functions are part of the MATLAB core so they are very efficient, but the computational details are not readily accessible. Other functions, like `gamma` and `sinh`, are implemented in M-files.

There are some differences between built-in functions and other functions. For example, for built-in functions, you cannot see the code. For other functions, you can see the code and even modify it if you want.

Several special functions provide values of useful constants.

`pi`	3.14159265...
`i`	Imaginary unit, $\sqrt{-1}$
`j`	Same as `i`
`eps`	Floating-point relative precision, $\varepsilon = 2^{-52}$
`realmin`	Smallest floating-point number, 2^{-1022}

`realmax`	Largest floating-point number, $(2-\varepsilon)2^{1023}$
`Inf`	Infinity
`NaN`	Not-a-number

Infinity is generated by dividing a nonzero value by zero, or by evaluating well defined mathematical expressions that *overflow*, i.e., exceed `realmax`. Not-a-number is generated by trying to evaluate expressions like `0/0` or `Inf-Inf` that do not have well defined mathematical values.

The function names are not reserved. It is possible to overwrite any of them with a new variable, such as

```
eps = 1.e-6
```

and then use that value in subsequent calculations. The original function can be restored with

```
clear eps
```

Examples of Expressions

You have already seen several examples of MATLAB expressions. Here are a few more examples, and the resulting values:

```
rho = (1+sqrt(5))/2
rho =
    1.6180

a = abs(3+4i)
a =
     5

z = sqrt(besselk(4/3,rho-i))
z =
   0.3730+ 0.3214i

huge = exp(log(realmax))
huge =
  1.7977e+308
```

```
toobig = pi*huge
toobig =
   Inf
```

Working with Matrices

In this section...

Generating Matrices

MATLAB provides four functions that generate basic matrices.

`zeros`	All zeros
`ones`	All ones
`rand`	Uniformly distributed random elements
`randn`	Normally distributed random elements

Here are some examples:

```
Z = zeros(2,4)
Z =
     0     0     0     0
     0     0     0     0

F = 5*ones(3,3)
F =
     5     5     5
     5     5     5
     5     5     5

N = fix(10*rand(1,10))
N =
     9     2     6     4     8     7     4     0     8     4
```

```
R = randn(4,4)
R =
    0.6353    0.0860   -0.3210   -1.2316
   -0.6014   -2.0046    1.2366    1.0556
    0.5512   -0.4931   -0.6313   -0.1132
   -1.0998    0.4620   -2.3252    0.3792
```

The load Function

The `load` function reads binary files containing matrices generated by earlier MATLAB sessions, or reads text files containing numeric data. The text file should be organized as a rectangular table of numbers, separated by blanks, with one row per line, and an equal number of elements in each row. For example, outside of MATLAB, create a text file containing these four lines:

```
16.0     3.0     2.0    13.0
 5.0    10.0    11.0     8.0
 9.0     6.0     7.0    12.0
 4.0    15.0    14.0     1.0
```

Save the file as `magik.dat` in the current directory. The statement

```
load magik.dat
```

reads the file and creates a variable, `magik`, containing the example matrix.

An easy way to read data into MATLAB in many text or binary formats is to use the Import Wizard.

M-Files

You can create your own matrices using *M-files*, which are text files containing MATLAB code. Use the MATLAB Editor or another text editor to create a file containing the same statements you would type at the MATLAB command line. Save the file under a name that ends in `.m`.

For example, create a file in the current directory named `magik.m` containing these five lines:

```
A = [16.0     3.0     2.0    13.0
      5.0    10.0    11.0     8.0
```

```
     9.0     6.0     7.0    12.0
     4.0    15.0    14.0     1.0 ];
```

The statement

```
magik
```

reads the file and creates a variable, `A`, containing the example matrix.

Concatenation

Concatenation is the process of joining small matrices to make bigger ones. In fact, you made your first matrix by concatenating its individual elements. The pair of square brackets, `[]`, is the concatenation operator. For an example, start with the 4-by-4 magic square, `A`, and form

```
B = [A  A+32; A+48  A+16]
```

The result is an 8-by-8 matrix, obtained by joining the four submatrices:

```
B =

    16     3     2    13    48    35    34    45
     5    10    11     8    37    42    43    40
     9     6     7    12    41    38    39    44
     4    15    14     1    36    47    46    33
    64    51    50    61    32    19    18    29
    53    58    59    56    21    26    27    24
    57    54    55    60    25    22    23    28
    52    63    62    49    20    31    30    17
```

This matrix is halfway to being another magic square. Its elements are a rearrangement of the integers `1:64`. Its column sums are the correct value for an 8-by-8 magic square:

```
sum(B)

ans =
   260   260   260   260   260   260   260   260
```

But its row sums, `sum(B')'`, are not all the same. Further manipulation is necessary to make this a valid 8-by-8 magic square.

Deleting Rows and Columns

You can delete rows and columns from a matrix using just a pair of square brackets. Start with

```
X = A;
```

Then, to delete the second column of `X`, use

```
X(:,2) = []
```

This changes `X` to

```
X =
    16     2    13
     5    11     8
     9     7    12
     4    14     1
```

If you delete a single element from a matrix, the result is not a matrix anymore. So, expressions like

```
X(1,2) = []
```

result in an error. However, using a single subscript deletes a single element, or sequence of elements, and reshapes the remaining elements into a row vector. So

```
X(2:2:10) = []
```

results in

```
X =
    16     9     2     7    13    12     1
```

More About Matrices and Arrays

In this section...

Linear Algebra

Informally, the terms *matrix* and *array* are often used interchangeably. More precisely, a *matrix* is a two-dimensional numeric array that represents a *linear transformation*. The mathematical operations defined on matrices are the subject of *linear algebra*.

Dürer's magic square

```
A = [16     3     2    13
      5    10    11     8
      9     6     7    12
      4    15    14     1 ]
```

provides several examples that give a taste of MATLAB matrix operations. You have already seen the matrix transpose, `A'`. Adding a matrix to its transpose produces a *symmetric* matrix:

```
A + A'

ans =
    32     8    11    17
     8    20    17    23
    11    17    14    26
    17    23    26     2
```

The multiplication symbol, `*`, denotes the *matrix* multiplication involving inner products between rows and columns. Multiplying the transpose of a matrix by the original matrix also produces a symmetric matrix:

```
A'*A

ans =
   378   212   206   360
   212   370   368   206
   206   368   370   212
   360   206   212   378
```

The determinant of this particular matrix happens to be zero, indicating that the matrix is *singular*:

```
d = det(A)

d =
     0
```

The reduced row echelon form of `A` is not the identity:

```
R = rref(A)

R =
     1     0     0     1
     0     1     0    -3
     0     0     1     3
     0     0     0     0
```

Since the matrix is singular, it does not have an inverse. If you try to compute the inverse with

```
X = inv(A)
```

you will get a warning message:

```
Warning: Matrix is close to singular or badly scaled.
         Results may be inaccurate. RCOND = 9.796086e-018.
```

Roundoff error has prevented the matrix inversion algorithm from detecting exact singularity. But the value of `rcond`, which stands for *reciprocal*

condition estimate, is on the order of `eps`, the floating-point relative precision, so the computed inverse is unlikely to be of much use.

The eigenvalues of the magic square are interesting:

```
e = eig(A)

e =
   34.0000
    8.0000
    0.0000
   -8.0000
```

One of the eigenvalues is zero, which is another consequence of singularity. The largest eigenvalue is 34, the magic sum. That is because the vector of all ones is an eigenvector:

```
v = ones(4,1)

v =
     1
     1
     1
     1

A*v

ans =
    34
    34
    34
    34
```

When a magic square is scaled by its magic sum,

```
P = A/34
```

the result is a *doubly stochastic* matrix whose row and column sums are all 1:

```
P =
    0.4706    0.0882    0.0588    0.3824
```

```
    0.1471    0.2941    0.3235    0.2353
    0.2647    0.1765    0.2059    0.3529
    0.1176    0.4412    0.4118    0.0294
```

Such matrices represent the transition probabilities in a *Markov process*. Repeated powers of the matrix represent repeated steps of the process. For our example, the fifth power

```
P^5
```

is

```
    0.2507    0.2495    0.2494    0.2504
    0.2497    0.2501    0.2502    0.2500
    0.2500    0.2498    0.2499    0.2503
    0.2496    0.2506    0.2505    0.2493
```

This shows that as k approaches infinity, all the elements in the kth power, P^k, approach $1/4$.

Finally, the coefficients in the characteristic polynomial

```
poly(A)
```

are

```
     1   -34   -64  2176     0
```

This indicates that the characteristic polynomial

$$\det(A - \lambda I)$$

is

$$\lambda^4 - 34\lambda^3 - 64\lambda^2 + 2176\lambda$$

The constant term is zero, because the matrix is singular, and the coefficient of the cubic term is -34, because the matrix is magic!

Arrays

When they are taken away from the world of linear algebra, matrices become two-dimensional numeric arrays. Arithmetic operations on arrays are done element by element. This means that addition and subtraction are the same for arrays and matrices, but that multiplicative operations are different. MATLAB uses a dot, or decimal point, as part of the notation for multiplicative array operations.

The list of operators includes

`+`	Addition
`-`	Subtraction
`.*`	Element-by-element multiplication
`./`	Element-by-element division
`.\`	Element-by-element left division
`.^`	Element-by-element power
`.'`	Unconjugated array transpose

If the Dürer magic square is multiplied by itself with array multiplication

```
A.*A
```

the result is an array containing the squares of the integers from 1 to 16, in an unusual order:

```
ans =
   256     9     4   169
    25   100   121    64
    81    36    49   144
    16   225   196     1
```

Building Tables

Array operations are useful for building tables. Suppose `n` is the column vector

```
n = (0:9)';
```

Then

```
pows = [n  n.^2  2.^n]
```

builds a table of squares and powers of 2:

```
pows =
     0     0     1
     1     1     2
     2     4     4
     3     9     8
     4    16    16
     5    25    32
     6    36    64
     7    49   128
     8    64   256
     9    81   512
```

The elementary math functions operate on arrays element by element. So

```
format short g
x = (1:0.1:2)';
logs = [x log10(x)]
```

builds a table of logarithms.

```
 logs =
     1.0           0
     1.1     0.04139
     1.2     0.07918
     1.3     0.11394
     1.4     0.14613
     1.5     0.17609
     1.6     0.20412
     1.7     0.23045
     1.8     0.25527
     1.9     0.27875
     2.0     0.30103
```

Multivariate Data

MATLAB uses column-oriented analysis for multivariate statistical data. Each column in a data set represents a variable and each row an observation. The `(i,j)`th element is the `i`th observation of the `j`th variable.

As an example, consider a data set with three variables:

- Heart rate
- Weight
- Hours of exercise per week

For five observations, the resulting array might look like

```
D = [ 72          134          3.2
      81          201          3.5
      69          156          7.1
      82          148          2.4
      75          170          1.2 ]
```

The first row contains the heart rate, weight, and exercise hours for patient 1, the second row contains the data for patient 2, and so on. Now you can apply many MATLAB data analysis functions to this data set. For example, to obtain the mean and standard deviation of each column, use

```
mu = mean(D), sigma = std(D)

mu =
      75.8       161.8         3.48

sigma =
    5.6303      25.499       2.2107
```

For a list of the data analysis functions available in MATLAB, type

```
help datafun
```

If you have access to Statistics Toolbox, type

```
help stats
```

Scalar Expansion

Matrices and scalars can be combined in several different ways. For example, a scalar is subtracted from a matrix by subtracting it from each element. The average value of the elements in our magic square is 8.5, so

```
B = A - 8.5
```

forms a matrix whose column sums are zero:

```
B =
      7.5     -5.5     -6.5      4.5
     -3.5      1.5      2.5     -0.5
      0.5     -2.5     -1.5      3.5
     -4.5      6.5      5.5     -7.5

sum(B)

ans =
     0     0     0     0
```

With scalar expansion, MATLAB assigns a specified scalar to all indices in a range. For example,

```
B(1:2,2:3) = 0
```

zeroes out a portion of `B`:

```
B =
      7.5        0        0      4.5
     -3.5        0        0     -0.5
      0.5     -2.5     -1.5      3.5
     -4.5      6.5      5.5     -7.5
```

Logical Subscripting

The logical vectors created from logical and relational operations can be used to reference subarrays. Suppose `X` is an ordinary matrix and `L` is a matrix of the same size that is the result of some logical operation. Then `X(L)` specifies the elements of `X` where the elements of `L` are nonzero.

This kind of subscripting can be done in one step by specifying the logical operation as the subscripting expression. Suppose you have the following set of data:

```
x = [2.1 1.7 1.6 1.5 NaN 1.9 1.8 1.5 5.1 1.8 1.4 2.2 1.6 1.8];
```

The `NaN` is a marker for a missing observation, such as a failure to respond to an item on a questionnaire. To remove the missing data with logical indexing, use `isfinite(x)`, which is true for all finite numerical values and false for `NaN` and `Inf`:

```
x = x(isfinite(x))
x =
  2.1 1.7 1.6 1.5 1.9 1.8 1.5 5.1 1.8 1.4 2.2 1.6 1.8
```

Now there is one observation, `5.1`, which seems to be very different from the others. It is an *outlier*. The following statement removes outliers, in this case those elements more than three standard deviations from the mean:

```
x = x(abs(x-mean(x)) <= 3*std(x))
x =
  2.1 1.7 1.6 1.5 1.9 1.8 1.5 1.8 1.4 2.2 1.6 1.8
```

For another example, highlight the location of the prime numbers in Dürer's magic square by using logical indexing and scalar expansion to set the nonprimes to 0. (See "The magic Function" on page 2-9.)

```
A(~isprime(A)) = 0

A =
     0     3     2    13
     5     0    11     0
     0     0     7     0
     0     0     0     0
```

The find Function

The `find` function determines the indices of array elements that meet a given logical condition. In its simplest form, `find` returns a column vector of indices. Transpose that vector to obtain a row vector of indices. For example, start again with Dürer's magic square. (See "The magic Function" on page 2-9.)

```
k = find(isprime(A))'
```

picks out the locations, using one-dimensional indexing, of the primes in the magic square:

```
k =
     2     5     9    10    11    13
```

Display those primes, as a row vector in the order determined by `k`, with

```
A(k)

ans =
     5     3     2    11     7    13
```

When you use `k` as a left-hand-side index in an assignment statement, the matrix structure is preserved:

```
A(k) = NaN

A =
    16   NaN   NaN   NaN
   NaN    10   NaN     8
     9     6   NaN    12
     4    15    14     1
```

Controlling Command Window Input and Output

In this section...

The format Function

The `format` function controls the numeric format of the values displayed by MATLAB. The function affects only how numbers are displayed, not how MATLAB computes or saves them. Here are the different formats, together with the resulting output produced from a vector `x` with components of different magnitudes.

Note To ensure proper spacing, use a fixed-width font, such as Courier.

```
x = [4/3 1.2345e-6]

format short

   1.3333    0.0000

format short e

   1.3333e+000  1.2345e-006

format short g

   1.3333  1.2345e-006

format long

   1.33333333333333   0.00000123450000
```

```
format long e

   1.333333333333333e+000    1.234500000000000e-006

format long g

   1.33333333333333               1.2345e-006

format bank

   1.33          0.00

format rat

   4/3          1/810045

format hex

   3ff5555555555555   3eb4b6231abfd271
```

If the largest element of a matrix is larger than 10^3 or smaller than 10^{-3}, MATLAB applies a common scale factor for the short and long formats.

In addition to the `format` functions shown above

```
format compact
```

suppresses many of the blank lines that appear in the output. This lets you view more information on a screen or window. If you want more control over the output format, use the `sprintf` and `fprintf` functions.

Suppressing Output

If you simply type a statement and press **Return** or **Enter**, MATLAB automatically displays the results on screen. However, if you end the line with a semicolon, MATLAB performs the computation but does not display any output. This is particularly useful when you generate large matrices. For example,

```
A = magic(100);
```

Entering Long Statements

If a statement does not fit on one line, use an ellipsis (three periods), `...`, followed by **Return** or **Enter** to indicate that the statement continues on the next line. For example,

```
s = 1 -1/2 + 1/3 -1/4 + 1/5 - 1/6 + 1/7 ...
      - 1/8 + 1/9 - 1/10 + 1/11 - 1/12;
```

Blank spaces around the =, +, and - signs are optional, but they improve readability.

Command Line Editing

Various arrow and control keys on your keyboard allow you to recall, edit, and reuse statements you have typed earlier. For example, suppose you mistakenly enter

```
rho = (1 + sqt(5))/2
```

You have misspelled `sqrt`. MATLAB responds with

```
Undefined function or variable 'sqt'.
```

Instead of retyping the entire line, simply press the ↑ key. The statement you typed is redisplayed. Use the ← key to move the cursor over and insert the missing `r`. Repeated use of the ↑ key recalls earlier lines. Typing a few characters and then the ↑ key finds a previous line that begins with those characters. You can also copy previously executed statements from the Command History. For more information, see “Command History” on page 7-7.

Following is the list of arrow and control keys you can use in the Command Window. If the preference you select for “Command Window Key Bindings” is `MATLAB standard (Emacs)`, you can also use the **Ctrl**+key combinations shown. See also general keyboard shortcuts for desktop tools in the MATLAB Desktop Tools and Development Environment documentation.

Key	Control Key for MATLAB Standard (Emacs) Preference	Operation
↑	**Ctrl+P**	Recall *p*revious line. Works only at command line.
↓	**Ctrl+N**	Recall *n*ext line. Works only at the prompt if you previously used the up arrow or **Ctrl+P**.
←	**Ctrl+B**	Move *b*ack one character.
→	**Ctrl+F**	Move *f*orward one character.
Ctrl+→	None	Move *r*ight one word.
Ctrl+←	None	Move *l*eft one word.
Home	**Ctrl+A**	Move to beginning of current statement.
End	**Ctrl+E**	Move to *e*nd of current statement.
Ctrl+Home	None	Move to top of Command Window.
Ctrl+End	None	Move to end of Command Window.
Esc	**Ctrl+U**	Clear command line when cursor is at the prompt. Otherwise, move cursor to the prompt.
Delete	**Ctrl+D**	Delete character after cursor.
Backspace	**Ctrl+H**	Delete character before cursor.
None	**Ctrl+K**	Cut contents (*k*ill) to end of command line.
Shift+Home	None	Select from cursor to beginning of statement.
Shift+End	None	Select from cursor to end of statement.

3

Graphics

Overview of MATLAB Plotting

In this section...

For More Information MATLAB Graphics and 3-D Visualization in the MATLAB documentation provide in-depth coverage of MATLAB graphics and visualization tools. Access these topics from the Help browser.

Plotting Process

MATLAB provides a wide variety of techniques to display data graphically. Interactive tools enable you to manipulate graphs to achieve results that reveal the most information about your data. You can also annotate and print graphs for presentations, or export graphs to standard graphics formats for presentation in web browsers or other media.

The process of visualizing data typically involves a series of operations. This section provides a "big picture" view of the plotting process and contains links to sections that have examples and specific details about performing each operation.

Creating a Graph

The type of graph you choose to create depends on the nature of your data and what you want to reveal about the data. MATLAB predefines many graph types, such as line, bar, histogram, and pie graphs. There are also 3-D graphs, such as surfaces, slice planes, and streamlines.

There are two basic ways to create graphs in MATLAB:

- Use plotting tools to create graphs interactively.

See “Some Ways to Use MATLAB Plotting Tools” on page 3-23.

- Use the command interface to enter commands in the Command Window or create plotting programs.

  See “Using Basic Plotting Functions” on page 3-49.

You might find it useful to combine both approaches. For example, you might issue a plotting command to create a graph and then modify the graph using one of the interactive tools.

Exploring Data

Once you create a graph, you can extract specific information about the data, such as the numeric value of a peak in a plot, the average value of a series of data, or you can perform data fitting.

For More Information See “Data Exploration Tools” in the MATLAB Graphics documentation and “Opening the Basic Fitting GUI” in the MATLAB Data Analysis documentation.

Editing the Graph Components

Graphs are composed of objects, which have properties you can change. These properties affect the way the various graph components look and behave.

For example, the axes used to define the coordinate system of the graph has properties that define the limits of each axis, the scale, color, etc. The line used to create a line graph has properties such as color, type of marker used at each data point (if any), line style, etc.

Note that the data used to create a line graph are properties of the line. You can, therefore, change the data without actually creating a new graph.

See “Editing Plots” on page 3-17.

Annotating Graphs

Annotations are the text, arrows, callouts, and other labels added to graphs to help viewers see what is important about the data. You typically add

annotations to graphs when you want to show them to other people or when you want to save them for later reference.

For More Information See "Annotating Graphs" in the MATLAB Graphics documentation or select **Annotating Graphs** from the figure **Help** menu.

Printing and Exporting Graphs

You can print your graph on any printer connected to your computer. The print previewer enables you to view how your graph will look when printed. It enables you to add headers, footers, a date, and so on. The print preview dialog lets you control the size, layout, and other characteristics of the graph (select **Print Preview** from the figure **File** menu).

Exporting a graph means creating a copy of it in a standard graphics file format, such as TIFF, JPEG, or EPS. You can then import the file into a word processor, include it in an HTML document, or edit it in a drawing package (select **Export Setup** from the figure **File** menu).

Adding and Removing Figure Content

By default, when you create a new graph in the same figure window, its data replaces that of the graph that is currently displayed, if any. You can add new data to a graph in several ways; see "Adding More Data to the Graph" on page 3-27 for how to do this using a GUI. You can manually remove all data, graphics and annotations from the current figure by typing `CLF` in the Command Window or by selecting **Clear Figure** from the figure's **Edit** menu.

For More Information See the `print` command reference page and "Printing and Exporting" in the MATLAB Graphics documentation or select **Printing and Exporting** from the figure **Help** menu.

Saving Graphs to Reload into MATLAB

There are two ways to save graphs that enable you to save the work you have invested in their preparation:

- Save the graph as a FIG-file (select **Save** from the figure **File** menu).
- Generate MATLAB code that can recreate the graph (select **Generate M-File** from the figure **File** menu).

FIG-Files. FIG-files are a binary format that saves a figure in its current state. This means that all graphics objects and property settings are stored in the file when you create it. You can reload the file into a different MATLAB session, even if you are running MATLAB on a different type of computer. When you load a FIG-file, MATLAB creates a new figure in the same state as the one you saved.

Note that the states of any figure tools (i.e., any items on the toolbars) are not saved in a FIG-file; only the contents of the graph are saved.

Generated Code. You can use the MATLAB M-code generator to create code that recreates the graph. Unlike a FIG-file, the generated code does not contain any data. You must pass appropriate data to the generated function when you run the code.

Studying the generated code for a graph is a good way to learn how to program with MATLAB.

For More Information See the `print` command reference page and "Saving Your Work" in the MATLAB Graphics documentation.

Graph Components

MATLAB displays graphs in a special window known as a figure. To create a graph, you need to define a coordinate system. Therefore every graph is placed within axes, which are contained by the figure.

The actual visual representation of the data is achieved with graphics objects like lines and surfaces. These objects are drawn within the coordinate system defined by the axes, which MATLAB automatically creates specifically to accommodate the range of the data. The actual data is stored as properties of the graphics objects.

See “Handle Graphics” on page 3-74 for more information about graphics object properties.

The following picture shows the basic components of a typical graph. You can find commands for plotting this graph in “Preparing Graphs for Presentation” on page 3-37.

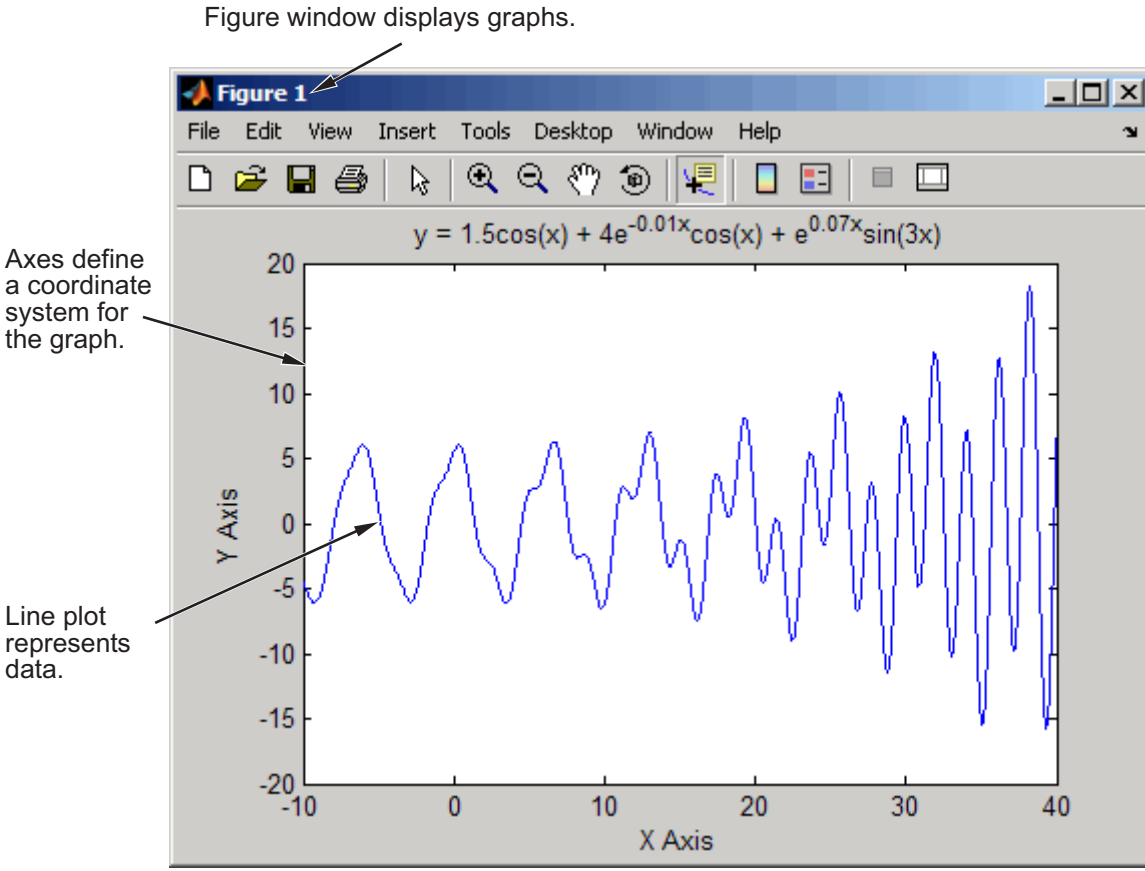


Figure Tools

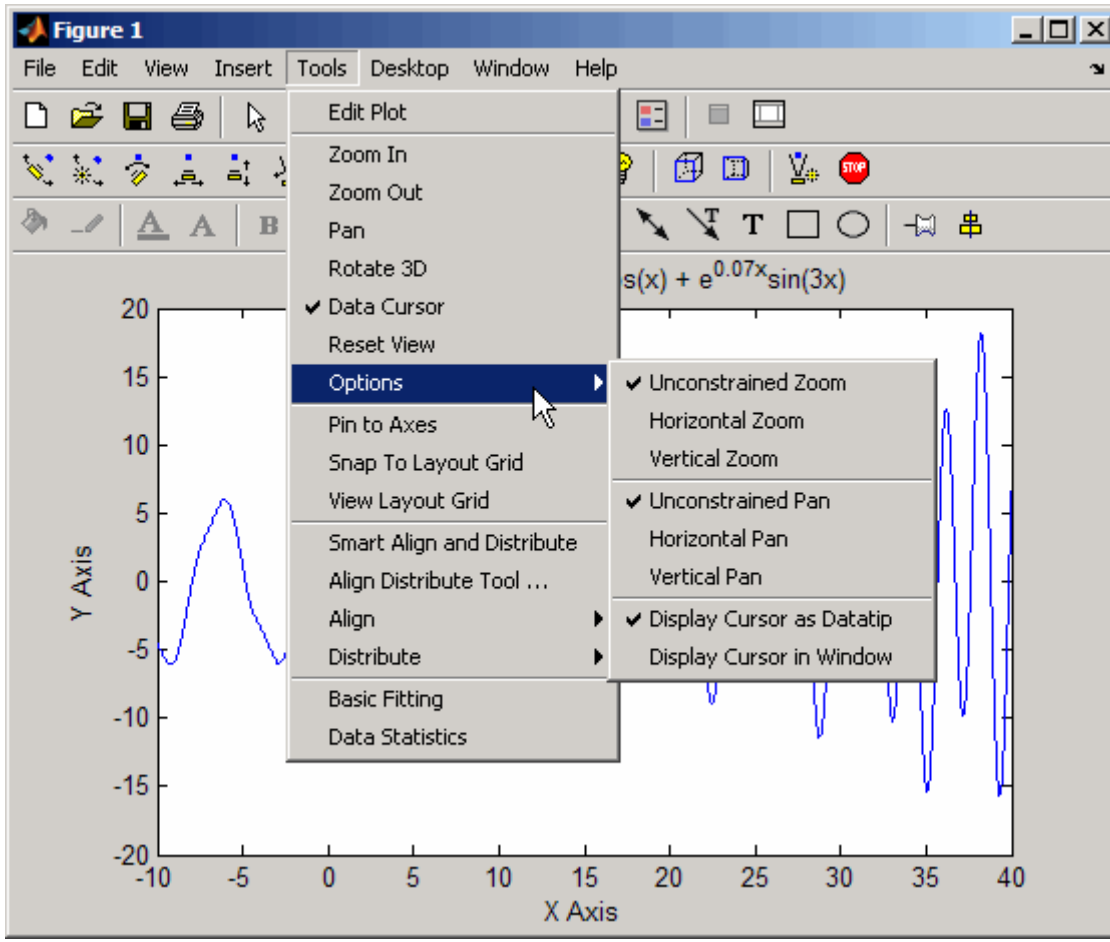
The figure is equipped with sets of tools that operate on graphs. The figure **Tools** menu provides access to many graph tools, as this view of the **Options** submenu illustrates. Many of the options shown here are also present as

context menu items for individual tools such as zoom and pan. The figure also shows three figure *toolbars*, discussed in “Figure Toolbars” on page 3-8.



For More Information See “Plots and Plotting Tools” in the MATLAB Graphics documentation or select **Plotting Tools** from the figure **Help** menu.

Accessing the Tools

You can access or remove the figure toolbars and the plotting tools from the **View** menu, as shown in the following picture. Toggle on and off the toolbars you need. Adding a toolbar stacks it beneath the lowest one.

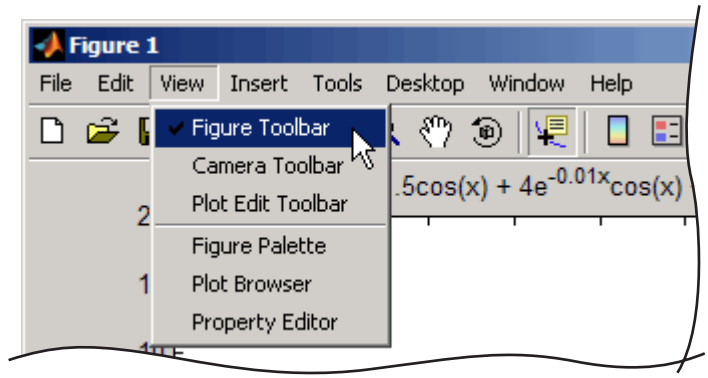


Figure Toolbars

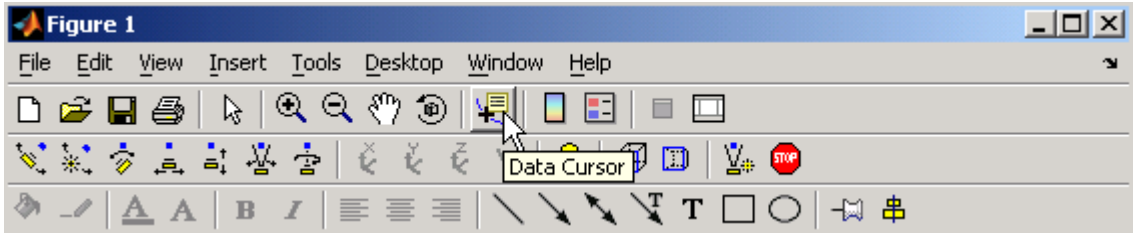
Figure toolbars provide easy access to many graph modification features. There are three toolbars. When you place the cursor over a particular tool, a text box pops up with the tool name. The following picture shows the three toolbars displayed with the cursor over the **Data Cursor** tool.



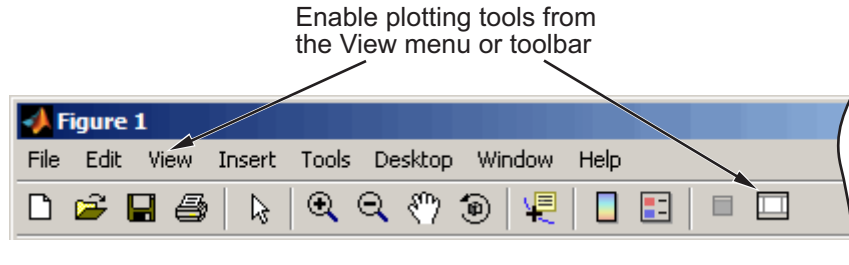
For More Information See “Anatomy of a Graph” in the MATLAB Graphics documentation.

Plotting Tools

Plotting tools are attached to figures and create an environment for creating graphs. These tools enable you to do the following:

- Select from a wide variety of graph types.
- Change the type of graph that represents a variable.
- See and set the properties of graphics objects.
- Annotate graphs with text, arrows, etc.
- Create and arrange subplots in the figure.
- Drag and drop data into graphs.

Display the plotting tools from the **View** menu or by clicking the **Show Plot Tools** icon in the figure toolbar, as shown in the following picture.



You can also start the plotting tools from the MATLAB prompt:

```
plottools
```

The plotting tools are made up of three independent GUI components:

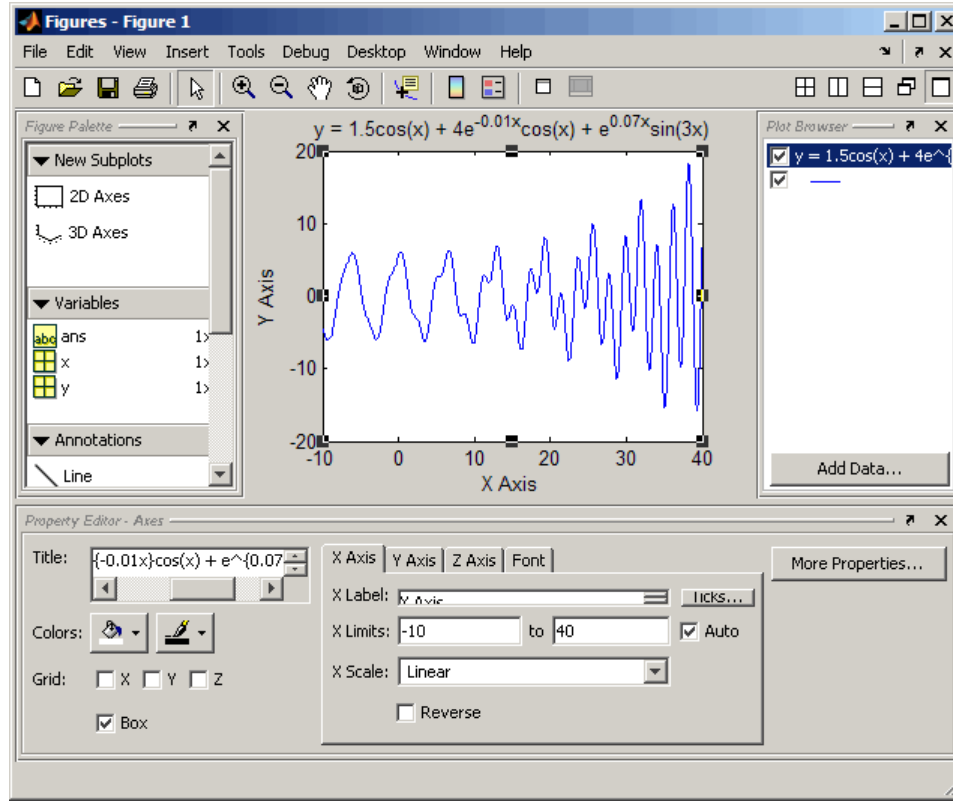
- Figure Palette — Specify and arrange subplots, access workspace variables for plotting or editing, and add annotations.
- Plot Browser — Select objects in the graphics hierarchy, control visibility, and add data to axes.
- Property Editor — Change key properties of the selected object. Click **More Properties** to access all object properties with the Property Inspector.

You can also control these components from the MATLAB Command Window, by typing the following:

```
figurepalette
plotbrowser
propertyeditor
```

See the reference pages for `plottools`, `figurepalette`, `plotbrowser`, and `propertyeditor` for information on syntax and options.

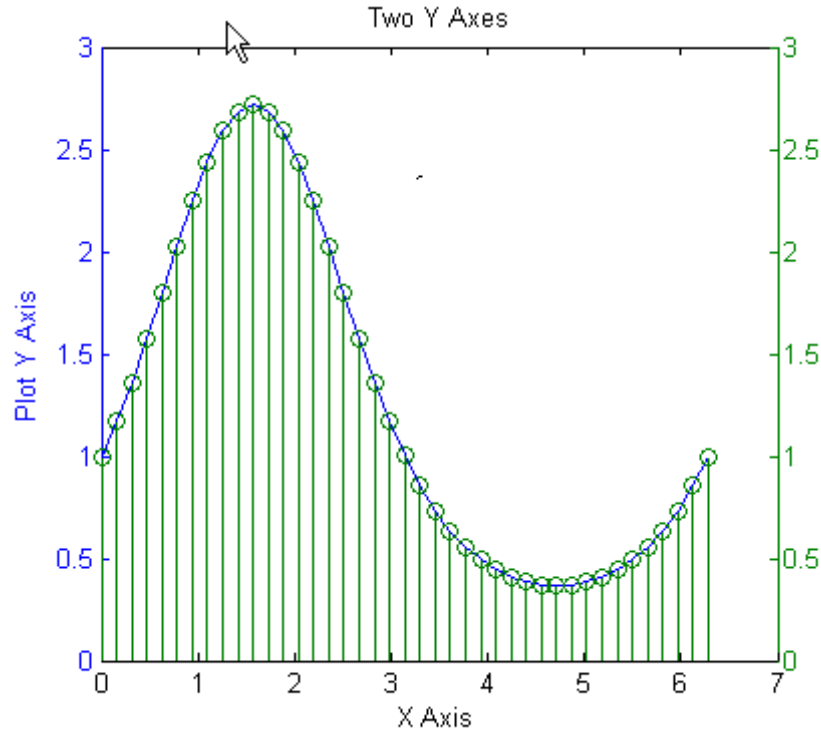
The following picture shows a figure with all three plotting tools enabled.



Using Plotting Tools and MATLAB Code

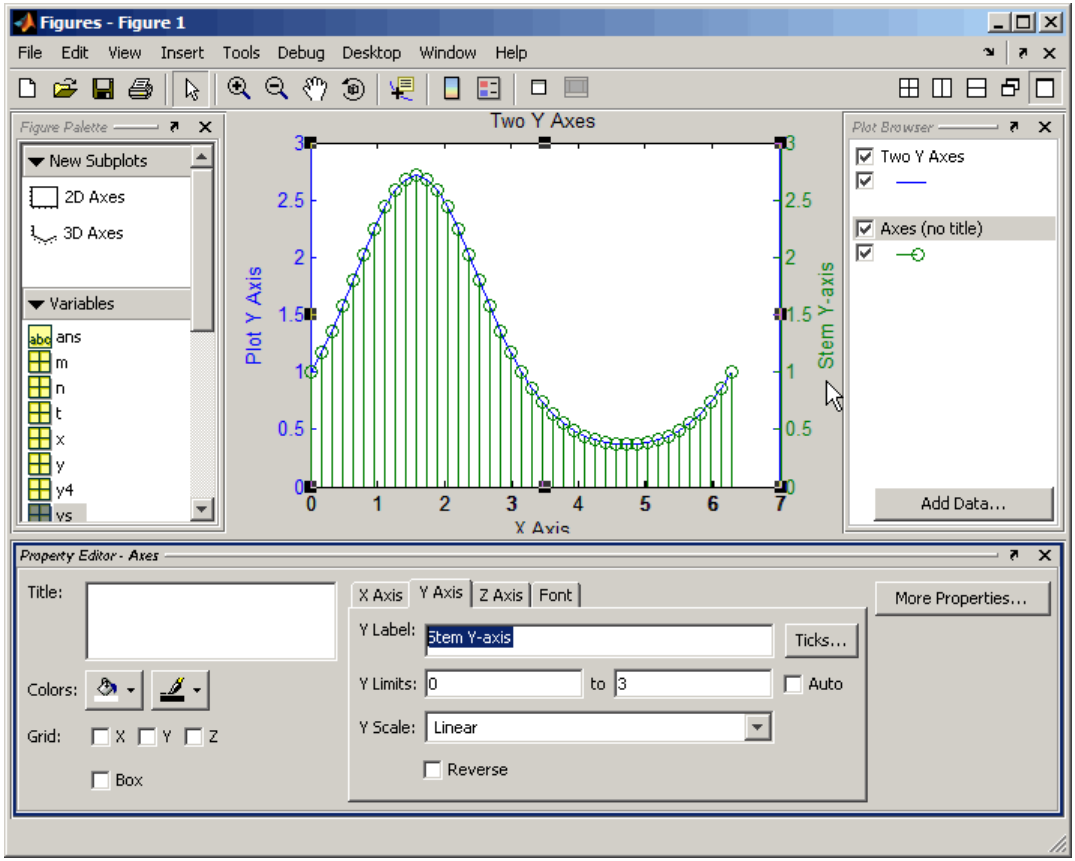
You can enable the plotting tools for any graph, even one created using MATLAB commands. For example, suppose you type the following code to create a graph:

```
t = 0:pi/20:2*pi;
y = exp(sin(t));
plotyy(t,y,t,y,'plot','stem')
xlabel('X Axis')
ylabel('Plot Y Axis')
title('Two Y Axes')
```



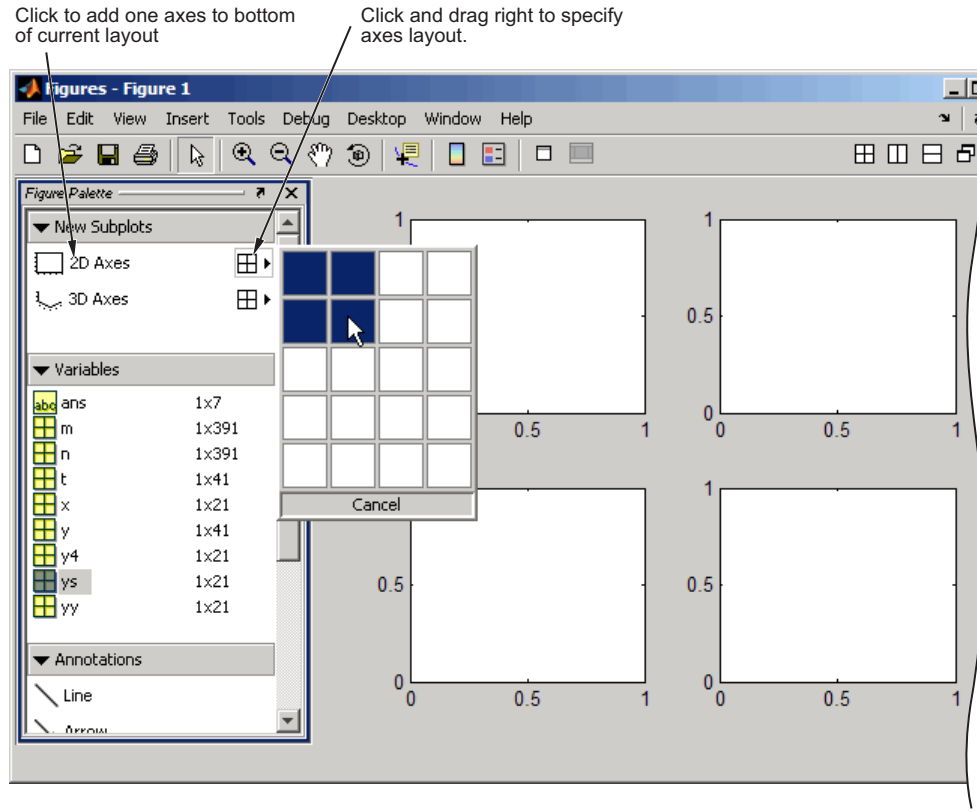
This graph contains two *y*-axes, one for each plot type (a lineseries and a stemseries). The plotting tools make it easy to select any of the objects that the graph contains and modify their properties.

For example, adding a label for the *y*-axis that corresponds to the stem plot is easily accomplished by selecting that axes in the Plot Browser and setting the **Y Label** property in the Property Editor (if you do not see that text field, stretch the Figures window to make it taller).



Arranging Graphs Within a Figure

You can place a number of axes within a figure by selecting the layout you want from the Figure Palette. For example, the following picture shows how to specify four 2-D axes in the figure.



Select the axes you want to target for plotting. You can also use the `subplot` function to create multiple axes.

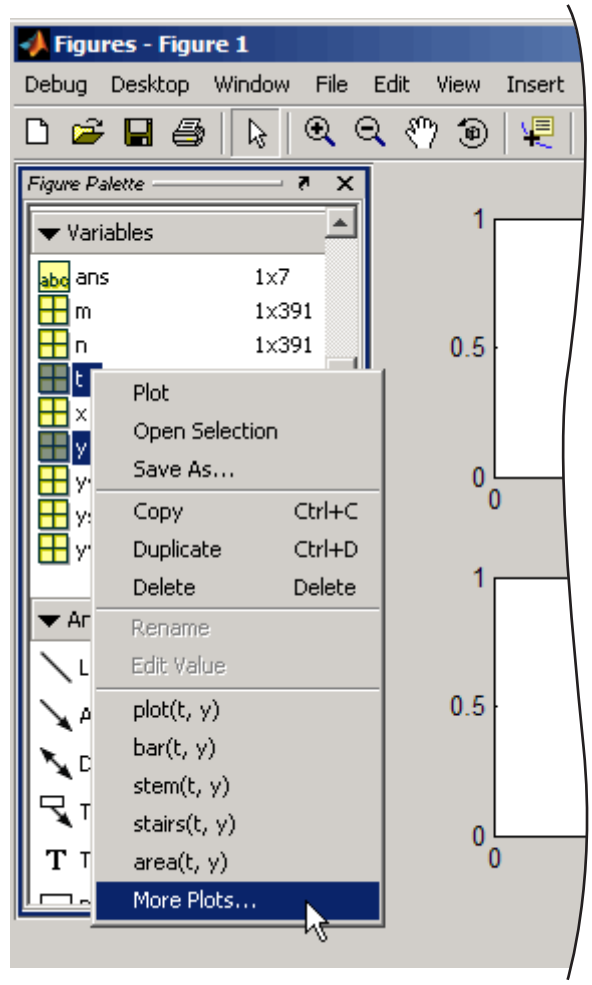
Choosing a Type of Graph to Plot

The many kinds of 2-D and 3-D graphs that MATLAB can make are described in “Types of Plots Available in MATLAB” in the MATLAB Graphics documentation. Almost all plot types are itemized, described, and illustrated by a tool called the Plot Catalog. You can use the Plot Catalog to browse graph types, choose one to visualize your selected variables, and then create it in the current or a new figure window. You can access the Plot Catalog by selecting one or more variables, as follows:

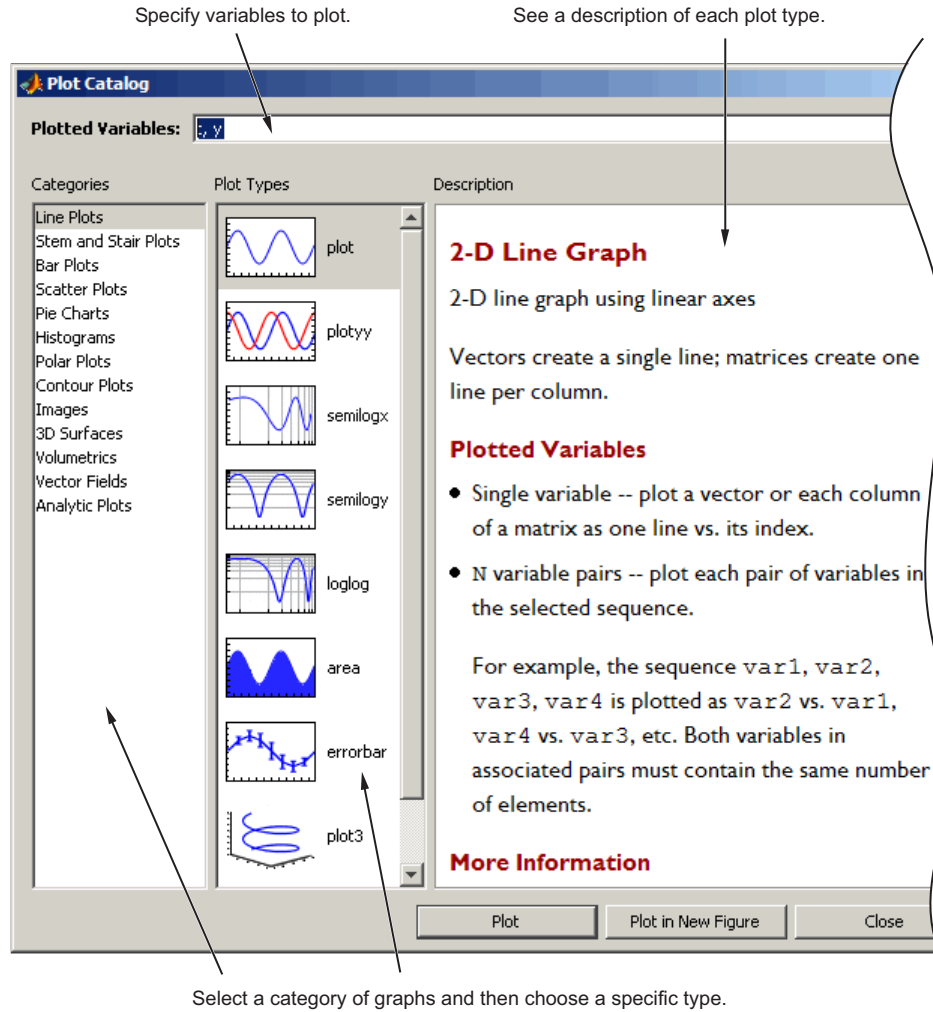
- In the Figure Palette, right-click a selected variable and choose **More Plots** from the context menu
- In the Workspace Browser, right-click a selected variable and choose **More Plots** from the context menu, or click the plot selector  tool and choose **More Plots** from its menu
- In the Array Editor, select the values you want to graph, click the plot selector  tool and choose **More Plots** from its menu

The icon on the plot selector tool represents a graph type, and changes depending on the type and dimensionality of the data you select. It is disabled if no data or non-numeric data is selected.

The following illustration shows how you can open the plot catalog from the Figure Palette:



MATLAB displays the Plot Catalog in a new, undocked window with the selected variables ready to plot, after you select a plot type and click **Plot** or **Plot in New Figure**. You can override the selected variables by typing other variable names or MATLAB expressions in the **Plotted Variables** edit field.



Specify variables to plot.
See a description of each plot type.

Editing Plots

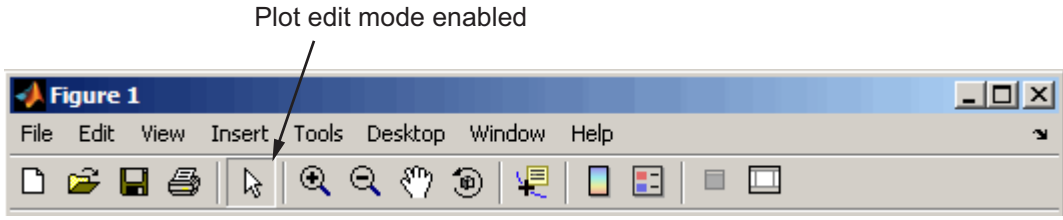
In this section...

Plot Edit Mode

Plot edit mode lets you select specific objects in a graph and enables you to perform point-and-click editing of most of them.

Enabling Plot Edit Mode

To enable plot edit mode, click the arrowhead in the figure toolbar:

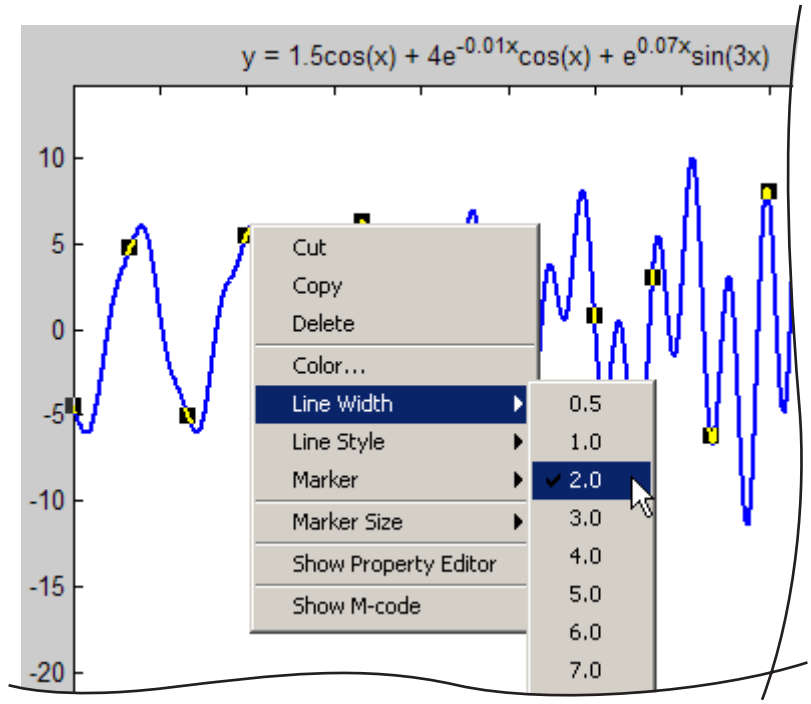


You can also select **Edit Plot** from the figure **Tools** menu.

Setting Object Properties

After you have enabled plot edit mode, you can select objects by clicking them in the graph. Selection handles appear and indicate that the object is selected. Select multiple objects using **Shift**+click.

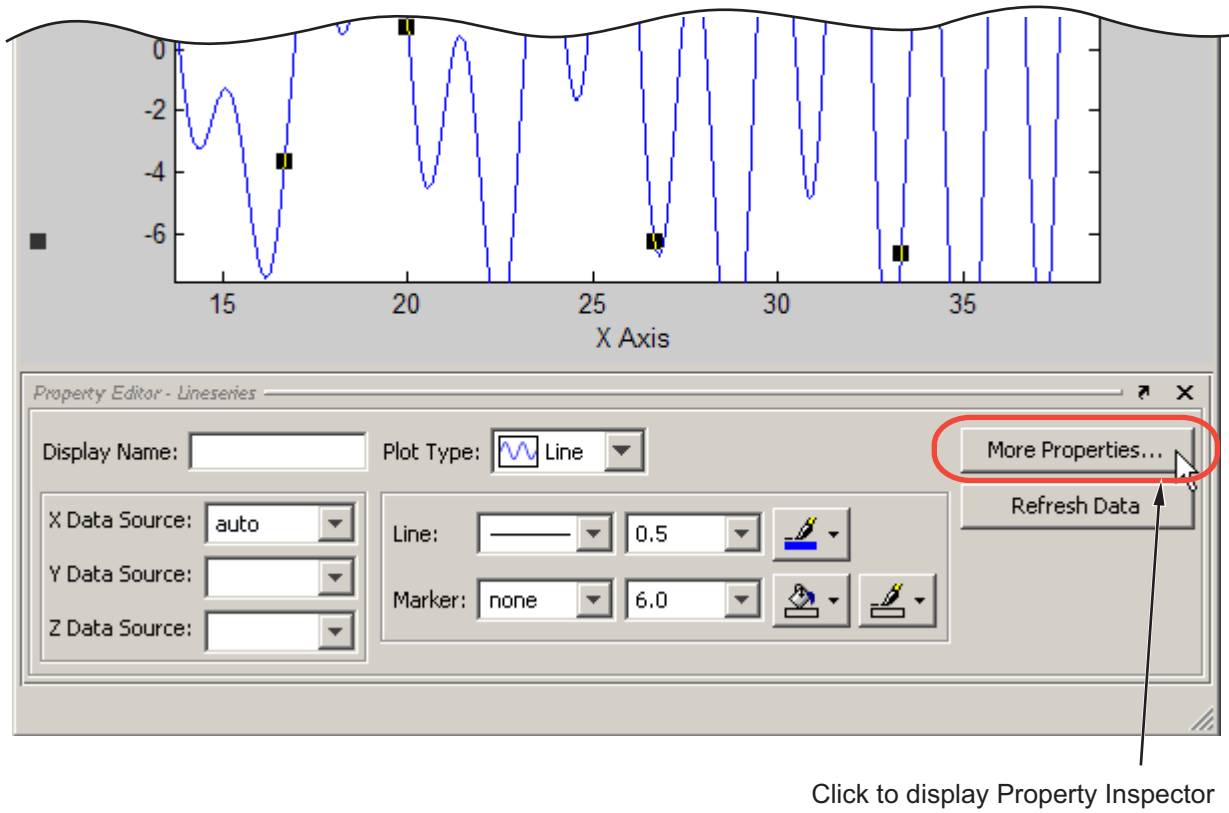
Right-click with the pointer over the selected object to display the object’s context menu:



The context menu provides quick access to the most commonly used operations and properties.

Using the Property Editor

In plot edit mode, double-clicking an object in a graph opens the Property Editor GUI with that object's major properties displayed. The Property Editor provides access to the most used object properties. It is updated to display the properties of whatever object you select.



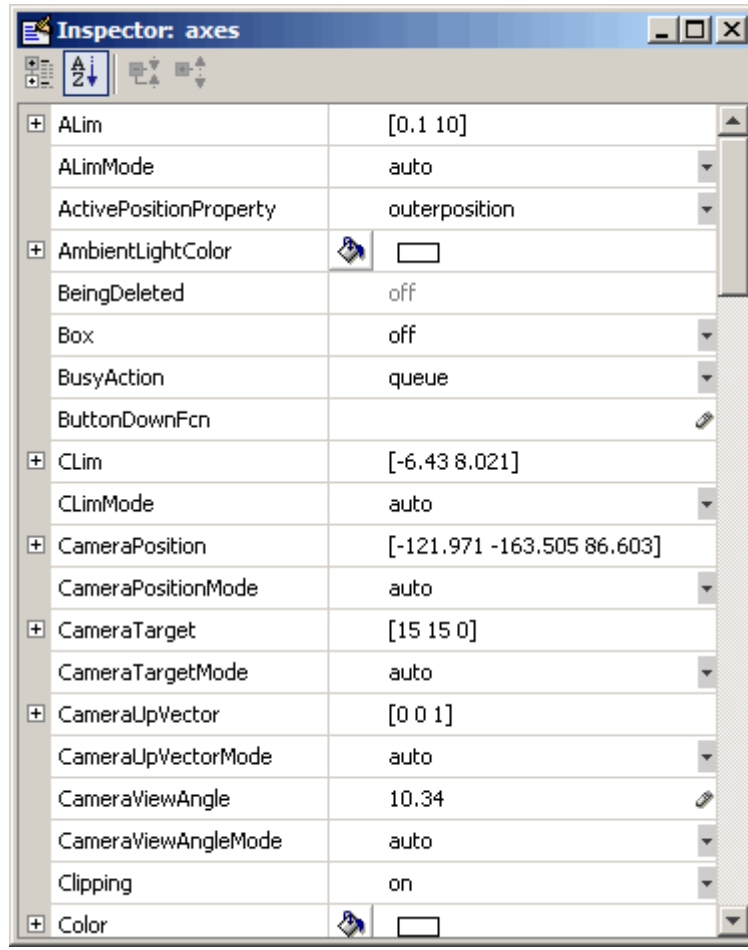
Accessing Properties with the Property Inspector

The Property Inspector is a tool that enables you to access most of the properties of Handle Graphics and other MATLAB objects. If you do not find the property you want to set in the Property Editor, click the **More Properties** button to display the Property Inspector. You can also use the `inspect` command to start the Property Inspector. For example, to inspect the properties of the current axes, type

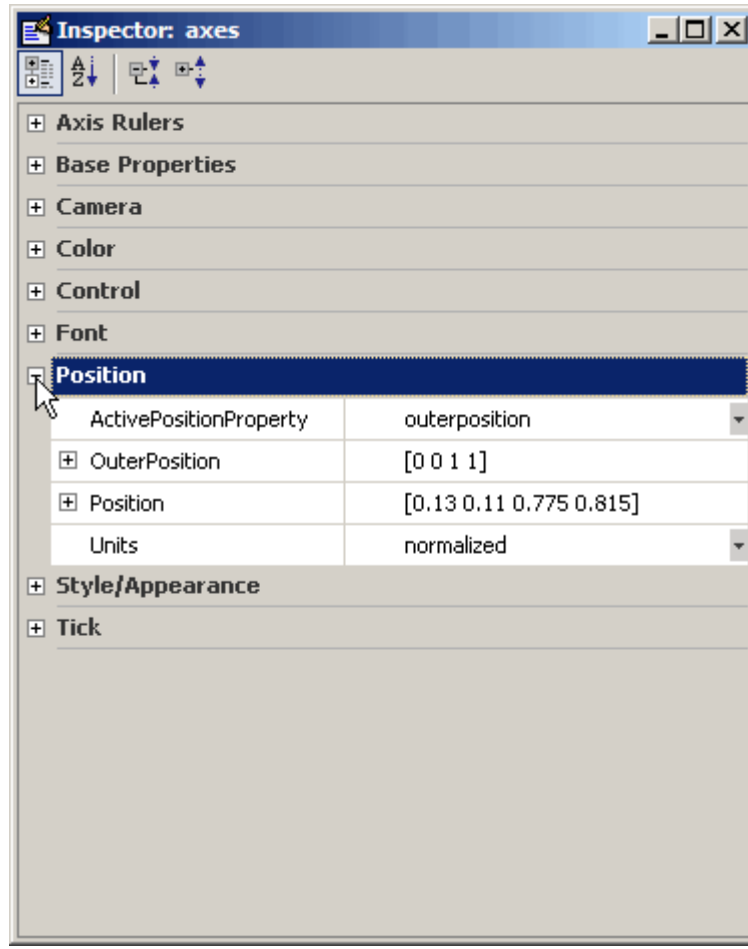
```
inspect(gca)
```

The following picture shows the Property Inspector displaying the properties of a graph's axes. It lists each property and provides a text field or other appropriate device (such as a color picker) from which you can set the value of the property.

As you select different objects, the Property Inspector is updated to display the properties of the current object.



The Property Inspector lists properties alphabetically by default. However, you can group Handle Graphics objects, such as axes, by categories which you can reveal or close in the Property Inspector. To do this, click the  icon at the upper left, then click the + next to the category you want to expand. For example, to see the position-related properties, click the + to the left of the **Position** category.



The **Position** category opens and the + changes to a - to indicate that you can collapse the category by clicking it.

Using Functions to Edit Graphs

If you prefer to work from the MATLAB command line, or if you are creating an M-file, you can use MATLAB commands to edit the graphs you create. You can use the `set` and `get` commands to change the properties of the objects in a graph. For more information about using graphics commands, see "Handle Graphics" on page 3-74.

Some Ways to Use MATLAB Plotting Tools

In this section...

Plotting Two Variables with Plotting Tools

Suppose you want to graph the function $y = x^3$ over the x domain -1 to 1. The first step is to generate the data to plot.

It is simple to evaluate a function because MATLAB can distribute arithmetic operations over all elements of a multivalued variable.

For example, the following statement creates a variable `x` that contains values ranging from -1 to 1 in increments of 0.1 (you could also use the `linspace` function to generate data for `x`). The second statement raises each value in `x` to the third power and stores these values in `y`:

```
x = -1:.1:1; % Define the range of x
y = x.^3;    % Raise each element in x to the third power
```

Now that you have generated some data, you can plot it using the MATLAB plotting tools. To start the plotting tools, type

```
plottools
```

MATLAB displays a figure with plotting tools attached.

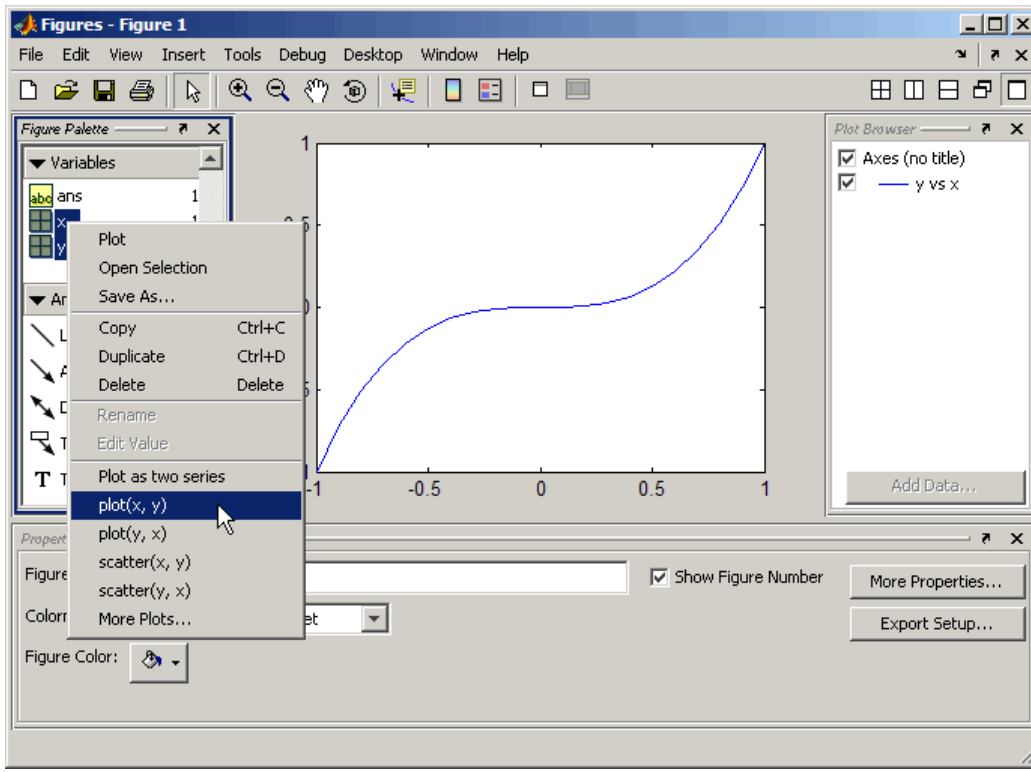
Jet
Figure Color:

Note When you invoke `plottools`, the set of plotting tools you see and their relative positions depend on how they were configured the last time you used them. Also, sometimes when you dock and undock figures with plotting tools attached, the size or proportions of the various components can change, and you may need to resize one or more of the tool panes.

A simple line graph is a suitable way to display x as the independent variable and y as the dependent variable. To do this, select both variables (click to select, and then **Shift**+click to select again), and then right-click to display the context menu.

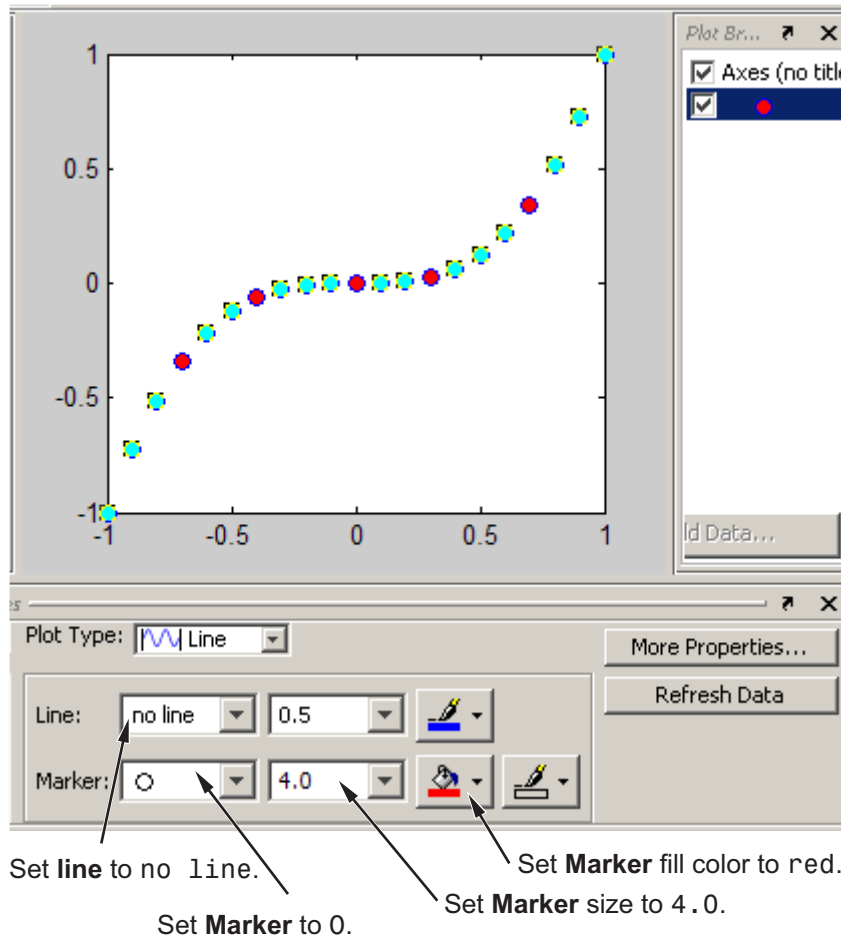


Select **plot(x, y)** from the menu. MATLAB creates the line graph in the figure area. The black squares indicate that the line is selected and you can edit its properties with the Property Editor.

Changing the Appearance of Lines and Markers

Next change the line properties so that the graph displays only the data point. Use the Property Editor to set following properties:

- Line to no line
- Marker to o (circle)
- Marker size to 4.0
- Marker fill color to red



Adding More Data to the Graph

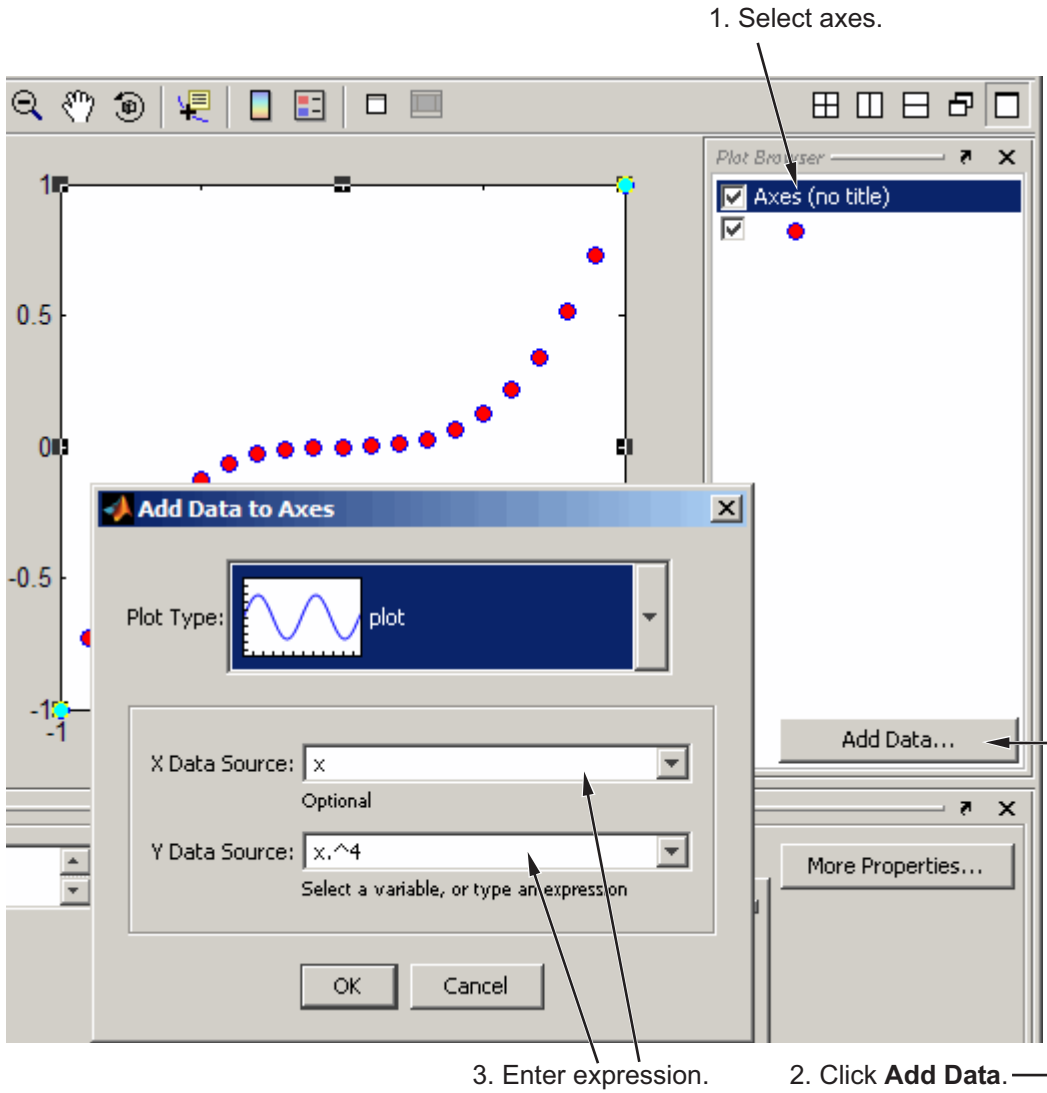
You can add more data to the graph by defining more variables or by specifying an expression that MATLAB uses to generate data for the plot. This second approach makes it easy to explore variations of the data already plotted.

To add data to the graph, select the axes in the Plot Browser and click the **Add Data** button. When you are using the plotting tools, MATLAB always adds data to the existing graph, instead of replacing the graph, as it would

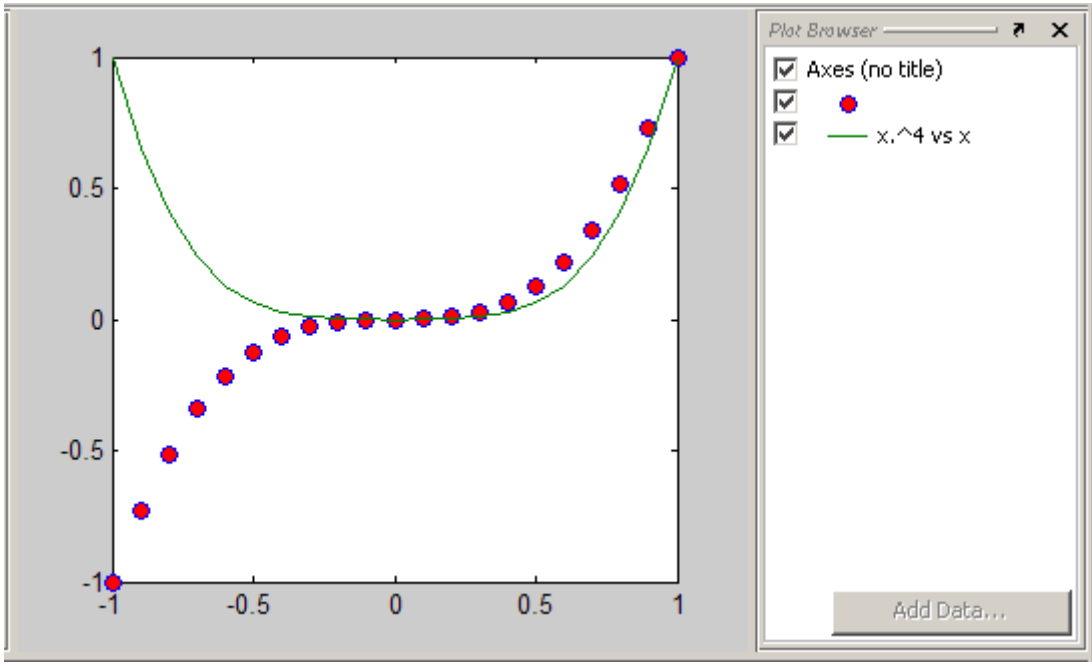
if you issued repeated plotting commands. That is, the plotting tools are in a `hold on` state.

To add data using the Plot Browser:

1. Click the **Edit Plot** tool  .
2. Select the axes to which you wish to add data; handles appear around it.
3. Click the **Add Data** button in the Plot Browser; the Add Data to Axes dialog box opens.
4. Select a plot type from the **Plot Type** drop-down menu.
5. Select a variable or type an expression for **X Data Source**.
6. Select a variable or type an expression for **Y Data Source**.
7. Click **OK**; a plot of the data you specified is added to the axes.



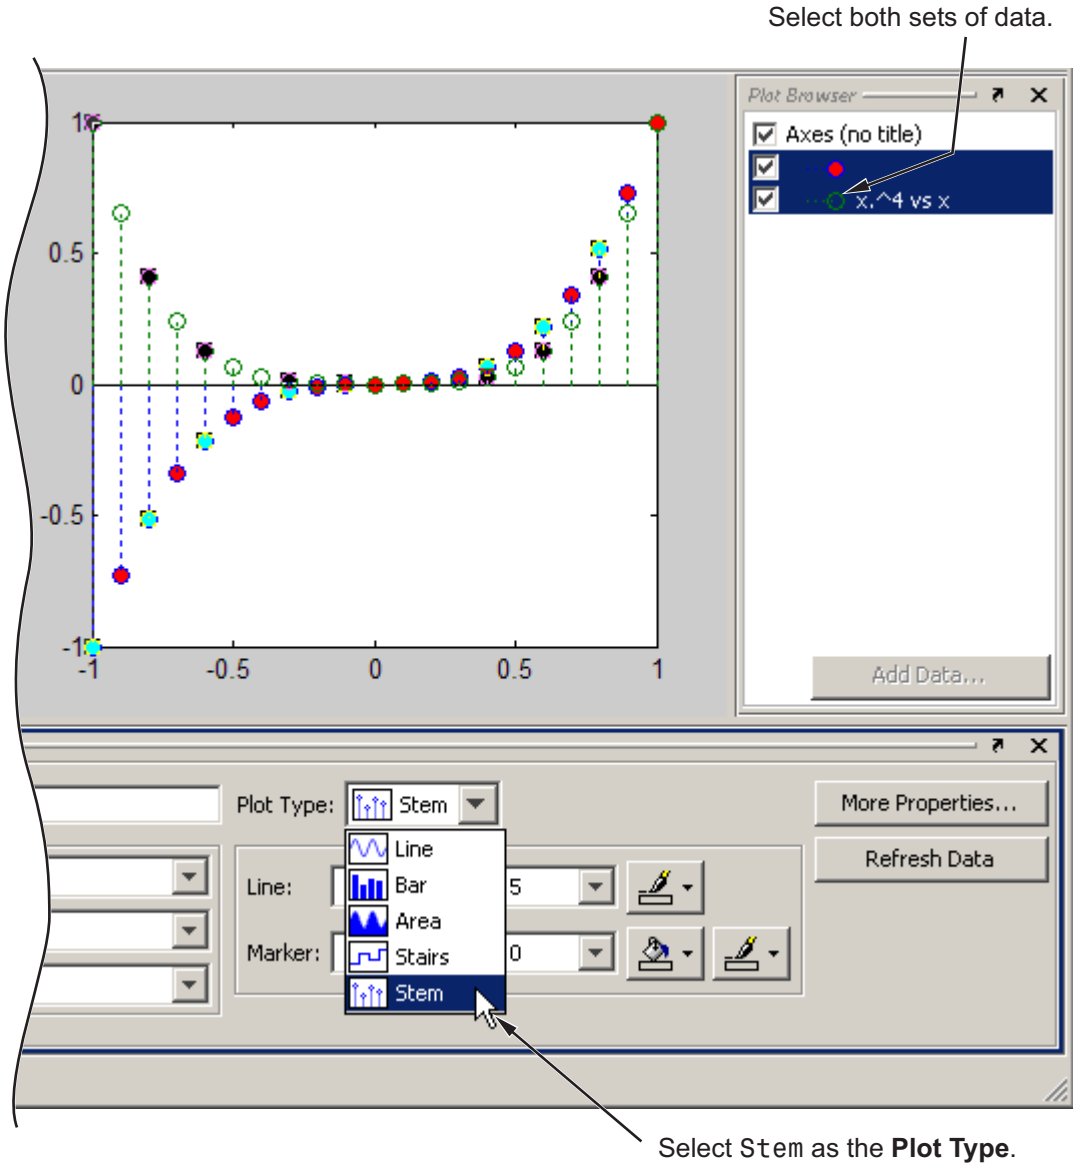
The picture above shows how to use the Add Data to Axes dialog box to create a line plot of $y = x^4$, which is added to the existing plot of $y = x^3$. The resulting plot is shown as follows with the Plot Browser:



Changing the Type of Graph

The plotting tools enable you to easily view your data with a variety of plot types. The following picture shows the same data as above converted to stem plots. To change the plot type,

1. Select both plotted series in the Plot Browser or **Shift**+click to select them in the plot itself.
2. Select short dashes from the **Line** drop-down menu in the Property Inspector; the line type of both series changes.
3. Select **Stem** from the **Plot Type** menu.



Select both sets of data.

Modifying the Graph Data Source

You can link graph data to variables in your workspace. When you change the values contained in the variables, you can then update the graph to use the new data without having to create a new graph. (See also the `refresh` function.)

1. Define 50 points between -3π and 3π and compute their sines and cosines:

```
x = linspace(-3*pi,3*pi,50);
ys = sin(x);
yc = cos(x);
```

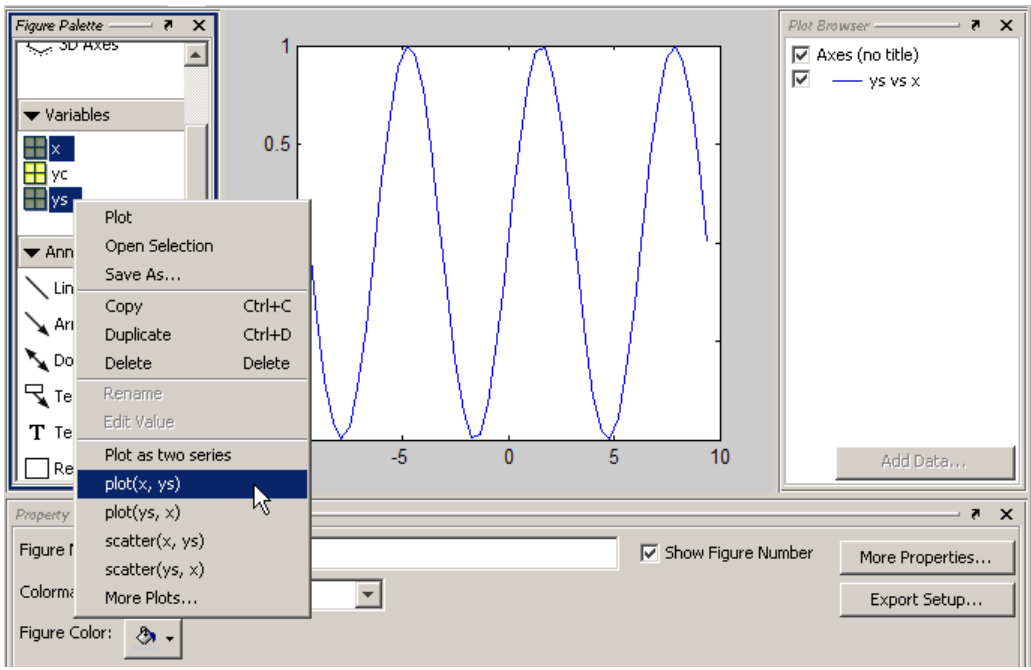
2. Using the plotting tools, create a graph of `ys = sin(x)`:

```
figure
plottools
```

3. In the Figure Palette, alternate-click to select *x* and *ys* in the **Variable** pane.

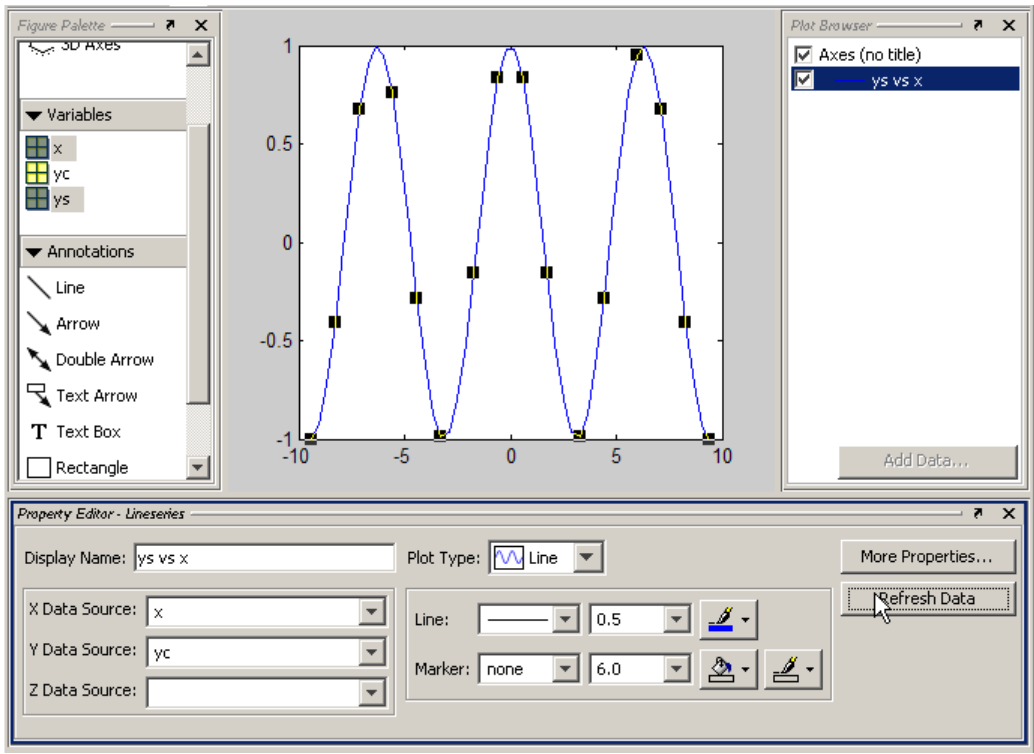
4. Right-click either selected variable and choose **plot(x, ys)** from the context menu, as shown below.

The resulting plot looks like this.



You can use the Property Editor to change the data that this plot displays:

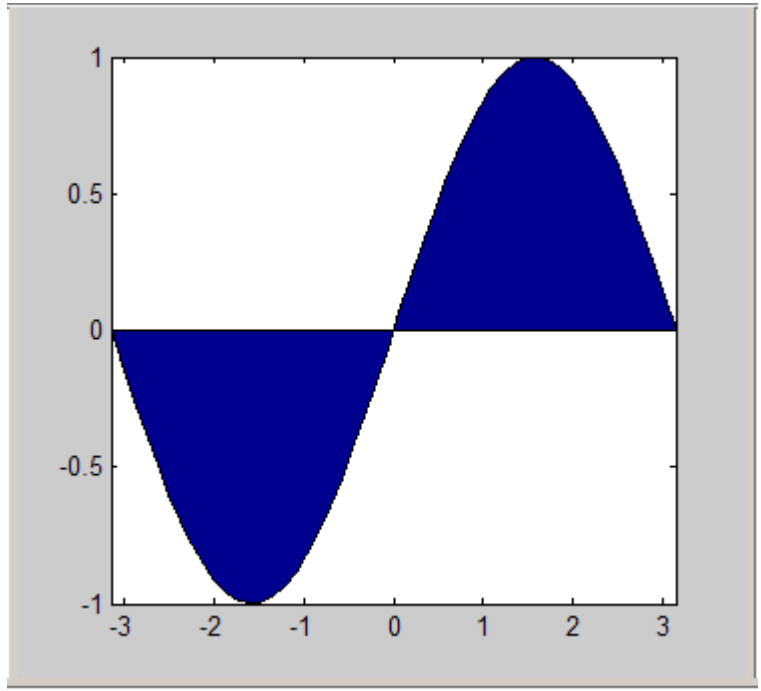
1. Select the line `ys vs x` in the Plot Browser or by clicking it.
2. In the Property Editor, select `yc` in the **Y Data Source** drop-down menu.
3. Click the **Refresh Data** button; the plot will change to display a plot of `yc vs x`.



Providing New Values for the Data Source

MATLAB copies the data that defines the graph from variables in the base workspace (for example, `x` and `y`) to the `XData` and `YData` properties of the plot object (for example, a lineseries). Therefore, in addition to being able to choose new data sources, you can assign new values to workspace variables in the Command Window and click the **Refresh Data** button to update a graph to use the new data.

```
x = linspace(-pi,pi,50); % Define 50 points between -π and π
y = sin(x);
area(x,y)  % Make an area plot of x and y
```



Now recalculate `y` at the command line:

```
y = cos(x)
```

Select the blue line on the plot. Select, `x` as the **X Data Source**, `y` as the **Y Data Source**, and click **Refresh Data**. The graph's `XData` and `YData` are replaced, making the plot look like this.

Preparing Graphs for Presentation

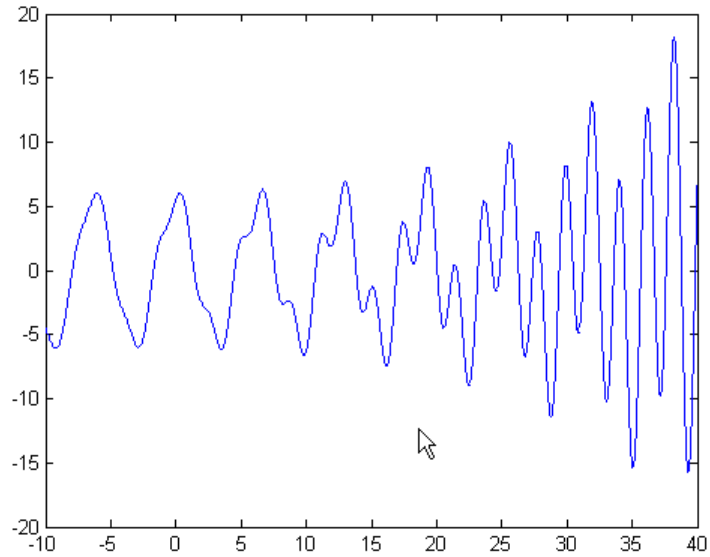
In this section...

Annotating Graphs for Presentation

Suppose you plot the following data and want to create a graph that presents certain information about the data:

```
x = -10:.005:40;
y = [1.5*cos(x)+4*exp(-.01*x).*cos(x)+exp(.07*x).*sin(3*x)];
plot(x,y)
```

This picture shows the graph created by the previous code.

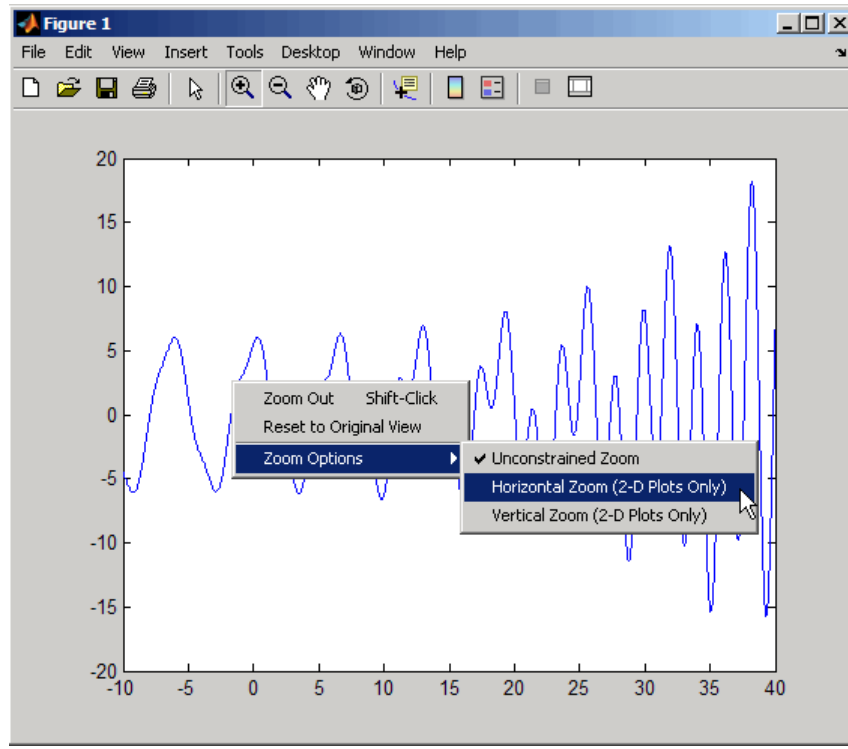


Now suppose you want to save copies of the graph by

- Printing the graph on a local printer so you have a copy for your notebook
- Exporting the graph to an Encapsulated PostScript (EPS) file to incorporate into a word processor document

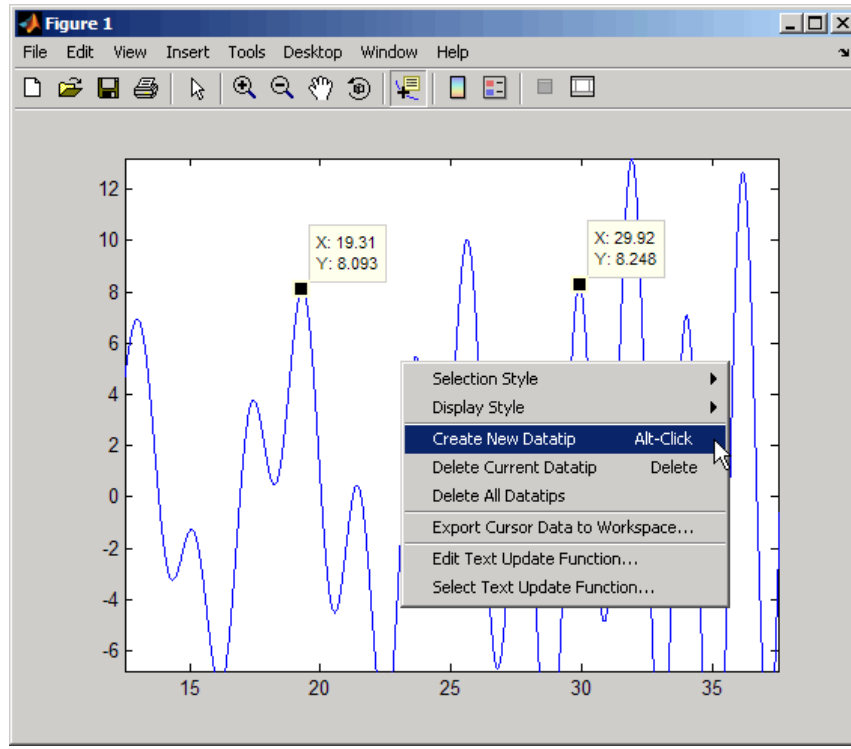
To obtain a better view, zoom in on the graph using horizontal zoom.

Enable zoom mode by clicking the **Zoom** tool on the figure toolbar, and then right-click to display the context menu. Select **Horizontal Zoom (2-D Plots Only)** from **Zoom Options**. Notice that you can reverse your zoom direction by **Shift**+left-clicking, or using the context menu.

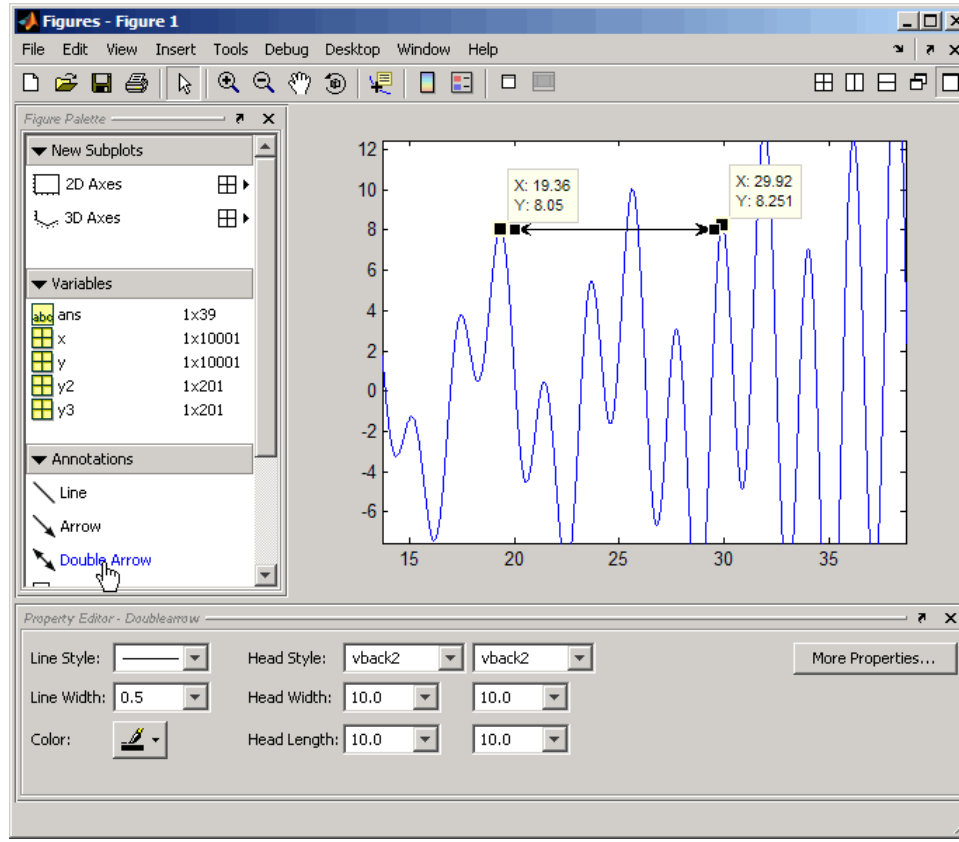


Left-click to zoom in on a region of the graph and use the **Pan** tool to position the points of interest where you want them on the graph.

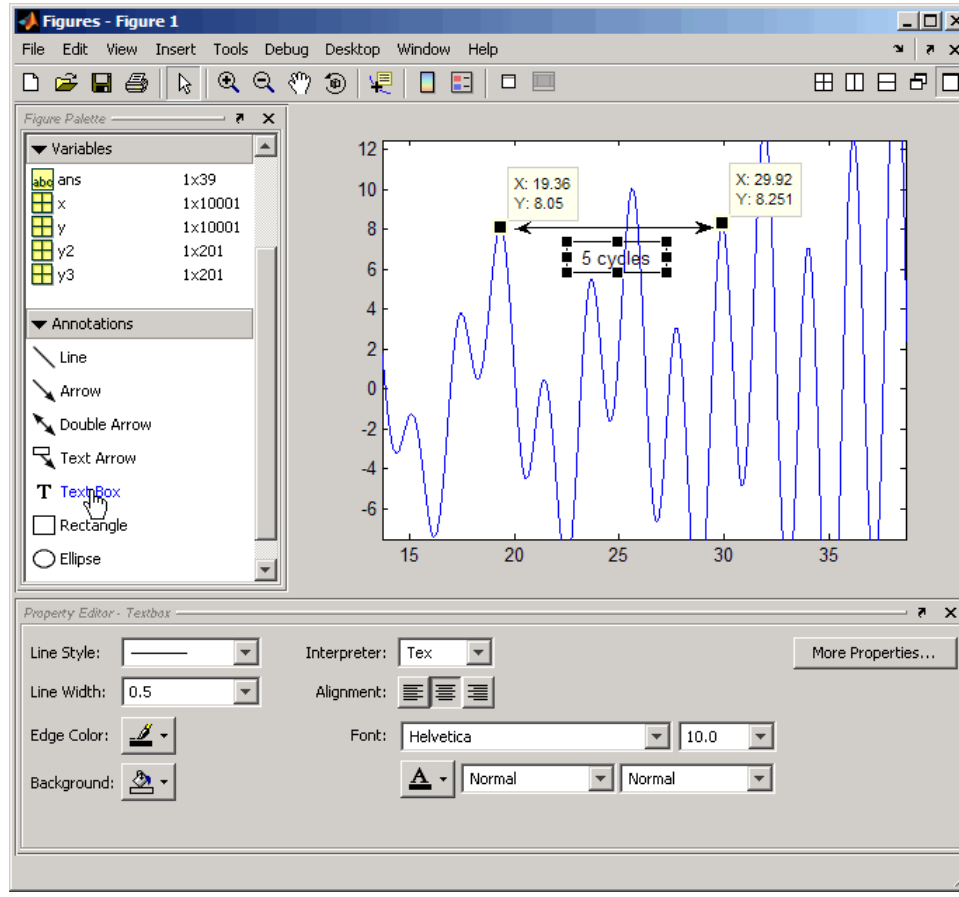
Label some key points with data tips using the **Data Cursor** tool  . Notice that left-clicking the line moves the last datatip you created to where you just clicked. To create a new datatip, press **Alt**+click or use the tool's context menu. See "Data Cursor — Displaying Data Values Interactively" in the MATLAB Graphics documentation for more information on using datatips.



Next use the Figure Palette to annotate the plot. Choose the Double arrow tool in the Annotations section to draw a line between two datatips, as shown below:



Now add a text box, also using the Figure Palette. You may have to scroll to see the text box icon. Drag out a box, and then type into it. You can stretch or shrink the box with its handles, and center the text with the Property Editor while the text box is selected. You can also use the Property Editor to change the text font, size, style, and color, as well as the text box line and background colors.

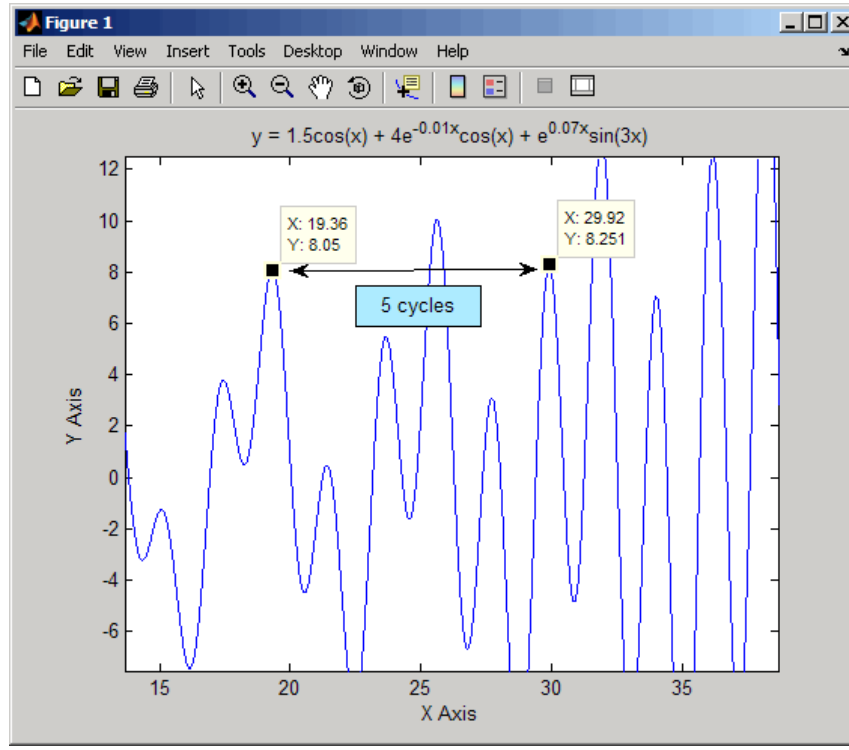


Finally, add text annotations, axis labels, and a title. You can add the title and axis labels using the following commands:

```
title ('y = 1.5cos(x) + 4e^{-0.01x}cos(x) + e^{0.07x}sin(3x)')
xlabel('X Axis')
ylabel('Y Axis')
```

Note that the text string passed to the `title` command uses T_EX syntax to produce the exponents. See “Information About Using T_EX” in the Text Properties page in the MATLAB Function Reference documentation about using T_EX syntax to produce mathematical symbols.

You can also add these annotations by selecting the axes and typing the above strings into their respective fields in the Property Editor. The graph is now ready to print and export.

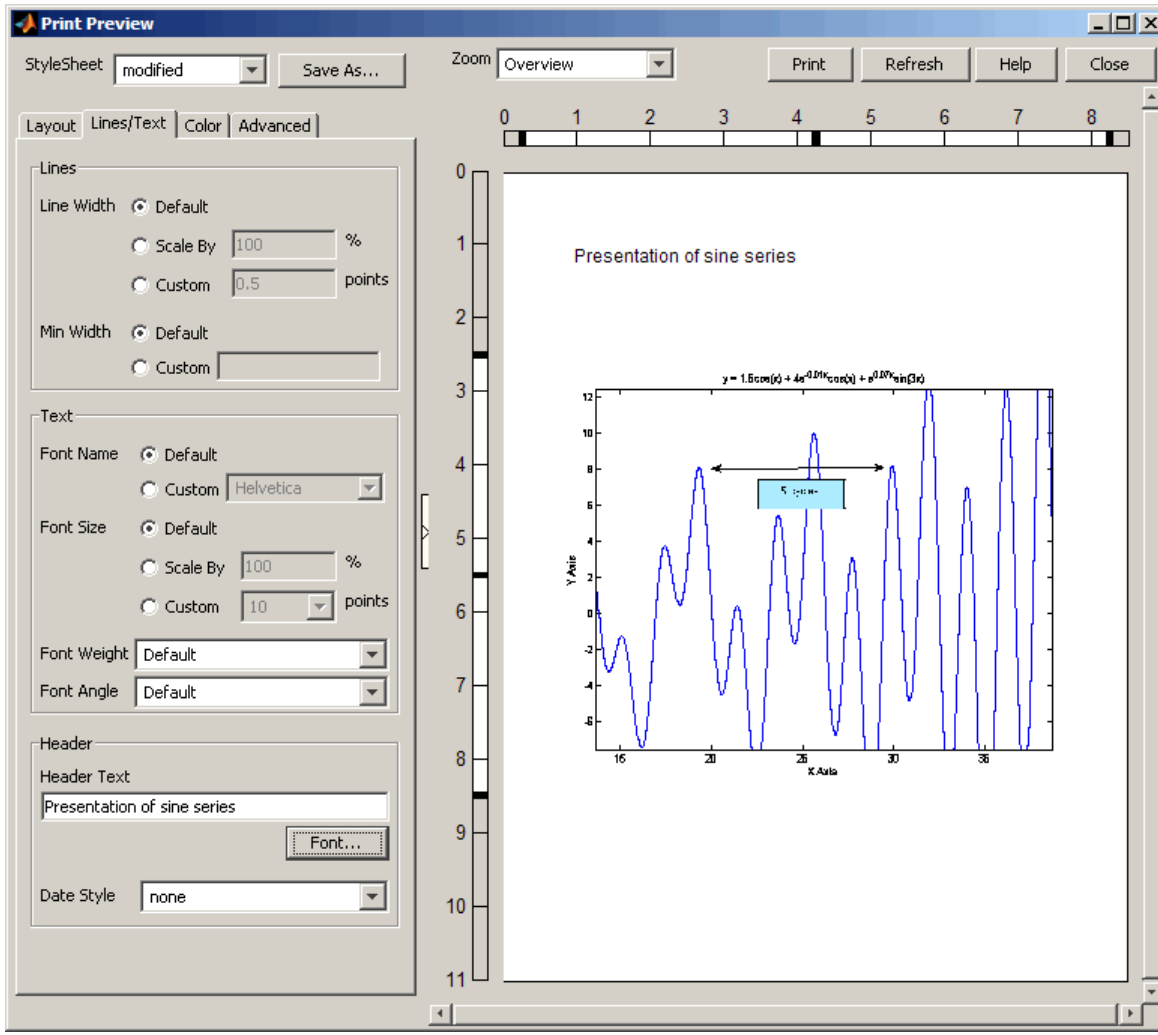


Printing the Graph

Before printing the graph, select **Print Preview** from the figure **File** menu to see and modify how the graph will be laid out on the page. The Print Preview window opens, containing a tabbed control panel on its left side and a page image on its right side.

- Click the **Lines/Text** tab, and enter a line of text in the **Header Text** edit field that you want to place at the top of the page. You can change the font, style, and size of the header by clicking the **Font** button beneath the text

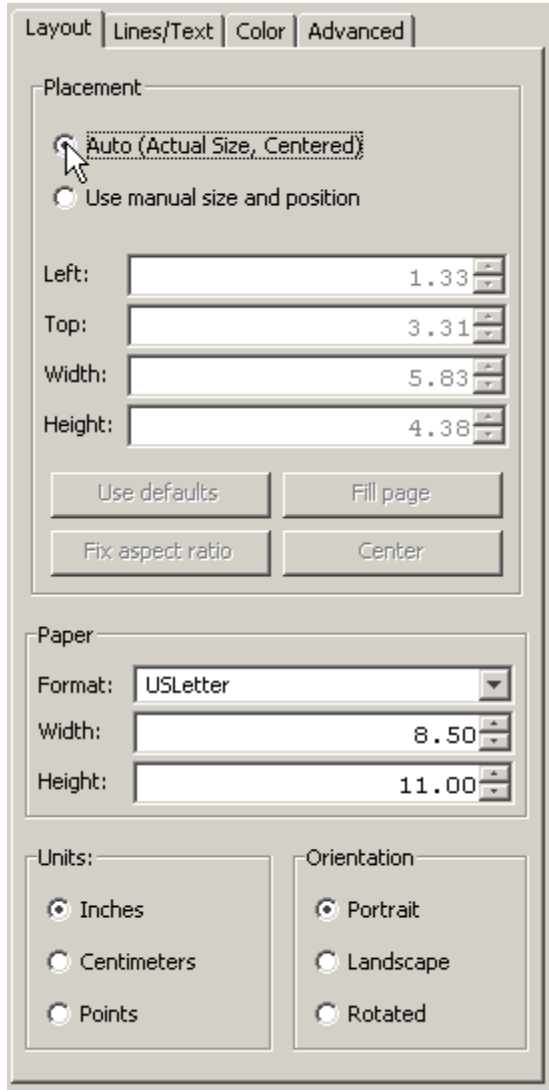
field, and also use the **Date Style** drop-down list to specify a date format to add the current date/time to the header.



- Notice the three black handlebars in the rulers along the left and top sides of the preview pane. The outside handlebars let you stretch one edge of the plot, leaving the other edges in place. The inner handlebars let you move

the plot up and down or left and right without stretching it. Using them does not affect the figure itself, only the printed version of it.

- You can also change the size and position of the plot on the page using the buttons and edit boxes on the **Layout** tab. You can revert to the original configuration by clicking the **Auto (Actual Size, Centered)** option button, and correct stretching and shrinking by clicking **Fix Aspect Ratio**. The following picture shows the **Layout** tab in Auto configuration.



- By default, MATLAB recalculates the locations of the axes tick marks because a printed graph is normally larger than the one displayed on your monitor. However, you can keep your graph's tick marks and limits when printing it by clicking the **Advanced** tab and selecting **Keep screen limits and ticks**.

- When you are ready to print your plot, click **Print** in the right pane. You can also click **Close** to accept the settings and dismiss the dialog box. Later, you can print the figure as you previewed it using **Print** on the figure's **File** menu. Both methods will open a standard Print dialog box, and will produce the same printed results.

Note There is no way to cancel a print preview; any changes you make will take effect if you print the figure. If you want to revert to a default page layout, you can generally accomplish this by selecting either the **Use Defaults** button or the **Auto (Actual Size, Centered)** option button on the **Layout** tab, although this will not affect every setting you can make.

The Print Preview dialog box provides many other options for controlling how printed graphs look. Click its **Help** button for more information.

Exporting the Graph

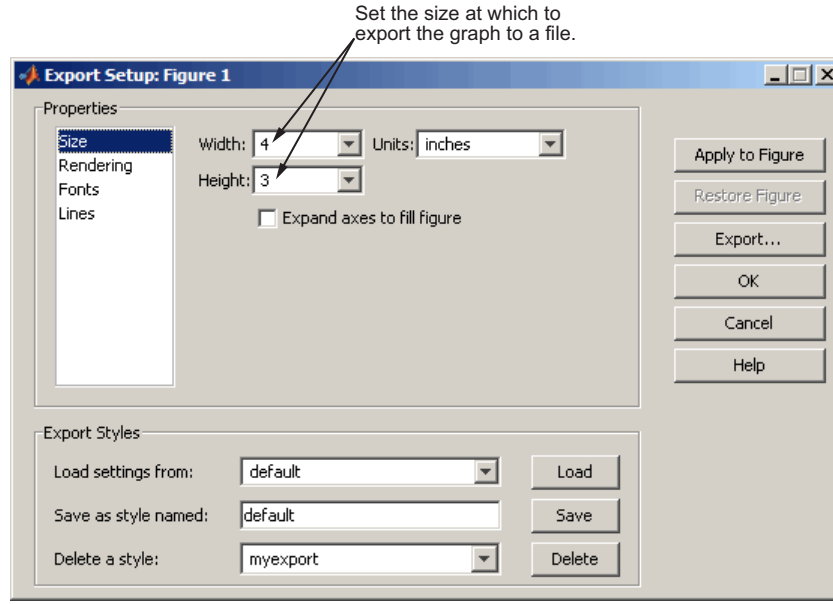
Exporting a graph is the process of creating a standard graphics file format of the graph (such as EPS or TIFF), which you can then import into other applications like word processors, drawing packages, etc.

This example exports the graph as an EPS file with the following requirements:

- The size of the picture when imported into the word processor document should be 4 inches wide and 3 inches high.
- All the text in the figure should have a size of 8 points.

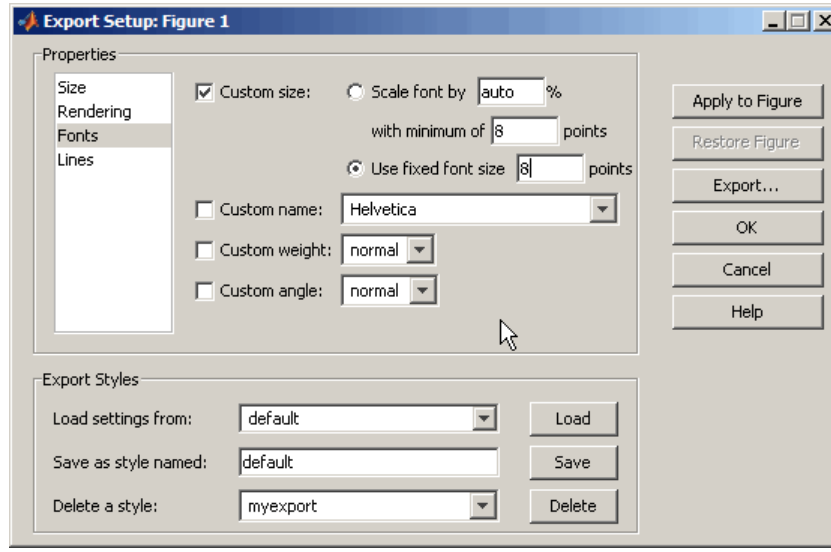
Specifying the Size of the Graph

To set the size, use the Export Setup dialog box (select **Export Setup** from the figure **File** menu). Then select 4 from the **Width** list and 3 from the **Height** list.



Specifying the Font Size

To set the font size of all the text in the graph, select `Fonts` in the Export Setup dialog box **Properties** selector. Then click **Use fixed font size** and enter `8` in the text box.



Selecting the File Format

After you finish setting options for the exported graph, click the **Export** button. MATLAB displays a standard Save As dialog box that enables you to specify a name for the file as well as select the type of file format you want to use.

The **Save as type** drop-down menu lists a number of other options for file formats. For this example, select `EPS (*.eps)` from the **Save as type** menu.

You can import the saved file into any application that supports EPS files.

You can also use the `print` command to print figures on your local printer or to export graphs to standard file types.

For More Information See the `print` command reference page and "Printing and Exporting" in the MATLAB Graphics documentation or select **Printing and Exporting** from the figure **Help** menu.

Using Basic Plotting Functions

In this section...

Creating a Plot

The `plot` function has different forms, depending on the input arguments. If `y` is a vector, `plot(y)` produces a piecewise linear graph of the elements of `y` versus the index of the elements of `y`. If you specify two vectors as arguments, `plot(x,y)` produces a graph of `y` versus `x`.

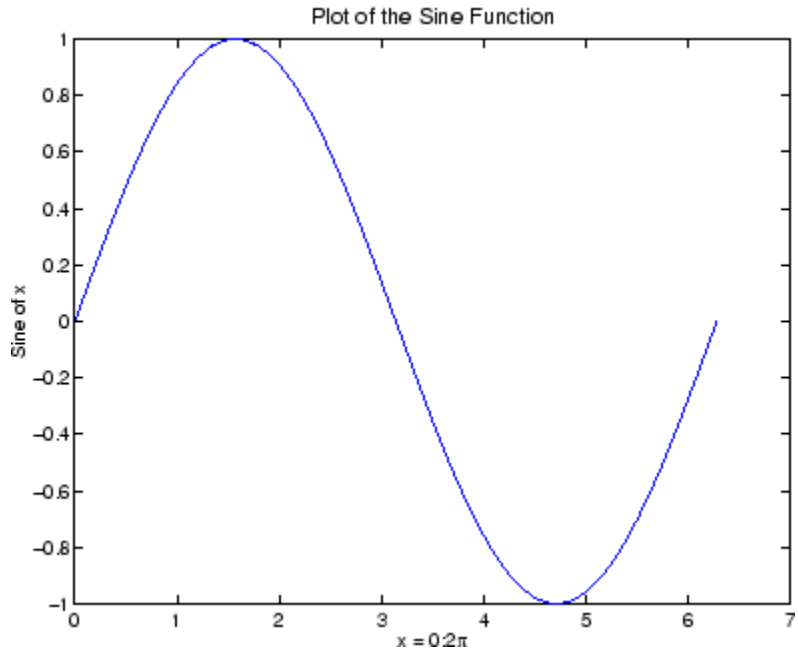
For example, these statements use the `colon` operator to create a vector of `x` values ranging from 0 to 2π, compute the sine of these values, and plot the result:

```
x = 0:pi/100:2*pi;
y = sin(x);
plot(x,y)
```

Now label the axes and add a title. The characters `\pi` create the symbol π. See "text strings" in the MATLAB Reference documentation for more symbols:

```
xlabel('x = 0:2\pi')
ylabel('Sine of x')
```

```
title('Plot of the Sine Function','FontSize',12)
```



Plotting Multiple Data Sets in One Graph

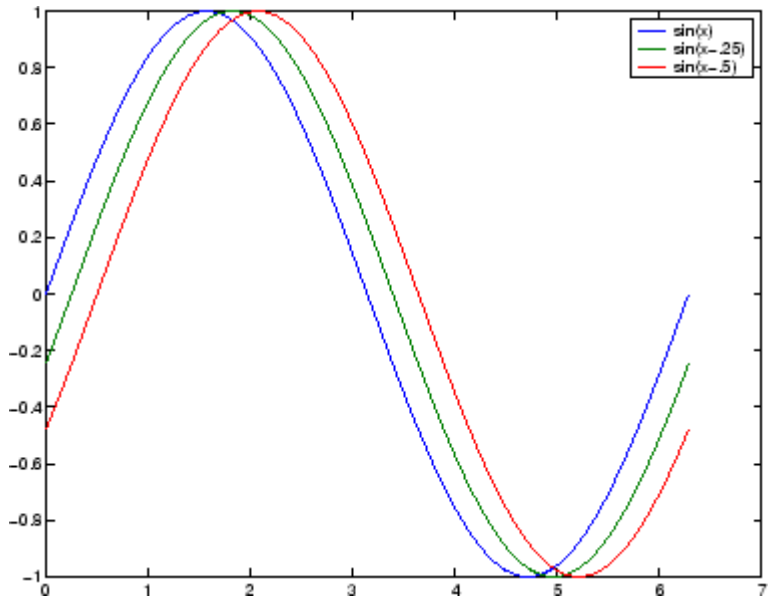
Multiple x-y pair arguments create multiple graphs with a single call to `plot`. MATLAB automatically cycles through a predefined (but user settable) list of colors to allow discrimination among sets of data. See the axes `ColorOrder` and `LineStyleOrder` properties.

For example, these statements plot three related functions of `x`, with each curve in a separate distinguishing color:

```
x = 0:pi/100:2*pi;
y = sin(x);
y2 = sin(x-.25);
y3 = sin(x-.5);
plot(x,y,x,y2,x,y3)
```

The `legend` command provides an easy way to identify the individual plots:

```
legend('sin(x)','sin(x-.25)','sin(x-.5)')
```



For More Information See “Defining the Color of Lines for Plotting” in the MATLAB Graphics documentation.

Specifying Line Styles and Colors

It is possible to specify color, line styles, and markers (such as plus signs or circles) when you plot your data using the `plot` command:

```
plot(x,y,'color_style_marker')
```

`color_style_marker` is a string containing from one to four characters (enclosed in single quotation marks) constructed from a color, a line style, and a marker type:

- Color strings are `'c'`, `'m'`, `'y'`, `'r'`, `'g'`, `'b'`, `'w'`, and `'k'`. These correspond to cyan, magenta, yellow, red, green, blue, white, and black.

- Line style strings are `'-'` for solid, `'--'` for dashed, `':'` for dotted, and `'-.'` for dash-dot. Omit the line style for no line.
- The marker types are `'+'`, `'o'`, `'*'`, and `'x'`, and the filled marker types are `'s'` for square, `'d'` for diamond, `'^'` for up triangle, `'v'` for down triangle, `'>'` for right triangle, `'<'` for left triangle, `'p'` for pentagram, `'h'` for hexagram, and `none` for no marker.

You can also edit color, line style, and markers interactively. See "Editing Plots" on page 3-17 for more information.

Plotting Lines and Markers

If you specify a marker type but not a line style, MATLAB draws only the marker. For example,

```
plot(x,y,'ks')
```

plots black squares at each data point, but does not connect the markers with a line.

The statement

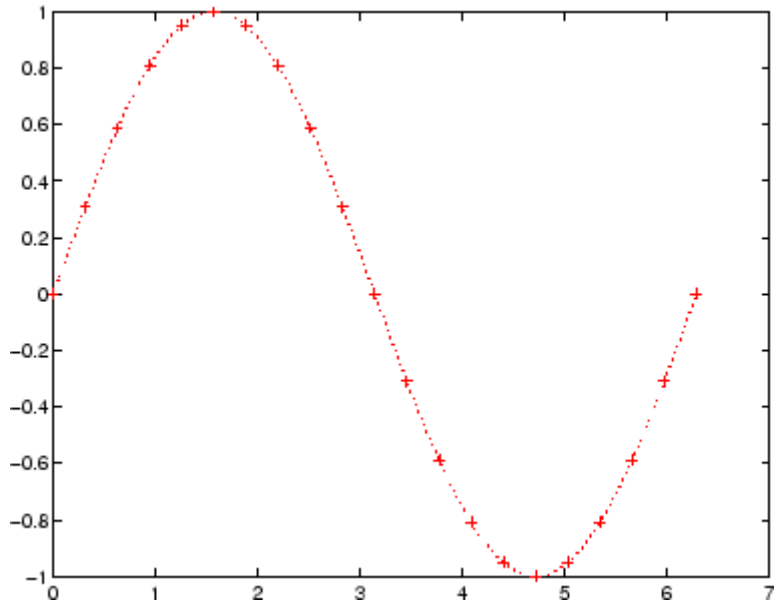
```
plot(x,y,'r:+')
```

plots a red dotted line and places plus sign markers at each data point.

Placing Markers at Every Tenth Data Point

You might want to use fewer data points to plot the markers than you use to plot the lines. This example plots the data twice using a different number of points for the dotted line and marker plots:

```
x1 = 0:pi/100:2*pi;
x2 = 0:pi/10:2*pi;
plot(x1,sin(x1),'r:',x2,sin(x2),'r+')
```



Graphing Imaginary and Complex Data

When the arguments to `plot` are complex, the imaginary part is ignored *except* when you pass `plot` a single complex argument. For this special case, the command is a shortcut for a graph of the real part versus the imaginary part. Therefore,

```
plot(Z)
```

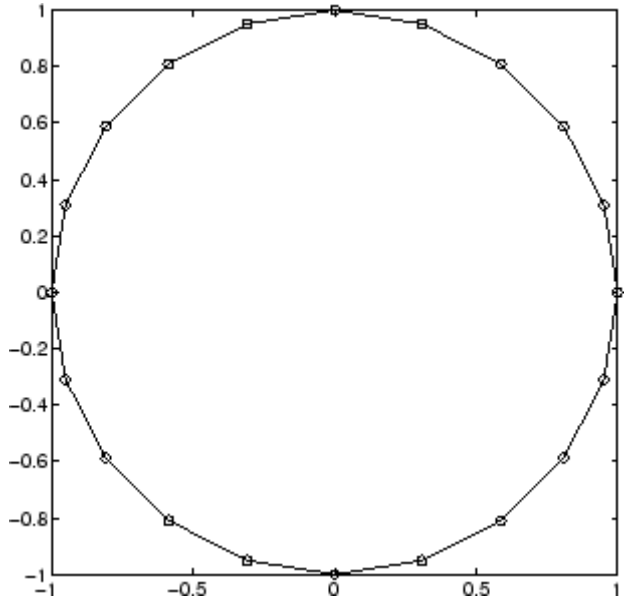
where `Z` is a complex vector or matrix, is equivalent to

```
plot(real(Z),imag(Z))
```

For example,

```
t = 0:pi/10:2*pi;
plot(exp(i*t),'-o')
axis equal
```

draws a 20-sided polygon with little circles at the vertices. The `axis equal` command makes the individual tick-mark increments on the *x*- and *y*-axes the same length, which makes this plot more circular in appearance.



Adding Plots to an Existing Graph

The `hold` command enables you to add plots to an existing graph. When you type

```
hold on
```

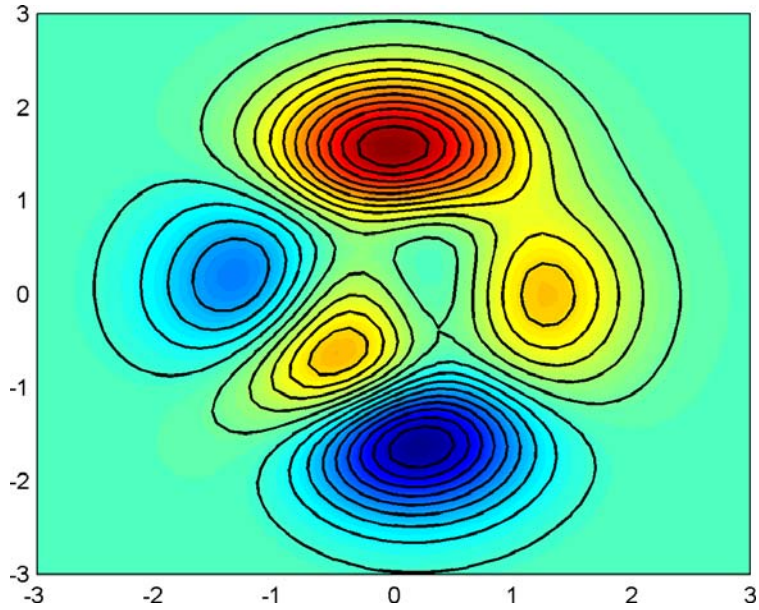
MATLAB does not replace the existing graph when you issue another plotting command; it adds the new data to the current graph, rescaling the axes if necessary.

For example, these statements first create a contour plot of the `peaks` function, then superimpose a pseudocolor plot of the same function:

```
[x,y,z] = peaks;
pcolor(x,y,z)
shading interp
```

```
hold on
contour(x,y,z,20,'k')
hold off
```

The `hold on` command combines the `pcolor` plot with the `contour` plot in one figure.



For More Information See “Creating Specialized Plots” in the MATLAB Graphics documentation for details about a variety of graph types.

Figure Windows

Graphing functions automatically open a new figure window if there are no figure windows already on the screen. If a figure window exists, MATLAB uses that window for graphics output. If there are multiple figure windows open, MATLAB targets the one that is designated the “current figure” (the last figure used or clicked in).

To make an existing figure window the current figure, you can click the mouse while the pointer is in that window or you can type

```
figure(n)
```

where `n` is the number in the figure title bar. The results of subsequent graphics commands are displayed in this window.

To open a new figure window and make it the current figure, type

```
figure
```

Clearing the Figure for a New Plot

When a figure already exists, most plotting commands clear the axes and use this figure to create the new plot. However, these commands do not reset figure properties, such as the background color or the colormap. If you have set any figure properties in the previous plot, you might want to use the `clf` command with the `reset` option,

```
clf reset
```

before creating your new plot to restore the figure's properties to their defaults.

For More Information See "Figure Properties" and "Graphics Windows — the Figure" in the MATLAB Graphics documentation for details about figures.

Displaying Multiple Plots in One Figure

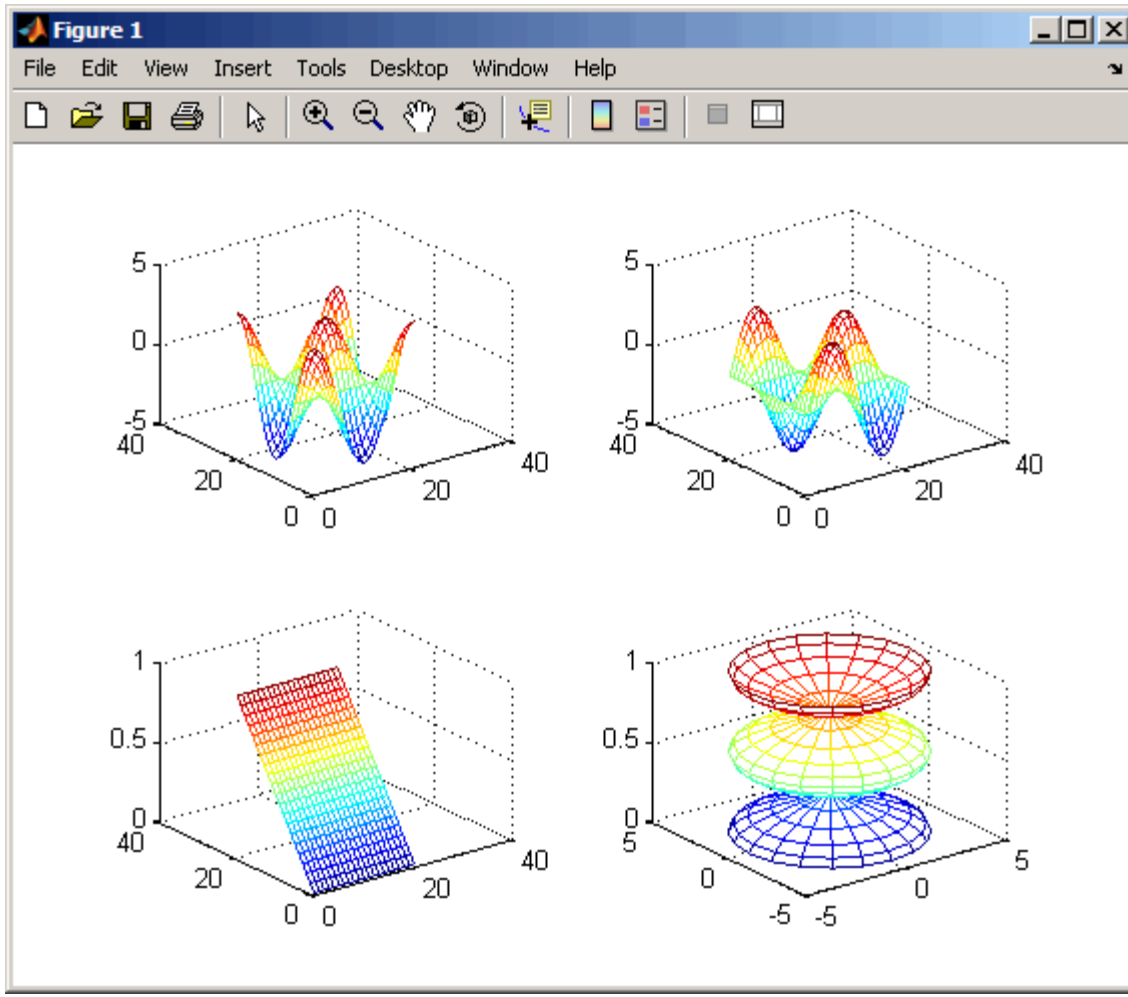
The `subplot` command enables you to display multiple plots in the same window or print them on the same piece of paper. Typing

```
subplot(m,n,p)
```

partitions the figure window into an `m`-by-`n` matrix of small subplots and selects the `p`th subplot for the current plot. The plots are numbered along the first row of the figure window, then the second row, and so on. For example, these statements plot data in four different subregions of the figure window:

```
t = 0:pi/10:2*pi;
```

```
[X,Y,Z] = cylinder(4*cos(t));
subplot(2,2,1); mesh(X)
subplot(2,2,2); mesh(Y)
subplot(2,2,3); mesh(Z)
subplot(2,2,4); mesh(X,Y,Z)
```



You can add subplots to GUIs as well as to figures. For details about creating subplots in a GUIDE-generated GUI, see "Creating Subplots" in the MATLAB Creating Graphical User Interfaces documentation.

Controlling the Axes

The `axis` command provides a number of options for setting the scaling, orientation, and aspect ratio of graphs. You can also set these options interactively. See "Editing Plots" on page 3-17 for more information.

Setting Axis Limits

By default, MATLAB finds the maxima and minima of the data and chooses the axis limits to span this range. The `axis` command enables you to specify your own limits:

```
axis([xmin xmax ymin ymax])
```

or for three-dimensional graphs,

```
axis([xmin xmax ymin ymax zmin zmax])
```

Use the command

```
axis auto
```

to reenable MATLAB automatic limit selection.

Setting the Axis Aspect Ratio

The `axis` command also enables you to specify a number of predefined modes. For example,

```
axis square
```

makes the *x*-axis and *y*-axis the same length.

```
axis equal
```

makes the individual tick mark increments on the *x*-axes and *y*-axes the same length. This means

```
plot(exp(i*[0:pi/10:2*pi]))
```

followed by either `axis square` or `axis equal` turns the oval into a proper circle:

```
axis auto normal
```

returns the axis scaling to its default automatic mode.

Setting Axis Visibility

You can use the `axis` command to make the axis visible or invisible.

```
axis on
```

makes the axes visible. This is the default.

```
axis off
```

makes the axes invisible.

Setting Grid Lines

The `grid` command toggles grid lines on and off. The statement

```
grid on
```

turns the grid lines on, and

```
grid off
```

turns them back off again.

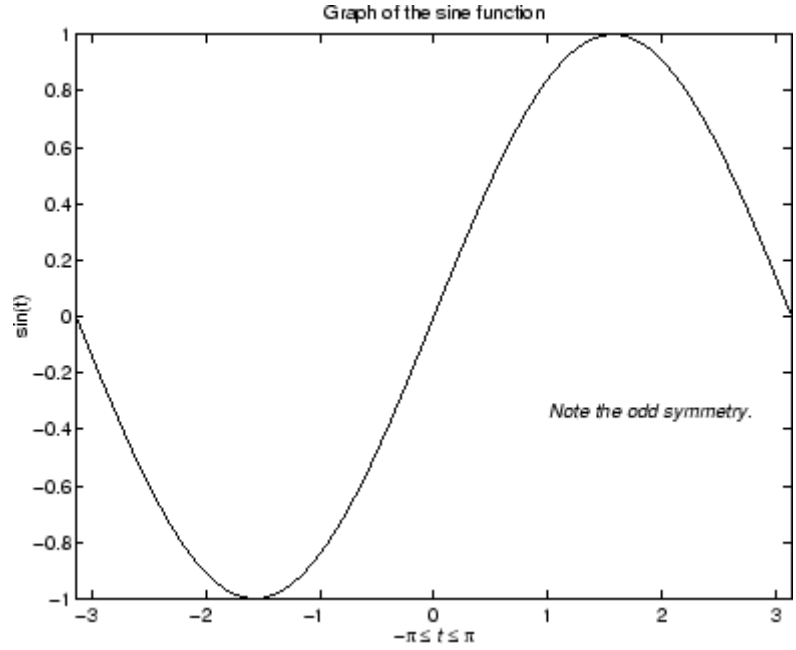
For More Information See the `axis` and `axes` reference pages and "Axes Properties" in the MATLAB Graphics documentation.

Adding Axis Labels and Titles

The `xlabel`, `ylabel`, and `zlabel` commands add *x*-, *y*-, and *z*-axis labels. The `title` command adds a title at the top of the figure and the `text` function inserts text anywhere in the figure.

You can produce mathematical symbols using LaTeX notation in the text string, as the following example illustrates:

```
t = -pi:pi/100:pi;
y = sin(t);
plot(t,y)
axis([-pi pi -1 1])
xlabel('-\pi \leq {\itt} \leq \pi')
ylabel('sin(t)')
title('Graph of the sine function')
text(1,-1/3,'{\itNote the odd symmetry.}')
```



You can also set these options interactively. See “Editing Plots” on page 3-17 for more information.

Note that the location of the text string is defined in axes units (i.e., the same units as the data). See the `annotation` function for a way to place text in normalized figure units.

Saving Figures

Save a figure by selecting **Save** from the **File** menu to display a Save dialog box. MATLAB saves the data it needs to recreate the figure and its contents (i.e., the entire graph) in a file with a `.fig` extension.

To save a figure using a standard graphics format, such as TIFF, for use with other applications, select **Export Setup** from the **File** menu. You can also save from the command line—use the `saveas` command, including any options to save the figure in a different format. The more restricted `hgexport` command, which saves figures to either bitmap or metafile files, depending on the rendering method in effect, is also available.

See “Exporting the Graph” on page 3-46 for an example.

Saving Workspace Data

You can save the variables in your workspace by selecting **Save Workspace As** from the figure **File** menu. You can reload saved data using the **Import Data** item in the figure **File** menu. MATLAB supports a variety of data file formats, including MATLAB data files, which have a `.mat` extension.

Generating M-Code to Recreate a Figure

You can generate MATLAB code that recreates a figure and the graph it contains by selecting **Generate M-File** from the figure **File** menu. This option is particularly useful if you have developed a graph using plotting tools and want to create a similar graph using the same or different data.

Saving Figures That Are Compatible with the Previous Version of MATLAB

Create backward-compatible FIG-files by following these two steps:

1. Ensure that any plotting functions used to create the contents of the figure are called with the `'v6'` argument, where applicable.
2. Use the `'-v6'` option with the `hgsave` command.

Note The `v6` option enables users of Version 7.x of MATLAB to create FIG-files that previous versions can open. It is obsolete and will be removed in a future version of MATLAB. For more information, see "Plot Objects and Backward Compatibility" in the MATLAB Graphics documentation.

Creating Mesh and Surface Plots

In this section...

About Mesh and Surface Plots

MATLAB defines a surface by the *z*-coordinates of points above a grid in the *x*-*y* plane, using straight lines to connect adjacent points. The `mesh` and `surf` plotting functions display surfaces in three dimensions. `mesh` produces wireframe surfaces that color only the lines connecting the defining points. `surf` displays both the connecting lines and the faces of the surface in color.

The figure colormap and figure properties determine how MATLAB colors the surface.

Visualizing Functions of Two Variables

To display a function of two variables, $z = f(x,y)$,

1. Generate `X` and `Y` matrices consisting of repeated rows and columns, respectively, over the domain of the function.
2. Use `X` and `Y` to evaluate and graph the function.

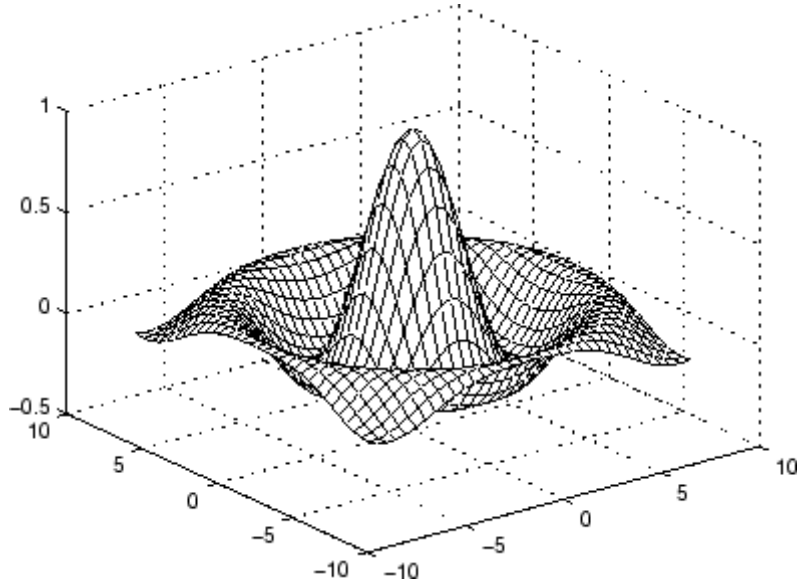
The `meshgrid` function transforms the domain specified by a single vector or two vectors `x` and `y` into matrices `X` and `Y` for use in evaluating functions of two variables. The rows of `X` are copies of the vector `x` and the columns of `Y` are copies of the vector `y`.

Example — Graphing the sinc Function

This example evaluates and graphs the two-dimensional `sinc` function, $\sin(r)/r$, between the *x* and *y* directions. `R` is the distance from the origin, which is at the center of the matrix. Adding `eps` (a MATLAB command that returns a small floating-point number) avoids the indeterminate 0/0 at the origin:

```
[X,Y] = meshgrid(-8:.5:8);
```

```
R = sqrt(X.^2 + Y.^2) + eps;
Z = sin(R)./R;
mesh(X,Y,Z,'EdgeColor','black')
```



By default, MATLAB colors the mesh using the current colormap. However, this example uses a single-colored mesh by specifying the `EdgeColor` surface property. See the `surface` reference page for a list of all surface properties.

You can create a mesh with see-through faces by disabling hidden line removal:

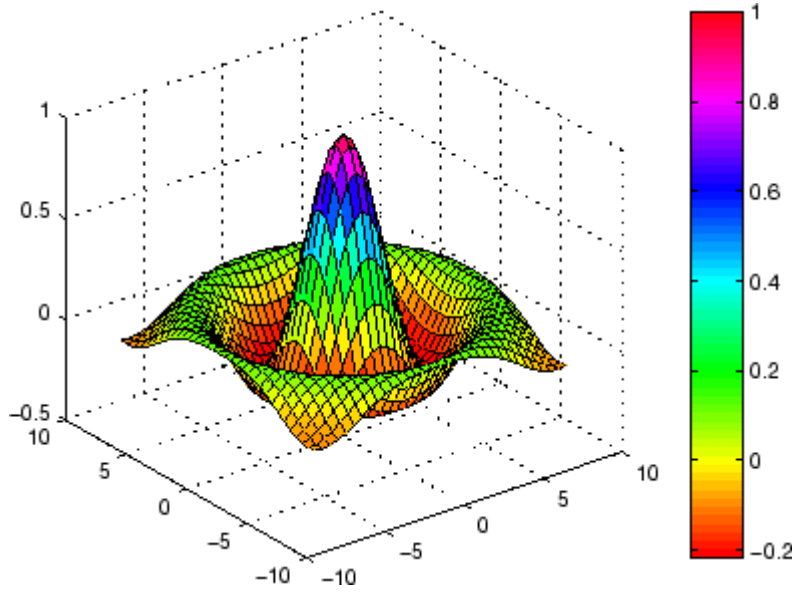
```
hidden off
```

See the `hidden` reference page for more information on this option.

Example — Colored Surface Plots

A surface plot is similar to a mesh plot except that MATLAB colors the rectangular faces of the surface. The color of each face is determined by the values of `Z` and the colormap (a colormap is an ordered list of colors). These statements graph the `sinc` function as a surface plot, specify a colormap, and add a color bar to show the mapping of data to color:

```
surf(X,Y,Z)
colormap hsv
colorbar
```



See the `colormap` reference page for information on colormaps.

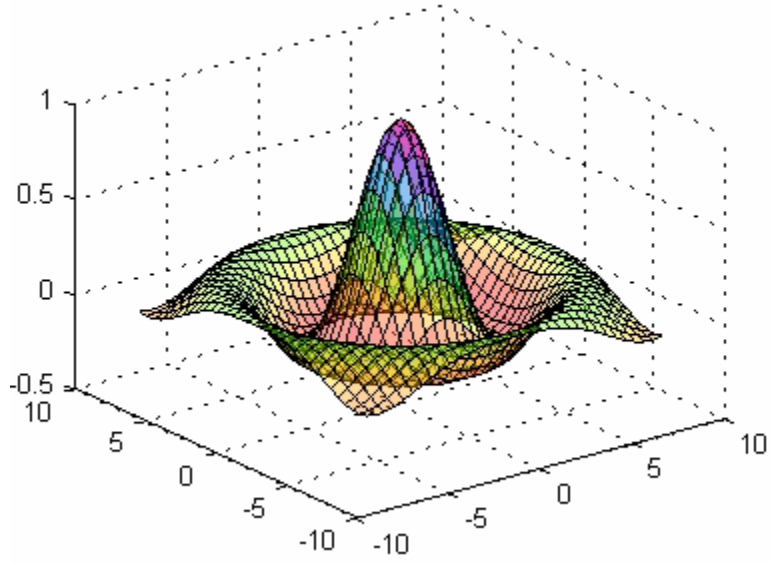
For More Information See "Creating 3-D Graphs" in the MATLAB 3-D Visualization documentation for more information on surface plots.

Making Surfaces Transparent

You can make the faces of a surface transparent to a varying degree. Transparency (referred to as the alpha value) can be specified for the whole object or can be based on an `alphamap`, which behaves similarly to colormaps. For example,

```
surf(X,Y,Z)
colormap hsv
alpha(.4)
```

produces a surface with a face alpha value of 0.4. Alpha values range from 0 (completely transparent) to 1 (not transparent).



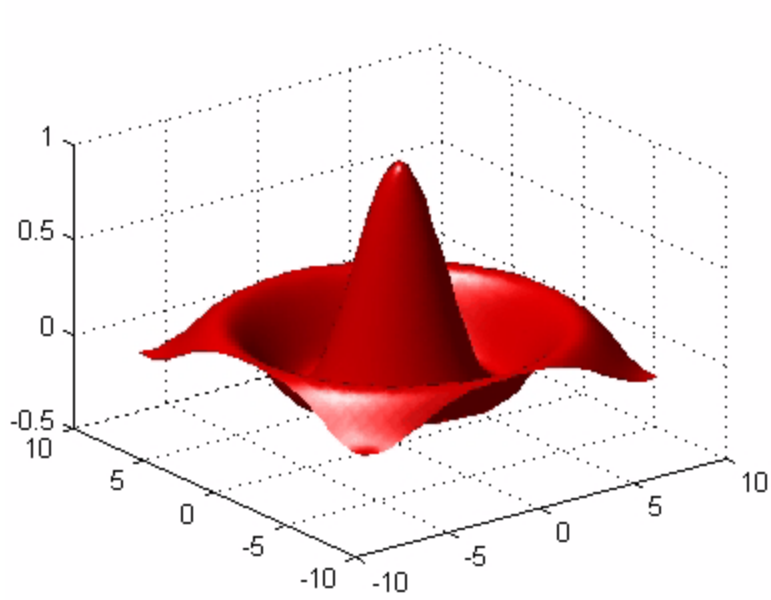
For More Information See "Transparency" in the MATLAB 3-D Visualization documentation for details about using this feature.

Illuminating Surface Plots with Lights

Lighting is the technique of illuminating an object with a directional light source. In certain cases, this technique can make subtle differences in surface shape easier to see. Lighting can also be used to add realism to three-dimensional graphs.

This example uses the same surface as the previous examples, but colors it red and removes the mesh lines. A light object is then added to the left of the "camera" (the camera is the location in space from where you are viewing the surface):

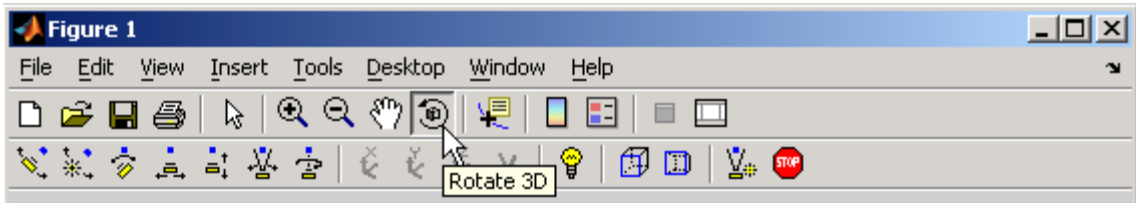
```
surf(X,Y,Z,'FaceColor','red','EdgeColor','none')
camlight left; lighting phong
```



Manipulating the Surface

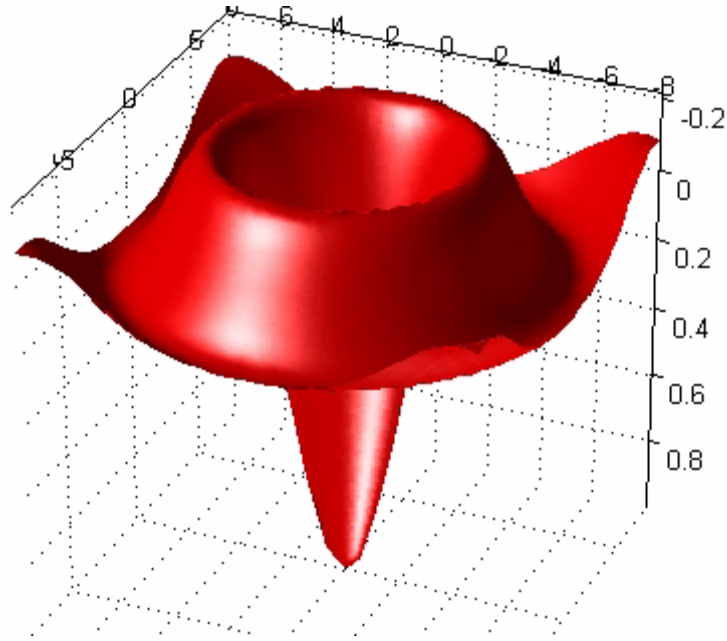
The figure toolbar and the camera toolbar provide ways to explore 3-D graphics interactively. Display the camera toolbar by selecting **Camera Toolbar** from the figure **View** menu.

The following picture shows both toolbars with the **Rotate 3D** tool selected.



These tools enable you to move the camera around the surface object, zoom, add lighting, and perform other viewing operations without issuing commands.

The following picture shows the surface viewed by orbiting the camera toward the bottom using **Rotate 3D**. A scene light has been added to illuminate the underside of the surface, which is not lit by the light added in the previous section.



For More Information See "Lighting as a Visualization Tool" and "View Control with the Camera Toolbar" in the MATLAB 3-D Visualization documentation for details about these techniques.

Plotting Image Data

In this section...

About Plotting Image Data

Two-dimensional arrays can be displayed as *images*, where the array elements determine brightness or color of the images. For example, the statements

```
load durer
whos
Name          Size         Bytes  Class

  X           648x509      2638656  double array
  caption     2x28             112  char array
  map         128x3           3072  double array
```

load the file `durer.mat`, adding three variables to the workspace. The matrix `X` is a 648-by-509 matrix and `map` is a 128-by-3 matrix that is the colormap for this image.

MAT-files, such as `durer.mat`, are binary files that can be created on one platform and later read by MATLAB on a different platform.

The elements of `X` are integers between 1 and 128, which serve as indices into the colormap, `map`. Then

```
image(X)
colormap(map)
axis image
```

reproduces Albrecht Dürer's etching shown in "Matrices and Magic Squares" on page 2-2. A high-resolution scan of the magic square in the upper-right corner is available in another file. Type

```
load detail
```

and then use the up arrow key on your keyboard to reexecute the `image`, `colormap`, and `axis` commands. The statement

```
colormap(hot)
```

adds some 21st century colorization to the 16th century etching. The function `hot` generates a colormap containing shades of reds, oranges, and yellows. Typically, a given image matrix has a specific colormap associated with it. See the `colormap` reference page for a list of other predefined colormaps.

Reading and Writing Images

You can read standard image files (TIFF, JPEG, BMP, etc.) into MATLAB using the `imread` function. The type of data returned by `imread` depends on the type of image you are reading.

You can write MATLAB data to a variety of standard image formats using the `imwrite` function. See the MATLAB reference pages for these functions for more information and examples.

For More Information See "Displaying Bit-Mapped Images" in the MATLAB Graphics documentation for details about the image processing capabilities of MATLAB.

Printing Graphics

In this section...

Overview of Printing

You can print a MATLAB figure directly on a printer connected to your computer or you can export the figure to one of the standard graphics file formats supported by MATLAB. There are two ways to print and export figures:

- Use the **Print**, **Print Preview**, or **Export Setup** GUI options under the **File** menu; see "Preparing Graphs for Presentation" on page 3-37 for an example.
- Use the `print` command to print or export the figure from the command line.

The `print` command provides greater control over drivers and file formats. The Print Preview dialog box gives you greater control over figure size, proportions, placement, and page headers. You can sometimes notice differences in output as printed from a GUI and as printed from the command line.

Printing from the File Menu

There are two menu options under the **File** menu that pertain to printing:

- The **Print Preview** option displays a dialog box that lets you lay out and style figures for printing while previewing the output page, and from which you can print the figure. It includes options that formerly were part of the Page Setup dialog box.

- The **Print** option displays a dialog box that lets you choose a printer, select standard printing options, and print the figure.

Use **Print Preview** to determine whether the printed output is what you want. Click the Print Preview dialog box **Help** button to display information on how to set up the page.

See "Printing the Graph" on page 3-42 for an example of printing from the Print Preview dialog. For details on printing from GUIs and from the Command Window, see "Printing and Exporting" in the MATLAB Graphics documentation.

Exporting the Figure to a Graphics File

The **Export Setup** option in the **File** menu opens a GUI that enables you to set graphic characteristics, such as text size, font, and style, for figures you save as graphics files. The Export Setup GUI lets you define and apply templates to customize and standardize output. After setup, you can export the figure to a number of standard graphics file formats such as EPS, PNG, and TIFF.

See "Exporting the Graph" on page 3-46 for an example of exporting a figure to a graphics file.

Using the Print Command

The `print` command provides more flexibility in the type of output sent to the printer and allows you to control printing from M-files. The result can be sent directly to your default printer or stored in a specified file. A wide variety of output formats, including TIFF, JPEG, and PostScript, is available.

For example, this statement saves the contents of the current figure window as color Encapsulated Level 2 PostScript in the file called `magicsquare.eps`. It also includes a TIFF preview, which enables most word processors to display the picture.

```
print -depsc2 -tiff magicsquare.eps
```

To save the same figure as a TIFF file with a resolution of 200 dpi, use the following command:

```
print -dtiff -r200 magicsquare.tiff
```

If you type `print` on the command line,

```
print
```

MATLAB prints the current figure on your default printer.

For More Information See the `print` reference page and "Printing and Exporting" in the MATLAB Graphics documentation for details about printing.

Handle Graphics

In this section...

Handle Graphics refers to a system of graphics objects that MATLAB uses to implement graphing and visualization functions. Each object created has a fixed set of properties. You can use these properties to control the behavior and appearance of your graph.

When you call a plotting function, MATLAB creates the graph using various graphics objects, such as a figure window, axes, lines, text, and so on. MATLAB enables you to query the value of each property and set the values of most properties.

For example, the following statement creates a figure with a white background color and without displaying the figure toolbar:

```
figure('Color','white','Toolbar','none')
```

Using the Handle

Whenever MATLAB creates a graphics object, it assigns an identifier (called a *handle*) to the object. You can use this handle to access the object's properties with the `set` and `get` functions. For example, the following statements create a graph and return a handle to a lineseries object in `h`:

```
x = 1:10;
y = x.^3;
h = plot(x,y);
```

You can use the handle `h` to set the properties of the lineseries object. For example, you can set its `Color` property:

```
set(h,'Color','red')
```

You can also specify properties when you call the plotting function:

```
h = plot(x,y,'Color','red');
```

When you query the lineseries properties,

```
get(h,'LineWidth')
```

MATLAB returns the answer:

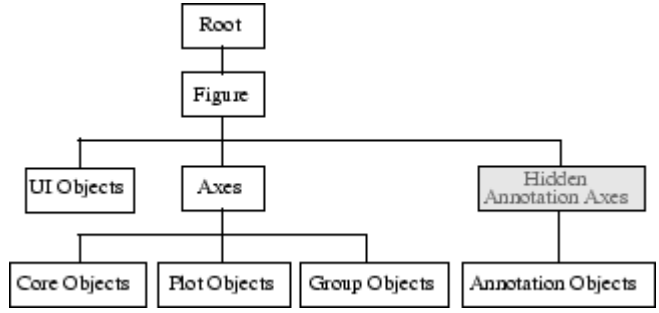
```
ans =
 0.5000
```

Use the handle to see what properties a particular object contains:

```
get(h)
```

Graphics Objects

Graphics objects are the basic elements used to display graphs and user interface components. These objects are organized into a hierarchy, as shown by the following diagram.



Key Graphics Objects

When you call a function to create a graph, MATLAB creates a hierarchy of graphics objects. For example, calling the `plot` function creates the following graphics objects:

- Lineseries plot objects — Represent the data passed to the `plot` function.

- Axes — Provide a frame of reference and scaling for the plotted lineseries.
- Text — Label the axes tick marks and are used for titles and annotations.
- Figures — Are the windows that contain axes toolbars, menus, etc.

Different types of graphs use different objects to represent data; however, all data objects are contained in axes and all objects (except root) are contained in figures.

The root is an abstract object that primarily stores information about your computer or MATLAB state. You cannot create an instance of the root object.

For More Information See "Handle Graphics Objects" in the MATLAB Graphics documentation for details about graphics objects.

User interface objects are used to create graphical user interfaces (GUIs). These objects include components like push buttons, editable text boxes, and list boxes.

For More Information See Chapter 6, "Creating Graphical User Interfaces" for details about user interface objects.

Creating Objects

Plotting functions (like `plot` and `surf`) call the appropriate low-level function to draw their respective graph. For information about an object's properties, you can use the Handle Graphics Property Browser in the MATLAB online Graphics documentation.

Functions for Working with Objects

This table lists functions commonly used when working with objects.

Function	Purpose
`allchild`	Find all children of specified objects.
`ancestor`	Find ancestor of graphics object.
`copyobj`	Copy graphics object.
`delete`	Delete an object.
`findall`	Find all graphics objects (including hidden handles).
`findobj`	Find the handles of objects having specified property values.
`gca`	Return the handle of the current axes.
`gcf`	Return the handle of the current figure.
`gco`	Return the handle of the current object.
`get`	Query the values of an object's properties.
`ishandle`	True if the value is a valid object handle.
`set`	Set the values of an object's properties.

Setting Object Properties

All object properties have default values. However, you might find it useful to change the settings of some properties to customize your graph. There are two ways to set object properties:

- Specify values for properties when you create the object.
- Set the property value on an object that already exists.

Setting Properties from Plotting Commands

You can specify object property value pairs as arguments to many plotting functions, such as `plot`, `mesh`, and `surf`.

For example, plotting commands that create lineseries or surfaceplot objects enable you to specify property name/property value pairs as arguments. The command

```
surf(x,y,z,'FaceColor','interp',...
   'FaceLighting','gouraud')
```

plots the data in the variables `x`, `y`, and `z` using a surfaceplot object with interpolated face color and employing the Gouraud face light technique. You can set any of the object's properties this way.

Setting Properties of Existing Objects

To modify the property values of existing objects, you can use the `set` command or the Property Editor. This section describes how to use the `set` command. See "Using the Property Editor" on page 3-18 for more information.

Most plotting functions return the handles of the objects that they create so you can modify the objects using the `set` command. For example, these statements plot a 5-by-5 matrix (creating five lineseries, one per column), and then set the `Marker` property to a square and the `MarkerFaceColor` property to green:

```
h = plot(magic(5));
set(h,'Marker','s','MarkerFaceColor','g')
```

In this case, `h` is a vector containing five handles, one for each of the five lineseries in the graph. The `set` statement sets the `Marker` and `MarkerFaceColor` properties of all lineseries to the same values.

Setting Multiple Property Values

If you want to set the properties of each lineseries to a different value, you can use cell arrays to store all the data and pass it to the `set` command. For example, create a plot and save the lineseries handles:

```
h = plot(magic(5));
```

Suppose you want to add different markers to each lineseries and color the marker's face color the same color as the lineseries. You need to define two cell arrays—one containing the property names and the other containing the desired values of the properties.

The `prop_name` cell array contains two elements:

```
prop_name(1) = {'Marker'};
```

```
prop_name(2) = {'MarkerFaceColor'};
```

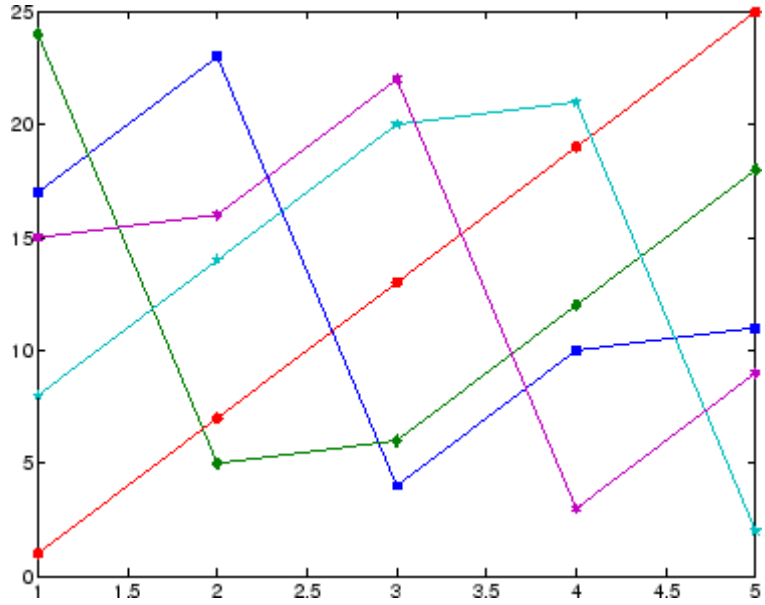
The `prop_values` cell array contains 10 values: five values for the `Marker` property and five values for the `MarkerFaceColor` property. Notice that `prop_values` is a two-dimensional cell array. The first dimension indicates which handle in `h` the values apply to and the second dimension indicates which property the value is assigned to:

```
prop_values(1,1) = {'s'};
prop_values(1,2) = {get(h(1),'Color')};
prop_values(2,1) = {'d'};
prop_values(2,2) = {get(h(2),'Color')};
prop_values(3,1) = {'o'};
prop_values(3,2) = {get(h(3),'Color')};
prop_values(4,1) = {'p'};
prop_values(4,2) = {get(h(4),'Color')};
prop_values(5,1) = {'h'};
prop_values(5,2) = {get(h(5),'Color')};
```

The `MarkerFaceColor` is always assigned the value of the corresponding line's color (obtained by getting the lineseries `Color` property with the `get` command).

After defining the cell arrays, call `set` to specify the new property values:

```
set(h,prop_name,prop_values)
```



Specifying the Axes or Figure

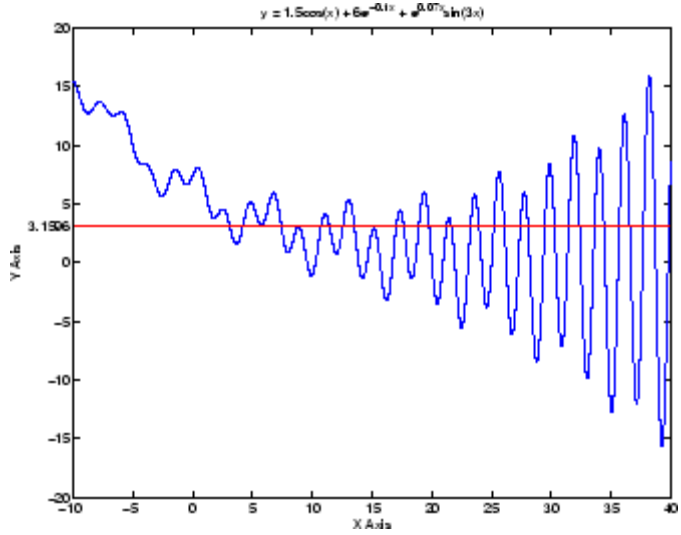
MATLAB always creates an axes or figure if one does not exist when you issue a plotting command. However, when you are creating a graphics M-file, it is good practice to explicitly create and specify the parent axes and figure, particularly if others will use your program. Specifying the parent prevents the following problems:

- Your M-file overwrites the graph in the current figure. Note that a figure becomes the current figure whenever a user clicks it.
- The current figure might be in an unexpected state and not behave as your program expects.

The following example shows a simple M-file that plots a function and the mean of the function over the specified range:

```
function myfunc(x)
% x = -10:.005:40; Here's a value you can use for x
y = [1.5*cos(x) + 6*exp(-.1*x) + exp(.07*x).*sin(3*x)];
ym = mean(y);
```

```
hfig = figure('Name','Function and Mean',...
  'Pointer','fullcrosshair');
hax = axes('Parent',hfig);
plot(hax,x,y)
hold on
plot(hax,[min(x) max(x)],[ym ym],'Color','red')
hold off
ylab = get(hax,'YTick');
set(hax,'YTick',sort([ylab ym]))
title ('y = 1.5cos(x) + 6e^{-0.1x} + e^{0.07x}sin(3x)')
xlabel('X Axis'); ylabel('Y Axis')
```



Finding the Handles of Existing Objects

The `findobj` function enables you to obtain the handles of graphics objects by searching for objects with particular property values. With `findobj` you can specify the values of any combination of properties, which makes it easy to pick one object out of many. `findobj` also recognizes regular expressions (`regexp`).

For example, you might want to find the blue line with square marker having blue face color. You can also specify which figures or axes to search, if there

are more than one. The following four sections provide examples illustrating how to use `findobj`.

Finding All Objects of a Certain Type

Because all objects have a `Type` property that identifies the type of object, you can find the handles of all occurrences of a particular type of object. For example,

```
h = findobj('Type','patch');
```

finds the handles of all patch objects.

Finding Objects with a Particular Property

You can specify multiple properties to narrow the search. For example,

```
h = findobj('Type','line','Color','r','LineStyle',':');
```

finds the handles of all red dotted lines.

Limiting the Scope of the Search

You can specify the starting point in the object hierarchy by passing the handle of the starting figure or axes as the first argument. For example,

```
h = findobj(gca,'Type','text','String','\pi/2');
```

finds the string π/2 only within the current axes.

Using findobj as an Argument

Because `findobj` returns the handles it finds, you can use it in place of the handle argument. For example,

```
set(findobj('Type','line','Color','red'),'LineStyle',':')
```

finds all red lines and sets their line style to dotted.

4

Programming

If you have an active Internet connection, you can watch the Writing a MATLAB Program video demo for an overview of the major functionality.

Flow Control

In this section...

Conditional Control – if, else, switch

This section covers those MATLAB functions that provide conditional program control.

if, else, and elseif

The `if` statement evaluates a logical expression and executes a group of statements when the expression is *true*. The optional `elseif` and `else` keywords provide for the execution of alternate groups of statements. An `end` keyword, which matches the `if`, terminates the last group of statements. The groups of statements are delineated by the four keywords—no braces or brackets are involved.

The MATLAB algorithm for generating a magic square of order *n* involves three different cases: when *n* is odd, when *n* is even but not divisible by 4, or when *n* is divisible by 4. This is described by

```
if rem(n,2) ~= 0
   M = odd_magic(n)
elseif rem(n,4) ~= 0
   M = single_even_magic(n)
else
   M = double_even_magic(n)
end
```

For most values of `n` in this example, the three cases are mutually exclusive. For values that are not mutually exclusive, such as `n=5`, the first *true* condition is executed.

It is important to understand how relational operators and `if` statements work with matrices. When you want to check for equality between two variables, you might use

```
if A == B, ...
```

This is valid MATLAB code, and does what you expect when `A` and `B` are scalars. But when `A` and `B` are matrices, `A == B` does not test *if* they are equal, it tests *where* they are equal; the result is another matrix of 0's and 1's showing element-by-element equality. (In fact, if `A` and `B` are not the same size, then `A == B` is an error.)

```
A = magic(4);     B = A;     B(1,1) = 0;

A == B
ans =
     0     1     1     1
     1     1     1     1
     1     1     1     1
     1     1     1     1
```

The proper way to check for equality between two variables is to use the `isequal` function:

```
if isequal(A, B), ...
```

`isequal` returns a *scalar* logical value of `1` (representing `true`) or `0` (`false`), instead of a matrix, as the expression to be evaluated by the `if` function. Using the `A` and `B` matrices from above, you get

```
isequal(A, B)
ans =
    0
```

Here is another example to emphasize this point. If `A` and `B` are scalars, the following program will never reach the "unexpected situation". But for most pairs of matrices, including our magic squares with interchanged columns, none of the matrix conditions `A > B`, `A < B`, or `A == B` is true for *all* elements and so the `else` clause is executed:

```
if A > B
   'greater'
```

```
elseif A < B
   'less'
elseif A == B
   'equal'
else
   error('Unexpected situation')
end
```

Several functions are helpful for reducing the results of matrix comparisons to scalar conditions for use with `if`, including

```
isequal
isempty
all
any
```

switch and case

The `switch` statement executes groups of statements based on the value of a variable or expression. The keywords `case` and `otherwise` delineate the groups. Only the first matching case is executed. There must always be an `end` to match the `switch`.

The logic of the magic squares algorithm can also be described by

```
switch (rem(n,4)==0) + (rem(n,2)==0)
   case 0
      M = odd_magic(n)
   case 1
      M = single_even_magic(n)
   case 2
      M = double_even_magic(n)
   otherwise
      error('This is impossible')
end
```

Note Unlike the C language `switch` statement, MATLAB `switch` does not fall through. If the first `case` statement is `true`, the other `case` statements do not execute. So, `break` statements are not required.

Loop Control – for, while, continue, break

This section covers those MATLAB functions that provide control over program loops.

for

The `for` loop repeats a group of statements a fixed, predetermined number of times. A matching `end` delineates the statements:

```
for n = 3:32
   r(n) = rank(magic(n));
end
r
```

The semicolon terminating the inner statement suppresses repeated printing, and the `r` after the loop displays the final result.

It is a good idea to indent the loops for readability, especially when they are nested:

```
for i = 1:m
   for j = 1:n
      H(i,j) = 1/(i+j);
   end
end
```

while

The `while` loop repeats a group of statements an indefinite number of times under control of a logical condition. A matching `end` delineates the statements.

Here is a complete program, illustrating `while`, `if`, `else`, and `end`, that uses interval bisection to find a zero of a polynomial:

```
a = 0; fa = -Inf;
b = 3; fb = Inf;
while b-a > eps*b
   x = (a+b)/2;
   fx = x^3-2*x-5;
   if sign(fx) == sign(fa)
      a = x; fa = fx;
```

```
   else
      b = x; fb = fx;
   end
end
x
```

The result is a root of the polynomial $x^3 - 2x - 5$, namely

```
x =
   2.09455148154233
```

The cautions involving matrix comparisons that are discussed in the section on the `if` statement also apply to the `while` statement.

continue

The `continue` statement passes control to the next iteration of the `for` loop or `while` loop in which it appears, skipping any remaining statements in the body of the loop. The same holds true for `continue` statements in nested loops. That is, execution continues at the beginning of the loop in which the `continue` statement was encountered.

The example below shows a `continue` loop that counts the lines of code in the file `magic.m`, skipping all blank lines and comments. A `continue` statement is used to advance to the next line in `magic.m` without incrementing the count whenever a blank line or comment line is encountered:

```
fid = fopen('magic.m','r');
count = 0;
while ~feof(fid)
    line = fgetl(fid);
    if isempty(line) | strncmp(line,'%',1)
        continue
    end
    count = count + 1;
end
disp(sprintf('%d lines',count));
```

break

The `break` statement lets you exit early from a `for` loop or `while` loop. In nested loops, `break` exits from the innermost loop only.

Here is an improvement on the example from the previous section. Why is this use of `break` a good idea?

```
a = 0; fa = -Inf;
b = 3; fb = Inf;
while b-a > eps*b
   x = (a+b)/2;
   fx = x^3-2*x-5;
   if fx == 0
      break
   elseif sign(fx) == sign(fa)
      a = x; fa = fx;
   else
      b = x; fb = fx;
   end
end
x
```

Error Control – try, catch

This section covers those MATLAB functions that provide error handling control.

try

The general form of a `try-catch` statement sequence is

```
try
   statement
   ...
   statement
catch
   statement
   ...
   statement
end
```

In this sequence the statements between `try` and `catch` are executed until an error occurs. The statements between `catch` and `end` are then executed. Use `lasterr` to see the cause of the error. If an error occurs between `catch` and `end`, MATLAB terminates execution unless another `try-catch` sequence has been established.

Program Termination – return

This section covers the MATLAB `return` function that enables you to terminate your program before it runs to completion.

return

`return` terminates the current sequence of commands and returns control to the invoking function or to the keyboard. `return` is also used to terminate `keyboard` mode. A called function normally transfers control to the function that invoked it when it reaches the end of the function. You can insert a `return` statement within the called function to force an early termination and to transfer control to the invoking function.

Other Data Structures

In this section...

Multidimensional Arrays

Multidimensional arrays in MATLAB are arrays with more than two subscripts. One way of creating a multidimensional array is by calling `zeros`, `ones`, `rand`, or `randn` with more than two arguments. For example,

```
R = randn(3,4,5);
```

creates a 3-by-4-by-5 array with a total of `3*4*5 = 60` normally distributed random elements.

A three-dimensional array might represent three-dimensional physical data, say the temperature in a room, sampled on a rectangular grid. Or it might represent a sequence of matrices, $A^{(k)}$, or samples of a time-dependent matrix, $A(t)$. In these latter cases, the (i, j)th element of the kth matrix, or the t_kth matrix, is denoted by `A(i,j,k)`.

MATLAB and Dürer's versions of the magic square of order 4 differ by an interchange of two columns. Many different magic squares can be generated by interchanging columns. The statement

```
p = perms(1:4);
```

generates the 4! = 24 permutations of `1:4`. The `k`th permutation is the row vector `p(k,:)`. Then

```
A = magic(4);
M = zeros(4,4,24);

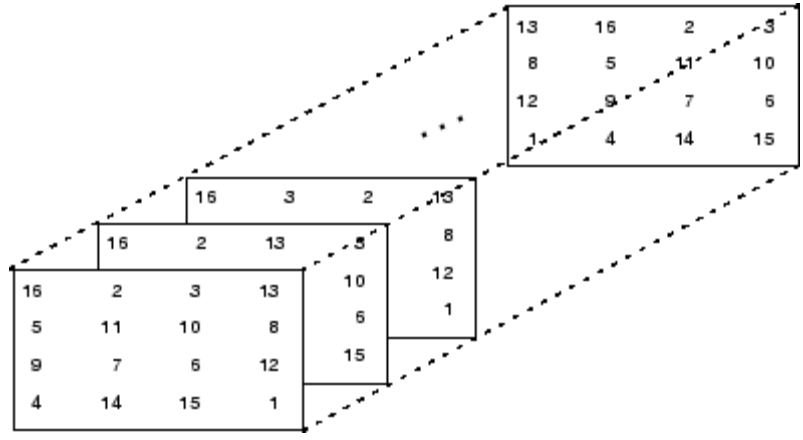
for k = 1:24
```

```
    M(:,:,k) = A(:,p(k,:));
end
```

stores the sequence of 24 magic squares in a three-dimensional array, `M`. The size of `M` is

```
size(M)

ans =
     4     4    24
```



Note The order of the matrices shown in this illustration might differ from your results. The `perms` function always returns all permutations of the input vector, but the order of the permutations might be different for different MATLAB versions.

The statement

```
sum(M,d)
```

computes sums by varying the `d`th subscript. So

```
sum(M,1)
```

is a 1-by-4-by-24 array containing 24 copies of the row vector

```
   34    34    34    34
```

and

```
sum(M,2)
```

is a 4-by-1-by-24 array containing 24 copies of the column vector

```
34
34
34
34
```

Finally,

```
S = sum(M,3)
```

adds the 24 matrices in the sequence. The result has size 4-by-4-by-1, so it looks like a 4-by-4 array:

```
S =
   204   204   204   204
   204   204   204   204
   204   204   204   204
   204   204   204   204
```

Cell Arrays

Cell arrays in MATLAB are multidimensional arrays whose elements are copies of other arrays. A cell array of empty matrices can be created with the `cell` function. But, more often, cell arrays are created by enclosing a miscellaneous collection of things in curly braces, `{}`. The curly braces are also used with subscripts to access the contents of various cells. For example,

```
C = {A sum(A) prod(prod(A))}
```

produces a 1-by-3 cell array. The three cells contain the magic square, the row vector of column sums, and the product of all its elements. When `C` is displayed, you see

```
C =
    [4x4 double]    [1x4 double]    [20922789888000]
```

This is because the first two cells are too large to print in this limited space, but the third cell contains only a single number, 16!, so there is room to print it.

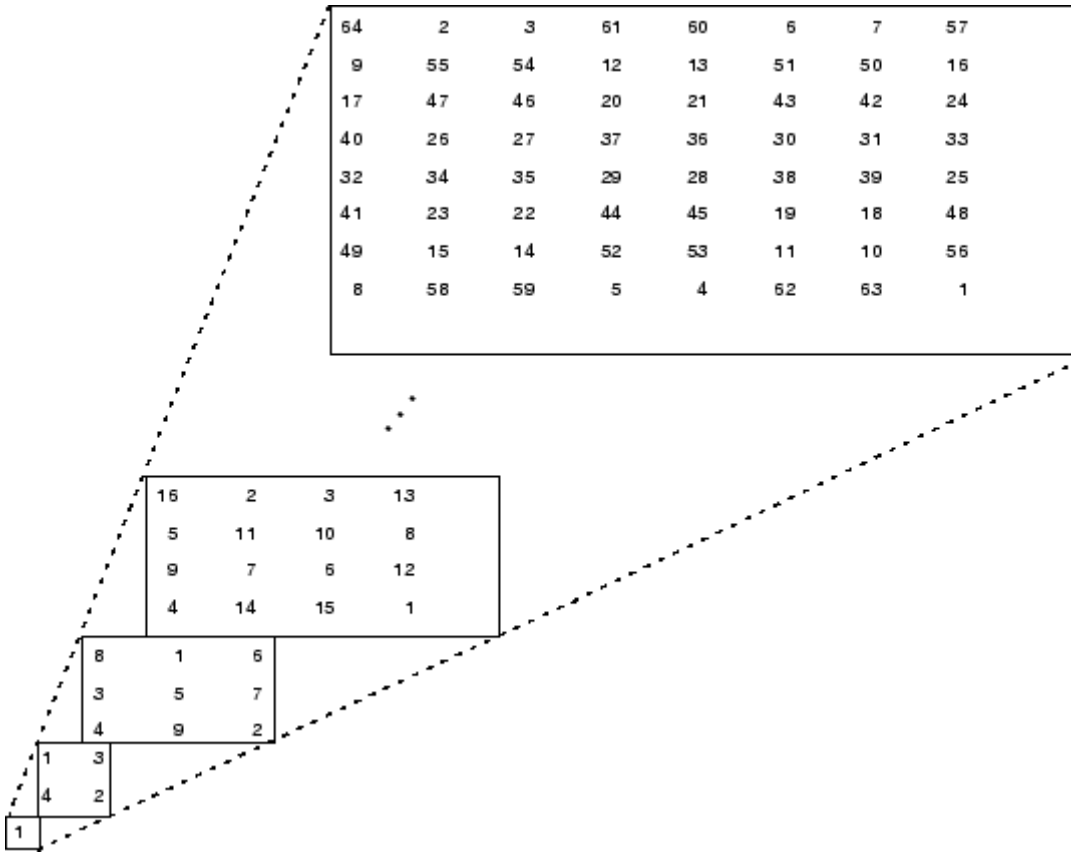
Here are two important points to remember. First, to retrieve the contents of one of the cells, use subscripts in curly braces. For example, `C{1}` retrieves the magic square and `C{3}` is 16!. Second, cell arrays contain *copies* of other arrays, not *pointers* to those arrays. If you subsequently change `A`, nothing happens to `C`.

You can use three-dimensional arrays to store a sequence of matrices of the *same* size. Cell arrays can be used to store a sequence of matrices of *different* sizes. For example,

```
M = cell(8,1);
for n = 1:8
   M{n} = magic(n);
end
M
```

produces a sequence of magic squares of different order:

```
M =
    [           1]
    [ 2x2  double]
    [ 3x3  double]
    [ 4x4  double]
    [ 5x5  double]
    [ 6x6  double]
    [ 7x7  double]
    [ 8x8  double]
```



You can retrieve the 4-by-4 magic square matrix with

```
M{4}
```

Characters and Text

Enter text into MATLAB using single quotes. For example,

```
s = 'Hello'
```

The result is not the same kind of numeric matrix or array you have been dealing with up to now. It is a 1-by-5 character array.

Internally, the characters are stored as numbers, but not in floating-point format. The statement

```
a = double(s)
```

converts the character array to a numeric matrix containing floating-point representations of the ASCII codes for each character. The result is

```
a =
    72    101    108    108    111
```

The statement

```
s = char(a)
```

reverses the conversion.

Converting numbers to characters makes it possible to investigate the various fonts available on your computer. The printable characters in the basic ASCII character set are represented by the integers `32:127`. (The integers less than 32 represent nonprinting control characters.) These integers are arranged in an appropriate 6-by-16 array with

```
F = reshape(32:127,16,6)';
```

The printable characters in the extended ASCII character set are represented by `F+128`. When these integers are interpreted as characters, the result depends on the font currently being used. Type the statements

```
char(F)
char(F+128)
```

and then vary the font being used for the Command Window. Select **Preferences** from the **File** menu to change the font. If you include tabs in lines of code, use a fixed-width font, such as Monospaced, to align the tab positions on different lines.

Concatenation with square brackets joins text variables together into larger strings. The statement

```
h = [s, ' world']
```

joins the strings horizontally and produces

```
h =
   Hello world
```

The statement

```
v = [s; 'world']
```

joins the strings vertically and produces

```
v =
   Hello
   world
```

Note that a blank has to be inserted before the `'w'` in `h` and that both words in `v` have to have the same length. The resulting arrays are both character arrays; `h` is 1-by-11 and `v` is 2-by-5.

To manipulate a body of text containing lines of different lengths, you have two choices—a padded character array or a cell array of strings. When creating a character array, you must make each row of the array the same length. (Pad the ends of the shorter rows with spaces.) The `char` function does this padding for you. For example,

```
S = char('A','rolling','stone','gathers','momentum.')
```

produces a 5-by-9 character array:

```
S =
A
rolling
stone
gathers
momentum.
```

Alternatively, you can store the text in a cell array. For example,

```
C = {'A';'rolling';'stone';'gathers';'momentum.'}
```

creates a 5-by-1 cell array that requires no padding because each row of the array can have a different length:

```
C =
    'A'
    'rolling'
    'stone'
    'gathers'
    'momentum.'
```

You can convert a padded character array to a cell array of strings with

```
C = cellstr(S)
```

and reverse the process with

```
S = char(C)
```

Structures

Structures are multidimensional MATLAB arrays with elements accessed by textual *field designators*. For example,

```
S.name = 'Ed Plum';
S.score = 83;
S.grade = 'B+'
```

creates a scalar structure with three fields:

```
S =
     name: 'Ed Plum'
    score: 83
    grade: 'B+'
```

Like everything else in MATLAB, structures are arrays, so you can insert additional elements. In this case, each element of the array is a structure with several fields. The fields can be added one at a time,

```
S(2).name = 'Toni Miller';
S(2).score = 91;
S(2).grade = 'A-';
```

or an entire element can be added with a single statement:

```
S(3) = struct('name','Jerry Garcia',...
              'score',70,'grade','C')
```

Now the structure is large enough that only a summary is printed:

```
S =
1x3 struct array with fields:
    name
    score
    grade
```

There are several ways to reassemble the various fields into other MATLAB arrays. They are mostly based on the notation of a *comma-separated list*. If you type

```
S.score
```

it is the same as typing

```
S(1).score, S(2).score, S(3).score
```

which is a comma-separated list.

If you enclose the expression that generates such a list within square brackets, MATLAB stores each item from the list in an array. In this example, MATLAB creates a numeric row vector containing the `score` field of each element of structure array `S`:

```
scores = [S.score]
scores =
    83    91    70

avg_score = sum(scores)/length(scores)
avg_score =
   81.3333
```

To create a character array from one of the text fields (`name`, for example), call the `char` function on the comma-separated list produced by `S.name`:

```
names = char(S.name)
names =
   Ed Plum
   Toni Miller
   Jerry Garcia
```

Similarly, you can create a cell array from the `name` fields by enclosing the list-generating expression within curly braces:

```
names = {S.name}
names =
    'Ed Plum'    'Toni Miller'    'Jerry Garcia'
```

To assign the fields of each element of a structure array to separate variables outside of the structure, specify each output to the left of the equals sign, enclosing them all within square brackets:

```
[N1 N2 N3] = S.name
N1 =
   Ed Plum
N2 =
   Toni Miller
N3 =
   Jerry Garcia
```

Dynamic Field Names

The most common way to access the data in a structure is by specifying the name of the field that you want to reference. Another means of accessing structure data is to use dynamic field names. These names express the field as a variable expression that MATLAB evaluates at run-time. The dot-parentheses syntax shown here makes `expression` a dynamic field name:

```
structName.(expression)
```

Index into this field using the standard MATLAB indexing syntax. For example, to evaluate `expression` into a field name and obtain the values of that field at columns `1` through `25` of row `7`, use

```
structName.(expression)(7,1:25)
```

Dynamic Field Names Example. The `avgscore` function shown below computes an average test score, retrieving information from the `testscores` structure using dynamic field names:

```
function avg = avgscore(testscores, student, first, last)
for k = first:last
   scores(k) = testscores.(student).week(k);
```

```
end
avg = sum(scores)/(last - first + 1);
```

You can run this function using different values for the dynamic field `student`. First, initialize the structure that contains scores for a 25-week period:

```
testscores.Ann_Lane.week(1:25) = ...
  [95 89 76 82 79 92 94 92 89 81 75 93 ...
   85 84 83 86 85 90 82 82 84 79 96 88 98];

testscores.William_King.week(1:25) = ...
  [87 80 91 84 99 87 93 87 97 87 82 89 ...
   86 82 90 98 75 79 92 84 90 93 84 78 81];
```

Now run `avgscore`, supplying the students name fields for the `testscores` structure at runtime using dynamic field names:

```
avgscore(testscores, 'Ann_Lane', 7, 22)
ans =
   85.2500

avgscore(testscores, 'William_King', 7, 22)
ans =
   87.7500
```

Scripts and Functions

In this section...

Overview

MATLAB is a powerful programming language as well as an interactive computational environment. Files that contain code in the MATLAB language are called M-files. You create M-files using a text editor, then use them as you would any other MATLAB function or command.

There are two kinds of M-files:

- Scripts, which do not accept input arguments or return output arguments. They operate on data in the workspace.
- Functions, which can accept input arguments and return output arguments. Internal variables are local to the function.

If you're a new MATLAB programmer, just create the M-files that you want to try out in the current directory. As you develop more of your own M-files, you will want to organize them into other directories and personal toolboxes that you can add to your MATLAB search path.

If you duplicate function names, MATLAB executes the one that occurs first in the search path.

To view the contents of an M-file, for example, `myfunction.m`, use

```
type myfunction
```

Scripts

When you invoke a *script*, MATLAB simply executes the commands found in the file. Scripts can operate on existing data in the workspace, or they can create new data on which to operate. Although scripts do not return output arguments, any variables that they create remain in the workspace, to be used in subsequent computations. In addition, scripts can produce graphical output using functions like `plot`.

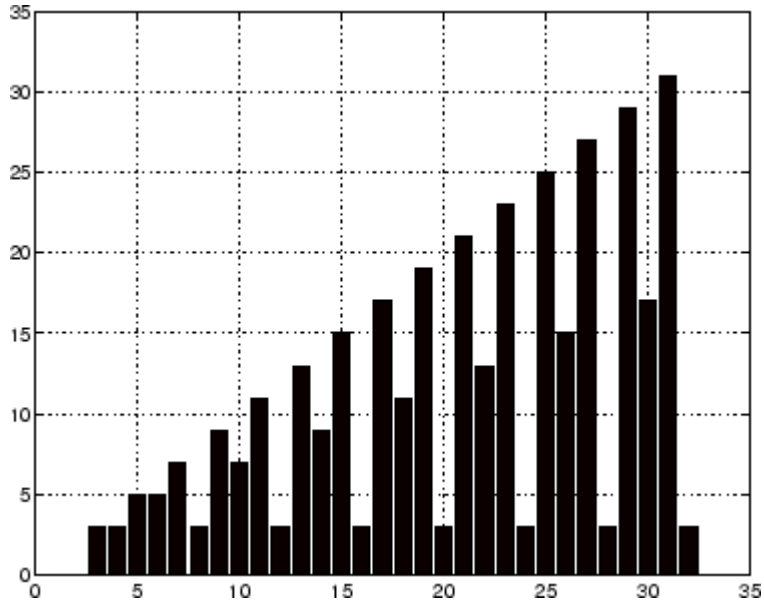
For example, create a file called `magicrank.m` that contains these MATLAB commands:

```
% Investigate the rank of magic squares
r = zeros(1,32);
for n = 3:32
   r(n) = rank(magic(n));
end
r
bar(r)
```

Typing the statement

```
magicrank
```

causes MATLAB to execute the commands, compute the rank of the first 30 magic squares, and plot a bar graph of the result. After execution of the file is complete, the variables `n` and `r` remain in the workspace.



Functions

Functions are M-files that can accept input arguments and return output arguments. The names of the M-file and of the function should be the same. Functions operate on variables within their own workspace, separate from the workspace you access at the MATLAB command prompt.

A good example is provided by `rank`. The M-file `rank.m` is available in the directory

```
toolbox/matlab/matfun
```

You can see the file with

```
type rank
```

Here is the file:

```
function r = rank(A,tol)
%   RANK Matrix rank.
%   RANK(A) provides an estimate of the number of linearly
```

```
%   independent rows or columns of a matrix A.
%   RANK(A,tol) is the number of singular values of A
%   that are larger than tol.
%   RANK(A) uses the default tol = max(size(A)) * norm(A) * eps.

s = svd(A);
if nargin==1
   tol = max(size(A)') * max(s) * eps;
end
r = sum(s > tol);
```

The first line of a function M-file starts with the keyword `function`. It gives the function name and order of arguments. In this case, there are up to two input arguments and one output argument.

The next several lines, up to the first blank or executable line, are comment lines that provide the help text. These lines are printed when you type

```
help rank
```

The first line of the help text is the H1 line, which MATLAB displays when you use the `lookfor` command or request `help` on a directory.

The rest of the file is the executable MATLAB code defining the function. The variable `s` introduced in the body of the function, as well as the variables on the first line, `r`, `A` and `tol`, are all *local* to the function; they are separate from any variables in the MATLAB workspace.

This example illustrates one aspect of MATLAB functions that is not ordinarily found in other programming languages—a variable number of arguments. The `rank` function can be used in several different ways:

```
rank(A)
r = rank(A)
r = rank(A,1.e-6)
```

Many M-files work this way. If no output argument is supplied, the result is stored in `ans`. If the second input argument is not supplied, the function computes a default value. Within the body of the function, two quantities named `nargin` and `nargout` are available that tell you the number of input

and output arguments involved in each particular use of the function. The `rank` function uses `nargin`, but does not need to use `nargout`.

Types of Functions

MATLAB offers several different types of functions to use in your programming.

Anonymous Functions

An *anonymous function* is a simple form of MATLAB function that does not require an M-file. It consists of a single MATLAB expression and any number of input and output arguments. You can define an anonymous function right at the MATLAB command line, or within an M-file function or script. This gives you a quick means of creating simple functions without having to create M-files each time.

The syntax for creating an anonymous function from an expression is

```
f = @(arglist)expression
```

The statement below creates an anonymous function that finds the square of a number. When you call this function, MATLAB assigns the value you pass in to variable `x`, and then uses `x` in the equation `x.^2`:

```
sqr = @(x) x.^2;
```

To execute the `sqr` function defined above, type

```
a = sqr(5)
a =
   25
```

Primary and Subfunctions

All functions that are not anonymous must be defined within an M-file. Each M-file has a required *primary function* that appears first in the file, and any number of *subfunctions* that follow the primary. Primary functions have a wider scope than subfunctions. That is, primary functions can be invoked from outside of their M-file (from the MATLAB command line or from functions in

other M-files) while subfunctions cannot. Subfunctions are visible only to the primary function and other subfunctions within their own M-file.

The `rank` function shown in the section on "Functions" on page 4-22 is an example of a primary function.

Private Functions

A *private function* is a type of primary M-file function. Its unique characteristic is that it is visible only to a limited group of other functions. This type of function can be useful if you want to limit access to a function, or when you choose not to expose the implementation of a function.

Private functions reside in subdirectories with the special name `private`. They are visible only to functions in the parent directory. For example, assume the directory `newmath` is on the MATLAB search path. A subdirectory of `newmath` called `private` can contain functions that only the functions in `newmath` can call.

Because private functions are invisible outside the parent directory, they can use the same names as functions in other directories. This is useful if you want to create your own version of a particular function while retaining the original in another directory. Because MATLAB looks for private functions before standard M-file functions, it will find a private function named `test.m` before a nonprivate M-file named `test.m`.

Nested Functions

You can define functions within the body of any MATLAB M-file function. These are said to be *nested* within the outer function. A nested function contains any or all of the components of any other M-file function. In this example, function `B` is nested in function `A`:

```
function x = A(p1, p2)
...
B(p2)
   function y = B(p3)
   ...
   end
...
end
```

Like other functions, a nested function has its own workspace where variables used by the function are stored. But it also has access to the workspaces of all functions in which it is nested. So, for example, a variable that has a value assigned to it by the primary function can be read or overwritten by a function nested at any level within the primary. Similarly, a variable that is assigned in a nested function can be read or overwritten by any of the functions containing that function.

Function Overloading

Overloaded functions act the same way as overloaded functions in most computer languages. Overloaded functions are useful when you need to create a function that responds to different types of inputs accordingly. For instance, you might want one of your functions to accept both double-precision and integer input, but to handle each type somewhat differently. You can make this difference invisible to the user by creating two separate functions having the same name, and designating one to handle `double` types and one to handle integers. When you call the function, MATLAB chooses which M-file to dispatch to based on the type of the input arguments.

Global Variables

If you want more than one function to share a single copy of a variable, simply declare the variable as `global` in all the functions. Do the same thing at the command line if you want the base workspace to access the variable. The global declaration must occur before the variable is actually used in a function. Although it is not required, using capital letters for the names of global variables helps distinguish them from other variables. For example, create an M-file called `falling.m`:

```
function h = falling(t)
global GRAVITY
h = 1/2*GRAVITY*t.^2;
```

Then interactively enter the statements

```
global GRAVITY
GRAVITY = 32;
y = falling((0:.1:5)');
```

The two global statements make the value assigned to `GRAVITY` at the command prompt available inside the function. You can then modify `GRAVITY` interactively and obtain new solutions without editing any files.

Passing String Arguments to Functions

You can write MATLAB functions that accept string arguments without the parentheses and quotes. That is, MATLAB interprets

```
foo a b c
```

as

```
foo('a','b','c')
```

However, when you use the unquoted form, MATLAB cannot return output arguments. For example,

```
legend apples oranges
```

creates a legend on a plot using the strings `apples` and `oranges` as labels. If you want the `legend` command to return its output arguments, then you must use the quoted form:

```
[legh,objh] = legend('apples','oranges');
```

In addition, you must use the quoted form if any of the arguments is not a string.

Caution While the unquoted syntax is convenient, in some cases it can be used incorrectly without causing MATLAB to generate an error.

Constructing String Arguments in Code

The quoted form enables you to construct string arguments within the code. The following example processes multiple data files, `August1.dat`, `August2.dat`, and so on. It uses the function `int2str`, which converts an integer to a character, to build the filename:

```
for d = 1:31
```

```
   s = ['August' int2str(d) '.dat'];
   load(s)
   % Code to process the contents of the d-th file
end
```

The eval Function

The `eval` function works with text variables to implement a powerful text macro facility. The expression or statement

```
eval(s)
```

uses the MATLAB interpreter to evaluate the expression or execute the statement contained in the text string `s`.

The example of the previous section could also be done with the following code, although this would be somewhat less efficient because it involves the full interpreter, not just a function call:

```
for d = 1:31
   s = ['load August' int2str(d) '.dat'];
   eval(s)
   % Process the contents of the d-th file
end
```

Function Handles

You can create a handle to any MATLAB function and then use that handle as a means of referencing the function. A function handle is typically passed in an argument list to other functions, which can then execute, or *evaluate*, the function using the handle.

Construct a function handle in MATLAB using the *at* sign, `@`, before the function name. The following example creates a function handle for the `sin` function and assigns it to the variable `fhandle`:

```
fhandle = @sin;
```

You can call a function by means of its handle in the same way that you would call the function using its name. The syntax is

```
fhandle(arg1, arg2, ...);
```

The function `plot_fhandle`, shown below, receives a function handle and data, generates y-axis data using the function handle, and plots it:

```
function x = plot_fhandle(fhandle, data)
plot(data, fhandle(data))
```

When you call `plot_fhandle` with a handle to the `sin` function and the argument shown below, the resulting evaluation produces a sine wave plot:

```
plot_fhandle(@sin, -pi:0.01:pi)
```

Function Functions

A class of functions called "function functions" works with nonlinear functions of a scalar variable. That is, one function works on another function. The function functions include

- Zero finding
- Optimization
- Quadrature
- Ordinary differential equations

MATLAB represents the nonlinear function by a function M-file. For example, here is a simplified version of the function `humps` from the `matlab/demos` directory:

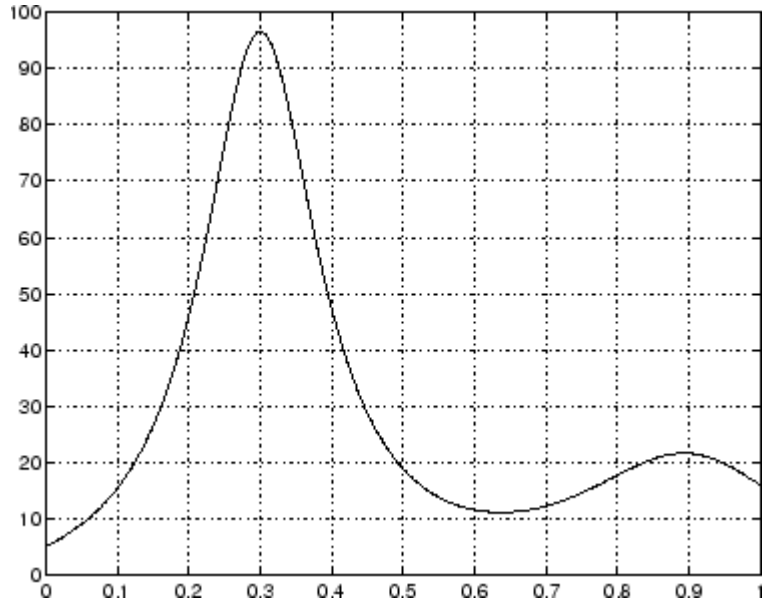
```
function y = humps(x)
y = 1./((x-.3).^2 + .01) + 1./((x-.9).^2 + .04) - 6;
```

Evaluate this function at a set of points in the interval $0 \le x \le 1$ with

```
x = 0:.002:1;
y = humps(x);
```

Then plot the function with

```
plot(x,y)
```



The graph shows that the function has a local minimum near $x = 0.6$. The function `fminsearch` finds the *minimizer*, the value of x where the function takes on this minimum. The first argument to `fminsearch` is a function handle to the function being minimized and the second argument is a rough guess at the location of the minimum:

```
p = fminsearch(@humps,.5)
p =
    0.6370
```

To evaluate the function at the minimizer,

```
humps(p)

ans =
   11.2528
```

Numerical analysts use the terms *quadrature* and *integration* to distinguish between numerical approximation of definite integrals and numerical integration of ordinary differential equations. MATLAB quadrature routines are `quad` and `quadl`. The statement

```
Q = quadl(@humps,0,1)
```

computes the area under the curve in the graph and produces

```
Q =
   29.8583
```

Finally, the graph shows that the function is never zero on this interval. So, if you search for a zero with

```
z = fzero(@humps,.5)
```

you will find one outside the interval

```
z =
   -0.1316
```

Vectorization

One way to make your MATLAB programs run faster is to vectorize the algorithms you use in constructing the programs. Where other programming languages might use `for` loops or `DO` loops, MATLAB can use vector or matrix operations. A simple example involves creating a table of logarithms:

```
x = .01;
for k = 1:1001
   y(k) = log10(x);
   x = x + .01;
end
```

A vectorized version of the same code is

```
x = .01:.01:10;
y = log10(x);
```

For more complicated code, vectorization options are not always so obvious.

For More Information See “Improving Performance and Memory Usage” in the MATLAB Programming documentation for other techniques that you can use.

Preallocation

If you cannot vectorize a piece of code, you can make your `for` loops go faster by preallocating any vectors or arrays in which output results are stored. For example, this code uses the function `zeros` to preallocate the vector created in the `for` loop. This makes the `for` loop execute significantly faster:

```
r = zeros(32,1);
for n = 1:32
    r(n) = rank(magic(n));
end
```

Without the preallocation in the previous example, the MATLAB interpreter enlarges the `r` vector by one element each time through the loop. Vector preallocation eliminates this step and results in faster execution.

5

Data Analysis

Introduction

Every data analysis has some standard components:

- Preprocessing — Consider outliers and missing values, and smooth data to identify possible models.
- Summarizing — Compute basic statistics to describe the overall location, scale, and shape of the data.
- Visualizing — Plot data to identify patterns and trends.
- Modeling — Give data trends fuller descriptions, suitable for predicting new values.

Data analysis moves among these components with two basic goals in mind:

1. Describe the patterns in the data with simple models that lead to accurate predictions.
2. Understand the relationships among variables that lead to the model.

This section of the Getting Started guide explains how to use MATLAB to carry out a basic data analysis.

Preprocessing Data

In this section...

Overview

Begin a data analysis by loading data into suitable MATLAB container variables and sorting out the "good" data from the "bad." This is a preliminary step that assures meaningful conclusions in subsequent parts of the analysis.

Note This section begins a data analysis that is continued in "Summarizing Data" on page 5-10, "Visualizing Data" on page 5-14, and "Modeling Data" on page 5-19.

Loading the Data

Begin by loading the data in `count.dat`:

```
load count.dat
```

The 24-by-3 array `count` contains hourly traffic counts (the rows) at three intersections (the columns) for a single day.

See "MATLAB for Data Analysis" and "Importing and Exporting Data" in the MATLAB Data Analysis documentation for more information on storing data in MATLAB variables for analysis.

Missing Data

In MATLAB, `NaN` (Not a Number) values represent missing data. `NaN` values allow variables with missing data to maintain their structure—in this case, 24-by-1 vectors with consistent indexing across all three intersections.

Check the data at the third intersection for `NaN` values using the MATLAB `isnan` function:

```
c3 = count(:,3); % Data at intersection 3
c3NaNCount = sum(isnan(c3))
c3NaNCount =
     0
```

`isnan` returns a logical vector the same size as `c3`, with entries indicating the presence (`1`) or absence (`0`) of `NaN` values for each of the 24 elements in the data. In this case, the logical values sum to `0`, so there are no `NaN` values in the data.

`NaN` values are introduced into the data in the section on “Outliers” on page 5-4.

See “Removing and Interpolating Missing Values” in the MATLAB Data Analysis documentation for more information on handling missing data in MATLAB.

Outliers

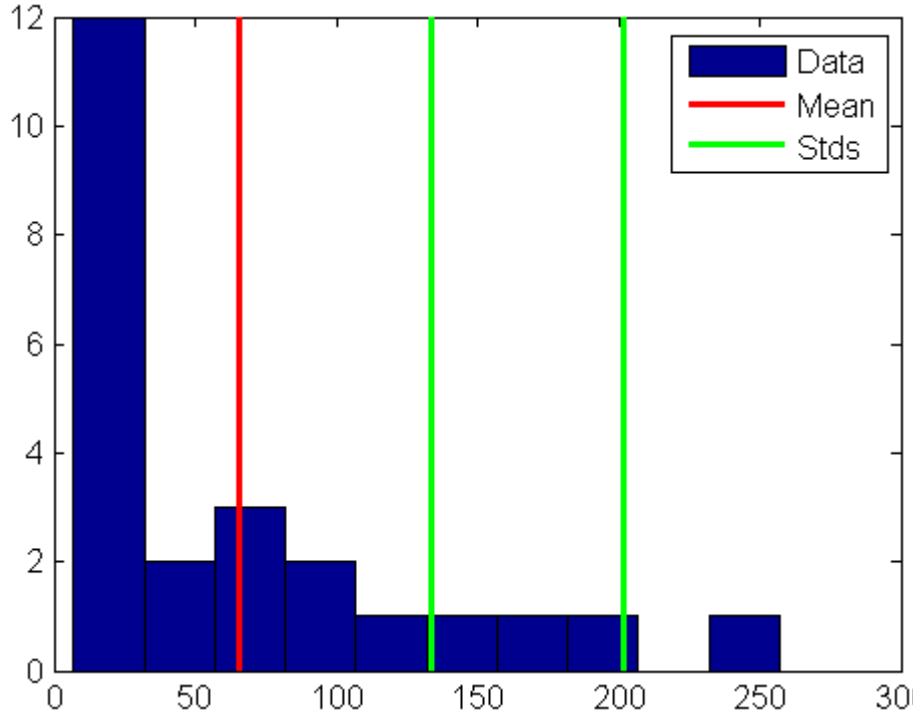
Outliers are data values that are dramatically different from patterns in the rest of the data. They may be due to measurement error, or they may represent significant features in the data. Identifying outliers, and deciding what to do with them, depends on an understanding of the data and its source.

One common method for identifying outliers is to look for values more than a certain number of standard deviations σ from the mean μ. The following code plots a histogram of the data at the third intersection together with lines at μ and $\mu + n\sigma$, for $n = 1, 2$:

```
bin_counts = hist(c3); % Histogram bin counts
N = max(bin_counts); % Maximum bin count
mu3 = mean(c3); % Data mean
```

```
sigma3 = std(c3); % Data standard deviation

hist(c3) % Plot histogram
hold on
plot([mu3 mu3],[0 N],'r','LineWidth',2) % Mean
X = repmat(mu3+(1:2)*sigma3,2,1);
Y = repmat([0;N],1,2);
plot(X,Y,'g','LineWidth',2) % Standard deviations
legend('Data','Mean','Stds')
hold off
```



The plot shows that some of the data are more than two standard deviations above the mean. If you identify these data as errors (not features), replace them with `NaN` values as follows:

```
outliers = (c3 - mu3) > 2*sigma3;
c3m = c3; % Copy c3 to c3m
```

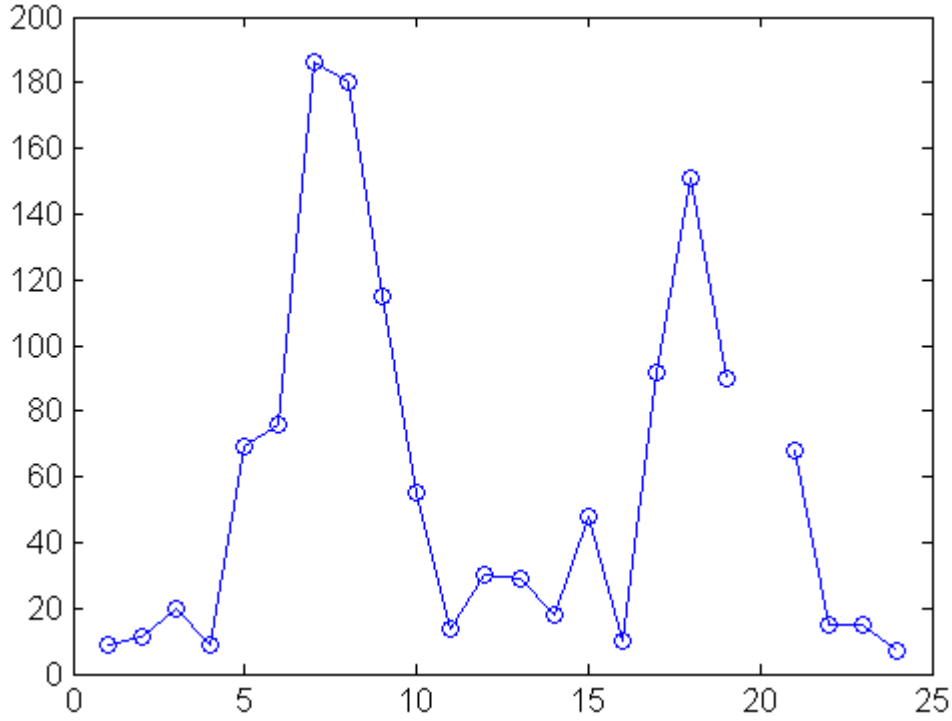
```
c3m(outliers) = NaN; % Add NaN values
```

See “Removing Outliers” in the MATLAB Data Analysis documentation for more information on handling outliers in MATLAB.

Smoothing and Filtering

A time-series plot of the data at the third intersection (with the outlier removed in “Outliers” on page 5-4) looks like this:

```
plot(c3m,'o-')
hold on
```



The `NaN` value at hour 20 appears as a gap in the plot. This handling of `NaN` values is typical of MATLAB plotting functions.

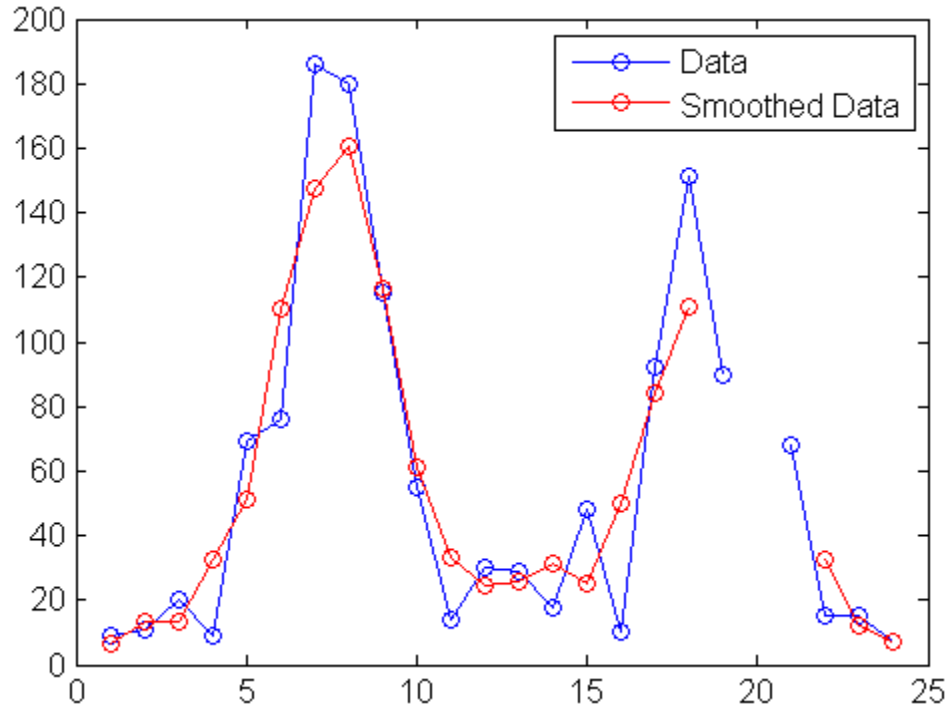
Noisy data shows random variations about expected values. You may want to smooth the data to reveal its main features before building a model. Two basic assumptions underlie smoothing:

- The relationship between the predictor (time) and the response (traffic volume) is smooth.
- The smoothing algorithm results in values that are better estimates of expected values because the noise has been reduced.

Apply a simple moving average smoother to the data using the MATLAB `convn` function:

```
span = 3; % Size of the averaging window
window = ones(span,1)/span;
smoothed_c3m = convn(c3m,window,'same');

h = plot(smoothed_c3m,'ro-');
legend('Data','Smoothed Data')
```

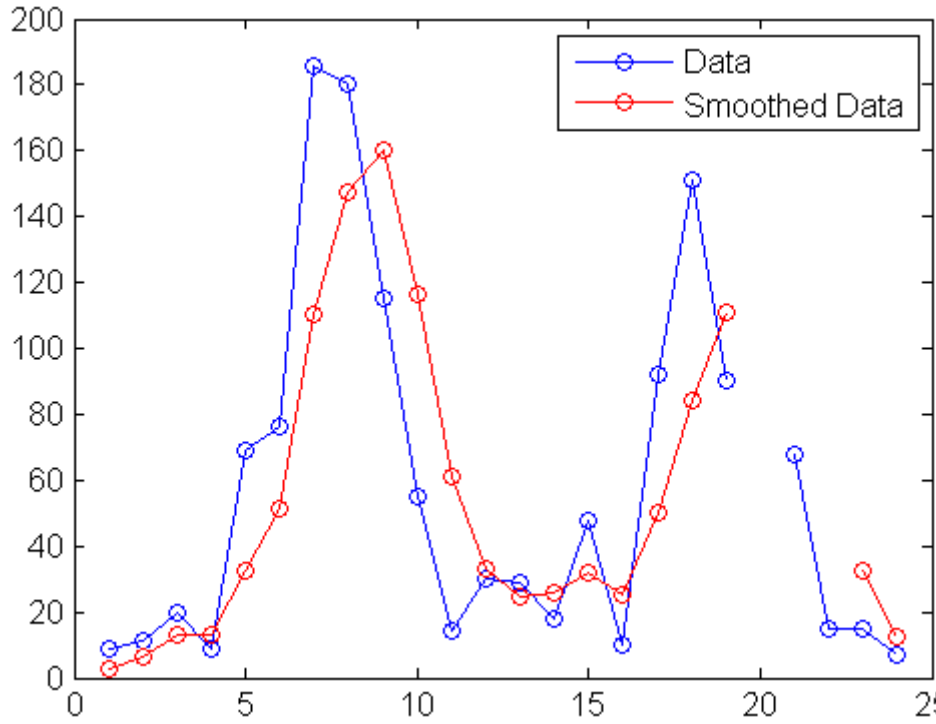


The extent of the smoothing is controlled with the variable `span`. The averaging calculation returns `NaN` values whenever the smoothing window includes the `NaN` value in the data, thus increasing the size of the gap in the smoothed data.

The MATLAB `filter` function is also used for smoothing data:

```
smoothed2_c3m = filter(window,1,c3m);

delete(h)
plot(smoothed2_c3m,'ro-');
```



The smoothed data are shifted from the previous plot. `convn` with the `'same'` parameter returns the central part of the convolution, the same length as the data. `filter` returns the initial part of the convolution, the same length as the data. Otherwise, the algorithms are identical.

Smoothing estimates the center of the distribution of response values at each value of the predictor. It invalidates a basic assumption of many fitting algorithms, namely, that the errors at each value of the predictor are normally distributed. Accordingly, smoothed data should not be used to fit a model. Use smoothed data to identify a model.

See “Filtering Data” in the MATLAB Data Analysis documentation for more information on smoothing and filtering.

Summarizing Data

In this section...

Overview

MATLAB includes many functions for summarizing the overall location, scale, and shape of a data sample.

One of the advantages of working in MATLAB is that functions operate on entire arrays of data, not just on single scalar values. The functions are said to be *vectorized*. Vectorization allows for both efficient problem formulation, using array-based data, and efficient computation, using vectorized statistical functions.

Note This section continues the data analysis from "Preprocessing Data" on page 5-3.

Measures of Location

Summarize the location of a data sample by finding a "typical" value. Common measures of location or "central tendency" are computed by the MATLAB functions `mean`, `median`, and `mode`:

```
x1 = mean(count)
x1 =
   32.0000   46.5417   65.5833

x2 = median(count)
x2 =
   23.5000   36.0000   39.0000
```

```
x3 = mode(count)
x3 =
    11     9     9
```

Like all of the statistical functions in MATLAB, the functions above summarize data across observations (rows) while preserving variables (columns). The functions compute the location of the data at each of the three intersections in a single call.

Measures of Scale

There are many ways to measure the scale or "dispersion" of a data sample. The MATLAB functions `max`, `min`, `std`, and `var` compute some common measures:

```
dx1 = max(count)-min(count)
dx1 =
   107   136   250

dx2 = std(count)
dx2 =
   25.3703   41.4057   68.0281

dx3 = var(count)
dx3 =
  1.0e+003 *
    0.6437    1.7144    4.6278
```

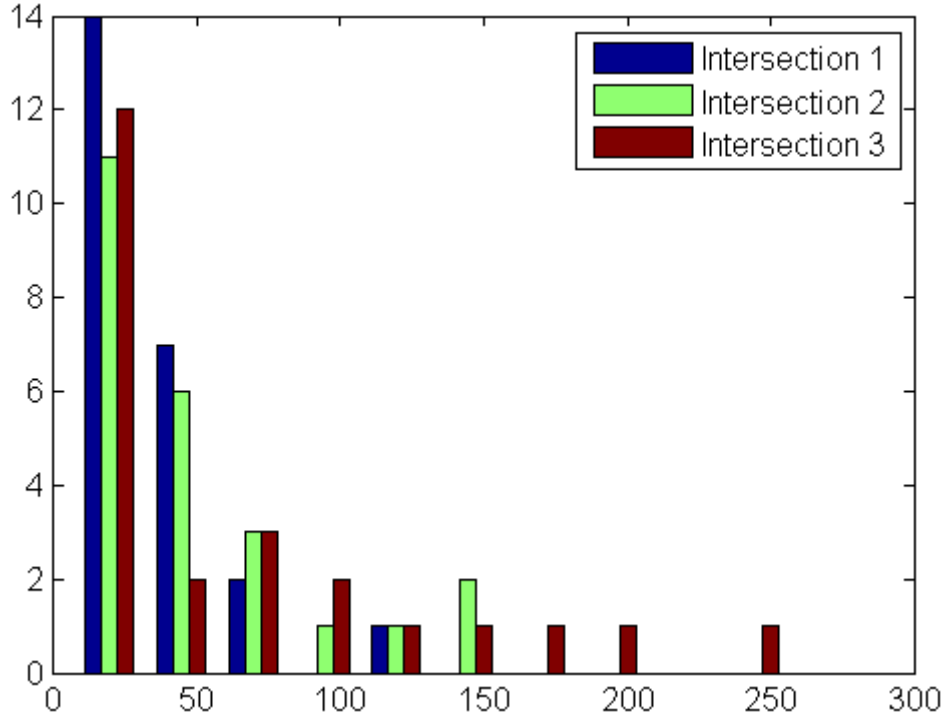
Like all of the statistical functions in MATLAB, the functions above summarize data across observations (rows) while preserving variables (columns). The functions compute the scale of the data at each of the three intersections in a single call.

Shape of a Distribution

The shape of a distribution is harder to summarize than its location or scale. The MATLAB `hist` function plots a histogram that provides a visual summary:

```
figure
hist(count)
```

```
legend('Intersection 1',...
       'Intersection 2',...
       'Intersection 3')
```

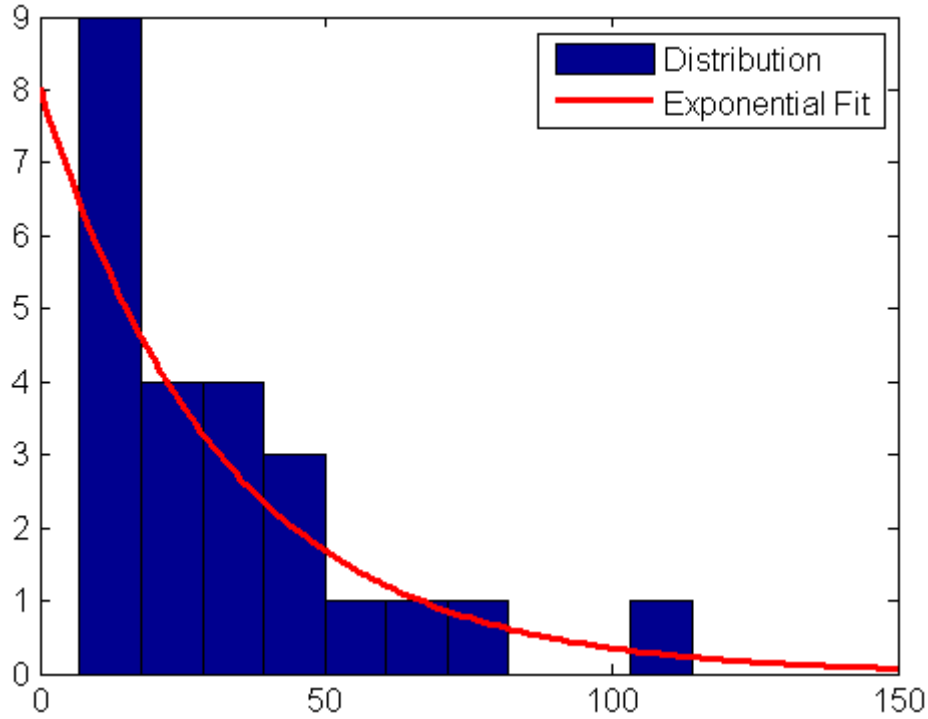


Parametric models give analytic summaries of distribution shapes. Exponential distributions, with parameter `mu` given by the data mean, are a good choice for the traffic data:

```
c1 = count(:,1); % Data at intersection 1
[bin_counts,bin_locations] = hist(c1);
bin_width = bin_locations(2) - bin_locations(1);
hist_area = (bin_width)*(sum(bin_counts));

figure
hist(c1)
hold on
```

```
mu1 = mean(c1);
exp_pdf = @(t)(1/mu1)*exp(-t/mu1); % Integrates
                                   % to 1
t = 0:150;
y = exp_pdf(t);
plot(t,(hist_area)*y,'r','LineWidth',2)
legend('Distribution','Exponential Fit')
```



Methods for fitting general parametric models to data distributions are beyond the scope of this Getting Started guide. Functions for computing maximum likelihood estimates of distribution parameters are available in Statistics Toolbox.

See “Descriptive Statistics” in the MATLAB Data Analysis documentation for more information on summarizing data samples.

Visualizing Data

In this section...

Overview

MATLAB provides many plots for visualizing data patterns and trends. Histograms and time-series plots of the traffic data are described in the sections on "Preprocessing Data" on page 5-3 and "Summarizing Data" on page 5-10. Scatter plots, described in this section, help to visualize relationships among the traffic data at different intersections.

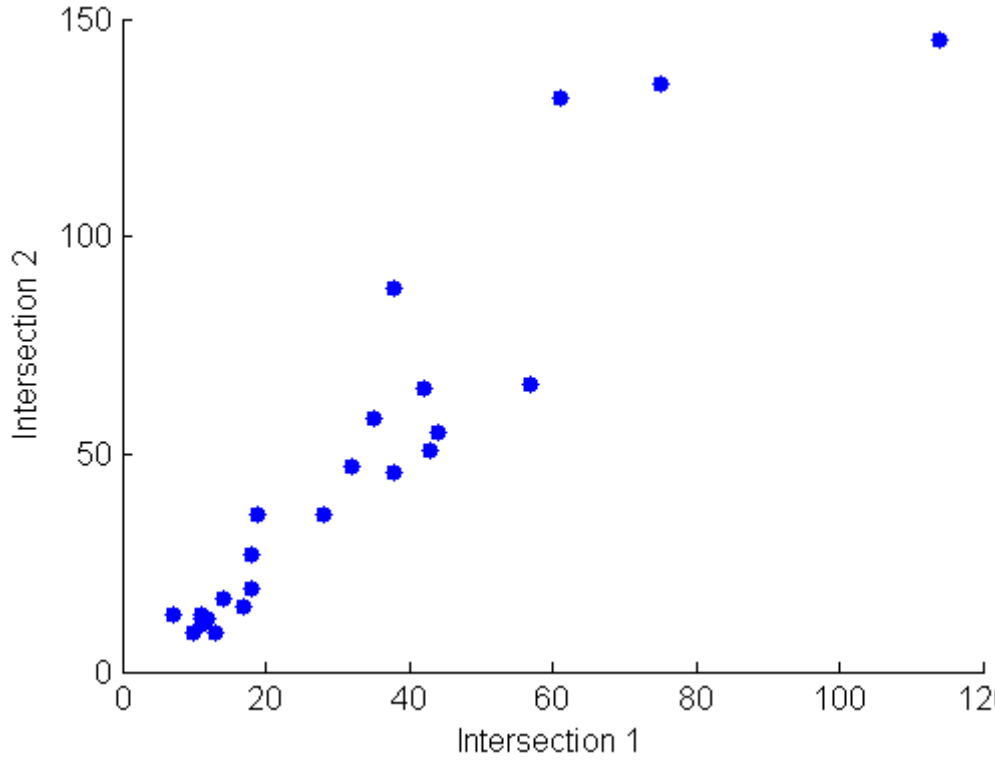
Note This section continues the data analysis from "Summarizing Data" on page 5-10.

2-D Scatter Plots

A 2-D scatter plot, created with the MATLAB `scatter` function, shows the relationship between the traffic volume at the first two intersections:

```
c1 = count(:,1); % Data at intersection 1
c2 = count(:,2); % Data at intersection 2

figure
scatter(c1,c2,'filled')
xlabel('Intersection 1')
ylabel('Intersection 2')
```



The strength of the linear relationship between the two variables (how tightly the data lies along a least-squares line through the scatter) is measured by the *covariance*, computed by the MATLAB `cov` function:

```
C12 = cov([c1 c2])
C12 =
  1.0e+003 *
    0.6437    0.9802
    0.9802    1.7144
```

The results are displayed in a symmetric square matrix, with the covariance of the i th and j th variables in the (i, j)th position. The i th diagonal element is the variance of the i th variable.

Covariances have the disadvantage of depending on the units used to measure the individual variables. They are often divided by the standard deviations

of the variables to normalize values between +1 and –1. The results are *correlation coefficients*, computed by the MATLAB `corrcoef` function:

```
R12 = corrcoef([c1 c2])
R12 =
    1.0000    0.9331
    0.9331    1.0000

r12 = R12(1,2) % Correlation coefficient
r12 =
    0.9331

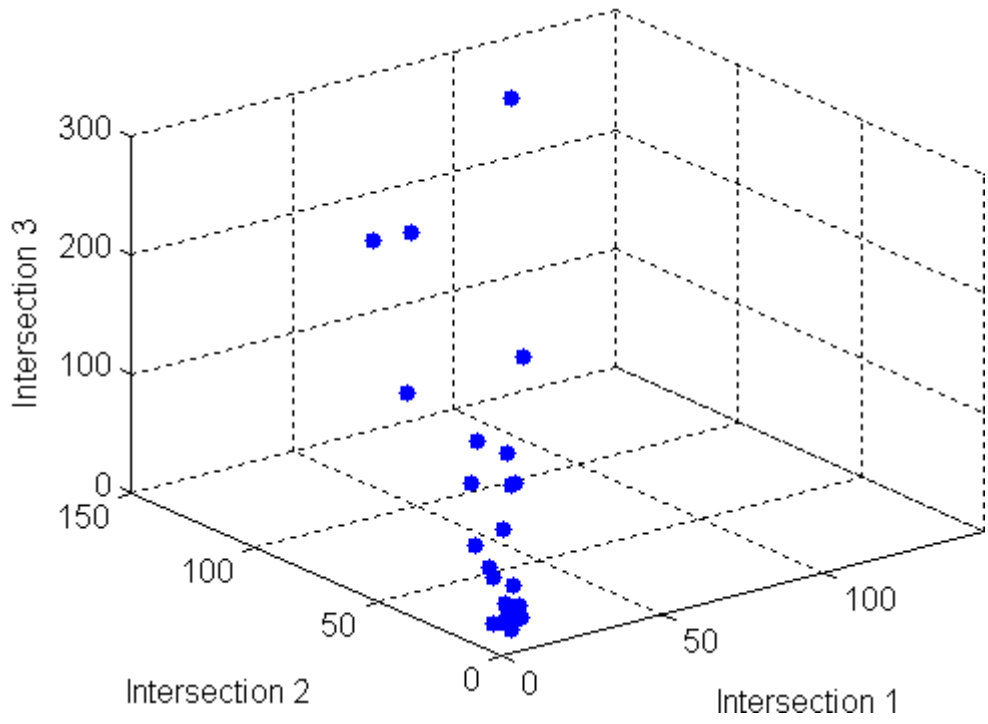
r12sq = r12^2 % Coefficient of determination
r12sq =
    0.8707
```

Because it is normalized, the value of the correlation coefficient is readily comparable to values for other pairs of intersections. Its square, the *coefficient of determination*, is the variance about the least-squares line divided by the variance about the mean. That is, it is the proportion of variation in the response (in this case, the traffic volume at intersection 2) that is eliminated or non-causally "explained" by a least-squares line through the scatter.

3-D Scatter Plots

A 3-D scatter plot, created with the MATLAB `scatter3` function, shows the relationship between the traffic volume at all three intersections:

```
figure
scatter3(c1,c2,c3,'filled')
xlabel('Intersection 1')
ylabel('Intersection 2')
zlabel('Intersection 3')
```



The strength of the linear relationship among the variables in the 3-D scatter is measured by computing eigenvalues of the covariance matrix with the MATLAB `eig` function:

```
vars = eig(cov([c1 c2 c3]))
vars =
  1.0e+003 *
    0.0442
    0.1118
    6.8300

explained = max(vars)/sum(vars)
explained =
    0.9777
```

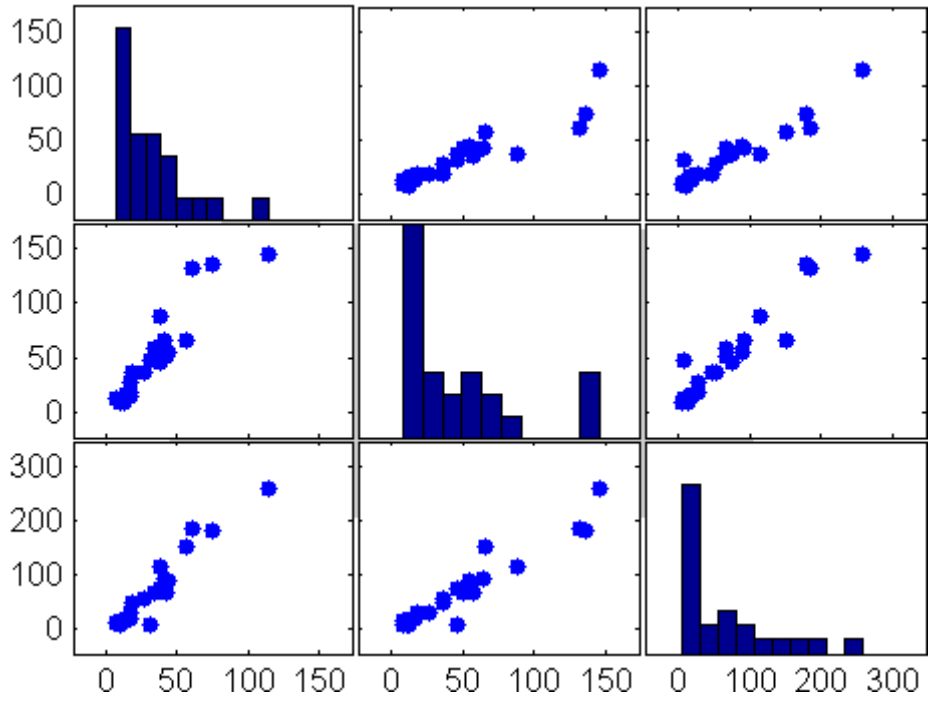
The eigenvalues are the variances along the *principal components* of the data. The variable `explained` measures the proportion of variation “explained” by

the first principal component, along the axis of the data. Unlike the coefficient of determination for 2-D scatters, this measure does distinguish predictor and response variables.

Scatter Plot Arrays

Use the MATLAB `plotmatrix` function to make comparisons of the relationships between multiple pairs of intersections:

```
figure
plotmatrix(count)
```



The plot in the (i, j)th position of the array is a scatter with the i th variable on the vertical axis and the j th variable on the horizontal axis. The plot in the i th diagonal position is a histogram of the i th variable.

See “Plotting Data” in the MATLAB Data Analysis documentation for more information on statistical visualization.

Modeling Data

In this section...

Overview

Parametric models translate an understanding of data relationships into analytic tools with predictive power. Polynomial and sinusoidal models are simple choices for the up and down trends in the traffic data.

Note This section continues the data analysis from "Visualizing Data" on page 5-14.

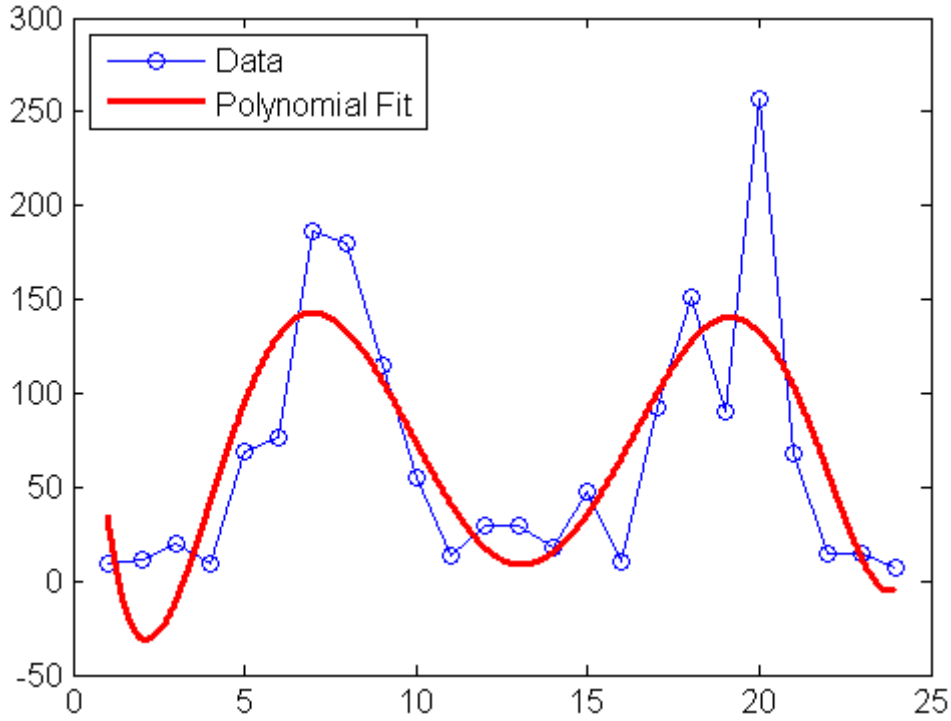
Polynomial Regression

Use the MATLAB `polyfit` function to estimate coefficients of polynomial models, then use the MATLAB `polyval` function to evaluate the model at arbitrary values of the predictor.

The following code fits the traffic data at the third intersection with a polynomial model of degree six:

```
c3 = count(:,3); % Data at intersection 3
tdata = (1:24)';
p_coeffs = polyfit(tdata,c3,6);

figure
plot(c3,'o-')
hold on
tfit = (1:0.01:24)';
yfit = polyval(p_coeffs,tfit);
plot(tfit,yfit,'r-','LineWidth',2)
legend('Data','Polynomial Fit','Location','NW')
```



The model has the advantage of being simple while following the up-and-down trend. The accuracy of its predictive power, however, is questionable, especially at the ends of the data.

General Linear Regression

Assuming that the data are periodic with a 12-hour period and a peak around hour 7, it is reasonable to fit a sinusoidal model of the form:

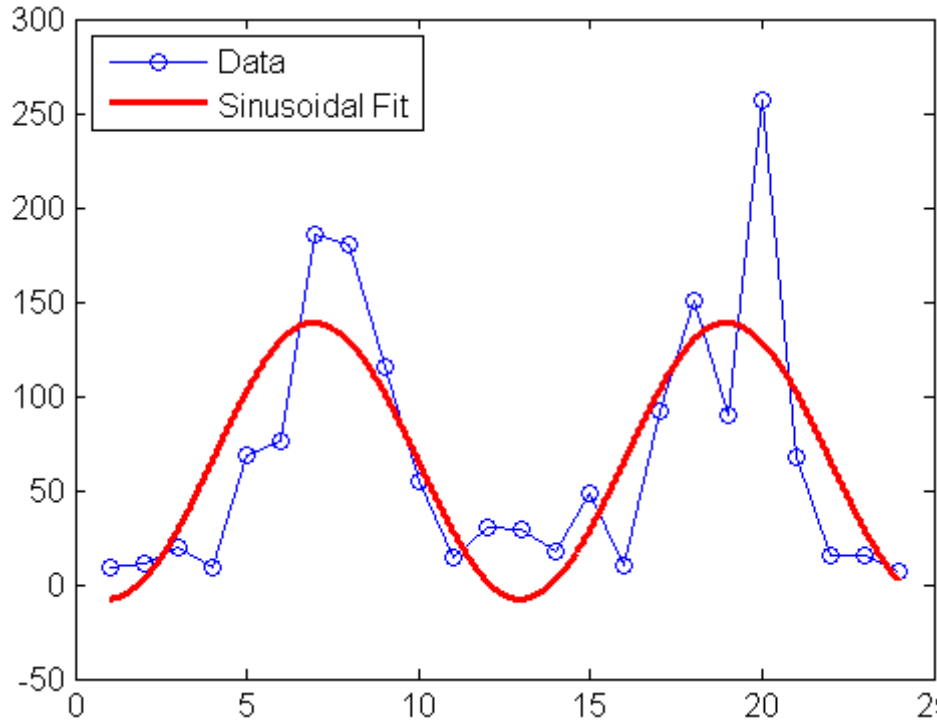
$$y = a + b\cos((2\pi/12)(t-7))$$

The coefficients a and b appear linearly. Use the MATLAB `mldivide` (backslash) operator to fit general linear models:

```
c3 = count(:,3); % Data at intersection 3
tdata = (1:24)';
```

```
X = [ones(size(tdata)) cos((2*pi/12)*(tdata-7))];
s_coeffs = X\c3;

figure
plot(c3,'o-')
hold on
tfit = (1:0.01:24)';
yfit = [ones(size(tfit)) cos((2*pi/12)*(tfit-7))]*s_coeffs;
plot(tfit,yfit,'r-','LineWidth',2)
legend('Data','Sinusoidal Fit','Location','NW')
```



Use the MATLAB `lscov` function to compute statistics on the fit, such as estimated standard errors of the coefficients and the mean squared error:

```
[s_coeffs,stdx,mse] = lscov(X,c3)
s_coeffs =
   65.5833
```

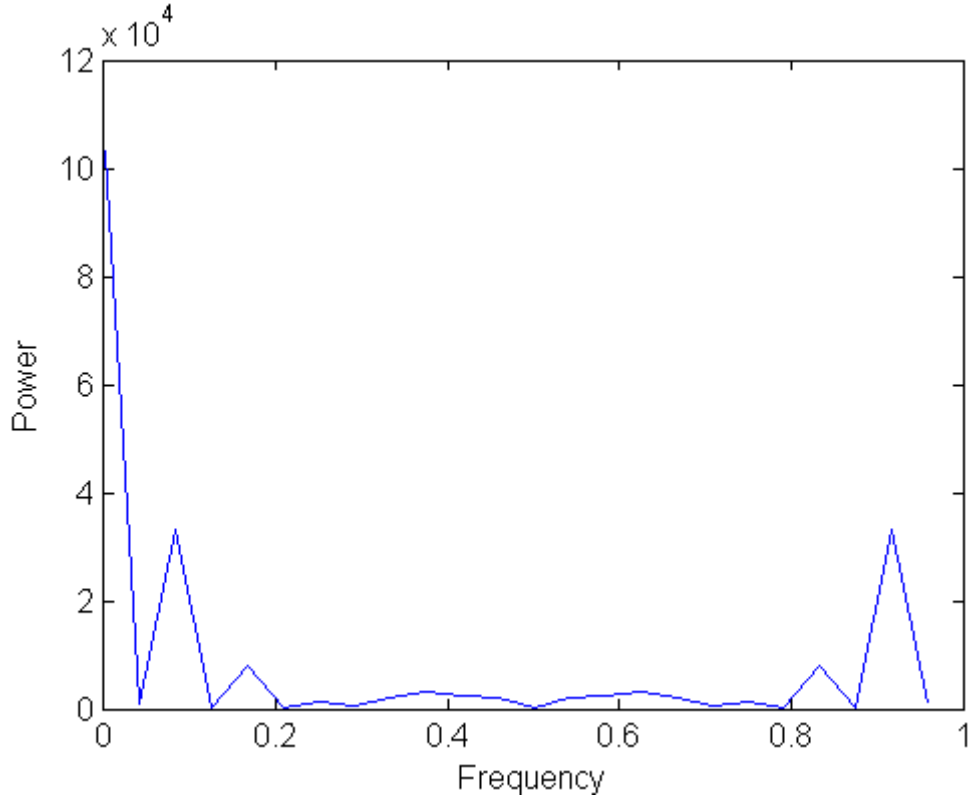
```
   73.2819
stdx =
    8.9185
   12.6127
mse =
  1.9090e+003
```

Check the assumption of a 12-hour period in the data with a *periodogram*, computed using the MATLAB `fft` function:

```
Fs = 1; % Sample frequency (per hour)
n = length(c3); % Window length
Y = fft(c3); % DFT of data
f = (0:n-1)*(Fs/n); % Frequency range
P = Y.*conj(Y)/n; % Power of the DFT

figure
plot(f,P)
xlabel('Frequency')
ylabel('Power')

predicted_f = 1/12
predicted_f =
    0.0833
```



The peak near `0.0833` supports the assumption, although it occurs at a slightly higher frequency. The model can be adjusted accordingly.

See “Linear Regression Analysis” and “Fourier Analysis” in the MATLAB Data Analysis documentation for more information on data modeling.

Creating Graphical User Interfaces

What Is GUIDE?

GUIDE, the MATLAB graphical user interface development environment, provides a set of tools for creating graphical user interfaces (GUIs). These tools greatly simplify the process of designing and building GUIs. You can use the GUIDE tools to

- Lay out the GUI.

  Using the GUIDE Layout Editor, you can lay out a GUI easily by clicking and dragging GUI components—such as panels, buttons, text fields, sliders, menus, and so on—into the layout area. GUIDE stores the GUI layout in a FIG-file.

- Program the GUI.

  GUIDE automatically generates an M-file that controls how the GUI operates. The M-file initializes the GUI and contains a framework for the most commonly used callbacks for each component—the commands that execute when a user clicks a GUI component. Using the M-file editor, you can add code to the callbacks to perform the functions you want.

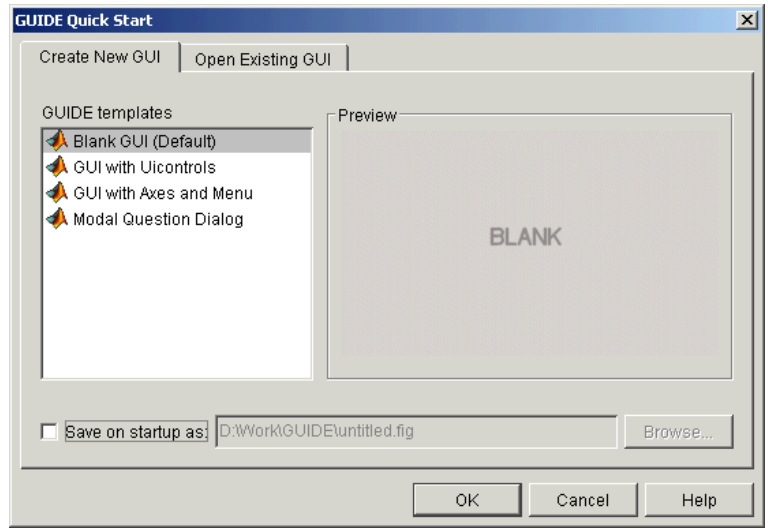
Note You can also create GUIs programmatically. For information on how to get started, see "Creating a Simple GUI Programmatically" in the MATLAB Creating Graphical User interfaces documentation.

Laying Out a GUI

In this section...

Starting GUIDE

Start GUIDE by typing `guide` at the MATLAB command prompt. This displays the GUIDE Quick Start dialog box, as shown in the following figure.

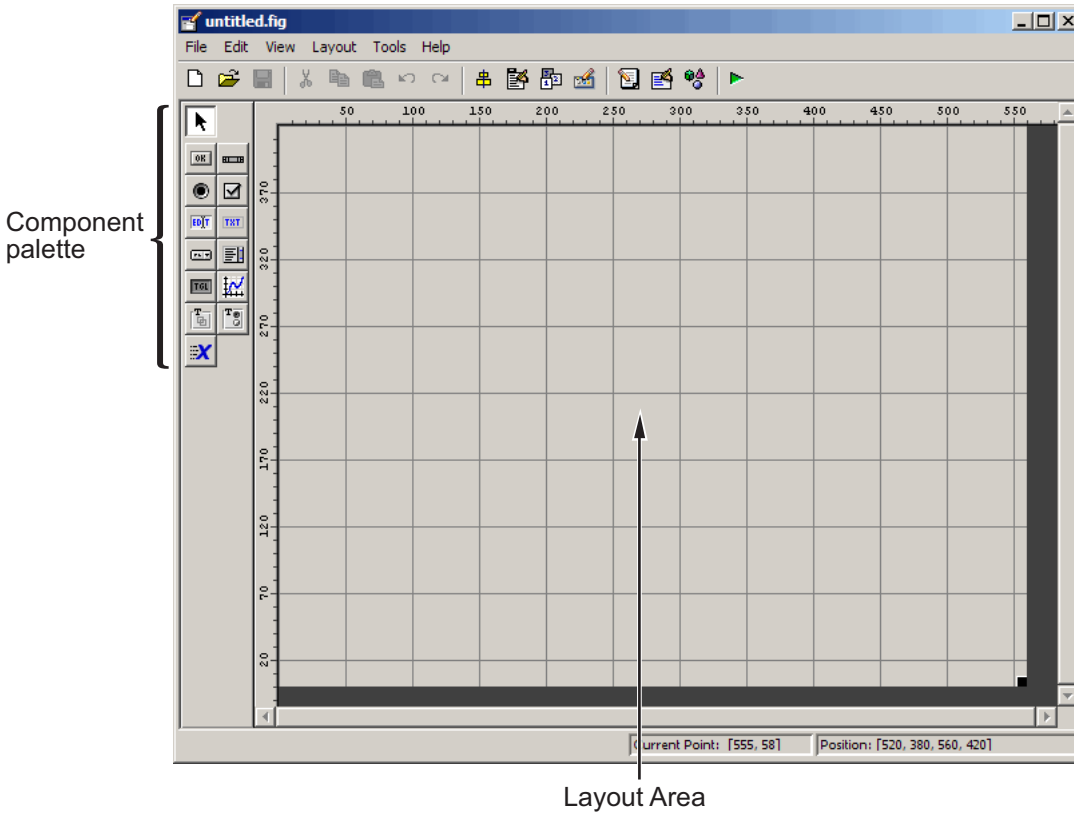


From the GUIDE Quick Start dialog box, you can

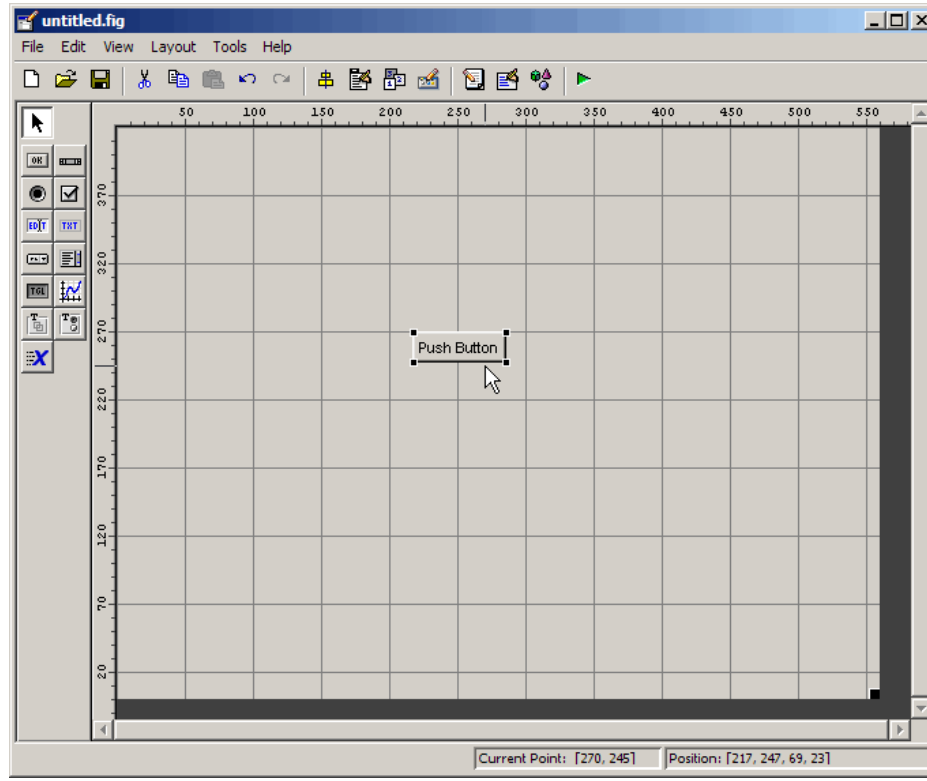
- Create a new GUI from one of the GUIDE templates—prebuilt GUIs that you can modify for your own purposes.
- Open an existing GUI.

The Layout Editor

When you open a GUI in GUIDE, it is displayed in the Layout Editor, which is the control panel for all of the GUIDE tools. The following figure shows the Layout Editor with a blank GUI template.



You can lay out your GUI by dragging components, such as panels, push buttons, pop-up menus, or axes, from the component palette, at the left side of the Layout Editor, into the layout area. For example, if you drag a push button into the layout area, it appears as in the following figure.



You can also use the Layout Editor (along with the Toolbar Editor and Icon Editor) to create menus and toolbars, create and modify tool icons, and set basic properties of the GUI components.

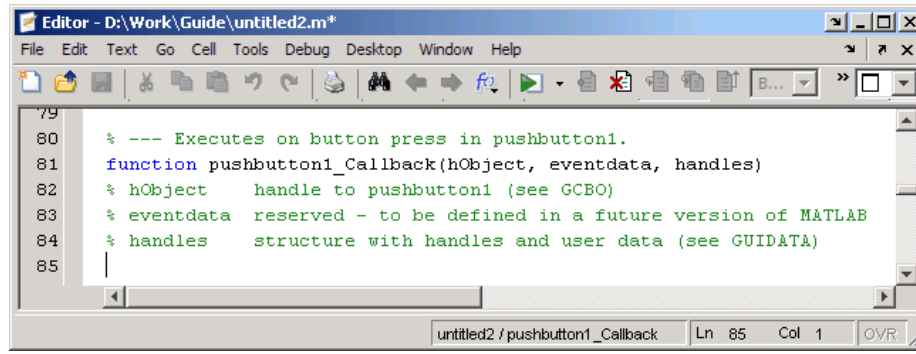
To get started using the Layout Editor and setting property values, see "Creating a Simple GUI with GUIDE" in the MATLAB Creating Graphical User Interfaces documentation. "Examples of GUIDE GUIs" in the same documentation illustrates the variety of GUIs that you can create with GUIDE.

Programming a GUI

After laying out the GUI and setting component properties, the next step is to program the GUI. You program the GUI by coding one or more callbacks for each of its components. Callbacks are functions that execute in response to some action by the user. A typical action is clicking a push button.

A GUI's callbacks are found in an M-file that GUIDE generates automatically. GUIDE adds templates for the most commonly used callbacks to this M-file, but you may want to add others. Use the M-file Editor to edit this file.

The following figure shows the Callback template for a push button.



To learn more about programming a GUI, see "Creating a Simple GUI with GUIDE" in the MATLAB Creating GUIs documentation.

7

Desktop Tools and Development Environment

If you have an active Internet connection, you can watch the Working in The Development Environment video demo for an overview of the major functionality.

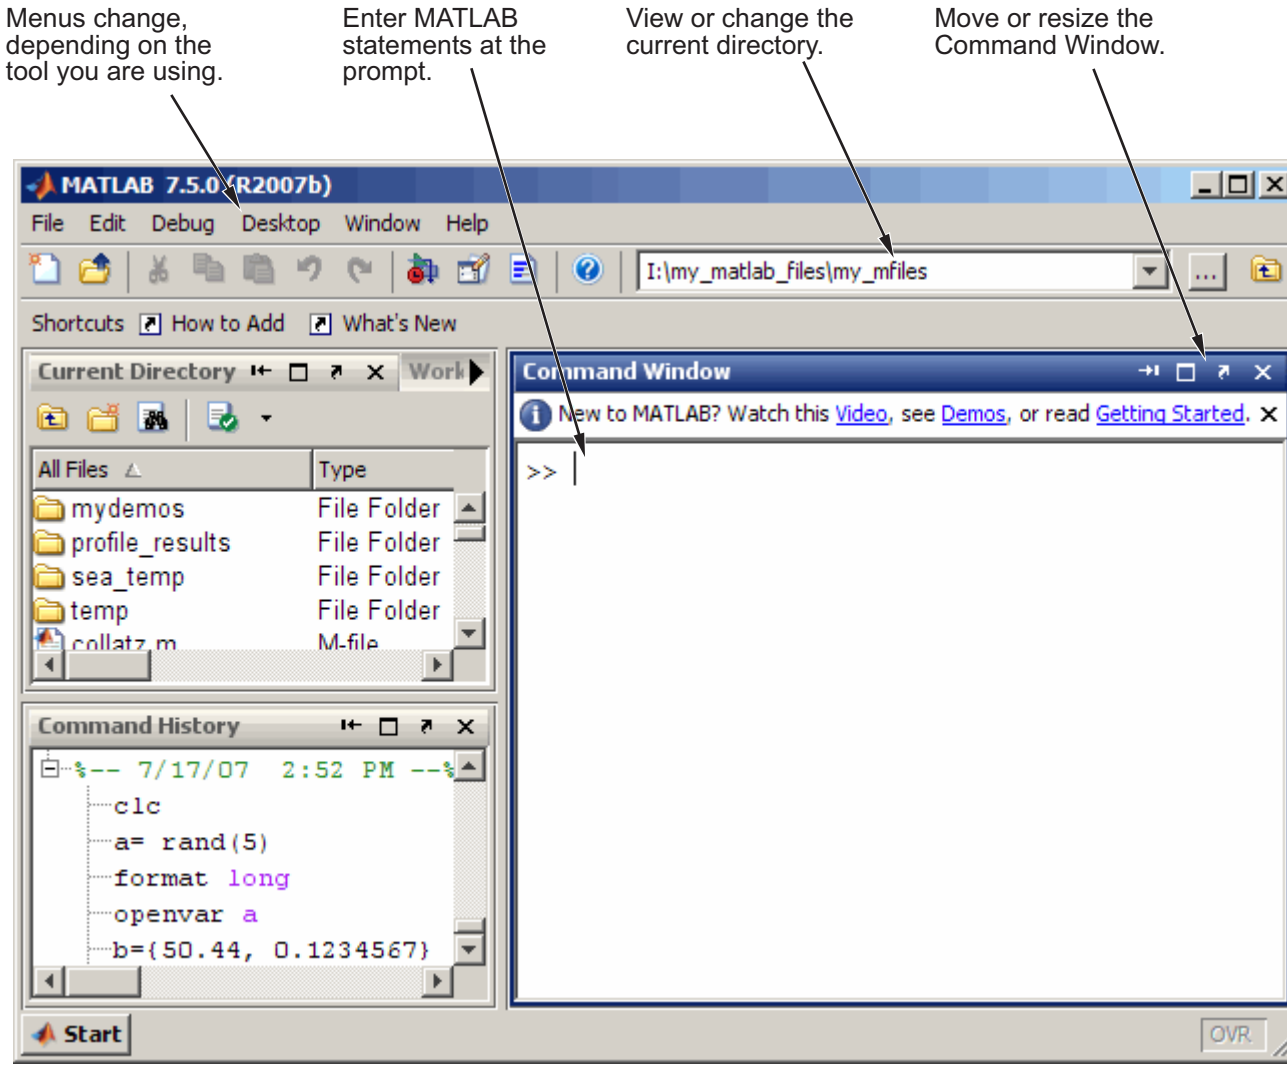
Desktop Overview

In this section...

Introduction to the Desktop

Use desktop tools to manage your work in MATLAB. You can also use MATLAB functions to perform the equivalent of most of the features found in the desktop tools.

The following illustration shows the default configuration of the MATLAB desktop. You can modify the setup to meet your needs.



Menus change, depending on the tool you are using.
Enter MATLAB statements at the prompt.
View or change the current directory.
Move or resize the Command Window.
MATLAB 7.5.0 (R2007b)

New to MATLAB? Watch this Video, see Demos, or read Getting Started.
>>
Start
OVR

For More Information For an overview of the desktop tools, watch the video tutorials, accessible by typing `demo matlab desktop` (requires an Internet connection). For complete details, see the MATLAB Desktop Tools and Development Environment documentation.

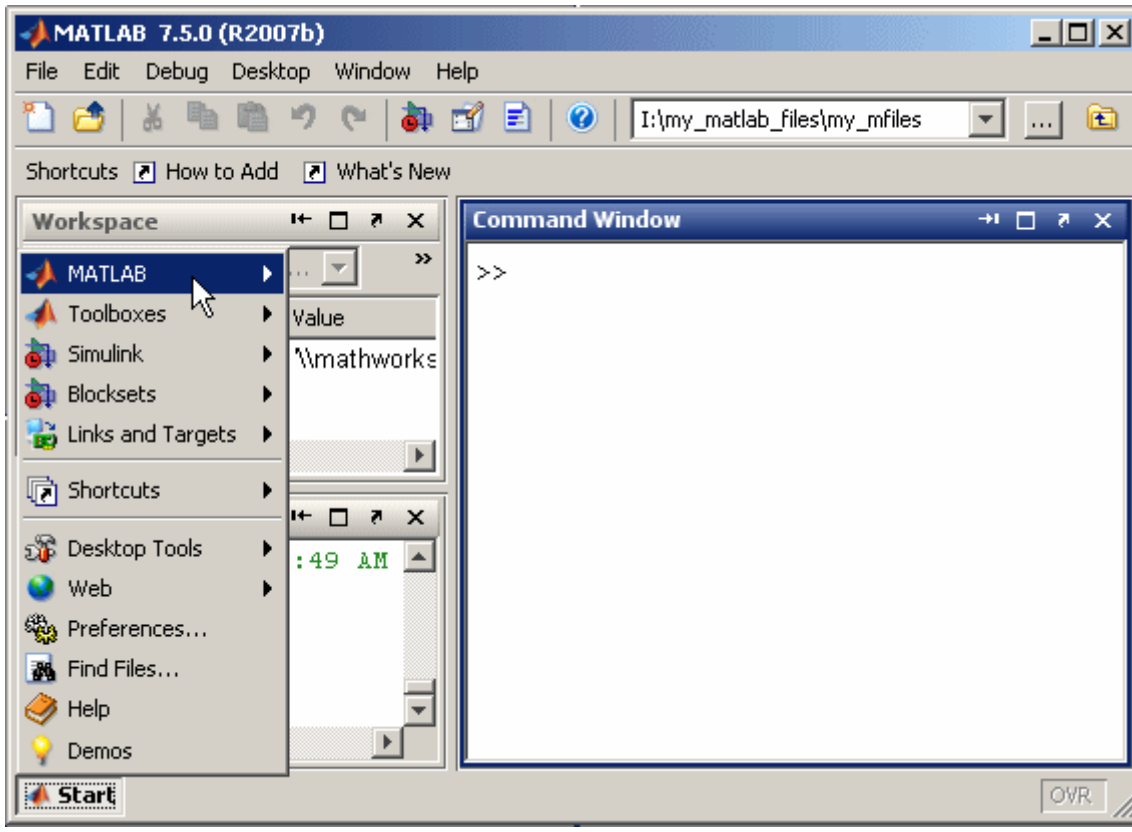
Arranging the Desktop

These are some common ways to customize the desktop:

- Show or hide desktop tools via the **Desktop** menu.
- Resize any tool by dragging one of its edges.
- Move a tool outside of the desktop by clicking the undock button in the tool's title bar.
- Reposition a tool within the desktop by dragging its title bar to the new location. Tools can occupy the same position, as shown for the Current Directory and Workspace browser in the preceding illustration, in which case, you access a tool via its name in the title bar.
- Maximize or minimize (temporarily hide) a tool within the desktop via the **Desktop** menu.
- Change fonts and other options by using **File > Preferences**.

Start Button

The MATLAB **Start** button provides easy access to tools, demos, shortcuts, and documentation. Click the **Start** button to see the options.



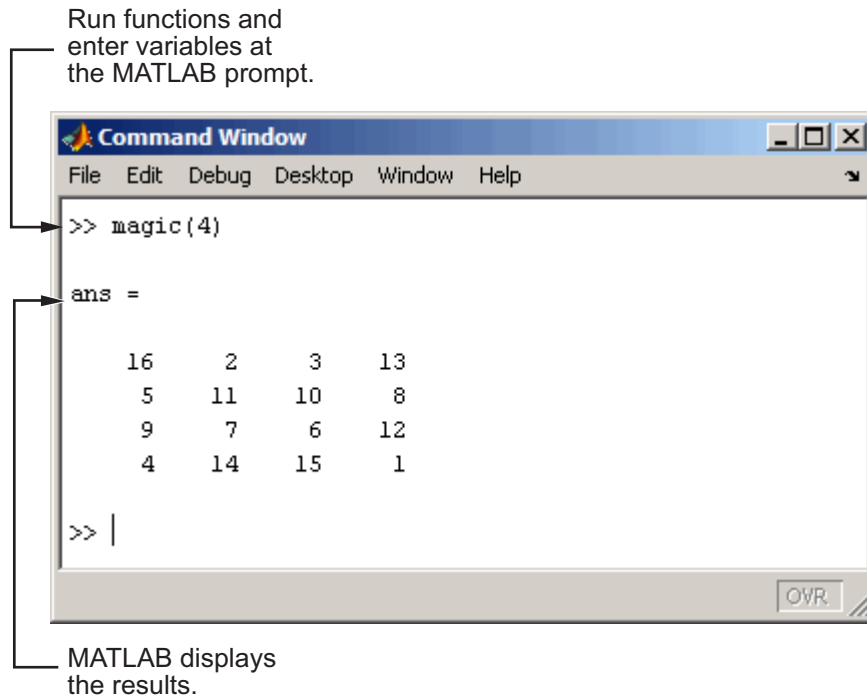
For More Information See "Desktop" in the MATLAB Desktop Tools and Development Environment documentation.

Command Window and Command History

In this section...

Command Window

Use the Command Window to enter variables and to run functions and M-file scripts.

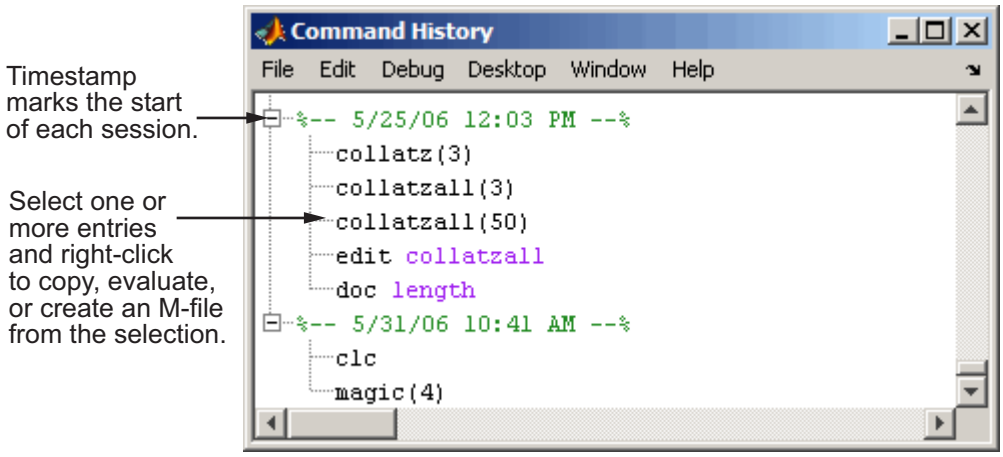


Press the up arrow key ↑ to recall a statement you previously typed. Edit the statement as needed and then press **Enter** to run it. For more information about entering statements in the Command Window, see “Controlling Command Window Input and Output” on page 2-30.

For More Information See "Running Functions — Command Window and History" in the MATLAB Desktop Tools and Development Environment documentation for complete details.

Command History

Statements you enter in the Command Window are logged in the Command History. From the Command History, you can view and search for previously run statements, as well as copy and execute selected statements. You can also create an M-file from selected statements.



To save the input and output from a MATLAB session to a file, use the `diary` function.

For More Information See "Command History Window" in the MATLAB Desktop Tools and Development Environment documentation, and the reference page for the `diary` function.

Help

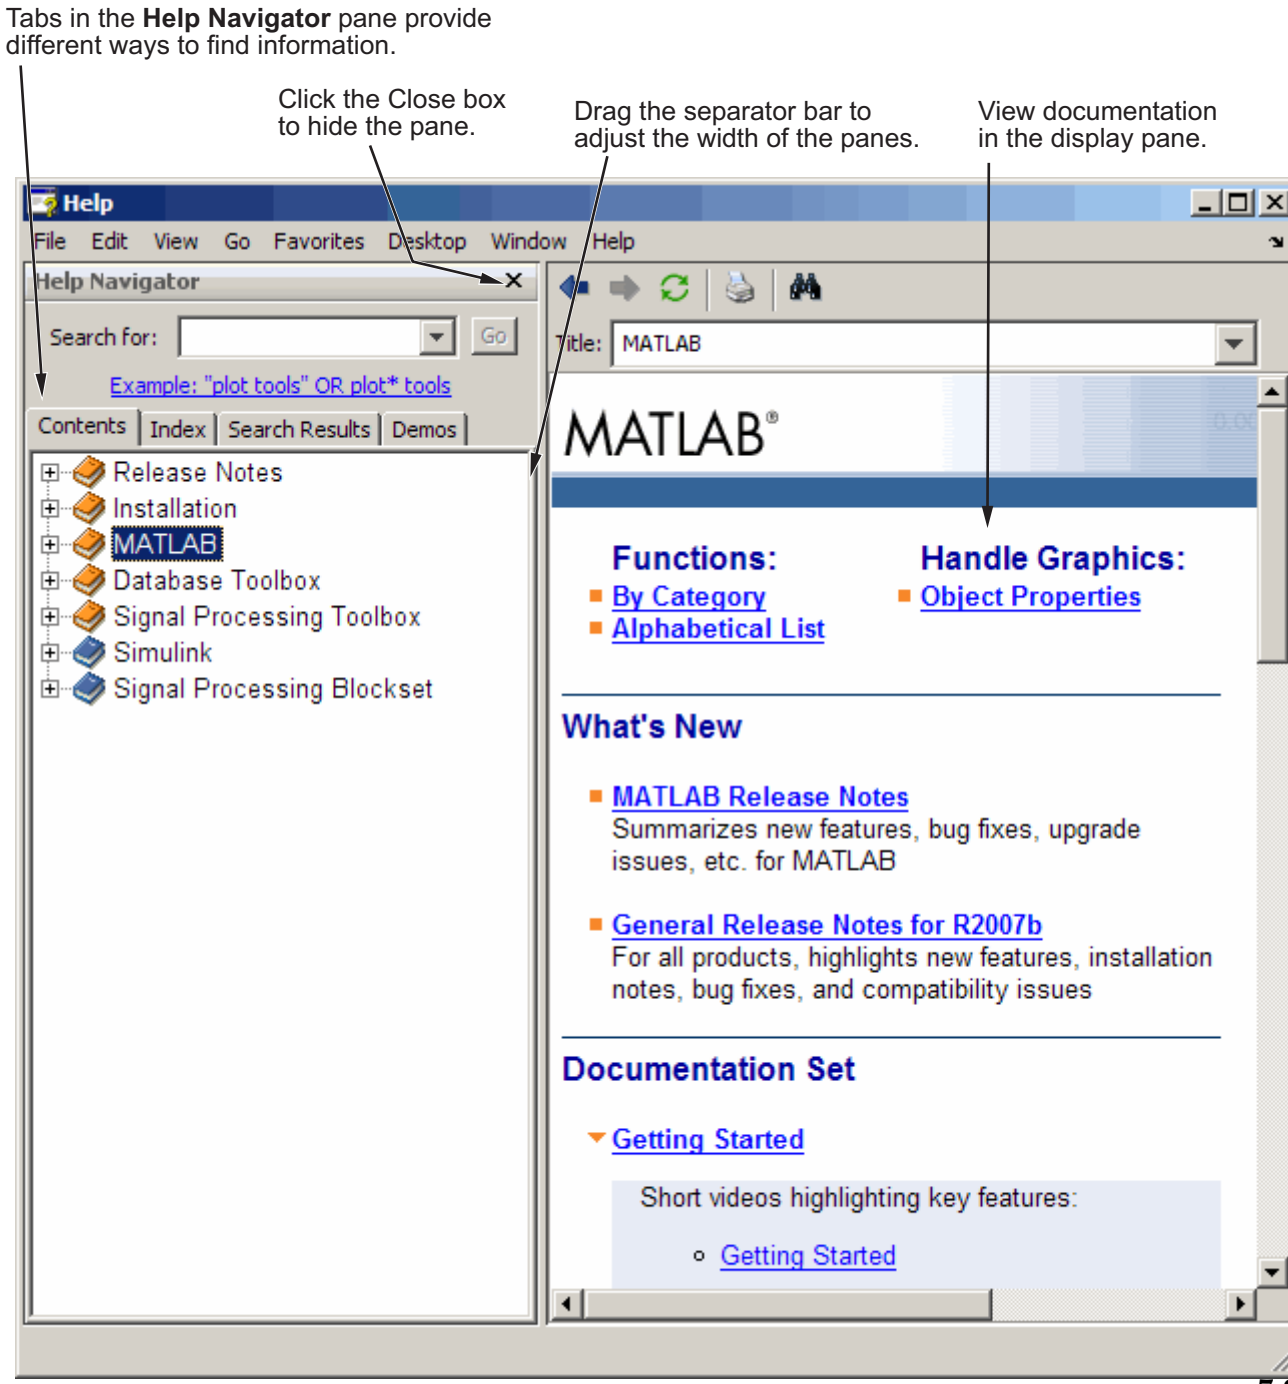
In this section...

Help Browser

Use the Help browser to search for and view documentation and demos for all your MathWorks products. The Help browser is an HTML viewer integrated into the MATLAB desktop.

To open the Help browser, click the Help button  in the desktop toolbar.

The Help browser consists of two panes, the **Help Navigator**, which you use to find information, and the display pane, where you view the information.



Tabs in the **Help Navigator** pane provide different ways to find information.
Click the Close box to hide the pane.
Drag the separator bar to adjust the width of the panes.
View documentation in the display pane.

Getting Started
Short videos highlighting key features:
Getting Started

These are the key features:

- **Search for** field — Look for specific words in the documentation and demos. You can
  - Specify an exact phrase by enclosing words in double quotation marks, such as `"word1 word2"`
  - Use a wildcard symbol (`*`) in place of letters, such as `wo*d1`
  - Include Boolean operators between words, such as `word1 NOT word2`
- **Contents** tab — View the titles and tables of contents of the documentation. By default, the contents synchronizes to the displayed page. If you get to a page from a search or by following a link, click the **Contents** tab if you want to see the context within the overall documentation for the page you are viewing.
- **Index** tab — Find specific index entries (selected keywords) in the documentation.
- **Search Results** tab — Displays results from **Search for**, separating the results in Documentation from the results in Demos.
- **Demos** tab — View and run demonstrations for your MathWorks products. Demos include code that you can use as a basis for creating your own M-files.

While viewing the documentation, you can

- Browse to other pages — Use the arrows at the tops and bottoms of the pages to move through the document, or use the back and forward buttons in the toolbar to go to previously viewed pages.
- Bookmark pages — Use the **Favorites** menu.
- Print a page — Click the print button in the toolbar.
- Find a term in the page — Click the find icon  in the toolbar.
- Copy or evaluate a selection — Select text, such as code from an example, then right-click and use a context menu item to copy the selection or evaluate (run) it.

Other Forms of Help

In addition to the Help browser, you can use help functions. To get help for a specific function, use the `doc` function. For example, `doc format` displays documentation for the `format` function in the Help browser.

To see a briefer form of the documentation for a function, type `help` followed by the function name. The resulting help text appears in the Command Window. It shows function names in all capital letters to distinguish them from the surrounding text. When you use the function names, type them in lowercase or they will not run. Some functions actually consist of both uppercase and lowercase letters, and the help text clearly indicates that. For those functions, match the case used in the `help` function.

Other means for getting help include contacting Technical Support (`www.mathworks.com/support`) and participating in the Usenet newsgroup for MATLAB users, `comp.soft-sys.matlab`.

Typographical Conventions

These conventions are used in the Help browser and PDF documentation.

Item	Convention	Example
Buttons and keys	**Boldface**	Press the **Enter** key.
Example code	`Monospace` font	To assign the value 5 to `A`, enter `A = 5`
Function names, syntax, filenames, directory/folder names, user input, items in drop-down lists	`Monospace` font	The `cos` function finds the cosine of each array element.
Literal strings (in syntax descriptions in reference chapters)	**`Monospace bold`** font	`f = freqspace(n,'whole')`
Mathematical expressions	*Italics* for variables Standard text font for functions, operators, and constants	This vector represents the polynomial $p = x^2 + 2x + 3$.

MATLAB output	`Monospace` font	MATLAB responds with
		`A =`
		`5`

Menu titles and items	**Boldface**	Select **File > Save**.

Item	Convention	Example
New terms and for emphasis	*Italics*	In MATLAB, a *matrix* is a rectangular array of numbers.
Omitted input arguments	`(...)` ellipsis denotes all of the input/output arguments from preceding syntaxes	`[c, ia, ib] = union(...)`
String variables (from a finite list)	*`Monospace italics`*	`format('type')`

For More Information See "Help for Using MATLAB" in the MATLAB Desktop Tools and Development Environment documentation, and the reference pages for the `doc` and `help` functions.

Current Directory Browser and Search Path

In this section...

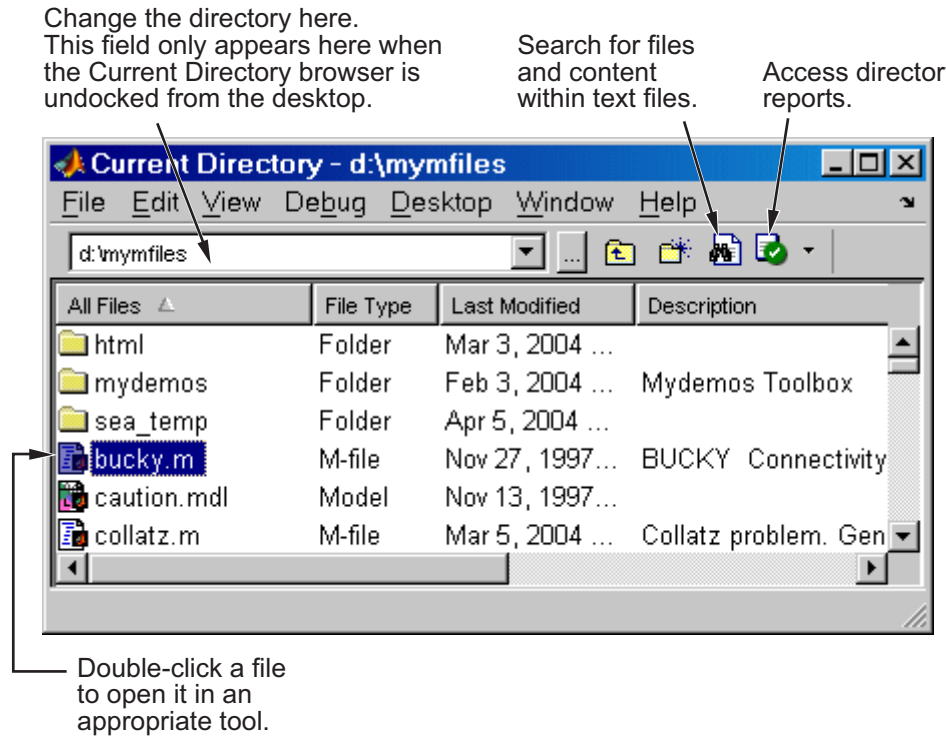
Running Files

MATLAB file operations use the current directory and the search path as reference points. Any file you want to run must either be in the current directory or on the search path.

Current Directory

A quick way to view or change the current directory is by using the current directory field in the desktop toolbar, shown here.

To search for, view, open, and make changes to MATLAB related directories and files, use the MATLAB Current Directory browser. Alternatively, you can use the functions `dir`, `cd`, and `delete`. Use “Directory Reports in Current Directory Browser” to help you tune and manage M-files.



For More Information See "File Management Operations" in the MATLAB Desktop Tools and Development Environment documentation, and the reference pages for the `dir`, `cd`, and `delete` functions.

Search Path

MATLAB uses a *search path* to find M-files and other MATLAB related files, which are organized in directories on your file system. Any file you want to run in MATLAB must reside in the current directory or in a directory that is on the search path. When you create M-files and related files for MATLAB, add the directories in which they are located to the MATLAB search path. By default, the files supplied with MATLAB and other MathWorks products are included in the search path.

To see which directories are on the search path or to change the search path, select **File > Set Path** and use the resulting Set Path dialog box. Alternatively, you can use the `path` function to view the search path, `addpath` to add directories to the path, and `rmpath` to remove directories from the path.

For More Information See "Search Path" in the MATLAB Desktop Tools and Development Environment documentation, and the reference pages for the `path`, `addpath`, and `rmpath` functions.

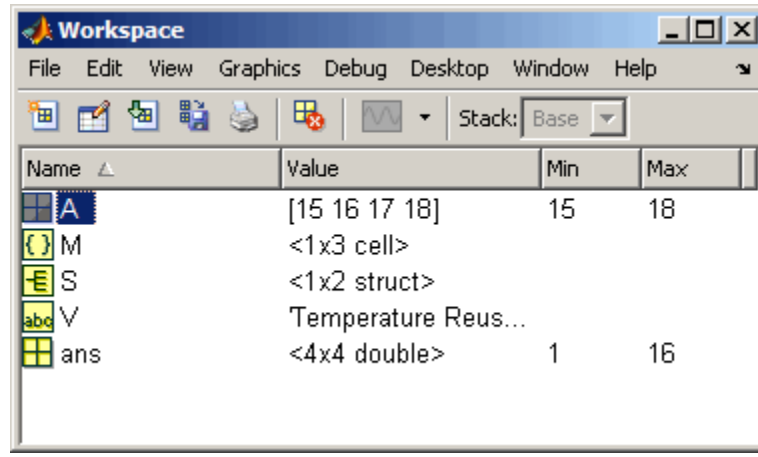
Workspace Browser and Array Editor

In this section...

Workspace Browser

The MATLAB workspace consists of the set of variables (named arrays) built up during a MATLAB session and stored in memory. You add variables to the workspace by using functions, running M-files, and loading saved workspaces.

To view the workspace and information about each variable, use the Workspace browser, or use the functions `who` and `whos`.



To delete variables from the workspace, select the variables and select **Edit > Delete**. Alternatively, use the `clear` function.

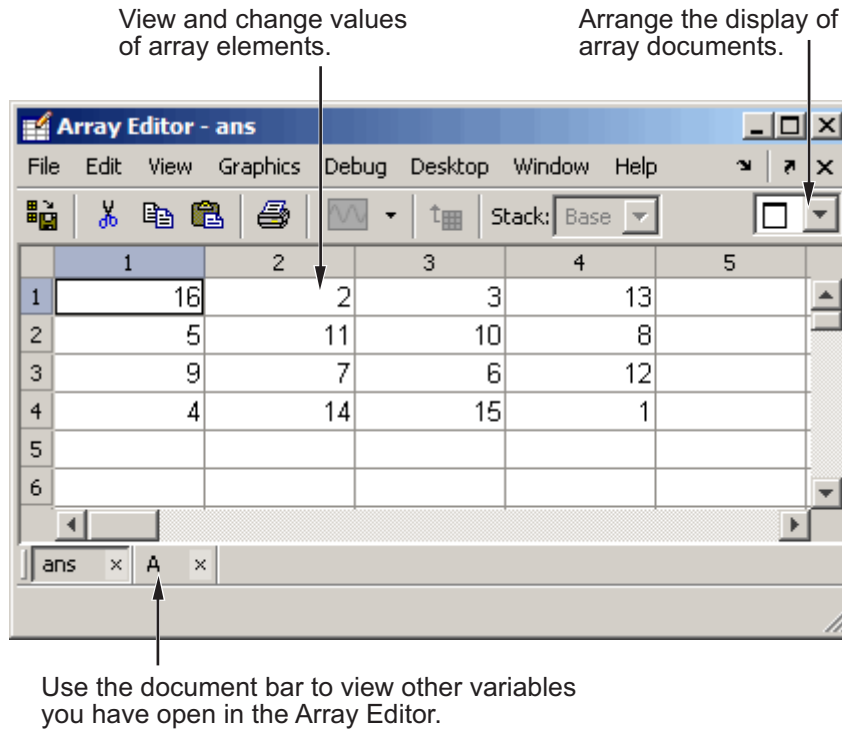
The workspace is not maintained after you end the MATLAB session. To save the workspace to a file that can be read during a later MATLAB session, select **File > Save**, or use the `save` function. This saves the workspace to a binary file called a MAT-file, which has a `.mat` extension. You can use options

to save to different formats. To read in a MAT-file, select **File > Import Data**, or use the `load` function.

For More Information See "MATLAB Workspace" in the MATLAB Desktop Tools and Development Environment documentation, and the reference pages for the `who`, `clear`, `save`, and `load` functions.

Array Editor

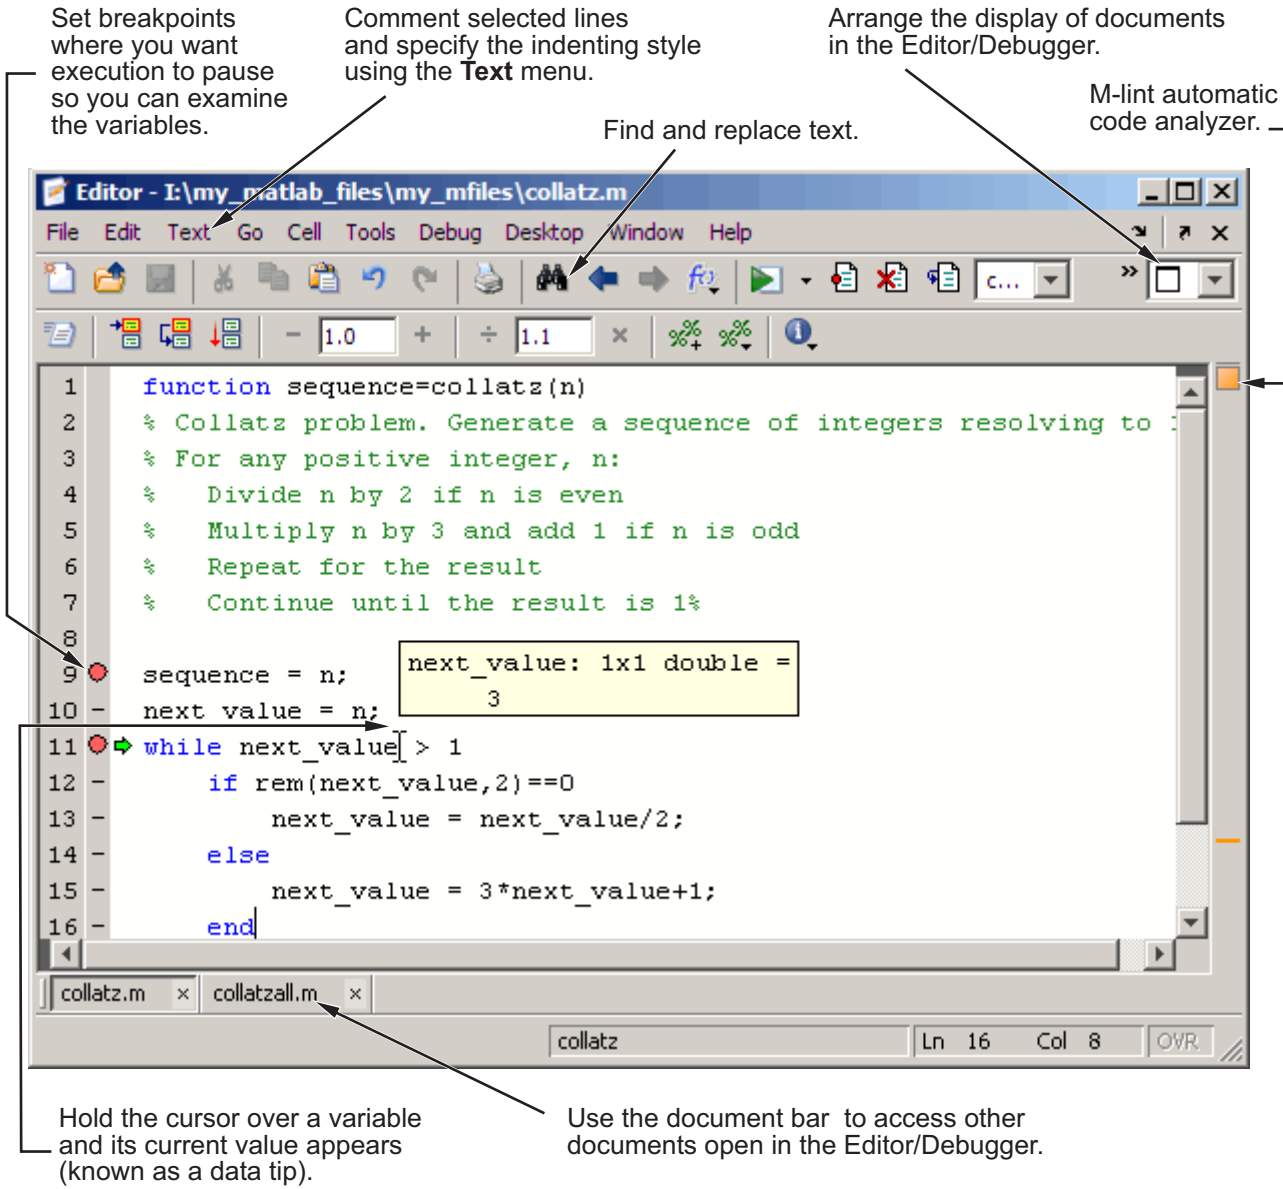
Double-click a variable in the Workspace browser, or use `openvar variablename`, to see it in the Array Editor. Use the Array Editor to view and edit a visual representation of variables in the workspace.



For More Information See “Viewing and Editing Workspace Variables with the Array Editor” in the MATLAB Desktop Tools and Development Environment documentation, and the reference page for the `openvar` function.

Editor/Debugger

Use the Editor/Debugger to create and debug M-files, which are programs you write to run MATLAB functions. The Editor/Debugger provides a graphical user interface for text editing, as well as for M-file debugging. To create or edit an M-file use **File > New** or **File > Open**, or use the `edit` function.



You can use any text editor to create M-files, such as Emacs. Use preferences (accessible from the desktop **File** menu) to specify that editor as the default.

If you use another editor, you can still use the MATLAB Editor/Debugger for debugging, or you can use debugging functions, such as `dbstop`, which sets a breakpoint.

If you just need to view the contents of an M-file, you can display the contents in the Command Window using the `type` function.

Use the M-Lint automatic code analyzer to help you identify problems and potential improvements in your code. For details, see "M-Lint Code Check and Profiler Reports" on page 7-23.

You can evaluate your code in sections, called cells, and can publish your code, including results, to popular output formats like HTML. For more information, see "Using Cells for Rapid Code Iteration and Publishing Results" in the MATLAB Desktop Tools and Development Environment documentation.

For More Information See "Editing and Debugging M-Files" in the MATLAB Desktop Tools and Development Environment documentation, and the function reference pages for `edit`, `type`, and `debug`.

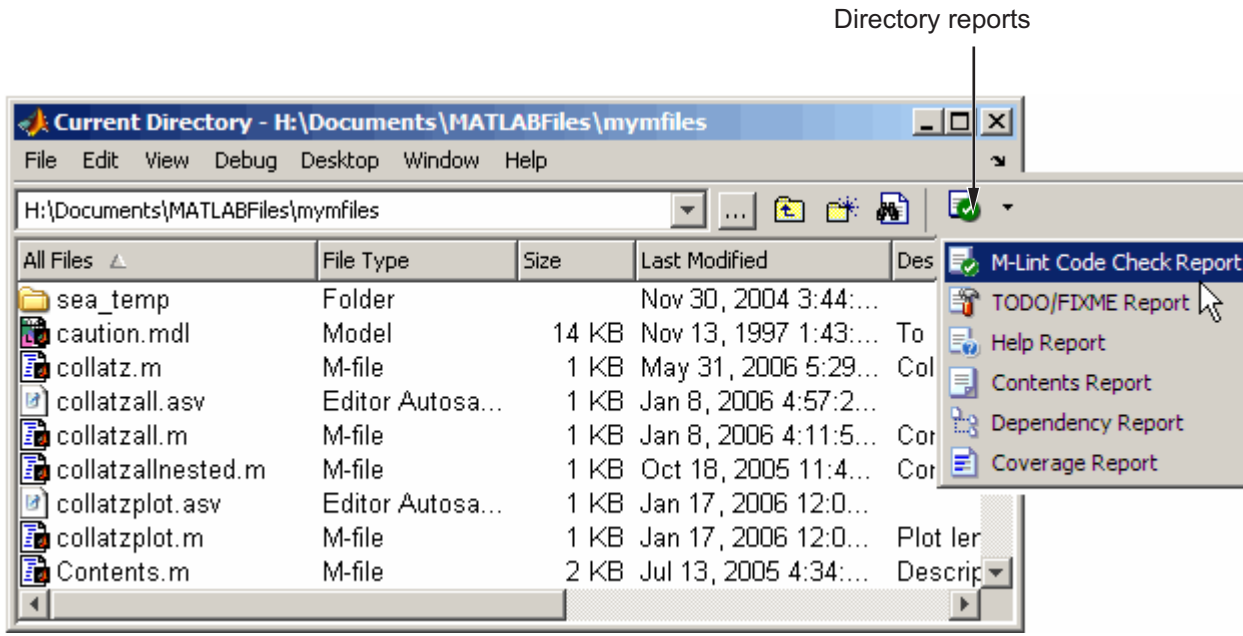
M-Lint Code Check and Profiler Reports

In this section...

M-Lint Code Check Report

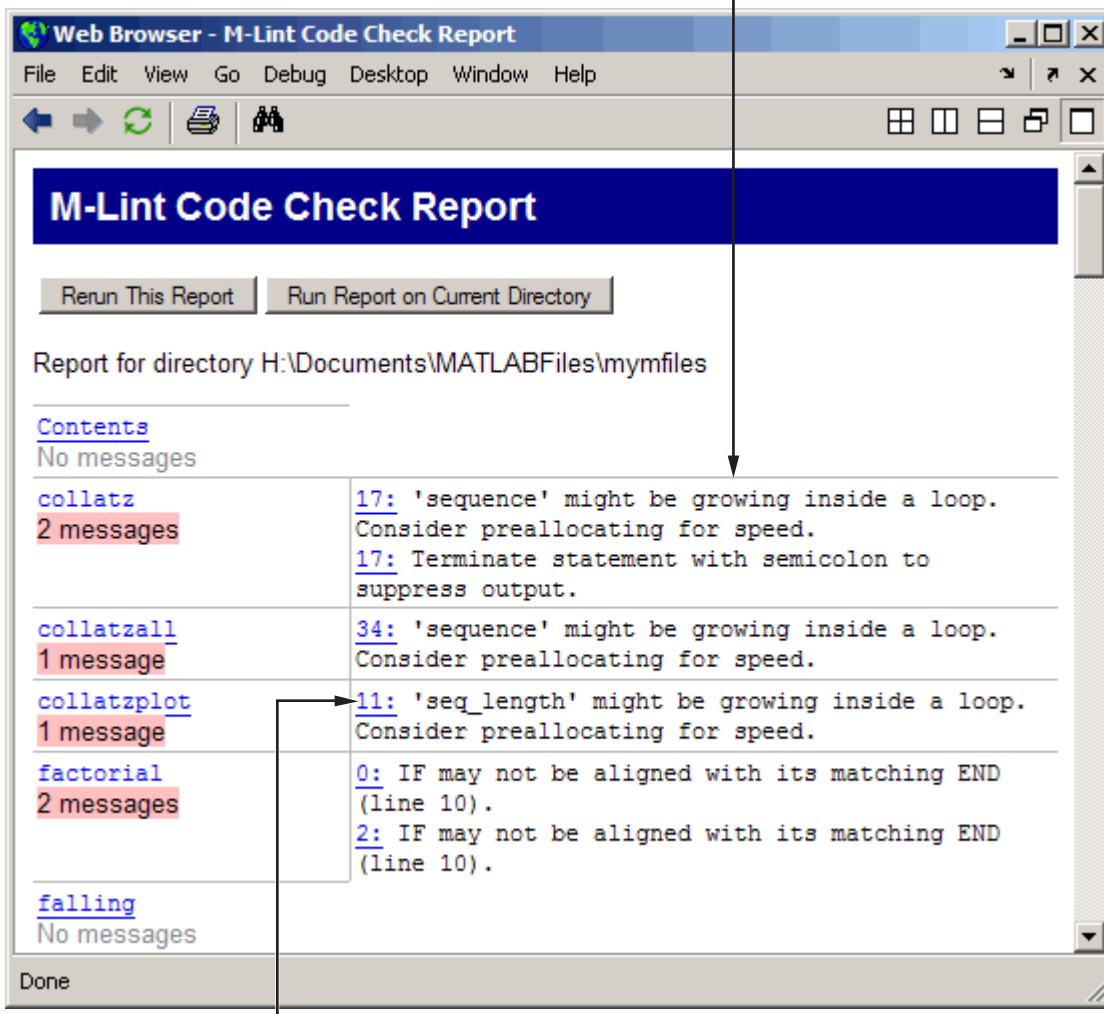
The M-Lint Code Check Report displays potential errors and problems, as well as opportunities for improvement in your M-files. The term *lint* is used by similar tools in other programming languages such as C.

Access the M-Lint Code Check Report and other directory reports from the Current Directory browser. You run a report for all files in the current directory.



In MATLAB, the M-Lint Code Check Report displays a message for each line of an M-file it determines might be improved. For example, a common M-Lint message is that a variable is defined but never used in the M-file.

The report displays a line number and message for each potential problem or improvement opportunity.



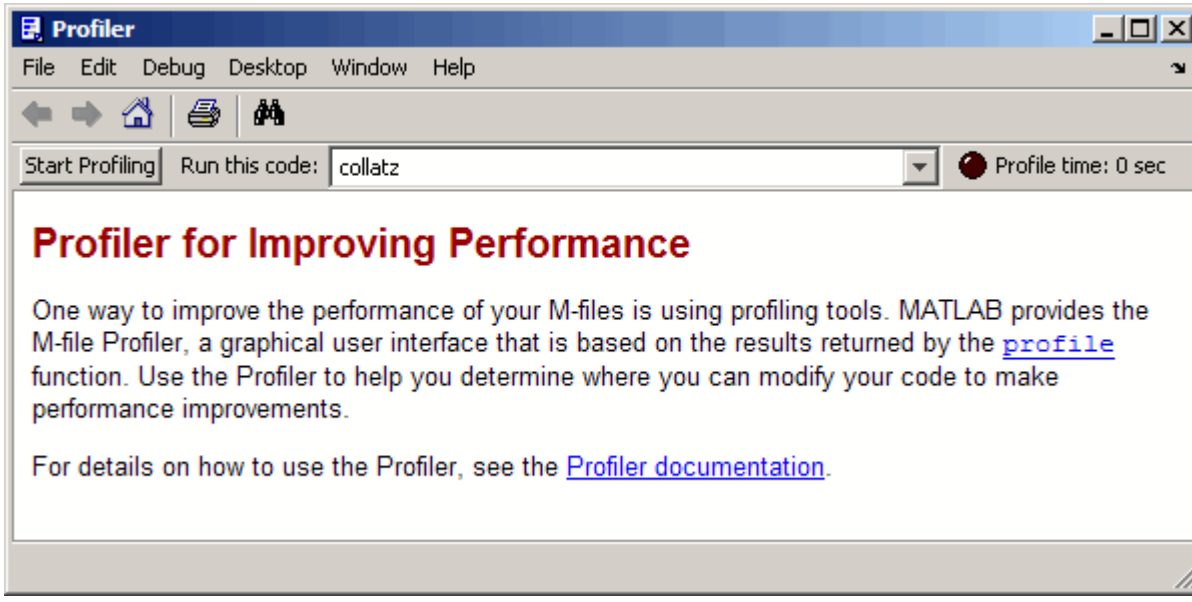
Click a line number to open the M-file in the Editor/Debugger at that line.

Alternatively, you can use automatic M-Lint code checking to view M-Lint messages while you work on a file in the Editor/Debugger. You can also use the `mlint` function to get results for a single M-file.

For More Information See "Tuning and Managing M-Files" and "M-Lint Code Analyzer" in the MATLAB Desktop Tools and Development Environment documentation, and the reference page for the `mlint` function.

Profiler

MATLAB includes the Profiler to help you improve the performance of your M-files. Run a MATLAB statement or an M-file in the Profiler and it produces a report of where the time is being spent. Access the Profiler from the **Desktop** menu, or use the `profile` function.



For More Information See “Tuning and Managing M-Files” in the MATLAB Desktop Tools and Development Environment documentation, and the reference page for the `profile` function.

Other Development Environment Features

Additional development environment features include

- Source Control — Access your source control system from within MATLAB.
- Publishing Results — Use the Editor/Debugger's cell features to publish M-files and results to popular output formats including HTML and Microsoft Word. You can also use MATLAB Notebook to access MATLAB functions from within Microsoft Word.

For More Information See "Source Control Interface" and "Publishing Results" in the MATLAB Desktop Tools and Development Environment documentation.

8

External Interfaces

Use MATLAB External Interfaces to connect MATLAB to programs, devices and data. Application developers use external interfaces to integrate MATLAB functionality with their applications. External interfaces also facilitate data collection, such as from peripheral devices like an oscilloscope or a remote network server.

Programming Interfaces

In this section...

Call MATLAB from C and Fortran Programs

Use the MATLAB engine library to call MATLAB from C and Fortran programs. When you call MATLAB from your own programs, MATLAB acts as a computation engine. For example, you can:

- Use MATLAB as a programmable mathematical subroutine library.
- Build an application with a front end (GUI) programmed in C and a back end (analysis) programmed in MATLAB.

Call C and Fortran Programs from MATLAB

Use MEX-files to call your own C or Fortran subroutines from MATLAB as if they were built-in functions. For example, you can:

- Call preexisting C and Fortran programs from MATLAB without having to rewrite them as M-files.
- Code bottleneck computations that do not run fast enough in MATLAB in C or Fortran for efficiency.

The mxArray access library creates and manipulates MATLAB arrays. The mex library performs operations in the MATLAB environment.

Call Java from MATLAB

MATLAB includes a Java Virtual Machine (JVM). This allows you to use the Java interpreter with MATLAB commands and to create and access Java objects. For example, you can:

- Access Java API class packages that support I/O and networking.
- Access third-party Java classes.
- Construct Java objects in MATLAB.
- Call Java methods, using either Java or MATLAB syntax.
- Pass data between MATLAB variables and Java objects.

Call Functions in Shared Libraries

Use the MATLAB interface to generic DLLs to interact with functions in a dynamic link library (`.dll`) on Windows, a shared object file (`.so`) on UNIX and Linux, or a dynamic shared library (`.dylib`) on Intel-based Macintosh platforms.

MATLAB supports any shared library written in C, or in any language that can provide a C interface.

Import and Export Data

MAT-files and the MAT-file access library provide a convenient mechanism for moving MATLAB binary data between platforms, and for importing and exporting data to stand-alone MATLAB applications.

Component Object Model Interface

With Component Object Model (COM) tools and technologies, you can integrate application-specific components from different vendors into your own applications. With COM, MATLAB can include ActiveX controls or OLE server processes, or you can configure MATLAB as a computational server controlled by your client application programs.

For example, you can:

- Include ActiveX components, like a calendar, in your MATLAB program.
- Access existing applications that expose objects via Automation, like Microsoft Excel.
- Access MATLAB as an Automation server from an application written in Visual Basic or C.

COM support in MATLAB is only available on the Microsoft Windows platform.

Web Services

Web services are XML-based technologies for making remote procedure calls over a network. They enable communication between applications running on disparate operating systems and development platforms. Web service technologies available in MATLAB are:

- Simple Object Access Protocol (SOAP)
- Web Services Description Language (WSDL)

Serial Port Interface

The MATLAB serial port interface provides direct access to peripheral devices that you connect to your computer's serial port, such as modems, printers, and scientific instruments. For example, you can:

- Configure serial port communications.
- Use serial port control pins.
- Write and read data.
- Use events and callbacks.
- Record information to disk.

Multidimensional Arrays (p. 1-56)	Create and work with arrays that have more than two dimensions.
Summary of Matrix and Array Functions (p. 1-76)	Quick reference to the functions commonly used in working with matrices.

Creating and Concatenating Matrices

In this section...

Overview

The most basic data structure in MATLAB® is the *matrix*: a two-dimensional, rectangularly shaped data structure capable of storing multiple elements of data in an easily accessible format. These data elements can be numbers, characters, logical states of `true` or `false`, or even other MATLAB structure types. MATLAB uses these two-dimensional matrices to store single numbers and linear series of numbers as well. In these cases, the dimensions are 1-by-1 and 1-by-n respectively, where `n` is the length of the numeric series. MATLAB also supports data structures that have more than two dimensions. These data structures are referred to as *arrays* in the MATLAB documentation.

MATLAB is a matrix-based computing environment. All of the data that you enter into MATLAB is stored in the form of a matrix or a multidimensional array. Even a single numeric value like `100` is stored as a matrix (in this case, a matrix having dimensions 1-by-1):

```
A = 100;

whos A
  Name      Size                    Bytes  Class

  A         1x1                         8  double array
```

Regardless of the data type being used, whether it is numeric, character, or logical `true` or `false` data, MATLAB stores this data in matrix (or array) form. For example, the string `'Hello World'` is a 1-by-11 matrix of individual character elements in MATLAB. You can also build matrices composed of more complex data types, such as MATLAB structures and cell arrays.

To create a matrix of basic data elements such as numbers or characters, see

- "Constructing a Simple Matrix" on page 1-4
- "Specialized Matrix Functions" on page 1-5

To build a matrix composed of other matrices, see

- "Concatenating Matrices" on page 1-8
- "Matrix Concatenation Functions" on page 1-9

This section also describes

- "Generating a Numeric Sequence" on page 1-11
- "Combining Unlike Data Types" on page 1-13

Constructing a Simple Matrix

The simplest way to create a matrix in MATLAB is to use the matrix constructor operator, `[]`. Create a row in the matrix by entering elements (shown as `E` below) within the brackets. Separate each element with a comma or space:

```
row = [E1, E2, ..., Em]          row = [E1 E2 ... Em]
```

For example, to create a one row matrix of five elements, type

```
A = [12 62 93 -8 22];
```

To start a new row, terminate the current row with a semicolon:

```
A = [row1; row2; ...; rown]
```

This example constructs a 3 row, 5 column (or 3-by-5) matrix of numbers. Note that all rows must have the same number of elements:

```
A = [12 62 93 -8 22; 16 2 87 43 91; -4 17 -72 95 6]
A =
    12    62    93    -8    22
    16     2    87    43    91
    -4    17   -72    95     6
```

The square brackets operator constructs two-dimensional matrices only, (including 0-by-0, 1-by-1, and 1-by-n matrices). To construct arrays of more than two dimensions, see “Creating Multidimensional Arrays” on page 1-58.

For instructions on how to read or overwrite any matrix element, see “Matrix Indexing” on page 1-18.

Entering Signed Numbers

When entering signed numbers into a matrix, make sure that the sign immediately precedes the numeric value. Note that while the following two expressions are equivalent,

```
7 -2 +5
ans =
    10
```

```
7 - 2 + 5
  ans =
      10
```

the next two are *not*:

```
[7 -2 +5]
ans =
     7    -2     5
```

```
[7 - 2 + 5]
   ans =
       10
```

Specialized Matrix Functions

MATLAB has a number of functions that create different kinds of matrices. Some create specialized matrices like the Hankel or Vandermonde matrix. The functions shown in the table below create matrices for more general use.

Function	Description
`ones`	Create a matrix or array of all ones.
`zeros`	Create a matrix or array of all zeros.
`eye`	Create a matrix with ones on the diagonal and zeros elsewhere.
`accumarray`	Distribute elements of an input matrix to specified locations in an output matrix, also allowing for accumulation.
`diag`	Create a diagonal matrix from a vector.
`magic`	Create a square matrix with rows, columns, and diagonals that add up to the same number.
`rand`	Create a matrix or array of uniformly distributed random numbers.
`randn`	Create a matrix or array of normally distributed random numbers and arrays.
`randperm`	Create a vector (1-by-n matrix) containing a random permutation of the specified integers.

Most of these functions return matrices of type `double` (double-precision floating point). However, you can easily build basic arrays of any numeric type using the `ones`, `zeros`, and `eye` functions.

To do this, specify the MATLAB class name as the last argument:

```
A = zeros(4, 6, 'uint32')
A =
        0        0        0        0        0        0
        0        0        0        0        0        0
        0        0        0        0        0        0
        0        0        0        0        0        0
```

Examples

Here are some examples of how you can use these functions.

Creating a Magic Square Matrix. A magic square is a matrix in which the sum of the elements in each column, or each row, or each main diagonal is the same. To create a 5-by-5 magic square matrix, use the `magic` function as shown.

```
A = magic(5)
A =
    17    24     1     8    15
    23     5     7    14    16
     4     6    13    20    22
    10    12    19    21     3
    11    18    25     2     9
```

Note that the elements of each row, each column, and each main diagonal add up to the same value: 65.

Creating a Random Matrix. The `rand` function creates a matrix or array with elements uniformly distributed between zero and one. This example multiplies each element by 20:

```
A = rand(5) * 20
A =
   19.0026   15.2419   12.3086    8.1141    1.1578
    4.6228    9.1294   15.8387   18.7094    7.0574
   12.1369    0.3701   18.4363   18.3381   16.2633
    9.7196   16.4281   14.7641    8.2054    0.1972
   17.8260    8.8941    3.5253   17.8730    2.7778
```

The sequence of numbers produced by `rand` is determined by the internal state of the generator. Setting the generator to the same fixed state enables you to repeat computations. Examples in this documentation that use the `rand` function are initialized to a state of 0 to make the output consistent each time they are run:

```
rand('state', 0);
```

Creating a Diagonal Matrix. Use `diag` to create a diagonal matrix from a vector. You can place the vector along the main diagonal of the matrix, or on a diagonal that is above or below the main one, as shown here. The `-1` input places the vector one row below the main diagonal:

```
A = [12 62 93 -8 22];

B = diag(A, -1)
B =
     0     0     0     0     0     0
    12     0     0     0     0     0
     0    62     0     0     0     0
     0     0    93     0     0     0
     0     0     0    -8     0     0
     0     0     0     0    22     0
```

Concatenating Matrices

Matrix concatenation is the process of joining one or more matrices to make a new matrix. The brackets `[]` operator discussed earlier in this section serves not only as a matrix constructor, but also as the MATLAB concatenation operator. The expression `C = [A B]` horizontally concatenates matrices `A` and `B`. The expression `C = [A; B]` vertically concatenates them.

This example constructs a new matrix `C` by concatenating matrices `A` and `B` in a vertical direction:

```
A = ones(2, 5) * 6;        % 2-by-5 matrix of 6's
B = rand(3, 5);            % 3-by-5 matrix of random values

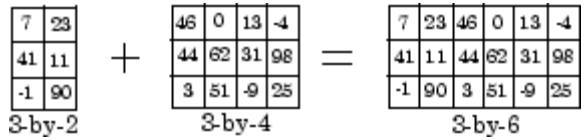
C = [A; B]                 % Vertically concatenate A and B
C =
    6.0000    6.0000    6.0000    6.0000    6.0000
    6.0000    6.0000    6.0000    6.0000    6.0000
    0.9501    0.4860    0.4565    0.4447    0.9218
    0.2311    0.8913    0.0185    0.6154    0.7382
    0.6068    0.7621    0.8214    0.7919    0.1763
```

Keeping Matrices Rectangular

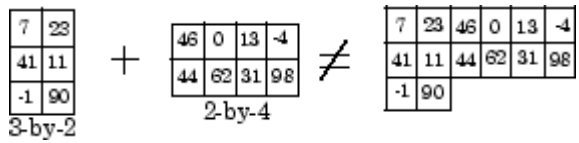
You can construct matrices, or even multidimensional arrays, using concatenation as long as the resulting matrix does not have an irregular shape (as in the second illustration shown below). If you are building a matrix horizontally, then each component matrix must have the same number of

rows. When building vertically, each component must have the same number of columns.

This diagram shows two matrices of the same height (i.e., same number of rows) being combined horizontally to form a new matrix.



The next diagram illustrates an attempt to horizontally combine two matrices of unequal height. MATLAB does not allow this.



Matrix Concatenation Functions

The following functions combine existing matrices to form a new matrix.

Function	Description
`cat`	Concatenate matrices along the specified dimension
`horzcat`	Horizontally concatenate matrices
`vertcat`	Vertically concatenate matrices
`repmat`	Create a new matrix by replicating and tiling existing matrices
`blkdiag`	Create a block diagonal matrix from existing matrices

Examples

Here are some examples of how you can use these functions.

Concatenating Matrices and Arrays. An alternative to using the `[]` operator for concatenation are the three functions `cat`, `horzcat`, and `vertcat`. With these functions, you can construct matrices (or multidimensional arrays) along a specified dimension. Either of the following commands accomplish the same task as the command `C = [A; B]` used in the section on "Concatenating Matrices" on page 1-8:

```
C = cat(1, A, B);       % Concatenate along the first dimension
C = vertcat(A, B);      % Concatenate vertically
```

Replicating a Matrix. Use the `repmat` function to create a matrix composed of copies of an existing matrix. When you enter

```
repmat(M, v, h)
```

MATLAB replicates input matrix `M` `v` times vertically and `h` times horizontally. For example, to replicate existing matrix `A` into a new matrix `B`, use

```
A = [8 1 6; 3 5 7; 4 9 2]
A =
   8   1   6
   3   5   7
   4   9   2

B = repmat(A, 2, 4)
B =
   8   1   6   8   1   6   8   1   6   8   1   6
   3   5   7   3   5   7   3   5   7   3   5   7
   4   9   2   4   9   2   4   9   2   4   9   2
   8   1   6   8   1   6   8   1   6   8   1   6
   3   5   7   3   5   7   3   5   7   3   5   7
   4   9   2   4   9   2   4   9   2   4   9   2
```

Creating a Block Diagonal Matrix. The `blkdiag` function combines matrices in a diagonal direction, creating what is called a block diagonal matrix. All other elements of the newly created matrix are set to zero:

```
A = magic(3);
B = [-5 -6 -9; -4 -4 -2];
C = eye(2) * 8;
```

```
D = blkdiag(A, B, C)
D =
   8   1   6   0   0   0   0   0
   3   5   7   0   0   0   0   0
   4   9   2   0   0   0   0   0
   0   0   0  -5  -6  -9   0   0
   0   0   0  -4  -4  -2   0   0
   0   0   0   0   0   0   8   0
   0   0   0   0   0   0   0   8
```

Generating a Numeric Sequence

Because numeric sequences can often be useful in constructing and indexing into matrices and arrays, MATLAB provides a special operator to assist in creating them.

This section covers

The Colon Operator

The colon operator (`first:last`) generates a 1-by-n matrix (or *vector*) of sequential numbers from the `first` value to the `last`. The default sequence is made up of incremental values, each 1 greater than the previous one:

```
A = 10:15
A =
    10    11    12    13    14    15
```

The numeric sequence does not have to be made up of positive integers. It can include negative numbers and fractional numbers as well:

```
A = -2.5:2.5
A =
   -2.5000   -1.5000   -0.5000    0.5000    1.5000    2.5000
```

By default, MATLAB always increments by exactly 1 when creating the sequence, even if the ending value is not an integral distance from the start:

```
A = 1:6.3
A =
     1     2     3     4     5     6
```

Also, the default series generated by the colon operator always increments rather than decrementing. The operation shown in this example attempts to increment from 9 to 1 and thus MATLAB returns an empty matrix:

```
A = 9:1
A =
   Empty matrix: 1-by-0
```

The next section explains how to generate a nondefault numeric series.

Using the Colon Operator with a Step Value

To generate a series that does not use the default of incrementing by 1, specify an additional value with the colon operator (`first:step:last`). In between the starting and ending value is a `step` value that tells MATLAB how much to increment (or decrement, if `step` is negative) between each number it generates.

To generate a series of numbers from 10 to 50, incrementing by 5, use

```
A = 10:5:50
A =
    10    15    20    25    30    35    40    45    50
```

You can increment by noninteger values. This example increments by `0.2`:

```
A = 3:0.2:3.8
A =
    3.0000    3.2000    3.4000    3.6000    3.8000
```

To create a sequence with a decrementing interval, specify a negative step value:

```
A = 9:-1:1
A =
    9    8    7    6    5    4    3    2    1
```

Combining Unlike Data Types

Matrices and arrays can be composed of elements of most any MATLAB data type as long as all elements in the matrix are of the same type. If you do include elements of unlike data types when constructing a matrix, MATLAB converts some elements so that all elements of the resulting matrix are of the same type. (See Chapter 2, "Data Types" for information on any of the MATLAB data types discussed here.)

Data type conversion is done with respect to a preset precedence of data types. The following table shows the five data types you can concatenate with an unlike type without generating an error (that is, with the exception of character and logical).

TYPE	character	integer	single	double	logical
character	character	character	character	character	invalid
integer	character	integer	integer	integer	integer
single	character	integer	single	single	single
double	character	integer	single	double	double
logical	invalid	integer	single	double	logical

For example, concatenating a `double` and `single` matrix always yields a matrix of type `single`. MATLAB converts the `double` element to `single` to accomplish this.

Combining Unlike Integer Types

If you combine different integer types in a matrix (e.g., signed with unsigned, or 8-bit integers with 16-bit integers), MATLAB returns a matrix in which all elements are of one common type. MATLAB sets all elements of the resulting matrix to the data type of the left-most element in the input matrix. For example, the result of the following concatenation is a vector of three 16-bit signed integers:

```
A = [int16(450) uint8(250) int32(1000000)]
```

MATLAB also displays a warning to inform you that the result may not be what you had expected:

```
A = [int16(450) uint8(250) int32(1000000)];
Warning: Concatenation with dominant (left-most) integer class
may overflow other operands on conversion to return class.
```

You can disable this warning by entering the following two commands directly after the operation that caused the warning. The first command retrieves the message identifier associated with the most recent warning issued by MATLAB. The second command uses this identifier to disable any further warnings of that type from being issued:

```
[msg, intcat_msgid] = lastwarn;
warning('off', intcat_msgid);
```

To reenable the warning so that it will now be displayed, use

```
warning('on', intcat_msgid);
```

You can use these commands to disable or enable the display of any MATLAB warning.

Example of Combining Unlike Integer Sizes. After disabling the integer concatenation warnings as shown above, concatenate the following two numbers once, and then switch their order. The return value depends on the order in which the integers are concatenated. The left-most type determines the data type for all elements in the vector:

```
A = [int16(5000) int8(50)]
A =
   5000   50

B = [int8(50) int16(5000)]
B =
   50   127
```

The first operation returns a vector of 16-bit integers. The second returns a vector of 8-bit integers. The element `int16(5000)` is set to `127`, the maximum value for an 8-bit signed integer.

The same rules apply to vertical concatenation:

```
C = [int8(50); int16(5000)]
```

```
C =
    50
   127
```

Note You can find the maximum or minimum values for any MATLAB integer type using the `intmax` and `intmin` functions. For floating-point types, use `realmax` and `realmin`.

Example of Combining Signed with Unsigned. Now do the same exercise with signed and unsigned integers. Again, the left-most element determines the data type for all elements in the resulting matrix:

```
A = [int8(-100) uint8(100)]
A =
   -100   100

B = [uint8(100) int8(-100)]
B =
   100   0
```

The element `int8(-100)` is set to zero because it is no longer signed.

MATLAB evaluates each element *prior to* concatenating them into a combined array. In other words, the following statement evaluates to an 8-bit signed integer (equal to 50) and an 8-bit unsigned integer (unsigned -50 is set to zero) before the two elements are combined. Following the concatenation, the second element retains its zero value but takes on the unsigned `int8` type:

```
A = [int8(50), uint8(-50)]
A =
  50    0
```

Combining Integer and Noninteger Data

If you combine integers with `double`, `single`, or `logical` data types, all elements of the resulting matrix are given the data type of the left-most integer. For example, all elements of the following vector are set to `int32`:

```
A = [true pi int32(1000000) single(17.32) uint8(250)]
```

Empty Matrices

If you construct a matrix using empty matrix elements, the empty matrices are ignored in the resulting matrix:

```
A = [5.36; 7.01; []; 9.44]
A =
    5.3600
    7.0100
    9.4400
```

Concatenation Examples

Here are some examples of data type conversion during matrix construction.

Combining Single and Double Types. Combining `single` values with `double` values yields a `single` matrix. Note that `5.73*10^300` is too big to be stored as a `single`, thus the conversion from `double` to `single` sets it to infinity. (The `class` function used in this example returns the data type for the input value):

```
x = [single(4.5) single(-2.8) pi 5.73*10^300]
x =
    4.5000   -2.8000    3.1416       Inf

class(x)              % Display the data type of x
ans =
   single
```

Combining Integer and Double Types. Combining integer values with `double` values yields an integer matrix. Note that the fractional part of `pi` is rounded to the nearest integer. (The `int8` function used in this example converts its numeric argument to an 8-bit integer):

```
x = [int8(21) int8(-22) int8(23) pi 45/6]
x =
    21   -22    23     3     7
```

```
class(x)
ans =
   int8
```

Combining Character and Double Types. Combining `character` values with `double` values yields a `character` matrix. MATLAB converts the `double` elements in this example to their `character` equivalents:

```
x = ['A' 'B' 'C' 68 69 70]
x =
   ABCDEF

class(x)
ans =
   char
```

Combining Logical and Double Types. Combining `logical` values with `double` values yields a `double` matrix. MATLAB converts the `logical` `true` and `false` elements in this example to `double`:

```
x = [true false false pi sqrt(7)]
x =
    1.0000         0         0    3.1416    2.6458

class(x)
ans =
   double
```

Matrix Indexing

In this section...

Accessing Single Elements

To reference a particular element in a matrix, specify its row and column number using the following syntax, where `A` is the matrix variable. Always specify the row first and column second:

```
A(row, column)
```

For example, for a 4-by-4 magic square `A`,

```
A = magic(4)
A =
    16     2     3    13
     5    11    10     8
     9     7     6    12
     4    14    15     1
```

you would access the element at row 4, column 2 with

```
A(4, 2)
ans =
    14
```

For arrays with more than two dimensions, specify additional indices following the `row` and `column` indices. See the section on "Multidimensional Arrays" on page 1-56.

Linear Indexing

With MATLAB, you can refer to the elements of a matrix with a single subscript, `A(k)`. MATLAB stores matrices and arrays not in the shape that they appear when displayed in the MATLAB Command Window, but as a single column of elements. This single column is composed of all of the columns from the matrix, each appended to the last.

So, matrix `A`

```
A = [2 6 9; 4 2 8; 3 5 1]
A =
     2     6     9
     4     2     8
     3     5     1
```

is actually stored in memory as the sequence

```
2, 4, 3, 6, 2, 5, 9, 8, 1
```

The element at row 3, column 2 of matrix `A` (value = `5`) can also be identified as element 6 in the actual storage sequence. To access this element, you have a choice of using the standard `A(3,2)` syntax, or you can use `A(6)`, which is referred to as *linear indexing*.

If you supply more subscripts, MATLAB calculates an index into the storage column based on the dimensions you assigned to the array. For example, assume a two-dimensional array like `A` has size `[d1 d2]`, where `d1` is the number of rows in the array and `d2` is the number of columns. If you supply two subscripts `(i, j)` representing row-column indices, the offset is

```
(j-1) * d1 + i
```

Given the expression `A(3,2)`, MATLAB calculates the offset into `A`'s storage column as `(2-1) * 3 + 3`, or `6`. Counting down six elements in the column accesses the value `5`.

Functions That Control Indexing Style

If you have row-column subscripts but want to use linear indexing instead, you can convert to the latter using the `sub2ind` function. In the 3-by-3 matrix

A used in the previous section, sub2ind changes a standard row-column index of (3,2) to a linear index of 6:

```
A = [2 6 9; 4 2 8; 3 5 1];

linearindex = sub2ind(size(A), 3, 2)
linearindex =
     6
```

To get the row-column equivalent of a linear index, use the ind2sub function:

```
[row col] = ind2sub(size(A), 6)
row =
     3
col =
     2
```

Accessing Multiple Elements

For the 4-by-4 matrix A shown below, it is possible to compute the sum of the elements in the fourth column of A by typing

```
A = magic(4);
A(1,4) + A(2,4) + A(3,4) + A(4,4)
```

You can reduce the size of this expression using the colon operator. Subscript expressions involving colons refer to portions of a matrix. The expression

```
A(1:m, n)
```

refers to the elements in rows 1 through m of column n of matrix A. Using this notation, you can compute the sum of the fourth column of A more succinctly:

```
sum(A(1:4, 4))
```

Nonconsecutive Elements

To refer to nonconsecutive elements in a matrix, use the colon operator with a step value. The m:3:n in this expression means to make the assignment to every third element in the matrix. Note that this example uses linear indexing:

```
B = A;

B(1:3:16) = -10
B =
   -10     2     3   -10
     5    11   -10     8
     9   -10     6    12
   -10    14    15   -10
```

MATLAB supports a type of array indexing that uses one array as the index into another array. You can base this type of indexing on either the values or the positions of elements in the indexing array.

Here is an example of value-based indexing where array `B` indexes into elements `1`, `3`, `6`, `7`, and `10` of array `A`. In this case, the *numeric values* of array `B` designate the intended elements of `A`:

```
A = 5:5:50
A =
     5    10    15    20    25    30    35    40    45    50
B = [1 3 6 7 10];

A(B)
ans =
     5    15    30    35    50
```

The end Keyword

MATLAB provides the keyword `end` to designate the last element in a particular dimension of an array. This keyword can be useful in instances where your program does not know how many rows or columns there are in a matrix. You can replace the expression in the previous example with

```
B(1:3:end) = -10
```

Note The keyword `end` has several meanings in MATLAB. It can be used as explained above, or to terminate a conditional block of code such as `if` and `for` blocks, or to terminate a nested function.

Specifying All Elements of a Row or Column

The colon by itself refers to *all* the elements in a row or column of a matrix. Using the following syntax, you can compute the sum of all elements in the second column of a 4-by-4 magic square `A`:

```
sum(A(:, 2))
ans =
    34
```

By using the colon with linear indexing, you can refer to all elements in the entire matrix. This example displays all the elements of matrix `A`, returning them in a column-wise order:

```
A(:)
ans =
    16
     5
     9
     4
     .
     .
     .
    12
     1
```

Using Logicals in Array Indexing

A logical array index designates the elements of an array `A` based on their *position* in the indexing array, `B`, not their value. In this *masking* type of operation, every `true` element in the indexing array is treated as a positional index into the array being accessed.

In the following example, `B` is a matrix of logical ones and zeros. The position of these elements in `B` determines which elements of `A` are designated by the expression `A(B)`:

```
A = [1 2 3; 4 5 6; 7 8 9]
A =
     1     2     3
     4     5     6
     7     8     9
```

```
B = logical([0 1 0; 1 0 1; 0 0 1]);
B =
     0     1     0
     1     0     1
     0     0     1

A(B)
ans =
     4
     2
     6
     9
```

The `find` function can be useful with logical arrays as it returns the linear indices of nonzero elements in `B`, and thus helps to interpret `A(B)`:

```
find(B)
ans =
     2
     4
     8
     9
```

Logical Indexing – Example 1

This example creates logical array `B` that satisfies the condition `A > 0.5`, and uses the positions of ones in `B` to index into `A`:

```
rand('twister', 5489);     % Initialize the state of the
                           % random number generator.
A = rand(5);
B = A > 0.5;

A(B) = 0
A =
         0    0.0975    0.1576    0.1419         0
         0    0.2785         0    0.4218    0.0357
    0.1270         0         0         0         0
         0         0    0.4854         0         0
         0         0         0         0         0
```

A simpler way to express this is

```
A(A > 0.5) = 0
```

Logical Indexing – Example 2

The next example highlights the location of the prime numbers in a magic square using logical indexing to set the nonprimes to 0:

```
A = magic(4)
A =
    16     2     3    13
     5    11    10     8
     9     7     6    12
     4    14    15     1

B = isprime(A)
B =
     0     1     1     1
     1     1     0     0
     0     1     0     0
     0     0     0     0

A(~B) = 0;                          % Logical indexing

A
A =
     0     2     3    13
     5    11     0     0
     0     7     0     0
     0     0     0     0

find(B)
ans =
     2
     5
     6
     7
     9
    13
```

Logical Indexing with a Smaller Array

In most cases, the logical indexing array should have the same number of elements as the array being indexed into, but this is not a requirement. The indexing array may have smaller (but not larger) dimensions:

```
A = [1 2 3;4 5 6;7 8 9]
A =
     1     2     3
     4     5     6
     7     8     9

B = logical([0 1 0; 1 0 1])
B =
     0     1     0
     1     0     1

isequal(numel(A), numel(B))
ans =
     0

A(B)
ans =
     4
     7
     8
```

MATLAB treats the missing elements of the indexing array as if they were present and set to zero, as in array `C` below:

```
% Add zeros to indexing array C to give it the same number of
% elements as A.
C = logical([B(:);0;0;0]);

isequal(numel(A), numel(C))
ans =
     1

A(C)
ans =
     4
```

```
     7
     8
```

Single-Colon Indexing with Different Array Types

When you index into a standard MATLAB array using a single colon, MATLAB returns a column vector (see variable `n`, below). When you index into a structure or cell array using a single colon, you get a comma-separated list "Comma-Separated Lists" on page 3-79 (see variables `c` and `s`, below).

Create three types of arrays:

```
n = [1 2 3; 4 5 6];
c = {1 2; 3 4};
s = cell2struct(c, {'a', 'b'}, 1);  s(:,2)=s(:,1);
```

Use single-colon indexing on each:

```
n(:)              c{:}              s(:).a
ans =             ans =             ans =
     1                 1                 1
     4             ans =             ans =
     2                 3                 2
     5             ans =             ans =
     3                 2                 1
     6             ans =             ans =
                       4                 2
```

Indexing on Assignment

When assigning values from one matrix to another matrix, you can use any of the styles of indexing covered in this section. Matrix assignment statements also have the following requirement.

In the assignment `A(J,K,...) = B(M,N,...)`, subscripts `J`, `K`, `M`, `N`, etc. may be scalar, vector, or array, provided that all of the following are true:

- The number of subscripts specified for `B`, not including trailing subscripts equal to 1, does not exceed `ndims(B)`.
- The number of nonscalar subscripts specified for `A` equals the number of nonscalar subscripts specified for `B`. For example, `A(5, 1:4, 1, 2)`

`= B(5:8)` is valid because both sides of the equation use one nonscalar subscript.

- The order and length of all nonscalar subscripts specified for `A` matches the order and length of nonscalar subscripts specified for `B`. For example, `A(1:4, 3, 3:9) = B(5:8, 1:7)` is valid because both sides of the equation (ignoring the one scalar subscript `3`) use a 4-element subscript followed by a 7-element subscript.

Getting Information About a Matrix

In this section...

Dimensions of the Matrix

These functions return information about the shape and size of a matrix.

Function	Description
`length`	Return the length of the longest dimension. (The length of a matrix or array with any zero dimension is zero.)
`ndims`	Return the number of dimensions.
`numel`	Return the number of elements.
`size`	Return the length of each dimension.

The following examples show some simple ways to use these functions. Both use the 3-by-5 matrix `A` shown here:

```
rand('state', 0);     % Initialize random number generator
A = rand(5) * 10;
A(4:5, :) = []
A =
    9.5013    7.6210    6.1543    4.0571    0.5789
    2.3114    4.5647    7.9194    9.3547    3.5287
    6.0684    0.1850    9.2181    9.1690    8.1317
```

Example Using numel

Using the `numel` function, find the average of all values in matrix `A`:

```
sum(A(:))/numel(A)
ans =
```

```
    5.8909
```

Example Using ndims, numel, and size

Using `ndims` and `size`, go through the matrix and find those values that are between 5 and 7, inclusive:

```
if ndims(A) ~= 2
   return
end

[rows cols] = size(A);
for m = 1:rows
   for n = 1:cols
      x = A(m, n);
      if x >= 5 && x <= 7
         disp(sprintf('A(%d, %d) = %5.2f', m, n, A(m,n)))
      end
   end
end
```

The code returns the following:

```
A(1, 3) =  6.15
A(3, 1) =  6.07
```

Data Types Used in the Matrix

These functions test elements of a matrix for a specific data type.

Function	Description
`isa`	Detect if input is of a given data type.
`iscell`	Determine if input is a cell array.
`iscellstr`	Determine if input is a cell array of strings.
`ischar`	Determine if input is a character array.
`isfloat`	Determine if input is a floating-point array.
`isinteger`	Determine if input is an integer array.

Function	Description
islogical	Determine if input is a logical array.
isnumeric	Determine if input is a numeric array.
isreal	Determine if input is an array of real numbers.
isstruct	Determine if input is a MATLAB structure array.

Example Using isnumeric and isreal

Pick out the real numeric elements from this vector:

```
A = [5+7i 8/7 4.23 39j pi 9-2i];

for m = 1:numel(A)
   if isnumeric(A(m)) && isreal(A(m))
      disp(A(m))
   end
end
```

The values returned are

```
    1.1429
    4.2300
    3.1416
```

Data Structures Used in the Matrix

These functions test elements of a matrix for a specific data structure.

Function	Description
isempty	Determine if input has any dimension with size zero.
isscalar	Determine if input is a 1-by-1 matrix.
issparse	Determine if input is a sparse matrix.
isvector	Determine if input is a 1-by-n or n-by-1 matrix.

Resizing and Reshaping Matrices

In this section...

Expanding the Size of a Matrix

You can expand the size of any existing matrix as long as doing so does not give the resulting matrix an irregular shape. (See "Keeping Matrices Rectangular" on page 1-8). For example, you can vertically combine a 4-by-3 matrix and 7-by-3 matrix because all rows of the resulting matrix have the same number of columns (3).

Two ways of expanding the size of an existing matrix are

- Concatenating new elements onto the matrix
- Storing to a location outside the bounds of the matrix

Note If you intend to expand the size of a matrix repeatedly over time as it requires more room (usually done in a programming loop), it is advisable to preallocate space for the matrix when you initially create it. See "Preallocating Memory" on page 1-38.

Concatenating Onto the Matrix

Concatenation is most useful when you want to expand a matrix by adding new elements or blocks that are compatible in size with the original matrix. This means that the size of all matrices being joined along a specific dimension must be equal along that dimension. See "Concatenating Matrices" on page 1-8.

This example runs a user-defined function `compareResults` on the data in matrices `stats04` and `stats03`. Each time through the loop, it concatenates the results of this function onto the end of the data stored in `comp04`:

```
col = 10;
comp04 = [];

for k = 1:50
   t = compareResults(stats04(k,1:col), stats03(k,1:col));
   comp04 = [comp04; t];
end
```

Concatenating to a Structure or Cell Array. You can add on to arrays of structures or cells in the same way as you do with ordinary matrices. This example creates a 3-by-8 matrix of structures `S`, each having 3 fields: `x`, `y`, and `z`, and then concatenates a second structure matrix `S2` onto the original:

Create a 3-by-8 structure array `S`:

```
for k = 1:24
   S(k) = struct('x', 10*k, 'y', 10*k+1, 'z', 10*k+2);
end
S = reshape(S, 3, 8);
```

Create a second array that is 3-by-2 and uses the same field names:

```
for k = 25:30
   S2(k-24) = struct('x', 10*k, 'y', 10*k+1, 'z', 10*k+2);
end
S2= reshape(S2, 3, 2);
```

Concatenate `S2` onto `S` along the horizontal dimension:

```
S = [S S2]
S =
3x10 struct array with fields:
    x
    y
    z
```

Adding Smaller Blocks to a Matrix

To add one or more elements to a matrix where the sizes are not compatible, you can often just store the new elements outside the boundaries of the original matrix. MATLAB automatically pads the matrix with zeros to keep it rectangular.

Construct a 3-by-5 matrix, and attempt to add a new element to it using concatenation. The operation fails because you are attempting to join a one-column matrix with one that has five columns:

```
A = [ 10  20  30  40  50; ...
      60  70  80  90 100; ...
     110 120 130 140 150];

A = [A; 160]
??? Error using ==> vertcat
All rows in the bracketed expression must have the same
number of columns.
```

Try this again, but this time do it in such a way that enables MATLAB to make adjustments to the size of the matrix. Store the new element in row 4, a row that does not yet exist in this matrix. MATLAB expands matrix `A` by an entire new row by padding columns 2 through 5 with zeros:

```
A(4,1) = 160
A =
    10    20    30    40    50
    60    70    80    90   100
   110   120   130   140   150
   160     0     0     0     0
```

Note Attempting to read from nonexistent matrix locations generates an error. You can only write to these locations.

You can also expand the matrix by adding a matrix instead of just a single element:

```
A(4:6,1:3) = magic(3)+100
```

```
A =
    10    20    30    40    50
    60    70    80    90   100
   110   120   130   140   150
   108   101   106     0     0
   103   105   107     0     0
   104   109   102     0     0
```

You do not have to add new elements sequentially. Wherever you store the new elements, MATLAB pads with zeros to make the resulting matrix rectangular in shape:

```
A(4,8) = 300
A =
    10    20    30    40    50     0     0     0
    60    70    80    90   100     0     0     0
   110   120   130   140   150     0     0     0
     0     0     0     0     0     0     0   300
```

Expanding a Structure or Cell Array. You can expand a structure or cell array in the same way that you can a matrix. This example adds an additional cell to a cell array by storing it beyond the bounds of the original array. MATLAB pads the data structure with empty cells (`[]`) to keep it rectangular.

The original array is 2-by-3:

```
C = {'Madison', 'G', [5 28 1967]; ...
     46, '325 Maple Dr', 3015.28}
```

Add a cell to `C{3,1}` and MATLAB appends an entire row:

```
C{3, 1} = ...
struct('Fund_A', .45, 'Fund_E', .35, 'Fund_G', 20);
C =
    'Madison'       'G'                [1x3 double]
    [        46]    '325 Maple Dr'    [3.0153e+003]
    [1x1 struct]               []               []
```

Expanding a Character Array. You can expand character arrays in the same manner as other MATLAB arrays, but it is generally not recommended. MATLAB expands any array by padding uninitialized elements with zeros. Because zero is interpreted by MATLAB and some other programming languages as a string terminator, you may find that some functions treat the expanded string as if it were less than its full length.

Expand a 1-by-5 character array to twelve characters. The result appears at first to be a typical string:

```
greeting = 'Hello';    greeting(1,8:12) = 'World'
greeting =
   Hello  World
```

Closer inspection however reveals string terminators at the point of expansion:

```
uint8(greeting)
ans =
   72  101  108  108  111    0    0   87  111  114  108  100
```

This causes some functions, like `strcmp`, to return what might be considered an unexpected result:

```
strcmp(greeting, 'Hello  World')
ans =
     0
```

Diminishing the Size of a Matrix

You can delete rows and columns from a matrix by assigning the empty array `[]` to those rows or columns. Start with

```
A = magic(4)
A =
    16     2     3    13
     5    11    10     8
     9     7     6    12
     4    14    15     1
```

Then, delete the second column of `A` using

```
A(:, 2) = []
```

This changes matrix A to

```
A =
    16     3    13
     5    10     8
     9     6    12
     4    15     1
```

If you delete a single element from a matrix, the result is not a matrix anymore. So expressions like

```
A(1,2) = []
```

result in an error. However, you can use linear indexing to delete a single element, or a sequence of elements. This reshapes the remaining elements into a row vector:

```
A(2:2:10) = []
```

results in

```
A =
    16     9     3     6    13    12     1
```

Reshaping a Matrix

The following functions change the shape of a matrix.

Function	Description
`reshape`	Modify the shape of a matrix.
`rot90`	Rotate the matrix by 90 degrees.
`fliplr`	Flip the matrix about a vertical axis.
`flipud`	Flip the matrix about a horizontal axis.
`flipdim`	Flip the matrix along the specified direction.

Function	Description
transpose	Flip a matrix about its main diagonal, turning row vectors into column vectors and vice versa.
ctranspose	Transpose a matrix and replace each element with its complex conjugate.

Examples

Here are a few examples to illustrate some of the ways you can reshape matrices.

Reshaping a Matrix. Reshape 3-by-4 matrix `A` to have dimensions 2-by-6:

```
A = [1 4 7 10; 2 5 8 11; 3 6 9 12]
A =
    1    4    7    10
    2    5    8    11
    3    6    9    12

B = reshape(A, 2, 6)
B =
    1    3    5    7    9   11
    2    4    6    8   10   12
```

Transposing a Matrix. Transpose `A` so that the row elements become columns. You can use either the `transpose` function or the transpose operator (`.'`) to do this:

```
B = A.'
B =
     1     2     3
     4     5     6
     7     8     9
    10    11    12
```

There is a separate function called ctransposethat performs a complex conjugate transpose of a matrix. The equivalent operator for `ctranpose` on a matrix `A` is `A'`:

```
A = [1+9i 2-8i 3+7i; 4-6i 5+5i 6-4i]
A =
   1.0000 + 9.0000i   2.0000 -8.0000i   3.0000 + 7.0000i
   4.0000 -6.0000i   5.0000 + 5.0000i   6.0000 -4.0000i

B = A'
B =
   1.0000 -9.0000i   4.0000 + 6.0000i
   2.0000 + 8.0000i   5.0000 -5.0000i
   3.0000 -7.0000i   6.0000 + 4.0000i
```

Rotating a Matrix. Rotate the matrix by 90 degrees:

```
B = rot90(A)
B =
    10    11    12
     7     8     9
     4     5     6
     1     2     3
```

Flipping a Matrix. Flip `A` in a left-to-right direction:

```
B = fliplr(A)
B =
    10     7     4     1
    11     8     5     2
    12     9     6     3
```

Preallocating Memory

Repeatedly expanding the size of an array over time, (for example, adding more elements to it each time through a programming loop), can adversely affect the performance of your program. This is because

- MATLAB has to spend time allocating more memory each time you increase the size of the array.
- This newly allocated memory is likely to be noncontiguous, thus slowing down any operations that MATLAB needs to perform on the array.

The preferred method for sizing an array that is expected to grow over time is to estimate the maximum possible size for the array, and preallocate this amount of memory for it at the time the array is created. In this way, your program performs one memory allocation that reserves one contiguous block.

The following command preallocates enough space for a 25,000 by 10,000 matrix, and initializes each element to zero:

```
A = zeros(25000, 10000);
```

Building a Preallocated Array

Once memory has been preallocated for the maximum estimated size of the array, you can store your data in the array as you need it, each time appending to the existing data. This example preallocates a large array, and then reads blocks of data from a file into the array until it gets to the end of the file:

```
blocksize = 5000;
maxrows = 2500000; cols = 20;
rp = 1;     % row pointer

% Preallocate A to its maximum possible size
A = zeros(maxrows, cols);

% Open the data file, saving the file pointer.
fid = fopen('statfile.dat', 'r');

while true
   % Read from file into a cell array.  Stop at EOF.
   block = textscan(fid, '%n', blocksize*cols);
   if isempty(block{1})   break,   end;

   % Convert cell array to matrix, reshape, place into A.
   A(rp:rp+blocksize-1, 1:cols) = ...
      reshape(cell2mat(block), blocksize, cols);

   % Process the data in A.
   evaluate_stats(A);              % User-defined function

   % Update row pointer
```

```
    rp = rp + blocksize;
end
```

Note If you eventually need more room in a matrix than you had preallocated, you can preallocate additional storage in the same manner, and concatenate this additional storage onto the original array.

Shifting and Sorting Matrices

In this section...

Shift and Sort Functions

Use these functions to shift or sort the elements of a matrix.

Function	Description
`circshift`	Circularly shift matrix contents.
`sort`	Sort array elements in ascending or descending order.
`sortrows`	Sort rows in ascending order.
`issorted`	Determine if matrix elements are in sorted order.

You can sort matrices, multidimensional arrays, and cell arrays of strings along any dimension and in ascending or descending order of the elements. The sort functions also return an optional array of indices showing the order in which elements were rearranged during the sorting operation.

Shifting the Location of Matrix Elements

The `circshift` function shifts the elements of a matrix in a circular manner along one or more dimensions. Rows or columns that are shifted out of the matrix circulate back into the opposite end. For example, shifting a 4-by-7 matrix one place to the left moves the elements in columns 2 through 7 to columns 1 through 6, and moves column 1 to column 7.

Create a 5-by-8 matrix named `A` and shift it to the right along the second (horizontal) dimension by three places. (You would use `[0, -3]` to shift to the left by three places):

```
A = [1:8; 11:18; 21:28; 31:38; 41:48]
A =
     1     2     3     4     5     6     7     8
    11    12    13    14    15    16    17    18
    21    22    23    24    25    26    27    28
    31    32    33    34    35    36    37    38
    41    42    43    44    45    46    47    48

B = circshift(A, [0, 3])
B =
     6     7     8     1     2     3     4     5
    16    17    18    11    12    13    14    15
    26    27    28    21    22    23    24    25
    36    37    38    31    32    33    34    35
    46    47    48    41    42    43    44    45
```

Now take `A` and shift it along both dimensions: three columns to the right and two rows up:

```
A = [1:8; 11:18; 21:28; 31:38; 41:48];

B = circshift(A, [-2, 3])
B =
    26    27    28    21    22    23    24    25
    36    37    38    31    32    33    34    35
    46    47    48    41    42    43    44    45
     6     7     8     1     2     3     4     5
    16    17    18    11    12    13    14    15
```

Since `circshift` circulates shifted rows and columns around to the other end of a matrix, shifting by the exact size of `A` returns all rows and columns to their original location:

```
B = circshift(A, size(A));

all(B(:) == A(:))          % Do all elements of B equal A?
ans =
     1                     % Yes
```

Sorting the Data in Each Column

The `sort` function sorts matrix elements along a specified dimension. The syntax for the function is

```
sort(matrix, dimension)
```

To sort the columns of a matrix, specify 1 as the `dimension` argument. To sort along rows, specify `dimension` as 2.

This example first constructs a 6-by-7 random matrix:

```
rand('state', 0);     % Initialize random number generator
A = floor(rand(6,7) * 100);
A =
    95    45    92    41    13     1    84
    23     1    73    89    20    74    52
    60    82    17     5    19    44    20
    48    44    40    35    60    93    67
    89    61    93    81    27    46    83
    76    79    91     0    19    41     1
```

Sort each column of `A` in ascending order:

```
c = sort(A, 1)
c =
    23     1    17     0    13     1     1
    48    44    40     5    19    41    20
    60    45    73    35    19    44    52
    76    61    91    41    20    46    67
    89    79    92    81    27    74    83
    95    82    93    89    60    93    84

issorted(c(:, 1))
ans =
     1
```

Sorting the Data in Each Row

Use `issorted` to sort data in each row. Using the example above, if you sort each row of `A` in descending order, `issorted` tests for an ascending sequence. You can flip the vector to test for a sorted descending sequence:

```
rand('state', 0);     A = floor(rand(6,7) * 100);

r = sort(A, 2, 'descend')
r =
    95    92    84    45    41    13     1
    89    74    73    52    23    20     1
    82    60    44    20    19    17     5
    93    67    60    48    44    40    35
    93    89    83    81    61    46    27
    91    79    76    41    19     1     0

issorted(fliplr(r(1, :)))
ans =
     1
```

When you specify a second output, `sort` returns the indices of the original matrix `A` positioned in the order they appear in the output matrix. In this next example, the second row of `index` contains the sequence `4 3 2 5 1`, which means that the sorted elements in output matrix `r` were taken from `A(2,4)`, `A(2,3)`, `A(2,2)`, `A(2,5)`, and `A(2,1)`:

```
[r index] = sort(A, 2, 'descend');
index
index =
     1     3     7     2     4     5     6
     4     6     3     7     1     5     2
     2     1     6     7     5     3     4
     6     7     5     1     2     3     4
     3     1     7     4     2     6     5
     3     2     1     6     5     7     4
```

Sorting Row Vectors

The `sortrows` function keeps the elements of each row in its original order, but sorts the entire row of vectors according to the order of the elements in the specified column.

The next example creates a random matrix `A`:

```
rand('state', 0);     % Initialize random number generator
A = floor(rand(6,7) * 100);
A =
    95    45    92    41    13     1    84
    23     1    73    89    20    74    52
    60    82    17     5    19    44    20
    48    44    40    35    60    93    67
    89    61    93    81    27    46    83
    76    79    91     0    19    41     1
```

To sort in ascending order based on the values in column 1, you can call `sortrows` with just the one input argument:

```
sortrows(A)
r =
    23     1    73    89    20    74    52
    48    44    40    35    60    93    67
    60    82    17     5    19    44    20
    76    79    91     0    19    41     1
    89    61    93    81    27    46    83
    95    45    92    41    13     1    84
```

To base the sort on a column other than the first, call `sortrows` with a second input argument that indicates the column number, column 4 in this case:

```
r = sortrows(A, 4)
r =
    76    79    91     0    19    41     1
    60    82    17     5    19    44    20
    48    44    40    35    60    93    67
    95    45    92    41    13     1    84
    89    61    93    81    27    46    83
    23     1    73    89    20    74    52
```

Operating on Diagonal Matrices

In this section...

Diagonal Matrix Functions

There are several MATLAB functions that work specifically on diagonal matrices.

Function	Description
`blkdiag`	Construct a block diagonal matrix from input arguments.
`diag`	Return a diagonal matrix or the diagonals of a matrix.
`trace`	Compute the sum of the elements on the main diagonal.
`tril`	Return the lower triangular part of a matrix.
`triu`	Return the upper triangular part of a matrix.

Constructing a Matrix from a Diagonal Vector

The `diag` function has two operations that it can perform. You can use it to generate a diagonal matrix:

```
A = diag([12:4:32])
A =
    12     0     0     0     0     0
     0    16     0     0     0     0
     0     0    20     0     0     0
     0     0     0    24     0     0
     0     0     0     0    28     0
     0     0     0     0     0    32
```

You can also use the `diag` function to scan an existing matrix and return the values found along one of the diagonals:

```
A = magic(5)
A =
    17    24     1     8    15
    23     5     7    14    16
     4     6    13    20    22
    10    12    19    21     3
    11    18    25     2     9

diag(A, 2)       % Return contents of second diagonal of A
ans =
     1
    14
    22
```

Returning a Triangular Portion of a Matrix

The `tril` and `triu` functions return a triangular portion of a matrix, the former returning the piece from the lower left and the latter from the upper right. By default, the main diagonal of the matrix divides these two segments. You can use an alternate diagonal by specifying an offset from the main diagonal as a second input argument:

```
A = magic(6);

B = tril(A, -1)
B =
     0     0     0     0     0     0
     3     0     0     0     0     0
    31     9     0     0     0     0
     8    28    33     0     0     0
    30     5    34    12     0     0
     4    36    29    13    18     0
```

Concatenating Matrices Diagonally

You can diagonally concatenate matrices to form a composite matrix using the `blkdiag` function. See “Creating a Block Diagonal Matrix” on page 1-10 for more information on how this works.

Empty Matrices, Scalars, and Vectors

In this section...

Overview

Although matrices are two dimensional, they do not always appear to have a rectangular shape. A 1-by-8 matrix, for example, has two dimensions yet is linear. These matrices are described in the following sections:

- "The Empty Matrix" on page 1-49

  An *empty matrix* has one of more dimensions that are equal to zero. A two-dimensional matrix with both dimensions equal to zero appears in MATLAB as `[]`. The expression `A = []` assigns a 0-by-0 empty matrix to `A`.

- "Scalars" on page 1-51

  A *scalar* is 1-by-1 and appears in MATLAB as a single real or complex number (e.g., `7`, `583.62`, `-3.51`, `5.46097e-14`, `83+4i`).

- "Vectors" on page 1-52

  A *vector* is 1-by-n or n-by-1, and appears in MATLAB as a row or column of real or complex numbers:

```
Column Vector          Row Vector

   53.2                53.2 87.39 4-12i 43.9
   87.39
   4-12i
   43.9
```

The Empty Matrix

A matrix having at least one dimension equal to zero is called an empty matrix. The simplest empty matrix is 0-by-0 in size. Examples of more complex matrices are those of dimension 0-by-5 or 10-by-0.

To create a 0-by-0 matrix, use the square bracket operators with no value specified:

```
A = [];

whos A
  Name      Size         Bytes  Class

  A         0x0              0  double array
```

You can create empty matrices (and arrays) of other sizes using the `zeros`, `ones`, `rand`, or `eye` functions. To create a 0-by-5 matrix, for example, use

```
A = zeros(0,5)
```

Operating on an Empty Matrix

The basic model for empty matrices is that any operation that is defined for `m`-by-`n` matrices, and that produces a result whose dimension is some function of `m` and `n`, should still be allowed when `m` or `n` is zero. The size of the result of this operation is consistent with the size of the result generated when working with nonempty values, but instead is evaluated at zero.

For example, horizontal concatenation

```
C = [A B]
```

requires that `A` and `B` have the same number of rows. So if `A` is `m`-by-`n` and `B` is `m`-by-`p`, then `C` is `m-by-(n+p)`. This is still true if `m` or `n` or `p` is zero.

As with all matrices in MATLAB, you must follow the rules concerning compatible dimensions. In the following example, an attempt to add a 1-by-3 matrix to a 0-by-3 empty matrix results in an error:

```
[1 2 3] + ones(0,3)
??? Error using ==> +
Matrix dimensions must agree.
```

Common Operations. The following operations on an empty scalar array return zero:

```
A = [];
size(A), length(A), numel(A), any(A), sum(A)
```

These operations on an empty scalar array return a nonzero value:

```
A = [];
ndims(A), isnumeric(A), isreal(A), isfloat(A), isempty(A), ...
   all(A), prod(A)
```

Using Empty Matrices in Relational Operations

You can use empty matrices in relational operations such as "equal to" (==) or "greater than" (>) as long as both operands have the same dimensions, or the nonempty operand is scalar. The result of any relational operation involving an empty matrix is the empty matrix. Even comparing an empty matrix for equality to itself does not return `true`, but instead yields an empty matrix:

```
x = ones(0,3);
y = x;

y == x
ans =
   Empty matrix: 0-by-3
```

Using Empty Matrices in Logical Operations

MATLAB has two distinct types of logical operators:

- Short-circuit (`&&`, `||`) — Used in testing multiple logical conditions (e.g., `x >= 50 && x < 100`) where each condition evaluates to a scalar `true` or `false`.
- Element-wise (`&`, `|`) — Performs a logical AND, OR, or NOT on each element of a matrix or array.

Short-circuit Operations. The rule for operands used in short-circuit operations is that each operand must be convertible to a logical scalar value. Because of this rule, empty matrices cannot be used in short-circuit logical operations. Such operations return an error.

The only exception is in the case where MATLAB can determine the result of a logical statement without having to evaluate the entire expression. This is true for the following two statements because the result of the entire statements are known by considering just the first term:

```
true || []
ans =
   1

false && []
ans =
   0
```

Elementwise Operations. Unlike the short-circuit operators, all elementwise operations on empty matrices are considered valid as long as the dimensions of the operands agree, or the nonempty operand is scalar. Element-wise operations on empty matrices always return an empty matrix:

```
true | []
ans =
   []
```

Note This behavior is consistent with the way MATLAB does scalar expansion with binary operators, wherein the nonscalar operand determines the size of the result.

•

Scalars

Any individual real or complex number is represented in MATLAB as a 1-by-1 matrix called a scalar value:

```
A = 5;

ndims(A)        % Check number of dimensions in A
ans =
     2

size(A)         % Check value of row and column dimensions
ans =
     1     1
```

Use the `isscalar` function to tell if a variable holds a scalar value:

```
isscalar(A)
ans =
    1
```

Vectors

Matrices with one dimension equal to one and the other greater than one are called vectors. Here is an example of a numeric vector:

```
A = [5.73 2-4i 9/7 25e3 .046 sqrt(32) 8j];

size(A)         % Check value of row and column dimensions
ans =
     1     7
```

You can construct a vector out of other vectors, as long as the critical dimensions agree. All components of a row vector must be scalars or other row vectors. Similarly, all components of a column vector must be scalars or other column vectors:

```
A = [29 43 77 9 21];
B = [0 46 11];

C = [A 5 ones(1,3) B]
C =
   29   43   77    9   21    5    1    1    1    0   46   11
```

Concatenating an empty matrix to a vector has no effect on the resulting vector. The empty matrix is ignored in this case:

```
A = [5.36; 7.01; []; 9.44]
A =
    5.3600
    7.0100
    9.4400
```

Use the `isvector` function to tell if a variable holds a vector:

```
isvector(A)
ans =
    1
```

Full and Sparse Matrices

In this section...

Overview

It is not uncommon to have matrices with a large number of zero-valued elements and, because MATLAB stores zeros in the same way it stores any other numeric value, these elements can use memory space unnecessarily and can sometimes require extra computing time.

Sparse matrices provide a way to store data that has a large percentage of zero elements more efficiently. While *full matrices* internally store every element in memory regardless of value, *sparse matrices* store only the nonzero elements and their row indices. Using sparse matrices can significantly reduce the amount of memory required for data storage.

You can create sparse matrices for the `double` and `logical` data types. All MATLAB built-in arithmetic, logical, and indexing operations can be applied to sparse matrices, or to mixtures of sparse and full matrices. Operations on sparse matrices return sparse matrices and operations on full matrices return full matrices.

See the section on Sparse Matrices in the MATLAB Mathematics documentation for more information on working with sparse matrices.

Sparse Matrix Functions

This table shows some of the functions most commonly used when working with sparse matrices.

Function	Description
`full`	Convert a sparse matrix to a full matrix.
`issparse`	Determine if a matrix is sparse.

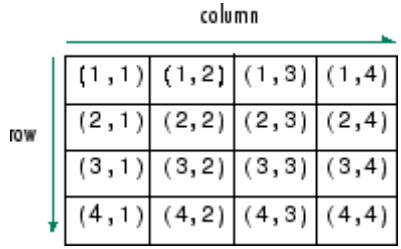
Function	Description
`nnz`	Return the number of nonzero matrix elements.
`nonzeros`	Return the nonzero elements of a matrix.
`nzmax`	Return the amount of storage allocated for nonzero elements.
`spalloc`	Allocate space for a sparse matrix.
`sparse`	Create a sparse matrix or convert full to sparse.
`speye`	Create a sparse identity matrix.
`sprand`	Create a sparse uniformly distributed random matrix.

Multidimensional Arrays

In this section...

Overview

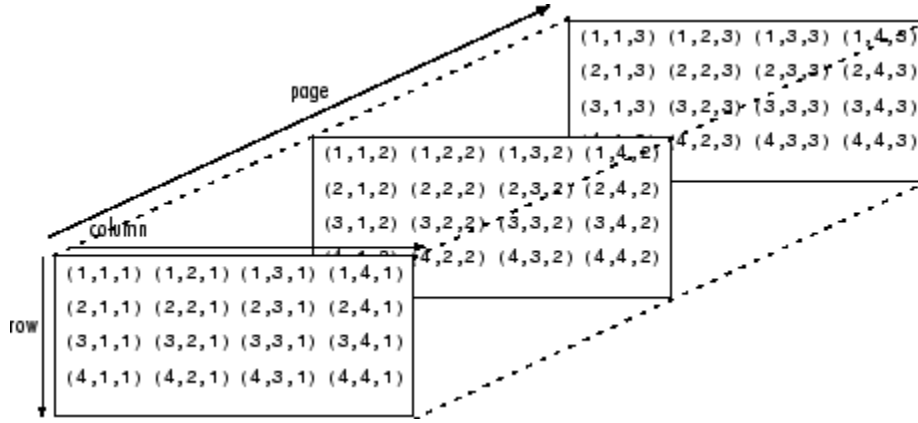
An array having more than two dimensions is called a multidimensional array in MATLAB. Multidimensional arrays in MATLAB are an extension of the normal two-dimensional matrix. Matrices have two dimensions: the row dimension and the column dimension.



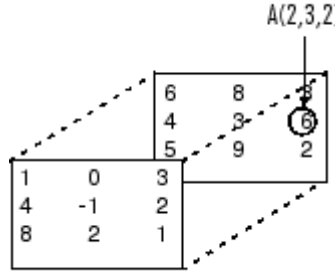
You can access a two-dimensional matrix element with two subscripts: the first representing the row index, and the second representing the column index.

Multidimensional arrays use additional subscripts for indexing. A three-dimensional array, for example, uses three subscripts:

- The first references array dimension 1, the row.
- The second references dimension 2, the column.
- The third references dimension 3. This illustration uses the concept of a *page* to represent dimensions 3 and higher.



To access the element in the second row, third column of page 2, for example, you use the subscripts `(2,3,2)`.



```
A(:,:,1) =

     1     0     3
     4    -1     2
     8     2     1

A(:,:,2) =

     6     8     3
     4     3     6
     5     9     2
```

As you add dimensions to an array, you also add subscripts. A four-dimensional array, for example, has four subscripts. The first two reference a row-column pair; the second two access the third and fourth dimensions of data.

Most of the operations that you can perform on matrices (i.e., two-dimensional arrays) can also be done on multidimensional arrays.

Note The general multidimensional array functions reside in the `datatypes` directory.

Creating Multidimensional Arrays

You can use the same techniques to create multidimensional arrays that you use for two-dimensional matrices. In addition, MATLAB provides a special concatenation function that is useful for building multidimensional arrays.

This section discusses

Generating Arrays Using Indexing

One way to create a multidimensional array is to create a two-dimensional array and extend it. For example, begin with a simple two-dimensional array `A`.

```
A = [5 7 8; 0 1 9; 4 3 6];
```

`A` is a 3-by-3 array, that is, its row dimension is 3 and its column dimension is 3. To add a third dimension to `A`,

```
A(:,:,2) = [1 0 4; 3 5 6; 9 8 7]
```

MATLAB responds with

```
A(:,:,1) =
     5     7     8
     0     1     9
     4     3     6

A(:,:,2) =
     1     0     4
     3     5     6
     9     8     7
```

You can continue to add rows, columns, or pages to the array using similar assignment statements.

Extending Multidimensional Arrays

To extend `A` in any dimension:

- Increment or add the appropriate subscript and assign the desired values.
- Assign the same number of elements to corresponding array dimensions. For numeric arrays, all rows must have the same number of elements, all pages must have the same number of rows and columns, and so on.

You can take advantage of the MATLAB scalar expansion capabilities, together with the colon operator, to fill an entire dimension with a single value:

```
A(:,:,3) = 5;

A(:,:,3)
ans =
     5     5     5
     5     5     5
     5     5     5
```

To turn `A` into a 3-by-3-by-3-by-2, four-dimensional array, enter

```
A(:,:,1,2) = [1 2 3; 4 5 6; 7 8 9];
A(:,:,2,2) = [9 8 7; 6 5 4; 3 2 1];
A(:,:,3,2) = [1 0 1; 1 1 0; 0 1 1];
```

Note that after the first two assignments MATLAB pads `A` with zeros, as needed, to maintain the corresponding sizes of dimensions.

Generating Arrays Using MATLAB Functions

You can use MATLAB functions such as `randn`, `ones`, and `zeros` to generate multidimensional arrays in the same way you use them for two-dimensional arrays. Each argument you supply represents the size of the corresponding dimension in the resulting array. For example, to create a 4-by-3-by-2 array of normally distributed random numbers:

```
B = randn(4,3,2)
```

To generate an array filled with a single constant value, use the `repmat` function. `repmat` replicates an array (in this case, a 1-by-1 array) through a vector of array dimensions.

```
B = repmat(5, [3 4 2])

B(:,:,1) =
     5     5     5     5
     5     5     5     5
     5     5     5     5

B(:,:,2) =
     5     5     5     5
     5     5     5     5
     5     5     5     5
```

Note Any dimension of an array can have size zero, making it a form of empty array. For example, 10-by-0-by-20 is a valid size for a multidimensional array.

Building Multidimensional Arrays with the cat Function

The `cat` function is a simple way to build multidimensional arrays; it concatenates a list of arrays along a specified dimension:

```
B = cat(dim, A1, A2...)
```

where A1, A2, and so on are the arrays to concatenate, and dim is the dimension along which to concatenate the arrays.

For example, to create a new array with cat:

```
B = cat(3, [2 8; 0 5], [1 3; 7 9])

B(:,:,1) =
     2     8
     0     5

B(:,:,2) =
     1     3
     7     9
```

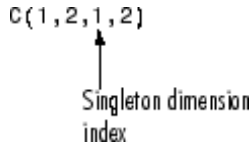
The cat function accepts any combination of existing and new data. In addition, you can nest calls to cat. The lines below, for example, create a four-dimensional array.

```
A = cat(3, [9 2; 6 5], [7 1; 8 4])
B = cat(3, [3 5; 0 1], [5 6; 2 1])
D = cat(4, A, B, cat(3, [1 2; 3 4], [4 3;2 1]))
```

cat automatically adds subscripts of 1 between dimensions, if necessary. For example, to create a 2-by-2-by-1-by-2 array, enter

```
C = cat(4, [1 2; 4 5], [7 8; 3 2])
```

In the previous case, cat inserts as many singleton dimensions as needed to create a four-dimensional array whose last dimension is not a singleton dimension. If the dim argument had been 5, the previous statement would have produced a 2-by-2-by-1-by-1-by-2 array. This adds additional 1s to indexing expressions for the array. To access the value 8 in the four-dimensional case, use



Accessing Multidimensional Array Properties

You can use the following MATLAB functions to get information about multidimensional arrays you have created.

- `size` — Returns the size of each array dimension.

```
size(C)
ans =
    2      2      1      2
  rows  columns  dim3   dim4
```

- `ndims` — Returns the number of dimensions in the array.

```
ndims(C)
ans =
    4
```

- `whos` — Provides information on the format and storage of the array.

```
whos
Name     Size       Bytes   Class

A        2x2x2         64   double array
B        2x2x2         64   double array
C        4-D           64   double array
D        4-D          192   double array

Grand total is 48 elements using 384 bytes
```

Indexing Multidimensional Arrays

Many of the concepts that apply to two-dimensional matrices extend to multidimensional arrays as well.

To access a single element of a multidimensional array, use integer subscripts. Each subscript indexes a dimension—the first indexes the row dimension, the second indexes the column dimension, the third indexes the first page dimension, and so on.

Consider a 10-by-5-by-3 array `nddata` of random integers:

```
nddata = fix(8 * randn(10,5,3));
```

To access element `(3,2)` on page 2 of `nddata`, for example, use `nddata(3,2,2)`.

You can use vectors as array subscripts. In this case, each vector element must be a valid subscript, that is, within the bounds defined by the dimensions of the array. To access elements `(2,1)`, `(2,3)`, and `(2,4)` on page 3 of `nddata`, use

```
nddata(2,[1 3 4],3);
```

The Colon and Multidimensional Array Indexing

The MATLAB colon indexing extends to multidimensional arrays. For example, to access the entire third column on page 2 of `nddata`, use `nddata(:,3,2)`.

The colon operator is also useful for accessing other subsets of data. For example, `nddata(2:3,2:3,1)` results in a 2-by-2 array, a subset of the data on page 1 of `nddata`. This matrix consists of the data in rows 2 and 3, columns 2 and 3, on the first page of the array.

The colon operator can appear as an array subscript on both sides of an assignment statement. For example, to create a 4-by-4 array of zeros:

```
C = zeros(4, 4)
```

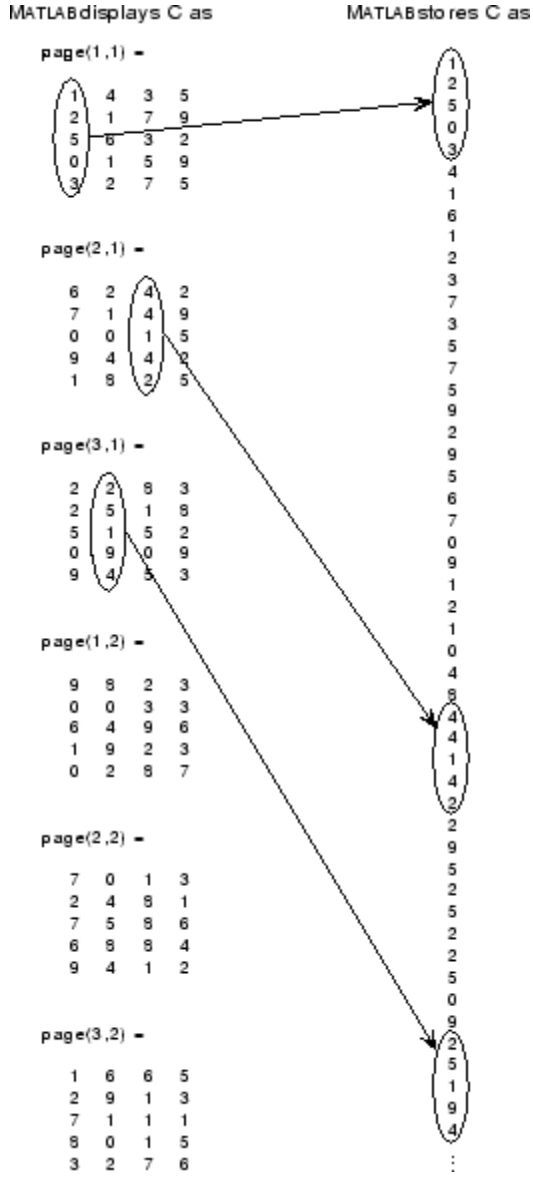
Now assign a 2-by-2 subset of array `nddata` to the four elements in the center of `C`.

```
C(2:3,2:3) = nddata(2:3,1:2,2)
```

Linear Indexing with Multidimensional Arrays

MATLAB linear indexing also extends to multidimensional arrays. In this case, MATLAB operates on a page-by-page basis to create the storage column, again appending elements columnwise. See “Linear Indexing” on page 1-19 for an introduction to this topic.

For example, consider a 5-by-4-by-3-by-2 array `C`.



Again, a single subscript indexes directly into this column. For example, `C(4)` produces the result

```
ans =
     0
```

If you specify two subscripts `(i,j)` indicating row-column indices, MATLAB calculates the offset as described above. Two subscripts always access the first page of a multidimensional array, provided they are within the range of the original array dimensions.

If more than one subscript is present, all subscripts must conform to the original array dimensions. For example, `C(6,2)` is invalid because all pages of `C` have only five rows.

If you specify more than two subscripts, MATLAB extends its indexing scheme accordingly. For example, consider four subscripts `(i,j,k,l)` into a four-dimensional array with size `[d1 d2 d3 d4]`. MATLAB calculates the offset into the storage column by

```
(l-1)(d3)(d2)(d1)+(k-1)(d2)(d1)+(j-1)(d1)+i
```

For example, if you index the array `C` using subscripts (3, 4, 2, 1), MATLAB returns the value 5 (index 38 in the storage column).

In general, the offset formula for an array with dimensions $[d_1\ d_2\ d_3\ \ldots\ d_n]$ using any subscripts $(s_1\ s_2\ s_3\ \ldots\ s_n)$ is

$$(s_n-1)(d_{n-1})(d_{n-2})\ldots(d_1)+(s_{n-1}-1)(d_{n-2})\ldots(d_1)+\ldots+(s_2-1)(d_1)+s_1$$

Because of this scheme, you can index an array using any number of subscripts. You can append any number of 1s to the subscript list because these terms become zero. For example,

```
C(3,2,1,1,1,1,1,1)
```

is equivalent to

```
C(3,2)
```

Avoiding Ambiguity in Multidimensional Indexing

Some assignment statements, such as

```
A(:,:,2) = 1:10
```

are ambiguous because they do not provide enough information about the shape of the dimension to receive the data. In the case above, the statement tries to assign a one-dimensional vector to a two-dimensional destination. MATLAB produces an error for such cases. To resolve the ambiguity, be sure you provide enough information about the destination for the assigned data, and that both data and destination have the same shape. For example:

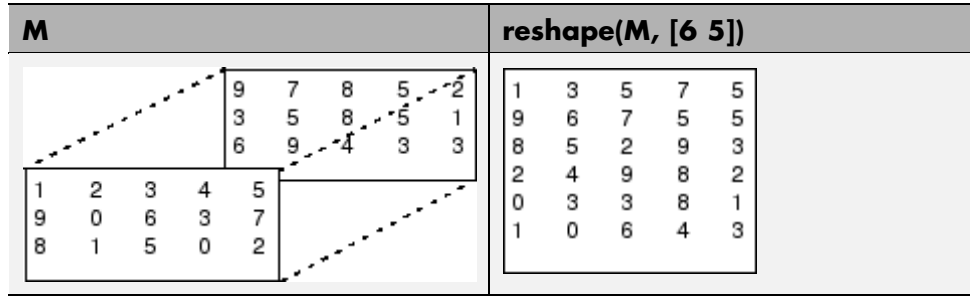
```
A(1,:,2) = 1:10;
```

Reshaping Multidimensional Arrays

Unless you change its shape or size, a MATLAB array retains the dimensions specified at its creation. You change array size by adding or deleting elements. You change array shape by respecifying the array's row, column, or page dimensions while retaining the same elements. The `reshape` function performs the latter operation. For multidimensional arrays, its form is

```
B = reshape(A,[s1 s2 s3 ...])
```

`s1`, `s2`, and so on represent the desired size for each dimension of the reshaped matrix. Note that a reshaped array must have the same number of elements as the original array (that is, the product of the dimension sizes is constant).



The `reshape` function operates in a columnwise manner. It creates the reshaped matrix by taking consecutive elements down each column of the original data construct.

C	reshape(C, [6 2])
	1 6 3 8 2 9 4 11 5 10 7 12

Here are several new arrays from reshaping `nddata`:

```
B = reshape(nddata, [6 25])
C = reshape(nddata, [5 3 10])
D = reshape(nddata, [5 3 2 5])
```

Removing Singleton Dimensions

MATLAB creates singleton dimensions if you explicitly specify them when you create or reshape an array, or if you perform a calculation that results in an array dimension of one:

```
B = repmat(5, [2 3 1 4]);

size(B)
ans =
     2     3     1     4
```

The `squeeze` function removes singleton dimensions from an array:

```
C = squeeze(B);

size(C)
ans =
     2     3     4
```

The `squeeze` function does not affect two-dimensional arrays; row vectors remain rows.

Permuting Array Dimensions

The `permute` function reorders the dimensions of an array:

```
B = permute(A, dims);
```

`dims` is a vector specifying the new order for the dimensions of `A`, where 1 corresponds to the first dimension (rows), 2 corresponds to the second dimension (columns), 3 corresponds to pages, and so on.

A

```
A(:,:,1) =

     1     2     3
     4     5     6
     7     8     9

A(:,:,2) =

     0     5     4
     2     7     6
     9     3     1
```

B = permute(A, [2 1 3])

```
B(:,:,1) =

     1     4     7
     2     5     8
     3     6     9

B(:,:,2) =

     0     2     9
     5     7     3
     4     6     1
```

Row and column subscripts are reversed (page-by-page transposition).

C = permute(A, [3 2 1])

```
C(:,:,1) =

     1     2     3
     0     5     4

C(:,:,2) =

     4     5     6
     2     7     6

C(:,:,3) =

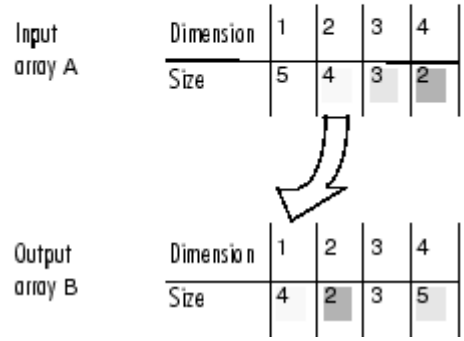
     7     8     9
     9     3     1
```

Row and page subscripts are reversed.

For a more detailed look at the `permute` function, consider a four-dimensional array `A` of size 5-by-4-by-3-by-2. Rearrange the dimensions, placing the column dimension first, followed by the second page dimension, the first page dimension, then the row dimension. The result is a 4-by-2-by-3-by-5 array.

```
B = permute(A,[2 4 3 1])
```

Move dimension 2 of A to first subscript position of B, dimension 4 to second subscript position, and so on.



The order of dimensions in `permute`'s argument list determines the size and shape of the output array. In this example, the second dimension moves to the first position. Because the second dimension of the original array had size 4, the output array's first dimension also has size 4.

You can think of `permute`'s operation as an extension of the `transpose` function, which switches the row and column dimensions of a matrix. For `permute`, the order of the input dimension list determines the reordering of the subscripts. In the example above, element `(4,2,1,2)` of `A` becomes element `(2,2,1,4)` of `B`, element `(5,4,3,2)` of `A` becomes element `(4,2,3,5)` of `B`, and so on.

Inverse Permutation

The `ipermute` function is the inverse of `permute`. Given an input array `A` and a vector of dimensions `v`, `ipermute` produces an array `B` such that `permute(B,v)` returns `A`.

For example, these statements create an array `E` that is equal to the input array `C`:

```
D = ipermute(C, [1 4 2 3]);
E = permute(D, [1 4 2 3])
```

You can obtain the original array after permuting it by calling `ipermute` with the same vector of dimensions.

Computing with Multidimensional Arrays

Many of the MATLAB computational and mathematical functions accept multidimensional arrays as arguments. These functions operate on specific dimensions of multidimensional arrays; that is, they operate on individual elements, on vectors, or on matrices.

Operating on Vectors

Functions that operate on vectors, like `sum`, `mean`, and so on, by default typically work on the first nonsingleton dimension of a multidimensional array. Most of these functions optionally let you specify a particular dimension on which to operate. There are exceptions, however. For example, the `cross` function, which finds the cross product of two vectors, works on the first nonsingleton dimension having length 3.

Note In many cases, these functions have other restrictions on the input arguments — for example, some functions that accept multiple arrays require that the arrays be the same size. Refer to the online help for details on function arguments.

Operating Element-by-Element

MATLAB functions that operate element-by-element on two-dimensional arrays, like the trigonometric and exponential functions in the `elfun` directory, work in exactly the same way for multidimensional cases. For example, the `sin` function returns an array the same size as the function's input argument. Each element of the output array is the sine of the corresponding element of the input array.

Similarly, the arithmetic, logical, and relational operators all work with corresponding elements of multidimensional arrays that are the same size in every dimension. If one operand is a scalar and one an array, the operator applies the scalar to each element of the array.

Operating on Planes and Matrices

Functions that operate on planes or matrices, such as the linear algebra and matrix functions in the `matfun` directory, do not accept multidimensional

arrays as arguments. That is, you cannot use the functions in the `matfun` directory, or the array operators *, `^`, `\`, or `/`, with multidimensional arguments. Supplying multidimensional arguments or operands in these cases results in an error.

You can use indexing to apply a matrix function or operator to matrices within a multidimensional array. For example, create a three-dimensional array `A`:

```
A = cat(3, [1 2 3; 9 8 7; 4 6 5], [0 3 2; 8 8 4; 5 3 5], ...
    [6 4 7; 6 8 5; 5 4 3]);
```

Applying the `eig` function to the entire multidimensional array results in an error:

```
eig(A)
??? Error using ==> eig
Input arguments must be 2-D.
```

You can, however, apply `eig` to planes within the array. For example, use colon notation to index just one page (in this case, the second) of the array:

```
eig(A(:,:,2))
ans =
   12.9129
   -2.6260
    2.7131
```

Note In the first case, subscripts are not colons; you must use `squeeze` to avoid an error. For example, `eig(A(2,:,:))` results in an error because the size of the input is `[1 3 3]`. The expression `eig(squeeze(A(2,:,:)))`, however, passes a valid two-dimensional matrix to `eig`.

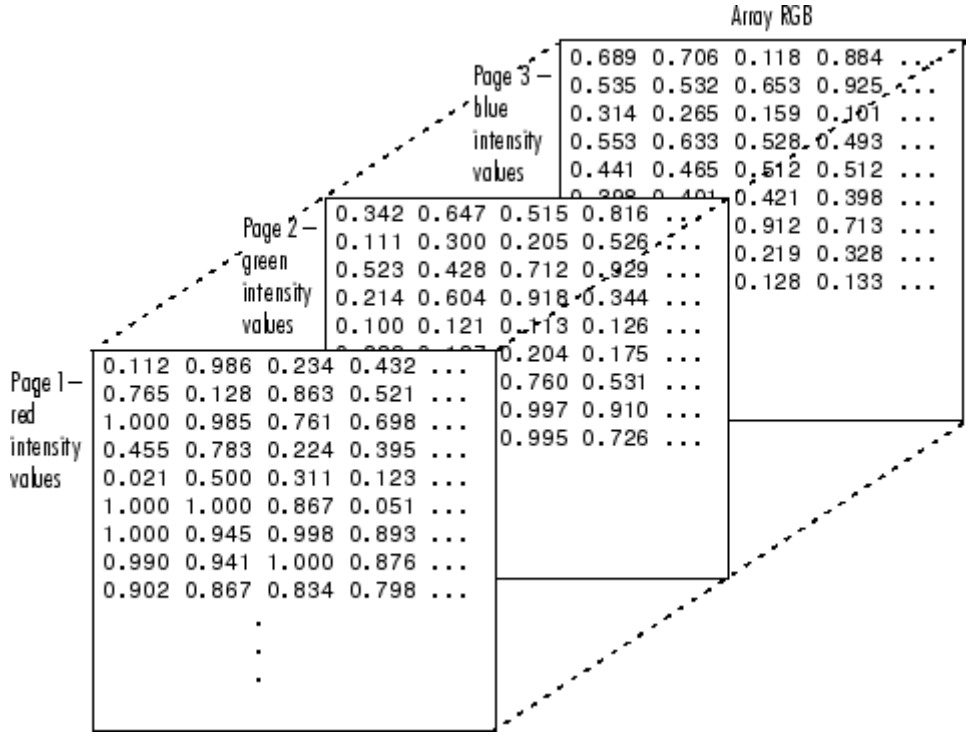
Organizing Data in Multidimensional Arrays

You can use multidimensional arrays to represent data in two ways:

- As planes or pages of two-dimensional data. You can then treat these pages as matrices.

- As multivariate or multidimensional data. For example, you might have a four-dimensional array where each element corresponds to either a temperature or air pressure measurement taken at one of a set of equally spaced points in a room.

For example, consider an RGB image. For a single image, a multidimensional array is probably the easiest way to store and access data.



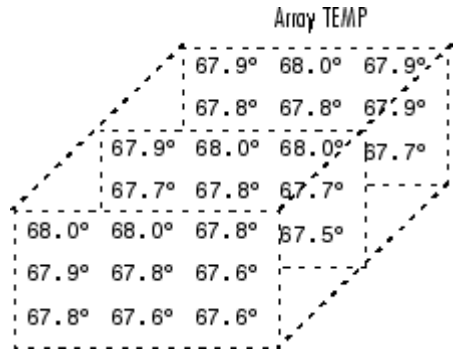
To access an entire plane of the image, use

```
redPlane = RGB(:,:,1);
```

To access a subimage, use

```
subimage = RGB(20:40,50:85,:);
```

The RGB image is a good example of data that needs to be accessed in planes for operations like display or filtering. In other instances, however, the data itself might be multidimensional. For example, consider a set of temperature measurements taken at equally spaced points in a room. Here the location of each value is an integral part of the data set—the physical placement in three-space of each element is an aspect of the information. Such data also lends itself to representation as a multidimensional array.



Now to find the average of all the measurements, use

```
mean(mean(mean(TEMP)));
```

To obtain a vector of the “middle” values (element (2,2)) in the room on each page, use

```
B = TEMP(2,2,:);
```

Multidimensional Cell Arrays

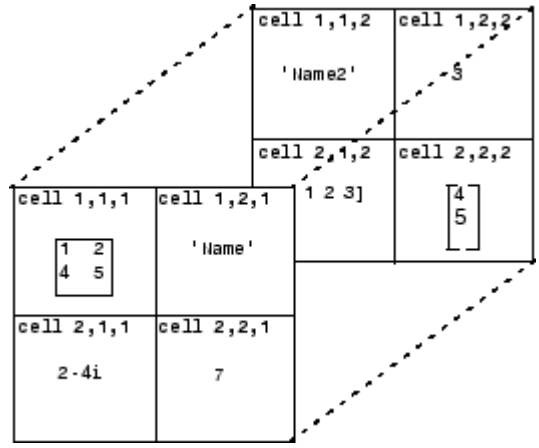
Like numeric arrays, the framework for multidimensional cell arrays in MATLAB is an extension of the two-dimensional cell array model. You can use the `cat` function to build multidimensional cell arrays, just as you use it for numeric arrays.

For example, create a simple three-dimensional cell array `C`:

```
A{1,1} = [1 2;4 5];
A{1,2} = 'Name';
A{2,1} = 2-4i;
```

```
A{2,2} = 7;
B{1,1} = 'Name2';
B{1,2} = 3;
B{2,1} = 0:1:3;
B{2,2} = [4 5]';
C = cat(3, A, B);
```

The subscripts for the cells of `C` look like

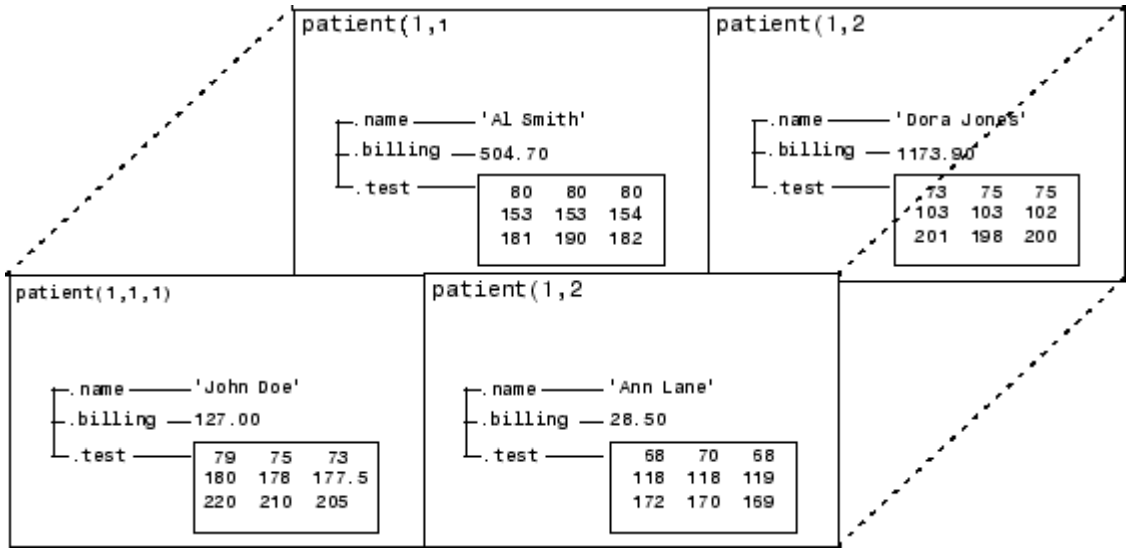


Multidimensional Structure Arrays

Multidimensional structure arrays are extensions of rectangular structure arrays. Like other types of multidimensional arrays, you can build them using direct assignment or the `cat` function:

```
patient(1,1,1).name = 'John Doe';
patient(1,1,1).billing = 127.00;
patient(1,1,1).test = [79 75 73; 180 178 177.5; 220 210 205];
patient(1,2,1).name = 'Ann Lane';
patient(1,2,1).billing = 28.50;
patient(1,2,1).test = [68 70 68; 118 118 119; 172 170 169];
patient(1,1,2).name = 'Al Smith';
patient(1,1,2).billing = 504.70;
patient(1,1,2).test = [80 80 80; 153 153 154; 181 190 182];
patient(1,2,2).name = 'Dora Jones';
```

```
patient(1,2,2).billing = 1173.90;
patient(1,2,2).test = [73 73 75; 103 103 102; 201 198 200];
```



Applying Functions to Multidimensional Structure Arrays

To apply functions to multidimensional structure arrays, operate on fields and field elements using indexing. For example, find the sum of the columns of the `test` array in `patient(1,1,2)`:

```
sum((patient(1,1,2).test));
```

Similarly, add all the `billing` fields in the `patient` array:

```
total = sum([patient.billing]);
```

Summary of Matrix and Array Functions

This section summarizes the principal functions used in creating and handling matrices. Most of these functions work on multidimensional arrays as well.

Functions to Create a Matrix

Function	Description
`[a,b]` or `[a;b]`	Create a matrix from specified elements, or concatenate matrices together.
`accumarray`	Construct a matrix using accumulation.
`blkdiag`	Construct a block diagonal matrix.
`cat`	Concatenate matrices along the specified dimension.
`diag`	Create a diagonal matrix from a vector.
`horzcat`	Concatenate matrices horizontally.
`magic`	Create a square matrix with rows, columns, and diagonals that add up to the same number.
`ones`	Create a matrix of all ones.
`rand`	Create a matrix of uniformly distributed random numbers.
`repmat`	Create a new matrix by replicating or tiling another.
`vertcat`	Concatenate two or more matrices vertically.
`zeros`	Create a matrix of all zeros.

Functions to Modify the Shape of a Matrix

Function	Description
ctranspose	Flip a matrix about the main diagonal and replace each element with its complex conjugate.
`flipdim`	Flip a matrix along the specified dimension.
`fliplr`	Flip a matrix about a vertical axis.

Functions to Modify the Shape of a Matrix (Continued)

Function	Description
`flipud`	Flip a matrix about a horizontal axis.
`reshape`	Change the dimensions of a matrix.
`rot90`	Rotate a matrix by 90 degrees.
transpose	Flip a matrix about the main diagonal.

Functions to Find the Structure or Shape of a Matrix

Function	Description
`isempty`	Return `true` for 0-by-0 or 0-by-n matrices.
`isscalar`	Return `true` for 1-by-1 matrices.
`issparse`	Return `true` for sparse matrices.
`isvector`	Return `true` for 1-by-n matrices.
`length`	Return the length of a vector.
`ndims`	Return the number of dimensions in a matrix.
`numel`	Return the number of elements in a matrix.
`size`	Return the size of each dimension.

Functions to Determine Data Type

Function	Description
`iscell`	Return `true` if the matrix is a cell array.
`ischar`	Return `true` if matrix elements are characters or strings.
`isfloat`	Determine if input is a floating point array.
`isinteger`	Determine if input is an integer array.
`islogical`	Return `true` if matrix elements are logicals.
`isnumeric`	Return `true` if matrix elements are numeric.

Functions to Determine Data Type (Continued)

Function	Description
`isreal`	Return `true` if matrix elements are real numbers.
`isstruct`	Return `true` if matrix elements are MATLAB structures.

Functions to Sort and Shift Matrix Elements

Function	Description
`circshift`	Circularly shift matrix contents.
`issorted`	Return `true` if the matrix elements are sorted.
`sort`	Sort elements in ascending or descending order.
`sortrows`	Sort rows in ascending order.

Functions That Work on Diagonals of a Matrix

Function	Description
`blkdiag`	Construct a block diagonal matrix.
`diag`	Return the diagonals of a matrix.
`trace`	Compute the sum of the elements on the main diagonal.

Functions That Work on Diagonals of a Matrix (Continued)

Function	Description
`tril`	Return the lower triangular part of a matrix.
`triu`	Return the upper triangular part of a matrix.

Functions to Change the Indexing Style

Function	Description
`ind2sub`	Convert a linear index to a row-column index.
`sub2ind`	Convert a row-column index to a linear index.

Functions for Working with Multidimensional Arrays

Function	Description
`cat`	Concatenate arrays.
`circshift`	Shift array circularly.
`ipermute`	Inverse permute array dimensions.
`ndgrid`	Generate arrays for `n`-dimensional functions and interpolation.
`ndims`	Return the number of array dimensions.
`permute`	Permute array dimensions.
`shiftdim`	Shift array dimensions.
`squeeze`	Remove singleton dimensions.

2

Data Types

Overview of MATLAB Data Types

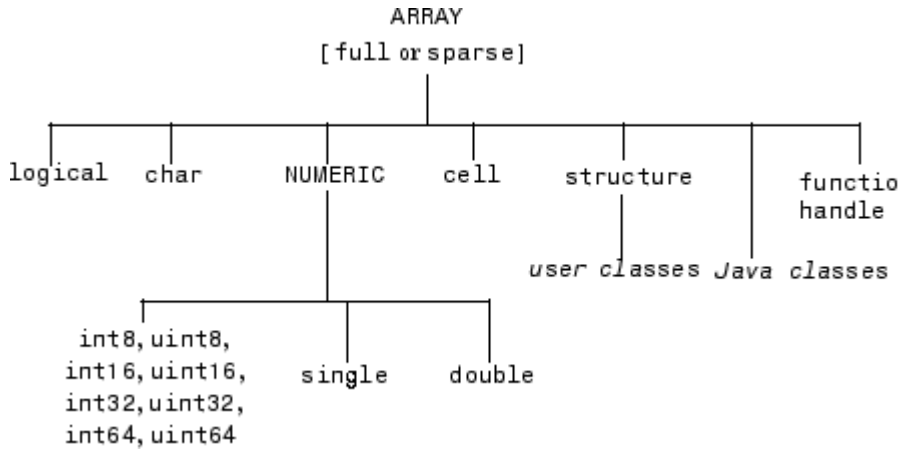
In this section...

Fundamental Data Types

There are many different types of data that you can work with in MATLAB. You can build matrices and arrays of floating-point and integer data, characters and strings, logical `true` and `false` states, etc. Two of the MATLAB data types, structures and cell arrays, provide a way to store dissimilar types of data in the same array. You can also develop your own data types using MATLAB classes.

There are 15 fundamental data types in MATLAB. Each of these data types is in the form of a matrix or array. This matrix or array is a minimum of 0-by-0 in size and can grow to an n-dimensional array of any size.

All of the fundamental data types are shown in lowercase, plain nonitalic text in the diagram below.



The two data types shown in italic text are user-defined, object-oriented *`user classes`* and *`Java classes`*. You can use the latter with the MATLAB interface to Java (see "Calling Java from MATLAB" in the MATLAB External Interfaces documentation).

You can create two-dimensional `double` and `logical` matrices using one of two storage formats: `full` or `sparse`. For matrices with mostly zero-valued elements, a sparse matrix requires a fraction of the storage space required for an equivalent full matrix. Sparse matrices invoke methods especially tailored to solve sparse problems

These data types require different amounts of storage, the smallest being a `logical` value or 8–bit integer which requires only 1 byte. It is important to keep this minimum size in mind if you work on data in files that were written using a precision smaller than 8 bits.

How to Use the Different Types

The following table describes these data types in more detail.

Data Type	Example	Description
`int8, uint8, int16, uint16, int32, uint32, int64, uint64`	`uint16(65000)`	Array of signed (`int`) and unsigned (`uint`) integers. Some integer types require less storage space than `single` or `double`. All integer types except for `int64` and `uint64` can be used in mathematical operations.
`single`	`single(3 * 10^38)`	Array of single-precision numbers. Requires less storage space than `double`, but has less precision and a smaller range.
`double`	`3 * 10^300` `5 + 6i`	Array of double-precision numbers. Two-dimensional arrays can be sparse. The default numeric type in MATLAB.
`logical`	`magic(4) > 10`	Array of logical values of `1` or `0` to represent `true` and `false` respectively. Two-dimensional arrays can be sparse.

Data Type	Example	Description
`char`	`'Hello'`	Array of characters. Strings are represented as vectors of characters. For arrays containing more than one string, it is best to use cell arrays.
`cell array`	`a{1,1} = 12; a{1,2} = 'Red'; a{1,3} = magic(4);`	Array of indexed cells, each capable of storing an array of a different dimension and data type.
`structure`	`a.day = 12; a.color = 'Red'; a.mat = magic(3);`	Array of C-like structures, each structure having named fields capable of storing an array of a different dimension and data type.
`function handle`	`@sin`	Pointer to a function. You can pass function handles to other functions.
`user class`	`polynom([0 -2 -5])`	Objects constructed from a user-defined class. See “MATLAB Classes” on page 2-117
`Java class`	`java.awt.Frame`	Objects constructed from a Java class. See “Java Classes” on page 2-118.

Numeric Types

In this section...

Overview

Numeric data types in MATLAB include signed and unsigned integers, and single- and double-precision floating-point numbers. By default, MATLAB stores all numeric values as double-precision floating point. (You cannot change the default type and precision.) You can choose to store any number, or array of numbers, as integers or as single-precision. Integer and single-precision arrays offer more memory-efficient storage than double-precision.

All numeric types support basic array operations, such as subscripting and reshaping. All numeric types except for `int64` and `uint64` can be used in mathematical operations.

Integers

MATLAB has four signed and four unsigned integer data types. Signed types enable you to work with negative integers as well as positive, but cannot represent as wide a range of numbers as the unsigned types because one bit is used to designate a positive or negative sign for the number. Unsigned types give you a wider range of numbers, but these numbers can only be zero or positive.

This section covers:

MATLAB supports 1-, 2-, 4-, and 8-byte storage for integer data. You can save memory and execution time for your programs if you use the smallest integer type that accommodates your data. For example, you don't need a 32-bit integer to store the value `100`.

Here are the eight integer data types, the range of values you can store with each type, and the MATLAB conversion function required to create that type:

Data Type	Range of Values	Conversion Function
Signed 8-bit integer	-2^7 to 2^7-1	`int8`
Signed 16-bit integer	-2^{15} to $2^{15}-1$	`int16`
Signed 32-bit integer	-2^{31} to $2^{31}-1$	`int32`
Signed 64-bit integer	-2^{63} to $2^{63}-1$	`int64`
Unsigned 8-bit integer	0 to 2^8-1	`uint8`
Unsigned 16-bit integer	0 to $2^{16}-1$	`uint16`
Unsigned 32-bit integer	0 to $2^{32}-1$	`uint32`
Unsigned 64-bit integer	0 to $2^{64}-1$	`uint64`

Creating Integer Data

MATLAB stores numeric data as double-precision floating point (`double`) by default. To store data as an integer, you need to convert from `double` to the desired integer type. Use one of the conversion functions shown in the table above.

For example, to store `325` as a 16-bit signed integer assigned to variable `x`, type

```
x = int16(325);
```

If the number being converted to an integer has a fractional part, MATLAB rounds to the nearest integer. If the fractional part is exactly `0.5`, then from the two equally nearby integers, MATLAB chooses the one for which the absolute value is larger in magnitude:

```
x = 325.499;                    x = x + .001;

int16(x)                        int16(x)
ans =                           ans =
     325                             326
```

If you need to round a number using a rounding scheme other than the default, MATLAB provides four rounding functions: `round`, `fix`, `floor`, and `ceil`. In this example, the `fix` function enables you to override the default and round *towards zero* when the fractional part of a number is `.5`:

```
x = 325.5;

int16(fix(x))
ans =
     325
```

Arithmetic operations that involve both integers and floating-point always result in an integer data type. MATLAB rounds the result, when necessary, according to the default rounding algorithm. The example below yields an exact answer of `1426.75` which MATLAB then rounds to the next highest integer:

```
int16(325) * 4.39
ans =
     1427
```

The integer conversion functions are also useful when converting other data types, such as strings, to integers:

```
str = 'Hello World';

int8(str)
ans =
   72  101  108  108  111   32   87  111  114  108  100
```

Arithmetic Operations on Integer Data Types

MATLAB can perform integer arithmetic on the following types of data:

- Integers or integer arrays of the same integer data type. This yields a result that has the same data type as the operands:

```
x = uint32([132 347 528]) .* uint32(75);
```

- Integers or integer arrays and scalar double-precision floating-point numbers. This yields a result that has the same data type as the integer operands:

```
x = uint32([132 347 528]) .* 75.49;
```

For all binary operations in which one operand is an array of integer data type and the other is a scalar `double`, MATLAB computes the operation using elementwise double-precision arithmetic, and then converts the result back to the original integer data type.

For a list of the operations that support integer data types, see Nondouble Data Type Support in the arithmetic operators reference page.

Largest and Smallest Values for Integer Data Types

For each integer data type, there is a largest and smallest number that you can represent with that type. The table shown under “Integers” on page 2-6 lists the largest and smallest values for each integer data type in the “Range of Values” column.

You can also obtain these values with the `intmax` and `intmin` functions:

```
intmax('int8')                intmin('int8')
ans =                         ans =
   127                           -128
```

If you convert a number that is larger than the maximum value of an integer data type to that type, MATLAB sets it to the maximum value. Similarly, if

you convert a number that is smaller than the minimum value of the integer data type, MATLAB sets it to the minimum value. For example,

```
x = int8(300)
x =
   127
```

```
x = int8(-300)
x =
   -128
```

Also, when the result of an arithmetic operation involving integers exceeds the maximum (or minimum) value of the data type, MATLAB sets it to the maximum (or minimum) value:

```
x = int8(100) * 3
x =
   127
```

```
x = int8(-100) * 3
x =
   -128
```

You can make MATLAB return a warning when your input is outside the range an integer data type. This is described in the next section.

Warnings for Integer Data Types

Use the `intwarning` function to make MATLAB return a warning message when it converts a number outside the range of an integer data type to that type, or when the result of an arithmetic operation overflows. There are four possible warning messages that you can turn on using `intwarning`:

Message Identifier	Reason for Warning
`MATLAB:intConvertOverflow`	Overflow when attempting to convert from a numeric class to an integer class
`MATLAB:intMathOverflow`	Overflow when attempting an integer arithmetic operation
`MATLAB:intConvertNonIntVal`	Attempt to convert a noninteger value to an integer
`MATLAB:intConvertNaN`	Attempt to convert NaN (Not a Number) to an integer

Querying the Present Warning State. Use the following command to display the state of all integer warnings:

```
intwarning('query')
   The state of warning 'MATLAB:intConvertNaN' is 'off'.
   The state of warning 'MATLAB:intConvertNonIntVal' is 'off'.
   The state of warning 'MATLAB:intConvertOverflow' is 'off'.
   The state of warning 'MATLAB:intMathOverflow' is 'off'.
```

To display the state of one or more selected warnings, index into the structure returned by `intwarning`. This example shows the current state of the `intConvertOverflow` warning:

```
iwState = intwarning('query');
iwState(3)
ans =
    identifier: 'MATLAB:intConvertOverflow'
         state: 'off'
```

Turning the Warning On. To enable all four integer warnings, use `intwarning` with the string `'on'`:

```
intwarning('on');
intwarning('query')
   The state of warning 'MATLAB:intConvertNaN' is 'on'.
   The state of warning 'MATLAB:intConvertNonIntVal' is 'on'.
   The state of warning 'MATLAB:intConvertOverflow' is 'on'.
   The state of warning 'MATLAB:intMathOverflow' is 'on'.
```

To enable one or more selected integer warnings, first make sure that all integer warnings are disabled:

```
intwarning('off');
```

Note that, in this state, the following conversion to a 16-bit integer overflows, but does not issue a warning:

```
x = int16(50000)
x =
  32767
```

Find which of the four warnings covers integer conversion. In this case, it is the third in the structure array:

```
iwState = intwarning('query');
iwState(3).identifier
ans =
   MATLAB:intConvertOverflow
```

Set the warning state to `'on'` in the structure, and then call `intwarning` using the structure as input:

```
iwState(3).state = 'on';
intwarning(iwState);
```

With the warning enabled, the overflow on conversion does issue the warning message:

```
x = int16(50000)
Warning: Out of range value converted to intmin('int16') or
intmax('int16').
x =
  32767
```

You can also use the following `for` loop to enable integer warnings selectively:

```
maxintwarn = 4;

for k = 1:maxintwarn
   if strcmp(iwState(k).identifier, 'MATLAB:intConvertOverflow')
      iwState(k).state = 'on';
      intwarning(iwState);
   end
end
```

Turning the Warning Off. To turn all integer warnings off (their default state when you start MATLAB), enter

```
intwarning('off')
```

To disable selected integer warnings, follow the steps shown for enabling warnings, but with the `state` field of the structure set to `'off'`:

```
iwState(3).identifier
ans =
```

```
   MATLAB:intConvertOverflow

iwState(3).state = 'off';
intwarning(iwState);
```

Turning Warnings On or Off Temporarily. When writing M-files that contain integer data types, it is sometimes convenient to temporarily turn integer warnings on, and then return the states of the warnings (`'on'` or `'off'`) to their previous settings. The following commands illustrate how to do this:

```
oldState = intwarning('on');

int8(200);
Warning: Out of range value converted to intmin('int8') or
intmax('int8').

intwarning(oldState)
```

To temporarily turn the warnings off, change the first line of the preceding code to

```
oldState = intwarning('off');
```

Recommended Usage of Math Overflow Warning. Enabling the `MATLAB:intMathOverflow` warning slows down integer arithmetic. It is recommended that you enable this particular warning only when you need to diagnose unusual behavior in your code, and disable it during normal program operation. The other integer warnings listed above do not affect program performance.

Note that calling `intwarning('on')` enables all four integer warnings, including the `intMathOverflow` warning that can have an effect on integer arithmetic.

Integer Functions

See Integer Functions on page 2-30 for a list of functions most commonly used with integers in MATLAB.

Floating-Point Numbers

MATLAB represents floating-point numbers in either double-precision or single-precision format. The default is double precision, but you can make any number single precision with a simple conversion function.

This section covers:

Double-Precision Floating Point

MATLAB constructs the double-precision (or `double`) data type according to IEEE Standard 754 for double precision. Any value stored as a `double` requires 64 bits, formatted as shown in the table below:

Bits	Usage
63	Sign (`0` = positive, `1` = negative)
62 to 52	Exponent, biased by `1023`
51 to 0	Fraction `f` of the number `1.f`

Single-Precision Floating Point

MATLAB constructs the single-precision (or `single`) data type according to IEEE Standard 754 for single precision. Any value stored as a `single` requires 32 bits, formatted as shown in the table below:

Bits	Usage
31	Sign (0 = positive, 1 = negative)
30 to 23	Exponent, biased by 127
22 to 0	Fraction `f` of the number `1.f`

Because MATLAB stores numbers of type `single` using 32 bits, they require less memory than numbers of type `double`, which use 64 bits. However, because they are stored with fewer bits, numbers of type `single` are represented to less precision than numbers of type `double`.

Creating Floating-Point Data

Use double-precision to store values greater than approximately 3.4×10^{38} or less than approximately -3.4×10^{38}. For numbers that lie between these two limits, you can use either double- or single-precision, but single requires less memory.

Double-Precision. Because the default numeric type for MATLAB is `double`, you can create a `double` with a simple assignment statement:

```
x = 25.783;
```

The `whos` function shows that MATLAB has created a 1-by-1 array of type `double` for the value you just stored in `x`:

```
whos(x)
  Name      Size                    Bytes  Class

  x         1x1                         8  double
```

Use `isfloat` if you just want to verify that `x` is a floating-point number. This function returns logical 1 (`true`) if the input is a floating-point number, and logical 0 (`false`) otherwise:

```
isfloat(x)
ans =
     1
```

You can convert other numeric data, characters or strings, and logical data to double precision using the MATLAB function, `double`. This example converts a signed integer to double-precision floating point:

```
y = int64(-589324077574);          % Create a 64-bit integer

x = double(y)                      % Convert to double
x =
   -5.8932e+011
```

Single-Precision. Because MATLAB stores numeric data as a `double` by default, you need to use the `single` conversion function to create a single-precision number:

```
x = single(25.783);
```

The `whos` function returns the attributes of variable `x` in a structure. The `bytes` field of this structure shows that when `x` is stored as a single, it requires just 4 bytes compared with the 8 bytes to store it as a `double`:

```
xAttrib = whos('x');
xAttrib.bytes
ans =
     4
```

You can convert other numeric data, characters or strings, and logical data to single precision using the `single` function. This example converts a signed integer to single-precision floating point:

```
y = int64(-589324077574);          % Create a 64-bit integer

x = single(y)                      % Convert to single
x =
   -5.8932e+011
```

Arithmetic Operations on Floating-Point Numbers

This section describes which data types you can use in arithmetic operations with floating-point numbers.

Double-Precision. You can perform basic arithmetic operations with `double` and any of the following other data types. When one or more operands is an integer (scalar or array), the `double` operand must be a scalar. The result is of type `double`, except where noted otherwise:

- `single` — The result is of type `single`
- `double`
- `int*` or `uint*` — The result has the same data type as the integer operand
- `char`
- `logical`

This example performs arithmetic on data of types `char` and `double`. The result is of type `double`:

```
c = 'uppercase' - 32;

class(c)
ans =
   double

char(c)
ans =
   UPPERCASE
```

Single-Precision. You can perform basic arithmetic operations with `single` and any of the following other data types. The result is always `single`:

- `single`
- `double`
- `char`
- `logical`

In this example, 7.5 defaults to type `double`, and the result is of type `single`:

```
x = single([1.32 3.47 5.28]) .* 7.5;

class(x)
ans =
   single
```

Largest and Smallest Values for Floating-Point Data Types

For the `double` and `single` data types, there is a largest and smallest number that you can represent with that type.

Double-Precision. The MATLAB functions `realmax` and `realmin` return the maximum and minimum values that you can represent with the `double` data type:

```
str = 'The range for double is:\n\t%g to %g and\n\t %g to  %g';
sprintf(str, -realmax, -realmin, realmin, realmax)

ans =
The range for double is:
   -1.79769e+308 to -2.22507e-308 and
    2.22507e-308 to  1.79769e+308
```

Numbers larger than `realmax` or smaller than `-realmax` are assigned the values of positive and negative infinity, respectively:

```
realmax + .0001e+308
ans =
   Inf

-realmax - .0001e+308
ans =
  -Inf
```

Single-Precision. The MATLAB functions `realmax` and `realmin`, when called with the argument `'single'`, return the maximum and minimum values that you can represent with the `single` data type:

```
str = 'The range for single is:\n\t%g to %g and\n\t %g to  %g';
sprintf(str, -realmax('single'), -realmin('single'), ...
   realmin('single'), realmax('single'))

ans =
The range for single is:
   -3.40282e+038 to -1.17549e-038 and
    1.17549e-038 to  3.40282e+038
```

Numbers larger than `realmax`('single') or smaller than `-realmax` ('single') are assigned the values of positive and negative infinity, respectively:

```
realmax('single') + .0001e+038
ans =
   Inf

-realmax('single') - .0001e+038
ans =
  -Inf
```

Accuracy of Floating-Point Data

If the result of a floating-point arithmetic computation is not as precise as you had expected, it is likely caused by the limitations of your computer's hardware. Probably, your result was a little less exact because the hardware had insufficient bits to represent the result with perfect accuracy; therefore, it truncated the resulting value.

Double-Precision. Because there are only a finite number of double-precision numbers, you cannot represent all numbers in double-precision storage. On any computer, there is a small gap between each double-precision number and the next larger double-precision number. You can determine the size of this gap, which limits the precision of your results, using the `eps` function. For example, to find the distance between `5` and the next larger double-precision number, enter

```
format long

eps(5)
ans =
```

```
    8.881784197001252e-016
```

This tells you that there are no double-precision numbers between 5 and `5 + eps(5)`. If a double-precision computation returns the answer 5, the result is only accurate to within `eps(5)`.

The value of `eps(x)` depends on `x`. This example shows that, as `x` gets larger, so does `eps(x)`:

```
eps(50)
ans =
    7.105427357601002e-015
```

If you enter `eps` with no input argument, MATLAB returns the value of `eps(1)`, the distance from `1` to the next larger double-precision number.

Single-Precision. Similarly, there are gaps between any two single-precision numbers. If `x` has type `single`, `eps(x)` returns the distance between `x` and the next larger single-precision number. For example,

```
x = single(5);
eps(x)
```

returns

```
ans =
  4.7684e-007
```

Note that this result is larger than `eps(5)`. Because there are fewer single-precision numbers than double-precision numbers, the gaps between the single-precision numbers are larger than the gaps between double-precision numbers. This means that results in single-precision arithmetic are less precise than in double-precision arithmetic.

For a number `x` of type `double`, `eps(single(x))` gives you an upper bound for the amount that `x` is rounded when you convert it from `double` to `single`. For example, when you convert the double-precision number `3.14` to `single`, it is rounded by

```
double(single(3.14) - 3.14)
ans =
```

```
  1.0490e-007
```

The amount that `3.14` is rounded is less than

```
eps(single(3.14))
ans =
  2.3842e-007
```

Avoiding Common Problems with Floating-Point Arithmetic

Almost all operations in MATLAB are performed in double-precision arithmetic conforming to the IEEE standard 754. Because computers only represent numbers to a finite precision (double precision calls for 52 mantissa bits), computations sometimes yield mathematically nonintuitive results. It is important to note that these results are not bugs in MATLAB.

Use the following examples to help you identify these cases:

Example 1 — Round-Off or What You Get Is Not What You Expect.
The decimal number `4/3` is not exactly representable as a binary fraction. For this reason, the following calculation does not give zero, but rather reveals the quantity `eps`.

```
e = 1 - 3*(4/3 - 1)

e =
  2.2204e-016
```

Similarly, `0.1` is not exactly representable as a binary number. Thus, you get the following nonintuitive behavior:

```
a = 0.0;
for i = 1:10
  a = a + 0.1;
end
a == 1

ans =
     0
```

Note that the order of operations can matter in the computation:

```
b = 1e-16 + 1 - 1e-16;
c = 1e-16 - 1e-16 + 1;
b == c

ans =
     0
```

There are gaps between floating-point numbers. As the numbers get larger, so do the gaps, as evidenced by:

```
(2^53 + 1) - 2^53

ans =
     0
```

Since `pi` is not really `pi`, it is not surprising that `sin(pi)` is not exactly zero:

```
sin(pi)

ans =
   1.224646799147353e-016
```

Example 2 — Catastrophic Cancellation. When subtractions are performed with nearly equal operands, sometimes cancellation can occur unexpectedly. The following is an example of a cancellation caused by swamping (loss of precision that makes the addition insignificant):

```
sqrt(1e-16 + 1) - 1

ans =
     0
```

Some functions in MATLAB, such as `expm1` and `log1p`, may be used to compensate for the effects of catastrophic cancellation.

Example 3 — Floating-Point Operations and Linear Algebra.
Round-off, cancellation, and other traits of floating-point arithmetic combine to produce startling computations when solving the problems of linear algebra. MATLAB warns that the following matrix `A` is ill-conditioned, and therefore the system `Ax = b` may be sensitive to small perturbations. Although the computation differs from what you expect in exact arithmetic, the result is correct.

```
A = [2 eps -eps; eps 1 1; -eps 1 1];
b = [2; eps + 2; -eps + 2];
x = A\b

x =
  1.0e+015 *
   0.000000000000001
   2.251799813685249
  -2.251799813685247
```

These are only a few of the examples showing how IEEE floating-point arithmetic affects computations in MATLAB. Note that all computations performed in IEEE 754 arithmetic are affected, this includes applications written in C or FORTRAN, as well as MATLAB. For more examples and information, see `Technical Note 1108  Common Problems with Floating-Point Arithmetic`.

Floating-Point Functions

See Floating-Point Functions on page 2-30 for a list of functions most commonly used with floating-point numbers in MATLAB.

References

The following references provide more information about floating-point arithmetic.

Complex Numbers

Complex numbers consist of two separate parts: a real part and an imaginary part. The basic imaginary unit is equal to the square root of `-1`. This is represented in MATLAB by either of two letters: `i` or `j`.

Creating Complex Numbers

The following statement shows one way of creating a complex value in MATLAB. The variable `x` is assigned a complex number with a real part of `2` and an imaginary part of `3`:

```
x = 2 + 3i;
```

Another way to create a complex number is using the `complex` function. This function combines two numeric inputs into a complex output, making the first input real and the second imaginary:

```
x = rand(3) * 5;
y = rand(3) * -8;

z = complex(x, y)
z =
   4.7842 -1.0921i   0.8648 -1.5931i   1.2616 -2.2753i
   2.6130 -0.0941i   4.8987 -2.3898i   4.3787 -3.7538i
   4.4007 -7.1512i   1.3572 -5.2915i   3.6865 -0.5182i
```

You can separate a complex number into its real and imaginary parts using the `real` and `imag` functions:

```
zr = real(z)
zr =
    4.7842    0.8648    1.2616
    2.6130    4.8987    4.3787
    4.4007    1.3572    3.6865

zi = imag(z)
zi =
   -1.0921   -1.5931   -2.2753
   -0.0941   -2.3898   -3.7538
   -7.1512   -5.2915   -0.5182
```

Complex Number Functions

See Complex Number Functions on page 2-31 for a list of functions most commonly used with MATLAB complex numbers in MATLAB.

Infinity and NaN

MATLAB uses the special values `inf`, `-inf`, and `NaN` to represent values that are positive and negative infinity, and not a number respectively.

Infinity

MATLAB represents infinity by the special value `inf`. Infinity results from operations like division by zero and overflow, which lead to results too large to represent as conventional floating-point values. MATLAB also provides a function called `inf` that returns the IEEE arithmetic representation for positive infinity as a `double` scalar value.

Several examples of statements that return positive or negative infinity in MATLAB are shown here.

`x = 1/0`
`x =`
`Inf`
	`x = 1.e1000`
	`x =`
	`Inf`

`x = exp(1000)`
`x =`
`Inf`
	`x = log(0)`
	`x =`
	`-Inf`

Use the `isinf` function to verify that `x` is positive or negative infinity:

```
x = log(0);

isinf(x)
ans =
     1
```

NaN

MATLAB represents values that are not real or complex numbers with a special value called `NaN`, which stands for Not a Number. Expressions like `0/0` and `inf/inf` result in `NaN`, as do any arithmetic operations involving a `NaN`.

For example, the statement `n/0`, where `n` is complex, returns `NaN` for the real part of the result:

```
x = 7i/0
x =
      NaN +    Infi
```

Use the `isnan` function to verify that the real part of `x` is NaN:

```
isnan(real(x))
ans =
     1
```

MATLAB also provides a function called `NaN` that returns the IEEE arithmetic representation for `NaN` as a `double` scalar value:

```
x = NaN;

whos x
  Name      Size                    Bytes  Class

  x         1x1                         8  double
```

Logical Operations on NaN. Because two `NaN`s are not equal to each other, logical operations involving `NaN` always return false, except for a test for inequality, (`NaN ~= NaN`):

```
NaN > NaN
ans =
     0

NaN ~= NaN
ans =
     1
```

Infinity and NaN Functions

See Infinity and NaN Functions on page 2-31 for a list of functions most commonly used with `inf` and `NaN` in MATLAB.

Identifying Numeric Types

You can check the data type of a variable `x` using any of these commands.

Command	Operation
`whos x`	Display the data type of `x`.
`xType = class(x);`	Assign the data type of `x` to a variable.
`isnumeric(x)`	Determine if `x` is a numeric type.

`isa(x, 'integer')`
`isa(x, 'uint64')`
`isa(x, 'float')`
`isa(x, 'double')`
`isa(x, 'single')`
	Determine if `x` is the specified numeric type. (Examples for any integer, unsigned 64-bit integer, any floating point, double precision, and single precision are shown here).

`isreal(x)`	Determine if `x` is real or complex.
`isnan(x)`	Determine if `x` is Not a Number (`NaN`).
`isinf(x)`	Determine if `x` is infinite.
`isfinite(x)`	Determine if `x` is finite.

Display Format for Numeric Values

By default, MATLAB displays numeric output as 5-digit scaled, fixed-point values. You can change the way numeric values are displayed to any of the following:

- 5-digit scaled fixed point, floating point, or the best of the two
- 15-digit scaled fixed point, floating point, or the best of the two
- A ratio of small integers
- Hexadecimal (base 16)
- Bank notation

All available formats are listed on the `format` reference page.

To change the numeric display setting, use either the `format` function or the **Preferences** dialog box (accessible from the MATLAB **File** menu). The `format` function changes the display of numeric values for the duration of a single MATLAB session, while your Preferences settings remain active from one session to the next. These settings affect only how numbers are displayed, not how MATLAB computes or saves them.

Display Format Examples

Here are a few examples of the various formats and the output produced from the following two-element vector `x`, with components of different magnitudes.

Check the current format setting:

```
get(0, 'format')
ans =
   short
```

Set the value for `x` and display in 5-digit scaled fixed point:

```
x = [4/3 1.2345e-6]
x =
    1.3333    0.0000
```

Set the format to 5-digit floating point:

```
format short e
x
x =
  1.3333e+000  1.2345e-006
```

Set the format to 15-digit scaled fixed point:

```
format long
x
x =
   1.33333333333333   0.00000123450000
```

Set the format to `'rational'` for small integer ratio output:

```
format rational
x
x =
     4/3          1/810045
```

Set an integer value for `x` and display it in hexadecimal (base 16) format:

```
format hex
x = uint32(876543210)
x =
   343efcea
```

Setting Numeric Format in a Program

To temporarily change the numeric format inside a program, get the original format using the `get` function and save it in a variable. When you finish working with the new format, you can restore the original format setting using the `set` function as shown here:

```
origFormat = get(0, 'format');
format('rational');

  -- Work in rational format --

set(0,'format', origFormat);
```

Function Summary

MATLAB provides these functions for working with numeric data types:

- Integer Functions on page 2-30
- Floating-Point Functions on page 2-30
- Complex Number Functions on page 2-31
- Infinity and NaN Functions on page 2-31
- Type Identification Functions on page 2-32
- Output Formatting Functions on page 2-32

Integer Functions

Function	Description
`int8, int16, int32, int64`	Convert to signed 1-, 2-, 4-, or 8-byte integer.
`uint8, uint16, uint32, uint64`	Convert to unsigned 1-, 2-, 4-, or 8-byte integer.
`ceil`	Round towards plus infinity to nearest integer
`class`	Return the data type of an object.
`fix`	Round towards zero to nearest integer
`floor`	Round towards minus infinity to nearest integer
`isa`	Determine if input value has the specified data type.
`isinteger`	Determine if input value is an integer array.
`isnumeric`	Determine if input value is a numeric array.
`round`	Round towards the nearest integer

Floating-Point Functions

Function	Description
`double`	Convert to double precision.
`single`	Convert to single precision.
`class`	Return the data type of an object.
`isa`	Determine if input value has the specified data type.
`isfloat`	Determine if input value is a floating-point array.
`isnumeric`	Determine if input value is a numeric array.
`eps`	Return the floating-point relative accuracy. This value is the tolerance MATLAB uses in its calculations.

Floating-Point Functions (Continued)

Function	Description
`realmax`	Return the largest floating-point number your computer can represent.
`realmin`	Return the smallest floating-point number your computer can represent.

Complex Number Functions

Function	Description
`complex`	Construct complex data from real and imaginary components.
`i` or `j`	Return the imaginary unit used in constructing complex data.
`real`	Return the real part of a complex number.
`imag`	Return the imaginary part of a complex number.
`isreal`	Determine if a number is real or imaginary.

Infinity and NaN Functions

Function	Description
`inf`	Return the IEEE value for infinity.
`isnan`	Detect `NaN` elements of an array.
`isinf`	Detect infinite elements of an array.

Infinity and NaN Functions (Continued)

Function	Description
`isfinite`	Detect finite elements of an array.
`nan`	Return the IEEE value for Not a Number.

Type Identification Functions

Function	Description
`class`	Return data type (or class).
`isa`	Determine if input value is of the specified data type.
`isfloat`	Determine if input value is a floating-point array.
`isinteger`	Determine if input value is an integer array.
`isnumeric`	Determine if input value is a numeric array.
`isreal`	Determine if input value is real.
`whos`	Display the data type of input.

Output Formatting Functions

Function	Description
`format`	Control display format for output.

Logical Types

In this section...

Overview

The `logical` data type represents a logical `true` or `false` state using the numbers `1` and `0`, respectively. Certain MATLAB functions and operators return logical `true` or `false` to indicate whether a certain condition was found to be true or not. For example, the statement `(5 * 10) > 40` returns a logical `true` value.

Logical data does not have to be scalar; MATLAB supports arrays of logical values as well. For example, the following statement returns a vector of logicals indicating `false` for the first two elements and `true` for the last three:

```
[30 40 50 60 70] > 40
ans =
     0     0     1     1     1
```

Creating a Logical Array

One way of creating an array of logicals is to just enter a `true` or `false` value for each element. The `true` function returns logical one; the `false` function returns logical zero:

```
x = [true, true, false, true, false];
```

Logical Operations on an Array

You can also perform some logical operation on an array that yields an array of logicals:

```
x = magic(4) >= 9
```

```
x =
     1     0     0     1
     0     1     1     0
     1     0     0     1
     0     1     1     0
```

The MATLAB functions that have names beginning with `is` (e.g., `ischar`, `issparse`) also return a logical value or array:

```
a = [2.5 6.7 9.2 inf 4.8];

isfinite(a)
ans =
     1     1     1     0     1
```

This table shows some of the MATLAB operations that return a logical `true` or `false`.

Function	Operation
`true`, `false`	Setting value to `true` or `false`
`logical`	Numeric to logical conversion
`&` (`and`), `|` (`or`), `~` (`not`), `xor`, `any`, `all`	Logical operations
`&&`, `||`	Short-circuit AND and OR
`==` (`eq`), `~=` (`ne`), `<` (`lt`), `>` (`gt`), `<=` (`le`), `>=` (`ge`)	Relational operations
All `is*` functions, `cellfun`	Test operations
`strcmp`, `strncmp`, `strcmpi`, `strncmpi`	String comparisons

Sparse Logical Arrays

Logical arrays can also be sparse as long as they have no more than two dimensions:

```
x = sparse(magic(20) > 395)
x =
   (1,1)        1
   (1,4)        1
```

```
 (1,5)        1
(20,18)       1
(20,19)       1
```

How Logical Arrays Are Used

MATLAB has two primary uses for logical arrays:

- "Using Logicals in Conditional Statements" on page 2-35
- "Logical Indexing" on page 2-35

Most mathematics operations are not supported on logical values.

Using Logicals in Conditional Statements

Conditional statements are useful when you want to execute a block of code only when a certain condition is met. For example, the `sprintf` command shown below is valid only if `str` is a nonempty string. The statement

```
if ~isempty(str) && ischar(str)
```

checks for this condition and allows the `sprintf` to execute only if it is `true`:

```
str = 'Hello';

if ~isempty(str) && ischar(str)
   sprintf('Input string is ''%s''', str)
   end

ans =
   Input string is 'Hello'
```

Logical Indexing

A logical matrix provides a different type of array indexing in MATLAB. While most indices are numeric, indicating a certain row or column number, logical indices are positional. That is, it is the *position* of each 1 in the logical matrix that determines which array element is being referred to.

See “Using Logicals in Array Indexing” on page 1-22 for more information on this subject.

Identifying Logical Arrays

This table shows the commands you can use to determine whether or not an array `x` is logical. The last function listed, `cellfun`, operates on cell arrays, which you can read about in the section “Cell Arrays” on page 2-93.

Command	Operation
`whos(x)`	Display value and data type for `x`.
`islogical(x)`	Return `true` if array is logical.
`isa(x, 'logical')`	Return `true` if array is logical.
`class(x)`	Return string with data type name.
`cellfun('islogical', x)`	Check each cell array element for logical.

Characters and Strings

In this section...

Overview

In MATLAB, the term *string* refers to an array of Unicode characters. MATLAB represents each character internally as its corresponding numeric value. Unless you want to access these values, you can simply work with the characters as they display on screen.

You can use `char` to hold an `m`-by-`n` array of strings as long as each string in the array has the same length. (This is because MATLAB arrays must be rectangular.) To hold an array of strings of unequal length, use a cell array.

The string is actually a vector whose components are the numeric codes for the characters. The actual characters displayed depend on the character set encoding for a given font.

Creating Character Arrays

Specify character data by placing characters inside a pair of single quotes. For example, this line creates a 1-by-13 character array called `name`:

```
name = 'Thomas R. Lee';
```

In the workspace, the output of `whos` shows

```
Name        Size          Bytes  Class

name        1x13             26  char
```

You can see that each character uses 2 bytes of storage internally.

The `class` and `ischar` functions show that `name` is a character array:

```
class(name)
ans =
   char

ischar(name)
ans =
    1
```

You also can join two or more character arrays together to create a new character array. To do this, use either the string concatenation function, `strcat`, or the MATLAB concatenation operator, `[]`. The latter preserves any trailing spaces found in the input arrays:

```
name = 'Thomas R. Lee';
title = ' Sr. Developer';

strcat(name,',',title)
ans =
   Thomas R. Lee, Sr. Developer
```

To concatenate strings vertically, use `strvcat`.

Creating Two-Dimensional Character Arrays

When creating a two-dimensional character array, be sure that each row has the same length. For example, this line is legal because both input rows have exactly 13 characters:

```
name = ['Thomas R. Lee' ; 'Sr. Developer']
name =
   Thomas R. Lee
```

```
    Sr. Developer
```

When creating character arrays from strings of different lengths, you can pad the shorter strings with blanks to force rows of equal length:

```
name = ['Thomas R. Lee   '; 'Senior Developer'];
```

A simpler way to create string arrays is to use the `char` function. `char` automatically pads all strings to the length of the longest input string. In the following example, `char` pads the 13-character input string `'Thomas R. Lee'` with three trailing blanks so that it will be as long as the second string:

```
name = char('Thomas R. Lee','Senior Developer')
name =
   Thomas R. Lee
   Senior Developer
```

When extracting strings from an array, use the `deblank` function to remove any trailing blanks:

```
trimname = deblank(name(1,:))
trimname =
   Thomas R. Lee

size(trimname)
ans =
    1    13
```

Expanding Character Arrays

Expanding the size of an existing character array by assigning additional characters to indices beyond the bounds of the array such that part of the array becomes padded with zeros, is generally not recommended. See the documentation on “Expanding a Character Array” on page 1-35 in the MATLAB Programming documentation.

Cell Arrays of Strings

Creating strings in a regular MATLAB array requires that all strings in the array be of the same length. This often means that you have to pad blanks at

the end of strings to equalize their length. However, another type of MATLAB array, the cell array, can hold different sizes and types of data in an array without padding. Cell arrays provide a more flexible way to store strings of varying length.

For details on cell arrays, see "Cell Arrays" on page 2-93.

Converting to a Cell Array of Strings

The `cellstr` function converts a character array into a cell array of strings. Consider the character array

```
data = ['Allison Jones';'Development  ';'Phoenix      '];
```

Each row of the matrix is padded so that all have equal length (in this case, 13 characters).

Now use `cellstr` to create a column vector of cells, each cell containing one of the strings from the `data` array:

```
celldata = cellstr(data)
celldata =
    'Allison Jones'
    'Development'
    'Phoenix'
```

Note that the `cellstr` function strips off the blanks that pad the rows of the input string matrix:

```
length(celldata{3})
ans =
    7
```

The `iscellstr` function determines if the input argument is a cell array of strings. It returns a logical 1 (`true`) in the case of `celldata`:

```
iscellstr(celldata)
ans =
     1
```

Use `char` to convert back to a standard padded character array:

```
strings = char(celldata)
strings =
   Allison Jones
   Development
   Phoenix

length(strings(3,:))
ans =
    13
```

Functions for Cell Arrays of Strings

This table describes the MATLAB functions for working with cell arrays.

Function	Description
`cellstr`	Convert a character array to a cell array of strings.
`char`	Convert a cell array of strings to a character array.
`deblank`	Remove trailing blanks from a string.
`iscellstr`	Return `true` for a cell array of strings.
`sort`	Sort elements in ascending or descending order.
`strcat`	Concatenate strings.
`strcmp`	Compare strings.
`strmatch`	Find possible matches for a string.

You can also use the following `set` functions with cell arrays of strings.

Function	Description
`intersect`	Set the intersection of two vectors.
`ismember`	Detect members of a set.
`setdiff`	Return the set difference of two vectors.
`setxor`	Set the exclusive OR of two vectors.

Function	Description
union	Set the union of two vectors.
unique	Set the unique elements of a vector.

Formatting Strings

The following MATLAB functions offer the capability to compose a string that includes ordinary text and data formatted to your specification:

- sprintf — Write formatted data to an output string
- fprintf — Write formatted data to an output file or the command window
- warning — Display formatted data in a warning message
- error — Display formatted data in an error message and abort
- assert — Generate an error when a condition is violated

The syntax of each of these functions includes formatting operators similar to those used by the printf function in the C programming language. For example, %s tells MATLAB to interpret an input value as a string, and %d means to format an integer using decimal notation.

The general formatting syntax for these functions is

```
functionname(..., format_string, value1, value2, ..., valueN)
```

where the format_string argument expresses the basic content and formatting of the final output string, and the value arguments that follow supply data values to be inserted into the string.

Here is a sample sprintf statement, also showing the resulting output string:

```
sprintf('The price of %s on %d/%d/%d was $%.2f.', ...
        'bread', 7, 1, 2006, 2.49)
ans =
    The price of bread on 7/1/2006 was $2.49.
```

The following sections cover

Note The examples in this section of the documentation use only the `sprintf` function to demonstrate how string formatting works. However, you can run the examples using the `fprintf`, `warning`, and `error` functions as well.

The Format String

The first input argument in the `sprintf` statement shown above is the format string:

```
'The price of %s on %d/%d/%d was $%.2f.'
```

The `string` argument can include ordinary text, formatting operators and, in some cases, special characters. The formatting operators for this particular string are: `%s`, `%d`, `%d`, `%d`, and `%.2f`.

Following the string argument are five additional input arguments, one for each of the formatting operators in the string:

```
'bread', 7, 1, 2006, 2.49
```

When MATLAB processes the format string, it replaces each operator with one of these input values.

Special Characters. Special characters are a part of the text in the string. But, because they cannot be entered as ordinary text, they require a unique character sequence to represent them. Use any of the following character sequences to insert special characters into the output string.

To Insert . . .	Use . . .
Backspace	\b
Form feed	\f
New line	\n
Carriage return	\r
Horizontal tab	\t
Backslash	\\
Percent character	%%

Input Value Arguments

In the syntax

```
functionname(..., format_string, value1, value2, ..., valueN)
```

The `value` arguments must immediately follow `string` in the argument list. In most instances, you supply one of these `value` arguments for each formatting operator used in `string`. Scalars, vectors, and numeric and character arrays are valid value arguments. You cannot use cell arrays or structures.

If you include fewer formatting operators than there are values to insert, MATLAB reuses the operators on the additional values. This example shows two formatting operators and six values to insert into the string:

```
sprintf('%s = %d\n', 'A', 479, 'B', 352, 'C', 651)
ans =
    A = 479
    B = 352
    C = 651
```

Sequential and Numbered Argument Specification.

You can place `value` arguments in the argument list either sequentially (that is, in the same order in which their formatting operators appear in the string), or by identifier (adding a number to each operator that identifies which `value` argument to replace it with). By default, MATLAB uses sequential ordering.

To specify arguments by a numeric identifier, add a positive integer followed by a $ sign immediately after the % sign in the operator. Numbered argument specification is explained in more detail under the topic “Value Identifiers” on page 2-51.

Ordered Sequentially	Ordered By Identifier

`sprintf('%s %s %s', ...`
`    '1st', '2nd', '3rd')`
`ans =`
`    1st 2nd 3rd`
	`sprintf('%3$s %2$s %1$s', ...`
	`    '1st', '2nd', '3rd')`
	`ans =`
	`     3rd 2nd 1st`

Vectorizing. Instead of using individual value arguments, you can use a vector or matrix as the source of data input values, as shown here:

```
sprintf('%d ', magic(4))
ans =
    16 5 9 4 2 11 7 14 3 10 6 15 13 8 12 1
```

When using the %s operator, MATLAB interprets integers as characters:

```
mvec = [77 65 84 76 65 66];

sprintf('%s ', mvec)
ans =
    MATLAB
```

The Formatting Operator

Formatting operators tell MATLAB how to format the numeric or character value arguments and where to insert them into the string. These operators control the notation, alignment, significant digits, field width, and other aspects of the output string.

A formatting operator begins with a % character, which may be followed by a series of one or more numbers, characters, or symbols, each playing a role in further defining the format of the insertion value. The final entry in this series is a single *conversion character* that MATLAB uses to define the notation style for the inserted data. Conversion characters used in MATLAB are based on those used by the `printf` function in the C programming language.

Here is a simple example showing five formatting variations for a common value:

```
A = pi*100*ones(1,5);

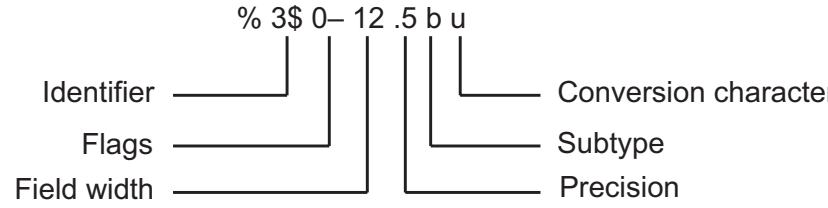
sprintf(' %f \n %.2f \n %+.2f \n %12.2f \n %012.2f \n', A)
ans =
    314.159265       % Display in fixed-point notation (%f)
    314.16           % Display 2 decimal digits (%.2f)
    +314.16          % Display + for positive numbers (%+.2f)
          314.16     % Set width to 12 characters (%12.2f)
    000000314.16     % Replace leading spaces with 0 (%012.2f)
```

Constructing the Formatting Operator

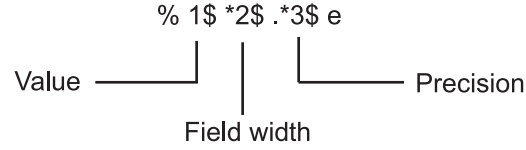
The fields that make up a formatting operator in MATLAB are as shown here, in the order they appear from right to left in the operator. The rightmost field, the conversion character, is required; the five to the left of that are optional. Each of these fields is explained in a section below:

- Conversion Character — Specifies the notation of the output.
- Subtype — Further specifies any nonstandard types.
- Precision — Sets the number of digits to display to the right of the decimal point.
- Field Width — Sets the minimum number of digits to display.
- Flags — Controls the alignment, padding, and inclusion of plus or minus signs.
- Value Identifiers — Map formatting operators to value input arguments. Use the identifier field when value arguments are not in a sequential order in the argument list.

Here is an example of a formatting operator that uses all six fields. (Space characters are not allowed in the operator. They are shown here only to improve readability of the figure).



An alternate syntax, that enables you to supply values for the field width and precision fields from values in the argument list, is shown below. See the section "Specifying Field Width and Precision Outside the format String" on page 2-52 for information on when and how to use this syntax. (Again, space characters are shown only to improve readability of the figure.)



Each field of the formatting operator is described in the following sections. These fields are covered as they appear going from right to left in the formatting operator, starting with the `Conversion Character` and ending with the `Identifier` field.

Conversion Character. The conversion character specifies the notation of the output. It consists of a single character and appears last in the format specifier. It is the only required field of the format specifier other than the leading `%` character.

Specifier	Description
`c`	Single character
`d`	Decimal notation (signed)
`e`	Exponential notation (using a lowercase `e` as in `3.1415e+00`)
`E`	Exponential notation (using an uppercase `E` as in `3.1415E+00`)
`f`	Fixed-point notation

Specifier	Description
g	The more compact of %e or %f. (Insignificant zeros do not print.)
G	Same as %g, but using an uppercase E
o	Octal notation (unsigned)
s	String of characters
u	Decimal notation (unsigned)
x	Hexadecimal notation (using lowercase letters a–f)
X	Hexadecimal notation (using uppercase letters A–F)

This example uses conversion characters to display the number 46 in decimal, fixed-point, exponential, and hexadecimal formats:

```
A = 46*ones(1,4);

sprintf('%d   %f   %e   %X', A)
ans =
    46   46.000000   4.600000e+001   2E
```

Subtype. The subtype field is a single alphabetic character that immediately precedes the conversion character. The following nonstandard subtype specifiers are supported for the conversion characters %o, %u, %x, and %X.

b	The underlying C data type is a double rather than an unsigned integer. For example, to print a double-precision value in hexadecimal, use a format like '%bx'.
t	The underlying C data type is a float rather than an unsigned integer.

Precision. precision in a formatting operator is a nonnegative integer that tells MATLAB how many digits to the right of the decimal point to use when formatting the corresponding input value. The precision field consists of a nonnegative integer that immediately follows a period and extends to the first alphabetic character after that period. For example, the specifier %7.3f, has a precision of 3.

Here are some examples of how the `precision` field affects different types of notation:

```
sprintf('%g   %.2g   %f   %.2f', pi*50*ones(1,4))
ans =
    157.08   1.6e+002   157.079633   157.08
```

Precision is not usually used in format specifiers for strings (i.e., `%s`). If you do use it on a string and if the value `p` in the precision field is less than the number of characters in the string, MATLAB displays only `p` characters of the string and truncates the rest.

You can also supply the value for a precision field from outside of the format specifier. See the section "Specifying Field Width and Precision Outside the format String" on page 2-52 for more information on this.

For more information on the use of `precision` in formatting, see "Setting Field Width and Precision" on page 2-51.

Field Width. `Field width` in a formatting operator is a nonnegative integer that tells MATLAB the minimum number of digits or characters to use when formatting the corresponding input value. For example, the specifier `%7.3f`, has a width of 7.

Here are some examples of how the `width` field affects different types of notation:

```
sprintf('|%e|%15e|%f|%15f|', pi*50*ones(1,4))
ans =
    |1.570796e+002|  1.570796e+002|157.079633|     157.079633|
```

When used on a string, the `field width` can determine whether MATLAB pads the string with spaces. If `width` is less than or equal to the number of characters in the string, it has no effect.

```
sprintf('%30s', 'Pad left with spaces')
ans =
          Pad left with spaces
```

You can also supply a value for `field width` from outside of the format specifier. See the section "Specifying Field Width and Precision Outside the format String" on page 2-52 for more information on this.

For more information on the use of `field width` in formatting, see "Setting Field Width and Precision" on page 2-51.

Flags. You can control the alignment of the output using any of these optional flags:

Character	Description	Example
A minus sign (`-`)	Left-justifies the converted argument in its field	`%-5.2d`
A plus sign (`+`)	Always prints a sign character (+ or –)	`%+5.2d`
Zero (`0`)	Pad with zeros rather than spaces.	`%05.2f`

Right- and left-justify the output. The default is to right-justify:

```
sprintf('right-justify: %12.2f\nleft-justify: %-12.2f', ...
        12.3, 12.3)
ans =
    right-justify:        12.30
    left-justify: 12.30
```

Display a + sign for positive numbers. The default is to omit the + sign:

```
sprintf('no sign: %12.2f\nsign: %+12.2f', ...
        12.3, 12.3)
ans =
    no sign:        12.30
    sign:       +12.30
```

Pad to the left with spaces or zeros. The default is to use space-padding:

```
sprintf('space-padded: %12.2f\nzero-padded: %012.2f', ...
```

```
        5.2, 5.2)
ans =
    space-padded:         5.20
    zero-padded: 000000005.20
```

Note You can specify more than one flag in a formatting operator.

Value Identifiers. By default, MATLAB inserts data values from the argument list into the string in a sequential order. If you have a need to use the value arguments in a nonsequential order, you can override the default by using a numeric identifier in each format specifier. Specify nonsequential arguments with an integer immediately following the % sign, followed by a $ sign.

Ordered Sequentially	Ordered By Identifier

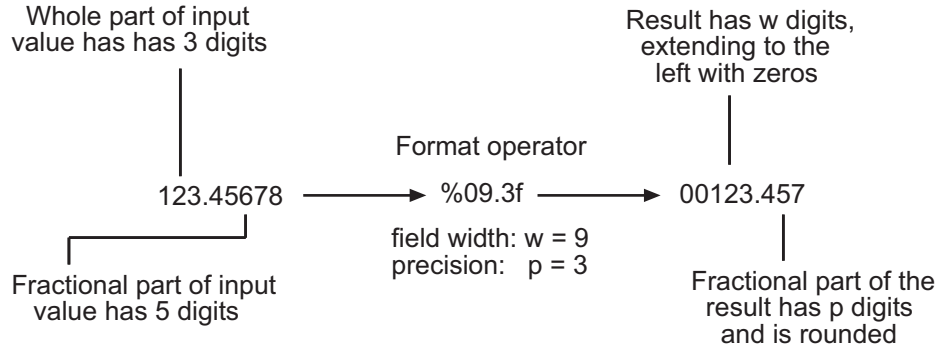
`sprintf('%s %s %s', ...`
`    '1st', '2nd', '3rd')`
`ans =`
`    1st 2nd 3rd`
	`sprintf('%3$s %2$s %1$s', ...`
	`    '1st', '2nd', '3rd')`
	`ans =`
	`     3rd 2nd 1st`

Setting Field Width and Precision

This section provides further information on the use of the field width and precision fields of the formatting operator:

- "Effect on the Output String" on page 2-51
- "Specifying Field Width and Precision Outside the format String" on page 2-52
- "Using Identifiers In the Width and Precision Fields" on page 2-53

Effect on the Output String. The figure below illustrates the way in which the field width and precision settings affect the output of the string formatting functions. In this figure, the zero following the % sign in the formatting operator means to add leading zeros to the output string rather than space characters:



General rules for formatting

- If precision is not specified, it defaults to 6.
- If precision (`p`) is less than the number of digits in the fractional part of the input value (`f`), then only `p` digits are shown to the right of the decimal point in the output, and that fractional value is rounded.
- If precision (`p`) is greater than the number of digits in the fractional part of the input value (`f`), then `p` digits are shown to the right of the decimal point in the output, and the fractional part is extended to the right with `p-f` zeros.
- If field width is not specified, it defaults to `precision + 1` + the number of digits in the whole part of the input value.
- If field width (`w`) is greater than `p+1` plus the number of digits in the whole part of the input value (`n`), then the whole part of the output value is extended to the left with `w-(n+1+p)` space characters or zeros, depending on whether or not the `zero` flag is set in the `Flags` field. The default is to extend the whole part of the output with space characters.

Specifying Field Width and Precision Outside the format String. To specify field width or precision using values from a sequential argument list, use an asterisk (`*`) in place of the `field width` or `precision` field of the formatting operator.

This example formats and displays three numbers. The formatting operator for the first, `%*f`, has an asterisk in the field width location of the formatting

operator, specifying that just the field width, 15, is to be taken from the argument list. The second operator, `%.*f` puts the asterisk after the decimal point meaning, that it is the precision that is to take its value from the argument list. And the third operator, `%*.*f`, specifies both field width and precision in the argument list:

```
 sprintf('%*f   %.*f   %*.*f', ...
        15, 123.45678, ...     % Width for 123.45678 is 15
        3, 16.42837, ...       % Precision for rand*20 is .3
        6, 4, pi)              % Width & Precision for pi is 6.4
ans =
     123.456780   16.428   3.1416
```

You can mix the two styles. For example, this statement gets the field width from the argument list and the precision from the format string:

```
sprintf('%*.2f', 5, 123.45678)
ans =
    123.46
```

Using Identifiers In the Width and Precision Fields. You can also derive field width and precision values from a nonsequential (i.e., numbered) argument list. Inside the formatting operator, specify `field width` and/or `precision` with an asterisk followed by an identifier number, followed by a `$` sign.

This example from the previous section shows how to obtain field width and precision from a sequential argument list:

```
sprintf('%*f   %.*f   %*.*f', ...
        15, 123.45678, ...
        3, 16.42837, ...
        6, 4, pi)

ans =
     123.456780   16.428   3.1416
```

Here is an example of how to do the same thing using numbered ordering. Field width for the first output value is 15, precision for the second value is 3, and field width and precision for the third value is 6 and 4, respectively.

If you specify field width or precision with identifiers, then you must specify the value with an identifier as well:

```
sprintf('%1$*4$f   %2$.*5$f   %3$*6$.*7$f', ...
123.45678, 16.42837, pi, 15, 3, 6, 4)

ans =
     123.456780   16.428   3.1416
```

Restrictions for Using Identifiers

If any of the formatting operators in a string include an identifier field, then all of the operators in that string must do the same; you cannot use both sequential and nonsequential ordering in the same function call.

Valid Syntax	Invalid Syntax

`sprintf('%d %d %d %d', ...`
`        1, 2, 3, 4)`
`ans =`
`    1 2 3 4`
	`sprintf('%d %3$d %d %d', ...`
	`        1, 2, 3, 4)`
	`ans =`
	`    1`

If your command provides more value arguments than there are formatting operators in the format string, MATLAB reuses the operators. However, MATLAB allows this only for commands that use sequential ordering. You cannot reuse formatting operators when making a function call with numbered ordering of the value arguments.

Valid Syntax	Invalid Syntax

`sprintf('%d', 1, 2, 3, 4)`
`ans =`
`    1234`
	`sprintf('%1$d', 1, 2, 3, 4)`
	`ans =`
	`    1`

Also, do not use identifiers when the value arguments are in the form of a vector or array:

Valid Syntax	Invalid Syntax

`v = [1.4 2.7 3.1];`
 	
`sprintf('%.4f %.4f %.4f', v)`
`ans =`
`    1.4000 2.7000 3.1000`
	`v = [1.4 2.7 3.1];`
	
	`sprintf('%3$.4f %1$.4f %2$.4f', v)`
	`ans =`
	`   Empty string: 1-by-0`

String Comparisons

There are several ways to compare strings and substrings:

- You can compare two strings, or parts of two strings, for equality.
- You can compare individual characters in two strings for equality.
- You can categorize every element within a string, determining whether each element is a character or white space.

These functions work for both character arrays and cell arrays of strings.

Comparing Strings for Equality

You can use any of four functions to determine if two input strings are identical:

- `strcmp` determines if two strings are identical.
- `strncmp` determines if the first `n` characters of two strings are identical.
- `strcmpi` and `strncmpi` are the same as `strcmp` and `strncmp`, except that they ignore case.

Consider the two strings

```
str1 = 'hello';
str2 = 'help';
```

Strings `str1` and `str2` are not identical, so invoking `strcmp` returns logical `0` (`false`). For example,

```
C = strcmp(str1,str2)
```

```
C =
     0
```

Note For C programmers, this is an important difference between the MATLAB `strcmp` and C `strcmp()`functions, where the latter returns 0 if the two strings are the same.

The first three characters of `str1` and `str2` are identical, so invoking `strncmp` with any value up to 3 returns `1`:

```
C = strncmp(str1, str2, 2)
C =
     1
```

These functions work cell-by-cell on a cell array of strings. Consider the two cell arrays of strings

```
A = {'pizza'; 'chips'; 'candy'};
B = {'pizza'; 'chocolate'; 'pretzels'};
```

Now apply the string comparison functions:

```
strcmp(A,B)
ans =
     1
     0
     0
strncmp(A,B,1)
ans =
     1
     1
     0
```

Comparing for Equality Using Operators

You can use MATLAB relational operators on character arrays, as long as the arrays you are comparing have equal dimensions, or one is a scalar. For example, you can use the equality operator (==) to determine where the matching characters are in two strings:

```
A = 'fate';
B = 'cake';

A == B
ans =
    0   1   0   1
```

All of the relational operators (>, >=, <, <=, ==, ~=) compare the values of corresponding characters.

Categorizing Characters Within a String

There are three functions for categorizing characters inside a string:

1. `isletter` determines if a character is a letter.
2. `isspace` determines if a character is white space (blank, tab, or new line).
3. `isstrprop` checks characters in a string to see if they match a category you specify, such as
   - Alphabetic
   - Alphanumeric
   - Lowercase or uppercase
   - Decimal digits
   - Hexadecimal digits
   - Control characters
   - Graphic characters
   - Punctuation characters
   - White-space characters

For example, create a string named `mystring`:

```
mystring = 'Room 401';
```

`isletter` examines each character in the string, producing an output vector of the same length as `mystring`:

```
A = isletter(mystring)
A =
    1   1   1   1   0   0   0   0
```

The first four elements in `A` are logical `1` (`true`) because the first four characters of `mystring` are letters.

Searching and Replacing

MATLAB provides several functions for searching and replacing characters in a string. (MATLAB also supports search and replace operations using regular expressions. See "Regular Expressions" on page 3-30.)

Consider a string named `label`:

```
label = 'Sample 1, 10/28/95';
```

The `strrep` function performs the standard search-and-replace operation. Use `strrep` to change the date from `'10/28'` to `'10/30'`:

```
newlabel = strrep(label, '28', '30')
newlabel =
   Sample 1, 10/30/95
```

`findstr` returns the starting position of a substring within a longer string. To find all occurrences of the string `'amp'` inside `label`, use

```
position = findstr('amp', label)
position =
    2
```

The position within `label` where the only occurrence of `'amp'` begins is the second character.

The `strtok` function returns the characters before the first occurrence of a delimiting character in an input string. The default delimiting characters are the set of white-space characters. You can use the `strtok` function to parse a sentence into words. For example,

```
function allWords = words(inputString)
remainder = inputString;
allWords = '';
```

```
while (any(remainder))
  [chopped,remainder] = strtok(remainder);
  allWords = strvcat(allWords, chopped);
end
```

The `strmatch` function looks through the rows of a character array or cell array of strings to find strings that begin with a given series of characters. It returns the indices of the rows that begin with these characters:

```
maxstrings = strvcat('max', 'minimax', 'maximum')
maxstrings =
   max
   minimax
   maximum

strmatch('max', maxstrings)
ans =
     1
     3
```

Converting from Numeric to String

The functions listed in this table provide a number of ways to convert numeric data to character strings.

Function	Description	Example
`char`	Convert a positive integer to an equivalent character. (Truncates any fractional parts.)	`[72 105]` → `'Hi'`
`int2str`	Convert a positive or negative integer to a character type. (Rounds any fractional parts.)	`[72 105]` → `'72 105'`
`num2str`	Convert a numeric type to a character type of the specified precision and format.	`[72 105]` → `'72/105/'` (format set to `%1d/`)
`mat2str`	Convert a numeric type to a character type of the specified precision, returning a string MATLAB can evaluate.	`[72 105]` → `'[72 105]'`

Function	Description	Example
dec2hex	Convert a positive integer to a character type of hexadecimal base.	[72 105] → '48 69'
dec2bin	Convert a positive integer to a character type of binary base.	[72 105] → '1001000 1101001'
dec2base	Convert a positive integer to a character type of any base from 2 through 36.	[72 105] → '110 151' (base set to 8)

Converting to a Character Equivalent

The char function converts integers to Unicode character codes and returns a string composed of the equivalent characters:

```
x = [77 65 84 76 65 66];
char(x)
ans =
   MATLAB
```

Converting to a String of Numbers

The int2str, num2str, and mat2str functions convert numeric values to strings where each character represents a separate digit of the input value. The int2str and num2str functions are often useful for labeling plots. For example, the following lines use num2str to prepare automated labels for the *x*-axis of a plot:

```
function plotlabel(x, y)
plot(x, y)
str1 = num2str(min(x));
str2 = num2str(max(x));
out = ['Value of f from ' str1 ' to ' str2];
xlabel(out);
```

Converting to a Specific Radix

Another class of conversion functions changes numeric values into strings representing a decimal value in another base, such as binary or hexadecimal representation. This includes dec2hex, dec2bin, and dec2base.

Converting from String to Numeric

The functions listed in this table provide a number of ways to convert character strings to numeric data.

Function	Description	Example
`uintN` (e.g., `uint8`)	Convert a character to an integer code that represents that character.	`'Hi'` → `72 105`
`str2num`	Convert a character type to a numeric type.	`'72 105'` → `[72 105]`
`str2double`	Similar to `str2num`, but offers better performance and works with cell arrays of strings.	`{'72' '105'}` → `[72 105]`
`hex2num`	Convert a numeric type to a character type of specified precision, returning a string that MATLAB can evaluate.	`'A'` → `'-1.4917e-154'`
`hex2dec`	Convert a character type of hexadecimal base to a positive integer.	`'A'` → `10`
`bin2dec`	Convert a positive integer to a character type of binary base.	`'1010'` → `10`
`base2dec`	Convert a positive integer to a character type of any base from 2 through 36.	`'12'` → `10` (if `base == 8`)

Converting from a Character Equivalent

Character arrays store each character as a 16-bit numeric value. Use one of the integer conversion functions (e.g., `uint8`) or the `double` function to convert strings to their numeric values, and `char` to revert to character representation:

```
name = 'Thomas R. Lee';

name = double(name)
name =
    84  104  111  109  97  115  32  82  46  32  76  101  101

name = char(name)
name =
   Thomas R. Lee
```

Converting from a Numeric String

Use `str2num` to convert a character array to the numeric value represented by that string:

```
str = '37.294e-1';

val = str2num(str)
val =
    3.7294
```

The `str2double` function converts a cell array of strings to the double-precision values represented by the strings:

```
c = {'37.294e-1'; '-58.375'; '13.796'};

d = str2double(c)
d =
    3.7294
  -58.3750
   13.7960

whos
  Name      Size                    Bytes  Class

  c         3x1                       224  cell
  d         3x1                        24  double
```

Converting from a Specific Radix

To convert from a character representation of a nondecimal number to the value of that number, use one of these functions: `hex2num`, `hex2dec`, `bin2dec`, or `base2dec`.

The `hex2num` and `hex2dec` functions both take hexadecimal (base 16) inputs, but `hex2num` returns the IEEE double-precision floating-point number it represents, while `hex2dec` converts to a decimal integer.

Function Summary

MATLAB provides these functions for working with character arrays:

Functions to Create Character Arrays

Function	Description
`'str'`	Create the string specified between quotes.
`blanks`	Create a string of blanks.
`sprintf`	Write formatted data to a string.
`strcat`	Concatenate strings.
`strvcat`	Concatenate strings vertically.

Functions to Modify Character Arrays

Function	Description
`deblank`	Remove trailing blanks.
`lower`	Make all letters lowercase.
`sort`	Sort elements in ascending or descending order.
`strjust`	Justify a string.
`strrep`	Replace one string with another.

Functions to Modify Character Arrays (Continued)

Function	Description
`strtrim`	Remove leading and trailing white space.
`upper`	Make all letters uppercase.

Functions to Read and Operate on Character Arrays

Function	Description
`eval`	Execute a string with MATLAB expression.
`sscanf`	Read a string under format control.

Functions to Search or Compare Character Arrays

Function	Description
`findstr`	Find one string within another.
`strcmp`	Compare strings.
`strcmpi`	Compare strings, ignoring case.
`strmatch`	Find matches for a string.
`strncmp`	Compare the first N characters of strings.
`strncmpi`	Compare the first N characters, ignoring case.
`strtok`	Find a token in a string.

Functions to Determine Data Type or Content

Function	Description
`iscellstr`	Return `true` for a cell array of strings.
`ischar`	Return `true` for a character array.
`isletter`	Return `true` for letters of the alphabet.

Functions to Determine Data Type or Content (Continued)

Function	Description
`isstrprop`	Determine if a string is of the specified category.
`isspace`	Return `true` for white-space characters.

Functions to Convert Between Numeric and String Data Types

Function	Description
`char`	Convert to a character or string.
`cellstr`	Convert a character array to a cell array of strings.
`double`	Convert a string to numeric codes.
`int2str`	Convert an integer to a string.
`mat2str`	Convert a matrix to a string you can run `eval` on.
`num2str`	Convert a number to a string.
`str2num`	Convert a string to a number.
`str2double`	Convert a string to a double-precision value.

Functions to Work with Cell Arrays of Strings as Sets

Function	Description
`intersect`	Set the intersection of two vectors.
`ismember`	Detect members of a set.
`setdiff`	Return the set difference of two vectors.
`setxor`	Set the exclusive OR of two vectors.
`union`	Set the union of two vectors.
`unique`	Set the unique elements of a vector.

Dates and Times

In this section...

Overview

MATLAB represents date and time information in either of three formats: date strings, serial date numbers, or date vectors. You have the choice of using any of these formats. If you work with more than one date and time format, MATLAB provides functions to help you easily convert from one format to another, (e.g., from a string to a serial date number).

When using date strings, you have an additional option of choosing from 19 different string styles to express date and/or time information.

Types of Date Formats

The three MATLAB date and time formats are

- "Date Strings" on page 2-67
- "Serial Date Numbers" on page 2-67
- "Date Vectors" on page 2-68

This table shows examples of the three formats.

Date Format	Example
Date string	`02-Oct-1996`
Serial date number	`729300`
Date vector	`1996 10 2 0 0 0`

Date Strings

There are a number of different styles in which to express date and time information as a date string. For example, several possibilities for October 31, 2003 at 3:45:17 in the afternoon are

```
31-Oct-2003 15:45:17
10/31/03
15:45:17
03:45:17 PM
```

If you are working with a small number of dates at the MATLAB command line, then date strings are often the most convenient format to use.

Note The MATLAB `date` function returns the current date as a string.

Serial Date Numbers

A serial date number represents a calendar date as the number of days that has passed since a fixed base date. In MATLAB, serial date number 1 is January 1, 0000. MATLAB also uses serial time to represent fractions of days beginning at midnight; for example, 6 p.m. equals 0.75 serial days. So the string '31-Oct-2003, 6:00 pm' in MATLAB is date number 731885.75.

MATLAB works internally with serial date numbers. If you are using functions that handle large numbers of dates or doing extensive calculations with dates, you get better performance if you use date numbers.

Note The MATLAB `now` function returns the current date and time as a serial date number.

Date Vectors

Date vectors are an internal format for some MATLAB functions; you do not typically use them in calculations. A date vector contains the elements `[year month day hour minute second]`.

Note The MATLAB `clock` function returns the current date and time as a serial vector.

Conversions Between Date Formats

Functions that convert between date formats are shown below.

Function	Description
`datenum`	Convert a date string to a serial date number.
`datestr`	Convert a serial date number to a date string.
`datevec`	Split a date number or date string into individual date elements.

Here are some examples of conversions from one date format to another:

```
d1 = datenum('02-Oct-1996')
d1 =
    729300

d2 = datestr(d1 + 10)
d2 =
   12-Oct-1996

dv1 = datevec(d1)
dv1 =
    1996      10       2       0       0       0

dv2 = datevec(d2)
dv2 =
    1996      10      12       0       0       0
```

Date String Formats

The `datenum` function is important for doing date calculations efficiently. `datenum` takes an input string in any of several formats, with `'dd-mmm-yyyy'`, `'mm/dd/yyyy'`, or `'dd-mmm-yyyy, hh:mm:ss.ss'` most common. You can form up to six fields from letters and digits separated by any other characters:

- The day field is an integer from 1 to 31.
- The month field is either an integer from 1 to 12 or an alphabetic string with at least three characters.
- The year field is a nonnegative integer: if only two digits are specified, then a year 19yy is assumed; if the year is omitted, then the current year is used as a default.
- The hours, minutes, and seconds fields are optional. They are integers separated by colons or followed by `'AM'` or `'PM'`.

For example, if the current year is 1996, then these are all equivalent:

```
'17-May-1996'
'17-May-96'
'17-May'
'May 17, 1996'
'5/17/96'
'5/17'
```

and both of these represent the same time:

```
'17-May-1996, 18:30'
'5/17/96/6:30 pm'
```

Note that the default format for numbers-only input follows the American convention. Thus `3/6` is March 6, not June 3.

If you create a vector of input date strings, use a column vector and be sure all strings are the same length. Fill in with spaces or zeros.

Output Formats

The command `datestr(D, dateform)` converts a serial date `D` to one of 19 different date string output formats showing date, time, or both. The default output for dates is a day-month-year string: 01-Mar-1996. You select an alternative output format by using the optional integer argument `dateform`.

This table shows the date string formats that correspond to each `dateform` value.

dateform	Format	Description
0	`01-Mar-1996 15:45:17`	day-month-year hour:minute:second
1	`01-Mar-1996`	day-month-year
2	`03/01/96`	month/day/year
3	`Mar`	month, three letters
4	`M`	month, single letter
5	`3`	month
6	`03/01`	month/day
7	`1`	day of month
8	`Wed`	day of week, three letters
9	`W`	day of week, single letter
10	`1996`	year, four digits
11	`96`	year, two digits
12	`Mar96`	month year
13	`15:45:17`	hour:minute:second
14	`03:45:17 PM`	hour:minute:second AM or PM
15	`15:45`	hour:minute
16	`03:45 PM`	hour:minute AM or PM
17	`Q1-96`	calendar quarter-year
18	`Q1`	calendar quarter

Converting Output Format with datestr

Here are some examples of converting the date March 1, 1996 to various forms using the `datestr` function:

```
d = '01-Mar-1999'
d =
   01-Mar-1999

datestr(d)
ans =
     01-Mar-1999

datestr(d, 2)
ans =
     03/01/99

datestr(d, 17)
ans =
     Q1-99
```

Current Date and Time

The function `date` returns a string for today's date:

```
date
ans =
     02-Oct-1996
```

The function `now` returns the serial date number for the current date and time:

```
now
ans =
     729300.71

datestr(now)
ans =
     02-Oct-1996 16:56:16

datestr(floor(now))
ans =
     02-Oct-1996
```

Function Summary

MATLAB provides the following functions for time and date handling:

Current Date and Time Functions

Function	Description
`clock`	Return the current date and time as a date vector.
`date`	Return the current date as date string.
`now`	Return the current date and time as serial date number.

Conversion Functions

Function	Description
`datenum`	Convert to a serial date number.
`datestr`	Convert to a string representation of the date.
`datevec`	Convert to a date vector.

Utility Functions

Function	Description
`addtodate`	Modify a date number by field.
`calendar`	Return a matrix representing a calendar.
`datetick`	Label axis tick lines with dates.

Utility Functions (Continued)

Function	Description
`eomday`	Return the last day of a year and month.
`weekday`	Return the current day of the week.

Timing Measurement Functions

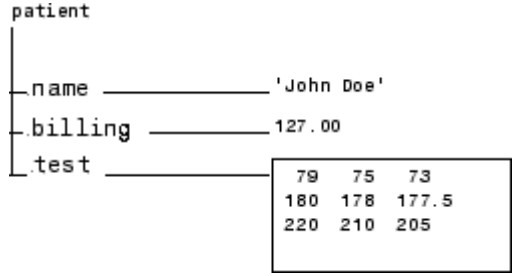
Function	Description
`cputime`	Return the total CPU time used by MATLAB since it was started.
`etime`	Return the time elapsed between two date vectors.
`tic, toc`	Measure the time elapsed between invoking `tic` and `toc`.

Structures

In this section...

Overview

Structures are MATLAB arrays with named “data containers” called *fields*. The fields of a structure can contain any kind of data. For example, one field might contain a text string representing a name, another might contain a scalar representing a billing amount, a third might hold a matrix of medical test results, and so on.



Like standard arrays, structures are inherently array oriented. A single structure is a 1-by-1 structure array, just as the value 5 is a 1-by-1 numeric array. You can build structure arrays with any valid size or shape, including multidimensional structure arrays.

Note The examples in this section focus on two-dimensional structure arrays. For examples of higher-dimension structure arrays, see "Multidimensional Arrays" on page 1-56.

Building Structure Arrays

You can build structures in two ways:

- Using assignment statements
- Using the `struct` function

Building Structure Arrays Using Assignment Statements

You can build a simple 1-by-1 structure array by assigning data to individual fields. MATLAB automatically builds the structure as you go along. For example, create the 1-by-1 `patient` structure array shown at the beginning of this section:

```
patient.name = 'John Doe';
patient.billing = 127.00;
patient.test = [79 75 73; 180 178 177.5; 220 210 205];
```

Now entering

```
patient
```

at the command line results in

```
name: 'John Doe'
billing: 127
test: [3x3 double]
```

`patient` is an array containing a structure with three fields. To expand the structure array, add subscripts after the structure name:

```
patient(2).name = 'Ann Lane';
patient(2).billing = 28.50;
patient(2).test = [68 70 68; 118 118 119; 172 170 169];
```

The `patient` structure array now has size `[1 2]`. Note that once a structure array contains more than a single element, MATLAB does not display individual field contents when you type the array name. Instead, it shows a summary of the kind of information the structure contains:

```
patient
patient =
1x2 struct array with fields:
    name
    billing
    test
```

You can also use the `fieldnames` function to obtain this information. `fieldnames` returns a cell array of strings containing field names.

As you expand the structure, MATLAB fills in unspecified fields with empty matrices so that

- All structures in the array have the same number of fields.
- All fields have the same field names.

For example, entering `patient(3).name = 'Alan Johnson'` expands the `patient` array to size `[1 3]`. Now both `patient(3).billing` and `patient(3).test` contain empty matrices.

Note Field sizes do not have to conform for every element in an array. In the `patient` example, the `name` fields can have different lengths, the `test` fields can be arrays of different sizes, and so on.

Building Structure Arrays Using the struct Function

You can preallocate an array of structures with the `struct` function. Its basic form is

```
strArray = struct('field1',val1,'field2',val2, ...)
```

where the arguments are field names and their corresponding values. A field value can be a single value, represented by any MATLAB data construct, or a cell array of values. All field values in the argument list must be of the same scale (single value or cell array).

You can use different methods for preallocating structure arrays. These methods differ in the way in which the structure fields are initialized. As an example, consider the allocation of a 1-by-3 structure array, `weather`, with the structure fields `temp` and `rainfall`. Three different methods for allocating such an array are shown in this table.

Method	Syntax	Initialization
`struct`	`weather(3) = struct('temp', 72, ... 'rainfall', 0.0);`	`weather(3)` is initialized with the field values shown. The fields for the other structures in the array, `weather(1)` and `weather(2)`, are initialized to the empty matrix.
`struct` with `repmat`	`weather = repmat(struct('temp', ... 72, 'rainfall', 0.0), 1, 3);`	All structures in the `weather` array are initialized using one set of field values.
`struct` with cell array syntax	`weather = ...` `struct('temp', {68, 80, 72}, ... 'rainfall', {0.2, 0.4, 0.0});`	The structures in the `weather` array are initialized with distinct field values specified with cell arrays.

Naming conventions for Structure Field Names

MATLAB structure field names are required to follow the same rules as standard MATLAB variables:

1. Field names must begin with a letter, which may be followed by any combination of letters, digits, and underscores. The following statements are all invalid:

```
w = setfield(w, 'My.Score', 3);
```

```
w = setfield(w, '1stScore', 3);
w = setfield(w, '1+1=3', 3);
w = setfield(w, '@MyScore', 3);
```

2. Although field names can be of any length, MATLAB uses only the first N characters of the field name, (where N is the number returned by the function `namelengthmax`), and ignores the rest.

```
N= namelengthmax
N=
   63
```

3. MATLAB distinguishes between uppercase and lowercase characters. Field name `length` is not the same as field name `Length`.

4. In most cases, you should refrain from using the names of functions and variables as field names.

See "Adding Fields to Structures" on page 2-82 and "Deleting Fields from Structures" on page 2-83 for more information on working with field names.

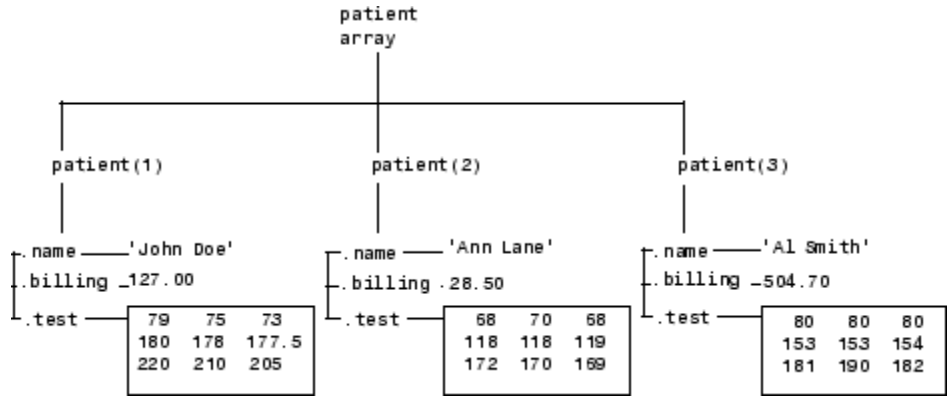
Memory Requirements for Structures

You do not necessarily need a contiguous block of memory to store a structure. The memory for each field in the structure needs to be contiguous, but not the entire structure itself.

Accessing Data in Structure Arrays

Using structure array indexing, you can access the value of any field or field element in a structure array. Likewise, you can assign a value to any field or field element. You can also access the fields of an array of structures in the form of a comma-separated list.

For the examples in this section, consider this structure array.



You can access subarrays by appending standard subscripts to a structure array name. For example, the line below results in a 1-by-2 structure array:

```
mypatients = patient(1:2)
1x2 struct array with fields:
    name
    billing
    test
```

The first structure in the `mypatients` array is the same as the first structure in the `patient` array:

```
mypatients(1)
ans =
       name: 'John Doe'
    billing: 127
       test: [3x3 double]
```

To access a field of a particular structure, include a period (.) after the structure name followed by the field name:

```
str = patient(2).name
str =
   Ann Lane
```

To access elements within fields, append the appropriate indexing mechanism to the field name. That is, if the field contains an array, use array subscripting; if the field contains a cell array, use cell array subscripting, and so on:

```
test2b = patient(3).test(2,2)
test2b =
   153
```

Use the same notations to assign values to structure fields, for example,

```
patient(3).test(2,2) = 7;
```

You can extract field values for multiple structures at a time. For example, the line below creates a 1-by-3 vector containing all of the `billing` fields:

```
bills = [patient.billing]
bills =
  127.0000   28.5000  504.7000
```

Similarly, you can create a cell array containing the `test` data for the first two structures:

```
tests = {patient(1:2).test}
tests =
    [3x3 double]    [3x3 double]
```

Using Dynamic Field Names

The most common way to access the data in a structure is by specifying the name of the field that you want to reference. Another means of accessing structure data is to use dynamic field names. These names express the field as a variable expression that MATLAB evaluates at run-time. The dot-parentheses syntax shown here makes `expression` a dynamic field name:

```
structName.(expression)
```

Index into this field using the standard MATLAB indexing syntax. For example, to evaluate *`expression`* into a field name and obtain the values of that field at columns `1` through `25` of row `7`, use

```
structName.(expression)(7,1:25)
```

Dynamic Field Names Example

The `avgscore` function shown below computes an average test score, retrieving information from the `testscores` structure using dynamic field names:

```
function avg = avgscore(student, first, last)
for k = first:last
   scores(k) = testscores.(student).week(k);
end
avg = sum(scores)/(last - first + 1);
```

You can run this function using different values for the dynamic field `student`. First, initialize the structure that contains scores for a 25 week period:

```
testscores.Ann_Lane.week(1:25) = ...
  [95 89 76 82 79 92 94 92 89 81 75 93 ...
   85 84 83 86 85 90 82 82 84 79 96 88 98];

testscores.William_King.week(1:25) = ...
  [87 80 91 84 99 87 93 87 97 87 82 89 ...
   86 82 90 98 75 79 92 84 90 93 84 78 81];
```

Now run `avgscore`, supplying the students name fields for the `testscores` structure at runtime using dynamic field names:

```
avgscore(testscores, 'Ann_Lane', 7, 22)
ans =
   85.2500

avgscore(testscores, 'William_King', 7, 22)
ans =
   87.7500
```

Finding the Size of Structure Arrays

Use the `size` function to obtain the size of a structure array, or of any structure field. Given a structure array name as an argument, `size` returns a vector of array dimensions. Given an argument in the form `array(n).field`, the `size` function returns a vector containing the size of the field contents.

For example, for the 1-by-3 structure array `patient`, `size(patient)` returns the vector `[1 3]`. The statement `size(patient(1,2).name)` returns the length of the `name` string for element `(1,2)` of `patient`.

Adding Fields to Structures

You can add a field to every structure in an array by adding the field to a single structure. For example, to add a social security number field to the `patient` array, use an assignment like

```
patient(2).ssn = '000-00-0000';
```

Now `patient(2).ssn` has the assigned value. Every other structure in the array also has the `ssn` field, but these fields contain the empty matrix until you explicitly assign a value to them.

See "Naming conventions for Structure Field Names" on page 2-77 for guidelines to creating valid field names.

Adding or Modifying Fields With the setfield Function

The `setfield` function offers another way to add or modify fields of a structure. Given the structure

```
mystr(1,1).name = 'alice';
mystr(1,1).ID = 0;
mystr(2,1).name = 'gertrude';
mystr(2,1).ID = 1;
```

You can change the name field of `mystr(2,1)` using

```
mystr = setfield(mystr, {2,1}, 'name', 'ted');

mystr(2,1).name
ans =
   ted
```

Adding New Fields Dynamically

To add new fields to a structure, specifying the names for these fields at run-time, see the section on "Using Dynamic Field Names" on page 2-80.

Deleting Fields from Structures

You can remove a given field from every structure within a structure array using the `rmfield` function. Its most basic form is

```
struc2 = rmfield(array, 'field')
```

where `array` is a structure array and `'field'` is the name of a field to remove from it. To remove the `name` field from the `patient` array, for example, enter

```
patient = rmfield(patient, 'name');
```

Applying Functions and Operators

Operate on fields and field elements the same way you operate on any other MATLAB array. Use indexing to access the data on which to operate.

For example, this statement finds the mean across the rows of the `test` array in `patient(2)`:

```
mean((patient(2).test)');
```

There are sometimes multiple ways to apply functions or operators across fields in a structure array. One way to add all the `billing` fields in the `patient` array is

```
total = 0;
for k = 1:length(patient)
      total = total + patient(k).billing;
end
```

To simplify operations like this, MATLAB enables you to operate on all like-named fields in a structure array. Simply enclose the `array.field` expression in square brackets within the function call. For example, you can sum all the `billing` fields in the `patient` array using

```
total = sum ([patient.billing]);
```

This is equivalent to using the comma-separated list:

```
total = sum ([patient(1).billing, patient(2).billing, ...]);
```

This syntax is most useful in cases where the operand field is a scalar field:

Writing Functions to Operate on Structures

You can write functions that work on structures with specific field architectures. Such functions can access structure fields and elements for processing.

Note When writing M-file functions to operate on structures, you must perform your own error checking. That is, you must ensure that the code checks for the expected fields.

As an example, consider a collection of data that describes measurements, at different times, of the levels of various toxins in a water source. The data consists of fifteen separate observations, where each observation contains three separate measurements.

You can organize this data into an array of 15 structures, where each structure has three fields, one for each of the three measurements taken.

The function `concen`, shown below, operates on an array of structures with specific characteristics. Its arguments must contain the fields `lead`, `mercury`, and `chromium`:

```
function [r1, r2] = concen(toxtest);
% Create two vectors:
%  r1 contains the ratio of mercury to lead at each observation.
%  r2 contains the ratio of lead to chromium.
r1 = [toxtest.mercury] ./ [toxtest.lead];
r2 = [toxtest.lead] ./ [toxtest.chromium];

% Plot the concentrations of lead, mercury, and chromium
% on the same plot, using different colors for each.
lead = [toxtest.lead];
mercury = [toxtest.mercury];
chromium = [toxtest.chromium];

plot(lead, 'r');   hold on
```

```
plot(mercury, 'b')
plot(chromium, 'y');   hold off
```

Try this function with a sample structure array like `test`:

```
test(1).lead = .007;
test(2).lead = .031;
test(3).lead = .019;

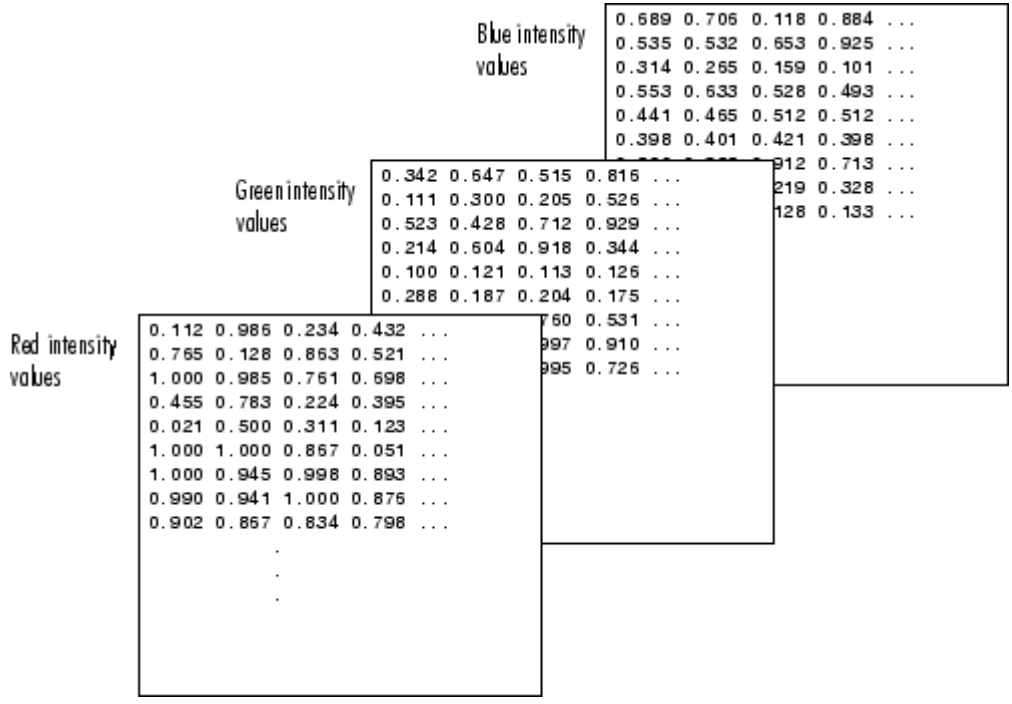
test(1).mercury = .0021;
test(2).mercury = .0009;
test(3).mercury = .0013;

test(1).chromium = .025;
test(2).chromium = .017;
test(3).chromium = .10;
```

Organizing Data in Structure Arrays

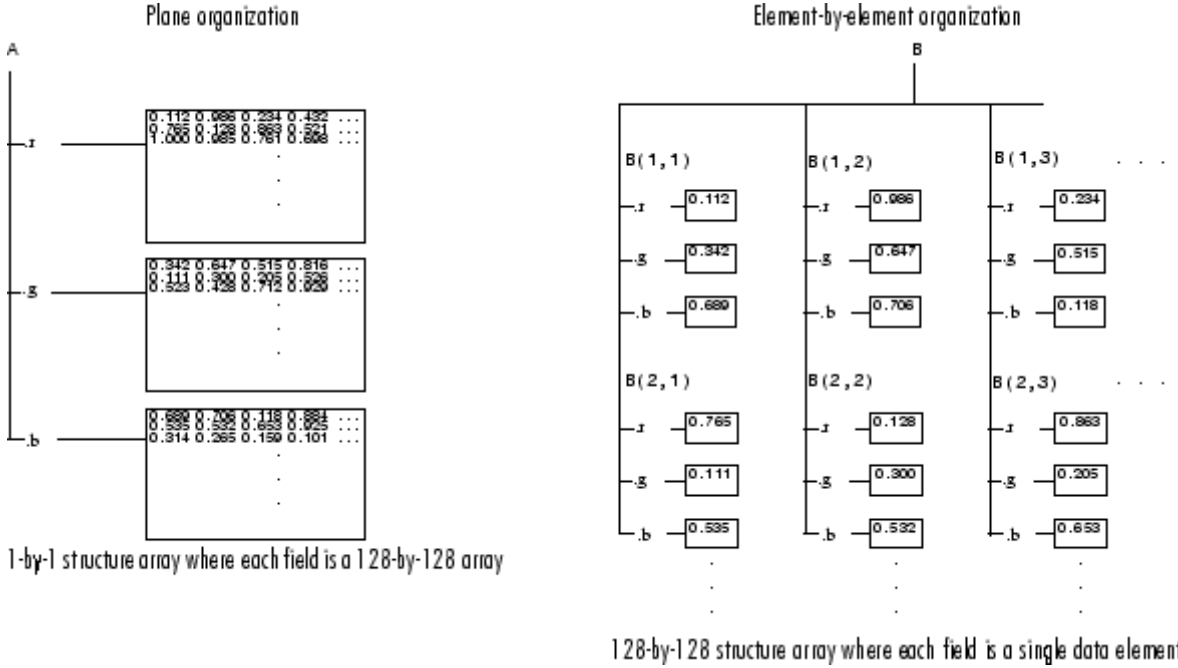
The key to organizing structure arrays is to decide how you want to access subsets of the information. This, in turn, determines how you build the array that holds the structures, and how you break up the structure fields.

For example, consider a 128-by-128 RGB image stored in three separate arrays; `RED`, `GREEN`, and `BLUE`.



Blue intensity values
0.689 0.706 0.118 0.884 ...
0.535 0.532 0.653 0.925 ...
0.314 0.265 0.159 0.101 ...
0.553 0.633 0.528 0.493 ...
0.441 0.465 0.512 0.512 ...
0.398 0.401 0.421 0.398 ...
Green intensity values
0.342 0.647 0.515 0.816 ...
0.111 0.300 0.205 0.526 ...
0.523 0.428 0.712 0.929 ...
0.214 0.604 0.918 0.344 ...
0.100 0.121 0.113 0.126 ...
0.288 0.187 0.204 0.175 ...
Red intensity values
0.112 0.986 0.234 0.432 ...
0.765 0.128 0.863 0.521 ...
1.000 0.985 0.761 0.698 ...
0.455 0.783 0.224 0.395 ...
0.021 0.500 0.311 0.123 ...
1.000 1.000 0.867 0.051 ...
1.000 0.945 0.998 0.893 ...
0.990 0.941 1.000 0.876 ...
0.902 0.867 0.834 0.798 ...

There are at least two ways you can organize such data into a structure array.



Plane Organization

In the plane organization, shown to the left in the figure above, each field of the structure is an entire plane of the image. You can create this structure using

```
A.r = RED;
A.g = GREEN;
A.b = BLUE;
```

This approach allows you to easily extract entire image planes for display, filtering, or other tasks that work on the entire image at once. To access the entire red plane, for example, use

```
redPlane = A.r;
```

Plane organization has the additional advantage of being extensible to multiple images in this case. If you have a number of images, you can store them as `A(2)`, `A(3)`, and so on, each containing an entire image.

The disadvantage of plane organization is evident when you need to access subsets of the planes. To access a subimage, for example, you need to access each field separately:

```
redSub = A.r(2:12,13:30);
greenSub = A.g(2:12,13:30);
blueSub = A.b(2:12,13:30);
```

Element-by-Element Organization

The element-by-element organization, shown to the right in the figure above, has the advantage of allowing easy access to subsets of data. To set up the data in this organization, use

```
for m = 1:size(RED,1)
   for n = 1:size(RED,2)
      B(m,n).r = RED(m,n);
      B(m,n).g = GREEN(m,n);
      B(m,n).b = BLUE(m,n);
   end
end
```

With element-by-element organization, you can access a subset of data with a single statement:

```
Bsub = B(1:10,1:10);
```

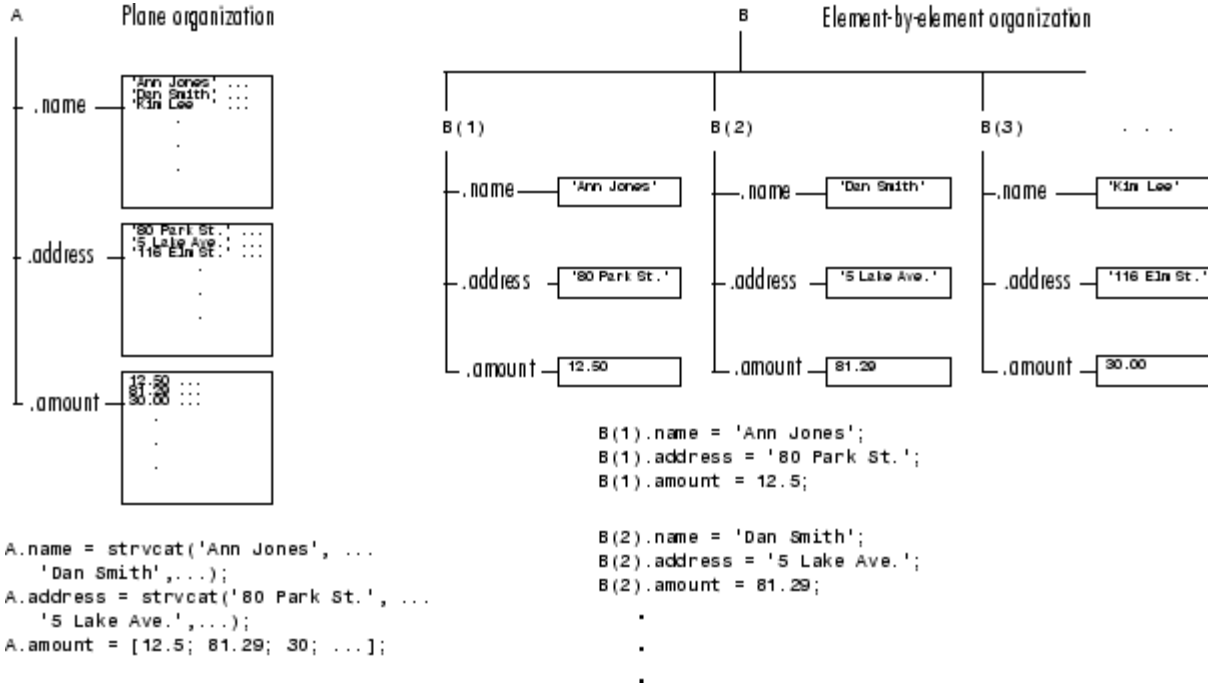
To access an entire plane of the image using the element-by-element method, however, requires a loop:

```
redPlane = zeros(128, 128);
for k = 1:(128 * 128)
    redPlane(k) = B(k).r;
end
```

Element-by-element organization is not the best structure array choice for most image processing applications; however, it can be the best for other applications wherein you will routinely need to access corresponding subsets of structure fields. The example in the following section demonstrates this type of application.

Example — A Simple Database

Consider organizing a simple database.



```
A.name = strvcat('Ann Jones', ...
   'Dan Smith',...);
A.address = strvcat('80 Park St.', ...
   '5 Lake Ave.',...);
A.amount = [12.5; 81.29; 30; ...];
```

```
B(1).name = 'Ann Jones';
B(1).address = '80 Park St.';
B(1).amount = 12.5;

B(2).name = 'Dan Smith';
B(2).address = '5 Lake Ave.';
B(2).amount = 81.29;
```

Each of the possible organizations has advantages depending on how you want to access the data:

- Plane organization makes it easier to operate on all field values at once. For example, to find the average of all the values in the `amount` field,
  - Using plane organization

```
avg = mean(A.amount);
```

- Using element-by-element organization

```
avg = mean([B.amount]);
```

- Element-by-element organization makes it easier to access all the information related to a single client. Consider an M-file, `client.m`, which displays the name and address of a given client on screen.

  Using plane organization, pass individual fields.

```
function client(name,address)
disp(name)
disp(address)
```

  To call the `client` function,

```
client(A.name(2,:),A.address(2,:))
```

  Using element-by-element organization, pass an entire structure.

```
function client(B)
disp(B)
```

  To call the `client` function,

```
client(B(2))
```

- Element-by-element organization makes it easier to expand the string array fields. If you do not know the maximum string length ahead of time for plane organization, you may need to frequently recreate the `name` or `address` field to accommodate longer strings.

Typically, your data does not dictate the organization scheme you choose. Rather, you must consider how you want to access and operate on the data.

Nesting Structures

A structure field can contain another structure, or even an array of structures. Once you have created a structure, you can use the `struct` function or direct assignment statements to nest structures within existing structure fields.

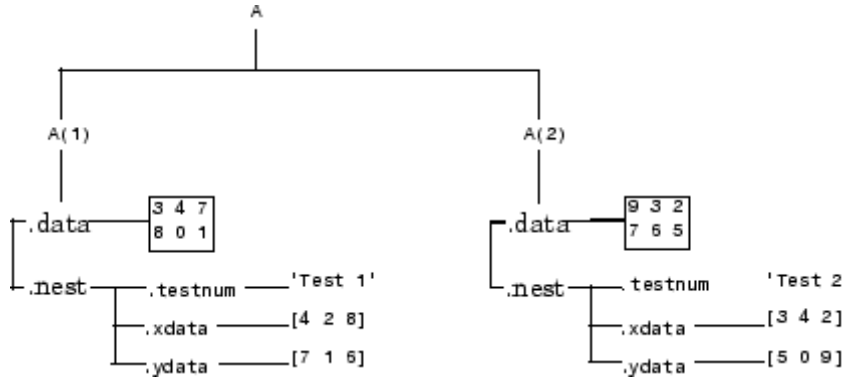
Building Nested Structures with the struct Function

To build nested structures, you can nest calls to the `struct` function. For example, create a 1-by-1 structure array:

```
A = struct('data', [3 4 7; 8 0 1], 'nest',...
    struct('testnum', 'Test 1', 'xdata', [4 2 8],...
    'ydata', [7 1 6]));
```

You can build nested structure arrays using direct assignment statements. These statements add a second element to the array:

```
A(2).data = [9 3 2; 7 6 5];
A(2).nest.testnum = 'Test 2';
A(2).nest.xdata = [3 4 2];
A(2).nest.ydata = [5 0 9];
```



Indexing Nested Structures

To index nested structures, append nested field names using dot notation. The first text string in the indexing expression identifies the structure array, and subsequent expressions access field names that contain other structures.

For example, the array `A` created earlier has three levels of nesting:

- To access the nested structure inside `A(1)`, use `A(1).nest`.
- To access the `xdata` field in the nested structure in `A(2)`, use `A(2).nest.xdata`.
- To access element 2 of the `ydata` field in `A(1)`, use `A(1).nest.ydata(2)`.

Function Summary

This table describes the MATLAB functions for working with structures.

Function	Description
`deal`	Deal inputs to outputs.
`fieldnames`	Get structure field names.
`isfield`	Return `true` if the field is in a structure array.
`isstruct`	Return `true` for structures.
`rmfield`	Remove a structure field.
`struct`	Create or convert to a structure array.
`struct2cell`	Convert a structure array into a cell array.

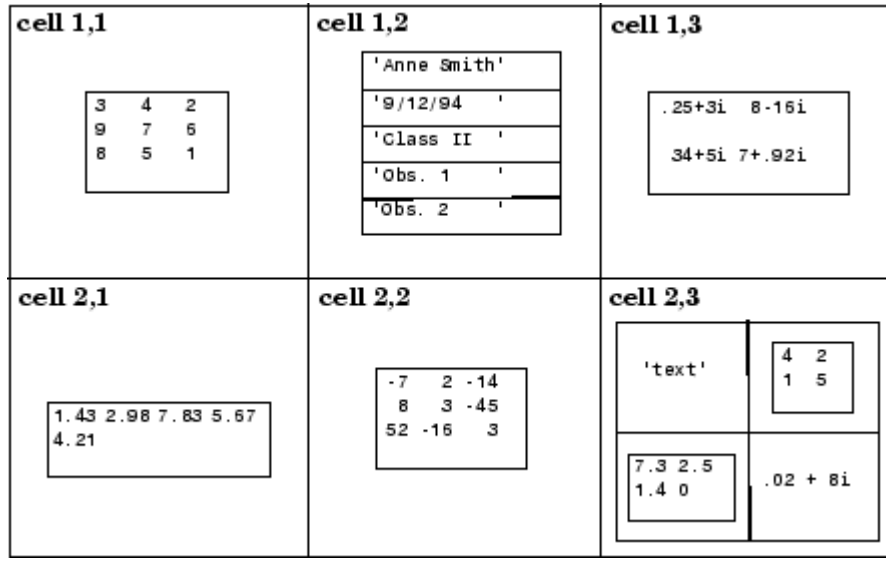
Cell Arrays

In this section...

Overview

A cell array provides a storage mechanism for dissimilar kinds of data. You can store arrays of different types and/or sizes within the cells of a cell array. For example, you can store a 1-by-50 char array, a 7-by-13 double array, and a 1-by-1 `uint32` in cells of the same cell array.

This illustration shows a cell array `A` that contains arrays of unsigned integers in `A{1,1}`, strings in `A{1,2}`, complex numbers in `A{1,3}`, floating-point numbers in `A{2,1}`, signed integers in `A{2,2}`, and another cell array in `A{2,3}`.



To access data in a cell array, you use the same type of matrix indexing as with other MATLAB matrices and arrays. However, with cell array indexing, you use curly braces, `{}`, instead of square brackets or parentheses around the array indices. For example, `A{2,3}` accesses the cell in row 2 and column 3 of cell array `A`.

Note The examples in this section focus on two-dimensional cell arrays. For examples of higher-dimension cell arrays, see “Multidimensional Arrays” on page 1-56.

Cell Array Operators

This table shows the operators used in constructing, concatenating, and indexing into the cells of a cell array.

Operation	Syntax	Description
Constructing	`C = {A B D E}`	Builds a cell array `C` that can contain data of unlike types in `A`, `B`, `D`, and `E`
Concatenating	`C3 = {C1 C2}`	Concatenates cell arrays `C1` and `C2` into a 2–element cell array `C3` such that `C3{1} = C1` and `C3{2} = C2`
	`C3 = [C1 C2]`	Concatenates the *contents* of cell arrays `C1` and `C2`
Indexing	`X = C(s)`	Returns the *cells* of array `C` that are specified by subscripts `s`
	`X = C{s}`	Returns the *contents* of the cells of `C` that are specified by subscripts `s`
	`X = C{s}(t)`	References one or more elements of an array that resides within a cell. Subscript `s` selects the cell, and subscript `t` selects the array element(s).

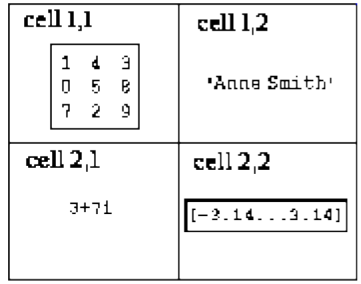
Creating a Cell Array

Creating cell arrays in MATLAB is similar to creating arrays of other MATLAB data types like double, character, etc. The main difference is that, when constructing a cell array, you enclose the array contents or indices with curly braces `{ }` instead of square brackets `[ ]`. The curly braces are cell array constructors, just as square brackets are numeric array constructors. Use commas or spaces to separate elements and semicolons to terminate each row.

For example, to create a 2-by-2 cell array `A`, type

```
A = {[1 4 3; 0 5 8; 7 2 9], 'Anne Smith'; 3+7i, -pi:pi/4:pi};
```

This results in the array shown below:



Note The notation `{}` denotes the empty cell array, just as `[]` denotes the empty matrix for numeric arrays. You can use the empty cell array in any cell array assignments.

For more information on cell arrays, refer to these topics:

- "Creating Cell Arrays Using Multiple Assignment Statements" on page 2-96
- "Building Cell Arrays with Concatenation" on page 2-98
- "Preallocating Cell Arrays with the cell Function" on page 2-99
- "Memory Requirements for Cell Arrays" on page 2-99

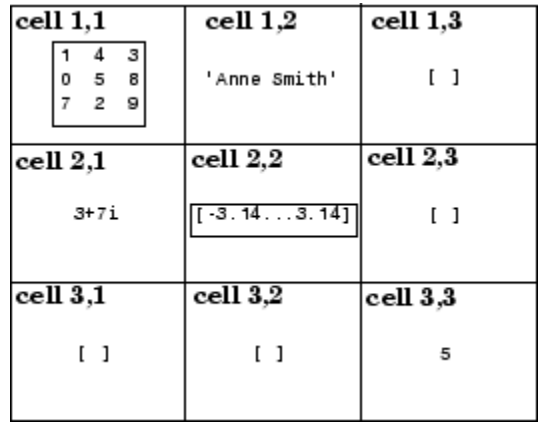
Creating Cell Arrays Using Multiple Assignment Statements

You also can create a cell array one cell at a time. MATLAB expands the size of the cell array with each assignment statement:

```
A(1,1) = {[1 4 3; 0 5 8; 7 2 9]};
A(1,2) = {'Anne Smith'};
A(2,1) = {3+7i};
A(2,2) = {-pi:pi/4:pi};
```

If you assign data to a cell that is outside the dimensions of the current array, MATLAB automatically expands the array to include the subscripts you specify. It fills any intervening cells with empty matrices. For example, the assignment below turns the 2-by-2 cell array `A` into a 3-by-3 cell array.

```
A(3,3) = {5};
```



3–by-3 Cell Array

Note If you already have a numeric array of a given name, don't try to create a cell array of the same name by assignment without first clearing the numeric array. If you do not clear the numeric array, MATLAB assumes that you are trying to "mix" cell and numeric syntaxes, and generates an error. Similarly, MATLAB does not clear a cell array when you make a single assignment to it. If any of the examples in this section give unexpected results, clear the cell array from the workspace and try again.

Alternative Assignment Syntax. When assigning values to a cell array, either of the syntaxes shown below is valid. You can use the braces on the right side of the equation, enclosing the value being assigned as shown here:

```
A(1,1) = {[1 4 3; 0 5 8; 7 2 9]};
A(1,2) = {'Anne Smith'};
```

Or use them on the left side, enclosing the array subscripts:

```
A{1,1} = [1 4 3; 0 5 8; 7 2 9];
A{1,2} = 'Anne Smith';
```

Building Cell Arrays with Concatenation

There are two ways that you can construct a new cell array from existing cell arrays:

- Concatenate entire cell arrays to individual cells of the new array. For example, join three cell arrays together to build a new cell array having three elements, each containing a cell array. This method uses the curly brace `{ }` operator.
- Concatenate the *contents* of the cells into a new array. For example, join cell arrays of size `m-by-n1`, `m-by-n2`, and `m-by-n3` together to yield a new cell array that is `m-by-(n1+n2+n3)` in size. This method uses the square bracket `[ ]` operator.

Here is an example. First, create three 3–row cell arrays of different widths.

```
C1 = {'Jan' 'Feb';  '10' '17';  uint16(2004) uint16(2001)};
C2 = {'Mar' 'Apr' 'May';  '31' '2' '10';  ...
      uint16(2006) uint16(2005) uint16(1994)};
C3 = {'Jun';  '23';  uint16(2002)};
```

This creates arrays `C1`, `C2`, and `C3`:

```
      C1                     C2                   C3
'Jan'   'Feb'       'Mar'   'Apr'   'May'       'Jun'
'10'    '17'        '31'    '2'     '10'        '23'
[2004]  [2001]      [2006]  [2005]  [1994]      [2002]
```

Use the curly brace operator to concatenate entire cell arrays, thus building a 1-by-3 cell array from the three initial arrays. Each cell of this new array holds its own cell array:

```
C4 = {C1 C2 C3}
C4 =
    {3x2 cell}    {3x3 cell}    {3x1 cell}
```

Now use the square bracket operator on the same combination of cell arrays. This time MATLAB concatenates the contents of the cells together and produces a 3-by-6 cell array:

```
C5 = [C1 C2 C3]
```

```
C5 =
    'Jan'     'Feb'     'Mar'     'Apr'     'May'     'Jun'
    '10'      '17'      '31'      '2'       '10'      '23'
    [2004]    [2001]    [2006]    [2005]    [1994]    [2002]
```

Preallocating Cell Arrays with the cell Function

The `cell` function enables you to preallocate empty cell arrays of the specified size. For example, this statement creates an empty 20-by-30 cell array:

```
B = cell(20, 30);
```

Use assignment statements to fill the cells of `B`.

It is more efficient to preallocate a cell array of a required size using the `cell` function and then assign data into it, than to grow a cell array as you go along using individual data assignments. The `cell` function, therefore, offers the most memory-efficient way of preallocating a cell array.

Memory Requirements for Cell Arrays

You do not necessarily need a contiguous block of memory to store a cell array. The memory for each cell needs to be contiguous, but not the entire array of cells.

Referencing Cells of a Cell Array

Because a cell array can contain different types of data stored in various array sizes, cell array indexing is a little more complex than indexing into a numeric or character array.

This section covers the following topics on constructing a cell array:

The examples in this section illustrate how to access the different components of a cell array. All of the examples use the following six-cell array which consists of different data types.

First, build the individual components of the example array:

```
rand('state', 0);    numArray = rand(3,5)*20;
chArray = ['Ann Lane'; 'John Doe'; 'Al Smith'];
cellArray = {1 4 3 9; 0 5 8 2; 7 2 9 2; 3 3 1 4};
logArray = numArray > 10;

stArray(1).name = chArray(1,:);
stArray(2).name = chArray(2,:);
stArray(1).billing = 28.50;
stArray(2).billing = 139.72;
stArray(1).test = numArray(1,:);
stArray(2).test = numArray(2,:);
```

and then construct the cell array from these components using the `{ }` operator:

```
A = {numArray, pi, stArray; chArray, cellArray, logArray};
```

To see what size and type of array occupies each cell in `A`, type the variable name alone:

```
A
A =
    [3x5 double]    [  3.1416]    [1x2 struct ]
    [3x8 char  ]    {4x4 cell}    [3x5 logical]
```

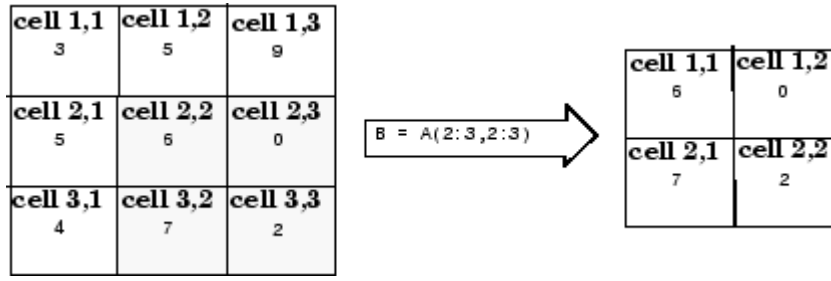
Manipulating Cells and the Contents of Cells

When working with cell arrays, you have a choice of selecting entire cells of an array to work with, or the contents of those cells. The first method is called *cell indexing*; the second is *content indexing*:

- Cell indexing enables you to work with whole cells of an array. You can access single or multiple cells within the array, but you cannot select anything less than the complete cell. If you want to manipulate the cells

of an array without regard to the contents of those cells, use cell indexing. This type of indexing is denoted by the parentheses operator `( )`.

Use cell indexing to assign any set of cells to another variable, creating a new cell array.



Creating a New Cell Array from an Existing One

- Content indexing gives you access to the contents of a cell. You can work with individual elements of an array within a cell, but you can only do so for one cell at a time. This indexing uses the curly brace operator `{ }`.

Displaying Parts of the Cell Array. Using the example cell array `A`, you can display information on the first row of cells using cell indexing. (The MATLAB colon operator functions the same when used with cell arrays as it does with numeric arrays):

```
A(1,:)
ans =
    [3x5 double]    [3.1416]    [1x2 struct]
```

To display the contents of these cells, use content indexing:

```
A{1,:}
ans =
   19.0026    9.7196    9.1294    8.8941   18.4363
    4.6228   17.8260    0.3701   12.3086   14.7641
   12.1369   15.2419   16.4281   15.8387    3.5253
ans =
    3.1416
ans =
1x2 struct array with fields:
    name
```

```
    billing
    test
```

In assignments, you can use content indexing to access only a single cell, not a subset of cells. For example, the statements `A{1,:} = value` and `B = A{1,:}` are both invalid. However, you can use a subset of cells any place you would normally use a comma-separated list of variables (for example, as function inputs or when building an array). See "Replacing Lists of Variables with Cell Arrays" on page 2-107 for details.

Assigning Cells. For cell indexing, assign the `double` array cell to `X`:

```
X = A(1,1)
X =
    [3x5 double]
```

`X` is a 1-by-1 cell array:

```
whos X
  Name      Size                    Bytes  Class

  X         1x1                       180  cell
```

For content indexing, assign the contents of the first cell of row 1 to `Y`:

```
Y = A{1,1}
Y =
   19.0026    9.7196    9.1294    8.8941   18.4363
    4.6228   17.8260    0.3701   12.3086   14.7641
   12.1369   15.2419   16.4281   15.8387    3.5253
```

`Y` is a 3-by-5 `double` array

```
whos Y
  Name      Size                    Bytes  Class

  Y         3x5                       120  double
```

Assigning Multiple Cells. Assigning multiple cells with cell indexing is similar to assigning a single cell. MATLAB creates a new cell array, each cell of which contains a cell array.

Create a 1-by-2 array with cells from `A(1,2)` and `A(1,3)`:

```
X = A(1,2:3)
X =
    [3.1416]    [1x2 struct]

whos X
  Name      Size                    Bytes  Class

  X         1x2                       808  cell
```

But assigning the contents of multiple cells returns a comma-separated list. In this case, you need one output variable on the left side of the assignment statement for each cell on the right side:

```
[Y1 Y2] = A{1,2:3}
Y1 =
    3.1416
Y2 =
1x2 struct array with fields:
    name
    billing
    test
```

Working With Arrays Within Cells

Append the parentheses operator to the cell designator `A{1,1}` to select specific elements of a cell. This example displays specific row and columns of the numeric array stored in cell `{1,1}` of `A`:

```
A{1,1}(2,3:end)
ans =
    0.3701   12.3086   14.7641
```

Working With Structures Within Cells

Use a combination of indexing operators to access the components of a structure array that resides in a cell of a cell array. The syntax for indexing into field `F` of a structure array that resides in a cell of array `C` is

```
X = C{CellArrayIndex}(StructArrayIndex).F(FieldArrayIndex);
```

For example, row 1, column 3 of cell array `A` contains a structure array. Use `A{1,3}` to select this cell, and `.name` to display the field name for all elements of the structure array:

```
A{1,3}.name
ans =
    Ann Lane
ans =
    John Doe
```

To display all fields of a particular element of the structure array, type

```
A{1,3}(2)
ans =
       name: 'John Doe'
    billing: 139.7200
       test: [4.6228 17.8260 0.3701 12.3086 14.7641]
```

The `test` field of this structure array contains a 1-by-5 numeric array. Access the odd numbered elements of this field in the second element of the structure array:

```
A{1,3}(2).test(1:2:end)
ans =
    4.6228    0.3701   14.7641
```

Working With Cell Arrays Within Cells

The syntax for indexing into a cell array that resides in a cell of array `C` using content indexing is shown below. To use cell indexing on the inner cell array, replace the curly brace operator enclosing the `InnerCellArrayIndes` with parentheses.

The syntax for content indexing is

```
X = C{OuterCellArrayIndex}{InnerCellArrayIndex}
```

In the example cell array created at the start of this section, `A{2,2}` is a cell array that resides in a cell of the outer array `A`. To get the third row of the inner cell array, type

```
A{2,2}{3,:}
```

```
ans =
     7
ans =
     2
ans =
     9
ans =
     2
```

Note that MATLAB returns a comma-separated list. To have MATLAB return the list of elements as a vector instead, surround the previous expression with square brackets:

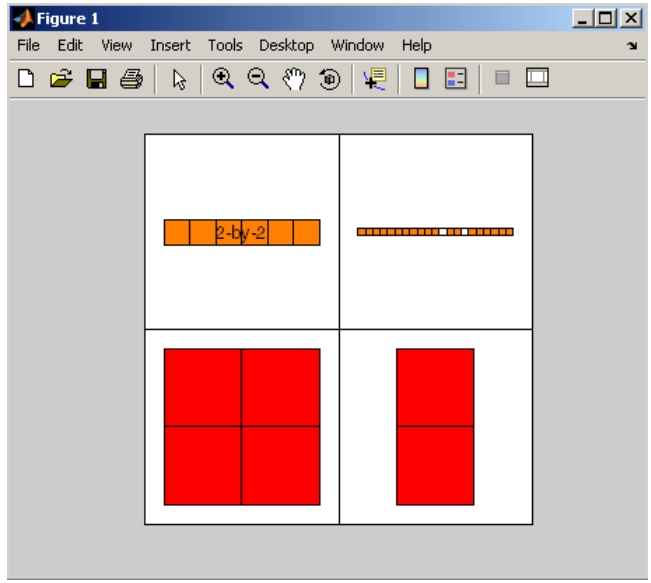
```
[A{2,2}{3,:}]
ans =
     7     2     9     2
```

Plotting the Cell Array

For a high-level graphical display of cell architecture, use the `cellplot` function. Consider a 2-by-2 cell array containing two text strings, a matrix, and a vector:

```
c{1,1} = '2-by-2';
c{1,2} = 'eigenvalues of eye(2)';
c{2,1} = eye(2);
c{2,2} = eig(eye(2));
```

The command `cellplot(c)` produces this figure:



Deleting Cells

You can delete an entire dimension of cells using a single statement. Like standard array deletion, use vector subscripting when deleting a row or column of cells and assign the empty matrix to the dimension:

```
A(cell_subscripts) = []
```

When deleting cells, curly braces do not appear in the assignment statement at all.

Reshaping Cell Arrays

Like other arrays, you can reshape cell arrays using the `reshape` function. The number of cells must remain the same after reshaping; you cannot use `reshape` to add or remove cells:

```
A = cell(3, 4);

size(A)
ans =
```

```
    3     4

B = reshape(A, 6, 2);

size(B)
ans =
    6     2
```

Replacing Lists of Variables with Cell Arrays

Cell arrays can replace comma-separated lists of MATLAB variables in

- Function input lists
- Function output lists
- Display operations
- Array constructions (square brackets and curly braces)

If you use the colon to index multiple cells in conjunction with the curly brace notation, MATLAB treats the contents of each cell as a separate variable. For example, assume you have a cell array `T` where each cell contains a separate vector. The expression `T{1:5}` is equivalent to a comma-separated list of the vectors in the first five cells of `T`.

Consider the cell array `C`:

```
C(1) = {[1 2 3]};
C(2) = {[1 0 1]};
C(3) = {1:10};
C(4) = {[9 8 7]};
C(5) = {3};
```

To convolve the vectors in `C(1)` and `C(2)` using `conv`,

```
d = conv(C{1:2})
d =
     1     2     4     2     3
```

Display vectors two, three, and four with

```
C{2:4}
ans =
    1   0   1

ans =
    1   2   3   4   5   6   7   8   9   10

ans =
    9   8   7
```

Similarly, you can create a new numeric array using the statement

```
B = [C{1}; C{2}; C{4}]
B =
    1   2   3
    1   0   1
    9   8   7
```

You can also use content indexing on the left side of an assignment to create a new cell array where each cell represents a separate output argument:

```
[D{1:2}] = eig(B)
D =
    [3x3 double]    [3x3 double]
```

You can display the actual eigenvectors and eigenvalues using `D{1}` and `D{2}`.

Note The `varargin` and `varargout` arguments allow you to specify variable numbers of input and output arguments for MATLAB functions that you create. Both `varargin` and `varargout` are cell arrays, allowing them to hold various sizes and kinds of MATLAB data. See "Passing Variable Numbers of Arguments" on page 4-34 in the MATLAB Programming documentation for details.

Applying Functions and Operators

Use indexing to apply functions and operators to the contents of cells. For example, use content indexing to call a function with the contents of a single cell as an argument:

```
A{1,1} = [1 2; 3 4];
A{1,2} = randn(3, 3);
A{1,3} = 1:5;

B = sum(A{1,1})
B =
     4     6
```

To apply a function to several cells of an unnested cell array, use a loop:

```
for k = 1:length(A)
    M{k} = sum(A{1,k});
end
```

Organizing Data in Cell Arrays

Cell arrays are useful for organizing data that consists of different sizes or kinds of data. Cell arrays are better than structures for applications where

- You need to access multiple fields of data with one statement.
- You want to access subsets of the data as comma-separated variable lists.
- You don't have a fixed set of field names.
- You routinely remove fields from the structure.

As an example of accessing multiple fields with one statement, assume that your data consists of

- A 3-by-4 array consisting of measurements taken for an experiment.
- A 15-character string containing a technician's name.
- A 3-by-4-by-5 array containing a record of measurements taken for the past five experiments.

For many applications, the best data construct for this data is a structure. However, if you routinely access only the first two fields of information, then a cell array might be more convenient for indexing purposes.

This example shows how to access the first and second elements of the cell array `TEST`:

```
[newdata,name] = deal(TEST{1:2})
```

This example shows how to access the first and second elements of the structure `TEST`:

```
newdata = TEST.measure
name = TEST.name
```

The `varargin` and `varargout` arguments are examples of the utility of cell arrays as substitutes for comma-separated lists. Create a 3-by-3 numeric array `A`:

```
A = [0 1 2; 4 0 7; 3 1 2];
```

Now apply the `normest` (2-norm estimate) function to `A`, and assign the function output to individual cells of `B`:

```
[B{1:2}] = normest(A)
B =
    [8.8826]    [4]
```

All of the output values from the function are stored in separate cells of `B`. `B(1)` contains the norm estimate; `B(2)` contains the iteration count.

Nesting Cell Arrays

A cell can contain another cell array, or even an array of cell arrays. (Cells that contain noncell data are called *leaf cells*.) You can use nested curly braces, the `cell` function, or direct assignment statements to create nested cell arrays. You can then access and manipulate individual cells, subarrays of cells, or cell elements.

Building Nested Arrays with Nested Curly Braces

You can nest pairs of curly braces to create a nested cell array. For example,

```
clear A
A(1,1) = {magic(5)};

A(1,2) = {{[5 2 8; 7 3 0; 6 7 3] 'Test 1'; [2-4i 5+7i] {17 []}}}
A =
```

```
    [5x5 double]    {2x2 cell}
```

Note that the right side of the assignment is enclosed in two sets of curly braces. The first set represents cell `(1,2)` of cell array `A`. The second "packages" the 2-by-2 cell array inside the outer cell.

Building Nested Arrays with the cell Function

To nest cell arrays with the `cell` function, assign the output of `cell` to an existing cell:

1 Create an empty 1-by-2 cell array.

```
A = cell(1,2);
```

2 Create a 2-by-2 cell array inside `A(1,2)`.

```
A(1,2) = {cell(2,2)};
```

3 Fill `A`, including the nested array, using assignments.

```
A(1,1) = {magic(5)};
A{1,2}(1,1) = {[5 2 8; 7 3 0; 6 7 3]};
A{1,2}(1,2) = {'Test 1'};
A{1,2}(2,1) = {[2-4i 5+7i]};
A{1,2}(2,2) = {cell(1, 2)}
A{1,2}{2,2}(1) = {17};
```

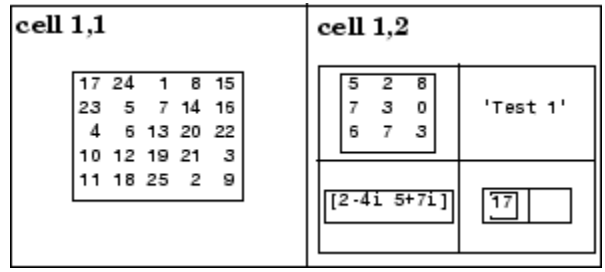
Note the use of curly braces until the final level of nested subscripts. This is required because you need to access cell contents to access cells within cells.

You can also build nested cell arrays with direct assignments using the statements shown in step 3 above.

Indexing Nested Cell Arrays

To index nested cells, concatenate indexing expressions. The first set of subscripts accesses the top layer of cells, and subsequent sets of parentheses access successively deeper layers.

For example, array A has three levels of nesting:



- To access the 5-by-5 array in cell `(1,1)`, use `A{1,1}`.
- To access the 3-by-3 array in position `(1,1)` of cell `(1,2)`, use `A{1,2}{1,1}`.
- To access the 2-by-2 cell array in cell `(1,2)`, use `A{1,2}`.
- To access the empty cell in position `(2,2)` of cell `(1,2)`, use `A{1,2}{2,2}{1,2}`.

Converting Between Cell and Numeric Arrays

Use `for` loops to convert between cell and numeric formats. For example, create a cell array `F`:

```
F{1,1} = [1 2; 3 4];
F{1,2} = [-1 0; 0 1];
F{2,1} = [7 8; 4 1];
F{2,2} = [4i 3+2i; 1-8i 5];
```

Now use three `for` loops to copy the contents of `F` into a numeric array `NUM`:

```
for k = 1:4
   for m = 1:2
      for n = 1:2
         NUM(m,n,k) = F{k}(m,n);
      end
   end
end
```

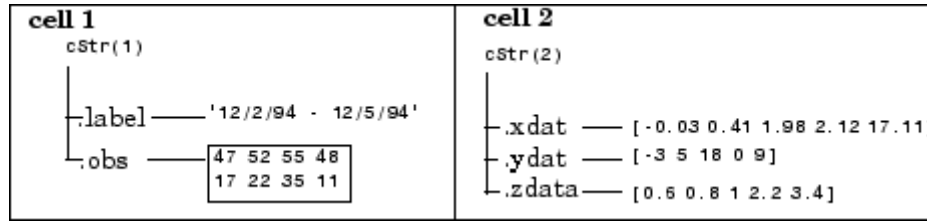
Similarly, you must use `for` loops to assign each value of a numeric array to a single cell of a cell array:

```
G = cell(1,16);
for m = 1:16
   G{m} = NUM(m);
end
```

Cell Arrays of Structures

Use cell arrays to store groups of structures with different field architectures:

```
cStr = cell(1,2);
cStr{1}.label = '12/2/94 - 12/5/94';
cStr{1}.obs = [47 52 55 48; 17 22 35 11];
cStr{2}.xdata = [-0.03 0.41 1.98 2.12 17.11];
cStr{2}.ydata = [-3 5 18 0 9];
cStr{2}.zdata = [0.6 0.8 1 2.2 3.4];
```



Cell 1 of the `cStr` array contains a structure with two fields, one a string and the other a vector. Cell 2 contains a structure with three vector fields.

When building cell arrays of structures, you must use content indexing. Similarly, you must use content indexing to obtain the contents of structures within cells. The syntax for content indexing is

```
cellArray{index}.field
```

For example, to access the `label` field of the structure in cell 1, use `cStr{1}.label`.

Function Summary

This table describes the MATLAB functions for working with cell arrays.

Function	Description
`cell`	Create a cell array.
`cell2struct`	Convert a cell array into a structure array.
`celldisp`	Display cell array contents.
`cellfun`	Apply a cell function to a cell array.
`cellplot`	Display a graphical depiction of a cell array.
`deal`	Copy input to separate outputs.
`iscell`	Return `true` for a cell array.
`num2cell`	Convert a numeric array into a cell array.

Function Handles

In this section...

Overview

A *function handle* is a MATLAB value and data type that provides a means of calling a function indirectly. You can pass function handles in calls to other functions (often called *function functions*). You can also store function handles in data structures for later use (for example, as Handle Graphics® callbacks).

Read more about function handles in the section, "Function Handles" on page 4-22.

Constructing and Invoking a Function Handle

You construct a handle for a specific function by preceding the function name with an `@` sign. Use only the function *name* (with no path information) after the `@` sign:

```
fhandle = @functionname
```

Handles to Anonymous Functions

Another way to construct a function handle is to create an anonymous function. For example,

```
sqr = @(x) x.^2;
```

creates an anonymous function that computes the square of its input argument `x`. The variable `sqr` contains a handle to the anonymous function. See "Anonymous Functions" on page 5-3 for more information.

Calling a Function Using Its Handle

To execute a function associated with a function handle, use the syntax shown here, treating the function handle `fhandle` as if it were a function name:

```
fhandle(arg1, arg2, ..., argn)
```

If the function being called takes no input arguments, then use empty parentheses after the function handle name:

```
fhandle()
```

Simple Function Handle Example

The following example calls a function `plotFHandle`, passing it a handle for the MATLAB `sin` function. `plotFHandle` then calls the `plot` function, passing it some data and the function handle to `sin`. The plot function calls the function associated with the handle to compute its y-axis values:

```
function x = plotFHandle(fhandle, data)
plot(data, fhandle(data))
```

Call `plotFhandle` with a handle to the `sin` function and the value shown below:

```
plotFHandle(@sin, -pi:0.01:pi)
```

MATLAB Classes

All MATLAB data types are implemented as object-oriented classes. You can add data types of your own to your MATLAB environment by creating additional classes. These user-defined classes define the structure of your new data type, and the M-file functions, or *methods*, that you write for each class define the behavior for that data type.

These methods can also define the way various MATLAB operators, including arithmetic operations, subscript referencing, and concatenation, apply to the new data types. For example, a class called `polynomial` might redefine the addition operator (+) so that it correctly performs the operation of addition on polynomials.

With MATLAB classes you can

- Create methods that override existing MATLAB functionality
- Restrict the operations that are allowed on an object of a class
- Enforce common behavior among related classes by inheriting from the same parent class
- Significantly increase the reuse of your code

Read more about MATLAB classes in Chapter 9, “Classes and Objects”.

Java Classes

MATLAB provides an interface to the Java programming language that enables you to create objects from Java classes and call Java methods on these objects. A Java class is a MATLAB data type. Native and third-party classes are already available through the MATLAB interface. You can also create your own Java class definitions and bring them into MATLAB.

The MATLAB Java interface enables you to

- Access Java API (application programming interface) class packages that support essential activities such as I/O and networking
- Access third-party Java classes
- Easily construct Java objects in MATLAB
- Call Java object methods, using either Java or MATLAB syntax
- Pass data between MATLAB variables and Java objects

Read more about Java classes in MATLAB in “Calling Java from MATLAB” in the MATLAB External Interfaces documentation.

Basic Program Components

Variables

In this section...

Types of Variables

A MATLAB variable is essentially a tag that you assign to a value while that value remains in memory. The tag gives you a way to reference the value in memory so that your programs can read it, operate on it with other data, and save it back to memory.

MATLAB provides three basic types of variables:

- "Local Variables" on page 3-2
- "Global Variables" on page 3-3
- "Persistent Variables" on page 3-5

Local Variables

Each MATLAB function has its own local variables. These are separate from those of other functions (except for nested functions), and from those of the base workspace. Variables defined in a function do not remain in memory from one function call to the next, unless they are defined as `global` or `persistent`.

Scripts, on the other hand, do not have a separate workspace. They store their variables in a workspace that is shared with the caller of the script. When called from the command line, they share the base workspace. When called from a function, they share that function's workspace.

Note If you run a script that alters a variable that already exists in the caller's workspace, that variable is overwritten by the script.

Global Variables

If several functions, and possibly the base workspace, all declare a particular name as `global`, then they all share a single copy of that variable. Any assignment to that variable, in any function, is available to all the other functions declaring it global.

Suppose, for example, you want to study the effect of the interaction coefficients, α and β, in the Lotka-Volterra predator-prey model.

$$\dot{y}_1 = y_1 - \alpha y_1 y_2$$

$$\dot{y}_2 = -y_2 + \beta y_1 y_2$$

Create an M-file, `lotka.m`.

```
function yp = lotka(t,y)
%LOTKA   Lotka-Volterra predator-prey model.
global ALPHA BETA
yp = [y(1) - ALPHA*y(1)*y(2); -y(2) + BETA*y(1)*y(2)];
```

Then interactively enter the statements

```
global ALPHA BETA
ALPHA = 0.01
BETA = 0.02
[t,y] = ode23(@lotka,[0,10],[1; 1]);
plot(t,y)
```

The two `global` statements make the values assigned to `ALPHA` and `BETA` at the command prompt available inside the function defined by `lotka.m`. They can be modified interactively and new solutions obtained without editing any files.

Creating Global Variables. Each function that uses a global variable must first declare the variable as `global`. It is usually best to put global declarations toward the beginning of the function. You would declare global variable `MAXLEN` as follows:

```
global MAXLEN
```

If the M-file contains subfunctions as well, then each subfunction requiring access to the global variable must declare it as `global`. To access the variable from the MATLAB command line, you must declare it as `global` at the command line.

MATLAB global variable names are typically longer and more descriptive than local variable names, and often consist of all uppercase characters. These are not requirements, but guidelines to increase the readability of MATLAB code, and to reduce the chance of accidentally redefining a global variable.

Displaying Global Variables. To see only those variables you have declared as global, use the `who` or `whos` functions with the literal, `global`.

```
global MAXLEN MAXWID
MAXLEN = 36;  MAXWID = 78;
len = 5;  wid = 21;

whos global
  Name         Size                Bytes  Class

  MAXLEN       1x1                     8  double array (global)
  MAXWID       1x1                     8  double array (global)

Grand total is 2 elements using 16 bytes
```

Suggestions for Using Global Variables. A certain amount of risk is associated with using global variables and, because of this, it is recommended that you use them sparingly. You might, for example, unintentionally give a global variable in one function a name that is already used for a global variable in another function. When you run your application, one function may overwrite the variable used by the other. This error can be difficult to track down.

Another problem comes when you want to change the variable name. To make a change without introducing an error into the application, you must find every occurrence of that name in your code (and other people's code, if you share functions).

Alternatives to Using Global Variables. Instead of using a global variable, you may be able to

- Pass the variable to other functions as an additional argument. In this way, you make sure that any shared access to the variable is intentional.

  If this means that you have to pass a number of additional variables, you can put them into a structure or cell array and just pass it as one additional argument.
- Use a persistent variable (described in the next section), if you only need to make the variable persist in memory from one function call to the next.

Persistent Variables

Characteristics of persistent variables are

- You can declare and use them within M-file functions only.
- Only the function in which the variables are declared is allowed access to it.
- MATLAB does not clear them from memory when the function exits, so their value is retained from one function call to the next.

You must declare persistent variables before you can use them in a function. It is usually best to put your persistent declarations toward the beginning of the function. You would declare persistent variable `SUM_X` as follows:

```
persistent SUM_X
```

If you clear a function that defines a persistent variable (i.e., using `clear` *`functionname`* or `clear all`), or if you edit the M-file for that function, MATLAB clears all persistent variables used in that function.

You can use the `mlock` function to keep an M-file from being cleared from memory, thus keeping persistent variables in the M-file from being cleared as well.

Initializing Persistent Variables. When you declare a persistent variable, MATLAB initializes its value to an empty matrix, `[]`. After the declaration statement, you can assign your own value to it. This is often done using an `isempty` statement, as shown here:

```
function findSum(inputvalue)
persistent SUM_X

if isempty(SUM_X)
   SUM_X = 0;
end
SUM_X = SUM_X + inputvalue
```

This initializes the variable to 0 the first time you execute the function, and then it accumulates the value on each iteration.

Naming Variables

MATLAB variable names must begin with a letter, which may be followed by any combination of letters, digits, and underscores. MATLAB distinguishes between uppercase and lowercase characters, so `A` and `a` are not the same variable.

Although variable names can be of any length, MATLAB uses only the first `N` characters of the name, (where `N` is the number returned by the function `namelengthmax`), and ignores the rest. Hence, it is important to make each variable name unique in the first `N` characters to enable MATLAB to distinguish variables.

```
N = namelengthmax
N =
    63
```

The `genvarname` function can be useful in creating variable names that are both valid and unique. See the `genvarname` reference page to find out how to do this.

Verifying a Variable Name

You can use the `isvarname` function to make sure a name is valid before you use it. `isvarname` returns 1 if the name is valid, and 0 otherwise.

```
isvarname 8th_column
ans =
     0                    % Not valid - begins with a number
```

Avoid Using Function Names for Variables

When naming a variable, make sure you are not using a name that is already used as a function name, either one of your own M-file functions or one of the functions in the MATLAB language. If you define a variable with a function name, you will not be able to call that function until you either remove the variable from memory with the `clear` function, or invoke the function using `builtin`.

For example, if you enter the following command, you will not be able to use the MATLAB `disp` function until you clear the variable with `clear disp`.

```
disp = 50;
```

To test whether a proposed variable name is already used as a function name, use

```
which -all variable_name
```

Potential Conflict with Function Names

There are some MATLAB functions that have names that are commonly used as variable names in programming code. A few examples of such functions are `i`, `j`, `mode`, `char`, `size`, and `path`.

If you need to use a variable that is also the name of a MATLAB function, and have determined that you have no need to call the function, you should be aware that there is still a possibility for conflict. See the following two examples:

- "Variables Loaded From a MAT-File" on page 3-8
- "Variables In Evaluation Statements" on page 3-9

Variables Loaded From a MAT-File. The function shown below loads previously saved data from MAT-file `settings.mat`. It is supposed to display the value of one of the loaded variables, `mode`. However, `mode` is also the name of a MATLAB function and, in this case, MATLAB interprets it as the function and not the variable loaded from the MAT-file:

```
function show_mode
load settings;
whos mode
fprintf('Mode is set to %s\n', mode)
```

Assume that `mode` already exists in the MAT-file. Execution of the function shows that, even though `mode` is successfully loaded into the function workspace as a variable, when MATLAB attempts to operate on it in the last line, it interprets `mode` as a function. This results in an error:

```
show_mode
  Name       Size                     Bytes  Class

  mode       1x6                         12  char array

Grand total is 6 elements using 12 bytes

??? Error using ==> mode
Not enough input arguments.

Error in ==> show_mode at 4
fprintf('Mode is set to %s\n', mode)
```

Because MATLAB parses function M-files before they are run, it needs to determine before runtime which identifiers in the code are variables and which are functions. The function in this example does not establish `mode` as a variable name and, as a result, MATLAB interprets it as a function name instead.

There are several ways to make this function work as intended without having to change the variable name. Both indicate to MATLAB that the name represents a variable, and not a function:

- Name the variable explicitly in the `load` statement:

```
function show_mode
load settings mode;
whos mode
fprintf('Mode is set to %s\n', mode)
```

- Initialize the variable (e.g., set it to an empty matrix or empty string) at the start of the function:

```
function show_mode
mode = '';
load settings;
whos mode
fprintf('Mode is set to %s\n', mode)
```

Variables In Evaluation Statements. Variables used in evaluation statements such as `eval`, `evalc`, and `evalin` can also be mistaken for function names. The following M-file defines a variable named `length` that conflicts with MATLAB `length` function:

```
function find_area
eval('length = 12;  width = 36;');
fprintf('The area is %d\n', length .* width)
```

The second line of this code would seem to establish `length` as a variable name that would be valid when used in the statement on the third line. However, when MATLAB parses this line, it does not consider the *contents* of the string that is to be evaluated. As a result, MATLAB has no way of knowing that `length` was meant to be used as a variable name in this program, and the name defaults to a function name instead, yielding the following error:

```
find_area
??? Error using ==> length
Not enough input arguments.
```

To force MATLAB to interpret `length` as a variable name, use it in an explicit assignment statement first:

```
function find_area
length = [];
eval('length = 12;  width = 36;');
fprintf('The area is %d\n', length .* width)
```

Guidelines to Using Variables

The same guidelines that apply to MATLAB variables at the command line also apply to variables in M-files:

- You do not need to type or declare variables used in M-files (with the possible exception of designating them as `global` or `persistent`).
- Before assigning one variable to another, you must be sure that the variable on the right-hand side of the assignment has a value.
- Any operation that assigns a value to a variable creates the variable, if needed, or overwrites its current value, if it already exists.

Scope of a Variable

MATLAB stores variables in a part of memory called a workspace. The *base workspace* holds variables created during your interactive MATLAB session and also any variables created by running M-file scripts. Variables created at the MATLAB command prompt can also be used by scripts without having to declare them as global.

Functions do not use the base workspace. Every function has its own *function workspace*. Each function workspace is kept separate from the base workspace and all other workspaces to protect the integrity of the data used by that function. Even subfunctions that are defined in the same M-file have a separate function workspace.

Extending Variable Scope

In most cases, variables created within a function are known only within that function. These variables are not available at the MATLAB command prompt or to any other function or subfunction.

Passing Variables from Another Workspace. The most secure way to extend the scope of a function variable is to pass it to other functions as an argument in the function call. Since MATLAB passes data only by value, you also need to add the variable to the return values of any function that modifies its value.

Evaluating in Another Workspace Using evalin. Functions can also obtain variables from either the base or the caller's workspace using the `evalin` function. The example below, `compareAB_1`, evaluates a command in the context of the MATLAB command line, taking the values of variables `A` and `B` from the base workspace.

Define `A` and `B` in the base workspace:

```
A = [13 25 82 68 9 15 77];  B = [63 21 71 42 30 15 22];
```

Use `evalin` to evaluate the command `A(find(A<=B))` in the context of the MATLAB base workspace:

```
function C = compareAB_1
C = evalin('base', 'A(find(A<=B))');
```

Call the function. You do not have to pass the variables because they are made available to the function via the `evalin` function:

```
C = compareAB_1
C =
    13     9    15
```

You can also evaluate in the context of the caller's workspace by specifying `'caller'` (instead of `'base'`) as the first input argument to `evalin`.

Using Global Variables. A third way to extend variable scope is to declare the variable as `global` within every function that needs access to it. If you do this, you need make sure that no functions with access to the variable overwrite its value unintentionally. For this reason, it is recommended that you limit the use of global variables.

Create global vectors `A` and `B` in the base workspace:

```
global A
global B
A = [13 25 82 68 9 15 77];  B = [63 21 71 42 30 15 22];
```

Also declare them in the function to be called:

```
function C = compareAB_2
global A
```

```
global B

C = A(find(A<=B));
```

Call the function. Again, you do not have to pass `A` and `B` as arguments to the called function:

```
C = compareAB_2
C =
    13     9    15
```

Scope in Nested Functions

Variables within nested functions are accessible to more than just their immediate function. As a general rule, the scope of a local variable is the largest containing function body in which the variable appears, and all functions nested within that function. For more information on nested functions, see “Variable Scope in Nested Functions” on page 5-19.

Lifetime of a Variable

Variables created at the MATLAB command prompt or in an M-file script exist until you clear them or end your MATLAB session. Variables in functions exist only until the function completes unless they have been declared as `global` or `persistent`.

Keywords

MATLAB reserves certain words for its own use as keywords of the language. To list the keywords, type

```
iskeyword
ans =
    'break'
    'case'
    'catch'
    'continue'
    'else'
    'elseif'
    'end'
    'for'
    'function'
    'global'
    'if'
    'otherwise'
    'persistent'
    'return'
    'switch'
    'try'
    'while'
```

See the online function reference pages to learn how to use these keywords.

You should not use MATLAB keywords other than for their intended purpose. For example, a keyword should not be used as follows:

```
while = 5;
??? while = 5;
          |
Error: Expected a variable, function, or constant, found "=".
```

Special Values

Several functions return important special values that you can use in your M-files.

Function	Return Value
`ans`	Most recent answer (variable). If you do not assign an output variable to an expression, MATLAB automatically stores the result in `ans`.
`eps`	Floating-point relative accuracy. This is the tolerance MATLAB uses in its calculations.
`intmax`	Largest 8-, 16-, 32-, or 64-bit integer your computer can represent.
`intmin`	Smallest 8-, 16-, 32-, or 64-bit integer your computer can represent.
`realmax`	Largest floating-point number your computer can represent.
`realmin`	Smallest positive floating-point number your computer can represent.
`pi`	`3.1415926535897...`
`i`, `j`	Imaginary unit.
`inf`	Infinity. Calculations like `n/0`, where `n` is any nonzero real value, result in `inf`.
`NaN`	Not a Number, an invalid numeric value. Expressions like `0/0` and `inf/inf` result in a `NaN`, as do arithmetic operations involving a `NaN`. Also, if `n` is complex with a zero real part, then `n/0` returns a value with a `NaN` real part.
`computer`	Computer type.
`version`	MATLAB version string.

Here are some examples that use these values in MATLAB expressions.

```
x = 2 * pi
x =
   6.2832

A = [3+2i 7-8i]
A =
   3.0000 + 2.0000i   7.0000 - 8.0000i

tol = 3 * eps
tol =
   6.6613e-016

intmax('uint64')
ans =
   18446744073709551615
```

Operators

In this section...

Arithmetic Operators

Arithmetic operators perform numeric computations, for example, adding two numbers or raising the elements of an array to a given power. The following table provides a summary. For more information, see the arithmetic operators reference page.

Operator	Description
+	Addition
-	Subtraction
.*	Multiplication
./	Right division
.\	Left division
+	Unary plus
-	Unary minus
:	Colon operator
.^	Power
.'	Transpose
'	Complex conjugate transpose
*	Matrix multiplication
/	Matrix right division

Operator	Description
\	Matrix left division
^	Matrix power

Arithmetic Operators and Arrays

Except for some matrix operators, MATLAB arithmetic operators work on corresponding elements of arrays with equal dimensions. For vectors and rectangular arrays, both operands must be the same size unless one is a scalar. If one operand is a scalar and the other is not, MATLAB applies the scalar to every element of the other operand—this property is known as *scalar expansion*.

This example uses scalar expansion to compute the product of a scalar operand and a matrix.

```
A = magic(3)
A =
     8     1     6
     3     5     7
     4     9     2

3 * A
ans =
    24     3    18
     9    15    21
    12    27     6
```

Relational Operators

Relational operators compare operands quantitatively, using operators like “less than” and “not equal to.” The following table provides a summary. For more information, see the relational operators reference page.

Operator	Description
<	Less than
<=	Less than or equal to

Operator	Description
>	Greater than
>=	Greater than or equal to
==	Equal to
~=	Not equal to

Relational Operators and Arrays

The MATLAB relational operators compare corresponding elements of arrays with equal dimensions. Relational operators always operate element-by-element. In this example, the resulting matrix shows where an element of `A` is equal to the corresponding element of `B`.

```
A = [2 7 6;9 0 5;3 0.5 6];
B = [8 7 0;3 2 5;4 -1 7];

A == B
ans =
     0     1     0
     0     0     1
     0     0     0
```

For vectors and rectangular arrays, both operands must be the same size unless one is a scalar. For the case where one operand is a scalar and the other is not, MATLAB tests the scalar against every element of the other operand. Locations where the specified relation is true receive logical `1`. Locations where the relation is false receive logical `0`.

Relational Operators and Empty Arrays

The relational operators work with arrays for which any dimension has size zero, as long as both arrays are the same size or one is a scalar. However, expressions such as

```
A == []
```

return an error if A is not 0-by-0 or 1-by-1. This behavior is consistent with that of all other binary operators, such as +, -, >, <, &, |, etc.

To test for empty arrays, use the function

```
isempty(A)
```

Logical Operators

MATLAB offers three types of logical operators and functions:

- Element-wise — operate on corresponding elements of logical arrays.
- Bit-wise — operate on corresponding bits of integer values or arrays.
- Short-circuit — operate on scalar, logical expressions.

The values returned by MATLAB logical operators and functions, with the exception of bit-wise functions, are of type `logical` and are suitable for use with logical indexing.

Element-Wise Operators and Functions

The following logical operators and functions perform elementwise logical operations on their inputs to produce a like-sized output array.

The examples shown in the following table use vector inputs `A` and `B`, where

```
A = [0 1 1 0 1];
B = [1 1 0 0 1];
```

Operator	Description	Example
`&`	Returns `1` for every element location that is `true` (nonzero) in both arrays, and `0` for all other elements.	`A & B = 01001`
`|`	Returns `1` for every element location that is `true` (nonzero) in either one or the other, or both arrays, and `0` for all other elements.	`A | B = 11101`
`~`	Complements each element of the input array, `A`.	`~A = 10010`
`xor`	Returns `1` for every element location that is `true` (nonzero) in only one array, and `0` for all other elements.	`xor(A,B) = 10100`

For operators and functions that take two array operands, (`&`, `|`, and `xor`), both arrays must have equal dimensions, with each dimension being the same size. The one exception to this is where one operand is a scalar and the other is not. In this case, MATLAB tests the scalar against every element of the other operand.

Note MATLAB converts any finite nonzero, numeric values used as inputs to logical expressions to logical `1`, or `true`.

Operator Overloading. You can overload the `&`, `|`, and `~` operators to make their behavior dependent upon the data type on which they are being used. Each of these operators has a representative function that is called whenever that operator is used. These are shown in the table below.

Logical Operation	Equivalent Function
`A & B`	`and(A, B)`
`A | B`	`or(A, B)`
`~A`	`not(A)`

Other Array Functions. Two other MATLAB functions that operate logically on arrays, but not in an elementwise fashion, are `any` and `all`. These functions show whether *any* or *all* elements of a vector, or a vector within a matrix or an array, are nonzero.

When used on a matrix, `any` and `all` operate on the columns of the matrix. When used on an N-dimensional array, they operate on the first nonsingleton dimension of the array. Or, you can specify an additional `dimension` input to operate on a specific dimension of the array.

The examples shown in the following table use array input `A`, where

```
A = [0   1   2;
     0  -3   8;
     0   5   0];
```

Function	Description	Example
`any(A)`	Returns `1` for a vector where *any* element of the vector is `true` (nonzero), and `0` if no elements are `true`.	`any(A) ans = 0 1 1`
`all(A)`	Returns `1` for a vector where *all* elements of the vector are `true` (nonzero), and `0` if all elements are not `true`.	`all(A) ans = 0 1 0`

Note The `all` and `any` functions ignore any `NaN` values in the input arrays.

Short-Circuiting in Elementwise Operators. When used in the context of an `if` or `while` expression, and only in this context, the elementwise `|` and `&` operators use short-circuiting in evaluating their expressions. That is, `A|B` and `A&B` ignore the second operand, `B`, if the first operand, `A`, is sufficient to determine the result.

So, although the statement `1|[]` evaluates to `false`, the same statement evaluates to `true` when used in either an `if` or `while` expression:

```
A = 1;   B = [];
if(A|B) disp 'The statement is true',  end;
   The statement is true
```

while the reverse logical expression, which does not short-circuit, evaluates to `false`

```
if(B|A) disp 'The statement is true',  end;
```

Another example of short-circuiting with elementwise operators shows that a logical expression such as the following, which under most circumstances is invalid due to a size mismatch between `A` and `B`,

```
A = [1 1];   B = [2 0 1];
A|B        % This generates an error.
```

works within the context of an `if` or `while` expression:

```
if (A|B) disp 'The statement is true',  end;
```

```
The statement is true
```

Logical Expressions Using the find Function. The `find` function determines the indices of array elements that meet a given logical condition. The function is useful for creating masks and index matrices. In its most general form, `find` returns a single vector of indices. This vector can be used to index into arrays of any size or shape.

For example,

```
A = magic(4)
A =
    16    2    3   13
     5   11   10    8
     9    7    6   12
     4   14   15    1

i = find(A > 8);
A(i) = 100
A =
   100    2    3  100
     5  100  100    8
   100    7    6  100
     4  100  100    1
```

Note An alternative to using `find` in this context is to index into the matrix using the logical expression itself. See the example below.

The last two statements of the previous example can be replaced with this one statement:

```
A(A > 8) = 100;
```

You can also use `find` to obtain both the row and column indices of a rectangular matrix for the array values that meet the logical condition:

```
A = magic(4)
A =
    16    2    3   13
```

```
     5    11    10     8
     9     7     6    12
     4    14    15     1

[row, col] = find(A > 12)
row =
     1
     4
     4
     1
col =
     1
     2
     3
     4
```

Bit-Wise Functions

The following functions perform bit-wise logical operations on nonnegative integer inputs. Inputs may be scalar or in arrays. If in arrays, these functions produce a like-sized output array.

The examples shown in the following table use scalar inputs `A` and `B`, where

```
A = 28;              % binary 11100
B = 21;              % binary 10101
```

Function	Description	Example
`bitand`	Returns the bit-wise AND of two nonnegative integer arguments.	`bitand(A,B) = 20 (binary 10100)`
`bitor`	Returns the bit-wise OR of two nonnegative integer arguments.	`bitor(A,B) = 29 (binary 11101)`

Function	Description	Example
`bitcmp`	Returns the bit-wise complement as an `n`-bit number, where `n` is the second input argument to `bitcmp`.	`bitcmp(A,5) = 3 (binary 00011)`
`bitxor`	Returns the bit-wise exclusive OR of two nonnegative integer arguments.	`bitxor(A,B) = 9 (binary 01001)`

Short-Circuit Operators

The following operators perform AND and OR operations on logical expressions containing scalar values. They are *short-circuit* operators in that they evaluate their second operand only when the result is not fully determined by the first operand.

Operator	Description
`&&`	Returns logical `1` (`true`) if both inputs evaluate to `true`, and logical `0` (`false`) if they do not.
`||`	Returns logical `1` (`true`) if either input, or both, evaluate to `true`, and logical `0` (`false`) if they do not.

The statement shown here performs an AND of two logical terms, `A` and `B`:

```
A && B
```

If `A` equals zero, then the entire expression will evaluate to logical `0` (`false`), regardless of the value of `B`. Under these circumstances, there is no need to evaluate `B` because the result is already known. In this case, MATLAB short-circuits the statement by evaluating only the first term.

A similar case is when you OR two terms and the first term is `true`. Again, regardless of the value of `B`, the statement will evaluate to `true`. There is no need to evaluate the second term, and MATLAB does not do so.

Advantage of Short-Circuiting. You can use the short-circuit operators to evaluate an expression only when certain conditions are satisfied. For example, you want to execute an M-file function only if the M-file resides on the current MATLAB path.

Short-circuiting keeps the following code from generating an error when the file, `myfun.m`, cannot be found:

```
comp = (exist('myfun.m') == 2) && (myfun(x) >= y)
```

Similarly, this statement avoids divide-by-zero errors when `b` equals zero:

```
x = (b ~= 0) && (a/b > 18.5)
```

You can also use the `&&` and `||` operators in `if` and `while` statements to take advantage of their short-circuiting behavior:

```
if (nargin >= 3) && (ischar(varargin{3}))
```

Operator Precedence

You can build expressions that use any combination of arithmetic, relational, and logical operators. Precedence levels determine the order in which MATLAB evaluates an expression. Within each precedence level, operators have equal precedence and are evaluated from left to right. The precedence rules for MATLAB operators are shown in this list, ordered from highest precedence level to lowest precedence level:

1. Parentheses ()
2. Transpose (`.'`), power (`.^`), complex conjugate transpose (’), matrix power (`^`)
3. Unary plus (`+`), unary minus (`-`), logical negation (`~`)
4. Multiplication (`.*`), right division (`./`), left division (`.\`), matrix multiplication (`*`), matrix right division (`/`), matrix left division (`\`)
5. Addition (`+`), subtraction (`-`)
6. Colon operator (`:`)

7. Less than (<), less than or equal to (<=), greater than (>), greater than or equal to (>=), equal to (==), not equal to (~=)
8. Element-wise AND (&)
9. Element-wise OR (|)
10. Short-circuit AND (&&)
11. Short-circuit OR (||)

Precedence of AND and OR Operators

MATLAB always gives the & operator precedence over the | operator. Although MATLAB typically evaluates expressions from left to right, the expression `a|b&c` is evaluated as `a|(b&c)`. It is a good idea to use parentheses to explicitly specify the intended precedence of statements containing combinations of & and |.

The same precedence rule holds true for the && and || operators.

Overriding Default Precedence

The default precedence can be overridden using parentheses, as shown in this example:

```
A = [3 9 5];
B = [2 1 5];
C = A./B.^2
C =
    0.7500    9.0000    0.2000

C = (A./B).^2
C =
    2.2500   81.0000    1.0000
```

MATLAB Expressions

In this section...

String Evaluation

String evaluation adds power and flexibility to the MATLAB language, letting you perform operations like executing user-supplied strings and constructing executable strings through concatenation of strings stored in variables.

eval

The `eval` function evaluates a string that contains a MATLAB expression, statement, or function call. In its simplest form, the `eval` syntax is

```
eval('string')
```

For example, this code uses `eval` on an expression to generate a Hilbert matrix of order `n`.

```
t = '1/(m + n - 1)';
for m = 1:k
    for n = 1:k
        a(m,n) = eval(t);
    end
end
```

Here is an example that uses `eval` on a statement.

```
eval('t = clock');
```

Constructing Strings for Evaluation. You can concatenate strings to create a complete expression for input to `eval`. This code shows how `eval` can create 10 variables named `P1`, `P2`, `...`, `P10`, and set each of them to a different value.

```
for n = 1:10
    eval(['P', int2str(n), '= n .^ 2'])
```

```
end
```

feval

The `feval` function differs from `eval` in that it executes a function rather than a MATLAB expression. The function to be executed is specified in the first argument by either a function handle or a string containing the function name.

You can use `feval` and the `input` function to choose one of several tasks defined by M-files. This example uses function handles for the `sin`, `cos`, and `log` functions.

```
fun = {@sin; @cos; @log};
k = input('Choose function number: ');
x = input('Enter value: ');
feval(fun{k}, x)
```

Shell Escape Functions

It is sometimes useful to access your own C or Fortran programs using *shell escape functions*. Shell escape functions use the shell escape command `!` to make external stand-alone programs act like new MATLAB functions. A shell escape M-function is an M-file that

1. Saves the appropriate variables on disk.
2. Runs an external program (which reads the data file, processes the data, and writes the results back out to disk).
3. Loads the processed file back into the workspace.

For example, look at the code for `garfield.m`, below. This function uses an external function, `gareqn`, to find the solution to Garfield's equation.

```
function y = garfield(a,b,q,r)
save gardata a b q r
!gareqn
load gardata
```

This M-file

1. Saves the input arguments `a`, `b`, `q`, and `r` to a MAT-file in the workspace using the `save` command.
2. Uses the shell escape operator to access a C or Fortran program called `gareqn` that uses the workspace variables to perform its computation. `gareqn` writes its results to the `gardata` MAT-file.
3. Loads the `gardata` MAT-file described in “Using MAT-Files” to obtain the results.

Regular Expressions

In this section...

Overview

A regular expression is a string of characters that defines a certain pattern. You would normally use a regular expression in searching through text for a group of words that matches this pattern, perhaps while parsing program input, or while processing a block of text.

The string `'Joh?n\w*'` is an example of a regular expression. It defines a pattern that starts with the letters `Jo`, is optionally followed by the letter `h` (indicated by `'h?'`), is then followed by the letter `n`, and ends with any

number of non-whitespace characters (indicated by `'\w*'`). This pattern matches any of the following:

```
Jon, John, Jonathan, Johnny
```

MATLAB supports most of the special characters, or *metacharacters*, commonly used with regular expressions and provides several functions to use in searching and replacing text with these expressions.

MATLAB Regular Expression Functions

Several MATLAB functions support searching and replacing characters using regular expressions:

Function	Description
`regexp`	Match regular expression.
`regexpi`	Match regular expression, ignoring case.
`regexprep`	Replace string using regular expression.
`regexptranslate`	Translate string into regular expression.

See the function reference pages to obtain more information on these functions. For more information on how to use regular expressions in general, consult a reference on that subject.

The `regexp` and `regexpi` functions return up to six outputs in the order shown in the reference page for `regexp`. You can select specific outputs to be returned by using one or more of the following qualifiers with these commands:

Qualifier	Value Returned
`'start'`	Starting index of each substring matching the expression
`'end'`	Ending index of each substring matching the expression
`'tokenExtents'`	Starting and ending indices of each substring matching a token in the expression
`'match'`	Text of each substring matching the expression

Qualifier	Value Returned
`'tokens'`	Text of each token captured
`'names'`	Name and text of each named token captured
`'split'`	Treating each match as a delimiter, the text of each substring between such delimiters.

There is an additional qualifier named `'once'` that you can use to return only the first match found.

Elements of an Expression

Tables and examples in the sections that follow show the metacharacters and syntax supported by the `regexp`, `regexpi`, and `regexprep` functions in MATLAB. Expressions shown in the left column have special meaning and match one or more characters according to the usage described in the right column. Any character not having a special meaning, for example, any alphabetic character, matches that same character literally. To force one of the regular expression functions to interpret a sequence of characters literally (rather than as an operator) use the `regexptranslate` function.

These elements are presented under these categories:

Each table is followed by a set of examples that show how to use the syntax presented in that table.

Character Classes

Character classes represent either a specific set of characters (e.g., uppercase) or a certain type of character (e.g., non-whitespace).

Operator	Usage
`.`	Any single character, including white space
`[c1c2c3]`	Any character contained within the brackets: c_1 or c_2 or c_3
`[^c1c2c3]`	Any character not contained within the brackets: anything but c_1 or c_2 or c_3
`[c1-c2]`	Any character in the range of c_1 through c_2
`\s`	Any white-space character; equivalent to `[ \f\n\r\t\v]`
`\S`	Any non-whitespace character; equivalent to `[^ \f\n\r\t\v]`
`\w`	Any alphabetic, numeric, or underscore character; equivalent to `[a-zA-Z_0-9]`. (This does not apply to non-English character sets).
`\W`	Any character that is not alphabetic, numeric, or underscore; equivalent to `[^a-zA-Z_0-9]`. (True only for English character sets).
`\d`	Any numeric digit; equivalent to `[0-9]`
`\D`	Any nondigit character; equivalent to `[^0-9]`

The following examples demonstrate how to use the character classes listed above. See the `regexp` reference page for help with syntax. Most of these examples use the following string:

```
str = 'The rain in Spain falls mainly on the plain.';
```

Any Character — .

Use `'..ain'` in an expression to match a sequence of five characters ending in `'ain'`. Note that `.` matches white-space characters as well:

```
regexp(str, '..ain')
ans =
     4    13    24    39
```

Matches `' rain'`, `'Spain'`, `' main'`, and `'plain'`.

Returning Strings Rather than Indices. Here is the same example, this time specifying the command qualifier `'match'`. In this case, `regexp` returns the *text* of the matching strings rather than the starting index:

```
regexp(str, '..ain', 'match')
ans =
    ' rain'    'Spain'    ' main'    'plain'
```

Selected Characters — [c1c2c3]

Use `[`$c_1c_2c_3$`]` in an expression to match selected characters `r`, `p`, or `m` followed by `'ain'`. Specify two qualifiers this time, `'match'` and `'start'`, along with an output argument for each, `mat` and `idx`. This returns the matching strings and the starting indices of those strings:

```
[mat idx] = regexp(str, '[rpm]ain', 'match', 'start')
mat =
    'rain'    'pain'    'main'
idx =
     5    14    25
```

Range of Characters — [c1 - c2]

Use `[c1-c2]` in an expression to find words that begin with a letter in the range of `A` through `Z`:

```
[mat idx] = regexp(str, '[A-Z]\w*', 'match', 'start')
mat =
    'The'    'Spain'
idx =
     1    13
```

Word and White-Space Characters — \w, \s

Use `\w` and `\s` in an expression to find words that end with the letter `n` followed by a white-space character. Add a new qualifier, `'end'`, to return the `str` index that marks the end of each match:

```
[mat ix1 ix2] = regexp(str, '\w*n\s', 'match', 'start', 'end')
mat =
    'rain '    'in '    'Spain '    'on '
ix1 =
     5    10    13    32
ix2 =
     9    12    18    34
```

Numeric Digits — \d

Use `\d` to find numeric digits in the following string:

```
numstr = 'Easy as 1, 2, 3';

[mat idx] = regexp(numstr, '\d', 'match', 'start')
mat =
    '1'    '2'    '3'
idx =
     9    12    15
```

Character Representation

The following character combinations represent specific character and numeric values.

Operator	Usage
`\a`	Alarm (beep)
`\\`	Backslash
`\$`	Dollar sign
`\b`	Backspace
`\f`	Form feed
`\n`	New line
`\r`	Carriage return
`\t`	Horizontal tab
`\v`	Vertical tab
`\oN` or `\o{N}`	Character of octal value `N`
`\xN` or `\x{N}`	Character of hexadecimal value `N`
`\char`	If a character has special meaning in a regular expression, precede it with backslash (`\`) to match it literally.

Octal and Hexadecimal — \o, \x

Use `\x` and `\o` in an expression to find a comma (hex `2C`) followed by a space (octal `40`) followed by the character `2`:

```
numstr = 'Easy as 1, 2, 3';

[mat idx] = regexp(numstr, '\x2C\o{40}2', 'match', 'start')
mat =
    ', 2'
idx =
    10
```

Grouping Operators

When you need to use one of the regular expression operators on a number of consecutive elements in an expression, group these elements together with one of the grouping operators and apply the operation to the entire group. For example, this command matches a capital letter followed by a numeral and then an optional space character. These elements have to occur at least two times in succession for there to be a match. To apply the `{2,}` multiplier to all three consecutive characters, you can first make a group of the characters and then apply the `(?:)` quantifier to this group:

```
regexp('B5 A2 6F 63 R6 P4 B2 BC', '(?:[A-Z]\d\s?){2,}', 'match')
ans =
    'B5 A2 '    'R6 P4 B2 '
```

There are three types of explicit grouping operators that you can use when you need to apply an operation to more than just one element in an expression. Also in the grouping category is the alternative match (logical OR) operator, `|`. This creates two or more groups of elements in the expression and applies an operation to one of the groups.

Operator	Usage
`(expr)`	Group regular expressions and capture tokens.
`(?:expr)`	Group regular expressions, but do not capture tokens.
`(?>expr)`	Group atomically.
$\texttt{expr}_1\texttt{|expr}_2$	Match expression $\texttt{expr}_1$ or expression $\texttt{expr}_2$.

Grouping and Capture — (expr)

When you enclose an expression in parentheses, MATLAB not only treats all of the enclosed elements as a group, but also captures a token from these elements whenever a match with the input string is found. For an example of how to use this, see “Using Tokens — Example 1” on page 3-50.

Grouping Only — (?:expr)

Use `(?:expr)` to group a nonvowel (consonant, numeric, whitespace, punctuation, etc.) followed by a vowel in the palindrome `pstr`. Specify at least

two consecutive occurrences (`{2,}`) of this group. Return the starting and ending indices of the matched substrings:

```
pstr = 'Marge lets Norah see Sharon''s telegram';
expr = '(?:[^aeiou][aeiou]){2,}';

[mat ix1 ix2] = regexp(pstr, expr, 'match', 'start', 'end')
mat =
    'Nora'    'haro'    'tele'
ix1 =
    12    23    31
ix2 =
    15    26    34
```

Remove the grouping, and the `{2,}` now applies only to `[aeiou]`. The command is entirely different now as it looks for a nonvowel followed by at least two consecutive vowels:

```
expr = '[^aeiou][aeiou]{2,}';

[mat ix1 ix2] = regexp(pstr, expr, 'match', 'start', 'end')
mat =
    'see'
ix1 =
    18
ix2 =
    20
```

Alternative Match — expr1|expr2

Use $p_1|p_2$ to pick out words in the string that start with `let` or `tel`:

```
regexpi(pstr, '(let|tel)\w+', 'match')
ans =
    'lets'    'telegram'
```

Nonmatching Operators

The `comment` operator enables you to insert comments into your code to make it more maintainable. The text of the comment is ignored by MATLAB when matching against the input string.

Operator	Usage
`(?#comment)`	Insert a comment into the expression. Comments are ignored in matching.

Including Comments — (?#expr)

Use `(?#expr)` to add a comment to this expression that matches capitalized words in `pstr`. Comments are ignored in the process of finding a match:

```
regexp(pstr, '(?# Match words in caps)[A-Z]\w+', 'match')
ans =
    'Marge'    'Norah'    'Sharon'
```

Positional Operators

Positional operators in an expression match parts of the input string not by content, but by where they occur in the string (e.g., the first N characters in the string).

Operator	Usage
`^expr`	Match `expr` if it occurs at the beginning of the input string.
`expr$`	Match `expr` if it occurs at the end of the input string.
`\<expr`	Match `expr` when it occurs at the beginning of a word.
`expr\>`	Match `expr` when it occurs at the end of a word.
`\<expr\>`	Match `expr` when it represents the entire word.

Start and End of String Match — ^expr, expr$

Use `^expr` to match words starting with the letter `m` or `M` only when it begins the string, and `expr$` to match words ending with `m` or `M` only when it ends the string:

```
regexpi(pstr, '^m\w*|\w*m$', 'match')
ans =
    'Marge'    'telegram'
```

Start and End of Word Match — \<expr, expr\>

Use `\<expr` to match any words starting with `n` or `N`, or ending with `e` or `E`:

```
regexpi(pstr, '\<n\w*|\w*e\>', 'match')
ans =
    'Marge'    'Norah'    'see'
```

Exact Word Match — \<expr\>

Use `\<expr\>` to match a word starting with an n or N and ending with an `h` or `H`:

```
regexpi(pstr, '\<n\w*h\>', 'match')
ans =
    'Norah'
```

Lookaround Operators

Lookaround operators tell MATLAB to look either ahead or behind the current location in the string for a specified expression. If the expression is found, MATLAB attempts to match a given pattern.

This table shows the four lookaround expressions: lookahead, negative lookahead, lookbehind, and negative lookbehind.

Operator	Usage
`(?=expr)`	Look ahead from current position and test if `expr` is found.
`(?!expr)`	Look ahead from current position and test if `expr` is not found

Operator	Usage
`(?<=expr)`	Look behind from current position and test if `expr` is found.
`(?<!expr)`	Look behind from current position and test if `expr` is not found.

Lookaround operators do not change the current parsing location in the input string. They are more of a condition that must be satisfied for a match to occur.

For example, the following command uses an expression that matches alphabetic, numeric, or underscore characters (`\w*`) that meet the condition that they *look ahead to* (i.e., are immediately followed by) the letters `vision`. The resulting match includes only that part of the string that matches the `\w*` operator; it does not include those characters that match the lookahead expression `(?=vision)`:

```
[s e] = regexp('telegraph television telephone', ...
               '\w*(?=vision)', 'start', 'end')
s =
    11
e =
    14
```

If you repeat this command and match one character beyond the lookahead expression, you can see that parsing of the input string resumes at the letter `v`, thus demonstrating that matching the lookahead operator has not consumed any characters in the string:

```
regexp('telegraph television telephone', ...
       '\w*(?=vision).', 'match')
ans =
    'telev'
```

Note You can also use lookaround operators to perform a logical AND of two elements. See “Using Lookaround as a Logical Operator” on page 3-44.

Lookahead — expr(?=test)

Look ahead to the location of each of these national parks to identify those situated in Tanzania:

```
AfricanParks = {'Arusha, Tanzania', 'Limpopo, Mozambique', ...
   'Chobe, Botswana', 'Amboseli, Kenya', 'Mikumi, Tanzania', ...
   'Kabelaga, Uganda', 'Gonarezhou, Zimbabwe', ...
   'Uangudi, Ethiopia', 'Akagera, Rwanda', ...
   'Etosha, Namibia', 'Kilimanjaro, Tanzania', ...
   'Kasanga, Zambia', 'Udzungwa, Tanzania', 'Omo, Ethiopia'};

T = regexp(AfricanParks, '.*(?=, Tanzania)', 'match');
```

The result `T` is a cell array of empty and full character strings. Display the results:

```
for k=1:numel(AfricanParks)
   if k==1, disp 'Parks in Tanzania:', end
   if ~isempty(T{k})
      fprintf('   %s\n', char(T{k}))
   end
end
```

```
Parks in Tanzania:
   Arusha
   Mikumi
   Kilimanjaro
   Udzungwa
```

Negative Lookahead — expr(?!test)

Generate a series of sequential numbers:

```
n = num2str(5:15)
n =
   5   6   7   8   9  10  11  12  13  14  15
```

Use both the negative lookbehind and negative lookahead operators together to precede only the single-digit numbers with zero:

```
regexprep(n, '(?<!\d)(\d)(?!\d)', '0$1')
```

```
ans =
   05   06   07   08   09   10   11   12   13   14   15
```

Lookbehind — (?<=test)expr

This example uses the lookbehind operator to extract different types of currency from a string. Start by identifying the euro, British pound, Japanese yen, and American dollar symbols using their hexadecimal Unicode values:

```
euro = char(hex2dec('20AC'))
euro =
   €

pound = char(hex2dec('00A3'))
pound =
   £

yen = char(hex2dec('00A5'))
yen =
   ¥

dollar = char(hex2dec('0024'))
dollar =
   $
```

Compose a string of monetary values:

```
str = [euro '10.50 ' pound '6.94 ' yen '1649.40 ' dollar ...
      '13.67']
str =
   €10.50 £6.94 ¥1649.40 $13.67
```

Using `regexp`, match numeric and decimal point characters, but only if you can look behind and find the desired currency symbol immediately preceding those characters:

```
regexp(str, '(?<=\x{20AC})[\d\.]+', 'match')
ans =
    '10.50'
```

```
regexp(str, '(?<=\x{00A3})[\d\.]+', 'match')
ans =
    '6.94'

regexp(str, '(?<=\x{00A5})[\d\.]+', 'match')
ans =
    '1649.40'

regexp(str, '(?<=\x{0024})[\d\.]+', 'match')
ans =
    '13.67'
```

Negative Lookbehind — (?<!test)expr

Use `(?<!test)expr` to find all words that do not follow a comma and zero or more spaces:

```
poestr = ['While I nodded, nearly napping, ' ...
          'suddenly there came a tapping,'];

[mat idx] = regexp(poestr, '(?<!,\s*\w*)\w*', 'match', 'start')
mat =
   'While' 'I' 'nodded' 'napping' 'there' 'came' 'a' 'tapping'
idx =
     1     7     9    24    42    48    53    55
```

Using Lookaround as a Logical Operator

You can use lookaround operators to perform a logical AND, as shown in this example. The expression used here finds all words that contain a sequence of two letters under the condition that the two letters are identical *and* are in the range a through m. (The expression `'(?=[a-m])'` is a lookahead test for the range a through m, and the expression `'(.)\1'` tests for identical characters using a token):

```
[mat idx] = regexp(poestr, '\<\w*(?=[a-m])(.)\1\w*\>', ...
   'match', 'start')
mat =
    'nodded'    'suddenly'
idx =
```

```
     9    33
```

Note that when using a lookahead operator to perform an AND, you need to place the match expression `expr` *after* the test expression `test`:

```
(?=test)expr or (?!test)expr
```

Quantifiers

With the quantifiers shown below, you can specify how many instances of an element are to be matched. The basic quantifying operators are listed in the first six rows of the table.

By default, MATLAB matches as much of an expression as possible. Using the operators shown in the last two rows of the table, you can override this default behavior. Specify these options by appending a `+` or `?` immediately following one of the six basic quantifying operators.

Operator	Usage
`expr{m,n}`	Must occur at least `m` times but no more than `n` times.
`expr{m,}`	Must occur at least `m` times.
`expr{n}`	Must match exactly `n` times. Equivalent to `{n,n}`.
`expr?`	Match the preceding element 0 times or 1 time. Equivalent to `{0,1}`.
`expr*`	Match the preceding element 0 or more times. Equivalent to `{0,}`.
`expr+`	Match the preceding element 1 or more times. Equivalent to `{1,}`.
`q_expr+`	Match as much of the quantified expression as possible, but do not rescan any portions of the string if the initial match fails. The term `q_expr` represents any of the expressions shown in the top six rows of this table.
`q_expr?`	Match only as much of the quantified expression as necessary. The term `q_expr` represents any of the expressions shown in the top six rows of this table. For an example, see “Lazy Quantifiers — expr*?” on page 3-47, below.

Zero or One — expr?

Use `?` to make the HTML `<code>` and `</code>` tags optional in the string. The first string, `hstr1`, contains one occurrence of each tag. Since the expression uses `()?` around the tags, one occurrence is a match:

```
hstr1 = '<td><a name="18854"></a><code>%%</code><br></td>';
expr = '</a>(<code>)?..(</code>)?<br>';

regexp(hstr1, expr, 'match')
ans =
    '</a><code>%%</code><br>'
```

The second string, `hstr2`, does not contain the code tags at all. Just the same, the expression matches because `()?` allows for zero occurrences of the tags:

```
hstr2 = '<td><a name="18854"></a>%%<br></td>';
expr = '</a>(<code>)?..(</code>)?<br>';

regexp(hstr2, expr, 'match')
ans =
    '</a>%%<br>'
```

Zero or More — expr*

The first `regexp` command looks for at least one occurrence of `<br>` and finds it. The second command parses a different string for at least one `<br>` and fails. The third command uses `*` to parse the same line for zero or more line breaks and this time succeeds.

```
hstr1 = '<p>This string has <br><br>line breaks</p>';
regexp(hstr1, '<p>.*(<br>).*</p>', 'match')
ans =
    '<p>This string has <br><br>line breaks</p>';

hstr2 = '<p>This string has no line breaks</p>';
regexp(hstr2, '<p>.*(<br>).*</p>', 'match')
ans =
     {}

regexp(hstr2, '<p>.*(<br>)*.*</p>', 'match')
```

```
ans =
    '<p>This string has no line breaks</p>';
```

One or More — expr+

Use + to verify that the HTML image source is not empty. This looks for one or more characters in the `gif` filename:

```
hstr = '<a href="s12.html"><img src="b_prev.gif" border=0>';
expr = '<img src="\w+.gif';

regexp(hstr, expr, 'match')
ans =
    '<img src="b_prev.gif'
```

Exact, Minimum, and Maximum Quantities — {min,max}

Use `{m}`, `{m,}`, and `{m,n}` to verify the `href` syntax used in HTML. This statement requires the `href` to have at least one non-whitespace character, followed by exactly one occurrence of `.html`, optionally followed by # and five to eight digits:

```
hstr = '<a name="18749"></a><a href="s13.html#18760">';
expr = '<a href="\w{1,}(\.html){1}(\#\d{5,8}){0,1}"';

regexp(hstr, expr, 'match')
ans =
    '<a href="s13.html#18760"'
```

Lazy Quantifiers — expr*?

This example shows the difference between the default (*greedy*) quantifier and the *lazy* quantifier (`?`). The first part of the example uses the default quantifier to match all characters from the opening `<tr` to the ending `</td`:

```
hstr = '<tr valign=top><td><a name="19184"></a><br></td>';
regexp(hstr, '</?t.*>', 'match')
ans =
```

```
    '<tr valign=top><td><a name="19184"></a><br></td>'
```

The second part uses the lazy quantifier to match the minimum number of characters between `<tr`, `<td`, or `</td` tags:

```
regexp(hstr, '</?t.*?>', 'match')
ans =
    '<tr valign=top>'    '<td>'    '</td>'
```

Tokens

Parentheses used in a regular expression not only group elements of that expression together, but also designate any matches found for that group as *tokens*. You can use tokens to match other parts of the same string. One advantage of using tokens is that they remember what they matched, so you can recall and reuse matched text in the process of searching or replacing.

This section covers

Operators Used with Tokens

Here are the operators you can use with tokens in MATLAB.

Operator	Usage
`(expr)`	Capture in a token all characters matched by the expression within the parentheses.
`\N`	Match the N^{th} token generated by this command. That is, use `\1` to match the first token, `\2` to match the second, and so on.

Operator	Usage
`$N`	Insert the match for the N^{th} token in the replacement string. Used only by the `regexprep` function. If `N` is equal to zero, then insert the entire match in the replacement string.
`(?(N)s1|s2)`	If N^{th} token is found, then match `s1`, else match `s2`

Introduction to Using Tokens

You can turn any pattern being matched into a token by enclosing the pattern in parentheses within the expression. For example, to create a token for a dollar amount, you could use '`(\$\d+)`'. Each token in the expression is assigned a number, starting from 1, going from left to right. To make a reference to a token later in the expression, refer to it using a backslash followed by the token number. For example, when referencing a token generated by the third set of parentheses in the expression, use `\3`.

As a simple example, if you wanted to search for identical sequential letters in a string, you could capture the first letter as a token and then search for a matching character immediately afterwards. In the expression shown below, the `(\S)` phrase creates a token whenever `regexp` matches any non-whitespace character in the string. The second part of the expression, `'\1'`, looks for a second instance of the same character immediately following the first:

```
poestr = ['While I nodded, nearly napping, ' ...
          'suddenly there came a tapping,'];

[mat tok ext] = regexp(poestr, '(\S)\1', 'match', ...
   'tokens', 'tokenExtents');
mat
mat =
    'dd'    'pp'    'dd'    'pp'
```

The tokens returned in cell array `tok` are:

```
'd', 'p', 'd', 'p'
```

Starting and ending indices for each token in the input string `poestr` are:

```
11 11,  26 26,  35 35,  57 57
```

Using Tokens — Example 1

Here is an example of how tokens are assigned values. Suppose that you are going to search the following text:

```
andy ted bob jim andrew andy ted mark
```

You choose to search the above text with the following search pattern:

```
and(y|rew)|(t)e(d)
```

This pattern has three parenthetical expressions that generate tokens. When you finally perform the search, the following tokens are generated for each match.

Match	Token 1	Token 2
andy	y	
ted	t	d
andrew	rew	
andy	y	
ted	t	d

Only the highest level parentheses are used. For example, if the search pattern `and(y|rew)` finds the text `andrew`, token 1 is assigned the value `rew`. However, if the search pattern `(and(y|rew))` is used, token 1 is assigned the value `andrew`.

Using Tokens — Example 2

Use `(expr)` and `\N` to capture pairs of matching HTML tags (e.g., `<a>` and `<\a>`) and the text between them. The expression used for this example is

```
expr = '<(\w+).*?>.*?</\1>';
```

The first part of the expression, '<(\w+)', matches an opening bracket (<) followed by one or more alphabetic, numeric, or underscore characters. The enclosing parentheses capture token characters following the opening bracket.

The second part of the expression, '.*?>.*?', matches the remainder of this HTML tag (characters up to the >), and any characters that may precede the next opening bracket.

The last part, `'</\1>'`, matches all characters in the ending HTML tag. This tag is composed of the sequence `</tag>`, where `tag` is whatever characters were captured as a token.

```
hstr = '<!comment><a name="752507"></a><b>Default</b><br>';
expr = '<(\w+).*?>.*?</\1>';

[mat tok] = regexp(hstr, expr, 'match', 'tokens');
mat{:}
ans =
    <a name="752507"></a>
ans =
    <b>Default</b>

tok{:}
ans =
    'a'
ans =
    'b'
```

Tokens That Are Not Matched

For those tokens specified in the regular expression that have no match in the string being evaluated, `regexp` and `regexpi` return an empty string (`''`) as the token output, and an extent that marks the position in the string where the token was expected.

The example shown here executes `regexp` on the path string `str` returned from the MATLAB `tempdir` function. The regular expression `expr` includes six token specifiers, one for each piece of the path string. The third specifier

`[a-z]+` has no match in the string because this part of the path, `Profiles`, begins with an uppercase letter:

```
str = tempdir
str =
   C:\WINNT\Profiles\bpascal\LOCALS~1\Temp\

expr = ['([A-Z]:)\\(WINNT)\\([a-z]+)?.*\\' ...
        '([a-z]+)\\([A-Z]+~\d)\\(Temp)\\'];

[tok ext] = regexp(str, expr, 'tokens', 'tokenExtents');
```

When a token is not found in a string, MATLAB still returns a token string and token extent. The returned token string is an empty character string (`''`). The first number of the extent is the string index that marks where the token was expected, and the second number of the extent is equal to one less than the first.

In the case of this example, the empty token is the third specified in the expression, so the third token string returned is empty:

```
tok{:}
ans =
    'C:'    'WINNT'     ''    'bpascal'    'LOCALS~1'    'Temp'
```

The third token extent returned in the variable `ext` has the starting index set to 10, which is where the nonmatching substring, `Profiles`, begins in the string. The ending extent index is set to one less than the starting index, or 9:

```
ext{:}
ans =
     1     2
     4     8
    10     9
    19    25
    27    34
    36    39
```

Using Tokens in a Replacement String

When using tokens in a replacement string, reference them using `$1`, `$2`, etc. instead of `\1`, `\2`, etc. This example captures two tokens and reverses their order. The first, `$1`, is `'Norma Jean'` and the second, `$2`, is `'Baker'`. Note that `regexprep` returns the modified string, not a vector of starting indices.

```
regexprep('Norma Jean Baker', '(\w+\s\w+)\s(\w+)', '$2, $1')
ans =
    Baker, Norma Jean
```

Named Capture

If you use a lot of tokens in your expressions, it may be helpful to assign them names rather than having to keep track of which token number is assigned to which token. Use the following operator to assign a name to a token that finds a match.

Operator	Usage
`(?<name>expr)`	Capture in a token all characters matched by the expression within the parentheses. Assign a `name` to the token.
`\k<name>`	Match the token referred to by `name`.
`$<name>`	Insert the match for named token in a replacement string. Used only with the `regexprep` function.
`(?(name)s1|s2)`	If named token is found, then match `s1`; otherwise, match `s2`

When referencing a named token within the expression, use the syntax `\k<name>` instead of the numeric `\1`, `\2`, etc.:

```
poestr = ['While I nodded, nearly napping, ' ...
          'suddenly there came a tapping,'];

regexp(poestr, '(?<anychar>.)\k<anychar>', 'match')
ans =
    'dd'    'pp'    'dd'    'pp'
```

Labeling Your Output

Named tokens can also be useful in labeling the output from the MATLAB regular expression functions. This is especially true when you are processing numerous strings.

This example parses different pieces of street addresses from several strings. A short name is assigned to each token in the expression string:

```
str1 = '134 Main Street, Boulder, CO, 14923';
str2 = '26 Walnut Road, Topeka, KA, 25384';
str3 = '847 Industrial Drive, Elizabeth, NJ, 73548';

p1 = '(?<adrs>\d+\s\S+\s(Road|Street|Avenue|Drive))';
p2 = '(?<city>[A-Z][a-z]+)';
p3 = '(?<state>[A-Z]{2})';
p4 = '(?<zip>\d{5})';

expr = [p1 ', ' p2 ', ' p3 ', ' p4];
```

As the following results demonstrate, you can make your output easier to work with by using named tokens:

```
loc1 = regexp(str1, expr, 'names')
loc1 =
     adrs: '134 Main Street'
     city: 'Boulder'
    state: 'CO'
      zip: '14923'

loc2 = regexp(str2, expr, 'names')
loc2 =
     adrs: '26 Walnut Road'
     city: 'Topeka'
    state: 'KA'
      zip: '25384'

loc3 = regexp(str3, expr, 'names')
loc3 =
     adrs: '847 Industrial Drive'
     city: 'Elizabeth'
```

```
    state: 'NJ'
      zip: '73548'
```

Conditional Expressions

With conditional expressions, you can tell MATLAB to match an expression only if a certain condition is true. A conditional expression is similar to an `if-then` or an `if-then-else` clause in programming. MATLAB first tests the state of a given condition, and the outcome of this tests determines what, if anything, is to be matched next. The following table shows the two conditional syntaxes you can use with MATLAB.

Operator	Usage
`(?(cond)expr)`	If condition `cond` is true, then match expression `expr`
`(?(cond)`$\texttt{expr}_1$`|`$\texttt{expr}_2$`)`	If condition `cond` is true, then match expression $\texttt{expr}_1$. Otherwise match expression $\texttt{expr}_2$

The first entry in this table is the same as an `if-then` statement. MATLAB tests the state of condition `cond` and then matches expression `expr` only if the condition was found to be true. In the form of an `if-then` statement, it would look like this:

```
if cond then expr
```

The second entry in the table is the same as an `if-then-else` statement. If the condition is true, MATLAB matches $\texttt{expr}_1$; if false, it matches $\texttt{expr}_2$ instead. This syntax is equivalent to the following programming statement:

```
if cond then expr1 else expr2
```

The condition `cond` in either of these syntaxes can be any one of the following:

- A specific token, identified by either number or name, is located in the input string. See “Conditions Based on Tokens” on page 3-56, below.
- A lookaround operation results in a match. See “Conditions Based on a Lookaround Match” on page 3-57, below.
- A dynamic expression of the form `(?@cmd)` returns a nonzero numeric value. See “Conditions Based on Return Values” on page 3-57, below.

Conditions Based on Tokens

In a conditional expression, MATLAB matches the expression only if the condition associated with it is met. If the condition is based on a token, then the condition is met if MATLAB matches more than one character for the token in the input string.

To specify a token in a condition, use either the token number or, for tokens that you have assigned a name to, its name. Token numbers are determined by the order in which they appear in an expression. For example, if you specify three tokens in an expression (that is, if you enclose three parts of the expression in parentheses), then you would refer to these tokens in a condition statement as `1`, `2`, and `3`.

The following example uses the conditional statement `(?(1)her|his)` to match the string regardless of the gender used. You could translate this into the phrase, "**if** token `1` is found (i.e., `Mr` is followed by the letter `s`), **then** match `her`, **else** match `his`."

```
expr = 'Mr(s?)\..*?(?(1)her|his) son';

[mat tok] = regexp('Mr. Clark went to see his son', ...
   expr, 'match', 'tokens')
mat =
    'Mr. Clark went to see his son'
tok =
    {1x2 cell}

tok{:}
ans =
     ''    'his'
```

In the second part of the example, the token `s` is found and MATLAB matches the word `her`:

```
[mat tok] = regexp('Mrs. Clark went to see her son', ...
expr, 'match', 'tokens')
mat =
    'Mrs. Clark went to see her son'
tok =
    {1x2 cell}
```

```
tok{:}
ans =
    's'    'her'
```

Note When referring to a token within a condition, use just the number of the token. For example, refer to token `2` by using the number `2` alone, and not `\2` or `$2`.

Conditions Based on a Lookaround Match

Lookaround statements look for text that either precedes or follows an expression. If this lookaround text is located, then MATLAB proceeds to match the expression. You can also use lookarounds in conditional statements. In this case, if the lookaround text is located, then MATLAB considers the condition to be met and matches the associated expression. If the condition is not met, then MATLAB matches the `else` part of the expression.

Conditions Based on Return Values

MATLAB supports different types of dynamic expressions. One type of dynamic expression, having the form `(?@cmd)`, enables you to execute a MATLAB command (shown here as `cmd`) while matching an expression. You can use this type of dynamic expression in a conditional statement if the command in the expression returns a numeric value. The condition is considered to be met if the return value is nonzero.

Dynamic Regular Expressions

In a dynamic expression, you can make the pattern that you want `regexp` to match dependent on the content of the input string. In this way, you can more closely match varying input patterns in the string being parsed. You can also use dynamic expressions in replacement strings for use with the `regexprep` function. This gives you the ability to adapt the replacement text to the parsed input.

You can include any number of dynamic expressions in the `match_expr` or `replace_expr` arguments of these commands:

```
regexp(string, match_expr)
regexpi(string, match_expr)
regexprep(string, match_expr, replace_expr)
```

MATLAB supports three types of dynamic operators for use in a match expression. See “Dynamic Operators for the Match Expression” on page 3-59 for more information.

Operator	Usage
`(??expr)`	Parse `expr` as a separate regular expression, and include the resulting string in the match expression. This gives you the same results as if you called `regexprep` inside of a `regexp` match expression.
`(?@cmd)`	Execute the MATLAB command `cmd`, discarding any output that may be returned. This is often used for diagnosing a regular expression.
`(??@cmd)`	Execute the MATLAB command `cmd`, and include the string returned by `cmd` in the match expression. This is a combination of the two dynamic syntaxes shown above: `(??expr)` and `(?@cmd)`.

MATLAB supports one type of dynamic expression for use in the replacement expression of a `regexprep` command. See “Dynamic Operators for the Replacement Expression” on page 3-64 for more information.

Operator	Usage
`${cmd}`	Execute the MATLAB command `cmd`, and include the string returned by `cmd` in the replacement expression.

Example of a Dynamic Expression

As an example of a dynamic expression, the following `regexprep` command correctly replaces the term `internationalization` with its abbreviated form, `i18n`. However, to use it on a different term such as `globalization`, you have to use a different replacement expression:

```
match_expr = '(^\w)(\w*)(\w$)';
```

```
replace_expr1 = '$118$3';
regexprep('internationalization', match_expr, replace_expr1)
ans =
    i18n

replace_expr2 = '$111$3';
regexprep('globalization', match_expr, replace_expr2)
ans =
    g11n
```

Using a dynamic expression `${num2str(length($2))}` enables you to base the replacement expression on the input string so that you do not have to change the expression each time. This example uses the dynamic syntax `${cmd}` from the second table shown above:

```
match_expr = '(^\w)(\w*)(\w$)';
replace_expr = '$1${num2str(length($2))}$3';

regexprep('internationalization', match_expr, replace_expr)
ans =
    i18n

regexprep('globalization', match_expr, replace_expr)
ans =
    g11n
```

Dynamic Operators for the Match Expression

There are three types of dynamic expressions you can use when composing a match expression:

- "Dynamic Expressions that Modify the Match Expression — (??expr)" on page 3-60

  "Dynamic Commands that Modify the Match Expression — (??@cmd)" on page 3-61

  "Dynamic Commands that Serve a Functional Purpose — (?@cmd)" on page 3-62

The first two of these actually modify the match expression itself so that it can be made specific to changes in the contents of the input string. When MATLAB

evaluates one of these dynamic statements, the results of that evaluation are included in the same location within the overall match expression.

The third operator listed here does not modify the overall expression, but instead enables you to run MATLAB commands during the parsing of a regular expression. This functionality can be useful in diagnosing your regular expressions.

Dynamic Expressions that Modify the Match Expression — (??expr). The `(??expr)` operator parses expression `expr`, and inserts the results back into the match expression. MATLAB then evaluates the modified match expression.

Here is an example of the type of expression that you can use with this operator:

```
str = {'5XXXXX', '8XXXXXXXX', '1X'};
regexp(str, '^(\d+)(??X{$1})$', 'match', 'once')
```

The purpose of this particular command is to locate a series of `X` characters in each of the strings stored in the input cell array. Note however that the number of `X`s varies in each string. If the count did not vary, you could use the expression `X{n}` to indicate that you want to match `n` of these characters. But, a constant value of `n` does not work in this case.

The solution used here is to capture the leading count number (e.g., the `5` in the first string of the cell array) in a token, and then to use that count in a dynamic expression. The dynamic expression in this example is `(??X{$1})`, where `$1` is the value captured by the token `\d+`. The metacharacter `{$1}` makes a quantifier of that token value. Because the expression is dynamic, the same pattern works on all three of the input strings in the cell array. With the first input string, `regexp` looks for five `X` characters; with the second, it looks for eight, and with the third, it looks for just one:

```
regexp(str, '^(\d+)(??X{$1})$', 'match', 'once')
ans =
    '5XXXXX'    '8XXXXXXXX'    '1X'
```

Dynamic Commands that Modify the Match Expression — (??@cmd). MATLAB uses the `(??@function)` operator to include the results of a MATLAB command in the match expression. This command must return a string that can be used within the match expression.

The `regexp` command below uses the dynamic expression `(??@flilplr($1))` to locate a palindrome string, "Never Odd or Even", that has been embedded into a larger string:

```
regexp(pstr, '(.{3,}).?(??@fliplr($1))', 'match')
```

The dynamic expression reverses the order of the letters that make up the string, and then attempts to match as much of the reversed-order string as possible. This requires a dynamic expression because the value for `$1` relies on the value of the token `(.{3,})`:

```
% Put the string in lowercase.
str = lower(...
  'Find the palindrome Never Odd or Even in this string');

% Remove all nonword characters.
str = regexprep(str, '\W*', '')
str =
   findthepalindromeneveroddoreveninthisstring

% Now locate the palindrome within the string.
palstr = regexp(str, '(.{3,}).?(??@fliplr($1))', 'match')
str =
   'neveroddoreven'
```

Dynamic expressions in MATLAB have access to the currently active workspace. This means that you can change any of the functions or variables used in a dynamic expression just by changing variables in the workspace. Repeat the last command of the example above, but this time define the function to be called within the expression using a function handle stored in the base workspace:

```
fun = @fliplr;

palstr = regexp(str, '(.{3,}).?(??@fun($1))', 'match')
palstr =
```

```
    'neveroddoreven'
```

Dynamic Commands that Serve a Functional Purpose — (?@cmd). The `(?@cmd)` operator specifies a MATLAB command that `regexp` or `regexprep` is to run while parsing the overall match expression. Unlike the other dynamic expressions in MATLAB, this operator does not alter the contents of the expression it is used in. Instead, you can use this functionality to get MATLAB to report just what steps it's taking as it parses the contents of one of your regular expressions.

The following example parses a word for zero or more characters followed by two identical characters followed again by zero or more characters:

```
regexp('mississippi', '\w*(\w)\1\w*', 'match')
ans =
    'mississippi'
```

To track the exact steps that MATLAB takes in determining the match, the example inserts a short script `(?@disp($1))` in the expression to display the characters that finally constitute the match. Because the example uses greedy quantifiers, MATLAB attempts to match as much of the string as possible. So, even though MATLAB finds a match toward the beginning of the string, it continues to look for more matches until it arrives at the very end of the string. From there, it backs up through the letters `i` then `p` and the next `p`, stopping at that point because the match is finally satisfied:

```
regexp('mississippi', '\w*(\w)(?@disp($1))\1\w*');
i
p
p
```

Now try the same example again, this time making the first quantifier lazy (`*?`). Again, MATLAB makes the same match:

```
regexp('mississippi', '\w*?(\w)\1\w*', 'match')
ans =
    'mississippi'
```

But by inserting a dynamic script, you can see that this time, MATLAB has matched the string quite differently. In this case, MATLAB uses the very first match it can find, and does not even consider the rest of the string:

```
regexp('mississippi', '\w*?(\w)(?@disp($1))\1\w*';)
m
i
s
```

To demonstrate how versatile this type of dynamic expression can be, consider the next example that progressively assembles a cell array as MATLAB iteratively parses the input string. The `(?!)` metacharacter found at the end of the expression is actually an empty lookahead operator, and forces a failure at each iteration. This forced failure is necessary if you want to trace the steps that MATLAB is taking to resolve the expression.

MATLAB makes a number of passes through the input string, each time trying another combination of letters to see if a fit better than last match can be found. On any passes in which no matches are found, the test results in an empty string. The dynamic script `(?@if(~isempty($&)))` serves to omit these strings from the `matches` cell array:

```
matches = {};
expr = ['(Euler\s)?(Cauchy\s)?(Boole)?(?@if(~isempty($&)),' ...
   'matches{end+1}=$&;end)(?!)'];

regexp('Euler Cauchy Boole', expr);

matches
matches =
    'Euler Cauchy Boole'    'Euler Cauchy '    'Euler '
'Cauchy Boole'    'Cauchy '    'Boole'
```

The metacharacters `$&` (or the equivalent `$0`), `$`` , and `$'` refer to that part of the input string that is currently a match, all characters that precede the current match, and all characters to follow the current match, respectively. These metacharacters are sometimes useful when working with dynamic expressions, particularly those that employ the `(?@cmd)` operator.

This example parses the input string looking for the letter `g`. At each iteration through the string, `regexp` compares the current character with `g`, and not finding it, advances to the next character. The example tracks the progress of scan through the string by marking the current location being parsed with a `^` character.

(The $` and $· metacharacters capture that part of the string that precedes and follows the current parsing location. You need two single-quotation marks ($'') to express the sequence $· when it appears within a string.)

```
str = 'abcdefghij';
expr = '(?@disp(sprintf(''starting match: [%s^%s]'',$`,$'')))g';

regexp(str, expr, 'once');
starting match: [^abcdefghij]
starting match: [a^bcdefghij]
starting match: [ab^cdefghij]
starting match: [abc^defghij]
starting match: [abcd^efghij]
starting match: [abcde^fghij]
starting match: [abcdef^ghij]
```

Dynamic Operators for the Replacement Expression

The three types of dynamic expressions discussed above can be used only in the match expression (second input) argument of the regular expression functions. MATLAB provides one more type of dynamic expression; this one is for use in a replacement string (third input) argument of the `regexprep` function.

Dynamic Commands that Modify the Replacement Expression — ${cmd}. The `${cmd}` operator modifies the contents of a regular expression replacement string, making this string adaptable to parameters in the input string that might vary from one use to the next. As with the other dynamic expressions used in MATLAB, you can include any number of these expressions within the overall replacement expression.

In the `regexprep` call shown here, the replacement string is `'${convert($1,$2)}'`. In this case, the entire replacement string is a dynamic expression:

```
regexprep('This highway is 125 miles long', ...
          '(\d+\.?\d*)\W(\w+)', '${convert($1,$2)}')
```

The dynamic expression tells MATLAB to execute an M-file function named `convert` using the two tokens `(\d+\.?\d*)` and `(\w+)`, derived from the

string being matched, as input arguments in the call to `convert`. The replacement string requires a dynamic expression because the values of `$1` and `$2` are generated at runtime.

The following example defines the M-file named `convert` that converts measurements from imperial units to metric. To convert values from the string being parsed, `regexprep` calls the `convert` function, passing in values for the quantity to be converted and name of the imperial unit:

```
function valout  = convert(valin, units)
switch(units)
    case 'inches'
        fun = @(in)in .* 2.54;    uout = 'centimeters';
    case 'miles'
        fun = @(mi)mi .* 1.6093;  uout = 'kilometers';
    case 'pounds'
        fun = @(lb)lb .* 0.4536;  uout = 'kilograms';
    case 'pints'
        fun = @(pt)pt .* 0.4731;  uout = 'litres';
    case 'ounces'
        fun = @(oz)oz .* 28.35;   uout = 'grams';
end
val = fun(str2num(valin));
valout = [num2str(val) ' ' uout];

regexprep('This highway is 125 miles long', ...
          '(\d+\.?\d*)\W(\w+)', '${convert($1,$2)}')
ans =
   This highway is 201.1625 kilometers long

regexprep('This pitcher holds 2.5 pints of water', ...
          '(\d+\.?\d*)\W(\w+)', '${convert($1,$2)}')
ans =
   This pitcher holds 1.1828 litres of water

regexprep('This stone weighs about 10 pounds', ...
          '(\d+\.?\d*)\W(\w+)', '${convert($1,$2)}')
```

```
ans =
   This stone weighs about 4.536 kilograms
```

As with the `(??@ )` operator discussed in an earlier section, the `${ }` operator has access to variables in the currently active workspace. The following `regexprep` command uses the array `A` defined in the base workspace:

```
A = magic(3)
A =
     8     1     6
     3     5     7
     4     9     2

regexprep('The columns of matrix _nam are _val', ...
          {'_nam', '_val'}, ...
          {'A', '${sprintf(''%d%d%d '', A)}'})
ans =
The columns of matrix A are 834 159 672
```

String Replacement

The `regexprep` function enables you to replace a string that is identified by a regular expression with another string. The following syntax replaces all occurrences of the regular expression `expr` in string `str` with the string `repstr`. The new string is returned in `s`. If no matches are found, return string `s` is the same as input string `str`.

```
s = regexprep('str', 'expr', 'repstr')
```

The replacement string can include any ordinary characters and also any of the metacharacters shown in the following table:

Operator	Usage
Operators from Character Representation on page 3-73 table	The character represented by the metacharacter sequence
$`	That part of the input string that precedes the current match

Operator	Usage
$& or $0	That part of the input string that is currently a match
$`	That part of the input string that follows the current match. In MATLAB, use $'' to represent the character sequence $`.
$N	The string represented by the token identified by name
$<name>	The string represented by the token identified by name
${cmd}	The string returned when MATLAB executes the command cmd

You can capture parts of the input string as tokens and then reuse them in the replacement string. Specify the parts of the string to capture using the token capture operator (...). Specify the tokens to use in the replacement string using the operators $1, $2, $N to reference the first, second, and Nth tokens captured. (See the section on "Tokens" on page 3-48 and the example "Using Tokens in a Replacement String" on page 3-53 in this documentation for information on using tokens.)

Note When referring to a token within a replacement string, use the number of the token preceded by a dollar sign. For example, refer to token 2 by using $2, and not 2 or \2.

The following example uses both the ${cmd} and $N operators in the replacement strings of nested regexprep commands to capitalize the first letter of each sentence. The inner regexprep looks for the start of the entire string and capitalizes the single instance; the outer regexprep looks for the first letter following a period and capitalizes the two instances:

```
s1 = 'here are a few sentences.';
s2 = 'none are capitalized.';
s3 = 'let''s change that.';
```

```
str = [s1 ' ' s2 ' ' s3]

regexprep(regexprep(str, '(^.)', '${upper($1)}'), ...
   '(?<=\.\s*)([a-z])','${upper($1)}')

ans =
Here are a few sentences. None are capitalized. Let's change that.
```

Make `regexprep` more specific to your needs by specifying any of a number of options with the command. See the `regexprep` reference page for more information on these options.

Handling Multiple Strings

You can use any of the MATLAB regular expression functions with cell arrays of strings as well as with single strings. Any or all of the input parameters (the string, expression, or replacement string) can be a cell array of strings. The `regexp` function requires that the string and expression arrays have the same number of elements. The `regexprep` function requires that the expression and replacement arrays have the same number of elements. (The cell arrays do not have to have the same shape.)

Whenever either input argument in a call to `regexp`, or the first input argument in a call to `regexprep` function is a cell array, all output values are cell arrays of the same size.

This section covers the following topics:

Finding a Single Pattern in Multiple Strings

The example shown here uses the `regexp` function on a cell array of strings `cstr`. It searches each string of the cell array for consecutive matching letters (e.g., `'oo'`). The function returns a cell array of the same size as the input array. Each row of the return array contains the indices for which there was a match against the input cell array.

Here is the input cell array:

```
cstr = {                                    ...
'Whose woods these are I think I know.' ; ...
'His house is in the village though;'   ; ...
'He will not see me stopping here'      ; ...
'To watch his woods fill up with snow.'};
```

Find consecutive matching letters by capturing a letter as a token `(.)` and then repeating that letter as a token reference, `\1`:

```
idx = regexp(cstr, '(.)\1');

whos idx
  Name      Size                    Bytes  Class

  idx       4x1                       296  cell array

idx{:}
ans =                 % 'Whose woods these are I think I know.'
    8                 %         |8

ans =                 % 'His house is in the village though;'
   23                 %                         |23

ans =                 % 'He will not see me stopping here'
    6    14    23     %       |6      |14      |23

ans =                 % 'To watch his woods fill up with snow.'
   15    22           %                |15    |22
```

To return substrings instead of indices, use the `'match'` parameter:

```
mat = regexp(cstr, '(.)\1', 'match');
mat{3}
ans =
   'll'    'ee'    'pp'
```

Finding Multiple Patterns in Multiple Strings

This example uses a cell array of strings in both the input string and the expression. The two cell arrays are of different shapes: `cstr` is 4-by-1 while `expr` is 1-by-4. The command is valid as long as they both have the same number of cells.

Find uppercase or lowercase `'i'` followed by a white-space character in `str{1}`, the sequence `'hou'` in `str{2}`, two consecutive matching letters in `str{3}`, and words beginning with `'w'` followed by a vowel in `str{4}`.

```
expr = {'i\s', 'hou', '(.)\1', '\<w[aeiou]'};
idx = regexpi(cstr, expr);

idx{:}
ans =                % 'Whose woods these are I think I know.'
   23    31          %                        |23     |31

ans =                % 'His house is in the village though;'
    5    30          %      |5                       |30

ans =                % 'He will not see me stopping here'
    6    14    23    %       |6      |14      |23

ans =                % 'To watch his woods fill up with snow.'
    4    14    28    %     |4        |14           |28
```

Note that the returned cell array has the dimensions of the input string, `cstr`. The dimensions of the return value are always derived from the input string, whenever the input string is a cell array. If the input string is not a cell array, then it is the dimensions of the expression that determine the shape of the return array.

Replacing Multiple Strings

When replacing multiple strings with `regexprep`, use a single replacement string if the expression consists of a single string. This example uses a common replacement value (`'--'`) for all matches found in the multiple string input `cstr`. The function returns a cell array of strings having the same dimensions as the input cell array:

```
s = regexprep(cstr, '(.)\1', '--', 'ignorecase')
```

```
s =
    'Whose w--ds these are I think I know.'
    'His house is in the vi--age though;'
    'He wi-- not s-- me sto--ing here'
    'To watch his w--ds fi-- up with snow.'
```

You can use multiple replacement strings if the expression consists of multiple strings. In this example, the input string and replacement string are both 4-by-1 cell arrays, and the expression is a 1-by-4 cell array. As long as the expression and replacement arrays contain the same number of elements, the statement is valid. The dimensions of the return value match the dimensions of the input string:

```
expr = {'i\s', 'hou', '(.)\1', '\<w[aeiou]'};
repl = {'-1-'; '-2-'; '-3-'; '-4-'};

s = regexprep(cstr, expr, repl, 'ignorecase')
s =
    'Whose w-3-ds these are -1-think -1-know.'
    'His -2-se is in the vi-3-age t-2-gh;'
    'He -4--3- not s-3- me sto-3-ing here'
    'To -4-tch his w-3-ds fi-3- up -4-th snow.'
```

Operator Summary

MATLAB provides these operators for working with regular expressions:

- Conditional Expression Operators on page 3-77
- Dynamic Expression Operators on page 3-77
- Replacement String Operators on page 3-78

Character Classes

Operator	Usage
`.`	Any single character, including white space
`[c1c2c3]`	Any character contained within the brackets: c_1 or c_2 or c_3
`[^c1c2c3]`	Any character not contained within the brackets: anything but c_1 or c_2 or c_3
`[c1-c2]`	Any character in the range of c_1 through c_2
`\s`	Any white-space character; equivalent to `[ \f\n\r\t\v]`
`\S`	Any non-whitespace character; equivalent to `[^ \f\n\r\t\v]`
`\w`	Any alphabetic, numeric, or underscore character; equivalent to `[a-zA-Z_0-9]`. (True only for English character sets).
`\W`	Any character that is not alphabetic, numeric, or underscore; equivalent to `[^a-zA-Z_0-9]`. (True only for English character sets).
`\d`	Any numeric digit; equivalent to `[0-9]`
`\D`	Any nondigit character; equivalent to `[^0-9]`

Character Classes (Continued)

Operator	Usage
`\oN` or `\o{N}`	Character of octal value `N`
`\xN` or `\x{N}`	Character of hexadecimal value `N`

Character Representation

Operator	Usage
`\\`	Backslash
`\$`	Dollar sign
`\a`	Alarm (beep)
`\b`	Backspace
`\f`	Form feed
`\n`	New line
`\r`	Carriage return
`\t`	Horizontal tab
`\v`	Vertical tab
`\char`	If a character has special meaning in a regular expression, precede it with backslash (`\`) to match it literally.

Grouping Operators

Operator	Usage
`(expr)`	Group regular expressions and capture tokens.
`(?:expr)`	Group regular expressions, but do not capture tokens.

Grouping Operators (Continued)

Operator	Usage
`(?>expr)`	Group atomically.
$\texttt{expr}_1\texttt{|expr}_2$	Match expression $\texttt{expr}_1$ or expression $\texttt{expr}_2$.

Nonmatching Operators

Operator	Usage
`(?#comment)`	Insert a comment into the expression. Comments are ignored in matching.

Positional Operators

Operator	Usage
`^expr`	Match `expr` if it occurs at the beginning of the input string.
`expr$`	Match `expr` if it occurs at the end of the input string.
`\<expr`	Match `expr` when it occurs at the beginning of a word.
`expr\>`	Match `expr` when it occurs at the end of a word.
`\<expr\>`	Match `expr` when it represents the entire word.

Lookaround Operators

Operator	Usage
`(?=expr)`	Look ahead from current position and test if `expr` is found.
`(?!expr)`	Look ahead from current position and test if `expr` is not found

Lookaround Operators (Continued)

Operator	Usage
`(?<=expr)`	Look behind from current position and test if `expr` is found.
`(?<!expr)`	Look behind from current position and test if `expr` is not found.

Quantifiers

Operator	Usage
`expr{m,n}`	Match `expr` when it occurs at least `m` times but no more than `n` times consecutively.
`expr{m,}`	Match `expr` when it occurs at least `m` times consecutively.
`expr{n}`	Match `expr` when it occurs exactly `n` times consecutively. Equivalent to `{n,n}`.
`expr?`	Match `expr` when it occurs 0 times or 1 time. Equivalent to `{0,1}`.
`expr*`	Match `expr` when it occurs 0 or more times consecutively. Equivalent to `{0,}`.
`expr+`	Match `expr` when it occurs 1 or more times consecutively. Equivalent to `{1,}`.
`q_expr*`	Match as much of the quantified expression as possible, where `q_expr` represents any of the expressions shown in the first six rows of this table.

Quantifiers (Continued)

Operator	Usage
`q_expr+`	Match as much of the quantified expression as possible, but do not rescan any portions of the string if the initial match fails.
`q_expr?`	Match only as much of the quantified expression as necessary.

Ordinal Token Operators

Operator	Usage
`(expr)`	Capture in a token all characters matched by the expression within the parentheses.
`\N`	Match the N^{th} token generated by this command. That is, use `\1` to match the first token, `\2` to match the second, and so on.
`$N`	Insert the match for the N^{th} token in the replacement string. Used only by the `regexprep` function. If `N` is equal to zero, then insert the entire match in the replacement string.
`(?(N)s1|s2)`	If N^{th} token is found, then match `s1`, else match `s2`

Named Token Operators

Operator	Usage
`(?<name>expr)`	Capture in a token all characters matched by the expression within the parentheses. Assign a `name` to the token.
`\k<name>`	Match the token referred to by `name`.

Named Token Operators (Continued)

Operator	Usage
`$<name>`	Insert the match for named token in a replacement string. Used only with the `regexprep` function.
`(?(name)s1|s2)`	If named token is found, then match `s1`; otherwise, match `s2`

Conditional Expression Operators

Operator	Usage
`(?(cond)expr)`	If condition `cond` is true, then match expression `expr`
`(?(cond)`$\texttt{expr}_1$`|`$\texttt{expr}_2$`)`	If condition `cond` is true, then match expression $\texttt{expr}_1$. Otherwise match expression $\texttt{expr}_2$

Dynamic Expression Operators

Operator	Usage
`(??expr)`	Parse `expr` as a separate regular expression, and include the resulting string in the match expression. This gives you the same results as if you called `regexprep` inside of a `regexp` match expression.
`(??@cmd)`	Execute the MATLAB command `cmd`, discarding any output that may be returned. This is often used for diagnosing a regular expression.

Dynamic Expression Operators (Continued)

Operator	Usage
`(?@cmd)`	Execute the MATLAB command `cmd`, and include the string returned by `cmd` in the match expression. This is a combination of the two dynamic syntaxes shown above: `(??expr)` and `(?@cmd)`.
`${cmd}`	Execute the MATLAB command `cmd`, and include the string returned by `cmd` in the replacement expression.

Replacement String Operators

Operator	Usage
Operators from Character Representation on page 3-73 table	The character represented by the metacharacter sequence
`$``	That part of the input string that precedes the current match
`$&` or `$0`	That part of the input string that is currently a match
`$·`	That part of the input string that follows the current match. In MATLAB, use `$''` to represent the character sequence `$·`.
`$N`	The string represented by the token identified by `name`
`$<name>`	The string represented by the token identified by `name`
`${cmd}`	The string returned when MATLAB executes the command `cmd`

Comma-Separated Lists

In this section...

What Is a Comma-Separated List?

Typing in a series of numbers separated by commas gives you what is called a *comma-separated list*. MATLAB returns each value individually:

```
1, 2, 3
ans =
     1
ans =
     2
ans =
     3
```

Such a list, by itself, is not very useful. But when used with large and more complex data structures like MATLAB structures and cell arrays, the comma-separated list can enable you to simplify your MATLAB code.

Generating a Comma-Separated List

This section describes how to generate a comma-separated list from either a cell array or a MATLAB structure.

Generating a List from a Cell Array

Extracting multiple elements from a cell array yields a comma-separated list. Given a 4-by-6 cell array as shown here

```
C = cell(4, 6);
for k = 1:24,   C{k} = k * 2;   end

C
C =
    [2]    [10]    [18]    [26]    [34]    [42]
    [4]    [12]    [20]    [28]    [36]    [44]
    [6]    [14]    [22]    [30]    [38]    [46]
    [8]    [16]    [24]    [32]    [40]    [48]
```

extracting the fifth column generates the following comma-separated list:

```
C{:, 5}
ans =
    34
ans =
    36
ans =
    38
ans =
    40
```

This is the same as explicitly typing

```
C{1, 5}, C{2, 5}, C{3, 5}, C{4, 5}
```

Generating a List from a Structure

For structures, extracting a field of the structure that exists across one of its dimensions yields a comma-separated list.

Start by converting the cell array used above into a 4-by-1 MATLAB structure with six fields: `f1` through `f6`. Read field `f5` for all rows and MATLAB returns a comma-separated list:

```
S = cell2struct(C, {'f1', 'f2', 'f3', 'f4', 'f5', 'f6'}, 2);

S.f5
ans =
    34
ans =
```

```
    36
ans =
    38
ans =
    40
```

This is the same as explicitly typing

```
S(1).f5, S(2).f5, S(3).f5, S(4).f5
```

Assigning Output from a Comma-Separated List

You can assign any or all consecutive elements of a comma-separated list to variables with a simple assignment statement. Using the cell array `C` from the previous section, assign the first row to variables `c1` through `c6`:

```
C = cell(4, 6);
for k = 1:24,   C{k} = k * 2;   end

[c1 c2 c3 c4 c5 c6] = C{1,1:6};

c5
c5 =
    34
```

If you specify fewer output variables than the number of outputs returned by the expression, MATLAB assigns the first N outputs to those N variables, and then discards any remaining outputs. In this next example, MATLAB assigns `C{1,1:3}` to the variables `c1`, `c2`, and `c3`, and then discards `C{1,4:6}`:

```
[c1 c2 c3] = C{1,1:6};
```

You can assign structure outputs in the same manner:

```
S = cell2struct(C, {'f1', 'f2', 'f3', 'f4', 'f5', 'f6'}, 2);

[sf1 sf2 sf3] = S.f5;

sf3
sf3 =
    38
```

You also can use the `deal` function for this purpose.

Assigning to a Comma-Separated List

The simplest way to assign multiple values to a comma-separated list is to use the `deal` function. This function distributes all of its input arguments to the elements of a comma-separated list.

This example initializes a comma-separated list to a set of vectors in a cell array, and then uses `deal` to overwrite each element in the list:

```
c{1} = [31 07];    c{2} = [03 78];

c{:}
ans =
    31     7
ans =
     3    78

[c{:}] = deal([10 20],[14 12]);

c{:}
ans =
    10    20
ans =
    14    12
```

This example does the same as the one above, but with a comma-separated list of vectors in a structure field:

```
s(1).field1 = [31 07];    s(2).field1 = [03 78];

s.field1
ans =
    31     7
ans =
     3    78
```

```
[s.field1] = deal([10 20],[14 12]);

s.field1
ans =
    10    20
ans =
    14    12
```

How to Use the Comma-Separated Lists

Common uses for comma-separated lists are

The following sections provide examples of using comma-separated lists with cell arrays. Each of these examples applies to MATLAB structures as well.

Constructing Arrays

You can use a comma-separated list to enter a series of elements when constructing a matrix or array. Note what happens when you insert a *list* of elements as opposed to adding the cell itself.

When you specify a list of elements with `C{:, 5}`, MATLAB inserts the four individual elements:

```
A = {'Hello', C{:, 5}, magic(4)}
A =
    'Hello'    [34]    [36]    [38]    [40]    [4x4 double]
```

When you specify the `C` cell itself, MATLAB inserts the entire cell array:

```
A = {'Hello', C, magic(4)}
A =
    'Hello'    {4x6 cell}    [4x4 double]
```

Displaying Arrays

Use a list to display all or part of a structure or cell array:

```
A{:}
ans =
    Hello
ans =
    34
ans =
    36
ans =
    38
  .
  .
  .
```

Concatenation

Putting a comma-separated list inside square brackets extracts the specified elements from the list and concatenates them:

```
A = [C{:, 5:6}]
A =
    34    36    38    40    42    44    46    48

whos A
  Name      Size                    Bytes  Class

  A         1x8                        64  double array
```

Function Call Arguments

When writing the code for a function call, you enter the input arguments as a list with each argument separated by a comma. If you have these arguments stored in a structure or cell array, then you can generate all or part of the argument list from the structure or cell array instead. This can be especially useful when passing in variable numbers of arguments.

This example passes several attribute-value arguments to the `plot` function:

```
X = -pi:pi/10:pi;
Y = tan(sin(X)) - sin(tan(X));

C{1,1} = 'LineWidth';         C{2,1} = 2;
C{1,2} = 'MarkerEdgeColor';   C{2,2} = 'k';
C{1,3} = 'MarkerFaceColor';   C{2,3} = 'g';

plot(X, Y, '--rs', C{:})
```

Function Return Values

MATLAB functions can also return more than one value to the caller. These values are returned in a list with each value separated by a comma. Instead of listing each return value, you can use a comma-separated list with a structure or cell array. This becomes more useful for those functions that have variable numbers of return values.

This example returns four values to a cell array:

```
C = cell(1, 4);
[C{:}] = fileparts('work/mytests/strArrays.mat')
C =
    'work/mytests'    'strArrays'    '.mat'     ''
```

Fast Fourier Transform Example

The `fftshift` function swaps the left and right halves of each dimension of an array. For a simple vector such as `[0 2 4 6 8 10]` the output would be `[6 8 10 0 2 4]`. For a multidimensional array, `fftshift` performs this swap along each dimension.

`fftshift` uses vectors of indices to perform the swap. For the vector shown above, the index `[1 2 3 4 5 6]` is rearranged to form a new index `[4 5 6 1 2 3]`. The function then uses this index vector to reposition the elements. For a multidimensional array, `fftshift` must construct an index vector for each dimension. A comma-separated list makes this task much simpler.

Here is the `fftshift` function:

```
function y = fftshift(x)
```

```
numDims = ndims(x);
idx = cell(1, numDims);

for k = 1:numDims
   m = size(x, k);
   p = ceil(m/2);
   idx{k} = [p+1:m 1:p];
   end

y = x(idx{:});
```

The function stores the index vectors in cell array `idx`. Building this cell array is relatively simple. For each of the `N` dimensions, determine the size of that dimension and find the integer index nearest the midpoint. Then, construct a vector that swaps the two halves of that dimension.

By using a cell array to store the index vectors and a comma-separated list for the indexing operation, `fftshift` shifts arrays of any dimension using just a single operation: `y = x(idx{:})`. If you were to use explicit indexing, you would need to write one `if` statement for each dimension you want the function to handle:

```
if ndims(x) == 1
   y = x(index1);
else if ndims(x) == 2
   y = x(index1, index2);
end
```

Another way to handle this without a comma-separated list would be to loop over each dimension, converting one dimension at a time and moving data each time. With a comma-separated list, you move the data just once. A comma-separated list makes it very easy to generalize the swapping operation to an arbitrary number of dimensions.

Program Control Statements

In this section...

Conditional Control — if, switch

This group of control statements enables you to select at run-time which block of code is executed. To make this selection based on whether a condition is true or false, use the `if` statement (which may include `else` or `elseif`). To select from a number of possible options depending on the value of an expression, use the `switch` and `case` statements (which may include `otherwise`).

if, else, and elseif

`if` evaluates a logical expression and executes a group of statements based on the value of the expression. In its simplest form, its syntax is

```
if logical_expression
    statements
end
```

If the logical expression is `true` (that is, if it evaluates to logical `1`), MATLAB executes all the statements between the `if` and `end` lines. It resumes execution at the line following the `end` statement. If the condition is `false` (evaluates to logical `0`), MATLAB skips all the statements between the `if` and `end` lines, and resumes execution at the line following the `end` statement.

For example,

```
if rem(a, 2) == 0
    disp('a is even')
    b = a/2;
end
```

You can nest any number of `if` statements.

If the logical expression evaluates to a nonscalar value, all the elements of the argument must be nonzero. For example, assume `X` is a matrix. Then the statement

```
if X
    statements
end
```

is equivalent to

```
if all(X(:))
    statements
end
```

The `else` and `elseif` statements further conditionalize the `if` statement:

- The `else` statement has no logical condition. The statements associated with it execute if the preceding `if` (and possibly `elseif` condition) evaluates to logical `0` (`false`).
- The `elseif` statement has a logical condition that it evaluates if the preceding `if` (and possibly `elseif` condition) is `false`. The statements associated with it execute if its logical condition evaluates to logical `1` (`true`). You can have multiple `elseif` statements within an `if` block.

```
if n < 0             % If n negative, display error message.
    disp('Input must be positive');
elseif rem(n,2) == 0 % If n positive and even, divide by 2.
    A = n/2;
else
    A = (n+1)/2;     % If n positive and odd, increment and divide.
end
```

if Statements and Empty Arrays. An `if` condition that reduces to an empty array represents a `false` condition. That is,

```
if A
   S1
else
   S0
```

```
end
```

executes statement `S0` when `A` is an empty array.

switch, case, and otherwise

`switch` executes certain statements based on the value of a variable or expression. Its basic form is

```
switch expression (scalar or string)
   case value1
      statements       % Executes if expression is value1
   case value2
      statements       % Executes if expression is value2
    .
    .
    .
   otherwise
      statements       % Executes if expression does not
                        % match any case
end
```

This block consists of

- The word `switch` followed by an expression to evaluate.
- Any number of `case` groups. These groups consist of the word `case` followed by a possible value for the expression, all on a single line. Subsequent lines contain the statements to execute for the given value of the expression. These can be any valid MATLAB statement including another `switch` block. Execution of a `case` group ends when MATLAB encounters the next `case` statement or the `otherwise` statement. Only the first matching `case` is executed.
- An optional `otherwise` group. This consists of the word `otherwise`, followed by the statements to execute if the expression's value is not handled by any of the preceding `case` groups. Execution of the `otherwise` group ends at the `end` statement.
- An `end` statement.

`switch` works by comparing the input expression to each case value. For numeric expressions, a case statement is true if `(value==expression)`. For string expressions, a case statement is true if `strcmp(value,expression)`.

The code below shows a simple example of the `switch` statement. It checks the variable `input_num` for certain values. If `input_num` is `-1`, `0`, or `1`, the `case` statements display the value as text. If `input_num` is none of these values, execution drops to the `otherwise` statement and the code displays the text `'other value'`.

```
switch input_num
    case -1
        disp('negative one');
    case 0
        disp('zero');
    case 1
        disp('positive one');
    otherwise
         disp('other value');
end
```

Note For C programmers, unlike the C language `switch` construct, the MATLAB `switch` does not "fall through." That is, if the first `case` statement is true, other `case` statements do not execute. Therefore, `break` statements are not used.

`switch` can handle multiple conditions in a single `case` statement by enclosing the case expression in a cell array.

```
switch var
    case 1
        disp('1')
    case {2,3,4}
        disp('2 or 3 or 4')
    case 5
        disp('5')
    otherwise
        disp('something else')
end
```

Loop Control — for, while, continue, break

With loop control statements, you can repeatedly execute a block of code, looping back through the block while keeping track of each iteration with an incrementing index variable. Use the `for` statement to loop a specific number of times. The `while` statement is more suitable for basing the loop execution on how long a condition continues to be true or false. The `continue` and `break` statements give you more control on exiting the loop.

Note You can often speed up the execution of MATLAB code by replacing `for` and `while` loops with vectorized code. See "Techniques for Improving Performance" on page 11-4 for more information on this.

---

for

The `for` loop executes a statement or group of statements a predetermined number of times. Its syntax is

```
for index = start:increment:end
    statements
end
```

The default increment is `1`. You can specify any increment, including a negative one. For positive indices, execution terminates when the value of the index exceeds the *`end`* value; for negative increments, it terminates when the index is less than the end value.

For example, this loop executes five times.

```
for n = 2:6
    x(n) = 2 * x(n - 1);
end
```

You can nest multiple `for` loops.

```
for m = 1:5
    for n = 1:100
        A(m, n) = 1/(m + n - 1);
    end
```

```
end
```

Note You can often speed up the execution of MATLAB code by replacing `for` and `while` loops with vectorized code. See "Vectorizing Loops" on page 11-4 for details.

Using Arrays as Indices. The index of a `for` loop can be an array. For example, consider an m-by-n array `A`. The statement

```
for k = A
    statements
end
```

sets `k` equal to the vector `A(:,i)`, where `i` is the iteration number of the loop. For the first loop iteration, `k` is equal to `A(:,1)`; for the second, `k` is equal to `A(:,2)`; and so on until `k` equals `A(:,n)`. That is, the loop iterates for a number of times equal to the number of columns in `A`. For each iteration, `k` is a vector containing one of the columns of `A`.

while

The `while` loop executes a statement or group of statements repeatedly as long as the controlling expression is true (`1`). Its syntax is

```
while expression
    statements
end
```

If the expression evaluates to a matrix, all its elements must be `1` for execution to continue. To reduce a matrix to a scalar value, use the `all` and `any` functions.

For example, this `while` loop finds the first integer `n` for which `n!` (`n` factorial) is a 100-digit number.

```
n = 1;
while prod(1:n) < 1e100
    n = n + 1;
end
```

Exit a `while` loop at any time using the `break` statement.

while Statements and Empty Arrays. A `while` condition that reduces to an empty array represents a `false` condition. That is,

```
while A, S1, end
```

never executes statement `S1` when `A` is an empty array.

continue

The `continue` statement passes control to the next iteration of the `for` or `while` loop in which it appears, skipping any remaining statements in the body of the loop. The same holds true for `continue` statements in nested loops. That is, execution continues at the beginning of the loop in which the `continue` statement was encountered.

The example below shows a `continue` loop that counts the lines of code in the file, `magic.m`, skipping all blank lines and comments. A `continue` statement is used to advance to the next line in `magic.m` without incrementing the count whenever a blank line or comment line is encountered.

```
fid = fopen('magic.m', 'r');
count = 0;
while ~feof(fid)
    line = fgetl(fid);
    if isempty(line) | strncmp(line, '%', 1)
        continue
    end
    count = count + 1;
end
disp(sprintf('%d lines', count));
```

break

The `break` statement terminates the execution of a `for` loop or `while` loop. When a `break` statement is encountered, execution continues with the next statement outside of the loop. In nested loops, `break` exits from the innermost loop only.

The example below shows a `while` loop that reads the contents of the file `fft.m` into a MATLAB character array. A `break` statement is used to exit the `while` loop when the first empty line is encountered. The resulting character array contains the M-file help for the `fft` program.

```
fid = fopen('fft.m', 'r');
s = '';
while ~feof(fid)
   line = fgetl(fid);
   if isempty(line)
      break
   end
   s = strvcat(s, line);
end
disp(s)
```

Error Control — try, catch

Error control statements provide a way for you to take certain actions in the event of an error. Use the `try` statement to test whether a certain command in your code generates an error. If an error does occur within the `try` block, MATLAB immediately jumps to the corresponding `catch` block. The `catch` part of the statement needs to respond in some way to the error.

try and catch

The general form of a try-catch statement sequence is

```
try
   statement
   ...
   statement
catch
   statement
   ...
   statement
end
```

In this sequence, the statements between `try` and `catch` are executed until an error occurs. The statements between `catch` and `end` are then executed. Use `lasterr` to see the cause of the error. If an error occurs between `catch`

and `end`, MATLAB terminates execution unless another `try-catch` sequence has been established.

Program Termination — return

Program termination control enables you to exit from your program at some point prior to its normal termination point.

return

After a MATLAB function runs to completion, it terminates and returns control either to the function that called it, or to the keyboard. If you need to exit a function prior to the point of normal completion, you can force an early termination using the `return` function. `return` immediately terminates the current sequence of commands and exits the currently running function.

`return` is also used to terminate `keyboard` mode.

Symbol Reference

In this section...

This section does not include symbols used in arithmetic, relational, and logical operations. For a description of these symbols, see the top of the list. "Functions — Alphabetical List" in the MATLAB Help browser.

Asterisk — *

An asterisk in a filename specification is used as a wildcard specifier, as described below.

Filename Wildcard

Wildcards are generally used in file operations that act on multiple files or directories. They usually appear in the string containing the file or directory specification. MATLAB matches all characters in the name exactly except for the wildcard character `*`, which can match any one or more characters.

To locate all files with names that start with `'january_'` and have a `mat` file extension, use

```
dir('january_*.mat')
```

You can also use wildcards with the `who` and `whos` functions. To get information on all variables with names starting with `'image'` and ending with `'Offset'`, use

```
whos image*Offset
```

At — @

The `@` sign signifies either a function handle constructor or a directory that supports a MATLAB class.

Function Handle Constructor

The `@` operator forms a handle to either the named function that follows the `@` sign, or to the anonymous function that follows the `@` sign.

Function Handles in General. Function handles are commonly used in passing functions as arguments to other functions. Construct a function handle by preceding the function name with an `@` sign:

```
fhandle = @myfun
```

You can read more about function handles in “Function Handles” on page 4-22.

Handles to Anonymous Functions. Anonymous functions give you a quick means of creating simple functions without having to create M-files each time. You can construct an anonymous function and a handle to that function using the syntax

```
fhandle = @(arglist) body
```

where `body` defines the body of the function and `arglist` is the list of arguments you can pass to the function.

See “Anonymous Functions” on page 5-3 for more information.

Class Directory Designator

A MATLAB class directory contains source files that define the methods and properties of a class. All MATLAB class directory names must begin with an `@` sign:

```
\@myclass\get.m
```

See “MATLAB Classes” on page 2-117 for more information.

Colon — :

The colon operator generates a sequence of numbers that you can use in creating or indexing into arrays. See “Generating a Numeric Sequence” on page 1-11 for more information on using the colon operator.

Numeric Sequence Range

Generate a sequential series of regularly spaced numbers from `first` to `last` using the syntax `first:last`. For an incremental sequence from 6 to 17, use

```
N = 6:17
```

Numeric Sequence Step

Generate a sequential series of numbers, each number separated by a `step` value, using the syntax `first:step:last`. For a sequence from 2 through 38, stepping by 4 between each entry, use

```
N = 2:4:38
```

Indexing Range Specifier

Index into multiple rows or columns of a matrix using the colon operator to specify a range of indices:

```
B = A(7, 1:5);          % Read columns 1-5 of row 7.
B = A(4:2:8, 1:5);      % Read columns 1-5 of rows 4, 6, and 8.
B = A(:, 1:5);          % Read columns 1-5 of all rows.
```

Conversion to Column Vector

Convert a matrix or array to a column vector using the colon operator as a single index:

```
A = rand(3,4);
B = A(:);
```

Preserving Array Shape on Assignment

Using the colon operator on the left side of an assignment statement, you can assign new values to array elements without changing the shape of the array:

```
A = rand(3,4);
A(:) = 1:12;
```

Comma — ,

A comma is used to separate the following types of elements.

Row Element Separator

When constructing an array, use a comma to separate elements that belong in the same row:

```
A = [5.92, 8.13, 3.53]
```

Array Index Separator

When indexing into an array, use a comma to separate the indices into each dimension:

```
X = A(2, 7, 4)
```

Function Input and Output Separator

When calling a function, use a comma to separate output and input arguments:

```
function [data, text] = xlsread(file, sheet, range, mode)
```

Command or Statement Separator

To enter more than one MATLAB command or statement on the same line, separate each command or statement with a comma:

```
for k = 1:10,   sum(A(k)),   end
```

Curly Braces — { }

Use curly braces to construct or get the contents of cell arrays.

Cell Array Constructor

To construct a cell array, enclose all elements of the array in curly braces:

```
C = {[2.6 4.7 3.9], rand(8)*6, 'C. Coolidge'}
```

Cell Array Indexing

Index to a specific cell array element by enclosing all indices in curly braces:

```
A = C{4,7,2}
```

See “Cell Arrays” on page 2-93 for more information.

Dot — .

The single dot operator has the following different uses in MATLAB.

Structure Field Definition

Add fields to a MATLAB structure by following the structure name with a dot and then a field name:

```
funds(5,2).bondtype = 'Corporate';
```

See “Structures” on page 2-74 for more information.

Object Method Specifier

Specify the properties of an instance of a MATLAB class using the object name followed by a dot, and then the property name:

```
val = asset.current_value
```

See “MATLAB Classes” on page 2-117 for more information.

Dot-Dot — ..

Two dots in sequence refer to the parent of the current directory.

Parent Directory

Specify the directory immediately above your current directory using two dots. For example, to go up two levels in the directory tree and down into the `testdir` directory, use

```
cd ..\..\testdir
```

Dot-Dot-Dot (Ellipsis) — ...

A series of three consecutive periods (`...`) is the line continuation operator in MATLAB. This is often referred to as an *ellipsis*, but it should be noted that the line continuation operator is a three-character operator and is different from the single-character ellipsis represented in ASCII by the hexadecimal number 2026.

Line Continuation

Continue any MATLAB command or expression by placing an ellipsis at the end of the line to be continued:

```
sprintf('The current value of %s is %d', ...
         vname, value)
```

Entering Long Strings. You cannot use an ellipsis within single quotes to continue a string to the next line:

```
string = 'This is not allowed and will generate an ...
   error in MATLAB.'
```

To enter a string that extends beyond a single line, piece together shorter strings using either the concatenation operator (`[]`) or the `sprintf` function.

Here are two examples:

```
quote1 = [
 'Tiger, tiger, burning bright in the forests of the night,' ...
 'what immortal hand or eye could frame thy fearful symmetry?'];
quote2 = sprintf('%s%s%s', ...
 'In Xanadu did Kubla Khan a stately pleasure-dome decree,', ...
 'where Alph, the sacred river, ran ', ...
 'through caverns measureless to man down to a sunless sea.');
```

Dot-Parentheses — .( )

Use dot-parentheses to specify the name of a dynamic structure field.

Dynamic Structure Fields

Sometimes it is useful to reference structures with field names that can vary. For example, the referenced field might be passed as an argument to a function. Dynamic field names specify a variable name for a structure field.

The variable `fundtype` shown here is a dynamic field name:

```
type = funds(5,2).(fundtype);
```

See “Using Dynamic Field Names” on page 2-80 for more information.

Exclamation Point — !

The exclamation point precedes operating system commands that you want to execute from within MATLAB.

Shell Escape

The exclamation point initiates a shell escape function. Such a function is to be performed directly by the operating system:

```
!rmdir oldtests
```

See “Shell Escape Functions” on page 3-28 for more information.

Parentheses — ( )

Parentheses are used mostly for indexing into elements of an array or for specifying arguments passed to a called function.

Array Indexing

When parentheses appear to the right of a variable name, they are indices into the array stored in that variable:

```
A(2, 7, 4)
```

Function Input Arguments

When parentheses follow a function name in a function declaration or call, the enclosed list contains input arguments used by the function:

```
function sendmail(to, subject, message, attachments)
```

Percent — %

The percent sign is most commonly used to indicate nonexecutable text within the body of a program. This text is normally used to include comments in your code. Some functions also interpret the percent sign as a conversion specifier.

See “Help Text” on page 4-11 for more information.

Single Line Comments

Precede any one-line comments in your code with a percent sign. MATLAB does not execute anything that follows a percent sign (that is, unless the sign is quoted, `'%'`):

```
% The purpose of this routine is to compute
% the value of ...
```

Conversion Specifiers

Some functions, like `sscanf` and `sprintf`, precede conversion specifiers with the percent sign:

```
sprintf('%s = %d', name, value)
```

Percent-Brace — %{ %}

The `%{` and `%}` symbols enclose a block of comments that extend beyond one line.

Block Comments

Enclose any multiline comments with percent followed by an opening or closing brace.

```
%{
The purpose of this routine is to compute
the value of ...
%}
```

Note With the exception of whitespace characters, the `%{` and `%}` operators must appear alone on the lines that immediately precede and follow the block of help text. Do not include any other text on these lines.

Semicolon — ;

The semicolon can be used to construct arrays, suppress output from a MATLAB command, or to separate commands entered on the same line.

Array Row Separator

When used within square brackets to create a new array or concatenate existing arrays, the semicolon creates a new row in the array:

```
A = [5, 8; 3, 4]
A =
     5     8
     3     4
```

Output Suppression

When placed at the end of a command, the semicolon tells MATLAB not to display any output from that command. In this example, MATLAB does not display the resulting 100-by-100 matrix:

```
A = ones(100, 100);
```

Command or Statement Separator

Like the comma operator, you can enter more than one MATLAB command on a line by separating each command with a semicolon. MATLAB suppresses output for those commands terminated with a semicolon, and displays the output for commands terminated with a comma.

In this example, assignments to variables `A` and `C` are terminated with a semicolon, and thus do not display. Because the assignment to `B` is comma-terminated, the output of this one command is displayed:

```
A = 12.5;  B = 42.7,  C = 1.25;
B =
   42.7000
```

Single Quotes — ' '

Single quotes are the constructor symbol for MATLAB character arrays.

Character and String Constructor

MATLAB constructs a character array from all characters enclosed in single quotes. If only one character is in quotes, then MATLAB constructs a 1-by-1 array:

```
S = 'Hello World'
```

See “Characters and Strings” on page 2-37 for more information.

Space Character

The space character serves a purpose similar to the comma in that it can be used to separate row elements in an array constructor, or the values returned by a function.

Row Element Separator

You have the option of using either commas or spaces to delimit the row elements of an array when constructing the array. To create a 1-by-3 array, use

```
A = [5.92 8.13 3.53]
A =
    5.9200    8.1300    3.5300
```

When indexing into an array, you must always use commas to reference each dimension of the array.

Function Output Separator

Spaces are allowed when specifying a list of values to be returned by a function. You can use spaces to separate return values in both function declarations and function calls:

```
function [data text] = xlsread(file, sheet, range, mode)
```

Slash and Backslash — / \

The slash (/) and backslash (\) characters separate the elements of a path or directory string. On Windows-based systems, both slash and backslash have the same effect. On UNIX-based systems, you must use slash only.

On a Windows system, you can use either backslash or slash:

```
dir([matlabroot '\toolbox\matlab\elmat\shiftdim.m'])
dir([matlabroot '/toolbox/matlab/elmat/shiftdim.m'])
```

On a UNIX system, use only the forward slash:

```
dir([matlabroot '/toolbox/matlab/elmat/shiftdim.m'])
```

Square Brackets — [ ]

Square brackets are used in array construction and concatenation, and also in declaring and capturing values returned by a function.

Array Constructor

To construct a matrix or array, enclose all elements of the array in square brackets:

```
A = [5.7, 9.8, 7.3; 9.2, 4.5, 6.4]
```

Concatenation

To combine two or more arrays into a new array through concatenation, enclose all array elements in square brackets:

```
A = [B, eye(6), diag([0:2:10])]
```

Function Declarations and Calls

When declaring or calling a function that returns more than one output, enclose each return value that you need in square brackets:

```
[data, text] = xlsread(file, sheet, range, mode)
```

Internal MATLAB Functions

In this section...

Overview

Many of the functions provided with MATLAB are implemented as M-files just like the M-files that you will create with MATLAB. Other MATLAB functions are precompiled executable programs called built-ins that run much more efficiently. Many of the MATLAB functions are also overloaded so that they handle different data types appropriately.

M-File Functions

If you look in the subdirectories of the `toolbox\matlab` directory, you can find the M-file sources to many of the functions supplied with MATLAB. You can locate your `toolbox\matlab` directory by typing

```
dir([matlabroot '\toolbox\matlab\'])
```

MATLAB functions with an M-file source are just like any other functions coded with MATLAB. When one of these M-file functions is called, MATLAB parses and executes each line of code in the M-file. It saves the parsed version of the function in memory, eliminating parsing time on any further calls to this function.

Identifying M-File Functions

To find out if a function is implemented with an M-file, use the `exist` function. The `exist` function searches for the name you enter on the MATLAB path and returns a number identifying the source. If the source is an M-file, then `exist` returns the number `2`. This example identifies the source for the `repmat` function as an M-file:

```
exist repmat
ans =
     2
```

The `exist` function also returns 2 for files that have a file type unknown to MATLAB. However, if you invoke `exist` on a MATLAB function name, the file type will be known to MATLAB and will return 2 only on M-files.

Viewing the Source Code

One advantage of functions implemented as M-files is that you can look at the source code. This may help when you need to understand why the function returns a value you did not expect, if you need to figure out how to code something in MATLAB that is already coded in a function, or perhaps to help you create a function that overloads one of the MATLAB functions.

To find the source code for any MATLAB M-file function, use `which`:

```
which repmat
   D:\matlabR14\toolbox\matlab\elmat\repmat.m
```

Built-In Functions

Functions that are frequently used or that can take more time to execute are often implemented as executable files. These functions are called *built-ins*.

Unlike M-file functions, you cannot see the source code for built-ins. Although most built-in functions do have an M-file associated with them, this file is there mainly to supply the help documentation for the function. Take the `reshape` function, for example, and find it on the MATLAB path:

```
which reshape
   D:\matlabR14\toolbox\matlab\elmat\reshape.m
```

If you type this M-file out, you will see that it consists almost entirely of help text. At the bottom is a call to the built-in executable image.

Identifying Built-In Functions

As with M-file functions, you can identify which functions are built-ins using the `exist` function. This function identifies built-ins by returning the number `5`:

```
exist reshape
ans =
     5
```

Forcing a Built-In Call

If you overload any of the MATLAB built-in functions to handle a specific data type, then MATLAB will always call the overloaded function on that type. If, for some reason, you need to call the built-in version, you can override the usual calling mechanism using a function called `builtin`. The expression

```
builtin('reshape', arg1, arg2, ..., argN);
```

forces a call to MATLAB built-in `reshape`, passing the arguments shown even though an overload exists for the data types in this argument list.

Overloaded MATLAB Functions

An overloaded function is an additional implementation of an existing function that has been designed specifically to handle a certain data type. When you pass an argument of this type in a call to the function, MATLAB looks for the function implementation that handles that type and executes that function code.

Each overloaded MATLAB function has an M-file on the MATLAB path. The M-files for a certain data type (or class) are placed in a directory named with an `@` sign followed by the class name. For example, to overload the MATLAB `plot` function to plot expressions of a class named `polynom` differently than other data types, you would create a directory called `@polynom` and store your own version of `plot.m` in that directory.

You can add your own overloads to any function by creating a class directory for the data type you wish to support for that function, and creating an M-file that handles that type in a manner different from the default. See “Setting

Up Class Directories” on page 9-6 and “Designing User Classes in MATLAB” on page 9-9.

When you use the `which` command with the `-all` option, MATLAB returns all occurrences of the file you are looking for. This is an easy way to find functions that are overloaded:

```
which -all set          % Show all implementations for 'set'
```

4

M-File Programming

Program Development

In this section...

Overview

When you write a program in MATLAB, you save it to a file called an M-file (named after its `.m` file extension). There are two types of M-files that you can write: scripts and functions. This section covers basic program development, describes how to write and call scripts and functions, and shows how to pass different types of data in a function call. Associated with each step of this process are certain MATLAB tools and utilities that are fully documented in the Desktop Tools and Development Environment documentation.

For more ideas on good programming style, see “Program Development” on page 12-20 in the MATLAB Programming Tips documentation. The Programming Tips section is a compilation of useful pieces of information that can show you alternate and often more efficient ways to accomplish common programming tasks while also expanding your knowledge of MATLAB.

Creating a Program

You can type in your program code using any text editor. This section focuses on using the MATLAB Editor/Debugger for this purpose. The Editor/Debugger is fully documented in Ways to Edit and Debug Files in the Desktop Tools and Development Environment documentation.

The first step in creating a program is to open an editing window. To create a new M-file, type the word `edit` at the MATLAB command prompt. To edit an existing M-file, type `edit` followed by the filename:

```
edit drawPlot.m
```

MATLAB opens a new window for entering your program code. As you type in your program, MATLAB keeps track of the line numbers in the left column.

Saving the Program

It is usually a good idea to save your program periodically while you are in the development process. To do this, click **File > Save** in the Editor/Debugger. Enter a filename with a `.m` extension in the **Save file as** dialog box that appears and click **OK**. It is customary and less confusing if you give the M-file the same name as the first function in the M-file.

Running the Program

Before trying to run your program, make sure that its M-file is on the MATLAB path. The MATLAB path defines those directories that you want MATLAB to know about when executing M-files. The path includes all the directories that contain functions provided with MATLAB. It should also include any directories that you use for your own functions.

Use the `which` function to see if your program is on the path:

```
which drawPlot
   D:\matlabR14\work\drawPlot.m
```

If not, add its directory to the path using the `addpath` function:

```
addpath('D:\matlabR14\work')
```

Now you can run the program just by typing the name of the M-file at the MATLAB command prompt:

```
drawPlot(xdata, ydata)
```

Getting the Bugs Out

In all but the simplest programs, you are likely to encounter some type of unexpected behavior when you run the program for the first time. Program defects can show up in the form of warning or error messages displayed in the command window, programs that hang (never terminate), inaccurate results,

or some number of other symptoms. This is where the second functionality of the MATLAB Editor/Debugger becomes useful.

The MATLAB Debugger enables you to examine the inner workings of your program while you run it. You can stop the execution of your program at any point and then continue from that point, stepping through the code line by line and examining the results of each operation performed. You have the choice of operating the debugger from the Editor window that displays your program, from the MATLAB command line, or both.

The Debugging Process

You can step through the program right from the start if you want. For longer programs, you will probably save time by stopping the program somewhere in the middle and stepping through from there. You can do this by approximating where the program code breaks and setting a stopping point (or *breakpoint*) at that line. Once a breakpoint has been set, start your program from the MATLAB command prompt. MATLAB opens an Editor/Debugger window (if it is not already open) showing a green arrow pointing to the next line to execute.

From this point, you can examine any values passed into the program, or the results of each operation performed. You can step through the program line by line to see which path is taken and why. You can step into any functions that your program calls, or choose to step over them and just see the end results. You can also modify the values assigned to a variable and see how that affects the outcome.

To learn about using the MATLAB Debugger, see Debugging and Improving M-Files in the Desktop Tools and Development Environment documentation. Type `help debug` for a listing of all MATLAB debug functions.

For programming tips on how to debug, see “Debugging” on page 12-23.

Cleaning Up the Program

Even after your program is bug-free, there are still some steps you can take to improve its performance and readability. The MATLAB M-Lint utility generates a report that can highlight potential problems in your code. For example, you may be using the elementwise AND operator (`&`) where the

short-circuit AND (&&) is more appropriate. You may be using the `find` function in a context where logical subscripting would be faster.

MATLAB offers M-Lint and several other reporting utilities to help you make the finishing touches to your program code. These tools are described under Tuning and Refining M-Files in the Desktop Tools and Development Environment documentation.

Improving Performance

The MATLAB Profiler generates a report that shows how your program spends its processing time. For details about using the MATLAB Profiler, see Profiling for Improving Performance in the MATLAB Desktop Tools and Development Environment documentation. For tips on other ways to improve the performance of your programs, see Chapter 11, "Improving Performance and Memory Usage".

Three types of reports are available:

- "Summary Report" on page 4-5
- "Detail Report" on page 4-5
- "File Listing" on page 4-6

Summary Report

The summary report provides performance information on your main program and on every function it calls. This includes how many times each function is called, the total time spent in that function, along with a bar graph showing the relative time spent by each function.

Detail Report

When you click a function name in the summary report, MATLAB displays a detailed report on that function. This report shows the lines of that function that take up the most time, the time spent executing that line, the percentage of total time for that function that is spent on that line, and a bar graph showing the relative time spent on the line.

File Listing

The detail report for a function also displays the entire M-file code for that function. This listing enables you to view the time-consuming code in the context of the entire function body. For every line of code that takes any significant time, additional performance information is provided by the statistics and by the color and degree of highlighting of the program code.

Checking It In

Source control systems offer a way to manage large numbers of files while they are under development. They keep track of the work done on these files as your project progresses, and also ensure that changes are made in a secure and orderly fashion.

If you have a source control system available to you, you will probably want to check your M-files into the system once they are complete. If further work is required on one of those files, you just check it back out, make the necessary modifications, and then check it back in again.

MATLAB provides an interface to external source control systems so that you can check files in and out directly from your MATLAB session. See Revision Control in the Desktop Tools and Development Environment documentation for instructions on how to use this interface.

Working with M-Files

In this section...

Overview

MATLAB provides a full programming language that enables you to write a series of MATLAB statements into a file and then execute them with a single command. You write your program in an ordinary text file, giving the file a name of `filename.m`. The term you use for `filename` becomes the new command that MATLAB associates with the program. The file extension of `.m` makes this a MATLAB M-file.

Types of M-Files

M-files can be *scripts* that simply execute a series of MATLAB statements, or they can be *functions* that also accept input arguments and produce output.

MATLAB scripts:

- Are useful for automating a series of steps you need to perform many times.
- Do not accept input arguments or return output arguments.
- Store variables in a workspace that is shared with other scripts and with the MATLAB command line interface.

MATLAB functions:

- Are useful for extending the MATLAB language for your application.
- Can accept input arguments and return output arguments.

- Store variables in a workspace internal to the function.

Basic Parts of an M-File

This simple function shows the basic parts of an M-file. Note that any line that begins with `%` is not executable:

```
function f = fact(n)                    Function
definition line
% Compute a factorial value.            H1 line
% FACT(N) returns the factorial of N,   Help text
% usually denoted by N!

% Put simply, FACT(N) is PROD(1:N).     Comment
f = prod(1:n);                          Function body
```

The table below briefly describes each of these M-file parts. Both functions and scripts can have all of these parts, except for the function definition line which applies to functions only. These parts are described in greater detail following the table.

M-File Element	Description
Function definition line (functions only)	Defines the function name, and the number and order of input and output arguments
H1 line	A one line summary description of the program, displayed when you request `help` on an entire directory, or when you use `lookfor`
Help text	A more detailed description of the program, displayed together with the H1 line when you request `help` on a specific function
Function or script body	Program code that performs the actual computations and assigns values to any output arguments
Comments	Text in the body of the program that explains the internal workings of the program

Function Definition Line

The function definition line informs MATLAB that the M-file contains a function, and specifies the argument calling sequence of the function. The function definition line for the `fact` function is

All MATLAB functions have a function definition line that follows this pattern.

Function Name. Function names must begin with a letter, may contain any alphanumeric characters or underscores, and must be no longer than the maximum allowed length (returned by the function `namelengthmax`). Because variables must obey similar rules, you can use the `isvarname` function to check whether a function name is valid:

```
isvarname myfun
```

Although function names can be of any length, MATLAB uses only the first `N` characters of the name (where `N` is the number returned by the function `namelengthmax`) and ignores the rest. Hence, it is important to make each function name unique in the first `N` characters:

```
N = namelengthmax
N =
    63
```

Note Some operating systems may restrict file names to shorter lengths.

The name of the text file that contains a MATLAB function consists of the function name with the extension `.m` appended. For example,

```
average.m
```

If the filename and the function definition line name are different, the internal (function) name is ignored. Thus, if `average.m` is the file that defines a function named `computeAverage`, you would invoke the function by typing

```
average
```

Note While the function name specified on the function definition line does not have to be the same as the filename, it is best to use the same name for both to avoid confusion.

Function Arguments. If the function has multiple output values, enclose the output argument list in square brackets. Input arguments, if present, are enclosed in parentheses following the function name. Use commas to separate multiple input or output arguments. Here is the declaration for a function named `sphere` that has three inputs and three outputs:

```
function [x, y, z] = sphere(theta, phi, rho)
```

If there is no output, leave the output blank

```
function printresults(x)
```

or use empty square brackets:

```
function [] = printresults(x)
```

The variables that you pass to the function do not need to have the same name as those in the function definition line.

The H1 Line

The H1 line, so named because it is the first help text line, is a comment line immediately following the function definition line. Because it consists of comment text, the H1 line begins with a percent sign, `%`. For the `average` function, the H1 line is

```
% AVERAGE Mean of vector elements.
```

This is the first line of text that appears when a user types `help` *`functionname`* at the MATLAB prompt. Further, the `lookfor` function searches on and displays only the H1 line. Because this line provides important summary information about the M-file, it is important to make it as descriptive as possible.

Help Text

You can create online help for your M-files by entering help text on one or more consecutive comment lines at the start of your M-file program. MATLAB considers the first group of consecutive lines immediately following the H1 line that begin with `%` to be the online help text for the function. The first line without `%` as the left-most character ends the help.

The help text for the `average` function is

```
% AVERAGE(X), where X is a vector, is the mean of vector
% elements. Nonvector input results in an error.
```

When you type `help` *`functionname`* at the command prompt, MATLAB displays the H1 line followed by the online help text for that function. The help system ignores any comment lines that appear after this help block.

Note Help text in an M-file can be viewed at the MATLAB command prompt only (using `help functionname`). You cannot display this text using the MATLAB Help browser. You can, however, use the Help browser to get help on MATLAB functions and also to read the documentation on any MathWorks products.

The Function or Script Body

The function body contains all the MATLAB code that performs computations and assigns values to output arguments. The statements in the function body can consist of function calls, programming constructs like flow control and interactive input/output, calculations, assignments, comments, and blank lines.

For example, the body of the `average` function contains a number of simple programming statements:

```
[m,n] = size(x);
if (~((m == 1) | (n == 1)) | (m == 1 & n == 1)) % Flow control
    error('Input must be a vector') % Error message display
end
y = sum(x)/length(x);             % Computation and assignment
```

Comments

As mentioned earlier, comment lines begin with a percent sign (%). Comment lines can appear anywhere in an M-file, and you can append comments to the end of a line of code. For example,

```
% Add up all the vector elements.
y = sum(x)           % Use the sum function.
```

In addition to comment lines, you can insert blank lines anywhere in an M-file. Blank lines are ignored. However, a blank line can indicate the end of the help text entry for an M-file.

Block Comments. To write comments that require more than one line, use the block comment operators, %{ and %}:

```
%{
This next block of code checks the number of inputs
passed in, makes sure that each input is a valid data
type, and then branches to start processing the data.
%}
```

Note The %{ and %} operators must appear alone on the lines that immediately precede and follow the block of help text. Do not include any other text on these lines.

Creating a Simple M-File

You create M-files using a text editor. MATLAB provides a built-in editor, but you can use any text editor you like. Once you have written and saved the M-file, you can run the program as you would any other MATLAB function or command.

The process looks like this:

1 Create an M-file using a text editor.

```
function c = myfile(a,b)
c = sqrt((a.^2)+(b.^2))
```

2 Call the M-file from the command line, or from within another M-file.

```
a = 7.5
b = 3.342
c = myfile(a,b)

c =

    8.2109
```

Using Text Editors

M-files are ordinary text files that you create using a text editor. If you use the MATLAB Editor/Debugger, open a new file by selecting **New > M-File** from the **File** menu at the top of the MATLAB Command Window.

Another way to edit an M-file is from the MATLAB command line using the `edit` function. For example,

```
edit foo
```

opens the editor on the file `foo.m`. Omitting a filename opens the editor on an untitled file.

You can create the `fact` function shown in “Basic Parts of an M-File” on page 4-8 by opening your text editor, entering the lines shown, and saving the text in a file called `fact.m` in your current directory.

Once you have created this file, here are some things you can:

- List the names of the files in your current directory:

```
what
```

- List the contents of M-file `fact.m`:

```
type fact
```

- Call the `fact` function:

```
fact(5)
ans =
     120
```

A Word of Caution on Saving M-Files

Save any M-files you create and any MathWorks supplied M-files that you edit in directories outside of the directory tree in which the MATLAB software is installed. If you keep your files in any of the installed directories, your files may be overwritten when you install a new version of MATLAB.

MATLAB installs its software into directories under *`matlabroot`*`/toolbox`. To see what *`matlabroot`* is on your system, type `matlabroot` at the MATLAB command prompt.

Also note that locations of files in the *`matlabroot`*`/toolbox` directory tree are loaded and cached in memory at the beginning of each MATLAB session to improve performance. If you save files to *`matlabroot`*`/toolbox` directories using an external editor, or if you add or remove files from these directories using file system operations, enter the commands `clear functionname` and `rehash toolbox` before you use the files in the current session.

For more information, see the `rehash` function reference page or the section Toolbox Path Caching in the Desktop Tools and Development Environment documentation.

Providing Help for Your Program

You can provide user information for the programs you write by including a help text section at the beginning of your M-file. (See “Help Text” on page 4-11).

You can also make help entries for an entire directory by creating a file with the special name `Contents.m` that resides in the directory. This file must contain only comment lines; that is, every line must begin with a percent sign. MATLAB displays the lines in a `Contents.m` file whenever you type

```
help directoryname
```

`Contents.m` files are optional. You might have directories of your own with M-files that you don’t necessarily want public. For this or other reasons, you might choose not to provide this type of help listing for these directories. If you have a directory that is on the path that does not have a `Contents.m` file, MATLAB displays `(No table of contents file)` for that directory in response to the `help` command. If you do not want to see this displayed, creating an empty `Contents.m` file will disable this message for that directory.

Also, if a directory does not contain a `Contents.m` file, typing

```
help directoryname
```

displays the first help line (the H1 line) for each M-file in the directory.

There is a tool in the Current Directory browser, called the Contents Report, that you can use to help create and validate your `Contents.m` files. See Contents File Report in the MATLAB Desktop Tools and Development Environment documentation for more information.

Creating P-Code Files

You can save a preparsed version of a function or script, called P-code files, for later MATLAB sessions using the `pcode` function. For example,

```
pcode average
```

parses `average.m` and saves the resulting pseudocode to the file named `average.p`. This saves MATLAB from reparsing `average.m` the first time you call it in each session.

MATLAB is very fast at parsing so the `pcode` function rarely makes much of a speed difference.

One situation where `pcode` does provide a speed benefit is for large GUI applications. In this case, many M-files must be parsed before the application becomes visible.

You can also use `pcode` to hide algorithms you have created in your M-file, if you need to do this for proprietary reasons.

M-File Scripts and Functions

In this section...

M-File Scripts

Scripts are the simplest kind of M-file because they have no input or output arguments. They are useful for automating series of MATLAB commands, such as computations that you have to perform repeatedly from the command line.

The Base Workspace

Scripts share the base workspace with your interactive MATLAB session and with other scripts. They operate on existing data in the workspace, or they can create new data on which to operate. Any variables that scripts create remain in the workspace after the script finishes so you can use them for further computations. You should be aware, though, that running a script can unintentionally overwrite data stored in the base workspace by commands entered at the MATLAB command prompt.

Simple Script Example

These statements calculate `rho` for several trigonometric functions of `theta`, then create a series of polar plots:

```
% An M-file script to produce       % Comment lines
% "flower petal" plots
theta = -pi:0.01:pi;                % Computations
rho(1,:) = 2 * sin(5 * theta) .^ 2;
rho(2,:) = cos(10 * theta) .^ 3;
rho(3,:) = sin(theta) .^ 2;
rho(4,:) = 5 * cos(3.5 * theta) .^ 3;
for k = 1:4
```

```
    polar(theta, rho(k,:))          % Graphics output
    pause
end
```

Try entering these commands in an M-file called `petals.m`. This file is now a MATLAB script. Typing `petals` at the MATLAB command line executes the statements in the script.

After the script displays a plot, press **Enter** or **Return** to move to the next plot. There are no input or output arguments; `petals` creates the variables it needs in the MATLAB workspace. When execution completes, the variables (`i`, `theta`, and `rho`) remain in the workspace. To see a listing of them, enter `whos` at the command prompt.

M-File Functions

Functions are program routines, usually implemented in M-files, that accept input arguments and return output arguments. They operate on variables within their own workspace. This workspace is separate from the workspace you access at the MATLAB command prompt.

The Function Workspace

Each M-file function has an area of memory, separate from the MATLAB base workspace, in which it operates. This area, called the function workspace, gives each function its own workspace context.

While using MATLAB, the only variables you can access are those in the calling context, be it the base workspace or that of another function. The variables that you pass to a function must be in the calling context, and the function returns its output arguments to the calling workspace context. You can, however, define variables as global variables explicitly, allowing more than one workspace context to access them. You can also evaluate any MATLAB statement using variables from either the base workspace or the workspace of the calling function using the `evalin` function. See “Extending Variable Scope” on page 3-10 for more information.

Simple Function Example

The `average` function is a simple M-file that calculates the average of the elements in a vector:

```
function y = average(x)
% AVERAGE Mean of vector elements.
% AVERAGE(X), where X is a vector, is the mean of vector
% elements. Nonvector input results in an error.
[m,n] = size(x);
if (~((m == 1) | (n == 1)) | (m == 1 & n == 1))
    error('Input must be a vector')
end
y = sum(x)/length(x);      % Actual computation
```

Try entering these commands in an M-file called `average.m`. The `average` function accepts a single input argument and returns a single output argument. To call the `average` function, enter

```
z = 1:99;

average(z)
ans =
    50
```

Types of Functions

MATLAB provides the following types of functions. Each function type is described in more detail in a later section of this documentation:

- The “Primary M-File Functions” on page 5-15 is the first function in an M-file and typically contains the main program.
- “Subfunctions” on page 5-33 act as subroutines to the main function. You can also use them to define multiple functions within a single M-file.
- “Nested Functions” on page 5-16 are functions defined within another function. They can help to improve the readability of your program and also give you more flexible access to variables in the M-file.
- “Anonymous Functions” on page 5-3 provide a quick way of making a function from any MATLAB expression. You can compose anonymous

functions either from within another function or at the MATLAB command prompt.

- "Overloaded Functions" on page 5-37 are useful when you need to create a function that responds to different types of inputs accordingly. They are similar to overloaded functions in any object-oriented language.
- "Private Functions" on page 5-35 give you a way to restrict access to a function. You can call them only from an M-file function in the parent directory.

You might also see the term function functions in the documentation. This is not really a separate function type. The term function functions refers to any functions that accept another function as an input argument. You can pass a function to another function using a function handle.

Identifying Dependencies

Most any program you write will make calls to other functions and scripts. If you need to know what other functions and scripts your program is dependent upon, use one of the techniques described below.

Simple Display of M-File Dependencies

For a simple display of all M-files referenced by a particular function, follow these steps:

1. Type `clear functions` to clear all functions from memory (see Note below).

   Note `clear functions` does not clear functions locked by `mlock`. If you have locked functions (which you can check using `inmem`) unlock them with `munlock`, and then repeat step 1.

2. Execute the function you want to check. Note that the function arguments you choose to use in this step are important, because you can get different results when calling the same function with different arguments.

3 Type `inmem` to display all M-files that were used when the function ran. If you want to see what MEX-files were used as well, specify an additional output:

```
[mfiles, mexfiles] = inmem
```

Detailed Display of M-File Dependencies

For a much more detailed display of dependent function information, use the `depfun` function. In addition to M-files, `depfun` shows which built-ins and classes a particular function depends on:

```
[list, builtins, classes] = depfun('strtok.m');

list
list =
   'D:\matlabR14\toolbox\matlab\strfun\strtok.m'
   'D:\matlabR14\toolbox\distcomp\toChar.m'
   'D:\matlabR14\toolbox\matlab\datafun\prod.m'
   'D:\matlabR14\toolbox\matlab\datatypes\@opaque\char.m'
           .
           .
           .
```

Function Handles

In this section...

Constructing a Function Handle

A *function handle* is a MATLAB value that provides a means of calling a function indirectly. You can pass function handles in calls to other functions (often called *function functions*). You can also store function handles in data structures for later use (for example, as Handle Graphics callbacks).

Use the following syntax to construct a function handle, preceding the name of the function with an `@` sign. Use only the function *name*, with no path information, after the `@` sign:

```
fhandle = @functionname
```

MATLAB maps the handle to the function you specify and saves this mapping information in the handle. If there is more than one function with this name, MATLAB maps to the one function source it would dispatch to if you were actually calling the function.

A function handle retains that same mapping even if its corresponding function goes out of scope. For example, if, after creating the handle, you change the MATLAB path so that a different function of the same name now takes precedence, invoking the function handle still executes the code to which the handle was originally mapped.

Handles to Anonymous Functions

Another way to construct a function handle is to create an anonymous function. For example,

```
sqr = @(x) x.^2;
```

creates an anonymous function that computes the square of its input argument `x`. The variable `sqr` contains a handle to the anonymous function. See “Anonymous Functions” on page 5-3 for more information.

Arrays of Function Handles

To store function handles in an array, use a cell array:

```
trigFun = {@sin, @cos, @tan};

plot(trigFun{2}(-pi:0.01:pi))
```

Invalid or Obsolete Function Handles

If you create a handle to a function that is not on the MATLAB path, or if you `load` a handle to a function that is no longer on the path, MATLAB catches the error only when the handle is invoked. You can assign an invalid handle and use it in such operations as `func2str`. MATLAB catches and reports an error only when you attempt to use it in a runtime operation.

Calling a Function Using Its Handle

To execute a function associated with a function handle, use the syntax shown here, treating the function handle `fhandle` as if it were a function name:

```
fhandle(arg1, arg2, ..., argn)
```

If the function being called takes no input arguments, then use empty parentheses after the function handle name:

```
fhandle()
```

Handling Return Values

When you invoke a function by means of its handle, you can capture any or all values returned from the call in the same way you would if you were calling the function directly. Just list the output variable to the left of the

equals sign. When assigning to multiple outputs, enclose the output variables within square brackets:

```
[out1 out2 ...] = fhandle(arg1, arg2, arg3, ...)
```

This example returns multiple values from a call to an anonymous function. Create anonymous function `f` that locates the nonzero elements of an array, and returns the row, column, and value of each element in variables `row`, `col`, and `val`:

```
f = @(X)find(X);
```

Call the function on matrix `m` using the function handle `f`. Because the function uses the MATLAB `find` function which returns up to 3 outputs, you can specify from 0 to 3 outputs in the call:

```
m = [3 2 0; -5 0 7; 0 0 1]
m =
     3     2     0
    -5     0     7
     0     0     1

[row col val] = f(m);

val
val =
     3
    -5
     2
     7
     1
```

Simple Function Handle Example

The following example calls a function `plotFHandle`, passing it a handle for the MATLAB `sin` function. `plotFHandle` then calls the `plot` function, passing it some data and the function handle to `sin`. The plot function calls the function associated with the handle to compute its *y*-axis values:

```
function x = plotFHandle(fhandle, data)
plot(data, fhandle(data))
```

Call `plotFhandle` with a handle to the `sin` function and the value shown below:

```
plotFHandle(@sin, -pi:0.01:pi)
```

Functions That Operate on Function Handles

MATLAB provides the following functions for working with function handles. See the reference pages for these functions for more information.

Function	Description
`functions`	Return information describing a function handle.
`func2str`	Construct a function name string from a function handle.
`str2func`	Construct a function handle from a function name string.
`save`	Save a function handle from the current workspace to a MAT-file.
`load`	Load a function handle from a MAT-file into the current workspace.
`isa`	Determine if a variable contains a function handle.
`isequal`	Determine if two function handles are handles to the same function.

Comparing Function Handles

This section describes how MATLAB determines whether or not separate function handles are equal to each other:

Handles Constructed from a Named Function

Function handles that you construct from the same named function, e.g., `handle = @sin`, are considered by MATLAB to be equal. The `isequal` function returns a value of `true` when comparing these types of handles:

```
func1 = @sin;
func2 = @sin;
isequal(func1, func2)
 ans =
     1
```

If you save these handles to a MAT-file and then load them back into the workspace later on, they are still equal:

```
save temp1 func1
save temp2 func2
clear

load temp1
load temp2
isequal(func1, func2)
ans =
     1
```

Handles to Anonymous Functions

Unlike handles to named functions, any two function handles that represent the same anonymous function (i.e., handles to anonymous functions that contain the same text) are not equal. This is because MATLAB cannot guarantee that the frozen values of non-argument variables are the same.

```
q = 1;
a1 = @(x)q * x.^2;

q = 2;
a2 = @(x)q * x.^2;

isequal(a1, a2)
ans =
     0
```

This `false` result is accurate because `a1` and `a2` do indeed behave differently.

Note In general, MATLAB may underestimate the equality of function handles. That is, a test for equality may return `false` even when the functions happen to behave the same. But in cases where MATLAB does indicate equality, the functions are guaranteed to behave in an identical manner.

On the other hand, if you make a copy of an anonymous function handle, the copy and the original are equal:

```
h1 = @(x)sin(x);
h2 = h1;

isequal(h1, h2)
ans =
     1
```

In this case, function handles `h1` and `h2` are guaranteed to behave identically.

Handles to Nested Functions

Function handles to the same nested function are considered equal only if your code constructs these handles on the same call to the function containing the nested functions. Given this function that constructs two handles to the same nested function,

```
function [h1, h2] = test_eq(a, b, c)
h1 = @findZ;
h2 = @findZ;

   function z = findZ
   z = a.^3 + b.^2 + c';
   end
end
```

any two function handles constructed from the same nested function and on the same call to the parent function are equal:

```
[h1 h2] = test_eq(4, 19, -7);
```

```
isequal(h1, h2)
ans =
     1

[q1 q2] = test_eq(3, -1, 2);
isequal(q1, q2)
ans =
     1
```

The answer makes sense because `h1` and `h2` will always produce the same answer:

```
x = h1(),   y = h2()
x =
   418
y =
   418
```

However, handles constructed on different calls to the parent function are not equal:

```
isequal(h1, q1)
ans =
     0
```

In this case, `h1` and `q1` behave differently:

```
x = h1(),   y = q1()
x =
   418
y =
    30
```

Handles Saved to a MAT-File

If you save equivalent anonymous or nested function handles to separate MAT-files and then load them back into the MATLAB workspace, they are no longer equal. This is because saving the function handle in effect loses track of the original circumstances under which the function handle was created, and reloading it results in a function handle that compares as being unequal to the original function handle.

Create two equivalent anonymous function handles:

```
h1 = @(x) sin(x);
h2 = h1;

isequal(h1, h2)
ans =
     1
```

Save each to a different MAT-file:

```
save fname1 h1;
save fname2 h2;
```

Clear the MATLAB workspace and then load the function handles back into the workspace:

```
clear all
load fname1
load fname2
```

The function handles are no longer equal:

```
isequal(h1, h2)
ans =
     0
```

Note however that equal anonymous and nested function handles that you save to the same MAT-file are equal when loaded back into MATLAB:

```
h1 = @(x) sin(x);
h2 = h1;

isequal(h1, h2)
ans =
     1

save fname h1 h2;

clear all
load fname
```

```
isequal(h1, h2)
ans =
     1
```

Additional Information on Function Handles

This section covers the following topics:

Maximum Length of a Function Name

Function names used in handles are unique up to `N` characters, where `N` is the number returned by the function `namelengthmax`. If the function name exceeds that length, MATLAB truncates the latter part of the name.

For function handles created for Java constructors, the length of any segment of the package name or class name must not exceed `namelengthmax` characters. (The term *segment* refers to any portion of the name that lies before, between, or after a dot. For example, `java.lang.String` has three segments). The overall length of the string specifying the package and class has no limit.

How MATLAB Constructs a Function Handle

At the time you create a function handle, MATLAB maps the handle to one or more implementations of the function specified in the constructor statement:

```
fhandle = @functionname
```

In selecting which function(s) to map to, MATLAB considers

- Scope — The function named must be on the MATLAB path at the time the handle is constructed.
- Precedence — MATLAB selects which function(s) to map to according to the function precedence rules described under "How MATLAB Determines Which Method to Call" on page 9-72.

- Overloading — If additional M-files on the path overload the function for any of the standard MATLAB data types, such as `double` or `char`, then MATLAB maps the handle to these M-files as well.

M-files that overload a function for classes outside of the standard MATLAB data types are not mapped to the function handle at the time it is constructed. Function handles do operate on these types of overloaded functions, but MATLAB determines which implementation to call at the time of evaluation in this case.

Saving and Loading Function Handles

You can save and load function handles in a MAT-file using the MATLAB `save` and `load` functions. If you load a function handle that you saved in an earlier MATLAB session, the following conditions could cause unexpected behavior:

- Any of the M-files that define the function have been moved, and thus no longer exist on the path stored in the handle.
- You load the function handle into an environment different from that in which it was saved. For example, the source for the function either doesn't exist or is located in a different directory than on the system on which the handle was saved.

In both of these cases, the function handle is now invalid because it no longer maps to any existing function code. Although the handle is invalid, MATLAB still performs the load successfully and without displaying a warning. Attempting to invoke the handle, however, results in an error.

Function Arguments

In this section...

Overview

When calling a function, the caller provides the function with any data it needs by passing the data in an argument list. Data that needs to be returned to the caller is passed back in a list of return values.

Semantically speaking, MATLAB always passes argument data by value. (Internally, MATLAB optimizes away any unnecessary copy operations.)

If you pass data to a function that then modifies this data, you will need to update your own copy of the data. You can do this by having the function return the updated value as an output argument.

Checking the Number of Input Arguments

The `nargin` and `nargout` functions enable you to determine how many input and output arguments a function is called with. You can then use conditional statements to perform different tasks depending on the number of arguments. For example,

```
function c = testarg1(a, b)
if (nargin == 1)
    c = a .^ 2;
elseif (nargin == 2)
    c = a + b;
end
```

Given a single input argument, this function squares the input value. Given two inputs, it adds them together.

Here is a more advanced example that finds the first token in a character string. A *token* is a set of characters delimited by white space or some other character. Given one input, the function assumes a default delimiter of white space; given two, it lets you specify another delimiter if desired. It also allows for two possible output argument lists:

```
function [token, remainder] = strtok(string, delimiters)
% Function requires at least one input argument
if nargin < 1
   error('Not enough input arguments.');
end
token = []; remainder = [];
len = length(string);
if len == 0
   return
end

% If one input, use white space delimiter
if (nargin == 1)
   delimiters = [9:13 32]; % White space characters
end
i = 1;

% Determine where nondelimiter characters begin
while (any(string(i) == delimiters))
   i = i + 1;
   if (i > len), return, end
end

% Find where token ends
start = i;
while (~any(string(i) == delimiters))
   i = i + 1;
   if (i > len), break, end
end
finish = i - 1;
token = string(start:finish);
```

```
% For two output arguments, count characters after
% first delimiter (remainder)
if (nargout == 2)
   remainder = string(finish+1:end);
end
```

The `strtok` function is a MATLAB M-file in the `strfun` directory.

Note The order in which output arguments appear in the function declaration line is important. The argument that the function returns in most cases appears first in the list. Additional, optional arguments are appended to the list.

Passing Variable Numbers of Arguments

The `varargin` and `varargout` functions let you pass any number of inputs or return any number of outputs to a function. This section describes how to use these functions and also covers

- "Unpacking varargin Contents" on page 4-35
- "Packing varargout Contents" on page 4-35
- "varargin and varargout in Argument Lists" on page 4-36

MATLAB packs all specified input arguments into a *cell array*, a special kind of MATLAB array that consists of cells instead of array elements. Each cell can hold any size or kind of data — one might hold a vector of numeric data, another in the same array might hold an array of string data, and so on. For output arguments, your function code must pack them into a cell array so that MATLAB can return the arguments to the caller.

Here is an example function that accepts any number of two-element vectors and draws a line to connect them:

```
function testvar(varargin)
for k = 1:length(varargin)
   x(k) = varargin{k}(1); % Cell array indexing
   y(k) = varargin{k}(2);
```

```
end
xmin = min(0,min(x));
ymin = min(0,min(y));
axis([xmin fix(max(x))+3 ymin fix(max(y))+3])
plot(x,y)
```

Coded this way, the `testvar` function works with various input lists; for example,

```
testvar([2 3],[1 5],[4 8],[6 5],[4 2],[2 3])
testvar([-1 0],[3 -5],[4 2],[1 1])
```

Unpacking varargin Contents

Because `varargin` contains all the input arguments in a cell array, it's necessary to use cell array indexing to extract the data. For example,

```
y(n) = varargin{n}(2);
```

Cell array indexing has two subscript components:

- The indices within curly braces `{}` specify which cell to get the contents of.
- The indices within parentheses `()` specify a particular element of that cell.

In the preceding code, the indexing expression `{i}` accesses the nth cell of `varargin`. The expression `(2)` represents the second element of the cell contents.

Packing varargout Contents

When allowing a variable number of output arguments, you must pack all of the output into the `varargout` cell array. Use `nargout` to determine how many output arguments the function is called with. For example, this code accepts a two-column input array, where the first column represents a set of `x` coordinates and the second represents `y` coordinates. It breaks the array into separate `[xi yi]` vectors that you can pass into the `testvar` function shown at the beginning of the section on "Passing Variable Numbers of Arguments" on page 4-34:

```
function [varargout] = testvar2(arrayin)
```

```
for k = 1:nargout
   varargout{k} = arrayin(k,:);   % Cell array assignment
end
```

The assignment statement inside the `for` loop uses cell array assignment syntax. The left side of the statement, the cell array, is indexed using curly braces to indicate that the data goes inside a cell. For complete information on cell array assignment, see "Cell Arrays" on page 2-93.

To call `testvar2`, type

```
a = [1 2; 3 4; 5 6; 7 8; 9 0];

[p1, p2, p3, p4, p5] = testvar2(a)
p1 =
     1     2
p2 =
     3     4
p3 =
     5     6
p4 =
     7     8
p5 =
     9     0
```

varargin and varargout in Argument Lists

`varargin` or `varargout` must appear last in the argument list, following any required input or output variables. That is, the function call must specify the required arguments first. For example, these function declaration lines show the correct placement of `varargin` and `varargout`:

```
function [out1,out2] = example1(a,b,varargin)
function [i,j,varargout] = example2(x1,y1,x2,y2,flag)
```

Parsing Inputs with inputParser

MATLAB provides a class called `inputParser` to handle the different types of arguments passed into an M-file function. Using `inputParser`, you create a schema that both represents and verifies the content of the entire list of

input arguments passed on a call to the function. When used in all of your code development, this schema offers a consistent and thorough means of managing and validating the input information.

This section covers the following topics

To illustrate how to use the inputParser class, the documentation in this section develops a new M-file program called `publish_ip`, (based on the MATLAB `publish` function). There are three calling syntaxes for this function:

```
publish_ip('script')
publish_ip('script', 'format')
publish_ip('script', options)
```

There is one required argument (`script`), one optional argument (`format`), and a number of optional arguments that are specified as parameter-value pairs (`options`).

Defining a Specification for Each Input Parameter

Most programs have a block of code toward the beginning that parses the values in the input argument list and checks these values against what is expected. The `inputParser` class provides the following methods with which you can specify what the inputs are and whether they are required, optional, or to be specified using the parameter-value syntax:

- `addRequired` — Add a required parameter to the schema
- `addOptional` — Add an optional parameter to the schema
- `addParamValue` — Add an optional parameter-value pair to the schema

Creating the inputParser Object. Call the class constructor for `inputParser` to create an instance of the class. This class instance, or object, gives you access to all of the methods and properties of the class.

Begin writing the example `publish_ip` M-file by entering the following two statements:

```
function x = publish_ip(script, varargin)
p = inputParser;   % Create an instance of the class.
```

After calling the constructor, use the `addRequired`, `addOptional`, and `addParamValue` methods to add arguments to the schema.

Note The constructor and all methods and properties of the `inputParser` class are case sensitive.

Adding Arguments to the Schema. Add any required arguments to the schema using the `addRequired` method. This method takes two inputs: the name of the required parameter, and an optional handle to a function that validates the parameter:

```
addRequired(name, validator);
```

Put an `addRequired` statement at the end of your `publish_ip` code. The two arguments for `addRequired` in this case are the filename input, `script`, and a handle to a function that will validate the filename, `ischar`. After adding the `addRequired` statement, your `publish_ip` function should now look like this:

```
function x = publish_ip(script, varargin)
p = inputParser;   % Create an instance of the class.

p.addRequired('script', @ischar);
```

Use the `addOptional` method to add any arguments that are not required. The syntax for `addOptional` is similar to that of `addRequired` except that you also need to specify a default value to be used whenever the optional argument is not passed:

```
addOptional(name, default, validator);
```

In this case, the `validator` input is a handle to an anonymous function:

```
p.addOptional('format', 'html', ...
    @(x)any(strcmpi(x,{'html','ppt','xml','latex'})));
```

Use `addParamValue` to specify any arguments that use a parameter-value format. The syntax is

```
addParamValue(name, default, validator);
```

For example,

```
p.addParamValue('outputDir', pwd, @ischar);
p.addParamValue('maxHeight', [], @(x)x>0 && mod(x,1)==0);
p.addParamValue('maxWidth', [], @(x)x>0 && mod(x,1)==0);
```

Listing the Arguments. At this point, the schema is complete. Here is the file `publish_ip.m`:

```
function x = publish_ip(script, varargin)
p = inputParser;   % Create an instance of the class.

p.addRequired('script', @ischar);

p.addOptional('format', 'html', ...
    @(x)any(strcmpi(x,{'html','ppt','xml','latex'})));p.

p.addParamValue('outputDir', pwd, @ischar);
p.addParamValue('maxHeight', [], @(x)x>0 && mod(x,1)==0);
p.addParamValue('maxWidth', [], @(x)x>0 && mod(x,1)==0);
```

When you call the program, MATLAB stores the name of each argument in the `Parameters` property of object `p`. Add the following two lines to your `publish_ip` M-file to display `p.Parameters`:

```
sprintf('%s\n  %s\n  %s\n  %s\n  %s\n  %s', ...
   'The input parameters for this program are:', ...
   p.Parameters{:})
```

Save the M-file, and then run it as shown here:

```
publish_ip('ipscript.m', 'ppt', 'outputDir', ...
    'C:/matlab/test', 'maxWidth', 500, 'maxHeight', 300);
```

The output is

```
The input parameters for this program are:
  format
  maxHeight
  maxWidth
  outputDir
  script
```

Parsing Parameter Values on the Function Call

Once you have constructed a schema that represents all possible inputs to the function, the next task is to write the code that parses and verifies these arguments whenever the function is called. The `parse` method of the `inputParser` class reads and validates the required `script` argument and any optional arguments that follow it in the argument list:

```
p.parse(script, varargin{:});
```

Execution of the parse method validates each argument and also builds a structure from the input arguments. The name of the structure is `Results`, which is accessible as a property of the object. To get the value of all arguments, type

```
p.Results
```

To get the value of any single input argument, type

```
p.Results.argname
```

where `argname` is the name of the argument. Continue with the `publish_ip` exercise started earlier in this section by removing the `sprintf` statement that was inserted in the last section, and then adding the following lines:

```
% Parse and validate all input arguments.
p.parse(script, varargin{:});

% Display the value of a specific argument.
disp(' ')
disp(sprintf('\nThe maximum height is %d.', ...
     p.Results.maxHeight))

% Display all arguments.
disp(' ')
disp 'List of all arguments:'
disp(p.Results)
```

Now save and execute the M-file, passing the required script argument, the optional format argument, as well as several parameter-value arguments. MATLAB assigns those values you pass in the argument list to the appropriate fields of the `Results` structure:

```
publish_ip('ipscript.m', 'ppt', 'outputDir', ...
    'C:/matlab/test', 'maxWidth', 500, 'maxHeight', 300);

The maximum height is 300.

List of all arguments:
              format: 'ppt'
           maxHeight: 300
            maxWidth: 500
           outputDir: 'C:/matlab/test'
              script: 'ipscript.m'
```

Packaging Arguments in a Structure

By setting the `StructExpand` property of the `inputParser` object to `true`, you can pass arguments to your function in the form of a structure instead of individually in the argument list. This property must be set prior to calling the `parse` method.

`StructExpand` defaults to the `true` state, so you don't have to make any changes to your test program to run this example.

Put all of the input arguments into a structure:

```
s.format = 'xml';
s.outputDir = 'C:/matlab/test';
s.maxWidth = 200;
s.maxHeight = 150;
```

Now call the function, passing the filename and input structure:

```
publish_ip('ipscript.m', s);

The maximum height is 150.

List of all arguments:
              format: 'xml'
           maxHeight: 150
            maxWidth: 200
           outputDir: 'C:/matlab/test'
              script: 'ipscript.m'
```

To disable struct expansion, include the following statement somewhere in your program code before the `p.parse` statement:

```
p.StructExpand = false;
```

Overriding the Input Structure. If you want to pass your argument list in a structure, as described in the previous section, but you also want to alter the value of one or more of these arguments without having to modify the structure, you can do so by passing both the structure and the modified argument:

```
publish_ip('ipscript.m', s, ...
           'outputDir', 'C:/matlab/R2007a/temp');

List of all arguments:
              format: 'xml'
           maxHeight: 150
            maxWidth: 200
           outputDir: 'C:/matlab/R2007a/temp'
              script: 'ipscript.m'
```

Arguments That Default

Any arguments that you do not include in a call to your function are given their default values by MATLAB. You defined these default values when you created your schema using the `addOptional` and `addParamValue` methods. The `UsingDefaults` property is actually a structure that contains the names of any arguments that were not passed in the function call, and thus were assigned default values.

Add the following to your M-file:

```
% Show which arguments were not specified in the call.
disp(' ')
disp 'List of arguments given default values:'
for k=1:numel(p.UsingDefaults)
   field = char(p.UsingDefaults(k));
   value = p.Results.(field);
   if isempty(value),   value = '[]';   end
   disp(sprintf('   ''%s''    defaults to %s', field, value))
end
```

Save the M-file and run it without specifying the `format`, `outputDir`, or `maxHeight` arguments:

```
publish_ip('ipscript.m', 'maxWidth', 500);

List of arguments given default values:
   'format'    defaults to html
   'outputDir'    defaults to D:\work_r14
   'maxHeight'    defaults to []
```

Validating the Input Arguments

When you call your function, MATLAB checks any arguments for which you have specified a validator function. If the validator finds an error, MATLAB displays an error message and aborts the function. In the `publish` function example, the `outputDir` argument validates the value passed in using `@ischar`.

Pass a number instead of a string for the `outputDir` argument:

```
publish_ip('ipscript.m', 'outputDir', 5);
??? Argument 'outputDir' failed validation ischar.

Error in ==> publish_ip at 14
p.parse(varargin{:});
```

Handling Unmatched Arguments. MATLAB throws an error if you call your function with any arguments that are not part of the `inputParser` schema. You can disable this error by setting the `KeepUnmatched` property to `true`. When `KeepUnmatched` is in the `true` state, MATLAB does not throw an error, but instead stores any arguments that are not in the schema in a cell array of strings accessible through the `Unmatched` property of the object. `KeepUnmatched` defaults to `false`.

At some point in your `publish_ip` M-file before executing the `parse` method, set the `KeepUnmatched` property to `true`, and following the `parse` statement, examine the `Unmatched` property:

```
p.KeepUnmatched = true;

% Parse and validate all input arguments.
p.parse(script, varargin{:});

disp(' ')
disp 'List of unmatched arguments:'
p.Unmatched
```

Save and run the function, passing two arguments that are not defined in the schema:

```
publish_ip('ipscript.m', s, ...
           'outputDir', 'C:/matlab/R2007a/temp', ...
           'colorSpace', 'CMYK', 'density', 200);

List of unmatched arguments:
    colorSpace: 'CMYK'
       density: 200
```

Enabling Case-Sensitive Matching. When you pass optional arguments in the function call, MATLAB compares these arguments with the names of parameter-value argument names in the schema. By default, MATLAB does not use case sensitivity in this comparison. So, an argument name entered into the schema (using `addParamValue`) as `maxHeight` will match an argument passed as `MAXHeight` in the function call. You can override the default and make these comparisons case sensitive by setting the `CaseSensitive` property of the object to `true`. MATLAB does not error on a case mismatch, however, unless the `KeepUnmatched` property is set to `false`: its default state.

At some point in your `publish_ip` M-file before executing the `parse` method, set `KeepUnmatched` to `false` and `CaseSensitive` to `true`, and then execute the `publish_ip` function using `MAXHeight` as the name of the argument for specifying maximum height:

```
p.KeepUnmatched = false;
p.CaseSensitive = true;

% Parse and validate all input arguments.
p.parse(script, varargin{:});
```

Save and run the function, using `MAXHeight` as the name of the argument for specifying maximum height:

```
publish_ip('ipscript.m', 'ppt', 'outputDir', ...
    'C:/matlab/test', 'maxWidth', 500, 'MAXHeight', 300);
??? Argument 'MAXHeight' did not match any valid parameter of
the parser.

Error in ==> publish_ip at 17
```

Adding the Function Name to Error Messages. Use the `FunctionName` property to include the name of your function in error messages thrown by the validating function:

At some point in your `publish_ip` M-file before executing the `parse` method, set the `FunctionName` property to `PUBLISH_IP`, and then run the function:

```
p.FunctionName = 'PUBLISH_IP';

% Parse and validate all input arguments.
```

```
p.parse(script, varargin{:});
```

Save and run the function and observe text of the error message:

```
publish_ip('ipscript.m', 'ppt', 'outputDir', 5, ...
    'maxWidth', 500, 'maxHeight', 300);
??? Argument 'outputDir' failed validation ischar in PUBLISH_IP.
```

Making a Copy of the Schema

The `createCopy` method enables you to make a copy of an existing schema. Because the `inputParser` class uses handle semantics, you cannot make a copy of the object using an assignment statement.

The following statement creates an `inputParser` object `s` that is a copy of `p`:

```
s = p.createCopy
```

Summary of inputParser Methods

Method	Description
`addOptional`	Add an optional argument to the schema
`addParamValue`	Add a parameter-value pair argument to the schema
`addRequired`	Add a required argument to the schema
`createCopy`	Create a copy of the `inputParser` object
`parse`	Parse and validate the named inputs

Summary of inputParser Properties that Control Parsing

Property	Description
`CaseSensitivity`	Enable or disable case-sensitive matching of argument names. Defaults to `false`.

Property	Description
`FunctionName`	Function name to be included in error messages. Defaults to an empty string.
`KeepUnmatched`	Enable or disable errors on unmatched arguments. Defaults to `false`.
`StructExpand`	Enable or disable passing arguments in a structure. Defaults to `true`.

Summary of inputParser Properties that Provide Information

Property	Description
`Parameters`	Names of arguments defined in `inputParser` schema.
`Results`	Names and values of arguments passed in function call that are in the schema for this function.
`Unmatched`	Names and values of arguments passed in function call that are not in the schema for this function.
`UsingDefaults`	Names of arguments not passed in function call that are given default values.

Passing Optional Arguments to Nested Functions

You can use optional input and output arguments with nested functions, but you should be aware of how MATLAB interprets `varargin`, `varargout`, `nargin`, and `nargout` under those circumstances.

`varargin` and `varargout` are variables and, as such, they follow exactly the same scoping rules as any other MATLAB variable. Because nested functions share the workspaces of all outer functions, `varargin` and `varargout` used in a nested function can refer to optional arguments passed to or from the nested function, or passed to or from one of its outer functions.

nargin and nargout, on the other hand, are functions and when called within a nested function, always return the number of arguments passed to or from the nested function itself.

Using varargin and varargout

varargin or varargout used in a nested function can refer to optional arguments passed to or from that function, or to optional arguments passed to or from an outer function.

- If a nested function includes varargin or varargout in its function declaration line, then the use of varargin or varargout within that function returns optional arguments passed to or from that function.
- If varargin or varargout are not in the nested function declaration but are in the declaration of an outer function, then the use of varargin or varargout within the nested function returns optional arguments passed to the outer function.

In the example below, function C is nested within function B, and function B is nested within function A. The term varargin{1} in function B refers to the second input passed to the primary function A, while varargin{1} in function C refers to the first argument, z, passed from function B:

```
function x = A(y, varargin)   % Primary function A
B(nargin, y * rand(4))

   function B(argsIn, z)      % Nested function B
   if argsIn >= 2
      C(z, varargin{1}, 4.512, 1.729)
   end

      function C(varargin)    % Nested function C
      if nargin >= 2
         x = varargin{1}
      end
      end   % End nested function C
   end   % End nested function B
end   % End primary function A
```

Using nargin and nargout

When `nargin` or `nargout` appears in a nested function, it refers to the number of inputs or outputs passed to that particular function, regardless of whether or not it is nested.

In the example shown above, `nargin` in function `A` is the number of inputs passed to `A`, and `nargin` in function `C` is the number of inputs passed to `C`. If a nested function needs the value of `nargin` or `nargout` from an outer function, you can pass this value in as a separate argument, as done in function `B`.

Example of Passing Optional Arguments to Nested Functions

This example references the primary function's `varargin` cell array from each of two nested functions. (Because the workspace of an outer function is shared with all functions nested within it, there is no need to pass `varargin` to the nested functions.)

Both nested functions make use of the `nargin` value that applies to the primary function. Calling `nargin` from the nested function would return the number of inputs passed to that nested function, and not those that had been passed to the primary. For this reason, the primary function must pass its `nargin` value to the nested functions.

```
function meters = convert2meters(miles, varargin)
% Converts MILES (plus optional FEET and INCHES input)
% values to METERS.

if nargin < 1 || nargin > 3
   error('1 to 3 input arguments are required');
end

   function feet = convert2Feet(argsIn)
   % Nested function that converts miles to feet and adds in
   % optional FEET argument.

   feet = miles .* 5280;

   if argsIn >= 2
      feet = feet + varargin{1};
   end
```

```
    end  % End nested function convert2Feet

    function inches = convert2Inches(argsIn)
    % Nested function that converts feet to inches and adds in
    % optional INCHES argument.

    inches = feet .* 12;

    if argsIn == 3
       inches = inches + varargin{2};
    end
    end  % End nested function convert2Inches

feet = convert2Feet(nargin);
inches = convert2Inches(nargin);

meters = inches .* 2.54 ./ 100;
end  % End primary function convert2meters

convert2meters(5)
ans =
  8.0467e+003

convert2meters(5, 2000, 4.7)
ans =
  8.6564e+003
```

Returning Modified Input Arguments

If you pass any input variables that the function can modify, you will need to include the same variables as output arguments so that the caller receives the updated value.

For example, if the function `readText`, shown below, reads one line of a file each time is it called, then it must keep track of the offset into the file. But when `readText` terminates, its copy of the `offset` variable is cleared from memory. To keep the offset value from being lost, `readText` must return this value to the caller:

```
function [text, offset] = readText(filestart, offset)
```

Calling Functions

In this section...

What Happens When You Call a Function

When you call a function M-file from either the command line or from within another M-file, MATLAB parses the function into pseudocode and stores it in memory. This prevents MATLAB from having to reparse a function each time you call it during a session. The pseudocode remains in memory until you clear it using the `clear` function, or until you quit MATLAB.

Clearing Functions from Memory

You can use `clear` in any of the following ways to remove functions from the MATLAB workspace.

Syntax	Description
`clear functionname`	Remove specified function from workspace.
`clear functions`	Remove all compiled M-functions.
`clear all`	Remove all variables and functions.

Determining Which Function Is Called

When more than one function has the same name, which one does MATLAB call? This section explains the process that MATLAB uses to make this decision. It covers the following topics:

Also keep in mind that there are certain situations in which function names can conflict with *variables* of the same name. See "Potential Conflict with Function Names" on page 3-7for more information.

Function Scope

Any functions you call must first be within the scope of (i.e., visible to) the calling function or your MATLAB session. MATLAB determines if a function is in scope by searching for the function's executable file according to a certain order (see "Precedence Order" on page 4-53).

One key part of this search order is the MATLAB path. The path is an ordered list of directories that MATLAB defines on startup. You can add or remove any directories you want from the path. MATLAB searches the path for the given function name, starting at the first directory in the path string and continuing until either the function file is found or the list of directories is exhausted. If no function of that name is found, then the function is considered to be out of scope and MATLAB issues an error.

Precedence Order

The function precedence order determines the precedence of one function over another based on the type of function and its location on the MATLAB path. MATLAB selects the correct function for a given context by applying the following function precedence rules in the order given here.

For items 3 through 7 in this list, the file MATLAB searches for can be any of four types: an M- or built-in file, preparsed M-file (P-Code), compiled

C or Fortran file (MEX-file), or Simulink® model (MDL-file). See "Multiple Implementation Types" on page 4-55 for more on this.

1. Variable

   Before assuming that a name should match a function, MATLAB checks the current workspace to see if it matches a variable name. If MATLAB finds a match, it stops the search.

2. Subfunction

   Subfunctions take precedence over all other M-file functions and overloaded methods that are on the path and have the same name. Even if the function is called with an argument of type matching that of an overloaded method, MATLAB uses the subfunction and ignores the overloaded method.

3. Private function

   Private functions are called if there is no subfunction of the same name within the current scope. As with subfunctions, even if the function is called with an argument of type matching that of an overloaded method, MATLAB uses the private function and ignores the overloaded method.

4. Class constructor

   Constructor functions (functions having names that are the same as the @ directory, for example `@polynom/polynom.m`) take precedence over other MATLAB functions. Therefore, if you create an M-file called `polynom.m` and put it on your path before the constructor `@polynom/polynom.m` version, MATLAB will always call the constructor version.

5. Overloaded method

   MATLAB calls an overloaded method if it is not superseded by a subfunction or private function. Which overloaded method gets called depends on the classes of the objects passed in the argument list.

6. Function in the current directory

   A function in the current working directory is selected before one elsewhere on the path.

7 Function elsewhere on the path

   Finally, a function elsewhere on the path is selected. A function in a directory that is toward the beginning of the path string is given higher precedence.

Note Because variables have the highest precedence, if you have created a variable of the same name as a function, MATLAB will not be able to run that function until you clear the variable from memory.

Multiple Implementation Types

There are five file precedence types. MATLAB uses file precedence to select between identically named functions in the same directory. The order of precedence for file types is

1 Built-in file

2 MEX-files

3 MDL (Simulink® model) file

4 P-code file

5 M-file

For example, if MATLAB finds a P-code and an M-file version of a method in a class directory, then the P-code version is used. It is, therefore, important to regenerate the P-code version whenever you edit the M-file.

Querying Which Function MATLAB Will Call

You can determine which function MATLAB will call using the `which` command. For example,

```
which pie3
matlabroot/toolbox/matlab/specgraph/pie3.m
```

However, if `p` is a portfolio object,

```
which pie3(p)
dir_on_your_path/@portfolio/pie3.m      % portfolio method
```

The `which` command determines which version of `pie3` MATLAB will call if you passed a portfolio object as the input argument. To see a list of all versions of a particular function that are on your MATLAB path, use the `-all` option. See the `which` reference page for more information on this command.

MATLAB Calling Syntax

This section explains how to use the MATLAB command and function syntax:

You can call function M-files from either the MATLAB command line or from within other M-files. Be sure to include all necessary arguments, enclosing input arguments in parentheses and output arguments in square brackets.

Note Function names are sensitive to case. When you call a function, use the correct combination of upper and lowercase letters so that the name is an exact match. Otherwise, you risk calling a different function that does match but is elsewhere on the path.

You often have the choice of using one of two syntaxes for a function call. You can use either a command or a function type of syntax. This is referred to in MATLAB as *command/function duality*.

MATLAB Command Syntax

A function call made in command syntax consists of the function name followed by one or more arguments separated by spaces:

```
functionname in1 in2 ... inN
```

While the command syntax is simpler to write, it has the restriction that you may not assign any return values the function might generate. Attempting to do so generates an error.

Two examples of command syntax are

```
save mydata.mat x y z
clear length width depth
```

In the command syntax, MATLAB treats all arguments as string literals.

MATLAB Function Syntax

Function calls written in the function syntax look essentially the same as those in many other programming languages. One difference is that, in MATLAB, functions can return more than one output value.

A function call with a single return value looks like this:

```
out = functionname(in1, in2, ..., inN)
```

If the function returns more than one value, separate the output variables with commas or spaces, and enclose them all in square brackets (`[]`):

```
[out1, out2, ..., outN] = functionname(in1, in2, ..., inN)
```

Here are two examples:

```
copyfile(srcfile, '..\mytests', 'writable')
[x1, x2, x3, x4] = deal(A{:})
```

In the function syntax, MATLAB passes arguments to the function by value. See the examples under “Passing Arguments with Command and Function Syntax” on page 4-57.

Passing Arguments with Command and Function Syntax

When you call a function using function syntax, MATLAB passes the *values* assigned to each variable in the argument list. For example, this expression passes the values assigned to `A0`, `A1`, and `A2` to the `polyeig` function:

```
e = polyeig(A0, A1, A2)
```

Function calls written in command syntax pass all arguments as string literals. This expression passes the strings `'mydata.mat'`, `'x'`, `'y'`, and `'z'` to the `save` function:

```
save mydata.mat x y z
```

The following examples show the difference between passing arguments in the two syntaxes.

Passing Arguments — Example 1. Calling `disp` with the function syntax, `disp(A)`, passes the value of variable `A` to the `disp` function:

```
A = pi;

disp(A)                     % Function syntax
   3.1416
```

Calling it with the command syntax, `disp A`, passes the string `'A'`:

```
A = pi;

disp A                      % Command syntax
   A
```

Passing Arguments — Example 2. Passing two variables representing equal strings to the `strcmp` function using function and command syntaxes gives different results. The function syntax passes the values of the arguments. `strcmp` returns a `1`, which means they are equal:

```
str1 = 'one';       str2 = 'one';

strcmp(str1, str2)                  % Function syntax
ans =
   1        (equal)
```

The command syntax passes the names of the variables, `'str1'` and `'str2'`, which are unequal:

```
str1 = 'one';       str2 = 'one';
```

```
strcmp str1 str2                    % Command syntax
ans =
   0        (unequal)
```

How MATLAB Recognizes Function Calls That Use Command Syntax

It can be difficult to tell whether a MATLAB expression is a function call using command syntax or another kind of expression, such as an operation on one or more variables. Consider the following example:

```
ls ./d
```

Is this a call to the `ls` function with the directory `./d` as its argument? Or is it a request to perform elementwise division on the array that is the value of the `ls` variable, using the value of the `d` variable as the divisor?

This example might appear unambiguous because MATLAB can determine whether `ls` and `d` are functions or variables. But that is not always true. Some MATLAB components, such as M-Lint and the Editor/Debugger, must operate without reference to the MATLAB path or workspace. MATLAB therefore uses syntactic rules to determine when an expression is a function call using command syntax.

The rules are complicated and have exceptions. In general, when MATLAB recognizes an identifier (which might name a function or a variable), it analyzes the characters that follow the identifier to determine what kind of expression exists. The expression is usually a function call using command syntax when all of the following are true:

1. The identifier is followed immediately by white space.
2. The characters following the white space are not parentheses or an assignment operator.
3. The characters following the white space are not an operator that is itself followed by additional white space and then by characters that can legitimately follow an operator.

The example above meets all three criteria and is therefore a function call using command syntax:

```
ls ./d
```

The following examples are not function calls using command syntax:

```
% No white space following the ls identifier
% Interpretation: elementwise division
ls./d

% Parenthesis following white space
% Interpretation: function call using function syntax
ls ('./d')

% Assignment operator following white space
% Interpretation: assignment to a variable
ls =d

% Operator following white space, followed in turn by
% more white space and a variable
% Interpretation: elementwise division
ls ./ d
```

Passing Certain Argument Types

This section explains how to pass the following types of data in a function call:

- "Passing Strings" on page 4-60
- "Passing Filenames" on page 4-61
- "Passing Function Handles" on page 4-62

Passing Strings

When using the function syntax to pass a string literal to a function, you must enclose the string in single quotes, (`'string'`). For example, to create a new directory called `myapptests`, use

```
mkdir('myapptests')
```

On the other hand, variables that contain strings do not need to be enclosed in quotes:

```
dirname = 'myapptests';
mkdir(dirname)
```

Passing Filenames

You can specify a filename argument using the MATLAB command or function syntax. For example, either of the following are acceptable. (The `.mat` file extension is optional for `save` and `load`):

```
load mydata.mat           % Command syntax
load('mydata.mat')        % Function syntax
```

If you assign the output to a variable, you must use the function syntax:

```
savedData = load('mydata.mat')
```

Specify ASCII files as shown here. In this case, the file extension is required:

```
load mydata.dat -ascii            % Command syntax
load('mydata.dat','-ascii')       % Function syntax
```

Determining Filenames at Run-Time. There are several ways that your function code can work on specific files without your having to hardcode their filenames into the program. You can

- Pass the filename as an argument:

  ```
  function myfun(datafile)
  ```

- Prompt for the filename using the `input` function:

  ```
  filename = input('Enter name of file:  ', 's');
  ```

- Browse for the file using the `uigetfile` function:

  ```
  [filename, pathname] = uigetfile('*.mat', 'Select MAT-file');
  ```

Passing Function Handles

The MATLAB function handle has several uses, the most common being a means of immediate access to the function it represents. You can pass function handles in argument lists to other functions, enabling the receiving function to make calls by means of the handle.

To pass a function handle, include its variable name in the argument list of the call:

```
fhandle = @humps;
x = fminbnd(fhandle, 0.3, 1);
```

The receiving function invokes the function being passed using the usual MATLAB calling syntax:

```
function [xf, fval, exitflag, output] = ...
         fminbnd(fhandle, ax, bx, options, varargin)
            .
            .
            .
113  fx = fhandle(x, varargin{:});
```

Passing Arguments in Structures or Cell Arrays

Instead of requiring an additional argument for every value you want to pass in a function call, you can package them in a MATLAB structure or cell array.

Passing Arguments in a Structure

Make each input you want to pass a separate field in the structure argument, using descriptive names for the fields. Structures allow you to change the number, contents, or order of the arguments without having to modify the function. They can also be useful when you have a number of functions that need similar information.

This example updates weather statistics from information in the following chart.

City	Temp.	Heat Index	Wind Speed	Wind Chill
Boston	43	32	8	37
Chicago	34	27	3	30
Lincoln	25	17	11	16
Denver	15	-5	9	0
Las Vegas	31	22	4	35
San Francisco	52	47	18	42

The information is stored in structure `W`. The structure has one field for each column of data:

```
W = struct('city', {'Bos','Chi','Lin','Dnv','Vgs','SFr'}, ...
           'temp', {43, 34, 25, 15, 31, 52}, ...
           'heatix', {32, 27, 17, -5, 22, 47}, ...
           'wspeed', {8, 3, 11, 9, 4, 18}, ...
           'wchill', {37, 30, 16, 0, 35, 42});
```

To update the data base, you can pass the entire structure, or just one field with its associated data. In the call shown here, `W.wchill` is a comma-separated list:

```
updateStats(W.wchill);
```

Passing Arguments in a Cell Array

You can also group arguments into cell arrays. The advantage over structures is that cell arrays are referenced by index, allowing you to loop through a cell array and access each argument passed in or out of the function. The disadvantage is that you don't have field names to describe each variable.

This example passes several attribute-value arguments to the `plot` function:

```
X = -pi:pi/10:pi;
Y = tan(sin(X)) - sin(tan(X));

C{1,1} = 'LineWidth';         C{2,1} = 2;
C{1,2} = 'MarkerEdgeColor';   C{2,2} = 'k';
```

```
C{1,3} = 'MarkerFaceColor';   C{2,3} = 'g';

plot(X, Y, '--rs', C{:})
```

Assigning Output Arguments

Use the syntax shown here to store any values that are returned by the function you are calling. To store one output, put the variable that is to hold that output to the left of the equal sign:

```
vout = myfun(vin1, vin2, ...);
```

To store more than one output, list the output variables inside square brackets and separate them with commas or spaces:

```
[vout1 vout2 ...] = myfun(vin1, vin2, ...);
```

The number of output variables in your function call statement does not have to match the number of return values declared in the function being called. For a function that declares N return values, you can specify anywhere from zero to N output variables in the call statement. Any return values that you do not have an output variable for are discarded.

Functions return output values in the order in which the corresponding output variables appear in the function definition line within the M-file. This function returns 100 first, then `x * y`, and lastly `x.^2`:

```
function [a b c] = myfun(x, y)
b = x * y;    a = 100;    c = x.^2;
```

If called with only one output variable in the call statement, the function returns only 100 and discards the values of `b` and `c`. If called with no outputs, the functions returns 100 in the MATLAB default variable `ans`.

Assigning Optional Return Values

The section "Passing Variable Numbers of Arguments" on page 4-34 describes the method of returning optional outputs in a cell array called `varargout`. A function that uses `varargout` to return optional values has a function definition line that looks like one of the following:

```
function varargout = myfun(vin1, vin2, ...)
```

```
function [vout1 vout2 ... varargout] = myfun(vin1, vin2, ...)
```

The code within the function builds the `varargout` cell array. The content and order of elements in the cell array determines how MATLAB assigns optional return values to output variables in the function call.

In the case where `varargout` is the only variable shown to the left of the equal sign in the function definition line, MATLAB assigns `varargout{1}` to the first output variable, `varargout{2}` to the second, and so on. If there are other outputs declared in the function definition line, then MATLAB assigns those outputs to the leftmost output variables in the call statement, and then assigns outputs taken from the `varargout` array to the remaining output variables in the order just described.

This function builds the `varargout` array using descending rows of a 5-by-5 matrix. The function is capable of returning up to six outputs:

```
function varargout = byRow(a)
varargout{1} = '    With VARARGOUT constructed by row ...';
for k = 1:5
    row = 5 - (k-1);              % Reverse row order
    varargout{k+1} = a(row,:);
end
```

Call the function, assigning outputs to four variables. MATLAB returns `varargout{1:4}`, with rows of the matrix in `varargout{2:4}` and in the order in which they were stored by the function:

```
[text r1 r2 r3] = byRow(magic(5))
text =
    With VARARGOUT constructed by row ...
r1 =
    11    18    25     2     9
r2 =
    10    12    19    21     3
r3 =
     4     6    13    20    22
```

A similar function builds the `varargout` array using diagonals of a 5-by-5 matrix:

```
function varargout = byDiag(a)
varargout{1} = '    With VARARGOUT constructed by diagonal ...';
for k = -4:4
    varargout{k + 6} = diag(a, k);
end
```

Call the function with five output variables. Again, MATLAB assigns elements of `varargout` according to the manner in which it was constructed within the function:

```
[text d1 d2 d3 d4] = byDiag(magic(5))
text =
    With VARARGOUT constructed by diagonal ...
d1 =
    11
d2 =
    10
    18
d3 =
     4
    12
    25
d4 =
    23
     6
    19
     2
```

Calling External Functions

The MATLAB external interface offers a number of ways to run external functions from MATLAB. This includes programs written in C or Fortran, methods invoked on Java or COM (Component Object Model) objects, functions that interface with serial port hardware, and functions stored in shared libraries. The *MATLAB External Interfaces* documentation describes these various interfaces and how to call these external functions.

Running External Programs

For information on how to invoke operating systems commands or execute programs that are external to MATLAB, see Running External Programs in the MATLAB Desktop Tools and Development documentation.

5

Types of Functions

Overview of MATLAB Function Types

There are essentially two ways to create a new function in MATLAB: in a command entered at run-time, or in a file saved to permanent storage.

The command-oriented function, called an *anonymous function*, is relatively brief in its content. It consists of a single MATLAB statement that can interact with multiple input and output arguments. The benefit of using anonymous functions is that you do not have to edit and maintain a file for functions that require only a brief definition.

There are several types of functions that are stored in files (called M-files). The most basic of these are *primary functions* and *subfunctions*. Primary functions are visible to other functions outside of their M-file, while subfunctions, generally speaking, are not. That is, you can call a primary function from an anonymous function or from a function defined in a separate M-file, whereas you can call a subfunction only from functions within the same M-file. (See the Description section of the `function_handle` reference page for information on making a subfunction externally visible.)

Two specific types of primary M-file functions are the *private* and *overloaded function*. Private functions are visible only to a limited group of other functions. This type of function can be useful if you want to limit access to a function, or when you choose not to expose the implementation of a function. Overloaded functions act the same way as overloaded functions in most computer languages. You can create multiple implementations of a function so that each responds accordingly to different types of inputs.

The last type of MATLAB function is the *nested function*. Nested functions are not an independent function type; they exist within the body of one of the other types of functions discussed here (with the exception of anonymous functions), and also within other nested functions.

One type of function that is not discussed in this chapter is the MATLAB built-in function. Built-ins are defined only as executables internal to MATLAB. See “Built-In Functions” on page 3-109 for more information.

Anonymous Functions

In this section...

Constructing an Anonymous Function

Anonymous functions give you a quick means of creating simple functions without having to create M-files each time. You can construct an anonymous function either at the MATLAB command line or in any M-file function or script.

The syntax for creating an anonymous function from an expression is

```
fhandle = @(arglist) expr
```

Starting from the right of this syntax statement, the term `expr` represents the body of the function: the code that performs the main task your function is to accomplish. This consists of any single, valid MATLAB expression. Next is `arglist`, which is a comma-separated list of input arguments to be passed to the function. These two components are similar to the body and argument list components of any function.

Leading off the entire right side of this statement is an `@` sign. The `@` sign is the MATLAB operator that constructs a function handle. Creating a function handle for an anonymous function gives you a means of invoking the function. It is also useful when you want to pass your anonymous function in a call to some other function. The `@` sign is a required part of an anonymous function definition.

Note Function handles not only provide access to anonymous functions. You can create a function handle to any MATLAB function. The constructor uses a different syntax: `fhandle = @functionname` (e.g., `fhandle = @sin`). To find out more about function handles, see "Function Handles" on page 4-22.

The syntax statement shown above constructs the anonymous function, returns a handle to this function, and stores the value of the handle in variable `fhandle`. You can use this function handle in the same way as any other MATLAB function handle.

Simple Example

The statement below creates an anonymous function that finds the square of a number. When you call this function, MATLAB assigns the value you pass in to variable `x`, and then uses `x` in the equation `x.^2`:

```
sqr = @(x) x.^2;
```

The `@` operator constructs a function handle for this function, and assigns the handle to the output variable `sqr`. As with any function handle, you execute the function associated with it by specifying the variable that contains the handle, followed by a comma-separated argument list in parentheses. The syntax is

```
fhandle(arg1, arg2, ..., argN)
```

To execute the `sqr` function defined above, type

```
a = sqr(5)
a =
   25
```

Because `sqr` is a function handle, you can pass it in an argument list to other functions. The code shown here passes the `sqr` anonymous function to the MATLAB `quad` function to compute its integral from zero to one:

```
quad(sqr, 0, 1)
ans =
   0.3333
```

A Two-Input Example

As another example, you could create the following anonymous function that uses two input arguments, `x` and `y`. (The example assumes that variables `A` and `B` are already defined):

```
sumAxBy = @(x, y) (A*x + B*y);

whos sumAxBy
Name        Size                    Bytes  Class

sumAxBy     1x1                        16  function_handle
```

To call this function, assigning `5` to `x` and `7` to `y`, type

```
sumAxBy(5, 7)
```

Evaluating With No Input Arguments

For anonymous functions that do not take any input arguments, construct the function using empty parentheses for the input argument list:

```
t = @() datestr(now);
```

Also use empty parentheses when invoking the function:

```
t()

ans =
04-Sep-2003 10:17:59
```

You must include the parentheses. If you type the function handle name with no parentheses, MATLAB just identifies the handle; it does not execute the related function:

```
t

t =
    @() datestr(now)
```

Arrays of Anonymous Functions

To store multiple anonymous functions in an array, use a cell array. The example shown here stores three simple anonymous functions in cell array A:

```
A = {@(x)x.^2, @(y)y+10, @(x,y)x.^2+y+10}
A =
    [@(x)x.^2]    [@(y)y+10]    [@(x,y)x.^2+y+10]
```

Execute the first two functions in the cell array by referring to them with the usual cell array syntax, A{1} and A{2}:

```
A{1}(4) + A{2}(7)
ans =
    33
```

Do the same with the third anonymous function that takes two input arguments:

```
A{3}(4, 7)
ans =
    33
```

Space Characters in Anonymous Function Elements

Note that while using space characters in the definition of any function can make your code easier to read, spaces in the body of an anonymous function that is defined in a cell array can sometimes be ambiguous to MATLAB. To ensure accurate interpretation of anonymous functions in cell arrays, you can do any of the following:

- Remove all spaces from at least the body (not necessarily the argument list) of each anonymous function:

  ```
  A = {@(x)x.^2, @(y)y+10, @(x, y)x.^2+y+10};
  ```

- Enclose in parentheses any anonymous functions that include spaces:

  ```
  A = {(@(x)x .^ 2), (@(y) y +10), (@(x, y) x.^2 + y+10)};
  ```

- Assign each anonymous function to a variable, and use these variable names in creating the cell array:

```
A1 = @(x)x .^ 2;  A2 = @(y) y +10;  A3 = @(x, y)x.^2 + y+10;
A = {A1, A2, A3};
```

Outputs from Anonymous Functions

As with other MATLAB functions, the number of outputs returned by an anonymous function depends mainly on how many variables you specify to the left of the equals (=) sign when you call the function.

For example, consider an anonymous function `getPersInfo` that returns a person's address, home phone, business phone, and date of birth, in that order. To get someone's address, you can call the function specifying just one output:

```
address = getPersInfo(name);
```

To get more information, specify more outputs:

```
[address, homePhone, busPhone] = getPersInfo(name);
```

Of course, you cannot specify more outputs than the maximum number generated by the function, which is four in this case.

Example

The anonymous `getXLSData` function shown here calls the MATLAB `xlsread` function with a preset spreadsheet filename (`records.xls`) and a variable worksheet name (`worksheet`):

```
getXLSData = @(worksheet) xlsread('records.xls', worksheet);
```

The `records.xls` worksheet used in this example contains both numeric and text data. The numeric data is taken from instrument readings, and the text data describes the category that each numeric reading belongs to.

Because the MATLAB `xlsread` function is defined to return up to three values (numeric, text, and raw data), `getXLSData` can also return this same number of values, depending on how many output variables you specify to the left of the equals sign in the call. Call `getXLSData` a first time, specifying only a single (numeric) output, `dNum`:

```
dNum = getXLSData('Week 12');
```

Display the data that is returned using a `for` loop. You have to use generic names (`v1`, `v2`, `v3`) for the categories, due to the fact that the text of the real category names was not returned in the call:

```
for k = 1:length(dNum)
   disp(sprintf('%s    v1: %2.2f    v2: %d    v3: %d', ...
      datestr(clock, 'HH:MM'), dNum(k,1), dNum(k,2), ...
      dNum(k,3)));
   end
```

Here is the output from the first call:

```
12:55   v1: 78.42    v2: 32    v3: 37
13:41   v1: 69.73    v2: 27    v3: 30
14:26   v1: 77.65    v2: 17    v3: 16
15:10   v1: 68.19    v2: 22    v3: 35
```

Now try this again, but this time specifying two outputs, numeric (`dNum`) and text (`dTxt`):

```
[dNum, dTxt] = getXLSData('Week 12');

for k = 1:length(dNum)
   disp(sprintf('%s    %s: %2.2f    %s: %d    %s: %d', ...
      datestr(clock, 'HH:MM'), dTxt{1}, dNum(k,1), ...
      dTxt{2}, dNum(k,2), dTxt{3}, dNum(k,3)));
   end
```

This time, you can display the category names returned from the spreadsheet:

```
12:55    Temp: 78.42    HeatIndex: 32    WindChill: 37
13:41    Temp: 69.73    HeatIndex: 27    WindChill: 30
14:26    Temp: 77.65    HeatIndex: 17    WindChill: 16
15:10    Temp: 68.19    HeatIndex: 22    WindChill: 35
```

Variables Used in the Expression

Anonymous functions commonly include two types of variables:

- Variables specified in the argument list. These often vary with each function call.

- Variables specified in the body of the expression. MATLAB captures these variables and holds them constant throughout the lifetime of the function handle.

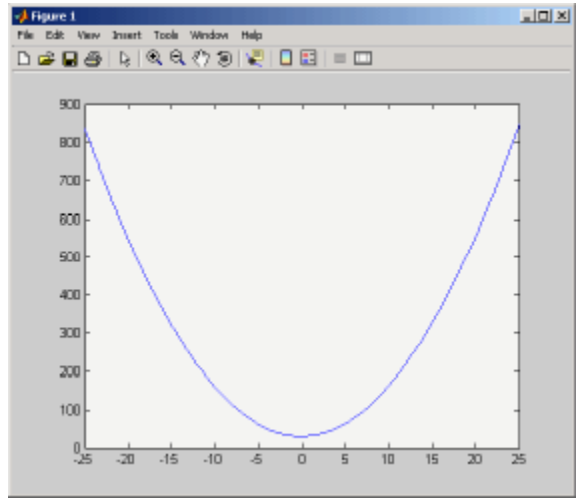
The latter variables must have a value assigned to them at the time you construct an anonymous function that uses them. Upon construction, MATLAB captures the current value for each variable specified in the body of that function. The function will continue to associate this value with the variable even if the value should change in the workspace or go out of scope.

The fact that MATLAB captures the values of these variables when the handle to the anonymous function is constructed enables you to execute an anonymous function from anywhere in the MATLAB environment, even outside the scope in which its variables were originally defined. But it also means that to supply new values for any variables specified within the expression, you must reconstruct the function handle.

Changing Variables Used in an Anonymous Function

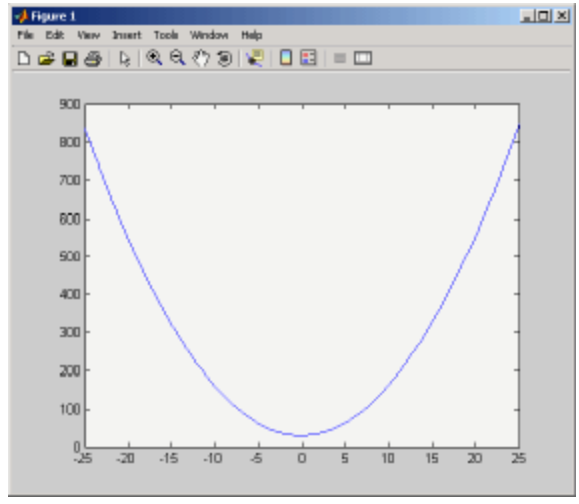
The second statement shown below constructs a function handle for an anonymous function called `parabola` that uses variables `a`, `b`, and `c` in the expression. Passing the function handle to the MATLAB `fplot` function plots it out using the initial values for these variables:

```
a = 1.3;   b = .2;   c = 30;
parabola = @(x) a*x.^2 + b*x + c;
fplot(parabola, [-25 25])
```



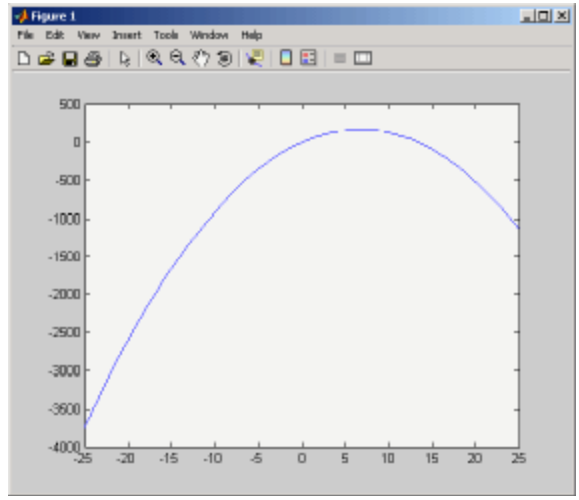
If you change the three variables in the workspace and replot the figure, the parabola remains unchanged because the `parabola` function is still using the initial values of `a`, `b`, and `c`:

```
a = -3.9;   b = 52;   c = 0;
fplot(parabola, [-25 25])
```



To get the function to use the new values, you need to reconstruct the function handle, causing MATLAB to capture the updated variables. Replot using the new construct, and this time the parabola takes on the new values:

```
a = -3.9;   b = 52;   c = 0;
parabola = @(x) a*x.^2 + b*x + c;
fplot(parabola, [-25 25])
```



For the purposes of this example, there is no need to store the handle to the anonymous function in a variable (`parabola`, in this case). You can just construct and pass the handle right within the call to `fplot`. In this way, you update the values of `a`, `b`, and `c` on each call:

```
fplot(@(x) a*x.^2 + b*x + c, [-25 25])
```

Examples of Anonymous Functions

This section shows a few examples of how you can use anonymous functions. These examples are intended to show you how to program with this type of function. For more mathematically oriented examples, see the MATLAB Mathematics documentation.

The examples in this section include

Example 1 — Passing a Function to quad

The equation shown here has one variable `t` that can vary each time you call the function, and two additional variables, `g` and `omega`. Leaving these two variables flexible allows you to avoid having to hardcode values for them in the function definition:

```
x = g * cos(omega * t)
```

One way to program this equation is to write an M-file function, and then create a function handle for it so that you can pass the function to other functions, such as the MATLAB `quad` function as shown here. However, this requires creating and maintaining a new M-file for a purpose that is likely to be temporary, using a more complex calling syntax when calling `quad`, and passing the `g` and `omega` parameters on every call. Here is the function M-file:

```
function f = vOut(t, g, omega)
f = g * cos(omega * t);
```

This code has to specify `g` and `omega` on each call:

```
g = 2.5;  omega = 10;

quad(@vOut, 0, 7, [], [], g, omega)
ans =
   0.1935

quad(@vOut, -5, 5, [], [], g, omega)
ans =
   -0.1312
```

You can simplify this procedure by setting the values for `g` and `omega` just once at the start, constructing a function handle to an anonymous function that only lasts the duration of your MATLAB session, and using a simpler syntax when calling `quad`:

```
g = 2.5;  omega = 10;
```

```
quad(@(t) (g * cos(omega * t)), 0, 7)
ans =
   0.1935

quad(@(t) (g * cos(omega * t)), -5, 5)
ans =
   -0.1312
```

To preserve an anonymous function from one MATLAB session to the next, `save` the function handle to a MAT-file

```
save anon.mat f
```

and then `load` it into the MATLAB workspace in a later session:

```
load anon.mat f
```

Example 2 — Multiple Anonymous Functions

This example solves the following equation by combining two anonymous functions:

$$g(c) = \int_0^1 (x^2 + cx + 1)dx$$

The equivalent anonymous function for this expression is

```
g = @(c) (quad(@(x) (x.^2 + c*x + 1), 0, 1));
```

This was derived as follows. Take the parenthesized part of the equation (the integrand) and write it as an anonymous function. You don't need to assign the output to a variable as it will only be passed as input to the `quad` function:

```
@(x) (x.^2 + c*x + 1)
```

Next, evaluate this function from zero to one by passing the function handle, shown here as the entire anonymous function, to `quad`:

```
quad(@(x) (x.^2 + c*x + 1), 0, 1)
```

Supply the value for c by constructing an anonymous function for the entire equation and you are done:

```
g = @(c) (quad(@(x) (x.^2 + c*x + 1), 0, 1));

g(2)
ans =
   2.3333
```

Primary M-File Functions

The first function in any M-file is called the *primary function*. Following the primary function can be any number of subfunctions, which can serve as subroutines to the primary function.

Under most circumstances, the primary function is the only function in an M-file that you can call from the MATLAB command line or from another M-file function. You invoke this function using the name of the M-file in which it is defined.

For example, the `average` function shown here resides in the file `average.m`:

```
function y = average(x)
% AVERAGE Mean of vector elements.

y = sum(x)/length(x);      % Actual computation
```

You can invoke this function from the MATLAB command line with this command to find the average of three numbers:

```
average([12 60 42])
```

Note that it is customary to give the primary function the same name as the M-file in which it resides. If the function name differs from the filename, then you must use the filename to invoke the function.

Nested Functions

In this section...

Writing Nested Functions

You can define one or more functions within another function in MATLAB. These inner functions are said to be *nested* within the function that contains them. You can also nest functions within other nested functions.

To write a nested function, simply define one function within the body of another function in an M-file. Like any M-file function, a nested function contains any or all of the components described in “Basic Parts of an M-File” on page 4-8. In addition, you must always terminate a nested function with an `end` statement:

```
function x = A(p1, p2)
...
   function y = B(p3)
   ...
   end
...
end
```

Note M-file functions don’t normally require a terminating `end` statement. This rule does not hold, however, when you nest functions. If an M-file contains one or more nested functions, you must terminate *all* functions (including subfunctions) in the M-file with `end`, whether or not they contain nested functions.

Example — More Than One Nested Function

This example shows function `A` and two additional functions nested inside `A` at the same level:

```
function x = A(p1, p2)
...
   function y = B(p3)
   ...
   end

   function z = C(p4)
   ...
   end
...
end
```

Example — Multiply Nested Functions

This example shows multiply nested functions, `C` nested inside `B`, and `B` in `A`:

```
function x = A(p1, p2)
...
   function y = B(p3)
   ...
      function z = C(p4)
      ...
      end
   ...
   end
...
end
```

Calling Nested Functions

You can call a nested function

- From the level immediately above it. (In the following code, function A can call B or D, but not C or E.)
- From a function nested at the same level within the same parent function. (Function B can call D, and D can call B.)

- From a function at any lower level. (Function C can call B or D, but not E.)

```
function A(x, y)              % Primary function
B(x, y);
D(y);

   function B(x, y)           % Nested in A
   C(x);
   D(y);

      function C(x)           % Nested in B
      D(x);
      end
   end

   function D(x)              % Nested in A
   E(x);

      function E(x)           % Nested in D
      ...
      end
   end
end
```

You can also call a subfunction from any nested function in the same M-file.

You can pass variable numbers of arguments to and from nested functions, but you should be aware of how MATLAB interprets `varargin`, `varargout`, `nargin`, and `nargout` under those circumstances. See "Passing Optional Arguments to Nested Functions" in the MATLAB Programming documentation for more information on this.

Note If you construct a function handle for a nested function, you can call the nested function from any MATLAB function that has access to the handle. See “Using Function Handles with Nested Functions” on page 5-21.

Variable Scope in Nested Functions

The scope of a variable is the range of functions that have direct access to the variable to set, modify, or acquire its value. When you define a local (i.e., nonglobal) variable within a function, its scope is normally restricted to that function alone. For example, subfunctions do not share variables with the primary function or with other subfunctions. This is because each function and subfunction stores its variables in its own separate workspace.

Like other functions, a nested function has its own workspace. But it also has access to the workspaces of all functions in which it is nested. So, for example, a variable that has a value assigned to it by the primary function can be read or overwritten by a function nested at any level within the primary. Similarly, a variable that is assigned in a nested function can be read or overwritten by any of the functions containing that function.

In the following two examples, variable `x` is stored in the workspace of the outer `varScope` function and can be read or written to by all functions nested within it.

```
function varScope1
x = 5;
nestfun1
   function nestfun1
      nestfun2

      function nestfun2
         x = x + 1
      end
   end
end
```

```
function varScope2
nestfun1
   function nestfun1
      nestfun2

      function nestfun2
         x = 5;
      end
   end
x = x + 1
end
```

As a rule, a variable used or defined within a nested function resides in the workspace of the outermost function that both contains the nested function and accesses that variable. The scope of this variable is then the function to which this workspace belongs, and all functions nested to any level within that function.

In the next example, the outer function, `varScope3`, does not access variable `x`. Following the rule just stated, `x` is unknown to the outer function and thus is

not shared between the two nested functions. In fact, there are two separate x variables in this example: one in the function workspace of nestfun1 and one in the function workspace of nestfun2. When nestfun2 attempts to update x, it fails because x does not yet exist in this workspace:

```
function varScope3
nestfun1
nestfun2

   function nestfun1
      x = 5;
   end

   function nestfun2
      x = x + 1
   end
end
```

The Scope of Output Variables

Variables containing values returned by a nested function are not in the scope of outer functions. In the two examples shown here, the one on the left fails in the second to last line because, although the *value* of y is returned by the nested function, the *variable* y is local to the nested function, and unknown to the outer function. The example on the right assigns the return value to a variable, z, and then displays the value of z correctly.

Incorrect	Correct

`function varScope4`
`x = 5; nestfun;`
`  function y = nestfun`
`  y = x + 1;`
`  end`
 	
`y`
`end`
	`function varScope5`
	`x = 5;`
	`z = nestfun;`
	`  function y = nestfun`
	`  y = x + 1;`
	`  end`
	
	`z`
	`end`

Using Function Handles with Nested Functions

Every function has a certain *scope*, that is, a certain range of other functions to which it is visible. A function's scope determines which other functions can call it. You can call a function that is out of scope by providing an alternative means of access to it in the form of a function handle. (The function handle, however, must be within the scope of its related function when you construct the handle.) Any function that has access to a function handle can call the function with which the handle is associated.

Note Although you can call an out of scope function by means of a function handle, the handle itself must be within the scope of its related function at the time it is constructed.

The section on "Calling Nested Functions" on page 5-17 defines the scope of a nested function. As with other types of functions, you can make a nested function visible beyond its normal scope with a function handle. The following function `getCubeHandle` constructs a handle for nested function `findCube` and returns its handle, `h`, to the caller. The `@` sign placed before a function name (e.g., `@findCube`) is the MATLAB operator that constructs a handle for that function:

```
function h = getCubeHandle
h = @findCube;                    % Function handle constructor

   function cube = findCube(X)    % Nested function
      cube = X .^ 3;
   end
end
```

Call `getCubeHandle` to obtain the function handle to the nested function `findCube`. Assign the function handle value returned by `getCubeHandle` to an output variable, `cubeIt` in this case:

```
cubeIt = getCubeHandle;
```

You can now use this variable as a means of calling `findCube` from outside of its M-file:

```
cubeIt(8)
ans =
    512
```

Note When calling a function by means of its handle, use the same syntax as if you were calling a function directly. But instead of calling the function by its name (e.g., `strcmp(S1, S2)`), use the variable that holds the function handle (e.g., `fhandle(S1, S2)`).

Function Handles and Nested Function Variables

One characteristic of nested functions that makes them different from other MATLAB functions is that they can share nonglobal variables with certain other functions within the same M-file. A nested function `nFun` can share variables with any outer function that contains `nFun`, and with any function nested within `nFun`. This characteristic has an impact on how certain variables are stored when you construct a handle for a nested function.

Defining Variables When Calling Via Function Handle. The example below shows a primary function `getHandle` that returns a function handle for the nested function `nestFun`. The `nestFun` function uses three different types of variables. The `VLoc` variable is local to the nested function, `VInp` is passed in when the nested function is called, and `VExt` is defined by the outer function:

```
function h = getHandle(X)
h = @nestFun;
VExt = someFun(X);

   function nestFun(VInp)
   VLoc = 173.5;
   doSomeTask(VInp, VLoc, VExt);
   end
end
```

As with any function, when you call `nestFun`, you must ensure that you supply the values for any variables it uses. This is a straightforward matter

when calling the nested function directly (that is, calling it from `getHandle`). `VLoc` has a value assigned to it within `nestFun`, `VInp` has its value passed in, and `VExt` acquires its value from the workspace it shares with `getHandle`.

However, when you call `nestFun` using a function handle, only the nested function executes; the outer function, `getHandle`, does not. It might seem at first that the variable `VExt`, otherwise given a value by `getHandle`, has no value assigned to it in the case. What in fact happens though is that MATLAB stores variables such as `VExt` inside the function handle itself when it is being constructed. These variables are available for as long as the handle exists.

The `VExt` variable in this example is considered to be *externally scoped* with respect to the nested function. Externally scoped variables that are used in nested functions for which a function handle exists are stored within the function handle. So, function handles not only contain information about accessing a function. For nested functions, a function handle also stores the values of any externally scoped variables required to execute the function.

Example Using Externally Scoped Variables

The `sCountFun` and `nCountFun` functions shown below return function handles for subfunction `subCount` and nested function `nestCount`, respectively.

These two inner functions store a persistent value in memory (the value is retained in memory between function calls), and then increment this value on every subsequent call. `subCount` makes its `count` value persistent with an explicit `persistent` declaration. In `nestCount`, the count variable is externally scoped and thus is maintained in the function handle:

Using a Subfunction	Using a Nested Function

`function h = sCountFun(X)`
`h = @subCount;`
`count = X`
`subCount(0, count);`
`function subCount(incr, ini)`
`persistent count;`
`initializing = nargin > 1;`
`if initializing`
`  count = ini; else`
`  count = count + incr`
`end`
	`function h = nCountFun(X)`
	`h = @nestCount;`
	`count = X`
	`  function nestCount(incr)`
	`  count = count + incr`
	`  end`
	`end`

When `sCountFun` executes, it passes the initial value for `count` to the `subCount` subfunction. Keep in mind that the `count` variable in `sCountFun` is not the same as the count variable in `subCount`; they are entirely independent of each other. Whenever `subCount` is called via its function handle, the value for `count` comes from its persistent place in memory.

In `nestCount`, the `count` variable again gets its value from the primary function when called from within the M-file. However, in this case the `count` variable in the primary and nested functions are one and the same. When `nestCount` is called by means of its function handle, the value for `count` is assigned from its storage within the function handle.

Running the Example. The `subCount` and `nestCount` functions increment a value in memory by another value that you pass as an input argument. Both of these functions give the same results.

Get the function handle to `nestCount`, and initialize the `count` value to a four-element vector:

```
h = nCountFun([100 200 300 400])
count =
   100   200   300   400
```

Increment the persistent vector by 25, and then by 42:

```
h(25)
```

```
count =
   125   225   325   425

h(42)
count =
   167   267   367   467
```

Now do the same using `sCountFun` and `subCount`, and verify that the results are the same.

Note If you construct a new function handle to `subCount` or `nestCount`, the former value for `count` is no longer retained in memory. It is replaced by the new value.

Separate Instances of Externally Scoped Variables

The code shown below constructs two separate function handles to the same nested function, `nestCount`, that was used in the last example. It assigns the handles to fields `counter1` and `counter2` of structure `s`. These handles reference different instances of the `nestCount` function. Each handle also maintains its own separate value for the externally scoped `count` variable.

Call `nCountFun` twice to get two separate function handles to `nestCount`. Initialize the two instances of `count` to two different vectors:

```
s.counter1 = nCountFun([100 200 300 400]);
count =
   100   200   300   400

s.counter2 = nCountFun([-100 -200 -300 -400]);
count =
  -100  -200  -300  -400
```

Now call `nestCount` by means of each function handle to demonstrate that MATLAB increments the two `count` variables individually.

Increment the first counter:

```
s.counter1(25)
```

```
count =
   125   225   325   425
s.counter1(25)
count =
   150   250   350   450
```

Now increment the second counter:

```
s.counter2(25)
count =
   -75  -175  -275  -375
s.counter2(25)
count =
   -50  -150  -250  -350
```

Go back to the first counter and you can see that it keeps its own value for `count`:

```
s.counter1(25)
count =
   175   275   375   475
```

Restrictions on Assigning to Variables

The scoping rules for nested, and in some cases anonymous, functions require that all variables used within the function be present in the text of the M-file code. Adding variables to the workspace of this type of function at run time is not allowed.

MATLAB issues an error if you attempt to dynamically add a variable to the workspace of an anonymous function, a nested function, or a function that contains a nested function. Examples of operations that might use dynamic assignment in this way are shown in the table below.

Type of Operation	How to Avoid Using Dynamic Assignment
Evaluating an expression using `eval` or `evalin`, or assigning a variable with `assignin`	As a general suggestion, it is best to avoid using the `eval`, `evalin`, and `assignin` functions altogether.
Loading variables from a MAT-file with the `load` function	Use the form of `load` that returns a MATLAB structure.
Assigning to a variable in a MATLAB script	Convert the script to a function, where argument- and result-passing can often clarify the code as well.
Assigning to a variable in the MATLAB debugger	You can declare the variable to be `global`. For example, to create a variable X for temporary use in debugging, use `K>> global X;  X = value`

One way to avoid this error in the other cases is to pre-declare the variable in the desired function.

Examples of Nested Functions

This section shows a few examples of how you can use nested functions. These examples are intended to show you how to program with this type of function. For more mathematically oriented examples, see the MATLAB Mathematics documentation.

The examples in this section include

Example 1 — Creating a Function Handle for a Nested Function

The following example constructs a function handle for a nested function and then passes the handle to the MATLAB `fplot` function to plot the parabola

shape. The `makeParabola` function shown here constructs and returns a function handle `fhandle` for the nested `parabola` function. This handle gets passed to `fplot`:

```
function fhandle = makeParabola(a, b, c)
% MAKEPARABOLA returns a function handle with parabola
% coefficients.

fhandle = @parabola;     % @ is the function handle constructor

   function y = parabola(x)
   y = a*x.^2 + b*x + c;
   end
end
```

Assign the function handle returned from the call to a variable (`h`) and evaluate the function at points 0 and 25:

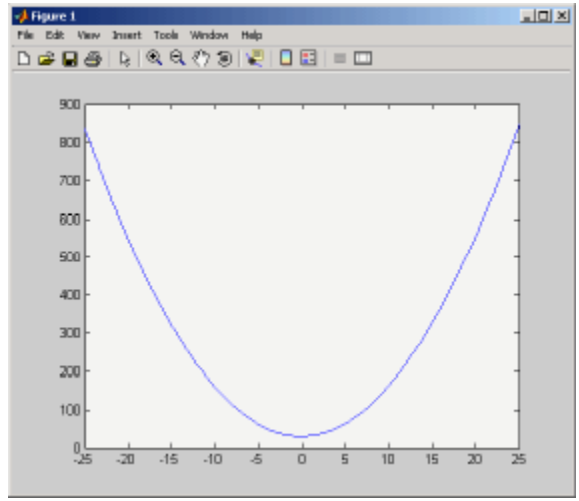
```
h = makeParabola(1.3, .2, 30)
h =
    @makeParabola/parabola

h(0)
ans =
    30

h(25)
ans =
  847.5000
```

Now pass the function handle `h` to the `fplot` function, evaluating the parabolic equation from `x = -25` to `x = +25`:

```
fplot(h, [-25 25])
```



Example 2 — Function-Generating Functions

The fact that a function handle separately maintains a unique instance of the function from which it is constructed means that you can generate multiple handles for a function, each operating independently from the others. The function in this example makes IIR filtering functions by constructing function handles from nested functions. Each of these handles maintains its own internal state independent of the others.

The function `makeFilter` takes IIR filter coefficient vectors `a` and `b` and returns a filtering function in the form of a function handle. Each time a new input value x_n is available, you can call the filtering function to get the new output value y_n. Each filtering function created by `makeFilter` keeps its own private `a` and `b` vectors, in addition to its own private state vector, in the form of a transposed direct form II delay line:

```
function [filtfcn, statefcn] = makeFilter(b, a)
%   FILTFCN = MAKEFILTER(B, A) creates an IIR filtering
%   function and returns it in the form of a function handle,
```

```
%   FILTFCN. Each time you call FILTFCN with a new filter
%   input value, it computes the corresponding new filter
%   output value, updating its internal state vector at the
%   same time.
%
%   [FILTFCN, STATEFCN] = MAKEFILTER(B, A) also returns a
%   function (in the form of a function handle, STATEFCN)
%   that can return the filter's internal state.  The internal
%   state vector is in the form of a transposed direct form
%   II delay line.

%   Initialize state vector. To keep this example a bit
%   simpler, assume that a and b have the same length.
%   Also assume that a(1) is 1.

v = zeros(size(a));

filtfcn =  @iirFilter;
statefcn = @getState;

   function yn = iirFilter(xn)
      % Update the state vector
      v(1) = v(2) + b(1) * xn;
      v(2:end-1) = v(3:end) + b(2:end-1) * xn - ...
         a(2:end-1) * v(1);
      v(end) = b(end) * xn - a(end) * v(1);

      % Output is the first element of the state vector.
      yn = v(1);
   end

   function vOut = getState
      vOut = v;
   end
end
```

This sample session shows how `makeFilter` works. Make a filter that has a decaying exponential impulse response and then call it a few times in succession to see the output values change:

```
[filt1, state1] = makeFilter([1 0], [1 -.5]);

% First input to the filter is 1.
filt1(1)
ans =
   1

% Second input to the filter is 0.
filt1(0)
ans =
   0.5000

filt1(0)
ans =
   0.2500

% Show the filter's internal state.
state1()
ans =
   0.2500    0.1250

% Hit the filter with another impulse.
filt1(1)
ans =
   1.1250

% How did the state change?
state1()
ans =
   1.1250    0.5625

% Make an averaging filter.
filt2 = makeFilter([1 1 1]/3, [1 0 0]);

% Put a step input into filt2.
filt2(1)
ans =
   0.3333

filt2(1)
```

```
ans =
   0.6667

filt2(1)
ans =
   1

% The two filter functions can be used independently.
filt1(0)
ans =
   0.5625
```

As an extension of this example, suppose you were looking for a way to develop simulations of different filtering structures and compare them. This might be useful if you were interested in obtaining the range of values taken on by elements of the state vector, and how those values compare with a different filter structure. Here is one way you could capture the filter state at each step and save it for later analysis:

Call `makeFilter` with inputs `v1` and `v2` to construct function handles to the `iirFilter` and `getState` subfunctions:

```
[filtfcn, statefcn] = makeFilter(v1, v2);
```

Call the `iirFilter` and `getState` functions by means of their handles, passing in random values:

```
x = rand(1, 20);
for k = 1:20
    y(k) = filtfcn(x(k));
    states{k} = statefcn();  % Save the state at each step.
end
```

Subfunctions

In this section...

Overview

M-files can contain code for more than one function. Additional functions within the file are called *subfunctions*, and these are only visible to the primary function or to other subfunctions in the same file.

Each subfunction begins with its own function definition line. The functions immediately follow each other. The various subfunctions can occur in any order, as long as the primary function appears first:

```
function [avg, med] = newstats(u) % Primary function
% NEWSTATS Find mean and median with internal functions.
n = length(u);
avg = mean(u, n);
med = median(u, n);

function a = mean(v, n)            % Subfunction
% Calculate average.
a = sum(v)/n;

function m = median(v, n)          % Subfunction
% Calculate median.
w = sort(v);
if rem(n, 2) == 1
   m = w((n+1) / 2);
else
   m = (w(n/2) + w(n/2+1)) / 2;
end
```

The subfunctions `mean` and `median` calculate the average and median of the input list. The primary function `newstats` determines the length of the list and calls the subfunctions, passing to them the list length `n`.

Subfunctions cannot access variables used by other subfunctions, even within the same M-file, or variables used by the primary function of that M-file, unless you declare them as global within the pertinent functions, or pass them as arguments.

Calling Subfunctions

When you call a function from within an M-file, MATLAB first checks the file to see if the function is a subfunction. It then checks for a private function (described in the following section) with that name, and then for a standard M-file or built-in function on your search path. Because it checks for a subfunction first, you can override existing M-files using subfunctions with the same name.

Accessing Help for a Subfunction

You can write help for subfunctions using the same rules that apply to primary functions. To display the help for a subfunction, precede the subfunction name with the name of the M-file that contains the subfunction (minus file extension) and a > character.

For example, to get help on subfunction `mysubfun` in file `myfun.m`, type

```
help myfun>mysubfun
```

Private Functions

In this section...

Overview

Private functions are functions that reside in subdirectories with the special name `private`. These functions are called *private* because they are visible only to M-file functions and M-file scripts that meet these conditions:

- A function that calls a private function must be defined in an M-file that resides in the directory immediately above that `private` subdirectory.
- A script that calls a private function must itself be called from an M-file function that has access to the private function according to the above rule.

For example, assume the directory `newmath` is on the MATLAB search path. A subdirectory of `newmath` called `private` can contain functions that only the functions in `newmath` can call.

Because private functions are invisible outside the parent directory, they can use the same names as functions in other directories. This is useful if you want to create your own version of a particular function while retaining the original in another directory. Because MATLAB looks for private functions before standard M-file functions, it will find a private function named `test.m` before a nonprivate M-file named `test.m`.

Primary functions and subfunctions can also be implemented as private functions.

Private Directories

You can create your own private directories simply by creating subdirectories called `private` using the standard procedures for creating directories or folders on your computer. Do not place these private directories on your path.

Accessing Help for a Private Function

You can write help for private functions using the same rules that apply to primary functions. To display the help for a private function, precede the private function name with `private/`.

For example, to get help on private function `myprivfun`, type

```
help private/myprivfun
```

Overloaded Functions

Overloaded functions are useful when you need to create a function that responds to different types of inputs accordingly. For instance, you might want one of your functions to accept both double-precision and integer input, but to handle each type somewhat differently. You can make this difference invisible to the user by creating two separate functions having the same name, and designating one to handle `double` types and one to handle integers.

MATLAB overloaded functions reside in subdirectories having a name starting with the symbol `@` and followed by the name of a recognized MATLAB data type. For example, functions in the `\@double` directory execute when invoked with arguments of MATLAB type `double`. Those in an `\@int32` directory execute when invoked with arguments of MATLAB type `int32`.

See “Classes and Objects: An Overview” on page 9-2 for more information on overloading functions in MATLAB.

Data Import and Export

Working with Audio and Video Data (p. 6-93)	Import and export audio and video data.
Working with Spreadsheets (p. 6-98)	Interact with Microsoft Excel and Lotus 123 spreadsheets.
Using Low-Level File I/O Functions (p. 6-104)	Use the MATLAB low-level file I/O functions, such as fopen, fread, and fwrite.
Exchanging Files over the Internet (p. 6-117)	Exchange files over the Internet with MATLAB URL, zip, and e-mail functions.

Overview

In this section...

For more information and examples on importing and exporting data, see Technical Note 1602:

`http://www.mathworks.com/support/tech-notes/1600/1602.html`

File Types Supported by MATLAB

MATLAB provides many ways to load data from disk files or the clipboard into the workspace, a process called *importing* data. Also there are many ways to save workspace variables to a disk file, a process called *exporting* data. Your choice of which import or export mechanism to use depends mainly on the format of the data being transferred: text, binary, or a standard format such as JPEG.

Note For unsupported high-level function data formats, you can use the MATLAB low-level file I/O functions if you know how the binary data is formatted in the file. See "Using Low-Level File I/O Functions" on page 6-104 for more information.

MATLAB has built-in capabilities to import and export the following types of data files:

- "Binary Data from a MATLAB Session" on page 6-4
- "Text Data" on page 6-4
- "Graphics Files" on page 6-4
- "Audio and Audio/Video Data" on page 6-4
- "Spreadsheets" on page 6-5

Binary Data from a MATLAB Session

Using the MATLAB `save` and `load` functions, you can store all or part of the data in your MATLAB workspaces to disk, and then read that data back into MATLAB at a later time.

Text Data

In text format, the data values are American Standard Code for Information Interchange (ASCII) codes that represent alphabetic and numeric characters. ASCII text data can be viewed in a text editor. For more information about working with text data in MATLAB, see

These sections also describe how to import and export to XML documents.

Graphics Files

MATLAB imports and exports images from many standard graphics file formats, including the Tagged Image File Format (TIFF), Graphics Interchange Format (GIF), Joint Photographic Experts Group (JPEG), and Portable Network Graphics (PNG) formats.

Audio and Audio/Video Data

MATLAB provides functions to enable you to interact with the following types of audio and audio/video files:

- NeXT/SUN SPARCstation sound
- Microsoft WAVE sound
- Audio/Video Interleaved (AVI)
- Windows-compatible sound devices
- Audio player and recorder objects

- Linear audio signals

Spreadsheets

You can use MATLAB to import and export data to the following types of spreadsheets:

- Microsoft Excel spreadsheets
- Lotus 123 spreadsheets

Data from the System Clipboard

Using the Import Wizard or the `clipboard` function, you can temporarily hold string data on your system's clipboard, and then paste it back into MATLAB.

Information from the Internet

From your MATLAB session, you can

- Send e-mail
- Download from the Internet
- Compress (zip) and decompress (unzip) files
- Connect to an FTP server to perform remote file operations

Other MATLAB I/O Capabilities

Using the Import Wizard

The Import Wizard is a graphical user interface that simplified the process of locating and loading various types of data files into MATLAB. You do not need to know the format of the data to use this tool. You simply specify the

file that contains the data and the Import Wizard processes the file contents automatically. See the section on “Using the Import Wizard” on page 6-11.

Mapping Files to Memory

Memory—mapping enables you to read and write data in a file as if were stored in the computer’s dynamic memory. The contents of the mapped file appear as if they were an array in the currently active workspace. You simply index into this array to read or write the desired data from the file. See the section on “Accessing Files with Memory-Mapping” on page 6-23.

Reading Files with Large Data Sets

An efficient way to read files with large data sets is to read the file in segments and process the data as you go. This method requires significantly less memory than if you were to try reading in the entire file at once. Using the `textscan` function, you can read a specified amount of data from a file, and maintain a pointer to the location in the file where your last read operation ended and your next read is to begin.

This example opens a large data file and reads the file a segment at a time in a `for` loop. The code calls `textscan` to read a particular pattern of data (as specified by `format`) 10,000 times for each segment. Following each read, the subfunction `process_data` processes the data collected in cell array `segarray`:

```
format = '%s %n %s %8.2f %8.2f %8.2f %8.2f %u8';
file_id = fopen('largefile.dat', 'r');

for k = 1:segcount
   segarray = textscan(file_id, format, 10000);
   process_data(segarray);
end

fclose(file_id);
```

Low-Level File I/O

MATLAB also supports C-style, low-level I/O functions that you can use with any data format. For more information, see “Using Low-Level File I/O Functions” on page 6-104.

Importing Data with Toolboxes

In addition to MATLAB import functions, you can perform specialized import features using toolboxes. For example, use Database Toolbox for importing data from relational databases. Refer to the documentation on the specific toolbox to see what import features are offered.

Functions Used in File Management

The following functions are available in MATLAB to help you to create, manage, and locate the files and directories you work with. For more information on these and other file management functions, see "File Management Operations" in the Desktop Tools and Development Environment documentation:

Function	Description
`cd`	Switch your current working directory to another directory
`clipboard`	Copy and paste strings to and from the system clipboard
`copyfile`	Copy a file or directory to another location
`delete`	Delete the specified files
`dir`	List the files that reside in the specified directory
`edit`	Create a new M-file or edit an existing one
`exist`	Check the existence of a file or directory
`fileattrib`	Set or get attributes of a file or directory
`filebrowser`	Start the Current Directory Browser
`fileparts`	Show the components of a file name and its place on the path
`fullfile`	Build a full file name from its components
`ls`	List the contents of a specific directory
`mkdir`	Create a new directory
`movefile`	Move a file or directory to a new location
`open`	Open files based on extension
`pwd`	Identify the directory you are currently working in

Function	Description
`recycle`	Set an option to move deleted files to recycle folder
`rmdir`	Delete a specific directory
`what`	List the MATLAB files in a specific directory
`which`	Locate functions and files

Supported File Formats

The table below shows the file formats that you can read or write from MATLAB along with the functions that support each format.

File Format	File Content	Extension	Functions
MATLAB formatted	Saved MATLAB workspace	`.mat`	`load`, `save`
Text	Text	any	`textscan`
	Text	any	`textread`
	Delimited text	any	`dlmread`, `dlmwrite`
	Comma-separated numbers	`.csv`	`csvread`, `csvwrite`
Extended Markup Language	XML-formatted text	`.xml`	`xmlread`, `xmlwrite`
Audio	NeXT/SUN sound	`.au`	`auread`, `auwrite`
	Microsoft WAVE sound	`.wav`	`wavread`, `wavwrite`
Movie	Audio/video	`.avi`	`aviread`
Scientific data	Data in Common Data Format	`.cdf`	`cdfread`, `cdfwrite`
	Flexible Image Transport System data	`.fits`	`fitsread`
	Data in Hierarchical Data Format	`.hdf`	`hdfread`
Spreadsheet	Excel worksheet	`.xls`	`xlsread`, `xlswrite`
	Lotus 123 worksheet	`.wk1`	`wk1read`, `wk1write`

File Format	File Content	Extension	Functions
Graphics	TIFF image	`.tiff`	`imread`, `imwrite`
	PNG image	`.png`	same
	HDF image	`.hdf`	same
	BMP image	`.bmp`	same
	JPEG image	`.jpeg`	same
	GIF image	`.gif`	same

Using the Import Wizard

In this section...

Overview

The easiest way to import data into MATLAB is to use the Import Wizard. You do not need to know the format of the data to use this tool. You simply specify the file that contains the data and the Import Wizard processes the file contents automatically. You can also use the Import Wizard to import HDF data. See "Using the HDF Import Tool" on page 7-36"Using the HDF Import Tool" on page 7-36 for more information.

The sections on Previewing Contents of the File or Clipboard and Specifying Delimiters and Header Format apply only to text files and the clipboard.

Starting the Import Wizard

To start the Import Wizard and select the source to import, see

- "Importing from a File" on page 6-12
- "Importing from the Clipboard" on page 6-12

If you use the `uiimport` function to start the Wizard, you can choose to have the imported data written to a MATLAB structure. See "Importing to a Structure" on page 6-12.

Importing from a File

To start the Wizard and use a file browser to locate the file to import, use one of the menu options or MATLAB commands shown here:

- Select **Import Data** from the **File** menu
- Type `uiimport -file`
- Type `uiimport`, and then click **Browse**

If you already know the name of the file to import, use one of the following means to initiate the operation:

- In the Current Directory browser, right-click the filename and select **Import Data**
- Type `uiimport filename`, where `filename` is an unquoted string containing the name of the file to import.

Importing from the Clipboard

To import from the system clipboard, use one of the menu options or MATLAB commands shown here:

- Select **Paste to Workspace** from the **Edit** menu
- Type `uiimport -pastespecial`
- Type `uiimport`, and then click **Clipboard**

Importing to a Structure

Specifying an output argument with the `uiimport` command tells MATLAB to return the imported data in the fields of a single structure rather than as separate variables.

The command

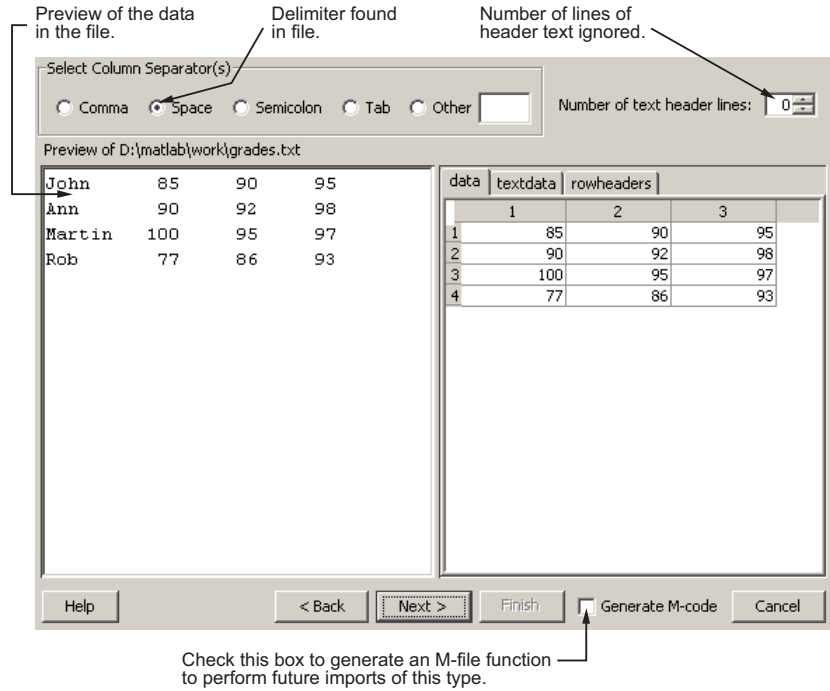
```
S = uiimport('filename')
```

imports the file `filename` to the fields of structure `S`. The `filename` argument is a single-quoted string containing the name of the file to import.

If you are importing from a binary file, skip ahead to step 4: Determine Assignment to Variables.

Previewing Contents of the File or Clipboard [Text only]

When the Import Wizard imports text data from a file or the clipboard, it opens the dialog box shown here and displays a portion of the raw data in the preview pane on the left. You can use this display to verify that the file contains the data you expect.



The pane on the right side of the dialog box shows how MATLAB has assigned the imported data to a default set of variables. The variable names appear in the tabs above the display pane. Click any of these tabs to see the values assigned to that variable. The variable names are derived from categories into which the Import Wizard has sorted the data. These are

- `rowheaders`—Column vector containing the names of all row headers.
- `colheaders`—Row vector containing the names of all column headers.
- `textdata`—Matrix containing all imported text data. Empty elements are set to `''`.
- `data`—Matrix containing all imported numeric data. Empty elements are set to `NaN`.

If the imported file or clipboard contains *only* numeric or *only* text data, then the Import Wizard does not use the variable names shown above. Instead, it assigns all of the data to just one variable:

- For data imported from a text file, the name of the variable is the same as the filename, minus the file extension.
- For data imported from the clipboard, the name of the variable is `A_pastespecial`.

Specifying Delimiters and Header Format [Text only]

Using the options shown at the top of the Import Wizard dialog box, you can specify a delimiter character for separating data items, and also the number of lines you want to use for column headers.

Delimiters

Most text files use a unique character called a *delimiter* or column separator to mark the separation between items of data. For example, data in a comma-separated value (CSV) file is, of course, separated by commas. Data in some other file might be separated by tab or space characters.

When the Import Wizard imports from a text file or the clipboard, it makes its best guess as to which character was intended as the delimiter and displays the data accordingly. If this is not correct, you will need to set the correct delimiter from the choices shown under **Select Column Separator(s)** in the upper left of the dialog box. When you do this, the Import Wizard immediately reformats the data, displaying new values for the data shown in the preview pane.

Header Format

When reading in data from a text file or the clipboard, the Wizard looks for any lines at the top that have no numeric characters, and assigns these lines to the variable `textdata`. MATLAB counts these lines and displays the count in the value field of **Number of text header lines** in the upper right of the Import Wizard window. You can adjust this count if it does not accurately represent the header format within the file.

Note The **Number of text header lines** selector applies only to column headers. It has no effect on row headers.

MATLAB creates a row vector from the bottommost of these lines and assigns it to the variable `colheaders`.

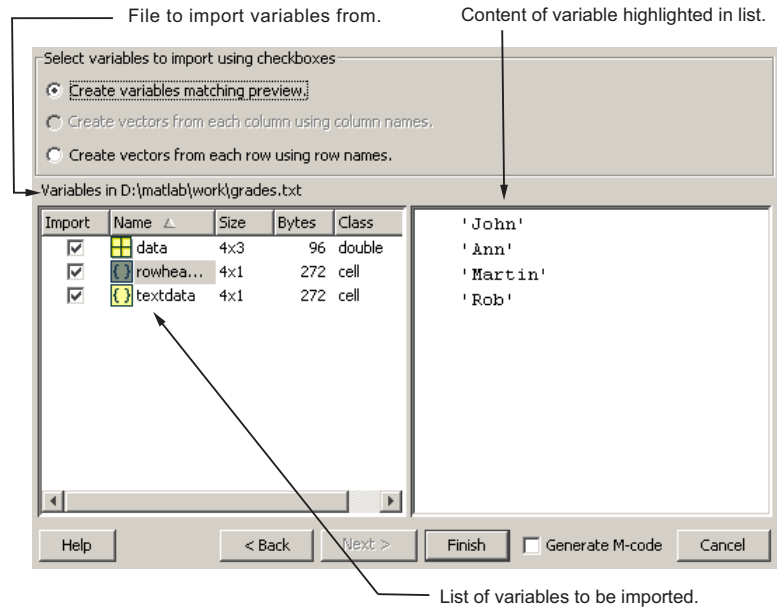
Generate M-Code Checkbox

The **Generate M-code** checkbox at the bottom of the Import Wizard dialog box applies to both text and binary data, and thus is described in "Automated M-Code Generation" on page 6-18.

To continue, click **Next** at the bottom of the dialog box.

Determining Assignment to Variables

At this point, the Import Wizard displays the dialog box shown below. This dialog displays data for both text and binary files.



The left pane of the dialog box displays a list of the variables MATLAB created for your data. For text files, MATLAB derives the variable names as described in step 2: Preview Contents of the File. For binary files, the variable names are taken directly from the file.

Click any variable name and MATLAB displays the contents of that variable in the pane to the right. MATLAB highlights the name of the variable that is currently displayed in the right pane.

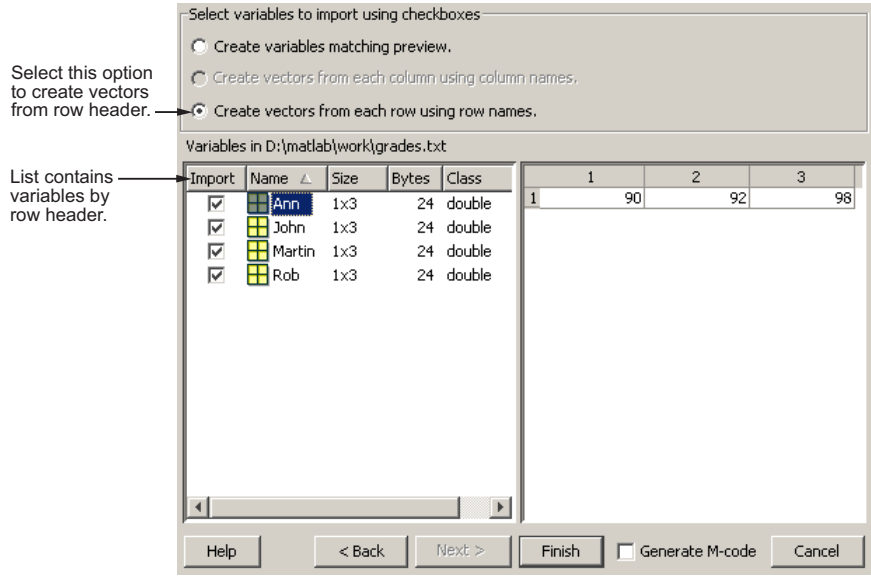
Structuring the Output Data

The top portion of this dialog box offers three options for organizing the file's data:

- **Create variables matching preview**
- **Create vectors from each column using column names**
- **Create vectors from each row using row names**

Note For data imported from a binary file, only the top option is active. Variable names and assignment are taken directly from the imported file. For text data, you can use any of the three options, however, the bottom two are active only if the file or clipboard contains row or column headers.

While importing from the example text file `grades.txt`, select the third option to create vectors from row names. Observe that the display replaces the default variable assignments with new variables derived from the row headers. Click any of these variable names, and the Wizard displays the contents of the corresponding row vector.



Selecting Which Variables to Write to the Workspace

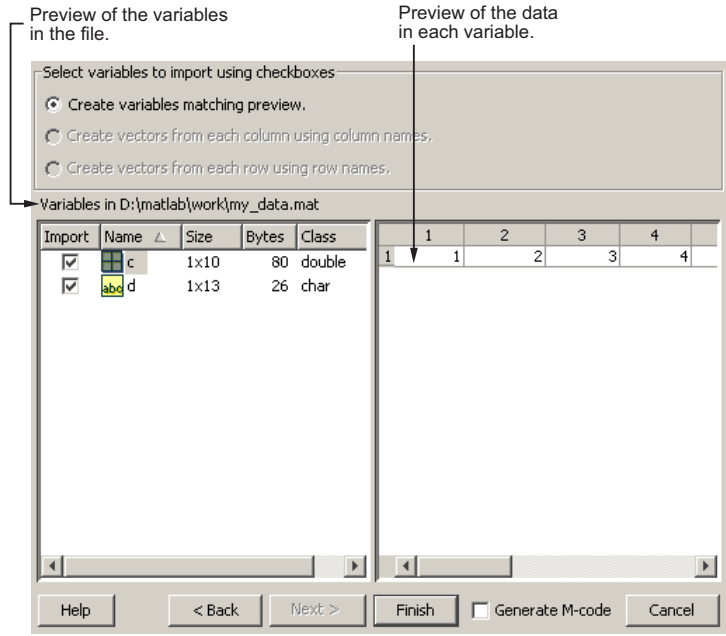
The checkboxes to the left of each variable name enable you to include or exclude individual variables from those that will be written to the workspace. By default, all variables are selected. Select the checkbox of any variable you do not want written to the workspace. The check mark is removed from any variables that you deselect.

Example of Selecting Variables to Load. Use the Import Wizard to import this sample binary MAT-file, `my_data.mat`,

```
C =
    1  2  3  4  5
    6  7  8  9  10

D =
    a test string
```

The Import Wizard displays two variables, as listed in the preview pane. To select a variable to import, select the check box next to its name. All variables are preselected by default.



Automated M-Code Generation

To perform additional imports from this or a similar type of file, you can automate this process by creating a MATLAB function that performs all of the steps you just went through. To have the Import Wizard write this function

for you, select the **Generate M-code** checkbox in the lower right corner of the Wizard dialog.

Once you click **Finish** to complete the import, MATLAB opens an Editor window displaying the generated M-file function. The function is called `importfile.m`. If this name is already taken, then MATLAB names the file `importfileN.m`, where `N` is a number that is one greater than the highest existing `importfile.m` file.

The generated function has the following input and output arguments:

- Input: `fileToRead1`—Name of the file to import from. This argument exists only when importing from a file.
- Output: `newData1`—Structure to assign all imported data to. This argument exists only if you have specified an output argument with the call to `uiimport` when starting the Import Wizard. Otherwise, variables retain the same naming as assigned within the Wizard.

The `newData1` output is a structure that has one field for each output of the import operation.

The workspace variables created by this generated M-code are the same as those created by running the Import Wizard. For example, if you elect to format the output in column vectors when running the Import Wizard, the generated M-file does the same. However, unlike the Import Wizard, you cannot mark any variables to be excluded from the output.

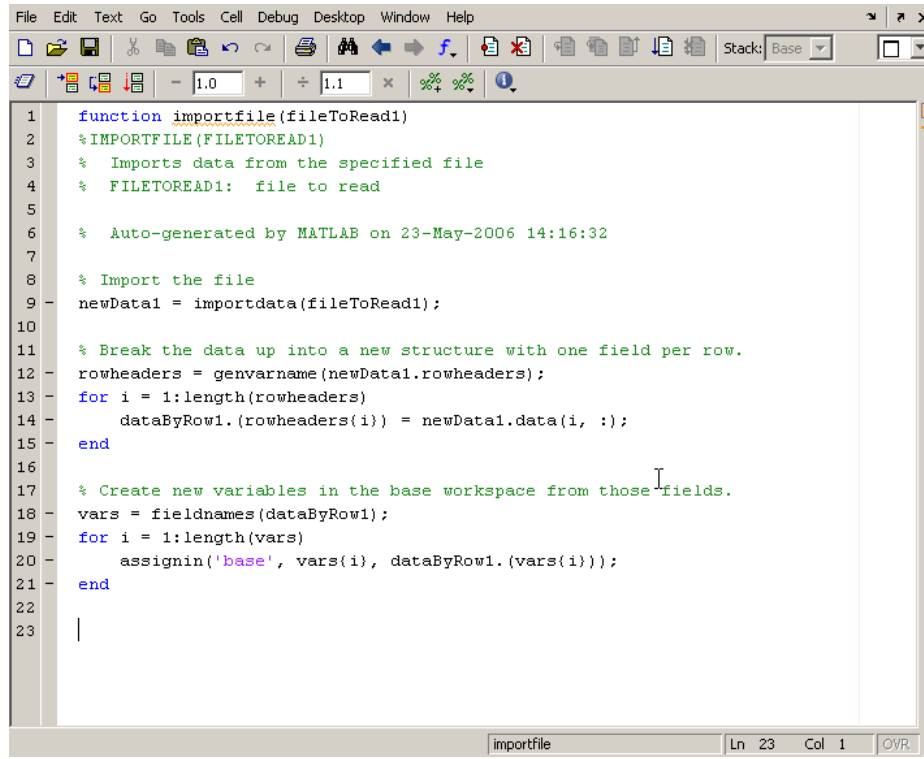
Make any necessary modifications to the generated M-file function in the Editor window. To save the M-file, select **Save** from the **File** menu at the top.

Caution You must save the file yourself; MATLAB does not automatically save it for you.

Example of M-Code Generation

The M-file shown below was generated by MATLAB during an import of the file `grades.txt`, shown earlier in this section. During the import that created this file, the option to **Create vectors from each row using row names**

was selected, thus generating four row vectors for output: `Ann`, `John`, `Martin`, and `Rob`. Also, the row vector for `John` was deselected by clearing the checkbox next to that name in the Wizard.



If you run the function, you find that the workspace now holds the four row vectors `Ann`, `John`, `Martin`, and `Rob`, instead of the default variables created by the Import Wizard (`data`, `textdata`, and `rowheaders`). Also, note that the vector for `John` is written to the workspace along with the others, even though this one variable had been deselected from the Import Wizard interface.

```
importfile grades.txt

whos
  Name        Size              Bytes  Class     Attributes

  Ann         1x3                  24  double
```

```
John        1x3                24  double
Martin      1x3                24  double
Rob         1x3                24  double
```

Writing Data to the Workspace

To complete the import operation, click **Finish** to bring the data into the MATLAB workspace. This button also dismisses the Import Wizard.

Variables written to the workspace are in one of the following formats. The first three apply only to data read from text files or the clipboard, the fourth applies only to binary files, and the last applies to both:

Variable Name	Output
`data`, `textdata`, `rowheaders`, `colheaders`	Separate matrices for numeric, text, and header data.
Variables named after row or column headers	One vector for each row or column.
Single variable named after the filename, or `A_pastespecial`	One matrix for all data named after the filename
Variable names taken from binary file	Data assigned to each variable stored in a binary file.
Output variable assigned during call to `uiimport`	A single structure having fields that match one of the formats described above.

Examples

Here are a few examples of how to use the Import Wizard.

Example 1—Text Data. Start by creating the text file `grades.txt` using the MATLAB editor. The file contains the following:

```
John      85     90     95
Ann       90     92     98
Martin   100     95     97
Rob       77     86     93
```

Import from text file `grades.txt`, using default variables to store the data:

```
uiimport grades.txt
whos
  Name            Size            Bytes  Class     Attributes

  data            4x3                96  double
  rowheaders      4x1               272  cell
  textdata        4x1               272  cell
```

Example 2—Partial Text File with Row Vectors. Import from the same file as in the above example, but this time select **Create vectors from each row using row names**. Also, clear the checkbox next to variable `John` so that this one vector does not get written to the workspace:

```
whos
  Name        Size            Bytes  Class     Attributes

  Ann         1x3                24  double
  Martin      1x3                24  double
  Rob         1x3                24  double
```

Example 3—Binary Data Assigned to a Structure. Save numeric and text data in binary format in file `importtest.mat` and use the Import Wizard to import the binary file into the workspace.

```
C = [1 2 3 4 5;6 7 8 9 10];
D = 'a test string';
save importtest C D

clear
s = uiimport('importtest.mat')
s =
    C: [2x5 double]
    D: 'a test string'
```

Accessing Files with Memory-Mapping

In this section...

Overview of Memory-Mapping in MATLAB

Memory-mapping is a mechanism that maps a portion of a file, or an entire file, on disk to a range of addresses within an application's address space. The application can then access files on disk in the same way it accesses dynamic memory. This makes file reads and writes faster in comparison with using functions such as `fread` and `fwrite`.

Another advantage of using memory-mapping in MATLAB is that it enables you to access file data using standard MATLAB indexing operations. Once you have mapped a file to memory, you can read the contents of that file using the same type of MATLAB statements used to read variables from the MATLAB workspace. The contents of the mapped file appear as if they were an array in the currently active workspace. You simply index into this array to read or write the desired data from the file.

This section describes the benefits and limitations of memory-mapping in MATLAB. The last part of this section gives details on which types of applications derive the greatest advantage from using memory-mapping:

- "Benefits of Memory-Mapping" on page 6-24
- "Limitations of Memory-Mapping in MATLAB" on page 6-25
- "When to Use Memory-Mapping" on page 6-26

Benefits of Memory-Mapping

The principal benefits of memory-mapping are efficiency, faster file access, the ability to share memory between applications, and more efficient coding.

Faster File Access. Accessing files via memory map is faster than using I/O functions such as `fread` and `fwrite`. Data is read and written using the virtual memory capabilities that are built in to the operating system rather than having to allocate, copy into, and then deallocate data buffers owned by the process.

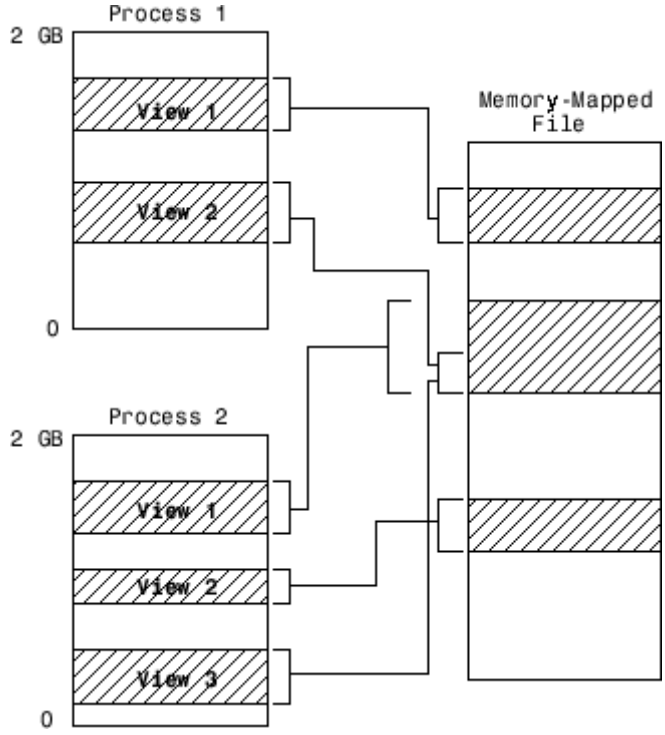
MATLAB does not access data from the disk when the map is first constructed. It only reads or writes the file on disk when a specified part of the memory map is accessed, and then it only reads that specific part. This provides faster random access to the mapped data.

Efficiency. Mapping a file into memory allows access to data in the file as if that data had been read into an array in the application's address space. Initially, MATLAB only allocates address space for the array; it does not actually read data from the file until you access the mapped region. As a result, memory-mapped files provide a mechanism by which applications can access data segments in an extremely large file without having to read the entire file into memory first.

Efficient Coding Style. Memory-mapping eliminates the need for explicit calls to the `fread` and `fwrite` functions. In MATLAB, if `x` is a memory-mapped variable, and `y` is the data to be written to a file, then writing to the file is as simple as

```
x.Data = y;
```

Sharing Memory Between Applications. Memory-mapped files also provide a mechanism for sharing data between applications, as shown in the figure below. This is achieved by having each application map sections of the same file. This feature can be used to transfer large data sets between MATLAB and other applications.



Also, within a single application, you can map the same segment of a file more than once.

Limitations of Memory-Mapping in MATLAB

MATLAB restricts the size of a memory map to 2 gigabytes, and on some platforms, requires that you set up your memory-mapping so that all data access is aligned properly. See the following section, “Maximum Size of a Memory Map”, for more information.

Maximum Size of a Memory Map. Due to limits set by the operating system, the maximum amount of data you can map with a single instance of a memory map is 2^{31} - 1 (or 2 GB). If you need to map more than 2 GB, you can either create separate maps for different regions of the file, or you can move the 2 GB window of one map to different locations in the file.

The 2 GB limit also applies to 64-bit platforms. However, because 64-bit platforms have a much larger address space, they can support having many more map instances in memory at any given time.

Aligned Access on Sol64. The Sol64 platform only supports aligned data access. This means that numeric values of type `double` that are to be read from a memory-mapped file must start at some multiple of 8 bytes from the start of the file. (Note that this is from the start of the *file*, and not the start of the mapped region.) Furthermore, numeric values of type `single` and also 32-bit integers must start at multiples of 4 bytes, and 16-bit integers at 2-byte multiples.

If you attempt to map a file on Sol64 that does not take into account these alignment considerations, MATLAB generates an error.

Byte Ordering

Memory-mapping works only with data that has the same byte ordering scheme as the native byte ordering of your operating system. For example, because both Linux and Windows use little-endian byte ordering, data created on a Linux system can be read on Windows. You can use the `computer` function to determine the native byte ordering of your current system.

When to Use Memory-Mapping

Just how much advantage you get from mapping a file to memory depends mostly on the size and format of the file, the way in which data in the file is used, and the computer platform you are using.

When Memory-Mapping Is Most Useful. Memory-mapping works best with binary files, and in the following scenarios:

- For large files that you want to access randomly one or more times

- For small files that you want to read into memory once and access frequently
- For data that you want to share between applications
- When you want to work with data in a file as if it were a MATLAB array

When the Advantage Is Less Significant. The following types of files do not fully utilize the benefits of memory-mapping:

- Formatted binary files like HDF or TIFF that require customized readers are not good for memory-mapping. For one thing, describing the data contained in these files can be a very complex task. Also, you cannot access data directly from the mapped segment, but must instead create arrays to hold the data.
- Text or ASCII files require that you convert the text in the mapped region to an appropriate type for the data to be meaningful. This takes up additional address space.
- Files that are larger than several hundred megabytes in size consume a significant amount of the virtual address space needed by MATLAB to process your program. Mapping files of this size may result in MATLAB reporting out-of-memory errors more often. This is more likely if MATLAB has been running for some time, or if the memory used by MATLAB becomes fragmented.

The memmapfile Class

MATLAB implements memory-mapping using an object-oriented class called `memmapfile`. The `memmapfile` class has the properties and methods you need to map to a file, read and write the file via the map, and remove the map from memory when you are done.

Properties of the memmapfile Class

There are six properties defined for the `memmapfile` class. These are shown in the table below. These properties control which file is being mapped, where in the file the mapping is to begin and end, how the contents of the file are to be formatted, and whether or not the file is writable. One property of the file contains the file data itself.

Property	Description	Data Type	Default
`Data`	Contains the data read from the file or to be written to the file. (See "Reading a Mapped File" on page 6-43 and "Writing to a Mapped File" on page 6-48)	Any of the numeric types	None
`Filename`	Path and name of the file to map into memory. (See "Selecting the File to Map" on page 6-32)	`char` array	None
`Format`	Format of the contents of the mapped region, including data type, array shape, and variable or field name by which to access the data. (See "Identifying the Contents of the Mapped Region" on page 6-34)	`char` array or N-by-3 cell array	`uint8`
`Offset`	Number of bytes from the start of the file to the start of the mapped region. This number is zero-based. That is, offset 0 represents the start of the file. Must be a nonnegative integer value. (See "Setting the Start of the Mapped Region" on page 6-34)	`double`	`0`
`Repeat`	Number of times to apply the specified format to the mapped region of the file. Must be a positive integer value or `Inf`. (See "Repeating a Format Scheme" on page 6-41)	`double`	`Inf`
`Writable`	Type of access allowed to the mapped region. Must be logical 1 or logical 0. (See "Setting the Type of Access" on page 6-42)	`logical`	`false`

You can set the values for any property except for `Data` at the time you call the `memmapfile` constructor, or at any time after that while the map is still valid. Any properties that are not explicitly set when you construct the object are given their default values as shown in the table above. For information on calling the constructor, see "Constructing a memmapfile Object" on page 6-29.

Once a `memmapfile` object has been constructed, you can change the value of any of its properties. Use the `objname.property` syntax in assigning the new value. For example, to set a new `Offset` value for memory map object `m`, type

```
m.Offset = 2048;
```

Note Property names are not case sensitive. For example, MATLAB considers `m.offset` to be the same as `m.Offset`.

To display the value of all properties of a `memmapfile` object, simply type the object name. For a `memmapfile` object `m`, typing the variable name `m` displays the following. Note that this example requires the file `records.dat` which you will create at the beginning of the next section.

```
m =
    Filename: 'records.dat'
    Writable: true
      Offset: 1024
      Format: 'uint32'
      Repeat: Inf
        Data: 4778x1 uint32 array
```

To display the value of any individual property, for example the `Writable` property of object `m`, type

```
m.Writable
ans =
   true
```

Constructing a memmapfile Object

The first step in mapping to any file is to construct an instance of the `memmapfile` class using the class constructor function. You can have MATLAB assign default values to each of the new object's properties, or you can specify property values yourself in the call to the `memmapfile` constructor.

For information on how to set these values, see the sections that cover

- "Constructing the Object with Default Property Values" on page 6-30
- "Changing Property Values" on page 6-31
- "Selecting the File to Map" on page 6-32
- "Setting the Start of the Mapped Region" on page 6-34
- "Identifying the Contents of the Mapped Region" on page 6-34

All the examples in this section use a file named `records.dat` that contains a 5000-by-1 matrix of double-precision floating point numbers. Use the following code to generate this file before going on to the next sections of this documentation.

First, save this function in your current working directory:

```
function gendatafile(filename, count)
dmax32 = double(intmax('uint32'));
rand('state', 0)

fid = fopen(filename,'w');
fwrite(fid, rand(count,1)*dmax32, 'double');
fclose(fid);
```

Now execute the `gendatafile` function to generate the `records.dat` file that is referenced in this section. You can use this function at any time to regenerate the file:

```
gendatafile('records.dat', 5000);
```

Constructing the Object with Default Property Values

The simplest and most general way to call the constructor is with one input argument that specifies the name of the file you want to map. All other properties are optional and are given their default values. Use the syntax shown here:

```
objname = memmapfile(filename)
```

To construct a map for the file `records.dat` that resides in your current working directory, type the following:

```
m = memmapfile('records.dat')
m =
    Filename: 'd:\matlab\mfiles\records.dat'
```

```
    Writable: false
      Offset: 0
      Format: 'uint8'
      Repeat: Inf
        Data: 40000x1 uint8 array
```

MATLAB constructs an instance of the `memmapfile` class, assigns it to the variable `m`, and maps the entire `records.dat` file to memory, setting all properties of the object to their default values. In this example, the command maps the entire file as a sequence of unsigned 8-bit integers, and gives the caller read-only access to its contents.

Changing Property Values

You can make the memory map more specific to your needs by including more information when calling the constructor. In addition to the `filename` argument, there are four other parameters that you can pass to the constructor. Each of these parameters represents a property of the object, and each requires an accompanying value to be passed as well:

```
objname = memmapfile(filename, prop1, value1, prop2, value2, ...)
```

For example, to construct a map using nondefault values for the `Offset`, `Format`, and `Writable` properties, type the following, enclosing all property names and string parameter values in quotes:

```
m = memmapfile('records.dat', ...
      'Offset', 1024,         ...
      'Format', 'double',     ...
      'Writable', true);
```

Type the object name to see the current settings for all properties:

```
m

m =
    Filename: 'd:\matlab\mfiles\records.dat'
    Writable: true
      Offset: 1024
      Format: 'double'
      Repeat: Inf
```

```
          Data: 4872x1 double array
```

You can also change the value of any property after the object has been constructed. Use the syntax

```
objname.property = newvalue;
```

For example, to set the format to `uint16`, type the following. (Property names, like `Format`, are not case sensitive.)

```
m.format = 'uint16'
m =
    Filename: 'd:\matlab\mfiles\records.dat'
    Writable: true
      Offset: 1024
      Format: 'uint16'
      Repeat: Inf
        Data: 19488x1 uint16 array
```

Further read and write operations to the region mapped by `m` will now treat the data in the file as a sequence of unsigned 16-bit integers. Whenever you change the value of a `memmapfile` property, MATLAB remaps the file to memory.

Selecting the File to Map

`filename` is the only required argument when you call the `memmapfile` constructor. When you call the `memmapfile` constructor, MATLAB assigns the filename that you specify to the `Filename` property of the new object instance.

Specify the filename as a quoted string, (e.g., `'records.dat'`). It must be first in the argument list and not specified as a parameter-value pair. `filename` must include a filename extension if the name of the file being mapped has an extension. The `filename` argument cannot include any wildcard characters (e.g., `*` or `?`), and is not case sensitive.

Note Unlike the other `memmapfile` constructor arguments, you must specify `filename` as a single string, and not as a parameter-value pair.

If the file to be mapped resides somewhere on the MATLAB path, you can use a partial pathname. If the path to the file is not fully specified, MATLAB searches for the file in your current working directory first, and then on the MATLAB path.

Once `memmapfile` locates the file, MATLAB stores the absolute pathname for the file internally, and then uses this stored path to locate the file from that point on. This enables you to work in other directories outside your current work directory and retain access to the mapped file.

You can change the value of the `Filename` property at any time after constructing the `memmapfile` object. You might want to do this if

- You want to use the same `memmapfile` object on more than one file.
- You save your `memmapfile` object to a MAT-file, and then later load it back into MATLAB in an environment where the mapped file has been moved to a different location. This requires that you modify the path segment of the `Filename` string to represent the new location.

For example, save `memmapfile` object `m` to file `mymap.mat`:

```
disp(m.Filename)
    d:\matlab\mfiles\records.dat

save mymat m
```

Now move the file to another location, load the object back into MATLAB, and update the path in the `Filename` property:

```
load mymat m
m.Filename = 'f:\testfiles\oct1\records.dat'
```

Note You can only map an existing file. You cannot create a new file and map that file to memory in one operation. Use the MATLAB file I/O functions to create the file before attempting to map it to memory.

Setting the Start of the Mapped Region

By default, MATLAB begins a memory map at the start of the file. To begin the mapped region at some point beyond the start of the file, specify an `Offset` parameter in the call to the `memmapfile` constructor:

```
objname = memmapfile(filename, 'Offset', bytecount)
```

The `bytecount` value is the number of bytes from the beginning of the file to the point in the file where you want the memory map to start (a zero-based offset). To map the file `records.dat` from a point 1024 bytes from the start and extending to the end of the file, type

```
m = memmapfile('records.dat', 'Offset', 1024);
```

You can change the starting position of an existing memory map by setting the `Offset` property for the associated object to a new value. The following command sets the offset of `memmapfile` object `m` to be 2,048 bytes from the start of the mapped file:

```
m.Offset = 2048;
```

Note The Sol64 platform supports aligned data access only. If you attempt to use a `memmapfile` offset on Sol64 that does not take the necessary alignment considerations into account, MATLAB generates an error. (See “Aligned Access on Sol64” on page 6-26).

Identifying the Contents of the Mapped Region

By default, MATLAB considers all the data in a mapped file to be a sequence of unsigned 8-bit integers. To have the data interpreted otherwise as it is read or written to in the mapped file, specify a `Format` parameter and value in your call to the constructor:

```
objname = memmapfile(filename, 'Format', formatspec)
```

The `formatspec` argument can either be a character string that identifies a single data type used throughout the mapped region, or a cell array that specifies more than one data type.

For example, say that you map a file that is 12K bytes in length. Data read from this file could be treated as a sequence of 6,000 16-bit (2-byte) integers, or as 1,500 8-byte double-precision floating-point numbers, to name just a couple of possibilities. Or you could read this data in as a combination of different types: for example, as 4,000 8-bit (1-byte) integers followed by 1,000 64-bit (8-byte) integers. You determine how MATLAB will interpret the mapped data by setting the `Format` property of the `memmapfile` object when you call its constructor.

Note MATLAB arrays are stored on disk in column-major order. (The sequence of array elements is column 1, row 1; column 1, row 2; column 1, last row; column 2, row 1, and so on.) You might need to transpose or rearrange the order of array elements when reading or writing via a memory map.

Note The Sol64 platform supports aligned data access only. If you attempt to use a `memmapfile` format on Sol64 that does not take the necessary alignment considerations into account, MATLAB generates an error. (See "Aligned Access on Sol64" on page 6-26).

Data types supported for the `Format` property are shown at the end of this section. See "Supported Data Types for the Format Property" on page 6-40.

For more information on format options see

- "Mapping a Single Data Type" on page 6-35
- "Formatting the Mapped Data to an Array" on page 6-36
- "Mapping Multiple Data Types and Arrays" on page 6-38

Mapping a Single Data Type. If the file region being mapped contains data of only one type, specify the `Format` value as a character string identifying that type:

```
objname = memmapfile(filename, 'Format', datatype)
```

The following command constructs a `memmapfile` object for the entire file `records.dat`, and sets the `Format` property for that object to `uint64`. Any read or write operations made via the memory map will read and write the file contents as a sequence of unsigned 64-bit integers:

```
m = memmapfile('records.dat', 'Format', 'uint64')
    Filename: 'd:\matlab\mfiles\records.dat'
    Writable: false
      Offset: 0
      Format: 'uint64'
      Repeat: Inf
        Data: 5000x1 uint64 array
```

You can change the value of the `Format` property at any time after the `memmapfile` object is constructed. Use the `object.property` syntax shown here in assigning the new value:

```
m.Format = 'int32';
```

Further read and write operations to the region mapped by `m` will now treat the data in the file as a sequence of signed 32-bit integers.

Property names, like `Format`, are not case sensitive.

Formatting the Mapped Data to an Array. You can also specify an array shape to be applied to the data read or written to the mapped file, and a field name to be used in referencing this array. Use a cell array to hold these values either when calling the `memmapfile` constructor or when modifying `m.Format` after the object has been constructed. The cell array contains three elements: the data type to be applied to the mapped region, the dimensions of the array shape that is applied to the region, and a field name to use in referencing the data:

```
objname = memmapfile(filename, ...
            'Format', {datatype, dimensions, varname})
```

The command below constructs a `memmapfile` object for a region of `records.dat` such that the contents of the region are handled by MATLAB as a 4-by-10-by-18 array of unsigned 32-bit integers, and can be referenced in the structure of the returned object using the field name `x`:

```
m = memmapfile('records.dat',   ...
      'Offset', 1024,           ...
      'Format', {'uint32' [4 10 18] 'x'})
m =
    Filename: 'd:\matlab\mfiles\records.dat'
    Writable: false
      Offset: 1024
      Format: {'uint32' [4 10 18] 'x'}
      Repeat: Inf
        Data: 13x1 struct array with fields:
                x

A = m.Data(1).x;

whos A
  Name      Size                            Bytes  Class

  A        4x10x18                          2880   uint32 array

Grand total is 720 elements using 2880 bytes
```

You can change the data type, array shape, or field name that MATLAB applies to the mapped region at any time by setting a new value for the `Format` property of the object:

```
m.Format = {'uint64' [30 4 10] 'x'};
A = m.Data(1).x;

whos A
  Name      Size                            Bytes  Class

  A        30x4x10                           9600  uint64 array

Grand total is 1200 elements using 9600 bytes
```

Mapping Multiple Data Types and Arrays. If the region being mapped is composed of segments of varying data types or array shapes, you can specify an individual format for each segment using an N-by-3 cell array, where N is the number of segments. The cells of each cell array row identify the data type for that segment, the array dimensions to map the data to, and a field name by which to reference that segment:

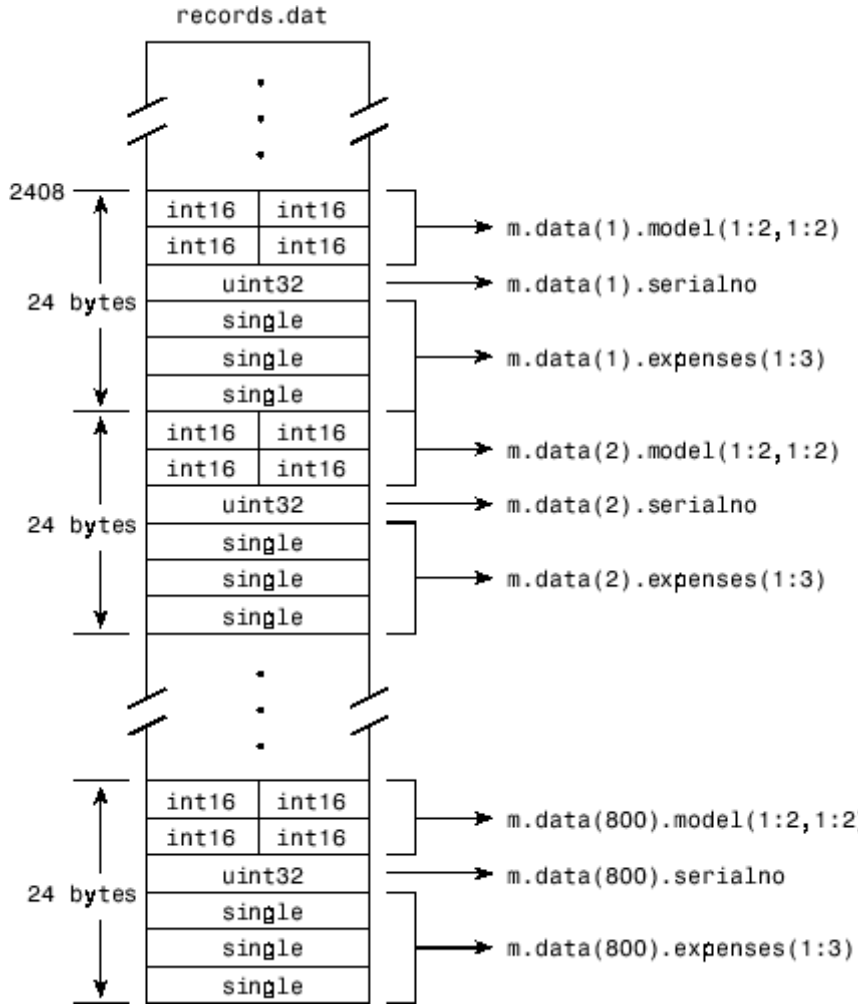
```
objname = memmapfile(filename,                          ...
            'Format', {                                 ...
               datatype1, dimensions1, fieldname1;      ...
               datatype2, dimensions2, fieldname2;      ...
                   :          :            :           ...
               datatypeN, dimensionsN, fieldnameN})
```

The following command maps a 24 kilobyte file containing data of three different data types: `int16`, `uint32`, and `single`. The `int16` data is mapped as a 2-by-2 matrix that can be accessed using the field name `model`. The `uint32` data is a scalar value accessed as field `serialno`. The `single` data is a 1-by-3 matrix named `expenses`.

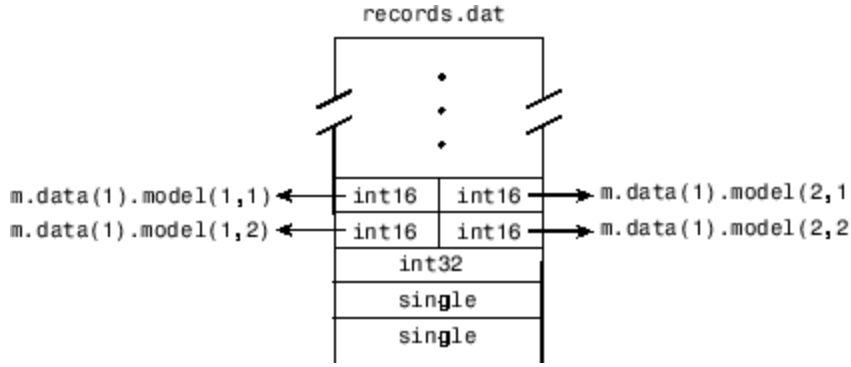
Each of these fields belongs to the 800-by-1 structure array `m.Data`:

```
m = memmapfile('records.dat',        ...
      'Offset', 2048,                ...
      'Format', {                    ...
         'int16'  [2 2] 'model';     ...
         'uint32' [1 1] 'serialno';  ...
         'single' [1 3] 'expenses'});
```

Mapping of the Example File



The figure below shows the ordering of the array elements more closely. In particular, it illustrates that MATLAB arrays are stored on the disk in column-major order. The sequence of array elements in the mapped file is row 1, column 1; row 2, column 1; row 1, column 2; and row 2, column 2.



If the data in your file is not stored in this order, you might need to transpose or rearrange the order of array elements when reading or writing via a memory map.

Supported Data Types for the Format Property. Any of the following data types can be used when you specify a `Format` value. The default type is `uint8`.

Format String	Data Type Description
`'int8'`	Signed 8-bit integers
`'int16'`	Signed 16-bit integers
`'int32'`	Signed 32-bit integers
`'int64'`	Signed 64-bit integers
`'uint8'`	Unsigned 8-bit integers
`'uint16'`	Unsigned 16-bit integers
`'uint32'`	Unsigned 32-bit integers
`'uint64'`	Unsigned 64-bit integers
`'single'`	32-bit floating-point
`'double'`	64-bit floating-point

Repeating a Format Scheme

Once you have set a `Format` value for the `memmapfile` object, you can have MATLAB apply that format to the file data multiple times by specifying a `Repeat` value when you call the `memmapfile` constructor:

```
objname = memmapfile(filename,    ...
            'Format', formatspec, ...
            'Repeat', count)
```

The `Repeat` value applies to the whole format specifier, whether that specifier describes just a single data type that repeats, or a more complex format that includes various data types and array shapes. The default `Repeat` value is infinity (`inf`), which means that the full extent of the `Format` specifier repeats as many times as possible within the mapped region.

The next example maps a file region identical to that of the previous example, except the pattern of `int16`, `uint32`, and `single` data types is repeated only three times within the mapped region of the file:

```
m = memmapfile('records.dat',         ...
      'Offset', 2048,                 ...
      'Format', {                     ...
         'int16'  [2 2] 'model';      ...
         'uint32' [1 1] 'serialno';   ...
         'single' [1 3] 'expenses'},  ...
      'Repeat', 3);
```

You can change the value of the `Repeat` property at any time. To change the repeat value to 5, type

```
m.Repeat = 5;
```

Property names, like `Repeat`, are not case sensitive.

Keeping the Repeated Format Within the Mapped Region. MATLAB maps only the *full* pattern specified by the `Format` property. If you repeat a format such that it would cause the map to extend beyond the end of the file, then either of two things can happen:

- If you specify a repeat value of `Inf`, then only those repeated segments that fit within the file in their entirety are applied to the map.

- If you specify a repeat value other than `Inf`, and that value would cause the map to extend beyond the end of the file, then MATLAB generates an error.

Considering the last example, if the part of the file from `m.Offset` to the end were 70 bytes (instead of the 72 bytes required to repeat `m.Format` three times) and you used a `Repeat` value of `Inf`, then only two full repetitions of the specified format would have been mapped. The end result would be as if you had constructed the map with this command:

```
m = memmapfile('records.dat',         ...
      'Offset', 2048,                 ...
      'Format', {                     ...
         'int16'  [2 2] 'model';      ...
         'uint32' [1 1] 'serialno';   ...
         'single' [1 3] 'expenses'},  ...
      'Repeat', 2);
```

If `Repeat` were set to 3 and you had only 70 bytes to the end of the file, you would get an error.

Note `memmapfile` does not expand or append to a mapped file. Use standard file I/O functions like `fopen` and `fwrite` to do this.

Setting the Type of Access

You can map a file region to allow either read-only or read and write access to its contents. Pass a `Writable` parameter and value in the `memmapfile` constructor, or set `m.Writable` on an existing object to set the type of access allowed:

```
objname = memmapfile(filename, 'Writable', trueorfalse)
```

The value passed can be either `true` (equal to `logical(1)`) or `false` (equal to `logical(0)`). By default, it is `false`, meaning that the mapped region is read only.

To map a read and write region of the file `records.dat` in memory, type

```
m = memmapfile('records.dat', 'Writable', true);
```

Note To successfully modify the file you are mapping to, you must have write permission for that file. If you do not have write permission, you can still set the `Writable` property to `true`, but attempting to write to the file generates an error.

You can change the value of the `Writable` property at any time. To make the memory map to `records.dat` read only, type

```
m.Writable = false;
```

Property names, like `Writable`, are not case sensitive.

Reading a Mapped File

The most commonly used property of the `memmapfile` class is the `Data` property. It is through this property of the memory-map object that MATLAB provides all read and write access to the contents of the mapped file.

The actual mapping of a file to the MATLAB address space does not take place when you construct a `memmapfile` object. A memory map, based on the information currently stored in the mapped object, is generated the first time you reference or modify the `Data` property for that object.

Once you have mapped a file to memory, you can read the contents of that file using the same MATLAB statements used to read variables from the MATLAB workspace. By accessing the `Data` property of the memory map object, the contents of the mapped file appear as if they were an array in the currently active workspace. You simply index into this array to read the desired data from the file.

This section covers the following topics:

Improving Performance

MATLAB accesses data in structures more efficiently than it does data contained in objects. The main reason is that structures do not require the extra overhead of a `subsref` routine. Instead of reading directly from the `memmapfile` object, as shown here

```
for k = 1 : N
   y(k) = m.Data(k);
end
```

you will get better performance when you assign the `Data` field to a variable and then read or write the mapped file through this variable, as shown in this second example:

```
dataRef = m.Data;
for k = 1 : N
   y(k) = dataRef(k);
end
```

Example 1 — Reading a Single Data Type

This example maps a file of 100 double-precision floating-point numbers to memory. The map begins 1024 bytes from the start of the file, and ends 800 bytes (8 bytes per `double` times a `Repeat` value of 100) from that point.

If you haven't done so already, generate a test data file for use in the following examples by executing the `gendatafile` function defined under "Constructing a memmapfile Object" on page 6-29:

```
gendatafile('records.dat', 5000);
```

Now, construct the `memmapfile` object `m`, and show the format of its `Data` property:

```
m = memmapfile('records.dat', 'Format', 'double', ...
      'Offset', 1024, 'Repeat', 100);
```

```
d = m.Data;

whos d
  Name      Size                    Bytes  Class

  d       100x1                       800  double array

Grand total is 100 elements using 800 bytes
```

Read a selected set of numbers from the file by indexing into the single-precision array `m.Data`:

```
d(15:20)
ans =
  1.0e+009 *
    3.6045
    2.7006
    0.5745
    0.8896
    2.6079
    2.7053
```

Example 2 — Formatting File Data as a Matrix

This example is similar to the last, except that the constructor of the `memmapfile` object now specifies an array shape of 4-by-6 to be applied to the data as it is read from the mapped file. MATLAB maps the file contents into a structure array rather than a numeric array, as in the previous example:

```
m = memmapfile('records.dat',            ...
      'Format', {'double', [4 6], 'x'},  ...
      'Offset', 1024, 'Repeat', 100);

d = m.Data;

whos d
  Name      Size                    Bytes  Class

  d       100x1                     25264  struct array

Grand total is 2500 elements using 25264 bytes
```

When you read an element of the structure array, MATLAB presents the data in the form of a 4-by-6 array:

```
d(5).x
ans =
  1.0e+009 *
    3.1564    0.6684    2.1056    1.9357    1.2773    4.2219
    2.9520    0.8208    3.5044    1.7705    0.2112    2.3737
    1.4865    1.8144    1.9790    3.8724    2.9772    1.7183
    0.7131    3.6764    1.9643    0.0240    2.7922    0.8538
```

To index into the structure array field, use

```
d(5).x(3,2:6)
ans =
  1.0e+009 *
    1.8144    1.9790    3.8724    2.9772    1.7183
```

Example 3 — Reading Multiple Data Types

This example maps a file containing more than one data type. The different data types contained in the file are mapped as fields of the returned structure array `m.Data`.

The `Format` parameter passed in the constructor specifies that the first 80 bytes of the file are to be treated as a 5-by-8 matrix of `uint16`, and the 160 bytes after that as a 4-by-5 matrix of `double`. This pattern repeats until the end of the file is reached. The example shows different ways of reading the `Data` property of the object.

Start by calling the `memmapfile` constructor to create a memory map object, `m`:

```
m = memmapfile('records.dat',  ...
      'Format', {              ...
         'uint16' [5 8] 'x';   ...
         'double' [4 5] 'y' });
```

If you examine the `Data` property, MATLAB shows a 166-element structure array with two fields, one for each format specifier in the constructor:

```
d = m.Data
```

```
ans =
166x1 struct array with fields:
    x
    y
```

Examine one structure in the array to show the format of each field:

```
d(3)
ans =
    x: [5x8 uint16]
    y: [4x5 double]
```

Now read the `x` and `y` fields of that structure from the file. MATLAB formats the first block of data as a 5-by-8 matrix of `uint16`, as specified in the `Format` property, and the second block as a 4-by-5 matrix of `double`:

```
d(3).x
ans =
  34432  47500  19145  16868  38165  47956  35550  16853
  60654  51944  16874  47166  35397  58072  16850  56576
  51075  16876  12471  34369   8341  16853  44509  57652
  16863  16453   6666  11480  16869  58695  36217   5932
  57883  15551  41755  16874  37774  31693  54813  16865

d(3).y
ans =
  1.0e+009 *
    3.1229    1.5909    2.9831    2.2445    1.1659
    1.3284    3.0182    2.6685    3.7802    1.0837
    3.6013    2.3475    3.4137    0.7428    3.7613
    2.4399    1.9107    4.1096    4.2080    3.1667
```

Example 4 — Modifying Map Parameters

This example plots the Fourier transform output of data read from a file via a memory map. It then modifies several parameters of the existing map, reads from a different part of the data file, and plots a histogram from that data.

Create a memory-mapped object, mapping 1,000 elements of type `double` starting at the 1025th byte:

```
m = memmapfile('mybinary.bin', 'Offset', 1024,  ...
      'Format', 'double', 'Repeat', 1000);
```

Get data associated with the map and plot the FFT of the first 1000 values of the map. This is when the map is actually created, because no data has been referenced until this point:

```
plot(abs(fft(m.Data(1:1000))));
```

Get information about the memory map:

```
mapStruct = get(m)

mapStruct =
    Filename: 'd:\matlab\mfiles\mybinary.bin'
    Writable: 0
      Offset: 1024
      Format: 'double'
      Repeat: 1000
        Data: [1000x1 double]
```

Change the map, but continue using the same file:

```
m.Offset = 4096;
m.Format = 'single';
m.Repeat = 800;
```

Read from a different area of the file, and plot a histogram of the data. This maps a new region and unmaps the previous region:

```
hist(m.Data)
```

Writing to a Mapped File

Writing to a mapped file is done with standard MATLAB subscripted assignment commands. To write to a particular location in the file mapped to `memmapfile` object `m`, assign the value to the `m.Data` structure array index and field that map to that location.

If you haven't done so already, generate a test data file for use in the following examples by executing the `gendatafile` function defined under "Constructing a memmapfile Object" on page 6-29:

```
gendatafile('records.dat', 5000);
```

Now call the `memmapfile` constructor to create the object:

```
m = memmapfile('records.dat',  ...
      'Format', {              ...
         'uint16' [5 8] 'x';   ...
         'double' [4 5] 'y' });
```

If you are going to modify the mapped file, be sure that you have write permission, and that you set the `Writable` property of the `memmapfile` object to `true` (logical 1):

```
m.Writable = true;
```

(You do not have to set `Writable` as a separate command, as done here. You can include a `Writable` parameter-value argument in the call to the `memmapfile` constructor.)

Read from the 5-by-8 matrix `x` at `m.Data(2)`:

```
d = m.Data;

d(2).x
ans =
  35330   4902  31861  16877  23791  61500  52748  16841
  51314  58795  16860  43523   8957   5182  16864  60110
  18415  16871  59373  61001  52007  16875  26374  28570
  16783   4356  52847  53977  16858  38427  16067  33318
  65372  48883  53612  16861  18882  39824  61529  16869
```

Update all values in that matrix using a standard MATLAB assignment statement:

```
d(2).x = d(2).x * 1.5;
```

Verify the results:

```
d(2).x
ans =
  52995   7353  47792  25316  35687  65535  65535  25262
  65535  65535  25290  65285  13436   7773  25296  65535
  27623  25307  65535  65535  65535  25313  39561  42855
  25175   6534  65535  65535  25287  57641  24101  49977
  65535  65535  65535  25292  28323  59736  65535  25304
```

This section covers the following topics:

Dimensions of the Data Field

The dimensions of a `memmapfile` object's `Data` field are set at the time you construct the object and cannot be changed. This differs from other MATLAB arrays that have dimensions you can modify using subscripted assignment.

For example, you can add a new column to the field of a MATLAB structure:

```
A.s = ones(4,5);

A.s(:,6) = [1 2 3 4];         % Add new column to A.s
size(A.s)
ans =
     4     6
```

But not to a similar field of a structure that represents data mapped from a file. The following assignment to `m.Data(60).y` does not expand the size of `y`, but instead generates an error:

```
m.Data(60)
ans =
    x: [5x8 uint16]
    y: [4x5 double]
```

```
m.Data(60).y(:,6) = [1 2 3 4];        % Generates an error.
```

Thus, if you map an entire file and then append to that file after constructing the map, the appended data is not included in the mapped region. If you need to modify the dimensions of data that you have mapped to a `memmapfile` object, you must either modify the `Format` or `Repeat` properties for the object, or reconstruct the object.

Examples. Two examples of statements that attempt to modify the dimensions of a mapped `Data` field are shown here. These statements result in an error.

The first example attempts to diminish the size of the array by removing a row from the mapped array `m.Data`.

```
m.Data(5) = [];
```

The second example attempts to expand the size of a 50-row mapped array `x` by adding another row to it:

```
m.Data(2).x(1:51,31) = 1:51;
```

Writing Matrices to a Mapped File

The syntax to use when writing to mapped memory can depend on what format was used when you mapped memory to the file.

When Memory Is Mapped in Nonstructure Format. When you map a file as a sequence of a single data type (e.g., a sequence of `uint16`), you can use the following syntax to write matrix `X` to the file:

```
m.Data = X;
```

This statement is valid only if all of the following conditions are true:

- The file is mapped as a sequence of elements of the same data type, making `m.Data` an array of a nonstructure type.
- The class of `X` is the same as the class of `m.Data`.
- The number of elements in `X` equals the number of elements in `m.Data`.

This example maps a file as a sequence of 16-bit unsigned integers, and then uses the syntax shown above to write a matrix to the file. Map only a small part of the file, using a `uint16` format for this segment:

```
m = memmapfile('records.dat', 'Writable', true', ...
    'Offset', 2000, 'Format', 'uint16', 'Repeat', 15);
```

Create a matrix `X` of the same size and write it to the mapped part of the file:

```
X = uint16(5:5:75);    % Sequence of 5 to 75, counting by fives.
m.data = X;
```

Verify that new values were written to the file:

```
m.offset = 1980;   m.repeat = 35;
reshape(m.data,5,7)'
ans =
  29158  16841  32915  37696    421      % <== At offset 1980
  16868  51434  17455  30645  16871
      5     10     15     20     25      % <== At offset 2000
     30     35     40     45     50
     55     60     65     70     75
  16872  50155  51100  26469  16873
  56776   6257  28746  16877  34374
```

When Memory Is Mapped in Scalar Structure Format. When you map a file as a sequence of a single data type (e.g., a sequence of `uint16`), you can use the following syntax to write matrix `X` to the file:

```
m.Data.f = X;
```

This statement is valid only if all of the following conditions are true:

- The file is mapped as containing multiple data types that do not repeat, making `m.Data` a scalar structure.
- The class of `X` is the same as the class of `m.Data.f`.
- The number of elements in `X` equals that of `m.Data.f`.

This example maps a file as a 300-by-8 matrix of type `uint16` followed by a 200-by-5 matrix of type `double`, and then uses the syntax shown above to write a matrix to the file.

```
m = memmapfile('records.dat',     ...
      'Format', {                 ...
         'uint16' [300 8] 'x';    ...
         'double' [200 5] 'y' },  ...
      'Repeat', 1, 'Writable', true);

m.Data.x = ones(300, 8, 'uint16');
```

When Memory Is Mapped in Nonscalar Structure Format. When you map a file as a repeating sequence of multiple data types, you can use the following syntax to write matrix `X` to the file, providing that `k` is a scalar index:

```
m.Data(k).field = X;
```

To do this, the following conditions must be true:

- The file is mapped as containing multiple data types that can repeat, making `m.Data` a nonscalar structure.
- `k` is a scalar index.
- The class of `X` is the same as the class of `m.Data(k).field`.
- The number of elements in `X` equals that of `m.Data(k).field`.

This example maps a file as a matrix of type `uint16` followed by a matrix of type `double` that repeat 20 times, and then uses the syntax shown above to write a matrix to the file.

```
m = memmapfile('records.dat',    ...
      'Format', {                ...
         'uint16' [25 8] 'x';    ...
         'double' [15 5] 'y' },  ...
      'Repeat', 20, 'Writable', true);

d = m.Data;

d(12).x = ones(25,8,'uint16');
```

You can write to specific elements of field `x` as shown here:

```
d(12).x(3:5,1:end) = uint16(500);
d(12).x(3:5,1:end)
```

```
ans =
    500    500    500    500    500    500    500    500
    500    500    500    500    500    500    500    500
    500    500    500    500    500    500    500    500
```

Selecting Appropriate Data Types

All of the usual MATLAB indexing and data type rules apply when assigning values to data via a memory map. The data type that you assign to must be big enough to hold the value being assigned. For example,

```
m = memmapfile('records.dat', 'Format', 'uint8', ...
      'Writable', true);

d = m.Data;
d(5) = 300;
```

saturates the `x` variable because `x` is defined as an 8-bit integer:

```
d(5)
ans =
   255
```

Working with Copies of the Mapped Data

In the following code, the data in variable `block2` is a *copy* of the file data mapped by `m.Data(2)`. Because it is a copy, modifying array data in `block2` does not modify the data contained in the file:

First, destroy the `memmapfile` object and restore the test file `records.dat`, since it has been modified by running the previous examples:

```
clear m
gendatafile('records.dat',50000);
```

Map the file as a series of `uint16` and `double` matrices and make a copy of `m.Data(2)` in `block2`:

```
m = memmapfile('records.dat',   ...
      'Format', {               ...
         'uint16' [5 8] 'x';    ...
         'double' [4 5] 'y' });
```

```
d = m.Data;
```

Write all zeros to the copy:

```
d(2).x(1:5,1:8) = 0;

d(2).x
ans =
     0     0     0     0     0     0     0     0
     0     0     0     0     0     0     0     0
     0     0     0     0     0     0     0     0
     0     0     0     0     0     0     0     0
     0     0     0     0     0     0     0     0
```

Verify that the data in the mapped file has not changed even though the copy of `m.Data(2).x` has been written with zeros:

```
m.Data(2).x
ans =
  35330   4902  31861  16877  23791  61500  52748  16841
  51314  58795  16860  43523   8957   5182  16864  60110
  18415  16871  59373  61001  52007  16875  26374  28570
  16783   4356  52847  53977  16858  38427  16067  33318
  65372  48883  53612  16861  18882  39824  61529  16869
```

Invalid Syntax for Writing to Mapped Memory

Although you can expand the dimensions of a typical MATLAB array by assigning outside its current dimensions, this does not apply to the `Data` property of a `memmapfile` object. The following operation is invalid if `m.Data` has only 100 elements:

```
m.Data(120) = x;
```

If you need to expand the size of the mapped data region, first extend the map by updating the `Format` or `Repeat` property of the `memmapfile` object to reflect the new structure of the data in the mapped file.

Methods of the memmapfile Class

You can use the following methods on objects constructed from the `memmapfile` class.

Syntax	Description
`disp`	Displays properties of the object. The display does not include the object's name.
`get(obj)`	Returns the values of all properties of the `memmapfile` object in a structure array.
`get(obj, property)`	Returns the value of the specified property. `property` can be a string or cell array of strings, each containing a property name.

Using the disp Method

Use the `disp` method to display all properties of a `memmapfile` object. The text displayed includes only the property value, and not the object name or the MATLAB response string, `ans =`.

Construct object `m`:

```
m = memmapfile('records.dat',        ...
      'Offset', 2048,                ...
      'Format', {                    ...
         'int16'  [2 2] 'model';     ...
         'uint32' [1 1] 'serialno';  ...
         'single' [1 3] 'expenses'});
```

and display all of its properties:

```
disp(m)
    Filename: 'd:\matlab\mfiles\records.dat'
    Writable: false
      Offset: 2048
      Format: {'int16' [2 2] 'model'
               'uint32' [1 1] 'serialno'
               'single' [1 3] 'expenses'}
      Repeat: Inf
```

```
    Data: 16581x1 struct array with fields:
        model
     serialno
     expenses
```

Using the get Method

You can use the `get` method of the `memmapfile` class to return information on any or all of the object's properties. Specify one or more property names to get the values of specific properties.

This example returns the values of the `Offset`, `Repeat`, and `Format` properties for a `memmapfile` object. Use the `get` method to return the specified property values in a 1-by-3 cell array, `m_props`:

```
m_props = get(m, {'Offset', 'Repeat', 'Format'})
m_props =
    [2048]    [Inf]    {3x3 cell}

m_props{3}
ans =
    'int16'     [1x2 double]    'model'
    'uint32'    [1x2 double]    'serialno'
    'single'    [1x2 double]    'expenses'
```

You can also choose to use the `objname.property` syntax:

```
m_props = {m.Offset, m.Repeat, m.Format}
m_props =
    [2048]    [Inf]    {3x3 cell}
```

To return the values for all properties with `get`, pass just the object name:

```
get(m)
    Filename: 'd:\matlab\mfiles\records.dat'
    Writable: 0
      Offset: 2048
      Format: {3x3 cell}
      Repeat: Inf
        Data: [16581x1 struct]
```

Deleting a Memory Map

It is not necessary to explicitly call a destructor method to clear a `memmapfile` object from memory when you no longer need it. MATLAB calls the destructor for you whenever you do any of the following:

- Reassign another value to the `memmapfile` object's variable
- Clear the object's variable from memory
- Exit the function scope in which the object was created

The Effect of Shared Data Copies On Performance

When you assign the `Data` field of the `memmapfile` object to a variable, MATLAB makes a shared data copy of the mapped data. This is very efficient as no memory actually gets copied. In the following statement, `memdat` is a shared data copy of the data mapped from the file:

```
memdat = m.Data;
```

When you finish using the mapped data, make sure to clear any variables that shared data with the mapped file before clearing the object itself. If you clear the object first, then the sharing of data between the file and dependent variables is broken, and the data assigned to such variables must be copied into memory before the object is destroyed. If access to the mapped file was over a network, then copying this data to local memory can take considerable time. So, if the statement shown above assigns data to the variable `memdat`, you should be sure to clear `memdat` before clearing `m` when you are finished with the object.

Note Keep in mind that the `memmapfile` object can be cleared in any of the three ways described under "Deleting a Memory Map" on page 6-58.

Memory-Mapping Demo

In this demonstration, two separate MATLAB processes communicate with each other by writing and reading from a shared file. They share the file by mapping part of their memory space to a common location in the file. A write operation to the memory map belonging to the first process can be read from the map belonging to the second, and vice versa.

One MATLAB process (running `send.m`) writes a message to the file via its memory map. It also writes the length of the message to byte 1 in the file, which serves as a means of notifying the other process that a message is available. The second process (running `answer.m`) monitors byte 1 and, upon seeing it set, displays the received message, puts it into uppercase, and echoes the message back to the sender.

The send Function

This function prompts you to enter a string and then, using memory-mapping, passes the string to another instance of MATLAB that is running the `answer` function.

Copy the `send` and `answer` functions to files `send.m` and `answer.m` in your current working directory. Begin the demonstration by calling `send` with no inputs. Next, start a second MATLAB session on the same machine, and call the `answer` function in this session. To exit, press **Enter**.

```
function send
% Interactively send a message to ANSWER using memmapfile class.

filename = fullfile(tempdir, 'talk_answer.dat');

% Create the communications file if it is not already there.
if ~exist(filename, 'file')
    [f, msg] = fopen(filename, 'wb');
    if f ~= -1
        fwrite(f, zeros(1,256), 'uint8');
        fclose(f);
    else
        error('MATLAB:demo:send:cannotOpenFile', ...
              'Cannot open file "%s": %s.', filename, msg);
    end
end

% Memory map the file.
m = memmapfile(filename, 'Writable', true, 'Format', 'uint8');

while true
    % Set first byte to zero, indicating a message is not
```

```
        % yet ready.
        m.Data(1) = 0;

        str = input('Enter send string (or RETURN to end): ', 's');

        len = length(str);
        if (len == 0)
            disp('Terminating SEND function.')
            break;
        end

        str = str(1:min(len, 255));  % Message limited to 255 chars.

        % Update the file via the memory map.
        m.Data(2:len+1) = str;
        m.Data(1)=len;

        % Wait until the first byte is set back to zero,
        % indicating that a response is available.
        while (m.Data(1) ~= 0)
            pause(.25);
        end

        % Display the response.
        disp('response from ANSWER is:')
        disp(char(m.Data(2:len+1))')
    end
```

The answer Function

The `answer` function starts a server that, using memory-mapping, watches for a message from `send`. When the message is received, `answer` replaces the message with an uppercase version of it, and sends this new message back to `send`.

To use `answer`, call it with no inputs.

```
function answer
% Respond to SEND using memmapfile class.
```

```
disp('ANSWER server is awaiting message');

filename = fullfile(tempdir, 'talk_answer.dat');

% Create the communications file if it is not already there.
if ~exist(filename, 'file')
    [f, msg] = fopen(filename, 'wb');
    if f ~= -1
        fwrite(f, zeros(1,256), 'uint8');
        fclose(f);
    else
        error('MATLAB:demo:answer:cannotOpenFile', ...
              'Cannot open file "%s": %s.', filename, msg);
    end
end

% Memory map the file.
m = memmapfile(filename, 'Writable', true, 'Format', 'uint8');

while true
    % Wait till first byte is not zero.
    while m.Data(1) == 0
        pause(.25);
    end

    % The first byte now contains the length of the message.
    % Get it from m.
    msg = char(m.Data(2:1+m.Data(1)))';

    % Display the message.
    disp('Received message from SEND:')
    disp(msg)

    % Transform the message to all uppercase.
    m.Data(2:1+m.Data(1)) = upper(msg);

    % Signal to SEND that the response is ready.
    m.Data(1) = 0;
end
```

Running the Demo

Here is what the demonstration looks like when it is run. First, start two separate MATLAB sessions on the same computer system. Call the `send` function in one and the `answer` function in the other to create a map in each of the processes' memory to the common file:

```
% Run SEND in the first MATLAB session.
send
Enter send string (or RETURN to end):

% Run ANSWER in the second MATLAB session.
answer
ANSWER server is awaiting message
```

Next, enter a message at the prompt displayed by the `send` function. MATLAB writes the message to the shared file. The second MATLAB session, running the `answer` function, loops on byte 1 of the shared file and, when the byte is written by `send`, `answer` reads the message from the file via its memory map. The `answer` function then puts the message into uppercase and writes it back to the file, and `send` (waiting for a reply) reads the message and displays it:

```
% SEND writes a message and reads the uppercase reply.
Hello. Is there anybody out there?
response from ANSWER is:
HELLO.  IS THERE ANYBODY OUT THERE?
Enter send string (or RETURN to end):

% ANSWER reads the message from SEND.
Received message from SEND:
Hello.  Is there anybody out there?
```

`send` writes a second message to the file. `answer` reads it, put it into uppercase, and then writes the message to the file:

```
% SEND writes a second message to the shared file.
I received your reply.
response from ANSWER is:
I RECEIVED YOUR REPLY.
Enter send string (or RETURN to end): <Enter>
```

```
Terminating SEND function.

% ANSWER reads the second message.
Received message from SEND:
I received your reply.
```

Exporting Data to MAT-Files

In this section...

MAT-Files

MAT-files are double-precision, binary, MATLAB format files. They can be created on one machine and later read by MATLAB on another machine with a different floating-point format, retaining as much accuracy and range as the different formats allow. They can also be manipulated by other programs external to MATLAB.

This section explains how to save the variables in your MATLAB session to a binary file called a MAT-file. The next section explains how to load them back into your MATLAB workspace.

Using the save Function

To export workspace variables to a binary or ASCII file, use the `save` function. You can save all variables from the workspace in a single operation (if you omit the filename, MATLAB uses the name `matlab.mat`):

```
save filename
```

or save just those variables that you specify:

```
save filename var1 var2 ... varN
```

Use the wildcard character (*) in the variable name to save those variables that match a specific pattern. For example, the following command saves all variables that start with `str`.

```
save strinfo str*
```

Use `whos -file` to examine what has been written to the MAT-file:

```
whos -file strinfo
  Name           Size                    Bytes  Class

  str2           1x15                       30  char array
  strarray       2x5                       678  cell array
  strlen         1x1                         8  double array
```

Saving Structures

When saving a MATLAB structure, you have the option of saving the entire structure, saving each structure field as an individual variable in the MAT-file, or saving specific fields as individual variables.

For structure `S`,

```
S.a = 12.7;  S.b = {'abc', [4 5; 6 7]};  S.c = 'Hello!';
```

Save the entire structure to `newstruct.mat` with the usual syntax:

```
save newstruct.mat S;

whos -file newstruct
  Name      Size                   Bytes  Class

  S         1x1                      550  struct array
```

Save the fields individually with the `-struct` option:

```
save newstruct.mat -struct S;

whos -file newstruct
```

```
  Name      Size                    Bytes  Class

  a         1x1                         8  double array
  b         1x2                       158  cell array
  c         1x6                        12  char array
```

Or save only selected fields using `-struct` and specifying each field name:

```
save newstruct.mat -struct S a c;

whos -file newstruct
  Name      Size                    Bytes  Class

  a         1x1                         8  double array
  c         1x6                        12  char array
```

Appending to an Existing File

You can add new variables to those already stored in an existing MAT-file by using `save -append`. When you append to a MAT-file, MATLAB first looks in the designated file for each variable name specified in the argument list, or for all variables if no specific variable names are specified. Based on that information, MATLAB does both of the following:

- For each variable that already exists in the MAT-file, MATLAB overwrites its saved value with the new value taken from the workspace.
- For each variable not found in the MAT-file, MATLAB adds that variable to the file and stores its value from the workspace.

Note Saving with the `-append` option does not append additional elements to any arrays that are already saved in the MAT-file.

Data Compression

MATLAB compresses the data that you save to a MAT-file. Data compression can save you a significant amount of storage space when you are working with large files or working over a network.

Data compression is optional, however, and you can disable it either for an individual `save` operation, or for all of your MATLAB sessions. Use the `-v6` option with the `save` function to turn off compression on a per-command basis:

```
save filename -v6
```

To disable data compression for all of your MATLAB sessions, open the **Preferences** dialog, select **General** and then **MAT-Files**, and click the option that is equivalent to the command `save -v6`. See General Preferences for MATLAB in the Desktop Tools and Development Environment documentation for more information.

Note You cannot read a compressed MAT-file with MATLAB versions earlier than Version 7. To write a MAT-file that you will be able to read with one of these versions, save to the file with data compression disabled.

Information returned by the command `whos -file` is independent of whether the variables in that file are compressed or not. The byte counts returned by this command represent the number of bytes data occupies in the MATLAB workspace, and not in the file the data was saved to.

Evaluating When to Compress

You should consider both data set size and the type of data being saved when deciding whether or not to compress the data you save to a file. The benefits of data compression are greater when saving large data sets (over 3 MB), and are usually negligible with smaller data sets. Data that has repeating patterns or more consistent values compresses better than random data. Compressing data that has a random pattern is not recommended as it slows down the performance of `save` and `load` significantly, and offers little benefit in return.

In general, data compression and decompression slows down all `save` and some `load` operations to some extent. In most cases, however, the resulting reduction in file size is worth the additional time spent compressing or decompressing. Because loading is typically done more frequently than saving, `load` is considered to be the most critical of the two operations. Up to a certain threshold (relative to the size of the uncompressed MAT-file), loading a compressed MAT-File is slightly slower than loading an uncompressed

file containing the same data. Beyond that threshold, however, loading the compressed file is *faster*.

For example, say that you have a block of data that takes up 100 MB in memory, and this data has been saved to both a 10 MB compressed file and a 100 MB uncompressed file. When you load each of these files back into the MATLAB workspace, the first 10 MB of data takes the same amount of time to load for each file. Loading the remaining 90 MB from the uncompressed file will take 9 times as long as the first 10 MB, while all that remains to be done with the compressed file is to decompress the data, and this takes a relatively short amount of time.

The loading size threshold is lower for network files, and also varies depending on the type of computer being used. Network users loading compressed MAT-files generally see faster load times than when loading uncompressed files, and at smaller data sizes than users loading the same files locally.

Note Compression and decompression during `save` and `load` is done transparently without the use of temporary files on disk. This is of significance to large dataset users in particular.

Unicode Character Encoding

MATLAB saves character data to a MAT-file using Unicode character encoding. As with data compression, Unicode character encoding is optional. If you disable it, MATLAB writes the MAT-file using the default encoding for your system. To disable Unicode character encoding on a per-command basis, use the `-v6` option with the `save` function:

```
save filename -v6
```

To disable Unicode character encoding for all of your MATLAB sessions, open the **Preferences** dialog, select **General** and then **MAT-Files**, and click the option that is equivalent to the command `save -v6`. See General Preferences for MATLAB in the Desktop Tools and Development Environment documentation for more information.

When writing character data to a non-HDF5-based MAT-file using Unicode encoding (the default), MATLAB checks if the data is 7-bit ASCII. If it is,

MATLAB writes the 7-bit ASCII character data to the MAT-file using 8 bits per character (UTF-8 format), thus minimizing the size of the resulting file. Any character data that is not 7-bit ASCII is written in 16-bit Unicode form (UTF-16). This algorithm operates on a per-string basis.

Note You cannot read a Unicode encoded MAT-file with MATLAB versions earlier than Version 7. To write a MAT-file that you will be able to read with one of these versions, save to the file with Unicode character encoding disabled.

For more information on how MATLAB saves specific ASCII data formats, and on preventing loss or corruption of character data, see "Writing Character Data" in the MATLAB External Interfaces documentation.

Optional Output Formats

You can choose from any of the following formats for your output file. If you do not specify a format, MATLAB uses the binary MAT-file format.

Output File Format	Command
Binary MAT-file (default)	`save` *`filename`*
8-digit ASCII	`save` *`filename`* `-ascii`
8-digit ASCII, tab delimited	`save` *`filename`* `-ascii -tabs`
16-digit ASCII	`save` *`filename`* `-ascii -double`
16-digit ASCII, tab delimited	`save` *`filename`* `-ascii -double -tabs`
MATLAB Version 4 compatible	`save` *`filename`* `-v4`

Saving in ASCII Format

When saving in any of the ASCII formats, consider the following:

- Each variable to be saved must be either a two-dimensional double array or a two-dimensional character array. Saving a complex double array causes the imaginary part of the data to be lost, as MATLAB cannot load nonnumeric data (`'i'`).

- To read the file with the MATLAB `load` function, make sure all the variables have the same number of columns. If you are using a program other than MATLAB to read the saved data, this restriction can be relaxed.
- Each MATLAB character in a character array is converted to a floating-point number equal to its internal ASCII code and written out as a floating-point number string. There is no information in the saved file that indicates whether the value was originally a number or a character.
- The values of all variables saved merge into a single variable that takes the name of the ASCII file (minus any extension). Therefore, it is advisable to save only one variable at a time.

Saving in Version 4 Format

With the `-v4` option, you can save only those data constructs that are compatible with MATLAB Version 4. Therefore, you cannot save structures, cell arrays, multidimensional arrays, or objects. Variable names cannot exceed 19 characters in length. In addition, you must use filenames that are supported by MATLAB Version 4.

Storage Requirements

The binary formats used by `save` depend on the size and type of each array. Arrays with any noninteger entries and arrays with 10,000 or fewer elements are saved in floating-point formats requiring 8 bytes per real element. Arrays with all integer entries and more than 10,000 elements are saved in the formats shown, requiring fewer bytes per element.

Element Range	Bytes per Element
0 to 255	1
0 to 65535	2
-32767 to 32767	2
-2^{31} to $2^{31}-1$	4
Other	8

Saving From External Programs

The *MATLAB External Interfaces* documentation provides details on reading and writing MAT-files from external C or Fortran programs. It is important to use recommended access methods, rather than rely upon the specific MAT-file format, which is likely to change in the future.

Importing Data From MAT-Files

In this section...

Using the load Function

To import variables from a binary or ASCII file on your disk to your workspace, use the `load` function. You can load all variables from the workspace in a single operation (if you omit the filename, MATLAB loads from file `matlab.mat`):

```
load filename
```

or load just those variables that you specify:

```
load filename var1 var2 ... varN
```

Use the wildcard character (*) in the variable name to load those variables that match a specific pattern. (This works for MAT-files only.) For example, the following command loads all variables that start with `str` from file `strinfo.mat`:

```
load strinfo str*
```

Caution When you import data into the MATLAB workspace, it overwrites any existing variable in the workspace with the same name.

Previewing MAT-File Contents

To see what variables are stored in a MAT-file before actually loading the file into your workspace, use `whos -file filename`. This command returns the name, dimensions, size, and data type of all variables in the specified MAT-file.

You can use `whos -file` on binary MAT-files only:

```
whos -file mydata.mat
  Name           Size             Bytes  Class

  javArray      10x1                     java.lang.Double[][]
  spArray        5x5                84  double array (sparse)
  strArray       2x5               678  cell array
  x              3x2x2              96  double array
  y              4x5              1230  cell array
```

Loading Into a Structure

To load MAT-file data into a MATLAB structure, specify an output variable in your `load` command. This example reads the data in `mydata.mat` into the fields of structure `S`:

```
S = load('mydata.mat')
S =
           x: [3x2x2 double]
           y: {4x5 cell}
     spArray: [5x5 double]
    strArray: {2x5 cell}
    javArray: [10x1 java.lang.Double[][]]

whos S
  Name      Size                    Bytes  Class

  S         1x1                      2840  struct array
```

Loading Binary Data

MAT-files are double-precision binary MATLAB format files created by the `save` function and readable by the `load` function. They can be created on one machine and later read by MATLAB on another machine with a different floating-point format, retaining as much accuracy and range as the different formats allow. They can also be manipulated by other programs, external to MATLAB.

MAT-files can contain data in an uncompressed or a compressed form, or both. MATLAB knows which variables in the file have been compressed by looking at a tag that it attaches to each variable during the `save` operation. When

loading data from a MAT-file into the workspace, MATLAB automatically handles the decompression of the appropriate data.

The External Interface libraries contain C- and Fortran-callable routines to read and write MAT-files from external programs.

Loading ASCII Data

ASCII files must be organized as a rectangular table of numbers, with each number in a row separated by a blank, comma, or tab character, and with an equal number of elements in each row. MATLAB generates an error if the number of values differs between any two rows. ASCII files can contain MATLAB comments (lines that begin with `%`).

MATLAB returns all the data in the file as a single two-dimensional array of type `double`. The number of rows in the array is equal to the number of lines in the file, and the number of columns is equal to the number of values on a line.

In the workspace, MATLAB assigns the array to a variable named after the file being loaded (minus any file extension). For example, the command

```
load mydata.dat
```

reads all of the data from `mydata.dat` into the MATLAB workspace as a single array, and assigns it to a variable called `mydata`. In naming the variable, `load` precedes any leading underscores or digits in `filename` with an `X` and replaces any other nonalphabetic characters with underscores.

For example, the command

```
load 10-May-data.dat
```

assigns the data in file `10-May-data.dat` to a new workspace variable called `X10_May_data`.

Importing Text Data

In this section...

Caution When you import data into the MATLAB workspace, you overwrite any existing variable in the workspace with the same name.

The MATLAB Import Wizard

The easiest way to import data into MATLAB is to use the Import Wizard. You do not need to know the format of the data to use this tool. You simply specify the file that contains the data and the Import Wizard processes the file contents automatically.

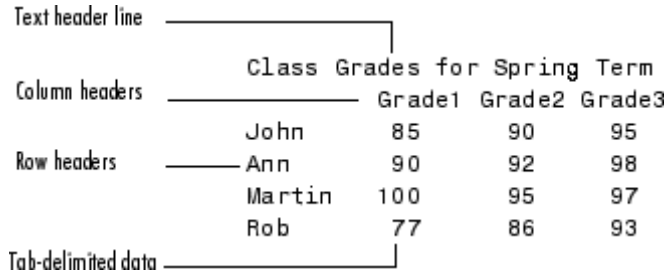
For more information, see "Using the Import Wizard" on page 6-11.

Using Import Functions with Text Data

To import text data from the command line or in an M-file, you must use one of the MATLAB import functions. Your choice of function depends on how the data in the text file is formatted.

The text data must be formatted in a uniform pattern of rows and columns, using a text character, called a *delimiter* or *column separator*, to separate each data item. The delimiter can be a space, comma, semicolon, tab, or any other character. The individual data items can be alphabetic or numeric characters or a mix of both.

The text file can also contain one or more lines of text, called *header lines*, or can use text headers to label each column or row. The following example illustrates a tab-delimited text file with header text and row and column headers.



To find out how your data is formatted, view it in a text editor. After you determine the format, find the sample in the table below that most closely resembles the format of your data. Then read the topic referred to in the table for information on how to import that format.

Table 6-1 ASCII Data File Formats

Data Format Sample	File Extension	Description

`1 2 3 4 5`
`6 7 8 9 10`
	`.txt`
	`.dat`
	or other
		See "Importing Numeric Text Data" on page 6-78 or "Using the Import Wizard" on page 6-11 for information.

`1; 2; 3; 4; 5`
`6; 7; 8; 9; 10`
`or`
`1, 2, 3, 4, 5`
`6, 7, 8, 9, 10`
	`.txt`
	`.dat`
	`.csv`
	or other
		See "Importing Delimited ASCII Data Files" on page 6-79 or "Using the Import Wizard" on page 6-11 for information.

Table 6-1 ASCII Data File Formats (Continued)

Data Format Sample	File Extension	Description

`Ann Type1 12.34 45 Yes`
`Joe Type2 45.67 67 No`
	`.txt`
	`.dat`
	or other
		See "Importing Mixed Alphabetic and Numeric Data" on page 6-81 for information.

`Grade1 Grade2 Grade3`
`91.5  89.2  77.3`
`88.0  67.8  91.0`
`67.3  78.1  92.5`
	`.txt`
	`.dat`
	or other
		See "Importing Numeric Data with Text Headers" on page 6-80 or "Using the Import Wizard" on page 6-11 for information.

If you are familiar with MATLAB import functions but are not sure when to use them, see the following table, which compares the features of each function.

Table 6-2 ASCII Data Import Function Features

Function	Data Type	Delimiters	Number of Return Values	Notes
`csvread`	Numeric data	Commas only	One	Primarily used with spreadsheet data. See "Working with Spreadsheets" on page 6-98.
`dlmread`	Numeric data	Any character	One	Flexible and easy to use.

Table 6-2 ASCII Data Import Function Features (Continued)

Function	Data Type	Delimiters	Number of Return Values	Notes
`fscanf`	Alphabetic and numeric; however, both types returned in a single return variable	Any character	One	Part of low-level file I/O routines. Requires use of `fopen` to obtain file identifier and `fclose` after read.
`load`	Numeric data	Spaces only	One	Easy to use. Use the functional form of `load` to specify the name of the output variable.
`textread`	Alphabetic and numeric	Any character	Multiple values in cell arrays	Flexible, powerful, and easy to use. Use format string to specify conversions.
`textscan`	Alphabetic and numeric	Any character	Multiple values returned to one cell array	More flexible than `textread`. Also more format options.

Importing Numeric Text Data

If your data file contains only numeric data, you can use many of the MATLAB import functions (listed in ASCII Data Import Function Features on page 6-77), depending on how the data is delimited. If the data is rectangular, that is, each row has the same number of elements, the simplest command to use is the `load` command. (The `load` function can also be used to import MAT-files, the MATLAB binary format for saving the workspace.)

For example, the file named `my_data.txt` contains two rows of numbers delimited by space characters:

```
1 2 3 4 5
6 7 8 9 10
```

When you use `load` as a command, it imports the data and creates a variable in the workspace with the same name as the filename, minus the file extension:

```
load my_data.txt;
whos
   Name          Size         Bytes   Class

   my_data       2x5           80    double array

my_data

my_data =
    1   2   3   4   5
    6   7   8   9   10
```

If you want to name the workspace variable something other than the filename, use the functional form of `load`. In the following example, the data from `my_data.txt` is loaded into the workspace variable `A`:

```
A = load('my_data.txt');
```

Importing Delimited ASCII Data Files

If your data file uses a character other than a space as a delimiter, you have a choice of several import functions you can use. (See ASCII Data Import Function Features on page 6-77 for a complete list.) The simplest to use is the `dlmread` function.

For example, consider a file named `ph.dat` whose contents are separated by semicolons:

```
7.2;8.5;6.2;6.6
5.4;9.2;8.1;7.2
```

To read the entire contents of this file into an array named `A`, enter

```
A = dlmread('ph.dat', ';');
```

You specify the delimiter used in the data file as the second argument to `dlmread`. Note that, even though the last items in each row are not followed by a delimiter, `dlmread` can still process the file correctly. `dlmread` ignores space characters between data elements. So, the preceding `dlmread` command works even if the contents of `ph.dat` are

```
7.2;   8.5;       6.2;6.6
5.4;   9.2   ;8.1;7.2
```

Importing Numeric Data with Text Headers

To import an ASCII data file that contains text headers, use the `textscan` function, specifying the `headerlines` parameter. `textscan` accepts a set of predefined parameters that control various aspects of the conversion. (For a complete list of these parameters, see the `textscan` reference page.) Using the `headerlines` parameter, you can specify the number of lines at the head of the file that `textscan` should ignore.

For example, the file `grades.dat` contains formatted numeric data with a one-line text header:

```
Grade1 Grade2 Grade3
  78.8   55.9   45.9
  99.5   66.8   78.0
  89.5   77.0   56.7
```

To import this data, first open the file and then use this `textscan` command to read the contents:

```
fid = fopen('grades.dat', 'r');
grades = textscan(fid, '%f %f %f', 3, 'headerlines', 1);

grades{:}
ans =
   78.8000
   99.5000
   89.5000

ans =
   55.9000
```

```
    66.8000
    77.0000

ans =
    45.9000
    78.0000
    56.7000

fclose(fid);
```

Importing Mixed Alphabetic and Numeric Data

If your data file contains a mix of alphabetic and numeric ASCII data, use the `textscan` or `textread` function to import the data. `textscan` returns its output in a single cell array, while `textread` returns its output in separate variables and you can specify the data type of each variable. The `textscan` function offers better performance than `textread`, making it a better choice when reading large files.

This example uses `textread` to import the file `mydata.dat` that contains a mix of alphabetic and numeric data:

```
Sally    Type1 12.34 45 Yes
Larry    Type2 34.56 54 Yes
Tommy    Type1 67.89 23 No
```

Note To read an ASCII data file that contains numeric data with text column headers, see "Importing Numeric Data with Text Headers" on page 6-80.

To read the entire contents of the file `mydata.dat` into the workspace, specify the name of the data file and the format string as arguments to `textread`. In the format string, you include conversion specifiers that define how you want each data item to be interpreted. For example, specify `%s` for string data, `%f` for floating-point data, and so on. (For a complete list of format specifiers, see the `textread` reference page.)

For each conversion specifier in your format string, you must specify a separate output variable. `textread` processes each data item in the file as specified in the format string and puts the value in the output variable. The

number of output variables must match the number of conversion specifiers in the format string.

In this example, `textread` reads the file `mydata.dat`, applying the format string to each line in the file until the end of the file:

```
[names, types, x, y, answer] = ...
   textread('mydata.dat', '%s %s %f %d %s', 3)
names =
    'Sally'
    'Larry'
    'Tommy'

types =
    'Type1'
    'Type2'
    'Type1'

x =
   12.3400
   34.5600
   67.8900

y =
    45
    54
    23

answer =
    'Yes'
    'Yes'
    'No'
```

If your data uses a character other than a space as a delimiter, you must use the `textread` parameter `'delimiter'` to specify the delimiter. For example, if the file `mydata.dat` used a semicolon as a delimiter, you would use this command:

```
[names, types, x, y, answer]= ...
   textread('mydata.dat', '%s %s %f %d %s', 'delimiter', ';')
```

See the `textread` reference page for more information about these optional parameters.

Importing from XML Documents

With the `xmlread` function, you can read from a given URL or file, generating a Document Object Model (DOM) node to represent the parsed document.

MATLAB also provides these other XML functions:

- `xmlwrite` — Serializes a Document Object Model node to a file
- `xslt` — Transforms an XML document using an XSLT engine

See the reference pages for these functions for more information.

Exporting Text Data

In this section...

Overview

This section describes how to use MATLAB functions to export data in several common ASCII formats. For example, you can use these functions to export a MATLAB matrix as a text file where the rows and columns are represented as space-separated, numeric values. The function you use depends on the amount of data you want to export and its format. Topics covered include

If you are not sure which section describes your data, find the sample in the table below that most nearly matches the data format you want to create. Then read the section referred to in the table.

If you are familiar with MATLAB export functions but are not sure when to use them, see ASCII Data Export Function Features on page 6-85, which compares the features of each function.

Note If C or Fortran routines for writing data files in the form needed by other applications exist, create a MEX-file to write the data. See the *MATLAB External Interfaces* documentation for more information.

Table 6-3 ASCII Data File Formats

Data Format Sample	MATLAB Export Function
`1 2 3 4 5 6` `7 8 9 10`	See "Exporting Delimited ASCII Data Files" on page 6-86 and "Using the diary Function to Export Data" on page 6-87 for information about these options.

`1; 2; 3; 4;`
`5; 6; 7; 8;`
`9; 10;`
	See "Exporting Delimited ASCII Data Files" on page 6-86 for information. The example shows a semicolon-delimited file, but you can specify another character as the delimiter.

Table 6-4 ASCII Data Export Function Features

Function	Use With	Delimiters	Notes
`csvwrite`	Numeric data	Commas only	Primarily used with spreadsheet data. See "Working with Spreadsheets" on page 6-98.
`diary`	Numeric data or cell array	Spaces only	Can be used for small arrays. Requires editing of data file to remove extraneous text.
`dlmwrite`	Numeric data	Any character	Easy to use, flexible.

Table 6-4 ASCII Data Export Function Features (Continued)

Function	Use With	Delimiters	Notes
`fprintf`	Alphabetic and numeric data	Any character	Part of low-level file I/O routines. This function is the most flexible but also the most difficult to use. You must use `fopen` to obtain a file identifier before writing the data and `fclose` to close the file after writing the data.
`save`	Numeric data	Tabs or spaces	Easy to use; output values are high precision.

Exporting Delimited ASCII Data Files

To export an array as a delimited ASCII data file, you can use either the `save` function, specifying the `-ASCII` qualifier, or the `dlmwrite` function. The `save` function is easy to use; however, the `dlmwrite` function provides more flexibility, allowing you to specify any character as a delimiter and to export subsets of an array by specifying a range of values.

Using the save Function

To export the array `A`,

```
A = [ 1 2 3 4 ; 5 6 7 8 ];
```

use the `save` function, as follows:

```
save my_data.out A -ASCII
```

If you view the created file in a text editor, it looks like this:

```
1.0000000e+000  2.0000000e+000  3.0000000e+000  4.0000000e+000
5.0000000e+000  6.0000000e+000  7.0000000e+000  8.0000000e+000
```

By default, `save` uses spaces as delimiters but you can use tabs instead of spaces by specifying the `-tabs` option.

When you use `save` to write a character array to an ASCII file, it writes the ASCII equivalent of the characters to the file. If you write the character string `'hello'` to a file, save writes the values

```
104 101 108 108 111
```

Using the dlmwrite Function

To export an array in ASCII format and specify the delimiter used in the file, use the `dlmwrite` function.

For example, to export the array `A`,

```
A = [ 1 2 3 4 ; 5 6 7 8 ];
```

as an ASCII data file that uses semicolons as a delimiter, use this command:

```
dlmwrite('my_data.out',A, ';')
```

If you view the created file in a text editor, it looks like this:

```
1;2;3;4
5;6;7;8
```

Note that `dlmwrite` does not insert delimiters at the end of rows.

By default, if you do not specify a delimiter, `dlmwrite` uses a comma as a delimiter. You can specify a space (`' '`) as a delimiter or, if you specify empty quotes (`''`), no delimiter.

Using the diary Function to Export Data

To export small numeric arrays or cell arrays, you can use the `diary` function. `diary` creates a verbatim copy of your MATLAB session in a disk file (excluding graphics).

For example, if you have the array `A` in your workspace,

```
A = [ 1 2 3 4; 5 6 7 8 ];
```

execute these commands at the MATLAB prompt to export this array using `diary`:

1. Turn on the `diary` function. You can optionally name the output file `diary` creates.

   ```
   diary my_data.out
   ```

2. Display the contents of the array you want to export. This example displays the array `A`. You could also display a cell array or other MATLAB data type.

   ```
   A =
       1     2     3     4
       5     6     7     8
   ```

3. Turn off the `diary` function.

   ```
   diary off
   ```

   `diary` creates the file `my_data.out` and records all the commands executed in the MATLAB session until it is turned off.

   ```
   A =

        1     2     3     4
        5     6     7     8

   diary off
   ```

4. Open the `diary` file `my_data.out` in a text editor and remove all the extraneous text.

Exporting to XML Documents

With the `xmlwrite` function, you can serialize a Document Object Model (DOM) node to an XML file.

MATLAB also provides these other XML functions:

- `xmlread` — Imports from a given URL or file to a Document Object Model node

- `xslt` — Transforms an XML document using an XSLT engine

See the reference pages for these functions for more information.

Working with Graphics Files

In this section...

Getting Information About Graphics Files

If you have a file in a standard graphics format, use the `imfinfo` function to get information about its contents. The `imfinfo` function returns a structure containing information about the file. The fields in the structure vary with the file format but `imfinfo` always returns some basic information including filename, last modification date, file size, and format.

This example returns information about a file in Joint Photographic Experts Group (JPEG) format:

```
info = imfinfo('ngc6543a.jpg')

info =

           Filename: [1x57 char]
        FileModDate: '01-Oct-1996 16:19:44'
           FileSize: 27387

```

Importing Graphics Data

To import data into the MATLAB workspace from a graphics file, use the `imread` function. Using this function, you can import data from files in many standard file formats, including the Tagged Image File Format (TIFF), Graphics Interchange Format (GIF), Joint Photographic Experts Group (JPEG), and Portable Network Graphics (PNG) formats. For a complete list of supported formats, see the `imread` reference page.

This example reads the image data stored in a file in JPEG format into the MATLAB workspace as the array `I`:

```
I = imread('ngc6543a.jpg');
```

`imread` represents the image in the workspace as a multidimensional array of class `uint8`. The dimensions of the array depend on the format of the data. For example, `imread` uses three dimensions to represent RGB color images:

```
whos I
  Name      Size                          Bytes  Class

  I       650x600x3                     1170000  uint8 array

Grand total is 1170000 elements using 1170000 bytes
```

Exporting Graphics Data

To export data from the MATLAB workspace using one of the standard graphics file formats, use the `imwrite` function. Using this function, you can export data in formats such as the Tagged Image File Format (TIFF), Joint Photographic Experts Group (JPEG), and Portable Network Graphics (PNG). For a complete list of supported formats, see the `imwrite` reference page.

The following example writes a multidimensional array of `uint8` data `I` from the MATLAB workspace into a file in TIFF format. The class of the output image written to the file depends on the format specified. For most formats, if the input array is of class `uint8`, `imwrite` outputs the data as 8-bit values. See the `imwrite` reference page for details.

```
whos I
  Name      Size                          Bytes  Class
```

```
  I       650x600x3                        1170000  uint8 array

Grand total is 1170000 elements using 1170000 bytes
imwrite(I, 'my_graphics_file.tif','tif');
```

Note `imwrite` supports different syntaxes for several of the standard formats. For example, with TIFF file format, you can specify the type of compression used to store the image. See the `imwrite` reference page for details.

Working with Audio and Video Data

In this section...

Getting Information About Audio/Video Files

MATLAB includes several functions that you can use to get information about files that contain audio data, video data, or both. Some work only with specific file formats. One function, the `mmfileinfo` function, can retrieve information about many file formats.

Format-Specific Functions

MATLAB includes several functions that return information about files that contain audio and video data in specific formats.

- `aufinfo` — Returns a text description of the contents of a sound (AU) file
- `aviinfo` — Returns a structure containing information about the contents of an Audio/Video Interleaved (AVI) file
- `wavfinfo` — Returns a text description of the contents of a sound (WAV) file

Using the General Multimedia Information Function

MATLAB also includes a general-purpose, audio/video file information function named `mmfileinfo`. The `mmfileinfo` function returns information about both the audio data in a file as well as the video data in the file, if present.

Note `mmfileinfo` can be used only on Windows systems.

Importing Audio/Video Data

MATLAB includes several functions that you can use to bring audio or video data into the MATLAB workspace. Some of these functions read audio or video data from files. Another way to import audio data into the MATLAB workspace is to record it using an audio input device, such as a microphone. The following sections describe

Reading Audio and Video Data from a File

MATLAB includes several functions for reading audio or video data from a file. These files are format-specific.

- `auread` — Returns sound data from a sound (AU) file
- `aviread` — Returns AVI data as a MATLAB movie
- `mmreader` — Returns AVI, MPG, or WMV video data
- `wavread` — Returns sound data from a sound (WAV) file

Note `mmreader` can be used only on Windows systems.

Recording Audio Data

To bring sound data into the MATLAB workspace by recording it from an audio input device, use the audio recorder object. This object represents the connection between MATLAB and an audio input device, such as a microphone, that is connected to your system. You use the `audiorecorder` function to create this object and then use methods and properties of the object to record the audio data.

On PCs running Windows, you can also use the `wavrecord` function to bring live audio data in WAV format into the MATLAB workspace.

Once you import audio data, MATLAB supports several ways to listen to the data. You can use an audio player object to play the audio data. Use the `audioplayer` function to create an audio player object.

You can also use the `sound` or `soundsc` function.

On PCs running Windows, you can use the `wavplay` function to listen to `.wav` files.

Exporting Audio/Video Data

MATLAB includes several functions that you can use to export audio or video data from the MATLAB workspace. These functions write audio data to a file using specific file formats. The following sections describe

- "Exporting Audio Data" on page 6-95
- "Exporting Video Data in AVI Format" on page 6-95

This section also provides an example of writing video data to a file in "Example: Creating an AVI file" on page 6-96.

Exporting Audio Data

In MATLAB, audio data is simply numeric data that you can export using standard MATLAB data export functions, such as `save`.

MATLAB also includes several functions that write audio data to files in specific file formats:

- `auwrite` — Exports sound data in AU file format
- `wavwrite` — Exports sound data in WAV file format

Exporting Video Data in AVI Format

You can export MATLAB video data as an Audio/Video Interleaved (AVI) file. To do this, you use the `avifile` function to create an `avifile` object. Once you have the object, you can use AVI file object methods and properties to control various aspects of the data export process.

For example, in MATLAB, you can save a sequence of graphs as a movie that can then be played back using the `movie` function. You can export a MATLAB movie by saving it in MAT-file format, like any other MATLAB workspace variable. However, anyone who wants to view your movie must have MATLAB. (For more information about MATLAB movies, see the Animation section in the MATLAB Graphics documentation.)

To export a sequence of MATLAB graphs in a format that does not require MATLAB for viewing, save the figures in Audio/Video Interleaved (AVI) format. AVI is a file format that allows animation and video clips to be played on a PC running Windows or on UNIX systems.

Note To convert an existing MATLAB movie into an AVI file, use the `movie2avi` function.

Example: Creating an AVI file

To export a sequence of MATLAB graphs as an AVI format movie, perform these steps:

1 Create an AVI file object, using the `avifile` function.

```
aviobj = avifile('mymovie.avi','fps',5);
```

AVI file objects support properties that let you control various characteristics of the AVI movie, such as colormap, compression, and quality. (See the `avifile` reference page for a complete list.) `avifile` uses default values for all properties, unless you specify a value. The example sets the value of the frames per second (`fps`) property.

2 Capture the sequence of graphs and put them into the AVI file, using the `addframe` function.

```
for k=1:25
    h = plot(fft(eye(k+16)));
    set(h,'EraseMode','xor');
    axis equal;
    frame = getframe(gca);
    aviobj = addframe(aviobj,frame);
```

```
end
```

The example uses a `for` loop to capture the series of graphs to be included in the movie. You typically use `addframe` to capture a sequence of graphs for AVI movies. However, because this particular MATLAB animation uses `XOR` graphics, you must call `getframe` to capture the graphs and then call `addframe` to add the captured frame to the movie.

3 Close the AVI file, using the `close` function.

```
aviobj = close(aviobj);
```

Working with Spreadsheets

In this section...

Microsoft Excel Spreadsheets

This section covers

See the `xlsfinfo`, `xlswrite`, and `xlsread` reference pages for more detailed information and examples.

Getting Information About the File

Use the `xlsfinfo` function to determine if a file contains a readable Microsoft Excel spreadsheet.

Inputs to `xlsfinfo` are

- Name of the spreadsheet file

Outputs from `xlsfinfo` are

- String `'Microsoft Excel Spreadsheet'` if the file contains an Excel worksheet readable with the `xlsread` function. Otherwise, it contains an empty string (`''`).
- Cell array of strings containing the names of each worksheet in the file.

Example — Querying an XLS File. This example returns information about spreadsheet file `tempdata.xls`:

```
[type, sheets] = xlsfinfo('tempdata.xls')
```

```
type =
Microsoft Excel Spreadsheet
sheets =
    'Locations'    'Rainfall'    'Temperatures'
```

Exporting to the File

Use the `xlswrite` function to export a matrix to an Excel spreadsheet file. With `xlswrite`, you can export data from the workspace to any worksheet in the file, and to any location within that worksheet.

Inputs to `xlswrite` are

- Name of the spreadsheet file
- Matrix to be exported
- Name of the worksheet to receive the data
- Range of cells on the worksheet in which to write the data

Outputs from `xlswrite` are

- Pass or fail status
- Any warning or error message generated along with its message identifier

Example — Writing To an XLS File. This example writes a mix of text and numeric data to the file `tempdata.xls`. Call `xlswrite`, specifying a worksheet labeled `Temperatures`, and the region within the worksheet to write the data to. The 4-by-2 matrix is written to the rectangular region that starts at cell `E1` in its upper-left corner:

```
d = {'Time', 'Temp'; 12 98; 13 99; 14 97}
d =
    'Time'    'Temp'
    [  12]    [  98]
    [  13]    [  99]
    [  14]    [  97]

xlswrite('tempdata.xls', d, 'Temperatures', 'E1');
```

Adding a New Worksheet. If the worksheet being written to does not already exist in the file, MATLAB displays the following warning:

```
Warning: Added specified worksheet.
```

You can disable these warnings with the command

```
warning off MATLAB:xlswrite:AddSheet
```

Importing from the File

Use `xlsread` to import a matrix from an Excel spreadsheet file into the MATLAB workspace. You can import data from any worksheet in the file, and from any location within that worksheet. You can also optionally have `xlsread` open an Excel window showing the file and then interactively select the worksheet and range of data to be read by the function.

Inputs to `xlsread` are

- Name of the spreadsheet file
- Matrix to be imported
- Name of the worksheet from which to read the data
- Range of cells on the worksheet from which to read the data
- Keyword that opens an Excel window, enabling you to interactively select the worksheet and range of data to read
- Keyword that imports using basic import mode

Three separate outputs from `xlsread` are

- Numeric data
- String data
- Any unprocessed cell content

Example — Reading from an XLS File. Continuing with the previous example, to import only the numeric data, use `xlsread` with a single return argument. `xlsread` ignores any leading row or column of text in the numeric result:

```
ndata = xlsread('tempdata.xls', 'Temperatures')
ndata =
    12    98
    13    99
    14    97
```

To import both numeric data and text data, specify two return values for `xlsread`:

```
[ndata, headertext] = xlsread('tempdata.xls', 'Temperatures')

headertext =
    'Time'    'Temp'

ndata =
    12    98
    13    99
    14    97
```

Lotus 123 Spreadsheets

This section covers

See the `wk1finfo`, `wk1write`, and `wk1read` reference pages for more detailed information and examples.

Getting Information About the File

Use the `wk1finfo` function to determine if a file contains a Lotus WK1 spreadsheet:

Inputs to `wk1finfo` are

- Name of the spreadsheet file

Outputs from `wk1finfo` are

- String 'WK1' if the file is a Lotus spreadsheet readable with the wk1read function. Otherwise, it contains an empty string ('').
- String 'Lotus 123 Spreadsheet'

Example — Querying a WK1 File. This example returns information about spreadsheet file matA.wk1:

```
[extens, type] = wk1finfo('matA.wk1')

extens =
   WK1
type =
   Lotus 123 Spreadsheet
```

Exporting to the File

Use the wk1write function to export a matrix to a Lotus spreadsheet file. You have the choice of positioning the matrix starting at the first row and column of the spreadsheet, or at any other location in the file.

To export to a specific location in the file, use the second syntax, indicating a zero-based starting row and column.

Inputs to wk1write are

- Name of the spreadsheet file
- Matrix to be exported
- Location in the file in which to write the data

Example — Writing to a WK1 File. This example exports an 8-by-8 matrix to spreadsheet file matA.wk1:

```
A = [1:8; 11:18; 21:28; 31:38; 41:48; 51:58; 61:68; 71:78];
A =
     1     2     3     4     5     6     7     8
    11    12    13    14    15    16    17    18
    21    22    23    24    25    26    27    28
    31    32    33    34    35    36    37    38
```

```
    41    42    43    44    45    46    47    48
    51    52    53    54    55    56    57    58
    61    62    63    64    65    66    67    68
    71    72    73    74    75    76    77    78

wk1write('matA.wk1', A);
```

Importing from the File

To import data from the spreadsheet into the MATLAB workspace, use `wk1read`. There are three ways to call `wk1read`. The first two shown here are similar to `wk1write`. The third enables you to select a range of values from the spreadsheet. You can specify the `range` argument with a one-based vector, spreadsheet notation (e.g., `'A1..B7'`), or using a named range (e.g., `'Sales'`).

Inputs to `wk1read` are

- Name of the spreadsheet file
- Spreadsheet location from which to read the data
- Range of cells from which to read the data

Outputs from `wk1read` are

- Requested data from the spreadsheet

Example — Reading from a WK1 File. Read in a limited block of the spreadsheet data by specifying the upper-left row and column of the block using zero-based indexing:

```
M = wk1read('matA.wk1', 3, 2)
M =
    33    34    35    36    37    38
    43    44    45    46    47    48
    53    54    55    56    57    58
    63    64    65    66    67    68
    73    74    75    76    77    78
```

Using Low-Level File I/O Functions

In this section...

Overview

MATLAB includes a set of low-level file I/O functions that are based on the I/O functions of the ANSI Standard C Library. If you know C, you are probably familiar with these routines.

To read or write data, perform these steps:

1. Open the file, using `fopen`. `fopen` returns a file identifier that you use with all the other low-level file I/O routines.
2. Operate on the file.
   a. Read binary data, using `fread`.
   b. Write binary data, using `fwrite`.
   c. Read text strings from a file line-by-line, using `fgets` or `fgetl`.
   d. Read formatted ASCII data, using `fscanf`.
   e. Write formatted ASCII data, using `fprintf`.
3. Close the file, using `fclose`.

This section also describes how these functions affect the current position in the file where read or write operations happen and how you can change the position in the file.

Note While the MATLAB file I/O commands are modeled on the C language I/O routines, in some ways their behavior is different. For example, the `fread` function is *vectorized*; that is, it continues reading until it encounters a text string or the end of file. These sections, and the MATLAB reference pages for these functions, highlight any differences in behavior.

Opening Files

Before reading or writing a text or binary file, you must open it with the `fopen` command.

```
fid = fopen('filename','permission')
```

Specifying the Permission String

The `permission` string specifies the kind of access to the file you require. Possible `permission` strings include

- `r` for reading only
- `w` for writing only
- `a` for appending only
- `r+` for both reading and writing

Note Systems such as Microsoft Windows that distinguish between text and binary files might require additional characters in the permission string, such as `'rb'` to open a binary file for reading.

Using the Returned File Identifier (fid)

If successful, `fopen` returns a nonnegative integer, called a *file identifier* (`fid`). You pass this value as an argument to the other I/O functions to access

the open file. For example, this `fopen` statement opens the data file named `penny.dat` for reading:

```
fid = fopen('penny.dat','r')
```

If `fopen` fails, for example if you try to open a file that does not exist, `fopen`

- Assigns `-1` to the file identifier.
- Assigns an error message to an optional second output argument. Note that the error messages are system dependent and are not provided for all errors on all systems. The function `ferror` can also provide information about errors.

Test the file identifier each time you open a file in your code. For example, this code loops until a readable filename is entered:

```
fid=0;
while fid < 1
   filename=input('Open file: ', 's');
   [fid,message] = fopen(filename, 'r');
   if fid == -1
     disp(message)
   end
end
```

When you run this code, if you specify a file that doesn't exist, such as `nofile.mat`, at the `Open file:` prompt, the results are

```
Open file: nofile.mat
Sorry. No help in figuring out the problem . . .
```

If you specify a file that does exist, such as `goodfile.mat`, the code example returns the file identifier, `fid`, and exits the loop.

```
Open file: goodfile.mat
```

Opening Temporary Files and Directories

The `tempdir` and `tempname` functions assist in locating temporary data on your system.

Function	Purpose
`tempdir`	Get temporary directory name.
`tempname`	Get temporary filename.

Use these functions to create temporary files. Some systems delete temporary files every time you reboot the system. On other systems, designating a file as temporary can mean only that the file is not backed up.

The `tempdir` function returns the name of the directory or folder that has been designated to hold temporary files on your system. For example, issuing `tempdir` on a UNIX system returns the `/tmp` directory.

MATLAB also provides a `tempname` function that returns a filename in the temporary directory. The returned filename is a suitable destination for temporary data. For example, if you need to store some data in a temporary file, then you might issue the following command first:

```
fid = fopen(tempname, 'w');
```

Note The filename that `tempname` generates is not guaranteed to be unique; however, it is likely to be so.

Reading Binary Data

The `fread` function reads all or part of a binary file (as specified by a file identifier) and stores it in a matrix. In its simplest form, it reads an entire file and interprets each byte of input as the next element of the matrix. For example, the following code reads the data from a file named `nickel.dat` into matrix `A`:

```
fid = fopen('nickel.dat','r');
A = fread(fid);
```

To echo the data to the screen after reading it, use `char` to display the contents of `A` as characters, transposing the data so it is displayed horizontally:

```
disp(char(A'))
```

The `char` function causes MATLAB to interpret the contents of `A` as characters instead of as numbers. Transposing `A` displays it in its more natural horizontal format.

Controlling the Number of Values Read

`fread` accepts an optional second argument that controls the number of values read (if unspecified, the default is the entire file). For example, this statement reads the first 100 data values of the file specified by `fid` into the column vector `A`.

```
A = fread(fid,100);
```

Replacing the number `100` with the matrix dimensions `[10 10]` reads the same 100 elements into a 10-by-10 array.

Controlling the Data Type of Each Value

An optional third argument to `fread` controls the data type of the input. The data type argument controls both the number of bits read for each value and the interpretation of those bits as character, integer, or floating-point values. MATLAB supports a wide range of precisions, which you can specify with MATLAB specific strings or their C or Fortran equivalents.

Some common precisions include

- `'char'` and `'uchar'` for signed and unsigned characters (usually 8 bits)
- `'short'` and `'long'` for short and long integers (usually 16 and 32 bits, respectively)
- `'float'` and `'double'` for single- and double-precision floating-point values (usually 32 and 64 bits, respectively)

Note The meaning of a given precision can vary across different hardware platforms. For example, a `'uchar'` is not always 8 bits. `fread` also provides a number of more specific precisions, such as `'int8'` and `'float32'`. If in doubt, use precisions that are not platform dependent. See `fread` for a complete list of precisions.

For example, if `fid` refers to an open file containing single-precision floating-point values, then the following command reads the next 10 floating-point values into a column vector `A`:

```
A = fread(fid,10,'float');
```

Writing Binary Data

The `fwrite` function writes the elements of a matrix to a file in a specified numeric precision, returning the number of values written. For instance, these lines create a 100-byte binary file containing the 25 elements of the 5-by-5 magic square, each stored as 4-byte integers:

```
fwriteid = fopen('magic5.bin','w');
count = fwrite(fwriteid,magic(5),'int32');
status = fclose(fwriteid);
```

In this case, `fwrite` sets the `count` variable to `25` unless an error occurs, in which case the value is less.

Controlling Position in a File

Once you open a file with `fopen`, MATLAB maintains a file position indicator that specifies a particular location within a file. MATLAB uses the file position indicator to determine where in the file the next read or write operation will begin. The following sections describe how to

- Determine whether the file position indicator is at the end of the file
- Move to a specific location in the file
- Retrieve the current location of the file position indicator
- Reset the file position indicator to the beginning of the file

Setting and Querying the File Position

The `fseek` and `ftell` functions enable you to set and query the position in the file at which the next input or output operation takes place:

- The `fseek` function repositions the file position indicator, letting you skip over data or back up to an earlier part of the file.
- The `ftell` function gives the offset in bytes of the file position indicator for a specified file.

The syntax for `fseek` is

```
status = fseek(fid,offset,origin)
```

`fid` is the file identifier for the file. `offset` is a positive or negative offset value, specified in bytes. `origin` is one of the following strings that specify the location in the file from which to calculate the position.

`'bof'`	Beginning of file
`'cof'`	Current position in file
`'eof'`	End of file

Example of Using fseek And ftell

To see how `fseek` and `ftell` work, consider this short M-file:

```
A = 1:5;
fid = fopen('five.bin','w');
fwrite(fid, A,'short');
status = fclose(fid);
```

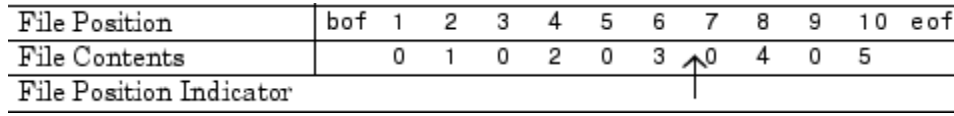
This code writes out the numbers 1 through 5 to a binary file named `five.bin`. The call to `fwrite` specifies that each numerical element be stored as a `short`. Consequently, each number uses two storage bytes.

Now reopen `five.bin` for reading:

```
fid = fopen('five.bin','r');
```

This call to `fseek` moves the file position indicator forward 6 bytes from the beginning of the file:

```
status = fseek(fid,6,'bof');
```



This call to `fread` reads whatever is at file positions 7 and 8 and stores it in variable `four`:

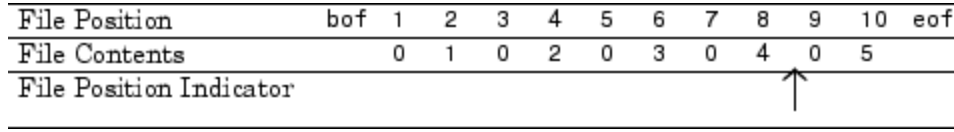
```
four = fread(fid,1,'short');
```

The act of reading advances the file position indicator. To determine the current file position indicator, call `ftell`:

```
position = ftell(fid)

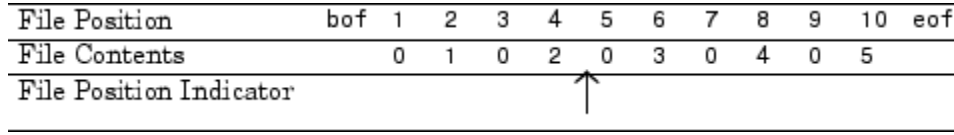
position =

     8
```



This call to `fseek` moves the file position indicator back 4 bytes:

```
status = fseek(fid,-4,'cof');
```



Calling `fread` again reads in the next value (3):

```
three = fread(fid,1,'short');
```

Reading Strings Line by Line from Text Files

MATLAB provides two functions, `fgetl` and `fgets`, that read lines from formatted text files and store them in string vectors. The two functions are almost identical; the only difference is that `fgets` copies the newline character to the string vector but `fgetl` does not.

The following M-file function demonstrates a possible use of `fgetl`. This function uses `fgetl` to read an entire file one line at a time. For each line, the function determines whether an input literal string (`literal`) appears in the line.

If it does, the function prints the entire line preceded by the number of times the literal string appears on the line.

```
function y = litcount(filename, literal)
% Search for number of string matches per line.

fid = fopen(filename, 'rt');
y = 0;
while feof(fid) == 0
   tline = fgetl(fid);
   matches = findstr(tline, literal);
   num = length(matches);
   if num > 0
      y = y + num;
      fprintf(1,'%d:%s\n',num,tline);
   end
end
fclose(fid);
```

For example, consider the following input data file called `badpoem`:

```
Oranges and lemons,
Pineapples and tea.
Orangutans and monkeys,
Dragonflys or fleas.
```

To find out how many times the string `'an'` appears in this file, use `litcount`:

```
litcount('badpoem','an')
2: Oranges and lemons,
```

```
1: Pineapples and tea.
3: Orangutans and monkeys,
```

Reading Formatted ASCII Data

The `fscanf` function is like the `fscanf` function in standard C. Both functions operate in a similar manner, reading data from a file and assigning it to one or more variables. Both functions use the same set of conversion specifiers to control the interpretation of the input data.

The conversion specifiers for `fscanf` begin with a `%` character; common conversion specifiers include.

Conversion Specifier	Description
`%s`	Match a string.
`%d`	Match an integer in base 10 format.
`%g`	Match a double-precision floating-point value.

You can also specify that `fscanf` skip a value by specifying an asterisk in a conversion specifier. For example, `%*f` means skip the floating-point value in the input data; `%*d` means skip the integer value in the input data.

Differences Between the MATLAB fscanf and the C fscanf

Despite all the similarities between the MATLAB and C versions of `fscanf`, there are some significant differences. For example, consider a file named `moon.dat` for which the contents are as follows:

```
3.654234533
2.71343142314
5.34134135678
```

The following code reads all three elements of this file into a matrix named `MyData`:

```
fid = fopen('moon.dat','r');
MyData = fscanf(fid,'%g');
status = fclose(fid);
```

Notice that this code does not use any loops. Instead, the `fscanf` function continues to read in text as long as the input format is compatible with the format specifier.

An optional size argument controls the number of matrix elements read. For example, if `fid` refers to an open file containing strings of integers, then this line reads 100 integer values into the column vector `A`:

```
A = fscanf(fid,'%5d',100);
```

This line reads 100 integer values into the 10-by-10 matrix `A`:

```
A = fscanf(fid,'%5d',[10 10]);
```

A related function, `sscanf`, takes its input from a string instead of a file. For example, this line returns a column vector containing 2 and its square root:

```
root2 = num2str([2, sqrt(2)]);
rootvalues = sscanf(root2,'%f');
```

Writing Formatted Text Files

The `fprintf` function converts data to character strings and outputs them to the screen or a file. A format control string containing conversion specifiers and any optional text specify the output format. The conversion specifiers control the output of array elements; `fprintf` copies text directly.

Common conversion specifiers include

Conversion Specifier	Description
`%e`	Exponential notation
`%f`	Fixed-point notation
`%g`	Automatically select the shorter of `%e` and `%f`

Optional fields in the format specifier control the minimum field width and precision. For example, this code creates a text file containing a short table of the exponential function:

```
x = 0:0.1:1;
y = [x; exp(x)];
```

The code below writes x and y into a newly created file named exptable.txt:

```
fid = fopen('exptable.txt','w');
fprintf(fid,'Exponential Function\n\n');
fprintf(fid,'%6.2f  %12.8f\n',y);
status = fclose(fid);
```

The first call to fprintf outputs a title, followed by two carriage returns. The second call to fprintf outputs the table of numbers. The format control string specifies the format for each line of the table:

- A fixed-point value of six characters with two decimal places
- Two spaces
- A fixed-point value of twelve characters with eight decimal places

fprintf converts the elements of array y in column order. The function uses the format string repeatedly until it converts all the array elements.

Now use fscanf to read the exponential data file:

```
fid = fopen('exptable.txt','r');
title = fgetl(fid);
[table,count] = fscanf(fid,'%f %f',[2 11]);
table = table';
status = fclose(fid);
```

The second line reads the file title. The third line reads the table of values, two floating-point values on each line, until it reaches end of file. count returns the number of values matched.

A function related to fprintf, sprintf, outputs its results to a string instead of a file or the screen. For example,

```
root2 = sprintf('The square root of %f is %10.8e.\n',2,sqrt(2));
```

Closing a File

When you finish reading or writing, use fclose to close the file. For example, this line closes the file associated with file identifier fid:

```
status = fclose(fid);
```

This line closes all open files:

```
status = fclose('all');
```

Both forms return `0` if the file or files were successfully closed or `-1` if the attempt was unsuccessful.

MATLAB automatically closes all open files when you exit from MATLAB. It is still good practice, however, to close a file explicitly with `fclose` when you are finished using it. Not doing so can unnecessarily drain system resources.

Note Closing a file does not clear the file identifier variable `fid`. However, subsequent attempts to access a file through this file identifier variable will not work.

Exchanging Files over the Internet

In this section...

Overview

MATLAB provides functions for exchanging files over the Internet. You can exchange files using common protocols, such as File Transfer Protocol (FTP), Simple Mail Transport Protocol (SMTP), and HyperText Transfer Protocol (HTTP). In addition, you can create zip archives to minimize the transmitted file size, and also save and work with Web pages.

Downloading Web Content and Files

MATLAB provides two functions for downloading Web pages and files using HTTP: `urlread` and `urlwrite`. With the `urlread` function, you can read and save the contents of a Web page to a string variable in the MATLAB workspace. With the `urlwrite` function, you can save a Web page's content to a file.

Because it creates a string variable in the workspace, the `urlread` function is useful for working with the contents of Web pages in MATLAB. The `urlwrite` function is useful for saving Web pages to a local directory.

Note When using `urlread`, remember that only the HTML in that specific Web page is retrieved. The hyperlink targets, images, and so on will not be retrieved.

If you need to pass parameters to a Web page, the `urlread` and `urlwrite` functions let you use HTTP `post` and `get` methods. For more information, see the `urlread` and `urlwrite` reference pages.

Example — Using the urlread Function

The following procedure demonstrates how to retrieve the contents of the Web page containing the Recent File list at the MATLAB Central File Exchange, `http://www.mathworks.com/matlabcentral/fileexchange/index.jsp`. It assigns the results to a string variable, `recentFile`, and it uses the `strfind` function to search the retrieved content for a specific word:

1. Retrieve the Web page content with the `urlread` function:

   ```
   recentFile =
   urlread('http://www.mathworks.com/matlabcentral/fileexchange/
   loadFileList.do?objectType=fileexchange&orderBy=date&srt3=0');
   ```

2. After retrieving the content, run the `strfind` function on the `recentFile` variable:

   ```
   hits = strfind(recentFile,'Simulink');
   ```

   If the file contains the word `Simulink`, MATLAB will store the matches in the `hits` variable.

While you can manually pass arguments using the URL, the `urlread` function also lets you pass parameters to a Web page using standard HTTP methods, including `post` and `form`. Using the HTTP `get` method, which passes parameters in the URL, the following code queries Google for the word `Simulink`:

```
s =
urlread('http://www.google.com/search','get',{'q','Simulink'})
```

For more information, see the `urlread` reference page.

Example — Using the urlwrite Function

The following example builds on the procedure in the previous section. This example still uses `urlread` and checks for a specific word, but it also uses `urlwrite` to save the file if it contains any matches:

```
% The urlread function loads the contents of the Web page into
the % MATLAB workspace.

recentFile =
urlread('http://www.mathworks.com/matlabcentral/fileexchange/
loadFileList.do?objectType=fileexchange&orderBy=date&srt3=0');

% The strfind function searches for the word "Simulink".
hits = strfind(recentFile,'Simulink');

% The if statement checks for any hits.
if ~isempty(hits)

% If there are hits, the Web page will be saved locally
% using the urlwrite function.

urlwrite('http://www.mathworks.com/matlabcentral/fileexchange/
loadFileList.do?objectType=fileexchange&orderBy=date&srt3=0',
'contains_simulink.html');
end;
```

MATLAB saves the Web page as `contains_simulink.html`.

Creating and Decompressing Zip Archives

Using the `zip` and `unzip` functions, you can compress and decompress files and directories. The `zip` function compresses files or directories into a zip archive. The `unzip` function decompresses zip archives.

Example — Using the zip Function

Again building on the example from previous sections, the following code creates a zip archive of the retrieved Web page:

```
% The urlread function loads the contents of the Web page into
the % MATLAB workspace.
recentFile =
urlread('http://www.mathworks.com/matlabcentral/fileexchange/
loadFileList.do?objectType=fileexchange&orderBy=date&srt3=0');

% The strfind function searches for the word "Simulink".
```

```
hits = strfind(recentFile,'Simulink');

% The if statement checks for any hits.
if ~isempty(hits)

% If there are hits, the Web page will be saved locally
% using the urlwrite function.
urlwrite('http://www.mathworks.com/matlabcentral/fileexchange/
loadFileList.do?objectType=fileexchange&orderBy=date&srt3=0',
'contains_simulink.html');

% The zip function creates a zip archive of the retrieved Web
page.
zip('simulink_matches.zip','contains_simulink.html');
end;
```

Sending E-Mail

To send an e-mail from within MATLAB, use the `sendmail` function. You can also attach files to an e-mail, which lets you mail files directly from MATLAB. To use `sendmail`, you must first set up your e-mail address and your SMTP server information with the `setpref` function.

The `setpref` function defines two mail-related preferences:

- E-mail address: This preference sets your e-mail address that will appear on the message. Here is an example of the syntax:

  ```
  setpref('Internet','E_mail','youraddress@yourserver.com');
  ```

- SMTP server: This preference sets your outgoing SMTP server address, which can be almost any e-mail server that supports the Post Office Protocol (POP) or the Internet Message Access Protocol (IMAP). Here is an example of the syntax:

  ```
  setpref('Internet', 'SMTP_Server', 'mail.server.network');
  ```

You should be able to find your outgoing SMTP server address in your e-mail account settings in your e-mail client application. You can also contact your system administrator for the information.

Note The `sendmail` function does not support e-mail servers that require authentication.

Once you have properly configured MATLAB, you can use the `sendmail` function. The `sendmail` function requires at least two arguments: the recipient's e-mail address and the e-mail subject:

```
sendmail('recepient@someserver.com', 'Hello From MATLAB!');
```

You can supply multiple e-mail addresses using a cell array of strings, such as:

```
sendmail({'recepient@someserver.com', ...
'recepient2@someserver.com'}, 'Hello From MATLAB!');
```

You can also specify a message body with the `sendmail` function, such as:

```
sendmail('recepient@someserver.com', 'Hello From MATLAB!', ...
'Thanks for using sendmail.');
```

In addition, you can also attach files to an e-mail using the `sendmail` function, such as:

```
sendmail('recepient@somesever.com', 'Hello from MATLAB!', ...
'Thanks for using sendmail.', 'C:\yourFileSystem\message.txt');
```

You cannot attach a file without including a message. However, the message can be empty. You can also attach multiple files to an e-mail with the `sendmail` function, such as:

```
sendmail('recepient@somesever.com', 'Hello from MATLAB!', ...
'Thanks for using sendmail.', ...
{'C:\yourFileSystem\message.txt',...
'C:\yourFileSystem\message2.txt'});
```

Example — Using the sendmail Function

The following example sends e-mail with the retrieved Web page archive attached if it contains any matches for the specified word:

```
% The urlread function loads the contents of the Web page into
the  % MATLAB workspace.
recentFile =
urlread('http://www.mathworks.com/matlabcentral/fileexchange/
loadFileList.do?objectType=fileexchange&orderBy=date&srt3=0');

% The strfind function searches for the word "Simulink".
hits = strfind(recentFile,'Simulink');

% The if statement checks for any hits.
if ~isempty(hits)

% If there are hits, the Web page will be saved locally
% using the urlwrite function.
urlwrite('http://www.mathworks.com/matlabcentral/fileexchange/
loadFileList.do?objectType=fileexchange&orderBy=date&srt3=0',
'contains_simulink.html');

% The zip function creates a zip archive of the retrieved web
page.
zip('simulink_matches.zip','contains_simulink.html');

% The setpref function supplies your e-mail address and SMTP
% server address to MATLAB.
setpref('Internet','SMTP_Server','mail.server.network');
setpref('Internet', 'E_mail', 'youraddress@yourserver.com');

% The sendmail function sends an e-mail with the zip archive of
the
% retrieved Web page attached.
sendmail('youraddress@yourserver.com', 'New Simulink Files
Found', 'New Simulink files uploaded to MATLAB Central. See
attached zip archive.', 'simulink_matches.zip');
end;
```

Performing FTP File Operations

From within MATLAB, you can connect to an FTP server to perform remote file operations. The following procedure uses a public MathWorks FTP server

(`ftp.mathworks.com`). To perform any file operation on an FTP server, follow these steps:

1. Connect to the server using the `ftp` function.

   For example, you can create an FTP object for the public MathWorks FTP server with `tmw=ftp('ftp.mathworks.com')`.

2. Perform the file operations using appropriate MATLAB FTP functions as methods acting on the server object.

   For example, you can display the file directories on the FTP server with `dir(tmw)`.

3. When you finish working on the server, close the connection object using the close function.

   For example, you can disconnect from the FTP server with `close(tmw)`.

Example — Retrieving a File from an FTP Server

In this example, you retrieve the file pub/pentium/Moler_1.txt, which is on the MathWorks FTP server. You can run this example; the FTP server and content are valid.

1. Connect to the MathWorks FTP server using `ftp`. This creates the server object `tmw`:

   ```
   tmw=ftp('ftp.mathworks.com');
   ```

2. List the contents of the server using the `dir` FTP function, which operates on the server object `tmw`:

   ```
   dir(tmw)
   ```

3. Change to the `pub` directory by using the FTP cd function. As with all FTP functions, you need to specify the server object you created using `ftp` as part of the syntax. In this case, this is `tmw`:

   ```
   cd(tmw,'pub');
   ```

The server object `tmw` represents the current directory on the FTP server, which now is pub.

4 Now when you run

```
dir(tmw)
```

you see the contents of pub, rather than the top level contents as displayed previously when you ran `dir(tmw)`.

5 Use `mget` to retrieve any of the files from the current directory on the FTP server to the MATLAB current directory:

```
mget(tmw,'filename');
```

6 Close the FTP connection using `close`.

```
close(tmw);
```

Summary of FTP Functions

The following table lists the available FTP functions. For more information, refer to the applicable reference pages.

Function	Description
`ascii`	Set FTP transfer type to ASCII (convert new lines).
`binary`	Set FTP transfer type to binary (transfer verbatim, default).
`cd (ftp)`	Change current directory on FTP server.
`delete (ftp)`	Delete file on FTP server.
`dir (ftp)`	List contents of directory on FTP server.
`close (ftp)`	Close connection with FTP server.
`ftp`	Connect to FTP server, creating an FTP object.
`mget`	Download file from FTP site.
`mkdir (ftp)`	Create new directory on FTP server.
`mput (ftp)`	Upload file or directory to FTP server.

Function	Description
`rename`	Rename file on FTP server.
`rmdir (ftp)`	Remove directory on FTP server.

7

Working with Scientific Data Formats

This section describes how to import and export data in several standard scientific data formats. Topics covered include

Common Data Format (CDF) Files (p. 7-2)	Reading and writing data and metadata using the Common Data Format (CDF) file format.
Flexible Image Transport System (FITS) Files (p. 7-8)	Reading data and metadata using the Flexible Image Transport System (FITS) file format.
Hierarchical Data Format (HDF5) Files (p. 7-11)	Reading and writing data and metadata using the Hierarchical Data Format (HDF5) file format.
Hierarchical Data Format (HDF4) Files (p. 7-36)	Reading and writing data and metadata using the Hierarchical Data Format (HDF4) file format.

Common Data Format (CDF) Files

In this section...

Getting Information About CDF Files

To get information about the contents of a Common Data Format (CDF) file, use the `cdfinfo` function. CDF was created by the National Space Science Data Center (NSSDC) to provide a self-describing data storage and manipulation format that matches the structure of scientific data and applications (i.e., statistical and numerical methods, visualization, and management). The `cdfinfo` function returns a structure containing general information about the file and detailed information about the variables and attributes in the file. For more information about this format, see the CDF Web site.

The following example returns information about the sample CDF file included with MATLAB. To determine the variables contained in the file, view the `Variables` field. This field contains a cell array that lists all the variables in the file with information that describes the variable, such as name, size, and data type. For an example, see "Importing Data from a CDF File" on page 7-3.

Note Because `cdfinfo` creates temporary files, make sure that your current working directory is writable before attempting to use the function.

```
info = cdfinfo('example.cdf')

info =

             Filename: 'example.cdf'
          FileModDate: '09-Mar-2001 16:45:22'
             FileSize: 1240
               Format: 'CDF'
```

```
      FormatVersion: '2.7.0'
       FileSettings: [1x1 struct]
           Subfiles: {}
          Variables: {5x6 cell}
    GlobalAttributes: [1x1 struct]
  VariableAttributes: [1x1 struct]
```

Importing Data from a CDF File

To import data into the MATLAB workspace from a Common Data Format (CDF) file, use the `cdfread` function. CDF was created by the National Space Science Data Center (NSSDC) to provide a self-describing data storage and manipulation format that matches the structure of scientific data and applications (i.e., statistical and numerical methods, visualization, and management). Using this function, you can import all the data in the file, specific variables, specific records, or subsets of the data in a specific variable. The following examples illustrate some of these capabilities.

1. To get information about the contents of a CDF file, such as the names of variables in the CDF file, use the `cdfinfo` function. In this example, the `Variables` field indicates that the file contains five variables. The first variable, `Time`, is made up of 24 records containing CDF epoch data. The next two variables, `Longitude` and `Latitude`, have only one associated record containing `int8` data. For details about how to interpret the data returned in the `Variables` field, see `cdfinfo`.

```
info = cdfinfo('example.cdf');

vars = info.Variables

vars =

  Columns 1 through 5

   'Time'               [1x2 double]   [24]   'epoch'    'T/'
   'Longitude'          [1x2 double]   [ 1]   'int8'     'F/FT'
   'Latitude'           [1x2 double]   [ 1]   'int8'     'F/TF'
   'Data'               [1x3 double]   [ 1]   'double'   'T/TTT'
   'multidimensional    [1x4 double]   [ 1]   'uint8'    'T/TTTT'

  Column 6
```

```
'Full'
'Full'
'Full'
'Full'
'Full'
```

2 To read all of the data in the CDF file, use the `cdfread` function. The function returns the data in a 24-by-5 cell array. The five columns of data correspond to the five variables; the 24 rows correspond to the 24 records associated with the Time variable and padding elements for the rows associated with the other variables. The padding value used is specified in the CDF file.

```
data = cdfread('example.cdf');

whos data
  Name       Size             Bytes  Class    Attributes

  data      24x5              14784  cell
```

3 To read the data associated with a particular variable, use the `'Variable'` parameter, specifying a cell array of variable names as the value of this parameter. Variable names are case sensitive. For example, the following code reads the Longitude and Latitude variables from the file. The return value `data` is a 24-by-2 cell array, where each cell contains `int8` data.

```
var_time = cdfread('example.cdf','Variable',{'Longitude','Latitude'});

whos var_time
  Name           Size            Bytes  Class    Attributes

  var_time      24x1              4608  cell
```

Speeding Up Read Operations

The `cdfread` function offers two ways to speed up read operations when working with large data sets:

- Reducing the number of elements in the returned cell array

- Returning CDF epoch values as MATLAB serial date numbers rather than as MATLAB `cdfepoch` objects

To reduce the number of elements in the returned cell array, specify the `'CombineRecords'` parameter. By default, `cdfread` creates a cell array with a separate element for every variable and every record in each variable, padding the records dimension to create a rectangular cell array. For example, reading all the data from the example file produces an output cell array, 24-by-5, where the columns represent variables and the rows represent the records for each variable. When you set the `'CombineRecords'` parameter to `true`, `cdfread` creates a separate element for each variable but saves time by putting all the records associated with a variable in a single cell array element. Thus, reading the data from the example file with `'CombineRecords'` set to `true` produces a 1-by-5 cell array, as shown below.

```
data_combined = cdfread('example.cdf','CombineRecords',true);

whos
  Name                Size            Bytes  Class    Attributes

  data               24x5             14784  cell
  data_combined       1x5              2364  cell
```

When combining records, note that the dimensions of the data in the cell change. For example, if a variable has 20 records, each of which is a scalar value, the data in the cell array for the combined element contains a 20-by-1 vector of values. If each record is a 3-by-4 array, the cell array element contains a 20-by-3-by-4 array. For combined data, `cdfread` adds a dimension to the data, the first dimension, that is the index into the records.

Another way to speed up read operations is to read CDF epoch values as MATLAB serial date numbers. By default, `cdfread` creates a MATLAB `cdfepoch` object for each CDF epoch value in the file. If you specify the `'ConvertEpochToDatenum'` parameter, setting it to `true`, `cdfread` returns CDF epoch values as MATLAB serial date numbers. For more information about working with MATLAB `cdfepoch` objects, see “Representing CDF Time Values” on page 7-6.

```
data_datenums = cdfread('example.cdf','ConvertEpochToDatenum',true);
```

```
whos
  Name                Size            Bytes  Class    Attributes

  data               24x5             14784  cell
  data_combined       1x5              2364  cell
  var_time           24x1              4608  cell
```

Representing CDF Time Values

CDF represents time differently than MATLAB. CDF represents date and time as the number of milliseconds since 1-Jan-0000. This is called an *epoch* in CDF terminology. MATLAB represents date and time as a serial date number, which is the number of days since 0-Jan-0000. To represent CDF dates, MATLAB uses an object called a CDF epoch object. To access the time information in a CDF object, use the object's `todatenum` method.

For example, this code extracts the date information from a CDF epoch object:

1. Extract the date information from the CDF epoch object returned in the cell array `data` (see "Importing Data from a CDF File" on page 7-3). Use the `todatenum` method of the CDF epoch object to get the date information, which is returned as a MATLAB serial date number.

   ```
   m_date = todatenum(data{1});
   ```

2. View the MATLAB serial date number as a string.

   ```
   datestr(m_date)
   ans =

   01-Jan-2001
   ```

Exporting Data to a CDF File

To export data from the MATLAB workspace to a Common Data Format (CDF) file, use the `cdfwrite` function. CDF was created by the National Space Science Data Center (NSSDC) to provide a self-describing data storage and manipulation format that matches the structure of scientific data and applications (i.e., statistical and numerical methods, visualization, and management). Using this function, you can write variables and attributes to the file, specifying their names and associated values. See the `cdfwrite` reference page for more information.

This example shows how to write date information to a CDF file. Note how the example uses the CDF epoch object constructor, `cdfepoch`, to convert a MATLAB serial date number into a CDF epoch.

```
cdfwrite('myfile',{'Time_val',cdfepoch(now)});
```

You can convert a `cdfepoch` object back into a MATLAB serial date number with the `todatenum` function.

Flexible Image Transport System (FITS) Files

In this section...

Getting Information About FITS Files

To get information about the contents of a Flexible Image Transport System (FITS) file, use the `fitsinfo` function. The FITS file format is the standard data format used in astronomy, endorsed by both NASA and the International Astronomical Union (IAU). For more information about the FITS standard, go to the official FITS Web site, `http://fits.gsfc.nasa.gov/`.

A data file in FITS format can contain multiple components, each marked by an ASCII text header followed by binary data. The first component in a FITS file is known as the *primary*, which can be followed by any number of other components, called *extensions,* in FITS terminology. The `fitsinfo` function returns a structure containing the information about the file and detailed information about the data in the file. This example returns information about a sample FITS file included with MATLAB. The structure returned contains fields for the primary component, `PrimaryData`, and all the extensions in the file, such as the `BinaryTable`, `Image`, and `AsciiTable` extensions.

```
info = fitsinfo('tst0012.fits')

info =

       Filename: 'tst0012.fits'
    FileModDate: '12-Mar-2001 18:37:46'
       FileSize: 109440
       Contents: {1x5 cell}
    PrimaryData: [1x1 struct]
    BinaryTable: [1x1 struct]
        Unknown: [1x1 struct]
          Image: [1x1 struct]
     AsciiTable: [1x1 struct]
```

Importing Data from a FITS File

To import data into the MATLAB workspace from a Flexible Image Transport System (FITS) file, use the `fitsread` function. The FITS file format is designed to store scientific data sets consisting of multidimensional arrays (1-D spectra, 2-D images, or 3-D data cubes) and two-dimensional tables containing rows and columns of data. Using this function, you can import the data in the `PrimaryData` section of the file or you can import the data in any of the extensions in the file, such as the `Image` extension. This example illustrates how to use the `fitsread` function to read data from a FITS file:

1 Determine which extensions the FITS file contains, using the `fitsinfo` function.

```
info = fitsinfo('tst0012.fits')

info =

       Filename: 'tst0012.fits'
    FileModDate: '12-Mar-2001 18:37:46'
       FileSize: 109440
       Contents: {1x5 cell}
    PrimaryData: [1x1 struct]
    BinaryTable: [1x1 struct]
        Unknown: [1x1 struct]
          Image: [1x1 struct]
     AsciiTable: [1x1 struct]
```

The `info` structure shows that the file contains several extensions including the `BinaryTable`, `AsciiTable`, and `Image` extensions.

2 Read data from the file.

To read the `PrimaryData` in the file, specify the filename as the only argument:

```
pdata = fitsread('tst0012.fits');
```

To read any of the extensions in the file, you must specify the name of the extension as an optional parameter. This example reads the `BinaryTable` extension from the FITS file:

```
bindata = fitsread('tst0012.fits','bintable');
```

Note To read the `BinaryTable` extension using `fitsread`, you must specify the parameter `'bintable'`. Similarly, to read the `AsciiTable` extension, you must specify the parameter `'table'`. See the `fitsread` reference page for more information.

Hierarchical Data Format (HDF5) Files

In this section...

Note For information about working with HDF4 data, which is a completely separate, incompatible format, see "Hierarchical Data Format (HDF4) Files" on page 7-36.

Using the MATLAB High-Level HDF5 Functions

Hierarchical Data Format, Version 5, (HDF5) is a general-purpose, machine-independent standard for storing scientific data in files, developed by the National Center for Supercomputing Applications (NCSA). HDF5 is used by a wide range of engineering and scientific fields that want a standard way to store data so that it can be shared. For more information about the HDF5 file format, read the HDF5 documentation available at the HDF Web site (`http://www.hdfgroup.org`).

The MATLAB high-level HDF5 functions provide an easy way to import data or metadata from an HDF5 file, or write data to an HDF5 file. The following sections provide more detail about using these functions.

Determining the Contents of an HDF5 File

HDF5 files can contain data and metadata, called *attributes*. HDF5 files organize the data and metadata in a hierarchical structure similar to the hierarchical structure of a UNIX file system.

In an HDF5 file, the directories in the hierarchy are called *groups*. A group can contain other groups, data sets, attributes, links, and data types. A data set is a collection of data, such as a multidimensional numeric array or string. An attribute is any data that is associated with another entity, such as a data set. A link is similar to a UNIX file system symbolic link. Links are a way to reference data without having to make a copy of the data.

Data types are a description of the data in the data set or attribute. Data types tell how to interpret the data in the data set. For example, a file might contain a data type called "Reading" that is comprised of three elements: a longitude value, a latitude value, and a temperature value.

To explore the hierarchical organization of an HDF5 file, use the `hdf5info` function. For example, to find out what the sample HDF5 file, `example.h5`, contains, use this syntax:

```
fileinfo = hdf5info('example.h5');
```

`hdf5info` returns a structure that contains various information about the HDF5 file, including the name of the file and the version of the HDF5 library that MATLAB is using:

```
fileinfo =

          Filename: 'example.h5'
        LibVersion: '1.6.5'
            Offset: 0
          FileSize: 8172
    GroupHierarchy: [1x1 struct]
```

In the information returned by `hdf5info`, look at the `GroupHierarchy` field. This field is a structure that describes the top-level group in the file, called the *root* group. Using the UNIX convention, HDF5 names this top-level group `/` (forward slash), as shown in the `Name` field of the `GroupHierarchy` structure.

```
toplevel = fileinfo.GroupHierarchy

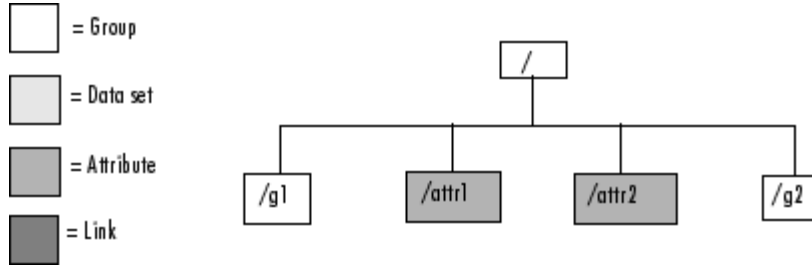
toplevel =

      Filename: 'C:\matlab\toolbox\matlab\demos\example.h5'
          Name: '/'
```

```
          Groups: [1x2 struct]
        Datasets: []
      Datatypes: []
           Links: []
      Attributes: [1x2 struct]
```

By looking at the `Groups` and `Attributes` fields, you can see that the file contains two groups and two attributes. The `Datasets`, `Datatypes`, and `Links` fields are all empty, indicating that the root group does not contain any data sets, data types, or links.

The following figure illustrates the organization of the root group in the sample HDF5 file `example.h5`.



Organization of the Root Group of the Sample HDF5 File

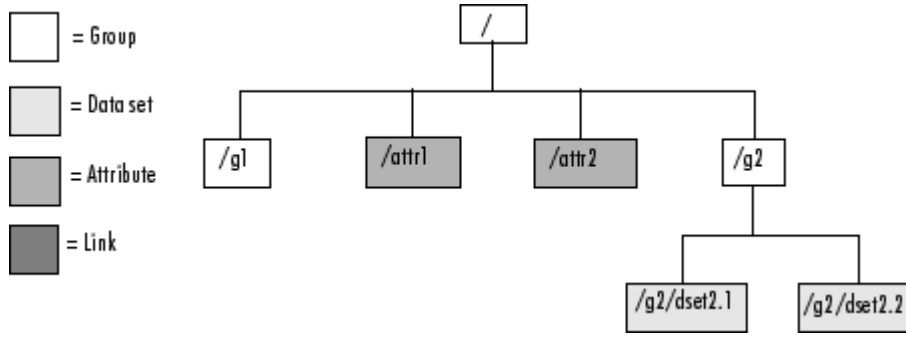
To explore the contents of the sample HDF5 file further, examine one of the two structures in the `Groups` field of the `GroupHierarchy` structure. Each structure in this field represents a group contained in the root group. The following example shows the contents of the second structure in this field.

```
level2 = toplevel.Groups(2)

level2 =

      Filename: 'C:\matlab\toolbox\matlab\demos\example.h5'
          Name: '/g2'
        Groups: []
      Datasets: [1x2 struct]
     Datatypes: []
         Links: []
    Attributes: []
```

In the sample file, the group named `/g2` contains two data sets. The following figure illustrates this part of the sample HDF5 file organization.



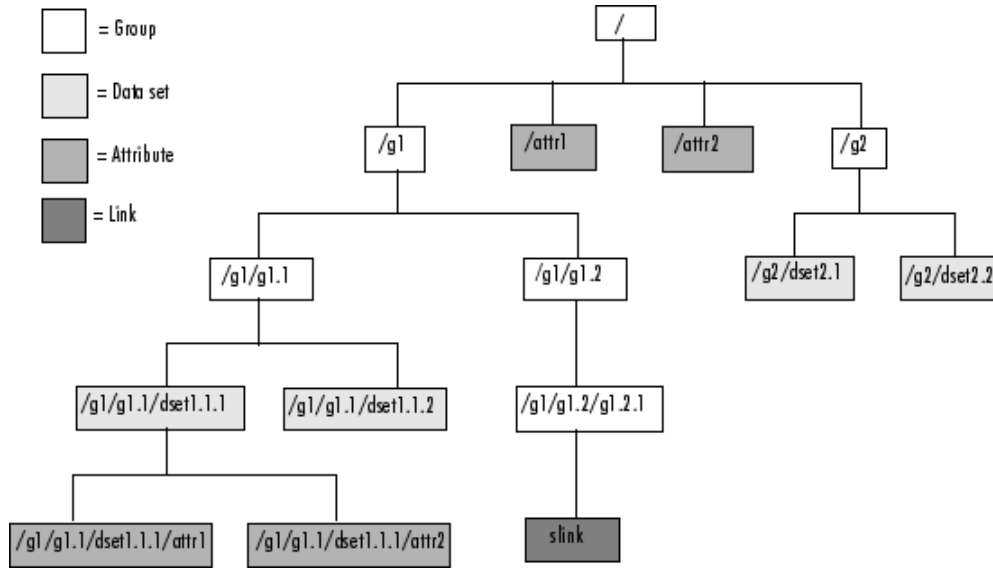
Organization of the Data Set /g2 in the Sample HDF5 File

To get information about a data set, look at either of the structures returned in the `Datasets` field. These structures provide information about the data set, such as its name, dimensions, and data type.

```
dataset1 = level2.Datasets(1)

dataset1 =
      Filename: 'L:\matlab\toolbox\matlab\demos\example.h5'
          Name: '/g2/dset2.1'
          Rank: 1
      Datatype: [1x1 struct]
          Dims: 10
       MaxDims: 10
        Layout: 'contiguous'
    Attributes: []
         Links: []
     Chunksize: []
     Fillvalue: []
```

By examining the structures at each level of the hierarchy, you can traverse the entire file. The following figure describes the complete hierarchical organization of the sample file `example.h5`.



Hierarchical Structure of example.h5 HDF5 File

Importing Data from an HDF5 File

To read data or metadata from an HDF5 file, use the `hdf5read` function. As arguments, you must specify the name of the HDF5 file and the name of the data set or attribute. Alternatively, you can specify just the field in the structure returned by `hdf5info` that contains the name of the data set or attribute; `hdf5read` can determine the file name from the `Filename` field in the structure. For more information about finding the name of a data set or attribute in an HDF5 file, see "Determining the Contents of an HDF5 File" on page 7-11.

To illustrate, this example reads the data set, `/g2/dset2.1` from the HDF5 sample file `example.h5`.

```
data = hdf5read('example.h5','/g2/dset2.1');
```

The return value contains the values in the data set, in this case a 1-by-10 vector of single-precision values:

```
data =

    1.0000
    1.1000
    1.2000
    1.3000
    1.4000
    1.5000
    1.6000
    1.7000
    1.8000
    1.9000
```

The `hdf5read` function maps HDF5 data types to appropriate MATLAB data types, whenever possible. If the HDF5 file contains data types that cannot be represented in MATLAB, `hdf5write` uses one of the predefined MATLAB HDF5 data type objects to represent the data.

For example, if an HDF5 data set contains four array elements, `hdf5read` can return the data as a 1-by-4 array of `hdf5.h5array` objects:

```
whos

Name    Size        Bytes     Class

data     1x4                hdf5.h5array

Grand total is 4 elements using 0 bytes
```

For more information about the MATLAB HDF5 data type objects, see "Mapping HDF5 Data Types to MATLAB Data Types" on page 7-18.

Exporting Data to HDF5 Files

To write data or metadata from the MATLAB workspace to an HDF5 file, use the `hdf5write` function. As arguments, specify:

- Name of an existing HDF5 file, or the name you want to assign to a new file.

- Name of an existing data set or attribute, or the name you want to assign to a new data set or attribute. To learn how to determine the name of data sets in an existing HDF5 file, see “Determining the Contents of an HDF5 File” on page 7-11.
- Data or metadata you want to write to the file. `hdf5write` converts MATLAB data types to the appropriate HDF5 data type automatically. For nonatomic data types, you can also create HDF5 objects to represent the data.

This example creates a 5-by-5 array of `uint8` values and then writes the array to an HDF5 file. By default, `hdf5write` overwrites the file, if it already exists. The example specifies an `hdf5write` mode option to append data to existing file.

1 Create a MATLAB variable in the workspace. This example creates a 5-by-5 array of `uint8` values.

```
testdata = uint8(magic(5))
```

2 Write the data to an HDF5 file. As arguments to `hdf5read`, the example specifies the name you want to assign to the HDF5 file, the name you want to assign to the data set, and the MATLAB variable.

```
hdf5write('myfile.h5', '/dataset1', testdata)
```

To add data to an existing file, you must use the `'writemode'` option, specifying the`'append'` value. The file must already exist and it cannot already contain a data set with the same name

```
hdf5write('myfile.h5', '/dataset12', testdata,'writemode','append')
```

If you are writing simple data sets, such as scalars, strings, or a simple compound data types, you can just pass the data directly to `hdf5write`; this function automatically maps the MATLAB data types to appropriate HDF5 data types. However, if your data is a complex data set, you might need to use one of the predefined MATLAB HDF5 objects to pass the data to the `hdf5write` function. The HDF5 objects are designed for situations where the mapping between MATLAB and HDF5 types is ambiguous.

For example, when passed a cell array of strings, the `hdf5write` function writes a data set made up of strings, not a data set of arrays containing

strings. If that is not the mapping you intend, use HDF5 objects to specify the correct mapping. In addition, note that HDF5 makes a distinction between the size of a data set and the size of a data type. In MATLAB, data types are always scalar. In HDF5, data types can have a size; that is, types can be either scalar (like MATLAB) or m-by-n. In HDF5, a 5-by-5 data set containing a single `uint8` value in each element is distinct from a 1-by-1 data set containing a 5-by-5 array of `uint8` values. In the first case, the data set contains 25 observations of a single value; in the second case, the data set contains a single observation with 25 values. For more information about the MATLAB HDF5 data type objects, see "Mapping HDF5 Data Types to MATLAB Data Types" on page 7-18.

Mapping HDF5 Data Types to MATLAB Data Types

When the `hdf5read` function reads data from an HDF5 file into the MATLAB workspace, it maps HDF5 data types to MATLAB data types, depending on whether the data in the data set is in an *atomic* data type or a nonatomic *composite* data type.

Mapping Atomic Data Types. Atomic data types describe commonly used binary formats for numbers (integers and floating point) and characters (ASCII). Because different computing architectures and programming languages support different number and character representations, the HDF5 library provides the platform-independent data types, which it then maps to an appropriate data type for each platform. For example, a computer may support 8-, 16-, 32-, and 64-bit signed integers, stored in memory in little endian byte order.

If the data in the data set is stored in one of the HDF5 atomic data types, `hdf5read` uses the equivalent MATLAB data type to represent the data. Each data set contains a `Datatype` field that names the data type. For example, the data set `/g2/dset2.2` in the sample HDF5 file includes atomic data and data type information.

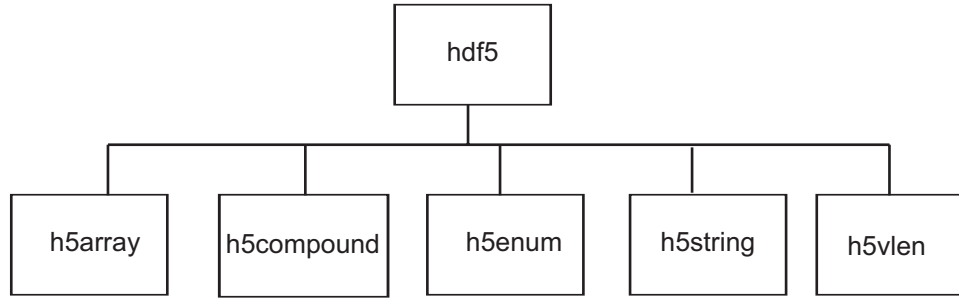
```
dtype = dataset1.Datatype
dtype =

        Name: []
       Class: 'H5T_IEEE_F32BE'
    Elements: []
```

The `H5T_IEEE_F32BE` class name indicates the data is a 4-byte, big endian, IEEE floating-point data type. (See the HDF5 specification for more information about atomic data types.)

Mapping Composite Data Types. A composite data type is an aggregation of one or more atomic data types. Composite data types include structures, multidimensional arrays, and variable-length data types (one-dimensional arrays).

If the data in the data set is stored in one of the HDF5 nonatomic data types and the data cannot be represented in the workspace using a native MATLAB data type,`hdf5read` uses one of a set of classes MATLAB defines to represent HDF5 data types. The following figure illustrates the `hdf5` class and its subclasses. For more information about a specific class, see the sections that follow. To learn more about the HDF5 data types in general, see the HDF Web page at `http://www.hdfgroup.org`.



For example, if an HDF5 file contains a data set made up of an enumerated data type which cannot be represented in MATLAB, `hdf5read` uses the HDF5 `h5enum` class to represent the data. An `h5enum` object has data members that store the enumerations (text strings), their corresponding values, and the enumerated data.

You might also need to use these HDF5 data type classes when using the `hdf5write` function to write data from the MATLAB workspace to an HDF5 file. By default, `hdf5write` can convert most MATLAB data to appropriate HDF5 data types. However, if this default data type mapping is not suitable, you can create HDF5 data types directly.

To access the data in the data set in the MATLAB workspace, you must access the `Data` field in the object.

This example converts a simple MATLAB vector into an `h5array` object and then displays the fields in the object:

```
vec = [ 1 2 3];

hhh = hdf5.h5array(vec);

hhh:

    Name: ''
    Data: [1 2 3]

hhh.Data

ans =

     1     2     3
```

MATLAB HDF5 h5array Data Class. The `h5array` data class associates a name with an array. The following tables list the class data members and methods.

Data Members	Description
`Data`	Multidimensional array
`Name`	Text string specifying name of the object

Methods	Description
`arr = hdf5.h5array`	Creates an `h5array` object.
`arr = hdf5.h5array(data)`	Creates an `h5array` object, where `data` specifies the value of the `Data` member. `data` can be numeric, a cell array, or an HDF5 data type.

Methods	Description
`setData(arr, data)`	Sets the value of the `Data` member, where `arr` is an `h5array` object and `data` can be numeric, a cell array, or an HDF5 data type.
`setName(arr, name)`	Sets the value of the `Name` member, where `arr` is an `h5array` object and `name` is a string or cell array.

MATLAB HDF5 h5compound Data Class. The `h5compound` data class associates a name with a structure. You can define the field names in the structure and their values. The following tables list the class data members and methods.

Data Members	Description
`Data`	Multidimensional array
`Name`	Text string specifying name of the object
`MemberNames`	Text strings specifying name of the object

Methods	Description
`C = hdf5.h5compound`	Creates an `h5compound` object.
`C = hdf5.h5compound(n1,n2,...)`	Creates an `h5compound` object, where `n1`, `n2` and so on are text strings that specify field names. The constructor creates a corresponding data field for every member name.
`addMember(C, mName)`	Creates a new field in the object `C`. `mName` specifies the name of the field.
`setMember(C, mName, mData)`	Sets the value of the `Data` element associated with the field specified by `mName`, where `C` is an `h5compound` object and `mData` can be numeric or an HDF5 data type.

Methods	Description
`setMemberNames(C, n1, n2,...)`	Specifies the names of fields in the structure, where `C` is an `h5compound` object and `n1`,`n2`, and so on are text strings that specify field names. The method creates a corresponding data field for every name specified.
`setName(C, name)`	Sets the value of the `Name` member, where `C` is an `h5compound` object and `name` is a string or cell array.

MATLAB HDF5 h5enum Data Class. The `h5enum` data class defines an enumerated type. You can specify the enumerations (text strings) and the values they represent. The following tables list the class data members and methods.

Data Members	Description
`Data`	Multidimensional array
`Name`	Text string specifying name of the object
`EnumNames`	Text string specifying the enumerations, that is, the text strings that represent values
`EnumValues`	Values associated with enumerations

Methods	Description
`E = hdf5.h5enum`	Creates an `h5enum` object.
`E = hdf5.h5enum(eNames, eVals)`	Creates an `h5enum` object, where `eNames` is a cell array of strings, and `eVals` is vector of integers. `eNames` and `eVals` must have the same number of elements.
`defineEnum(E, eNames, eVals)`	Defines the set of enumerations with the integer values they represent where `eNames` is a cell array of strings, and `eVals` is vector of integers. `eNames` and `eVals` must have the same number of elements.

Methods	Description
`enumdata = getString(E)`	Returns a cell array containing the names of the enumerations, where `E` is an `h5enum` object.
`setData(E, eData)`	Sets the value of the object's `Data` member, where `E` is an `h5enum` object and `eData` is a vector of integers.
`setEnumNames(E, eNames)`	Specifies the enumerations, where `E` is an `h5enum` object and `eNames` is a cell array of strings.
`setEnumValues(E, eVals)`	Specifies the value associated with each enumeration, where `E` is an `h5enum` object and `eVals` is a vector of integers.
`setName(E, name)`	Sets the value of the object's `Name` member, where `E` is an `h5enum` object and `name` is a string or cell array.

This example uses an HDF5 enumeration object.

1 Create an HDF5 enumerated object.

```
enum_obj = hdf5.h5enum;
```

2 Define the enumerated values and their corresponding names.

```
enum_obj.defineEnum({'RED' 'GREEN' 'BLUE'}, uint8([1 2 3]));
```

`enum_obj` now contains the definition of the enumeration that associates the names `RED`, `GREEN`, and `BLUE` with the numbers 1, 2, and 3.

3 Add enumerated data to the object.

```
enum_obj.setData(uint8([2 1 3 3 2 3 2 1]));
```

In the HDF5 file, these numeric values map to the enumerated values `GREEN`, `RED`, `BLUE`, `BLUE`, `GREEN`, etc.

4 Write the enumerated data to a data set named `objects` in an HDF5 file.

```
hdf5write('myfile3.h5', '/g1/objects', enum_obj);
```

5 Read the enumerated data set from the file.

```
ddd = hdf5read('myfile3.h5','/g1/objects')

hdf5.h5enum:

          Name: ''
          Data: [2 1 3 3 2 3 2 1]
     EnumNames: {'RED'  'GREEN'  'BLUE'}
    EnumValues: [1 2 3]
```

MATLAB HDF5 h5string Data Class. The `h5string` data class associates a name with a text string and provides optional padding behavior. The following tables list the class data members and methods.

Data Members	Description
`Data`	Multidimensional array
`Name`	Text string specifying name of the object
`Length`	Scalar defining length of string

`Padding`	Type of padding to use:
	`'spacepad'`
	`'nullterm'`
	`'nullpad'`

Methods	Description
`str = hdf5.h5string`	Creates an `h5string` object.
`str = hdf5.h5string(data)`	Creates an `h5string` object, where `data` is a text string.
`str = hdf5.h5string(data, padtype)`	Creates an `h5string`object, where `data` is a text string and `padtype` specifies the type of padding to use.
`setData(str, data)`	Sets the value of the object's `Data` member, where `str` is an `h5string` object and`data` is a text string.

Methods	Description
`setLength(str, lenVal)`	Sets the value of the object's `Length` member, where `str` is an `h5string` object and `lenVal` is a scalar.
`setName(str, name)`	Sets the value of the object's `Name` member, where `str` is an `h5string` object and `name` is a string or cell array.
`setPadding(str, padType)`	Specifies the value of the object's `Padding` member, where `str` is an `h5string` object and `padType` is a text string specifying one of the supported pad types.

The following example creates an HDF5 string object.

```
hdf5.h5vlen({0 [0 1] [0 2] [0:10]})

hdf5.h5vlen:

    Name: ''
    Data: [0 0 1 0 2 0 1 2 3 4 5 6 7 8 9 10]
```

The following example creates an HDF5 `h5vlen` object.

```
hdf5.h5vlen({0 [0 1] [0 2] [0:10]})

hdf5.h5vlen:

    Name: ''
    Data: [0 0 1 0 2 0 1 2 3 4 5 6 7 8 9 10]
```

MATLAB HDF5 h5vlen Data Class. The `h5vlen` data class associates a name with an array. The following tables list the class data members and methods.

Data Members	Description
`Data`	Multidimensional array
`Name`	Text string specifying name of the object

Methods	Description
`V = hdf5.h5vlen`	Creates an `h5vlen` object.
`V = hdf5.h5vlen(data)`	Creates an `h5vlen` object, where `data` specifies the value of the `Data` member. `data` can be numeric, a cell array, or an HDF5 data type.
`setData(V, data)`	Sets the value of the object's `Data` member, where `V` is an `h5vlen` object and `data` can be a scalar, vector, text string, a cell array, or an HDF5 data type.
`setName(V, name)`	Sets the value of the object's`Name` member, where `V` is an `h5vlen` object and `name` is a string or cell array.

Using the MATLAB Low-Level HDF5 Functions

MATLAB provides direct access to the over 200 functions in the HDF5 library by creating MATLAB functions that correspond to the functions in the HDF5 library. In this way, you can access the features of the HDF5 library from MATLAB, such as reading and writing complex data types and using the HDF5 subsetting capabilities.

The HDF5 library organizes the library functions into groups, called *interfaces*. For example, all the routines related to working with files, such as opening and closing, are in the H5F interface, where *F* stands for file. MATLAB organizes the low-level HDF5 functions into classes that correspond to each HDF5 interface. For example, the MATLAB functions that correspond to the HDF5 file interface (H5F) are in the @H5F class directory. For a complete list of the HDF5 interfaces and the corresponding MATLAB class directories, see `hdf5`.

The following sections provide more details about how to use the MATLAB HDF5 low-level functions. Topics covered include:

Note This section does not attempt to describe all features of the HDF5 library or explain basic HDF5 programming concepts. To use the MATLAB HDF5 low-level functions effectively, you must refer to the official HDF5 documentation available at the HDF Web site (`http://www.hdfgroup.org`).

Mapping HDF5 Function Syntax to MATLAB Function Syntax

In most cases, the syntax of the MATLAB low-level HDF5 functions is identical to the syntax of the corresponding HDF5 library functions. For example, the following is the function signature of the `H5Fopen` function in the HDF5 library. In the HDF5 function signatures, `hid_t` and `herr_t` are HDF5 types that return numeric values that represent object identifiers or error status values.

```
hid_t H5Fopen(const char *name, unsigned flags, hid_t access_id ) /* C syntax */
```

In MATLAB, each function in an HDF5 interface is a method of a MATLAB class. To view the function signature for a function, specify the class directory name and then the function name, as in the following.

```
help @H5F/open
```

The following shows the signature of the corresponding MATLAB function. First note that, because it's a method of a class, you must use the dot notation to call the MATLAB function: `H5F.open`. This MATLAB function accepts the same three arguments as the HDF5 function: a text string for the name, an HDF5-defined constant for the flags argument, and an HDF5 property list ID. You use property lists to specify characteristics of many different HDF5 objects. In this case, it's a file access property list. Refer to the HDF5

documentation to see which constants can be used with a particular function and note that, in MATLAB, constants are passed as text strings.

```
file_id = H5F.open(name, flags, plist_id)
```

There are, however, some functions where the MATLAB function signature is different than the corresponding HDF5 library function. The following sections describe some general differences that you should keep in mind when using the MATLAB low-level HDF5 functions.

Output Parameters Become Return Values. Some HDF5 library functions use function parameters to return data on the right-hand side (RHS) of the function signature, i.e. as input parameters. The corresponding MATLAB function, because MATLAB allows multiple return values, moves these output parameters to the left-hand side (LHS) of the function signature, i.e. as return values. To illustrate, look at the `H5Dread` function. This function returns data in the `buf` parameter.

```
herr_t H5Dread(hid_t dataset_id, hid_t mem_type_id, hid_t mem_space_id,
        hid_t file_space_id, hid_t xfer_plist_id, void * buf ) /* C syntax */
```

The corresponding MATLAB function changes the output parameter `buf` into a return value. Note that the HDF5 error return is not used. In MATLAB, the nonzero or negative value `herr_t` return values become MATLAB errors. Use MATLAB `try-catch` statements to handle errors.

```
buf = H5D.read(dataset_id, mem_type_id, mem_space_id, file_space_id, plist_id)
```

String Length Parameters Unnecessary. The length parameter used by some HDF5 library functions to specify the length of string parameters are not necessary in the corresponding MATLAB function. For example, the `H5Aget_name` function in the HDF5 library includes a buffer as an output parameter and the size of the buffer as an input parameter.

```
ssize_t H5Aget_name(hid_t attr_id,size_t buf_size,char *buf ) /* C syntax */
```

The corresponding MATLAB function changes the output parameter `buf` into a return value and drops the `buf_size` parameter:

```
attr_name = H5A.get_name(attr_id)
```

Use Empty Array to Specify NULL. The MATLAB functions use empty arrays (`[]`) where HDF5 library functions accept the value `NULL`. For example, the `H5Dfill` function in the HDF5 library accepts the value `NULL` in place of a specified fill value.

```
herr_t H5Dfill(const void *fill, hid_t fill_type_id, void *buf,
               hid_t buf_type_id, hid_t space_id ) /* C syntax */
```

When using the corresponding MATLAB function, you can specify an empty array (`[]`) instead of `NULL`.

Specifying Multiple Constants. Some functions in the HDF5 library require you to specify an array of constants. For example, in the `H5Screate_simple` function, if you want to specify that each dimension in the data space can be unlimited, you use the constant `H5S_UNLIMITED` for each dimension in `maxdims`. In MATLAB, because you pass constants as text strings, you must use a cell array to achieve the same result. The following code fragment provides an example of using a cell array to specify this constant for each dimension of this data space.

```
ds_id = H5S.create_simple(2,[3 4],{'H5S_UNLIMITED' 'H5S_UNLIMITED'});
```

Mapping Between HDF5 Data Types and MATLAB Data Types

When the HDF5 low-level functions read data from an HDF5 file or write data to an HDF5 file, the functions map HDF5 data types to MATLAB data types automatically.

For *atomic* data types, such as commonly used binary formats for numbers (integers and floating point) and characters (ASCII), the mapping is typically straightforward because MATLAB supports similar types. See the table Mapping Between HDF5 Atomic Data Types and MATLAB Data Types on page 7-30 for a list of these mappings.

Mapping Between HDF5 Atomic Data Types and MATLAB Data Types

HDF5 Atomic Data Type	MATLAB Data Type
Bit-field	Array of packed 8-bit integers
Float	MATLAB single and double types, provided that they occupy 64 bits or fewer
Integer types, signed and unsigned	Equivalent MATLAB integer types, signed and unsigned
Opaque	Array of `uint8` values
Reference	Array of `uint8` values
String	MATLAB character arrays.

For *composite* data types, such as aggregations of one or more atomic data types into structures, multidimensional arrays, and variable-length data types (one-dimensional arrays), the mapping is sometimes ambiguous with reference to the HDF5 data type. In HDF5, a 5-by-5 data set containing a single `uint8` value in each element is distinct from a 1-by-1 data set containing a 5-by-5 array of `uint8` values. In the first case, the data set contains 25 observations of a single value; in the second case, the data set contains a single observation with 25 values. In MATLAB both of these data sets are represented by a 5-by-5 matrix.

If your data is a complex data set, you might need to create HDF5 data types directly to make sure you have the mapping you intend. See the table Mapping Between HDF5 Composite Data Types and MATLAB Data Types on page 7-31 for a list of the default mappings. You can specify the data type when you write data to the file using the `H5Dwrite` function. See the HDF5 data type interface documentation for more information.

Mapping Between HDF5 Composite Data Types and MATLAB Data Types

HDF5 Composite Data Type	MATLAB Data Type
Array	Extends the dimensionality of the data type which it contains. For example, an array of an array of integers in HDF5 would map onto a two dimensional array of integers in MATLAB.
Compound	MATLAB structure. Note: All structures representing HDF5 data in MATLAB are scalar.
Enumeration	Array of integers which each have an associated name
Variable Length	MATLAB 1-D cell arrays

Reporting Data Set Dimensions. The MATLAB low-level HDF5 functions report data set dimensions and the shape of data sets differently than the MATLAB high-level functions. For ease of use, the MATLAB high-level functions report data set dimensions consistent with MATLAB column-major indexing. To be consistent with the HDF5 library, and to support the possibility of nested data sets and complicated data types, the MATLAB low-level functions report array dimensions using the C row-major orientation.

Example: Using the MATLAB HDF5 Low-level Functions

This example shows how to use the MATLAB HDF5 low-level functions to write a data set to an HDF5 file and then read the data set from the file.

1. Create the MATLAB variable that you want to write to the HDF5 file. The examples creates a three-dimensional array of `uint8` data.

```
testdata = uint8(ones(5,10,3));
```

2. Create the HDF5 file or open an existing file. The example creates a new HDF5 file, named `my_file.h5`, in the system temp directory.

```
filename = fullfile(tempdir,'my_file.h5');

fileID = H5F.create(filename,'H5F_ACC_TRUNC','H5P_DEFAULT','H5P_DEFAULT');
```

In HDF5, you use the `H5Fcreate` function to create a file. The example uses the MATLAB equivalent, `H5F.create`. As arguments, specify the name you want to assign to the file, the type of access you want to the file (`'H5F_ACC_TRUNC'` in the example), and optional additional characteristics specified by a file creation property list and a file access property list. This example uses default values for these property lists (`'H5P_DEFAULT'`). In the example, note how the C constants are passed to the MATLAB functions as strings. The function returns an ID to the HDF5 file.

3. Create the data set in the file to hold the MATLAB variable. In the HDF5 programming model, you must define the data type and dimensionality (data space) of the data set as separate entities.

   a. Specify the data type used by the data set. In HDF5, you use the `H5Tcopy` function to create integer or floating-point data types. The example uses the corresponding MATLAB function, `H5T.copy`, to create a `uint8` data type because the MATLAB data is `uint8`. The function returns a data type ID.

   ```
   datatypeID = H5T.copy('H5T_NATIVE_UINT8');
   ```

   b. Specify the dimensions of the data set. In HDF5, you use the `H5Screate_simple` routine to create a data space. The example uses the corresponding MATLAB function, `H5S.create_simple`, to specify the dimensions. The function returns a data space ID.

   ```
   dims(1) = 5;
   dims(2) = 10;
   dims(3) = 3
   dataspaceID = H5S.create_simple(3, dims, []);
   ```

   c. Create the data set. In HDF5, you use the `H5Dcreate` routine to create a data set. The example uses the corresponding MATLAB function, `H5D.create`, specifying the file ID, the name you want to assign to the data set, data type ID, the data space ID, and a data set creation property list ID as arguments. The example uses the defaults for the property lists. The function returns a data set ID.

   ```
   dsetname = 'my_dataset';
   datasetID = H5D.create(fileID,dsetname,datatypeID,dataspaceID,'H5P_DEFAULT');
   ```

Note To write a large data set, you must use the chunking capability of the HDF5 library. To do this, create a property list and use the `H5P.set_chunk` function to set the chunk size in the property list. In the following example, the dimensions of the data set are `dims = [2^16 2^16]` and the chunk size is 1024-by-1024. You then pass the property list as the last argument to the data set creation function, `H5D.create`, instead of using the `H5P_DEFAULT` value.

```
plistID = H5P.create('H5P_DATASET_CREATE'); % create property list

chunk_size = min([1024 1024], dims); % define chunk size
H5P.set_chunk(plistID, chunk_size); % set chunk size in property list

datasetID = H5D.create(fileID, dsetname, datatypeID, dataspaceID, plistID);
```

---

4. Write the data to the data set. In HDF5, you use the `H5Dwrite` routine to write data to a data set. The example uses the corresponding MATLAB function, `H5D.write`, specifying as arguments the data set ID, the memory data type ID, the memory space ID, the data space ID, the transfer property list ID and the name of the MATLAB variable to be written to the data set.

   You can use the memory data type to specify the data type used to represent the data in the file. The example uses the constant `'H5ML_DEFAULT'` which lets the MATLAB function do an automatic mapping to HDF5 data types. The memory data space ID and the data set's data space ID specify to write subsets of the data set to the file. The example uses the constant `'H5S_ALL'` to write all the data to the file and uses the default property list.

Note Because HDF5 stores data in row-major order and MATLAB accesses data in column-major order, you should permute your data before writing it to the file.

```
data_perm = permute(testdata,[3 2 1]);
```

```
H5D.write(datasetID,'H5ML_DEFAULT','H5S_ALL','H5S_ALL', ...
          'H5P_DEFAULT',data_perm);
```

5. Close the data set, data space, data type, and file objects. If used inside a MATLAB function, these identifiers are closed automatically when they go out of scope.

   ```
   H5D.close(datasetID);
   H5S.close(dataspaceID);
   H5T.close(datatypeID);
   H5F.close(fileID);
   ```

6. To read the data set you wrote to the file, you must open the file. In HDF5, you use the `H5Fopen` routine to open an HDF5 file, specifying the name of the file, the access mode, and a property list as arguments. The example uses the corresponding MATLAB function, `H5F.open`, opening the file for read-only access.

   ```
   fileID = H5F.open(filename,'H5F_ACC_RDONLY','H5P_DEFAULT');
   ```

7. After opening the file, you must open the data set. In HDF5, you use the `H5Dopen` function to open a data set. The example uses the corresponding MATLAB function, `H5D.open`, specifying as arguments the file ID and the name of the data set, defined earlier in the example.

   ```
   datasetID = H5D.open(fileID, dsetname);
   ```

8. After opening the data set, you can read the data into the MATLAB workspace. In HDF5, you use the `H5Dread` function to read an HDF5 file. The example uses the corresponding MATLAB function, `H5D.read`, specifying as arguments the data set ID, the memory data type ID, the memory space ID, the data space ID, and the transfer property list ID.

   ```
   returned_data = H5D.read(datasetID,'H5ML_DEFAULT',...
                            'H5S_ALL','H5S_ALL','H5P_DEFAULT');
   ```

   Note that the data returned must be indexed in reverse order: HDF5 stores the data in row-major order; MATLAB accesses data in column-major order. To rearrange the data into column-major order, use the MATLAB `permute` function.

```
data = permute(returned_data,[3 2 1]);
```

You can compare the original MATLAB variable, `testdata`, with the variable just created, `data`, to see if they are the same.

Hierarchical Data Format (HDF4) Files

In this section...

Note For information about importing HDF5 data, which is a separate, incompatible format, see "Hierarchical Data Format (HDF5) Files" on page 7-11.

Using the HDF Import Tool

Hierarchical Data Format (HDF4) is a general-purpose, machine-independent standard for storing scientific data in files, developed by the National Center for Supercomputing Applications (NCSA). For more information about these file formats, read the HDF documentation at the HDF Web site (`www.hdfgroup.org`).

HDF-EOS is an extension of HDF4 that was developed by the National Aeronautics and Space Administration (NASA) for storage of data returned from the Earth Observing System (EOS). For more information about this extension to HDF4, see the HDF-EOS documentation at the NASA Web site (`www.hdfeos.org`).

The HDF Import Tool is a graphical user interface that you can use to navigate through HDF4 or HDF-EOS files and import data from them. Importing data using the HDF Import Tool involves these steps:

- "Step 1: Opening an HDF4 File in the HDF Import Tool" on page 7-37
- "Step 2: Selecting a Data Set in an HDF File" on page 7-38
- "Step 3: Specifying a Subset of the Data (Optional)" on page 7-39
- "Step 4: Importing Data and Metadata" on page 7-40

- "Step 5: Closing HDF Files and the HDF Import Tool" on page 7-41

The following sections provide more detail about each of these steps.

Step 1: Opening an HDF4 File in the HDF Import Tool

Open an HDF4 or HDF-EOS file in MATLAB using one of the following methods:

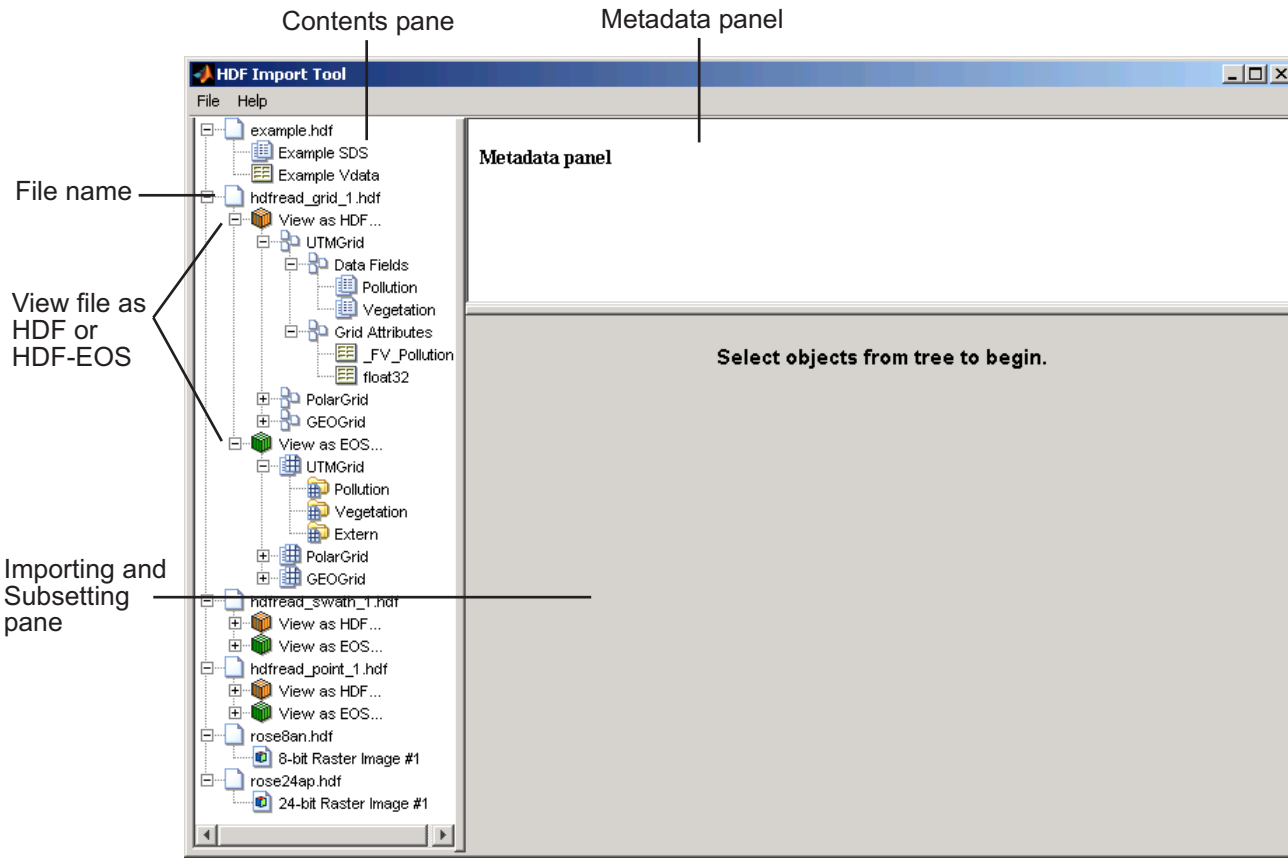
- Choose the **Import Data** option from the MATLAB **File** menu. If you select an HDF4 or HDF-EOS file, the MATLAB Import Wizard automatically starts the HDF Import Tool.
- Start the HDF Import Tool by entering the `hdftool` command at the MATLAB command line:

  ```
  hdftool
  ```

  This opens an empty HDF Import Tool. To open a file, click the **Open** option on the HDFTool **File** menu and select the file you want to open. You can open multiple files in the HDF Import Tool.
- Open an HDF or HDF-EOS file by specifying the file name with the `hdftool` command on the MATLAB command line:

  ```
  hdftool('example.hdf')
  ```

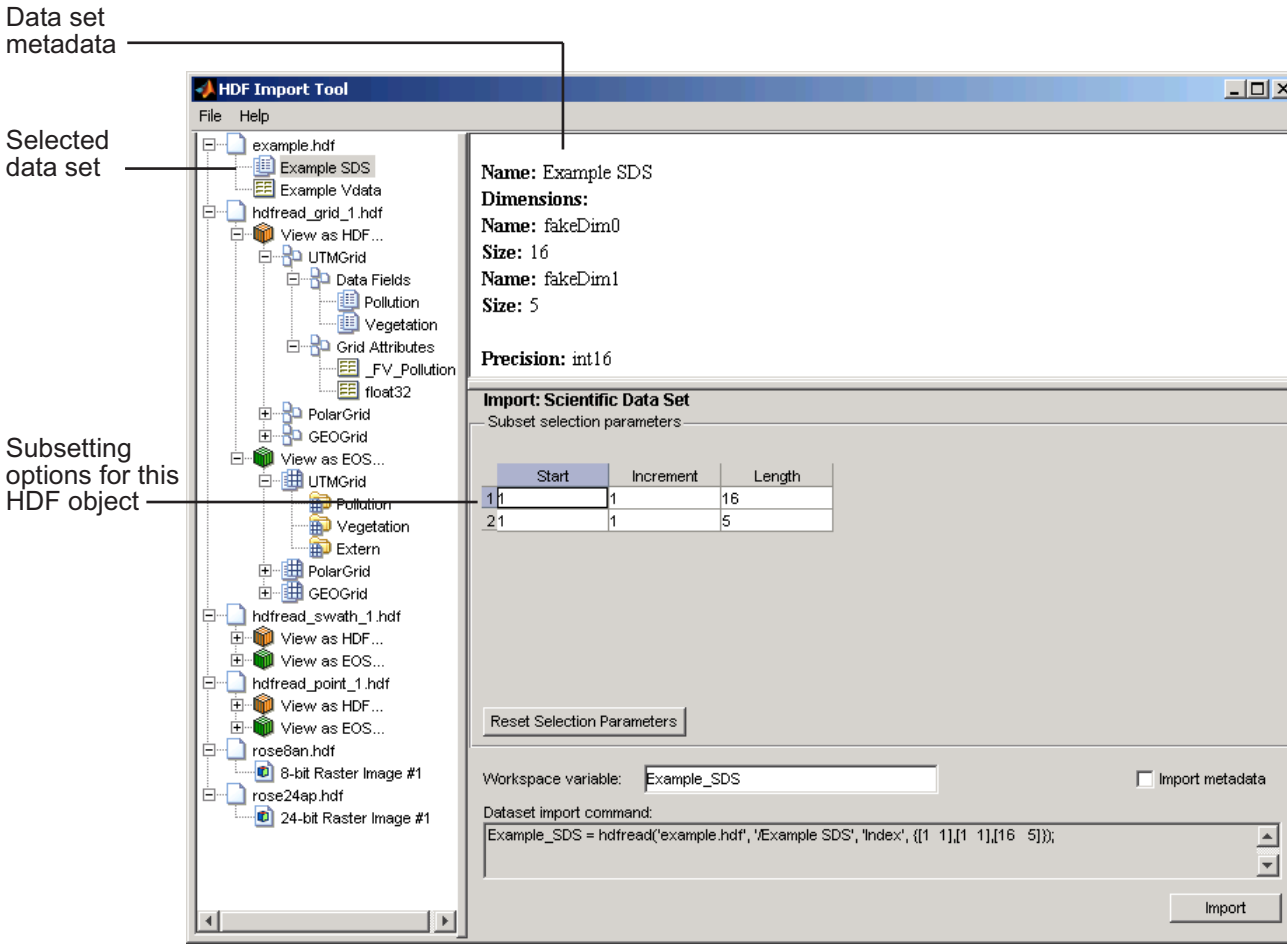
Viewing a File in the HDF Import Tool. When you open an HDF4 or HDF-EOS file in the HDF Import Tool, the tool displays the contents of the file in the Contents pane. You can use this pane to navigate within the file to see what data sets it contains. You can view the contents of HDF-EOS files as HDF data sets or as HDF-EOS files. The icon in the contents pane indicates the view, as illustrated in the following figure. Note that these are just two views of the same data.



Step 2: Selecting a Data Set in an HDF File

To import a data set, you must first select the data set in the contents pane of the HDF Import Tool. Use the Contents pane to view the contents of the file and navigate to the data set you want to import.

For example, the following figure shows the data set `Example SDS` in the HDF file selected. Once you select a data set, the Metadata panel displays information about the data set and the importing and subsetting pane displays subsetting options available for this type of HDF object.



Step 3: Specifying a Subset of the Data (Optional)

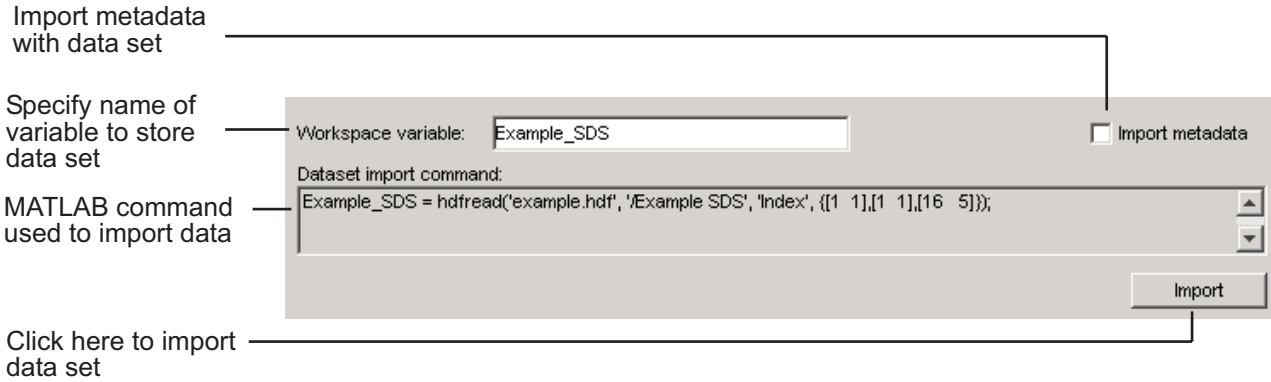
When you select a data set in the contents pane, the importing and subsetting pane displays the subsetting options available for that type of HDF object. The subsetting options displayed vary depending on the type of HDF object. For more information, see “Using the HDF Import Tool Subsetting Options” on page 7-41.

Step 4: Importing Data and Metadata

To import the data set you have selected, click the **Import** button, bottom right corner of the Importing and Subsetting pane. Using the Importing and Subsetting pane, you can

- Specify the name of the workspace variable — By default, the HDF Import Tool uses the name of the HDF4 data set as the name of the MATLAB workspace variable. In the following figure, the variable name is `Example_SDS`. To specify another name, enter text in the **Workspace Variable** text box.
- Specify whether to import metadata associated with the data set — To import any metadata that might be associated with the data set, select the **Import Metadata** check box. To store the metadata, the HDF Import Tool creates a second variable in the workspace with the same name with "`_info`" appended to it. For example, if you select this check box, the name of the metadata variable for the data set in the figure would be `Example_SDS_info`.
- Save the data set import command syntax — The **Dataset import command** text window displays the MATLAB command used to import the data set. This text is not editable, but you can copy and paste it into the MATLAB Command Window or a text editor for reuse.

The following figure shows how to specify these options in the HDF Import Tool.



Step 5: Closing HDF Files and the HDF Import Tool

To close a file, select the file in the contents pane and click **Close File** on the HDF Import Tool **File** menu.

To close all the files open in the HDF Import Tool, click **Close All Files** on the HDF Import Tool **File** menu.

To close the tool, click **Close HDFTool** in the HDF Import Tool **File** menu or click the **Close** button in the upper right corner of the tool.

If you used the `hdftool` syntax that returns a handle to the tool,

```
h = hdftool('example.hdf')
```

you can use the `close(h)` command to close the tool from the MATLAB command line.

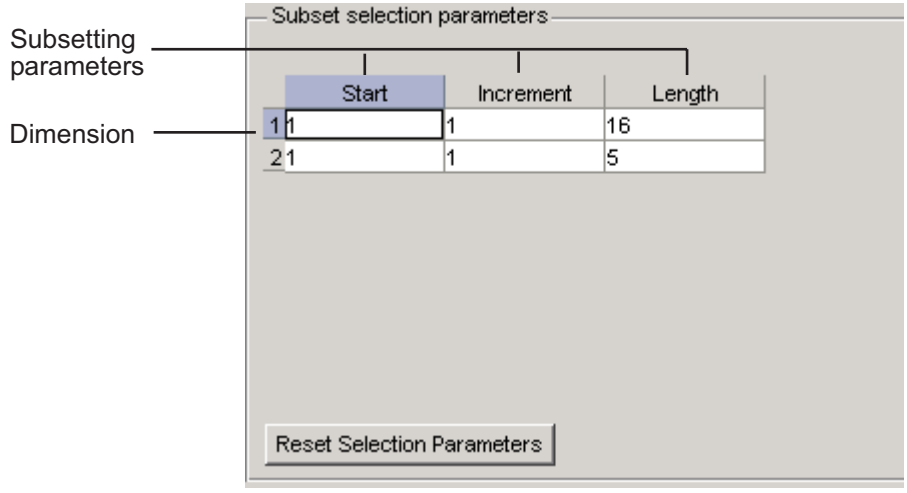
Using the HDF Import Tool Subsetting Options

When you select a data set, the importing and subsetting pane displays the subsetting options available for that type of data set. The following sections provide information about these subsetting options for all supported data set types. For general information about the HDF Import tool, see “Using the HDF Import Tool” on page 7-36.

Note To use these data subsetting options effectively, you must understand the HDF and HDF-EOS data formats. Therefore, use this documentation in conjunction with the HDF documentation (`www.hdfgroup.org`) and the HDF-EOS documentation (`www.hdfeos.org`).

HDF Scientific Data Sets (SD)

The HDF scientific data set (SD) is a group of data structures used to store and describe multidimensional arrays of scientific data. Using the HDF Import Tool subsetting parameters, you can import a subset of an HDF scientific data set by specifying the location, range, and number of values to be read along each dimension.



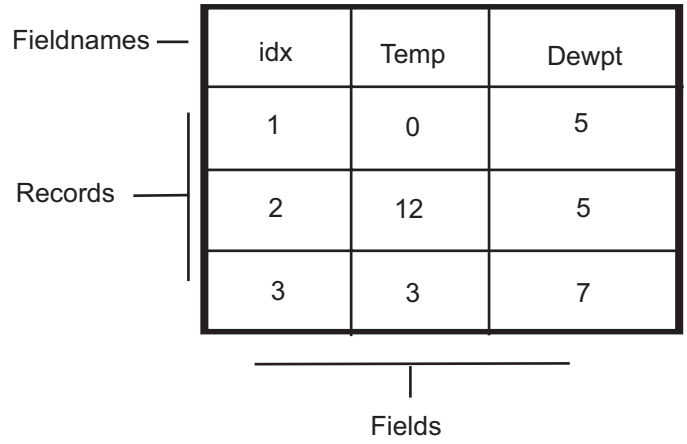
The subsetting parameters are:

- **Start** — Specifies the position on the dimension to begin reading. The default value is 1, which starts reading at the first element of each dimension. The values specified must not exceed the size of the relevant dimension of the data set.
- **Increment** — Specifies the interval between the values to read. The default value is 1, which reads every element of the data set.
- **Length** — Specifies how much data to read along each dimension. The default value is the length of the dimension, which causes all the data to be read.

HDF Vdata

HDF Vdata data sets provide a framework for storing customized tables. A Vdata table consists of a collection of records whose values are stored in

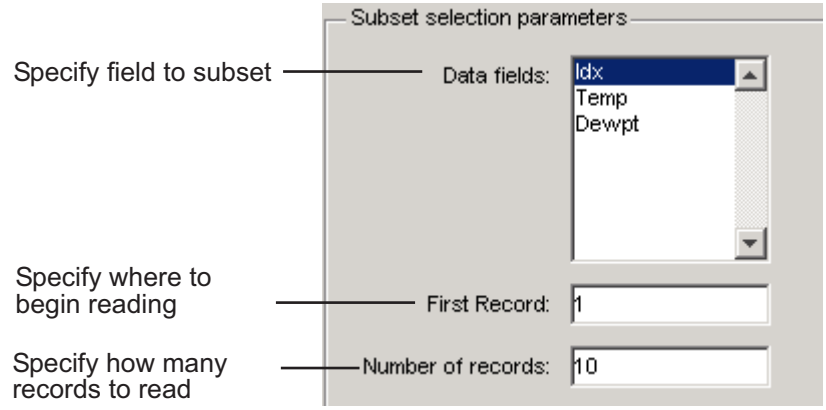
fixed-length fields. All records have the same structure and all values in each field have the same data type. Each field is identified by a name. The following figure illustrates a Vdata table.



You can import a subset of an HDF Vdata data set in the following ways:

- Specifying the name of the field that you want to import
- Specifying the range of records that you want to import

The following figure shows how you specify these subsetting parameters for Vdata.

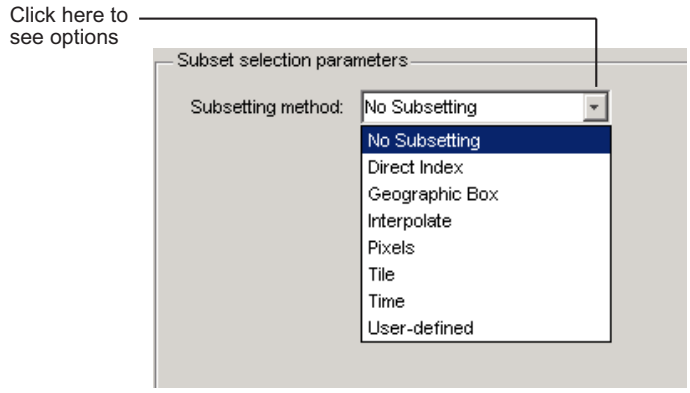


HDF-EOS Grid Data

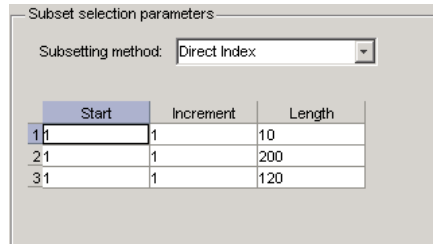
In HDF-EOS Grid data, a rectilinear grid overlays a map. The map uses a known map projection. The HDF Import Tool supports the following mutually exclusive subsetting options for Grid data:

- "Direct Index" on page 7-44
- "Geographic Box" on page 7-45
- "Interpolation" on page 7-46
- "Pixels" on page 7-47
- "Tile" on page 7-47
- "Time" on page 7-47
- "User-Defined" on page 7-48

To access these options, click the Subsetting method menu in the importing and subsetting pane.



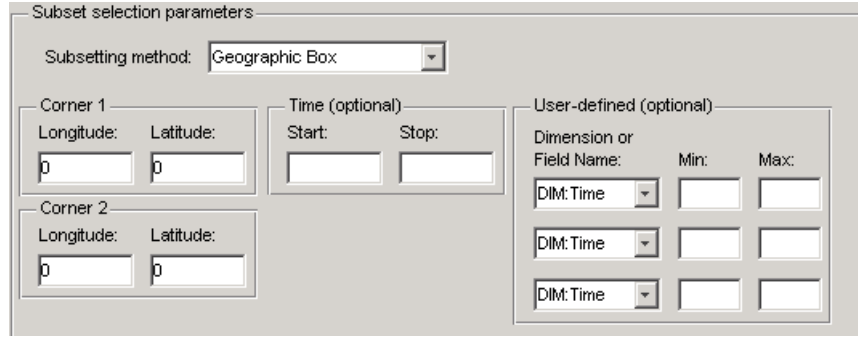
Direct Index. You can import a subset of an HDF-EOS Grid data set by specifying the location, range, and number of values to be read along each dimension.



Each row represents a dimension in the data set and each column represents these subsetting parameters:

- **Start** — Specifies the position on the dimension to begin reading. The default value is 1, which starts reading at the first element of each dimension. The values specified must not exceed the size of the relevant dimension of the data set.
- **Increment** — Specifies the interval between the values to read. The default value is 1, which reads every element of the data set.
- **Length** — Specifies how much data to read along each dimension. The default value is the length of the dimension, which causes all the data to be read.

Geographic Box. You can import a subset of an HDF-EOS Grid data set by specifying the rectangular area of the grid that you are interested in. To define this rectangular area, you must specify two points, using longitude and latitude in decimal degrees. These points are two corners of the rectangular area. Typically, **Corner 1** is the upper-left corner of the box, and **Corner 2** is the lower-right corner of the box.

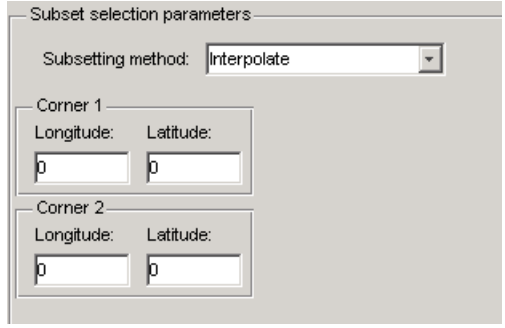


Optionally, you can further define the subset of data you are interested in by using Time parameters (see “Time” on page 7-47) or by specifying other User-Defined subsetting parameters (see “User-Defined” on page 7-48).

Interpolation. Interpolation is the process of estimating a pixel value at a location in between other pixels. In interpolation, the value of a particular pixel is determined by computing the weighted average of some set of pixels in the vicinity of the pixel.

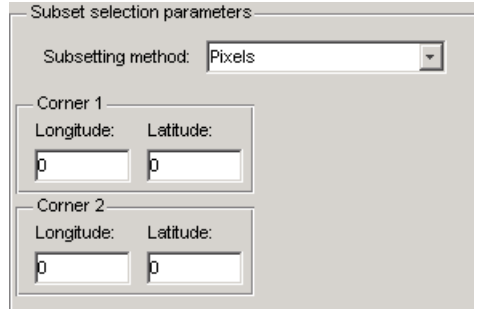
You define the region used for bilinear interpolation by specifying two points that are corners of the interpolation area:

- **Corner 1** – Specify longitude and latitude values in decimal degrees. Typically, **Corner 1** is the upper-left corner of the box.
- **Corner 2** — Specify longitude and latitude values in decimal degrees. Typically, **Corner 2** is the lower-right corner of the box

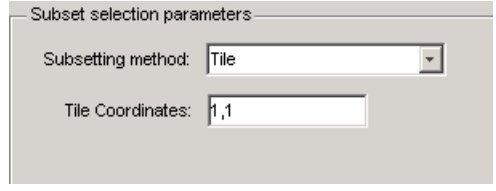


Pixels. You can import a subset of the pixels in a Grid data set by defining a rectangular area over the grid. You define the region used for bilinear interpolation by specifying two points that are corners of the interpolation area:

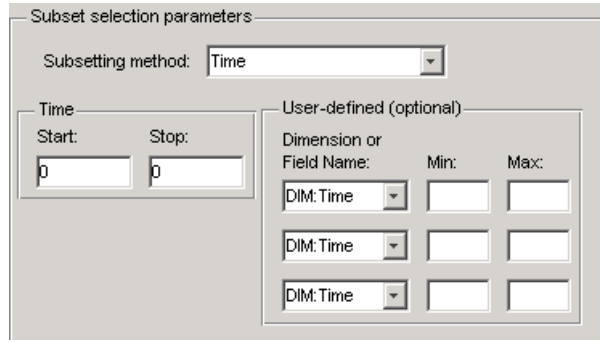
- **Corner 1** – Specify longitude and latitude values in decimal degrees. Typically, **Corner 1** is the upper-left corner of the box.
- **Corner 2** — Specify longitude and latitude values in decimal degrees. Typically, **Corner 2** is the lower-right corner of the box



Tile. In HDF-EOS Grid data, a rectilinear grid overlays a map. Each rectangle defined by the horizontal and vertical lines of the grid is referred to as a *tile*. If the HDF-EOS Grid data is stored as tiles, you can import a subset of the data by specifying the coordinates of the tile you are interested in. Tile coordinates are 1-based, with the upper-left corner of a two-dimensional data set identified as `1,1`. In a three-dimensional data set, this tile would be referenced as `1,1,1`.

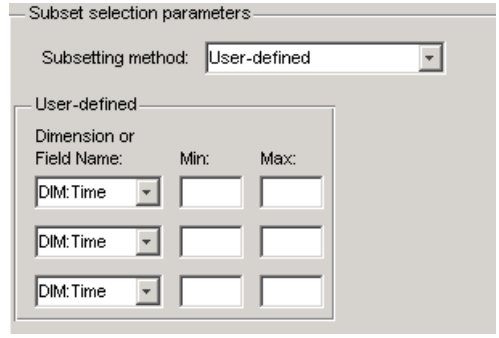


Time. You can import a subset of the Grid data set by specifying a time period. You must specify both the start time and the stop time (the endpoint of the time span). The units (hours, minutes, seconds) used to specify the time are defined by the data set.



Along with these time parameters, you can optionally further define the subset of data to import by supplying user-defined parameters.

User-Defined. You can import a subset of the Grid data set by specifying user-defined subsetting parameters.

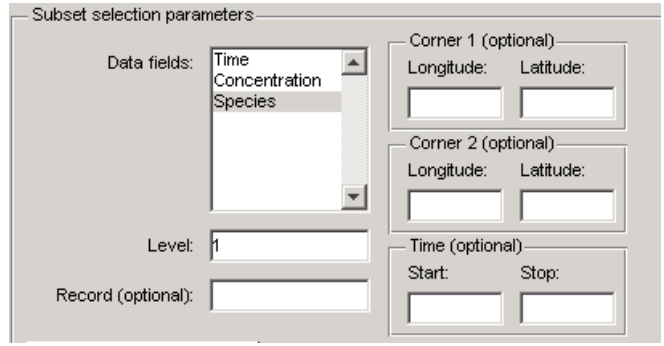


When specifying user-defined parameters, you must first specify whether you are subsetting along a dimension or by field. Select the dimension or field by name using the **Dimension or Field Name** menu. Dimension names are prefixed with the characters `DIM:`.

Once you specify the dimension or field, you use **Min** and **Max** to specify the range of values that you want to import. For dimensions, **Min** and **Max** represent a range of *elements*. For fields, **Min** and **Max** represent a range of *values*.

HDF-EOS Point Data

HDF-EOS Point data sets are tables. You can import a subset of an HDF-EOS Point data set by specifying field names and level. Optionally, you can refine the subsetting by specifying the range of records you want to import, by defining a rectangular area, or by specifying a time period. For information about specifying a rectangular area, see “Geographic Box” on page 7-45. For information about subsetting by time, see “Time” on page 7-47.



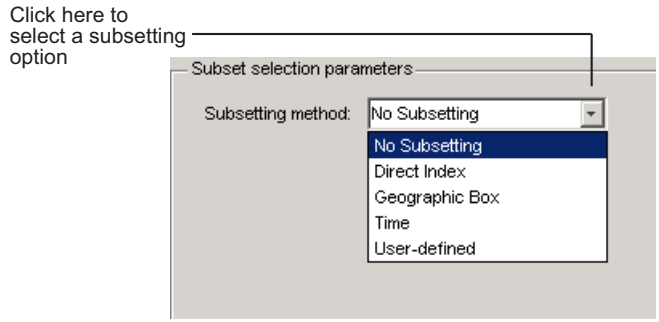
HDF-EOS Swath Data

HDF-EOS Swath data is data that is produced by a satellite as it traces a path over the earth. This path is called its ground track. The sensor aboard the satellite takes a series of scans perpendicular to the ground track. Swath data can also include a vertical measure as a third dimension. For example, this vertical dimension can represent the height above the Earth of the sensor.

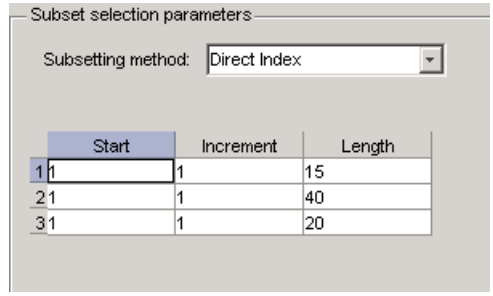
The HDF Import Tool supports the following mutually exclusive subsetting options for Swath data:

- “Direct Index” on page 7-50
- “Geographic Box” on page 7-51
- “Time” on page 7-52
- “User-Defined” on page 7-52

To access these options, click the `Subsetting method` menu in the **Importing and Subsetting** pane.



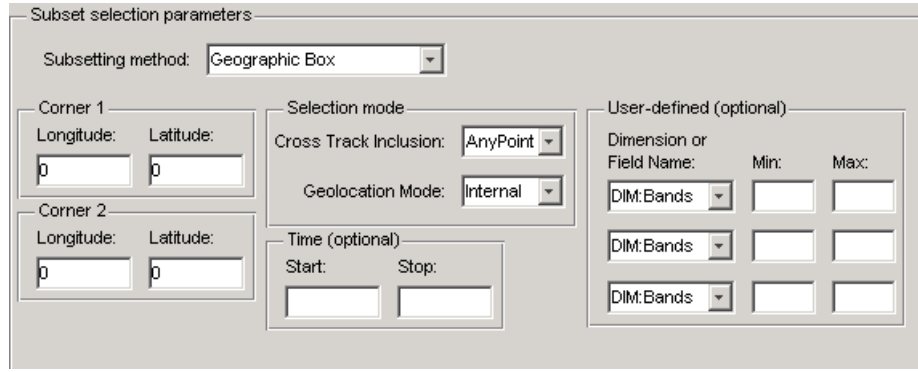
Direct Index. You can import a subset of an HDF-EOS Swath data set by specifying the location, range, and number of values to be read along each dimension.



Each row represents a dimension in the data set and each column represents these subsetting parameters:

- **Start** — Specifies the position on the dimension to begin reading. The default value is 1, which starts reading at the first element of each dimension. The values specified must not exceed the size of the relevant dimension of the data set.
- **Increment** — Specifies the interval between the values to read. The default value is 1, which reads every element of the data set.
- **Length** — Specifies how much data to read along each dimension. The default value is the length of the dimension, which causes all the data to be read.

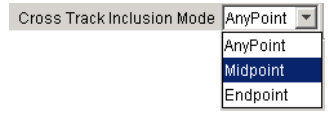
Geographic Box. You can import a subset of an HDF-EOS Swath data set by specifying the rectangular area of the grid that you are interested in and by specifying the selection Mode.



You define the rectangular area by specifying two points that specify two corners of the box:

- **Corner 1** — Specify longitude and latitude values in decimal degrees. Typically, **Corner 1** is the upper-left corner of the box.
- **Corner 2** — Specify longitude and latitude values in decimal degrees. Typically, **Corner 2** is the lower-right corner of the box.

You specify the selection mode by choosing the type of **Cross Track Inclusion** and the **Geolocation mode**. The **Cross Track Inclusion** value determines how much of the area of the geographic box that you define must fall within the boundaries of the swath.

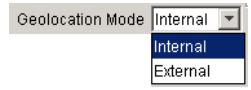


Select from these values:

- **AnyPoint** — Any part of the box overlaps with the swath.
- **Midpoint** — At least half of the box overlaps with the swath.

- **Endpoint** — All of the area defined by the box overlaps with the swath.

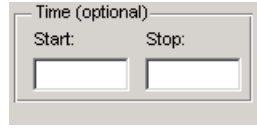
The **Geolocation Mode** value specifies whether geolocation fields and data must be in the same swath.



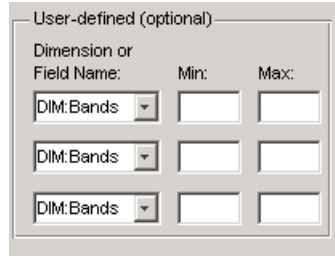
Select from these values:

- **Internal** — Geolocation fields and data fields must be in the same swath.
- **External** — Geolocation fields and data fields can be in different swaths.

Time. You can optionally also subset swath data by specifying a time period. The units used (hours, minutes, seconds) to specify the time are defined by the data set



User-Defined. You can optionally also subset a swath data set by specifying user-defined parameters.



When specifying user-defined parameters, you must first specify whether you are subsetting along a dimension or by field. Select the dimension or field by name using the **Dimension or Field Name** menu. Dimension names are prefixed with the characters `DIM:`.

Once you specify the dimension or field, you use **Min** and **Max** to specify the range of values that you want to import. For dimensions, **Min** and **Max** represent a range of *elements*. For fields, **Min** and **Max** represent a range of *values*.

HDF Raster Image Data

For 8-bit HDF raster image data, you can specify the colormap.

Using the MATLAB HDF4 High-Level Functions

To import data from an HDF or HDF-EOS file, you can use the MATLAB HDF4 high-level function `hdfread`. The `hdfread` function provides a programmatic way to import data from an HDF4 or HDF-EOS file that still hides many of the details that you need to know if you use the low-level HDF functions, described in "Using the HDF4 Low-Level Functions" on page 7-56. You can also import HDF4 data using an interactive GUI, described in "Using the HDF Import Tool" on page 7-36.

This section describes these high-level MATLAB HDF functions, including

- "Using hdfinfo to Get Information About an HDF4 File" on page 7-53
- "Using hdfread to Import Data from an HDF4 File" on page 7-54

To export data to an HDF4 file, you must use the MATLAB HDF4 low-level functions.

Using hdfinfo to Get Information About an HDF4 File

To get information about the contents of an HDF4 file, use the `hdfinfo` function. The `hdfinfo` function returns a structure that contains information about the file and the data in the file.

Note You can also use the HDF Import Tool to get information about the contents of an HDF4 file. See "Using the HDF Import Tool" on page 7-36 for more information.

This example returns information about a sample HDF4 file included with MATLAB:

```
info = hdfinfo('example.hdf')

info =

    Filename: 'example.hdf'
         SDS: [1x1 struct]
       Vdata: [1x1 struct]
```

To get information about the data sets stored in the file, look at the `SDS` field.

Using hdfread to Import Data from an HDF4 File

To use the`hdfread` function, you must specify the data set that you want to read. You can specify the filename and the data set name as arguments, or you can specify a structure returned by the `hdfinfo` function that contains this information. The following example shows both methods. For information about how to import a subset of the data in a data set, see "Reading a Subset of the Data in a Data Set" on page 7-56.

1. Determine the names of data sets in the HDF4 file, using the `hdfinfo` function.

   ```
   info = hdfinfo('example.hdf')

   info =

       Filename: 'example.hdf'
            SDS: [1x1 struct]
          Vdata: [1x1 struct]
   ```

   To determine the names and other information about the data sets in the file, look at the contents of the `SDS` field. The `Name` field in the SDS structure gives the name of the data set.

   ```
   dsets = info.SDS

   dsets =
   ```

```
      Filename: 'example.hdf'
          Type: 'Scientific Data Set'
          Name: 'Example SDS'
          Rank: 2
      DataType: 'int16'
    Attributes: []
          Dims: [2x1 struct]
         Label: {}
   Description: {}
         Index: 0
```

2 Read the data set from the HDF4 file, using the `hdfread` function. Specify the name of the data set as a parameter to the function. Note that the data set name is case sensitive. This example returns a 16-by-5 array:

```
dset = hdfread('example.hdf', 'Example SDS');

dset =

     3     4     5     6     7
     4     5     6     7     8
     5     6     7     8     9
     6     7     8     9    10
     7     8     9    10    11
     8     9    10    11    12
     9    10    11    12    13
    10    11    12    13    14
    11    12    13    14    15
    12    13    14    15    16
    13    14    15    16    17
    14    15    16    17    18
    15    16    17    18    19
    16    17    18    19    20
    17    18    19    20    21
    18    19    20    21    22
```

Alternatively, you can specify the specific field in the structure returned by `hdfinfo` that contains this information. For example, to read a scientific data set, use the `SDS` field.

```
dset = hdfread(info.SDS);
```

Reading a Subset of the Data in a Data Set. To read a subset of a data set, you can use the optional `'index'` parameter. The value of the index parameter is a cell array of three vectors that specify the location in the data set to start reading, the skip interval (e.g., read every other data item), and the amount of data to read (e.g., the length along each dimension). In HDF4 terminology, these parameters are called the *start*, *stride*, and *edge* values.

For example, this code

- Starts reading data at the third row, third column (`[3 3]`).
- Reads every element in the array (`[]`).
- Reads 10 rows and 2 columns (`[10 2]`).

```
subset = hdfread('Example.hdf','Example SDS',...
                 'Index',{[3 3],[],[10 2 ]})

subset =

      7      8
      8      9
      9     10
     10     11
     11     12
     12     13
     13     14
     14     15
     15     16
     16     17
```

Using the HDF4 Low-Level Functions

This section describes how to use MATLAB functions to access the HDF4 Application Programming Interfaces (APIs). These APIs are libraries of C routines that you can use to import data from an HDF4 file or export data from the MATLAB workspace into an HDF4 file. To import or export data, you must use the functions in the HDF4 API associated with the particular HDF4 data type you are working with. Each API has a particular programming model, that is, a prescribed way to use the routines to write data sets to the file. To illustrate this concept, this section describes the programming

model of one particular HDF4 API: the HDF4 Scientific Data (SD) API. For a complete list of the HDF4 APIs supported by MATLAB and the functions you use to access each one, see the `hdf` reference page.

Note This section does not attempt to describe all HDF4 features and routines. To use the MATLAB HDF4 functions effectively, you must refer to the official NCSA documentation at the HDF Web site (`www.hdfgroup.org`).

Topics covered include

Understanding the HDF4 to MATLAB Syntax Mapping

Each HDF4 API includes many individual routines that you use to read data from files, write data to files, and perform other related functions. For example, the HDF4 Scientific Data (SD) API includes separate C routines to open (`SDopen`), close (`SDend`), and read data (`SDreaddata`).

Instead of supporting each routine in the HDF4 APIs, MATLAB provides a single function that serves as a gateway to all the routines in a particular HDF4 API. For example, the HDF Scientific Data (SD) API includes the C routine `SDend` to close an HDF4 file:

```
status = SDend(sd_id); /* C code */
```

To call this routine from MATLAB, use the MATLAB function associated with the SD API, `hdfsd`. You must specify the name of the routine, minus the API acronym, as the first argument and pass any other required arguments to the routine in the order they are expected. For example,

```
status = hdfsd('end',sd_id); % MATLAB code
```

Handling HDF4 Routines with Output Arguments. Some HDF4 API routines use output arguments to return data. Because MATLAB does not support output arguments, you must specify these arguments as return values.

For example, the `SDfileinfo` routine returns data about an HDF4 file in two output arguments, `ndatasets` and `nglobal_atts`. Here is the C code:

```
status = SDfileinfo(sd_id, ndatasets, nglobal_atts);
```

To call this routine from MATLAB, change the output arguments into return values:

```
[ndatasets, nglobal_atts, status] = hdfsd('fileinfo',sd_id);
```

Specify the return values in the same order as they appear as output arguments. The function status return value is always specified as the last return value.

Example: Importing Data Using the HDF4 SD API Functions

To illustrate using HDF4 API routines in MATLAB, the following sections provide a step-by-step example of how to import HDF4 Scientific Data (SD) into the MATLAB workspace.

Note The following sections, when referring to specific routines in the HDF4 SD API, use the C library name rather than the MATLAB function name. The MATLAB syntax is used in all examples.

Step 1: Opening the HDF4 File. To import an HDF4 SD data set, you must first open the file using the SD API routine `SDstart`. (In HDF4 terminology, the numeric arrays stored in HDF4 files are called data sets.) In MATLAB, you use the `hdfsd` function, specifying as arguments:

- Name of the SD API routine, `start` in this case.
- Name of the file you want to open.
- Mode in which you want to open it. The following table lists the file access modes supported by the `SDstart` routine. In MATLAB, you specify these modes as text strings. You can specify the full HDF4 mode name or one of the abbreviated forms listed in the table.

HDF4 File Creation Mode	HDF4 Mode Name	MATLAB String
Create a new file	`'DFACC_CREATE'`	`'create'`
Read access	`'DFACC_RDONLY'`	`'read'` or `'rdonly'`
Read and write access	`'DFACC_RDWR'`	`'rdwr'` or `'write'`

For example, this code opens the file `mydata.hdf` for read access:

```
sd_id = hdfsd('start','mydata.hdf','read');
```

If `SDstart` can find and open the file specified, it returns an HDF4 SD file identifier, named `sd_id` in the example. Otherwise, it returns `-1`.

Step 2: Retrieving Information About the HDF4 File. To get information about an HDF4 file, you must use the SD API routine `SDfileinfo`. This function returns the number of data sets in the file and the number of global attributes in the file, if any. (For more information about global attributes, see “Example: Exporting Data Using the HDF4 SD API Functions” on page 7-64.) In MATLAB, you use the `hdfsd` function, specifying the following arguments:

- Name of the SD API routine, `fileinfo` in this case
- SD file identifier, `sd_id`, returned by `SDstart`

In this example, the HDF4 file contains three data sets and one global attribute.

```
[ndatasets, nglobal_atts, stat] = hdfsd('fileinfo',sd_id)

ndatasets =
    3

nglobal_atts =
    1

status =
    0
```

Step 3: Retrieving Attributes from an HDF4 File (Optional). HDF4 files can optionally include information, called *attributes*, that describes the data the file contains. Attributes associated with an entire HDF4 file are called *global* attributes. Attributes associated with a data set are called *local* attributes. (You can also associate attributes with files or dimensions. For more information, see "Step 4: Writing Metadata to an HDF4 File" on page 7-69.)

To retrieve attributes from an HDF4 file, use the HDF4 API routine `SDreadattr`. In MATLAB, use the `hdfsd` function, specifying as arguments:

- Name of the SD API routine, `readattr` in this case.
- File identifier (`sd_id`) returned by `SDstart`, for global attributes, or the data set identifier for local attributes. (See "Step 4: Selecting the Data Sets to Import" on page 7-61 to learn how to get a data set identifier.)
- Index identifying the attribute you want to view. HDF4 uses zero-based indexing. If you know the name of an attribute but not its index, use the `SDfindattr` routine to determine the index value associated with the attribute.

For example, this code returns the contents of the first global attribute, which is the character string `my global attribute`:

```
attr_idx = 0;
[attr, status] = hdfsd('readattr', sd_id, attr_idx);

attr =
    my global attribute
```

Step 4: Selecting the Data Sets to Import. To select a data set, use the SD API routine `SDselect`. In MATLAB, you use the `hdfsd` function, specifying as arguments:

- Name of the SD API routine, `select` in this case
- HDF4 SD file identifier (`sd_id`) returned by `SDstart`

If `SDselect` finds the specified data set in the file, it returns an HDF4 SD data set identifier, called `sds_id` in the example. If it cannot find the data set, it returns `-1`.

Note Do not confuse HDF4 SD *file* identifiers, named `sd_id` in the examples, with HDF4 SD *data set* identifiers, named `sds_id` in the examples.

```
sds_id = hdfsd('select',sd_id,1)
```

Step 5: Getting Information About a Data Set. To read a data set, you must get information about the data set, such as its name, size, and data type. In the HDF4 SD API, you use the `SDgetinfo` routine to gather this information. In MATLAB, use the `hdfsd` function, specifying as arguments:

- Name of the SD API routine, `getinfo` in this case
- HDF4 SD data set identifier (`sds_id`) returned by `SDselect`

This code retrieves information about the data set identified by `sds_id`:

```
[dsname, dsndims, dsdims, dstype, dsatts, stat] =
              hdfsd('getinfo',sds_id)
dsname =
      A
```

```
dsndims =
      2

dsdims =
      5     3

dstype =
      double

dsatts =
      0

stat =
      0
```

Step 6: Reading Data from the HDF4 File. To read data from an HDF4 file, you must use the `SDreaddata` routine. In MATLAB, use the `hdfsd` function, specifying as arguments:

- Name of the SD API function, `readdata` in this case.
- HDF4 SD data set identifier (`sds_id`) returned by `SDselect`.
- Location in the data set where you want to start reading data, specified as a vector of index values, called the *start* vector. To read from the beginning of a data set, specify zero for each element of the start vector. Use `SDgetinfo` to determine the dimensions of the data set.
- Number of elements along each dimension to skip between each read operation, specified as a vector of scalar values, called the *stride* vector. To read every element of a data set, specify `1` as the value for each element of the vector or specify an empty array (`[]`).
- Total number of elements to read along each dimension, specified as a vector of scalar values, called the *edges* vector. To read every element of a data set, set each element of the edges vector to the size of each dimension of the data set. Use `SDgetinfo` to determine these sizes.

Note `SDgetinfo` returns dimension values in row-major order, the ordering used by HDF4. Because MATLAB stores data in column-major order, you must specify the dimensions in column-major order, that is, `[columns,rows]`. In addition, you must use zero-based indexing in these arguments.

For example, to read the entire contents of a data set, use this code:

```
[ds_name, ds_ndims, ds_dims, ds_type, ds_atts, stat] =
hdfsd('getinfo',sds_id);

ds_start = zeros(1,ds_ndims); % Creates the vector [0 0]
ds_stride = [];
ds_edges = ds_dims;

[ds_data, status] =
            hdfsd('readdata',sds_id,ds_start,ds_stride,ds_edges);

disp(ds_data)
    1    2    3    4    5
    6    7    8    9    10
   11   12   13   14    15
```

To read less than the entire data set, use the start, stride, and edges vectors to specify where you want to start reading data and how much data you want to read. For example, this code reads the entire second row of the sample data set:

```
ds_start = [0 1]; % Start reading at the first column, second row
ds_stride = []; % Read each element
ds_edges = [5 1]; % Read a 1-by-5 vector of data

[ds_data, status] =
           hdfsd('readdata',sds_id,ds_start,ds_stride,ds_edges);
```

Step 7: Closing the HDF4 Data Set. After writing data to a data set in an HDF4 file, you must close access to the data set. In the HDF4 SD API, you use the `SDendaccess` routine to close a data set. In MATLAB, use the `hdfsd` function, specifying as arguments:

- Name of the SD API routine, `endaccess` in this case
- HDF4 SD data set identifier (`sds_id`) returned by `SDselect`

For example, this code closes the data set:

```
stat = hdfsd('endaccess',sds_id);
```

You must close access to all the data sets in an HDF4 file before closing it.

Step 8: Closing the HDF4 File. After writing data to a data set and closing the data set, you must also close the HDF4 file. In the HDF4 SD API, you use the `SDend` routine. In MATLAB, use the `hdfsd` function, specifying as arguments:

- Name of the SD API routine, `end` in this case
- HDF4 SD file identifier (`sd_id`) returned by `SDstart`

For example, this code closes the data set:

```
stat = hdfsd('end',sd_id);
```

Example: Exporting Data Using the HDF4 SD API Functions

The following sections provide a step-by-step example of how to export data from the MATLAB workspace to an HDF4 file using Scientific Data (SD) API functions.

Step 1: Creating an HDF4 File. To export MATLAB data in HDF4 format, you must first create an HDF4 file, or open an existing one. In the HDF4 SD API, you use the `SDstart` routine. In MATLAB, use the `hdfsd` function, specifying `start` as the first argument. As other arguments, specify

- A text string specifying the name you want to assign to the HDF4 file (or the name of an existing HDF4 file)
- A text string specifying the HDF4 SD interface file access mode

For example, this code creates an HDF4 file named `mydata.hdf`:

```
sd_id = hdfsd('start','mydata.hdf','DFACC_CREATE');
```

When you specify the `DFACC_CREATE` access mode, `SDstart` creates the file and initializes the HDF4 SD multifile interface, returning an HDF4 SD file identifier, named `sd_id` in the example.

If you specify `DFACC_CREATE` mode and the file already exists, `SDstart` fails, returning `-1`. To open an existing HDF4 file, you must use HDF4 read or write modes. For information about using `SDstart` in these modes, see “Step 1: Opening the HDF4 File” on page 7-59.

Step 2: Creating an HDF4 Data Set. After creating the HDF4 file, or opening an existing one, you must create a data set in the file for each MATLAB array you want to export. If you are writing data to an existing data set, you can skip ahead to the next step.

In the HDF4 SD API, you use the `SDcreate` routine to create data sets. In MATLAB, you use the `hdfsd` function, specifying as arguments:

- Name of the SD API routine, `'create'` in this case
- Valid HDF4 SD file identifier, `sd_id`, returned by `SDstart`
- Name you want assigned to the data set
- Data type of the data set.
- Number of dimensions in the data set. This is called the *rank* of the data set in HDF4 terminology.
- Size of each dimension, specified as a vector

Once you create a data set, you cannot change its name, data type, or dimensions.

For example, to create a data set in which you can write the following MATLAB 3-by-5 array of `doubles`,

```
A = [ 1 2 3 4 5 ; 6 7 8 9 10 ; 11 12 13 14 15 ];
```

you could call `hdfsd`, specifying as arguments `'create'` and a valid HDF file identifier, `sd_id`. In addition, set the values of the other arguments as in this code fragment:

```
ds_name = 'A';
ds_type = 'double';
ds_rank = ndims(A);
ds_dims = fliplr(size(A));

sds_id = hdfsd('create',sd_id,ds_name,ds_type,ds_rank,ds_dims);
```

If `SDcreate` can successfully create the data set, it returns an HDF4 SD data set identifier, (`sds_id`). Otherwise, `SDcreate` returns `-1`.

In this example, note the following:

- The data type you specify in `ds_type` must match the data type of the MATLAB array that you want to write to the data set. In the example, the array is of class `double` so the value of `ds_type` is set to `'double'`. If you wanted to use another data type, such as `uint8`, convert the MATLAB array to use this data type,

  ```
  A = uint8([ 1 2 3 4 5 ; 6 7 8 9 10 ; 11 12 13 14 15 ]);
  ```

  and specify the name of the MATLAB data type, `uint8` in this case, in the `ds_type` argument.

  ```
  ds_type = 'uint8';
  ```

- The code fragment reverses the order of the values in the dimensions argument (`ds_dims`). This processing is necessary because the MATLAB `size` function returns the dimensions in column-major order and HDF4 expects to receive dimensions in row-major order.

Step 3: Writing MATLAB Data to an HDF4 File. After creating an HDF4 file and creating a data set in the file, you can write data to the entire data set or just a portion of the data set. In the HDF4 SD API, you use the `SDwritedata` routine. In MATLAB, use the `hdfsd` function, specifying as arguments:

- Name of the SD API routine, `'writedata'` in this case
- Valid HDF4 SD data set identifier, `sds_id`, returned by `SDcreate`
- Location in the data set where you want to start writing data, called the *start* vector in HDF4 terminology
- Number of elements along each dimension to skip between each write operation, called the *stride* vector in HDF4 terminology
- Total number of elements to write along each dimension, called the *edges* vector in HDF4 terminology
- MATLAB array to be written

Note You must specify the values of the start, stride, and edges arguments in row-major order, rather than the column-major order used in MATLAB. Note how the example uses `fliplr` to reverse the order of the dimensions in the vector returned by the `size` function before assigning it as the value of the edges argument.

The values you assign to these arguments depend on the MATLAB array you want to export. For example, the following code fragment writes this MATLAB 3-by-5 array of doubles,

```
A = [ 1 2 3 4 5; 6 7 8 9 10; 11 12 13 14 15 ];
```

into an HDF4 file:

```
ds_start = zeros(1:ndims(A)); % Start at the beginning
ds_stride = [];               % Write every element.
ds_edges = fliplr(size(A));   % Reverse the dimensions.

stat = hdfsd('writedata',sds_id,...
                         ds_start, ds_stride, ds_edges, A);
```

If it can write the data to the data set, `SDwritedata` returns `0`; otherwise, it returns `-1`.

Note `SDwritedata` queues write operations. To ensure that these queued write operations are executed, you must close the file, using the `SDend` routine. See "Step 6: Closing an HDF4 File" on page 7-71 for more information. As a convenience, MATLAB provides a function, `MLcloseall`, that you can use to close all open data sets and file identifiers with a single call. See "Using the MATLAB HDF4 Utility API" on page 7-71 for more information.

To write less than the entire data set, use the start, stride, and edges vectors to specify where you want to start writing data and how much data you want to write.

For example, the following code fragment uses `SDwritedata` to replace the values of the entire second row of the sample data set:

```
1  2  3  4  5
6  7  8  9  10
11  12  13  14  15
```

with the vector `B`:

```
B = [ 9 9 9 9 9];
```

In the example, the start vector specifies that you want to start the write operation in the first column of the second row. Note how HDF4 uses zero-based indexing and specifies the column dimension first. In MATLAB, you would specify this location as `(2,1)`. The edges argument specifies the dimensions of the data to be written. Note that the size of the array of data to be written must match the edge specification.

```
ds_start = [0 1]; % Start writing at the first column, second row.
ds_stride = []; % Write every element.
ds_edges = [5 1]; % Each row is a 1-by-5 vector.

stat = hdfsd('writedata',sds_id,ds_start,ds_stride,ds_edges,B);
```

Step 4: Writing Metadata to an HDF4 File. You can optionally include information in an HDF4 file, called attributes, that describes the file and its contents. Using the HDF4 SD API, you can associate attributes with three types of HDF4 objects:

- An entire HDF4 file — File attributes, also called *global* attributes, generally contain information pertinent to all the data sets in the file.
- A data set in an HDF4 file — Data set attributes, also called *local* attributes, describe individual data sets.
- A dimension of a data set — Dimension attributes provide information about one particular dimension of a data set.

To create an attribute in the HDF4 SD API, use the `SDsetattr` routine. In MATLAB, use the `hdfsd` function, specifying `'setattr'` as the first argument. As other arguments, specify

- A valid HDF4 SD identifier associated with the object. This value can be a file identifier (`sd_id`), a data set identifier (`sds_id`), or a dimension identifier (`dim_id`).
- A text string that defines the name of the attribute.
- The attribute value.

For example, this code creates a global attribute, named `my_global_attr`, and associates it with the HDF4 file identified by `sd_id`:

```
status = hdfsd('setattr',sd_id,'my_global_attr','my_attr_val');
```

Note In the NCSA documentation, the `SDsetattr` routine has two additional arguments: data type and the number of values in the attribute. When calling this routine from MATLAB, you do not have to include these arguments. The MATLAB HDF4 function can determine the data type and size of the attribute from the value you specify.

The SD interface supports predefined attributes that have reserved names and, in some cases, data types. Predefined attributes are identical to user-defined attributes except that the HDF4 SD API has already defined

their names and data types. For example, the HDF4 SD API defines an attribute, named `cordsys`, in which you can specify the coordinate system used by the data set. Possible values of this attribute include the text strings `'cartesian'`, `'polar'`, and `'spherical'`.

Predefined attributes can be useful because they establish conventions that applications can depend on. The HDF4 SD API supports predefined attributes for data sets and dimensions only; there are no predefined attributes for files. For a complete list of the predefined attributes, see the NCSA documentation.

In the HDF4 SD API, you create predefined attributes the same way you create user-defined attributes, using the `SDsetattr` routine. In MATLAB, use the `hdfsd` function, specifying `setattr` as the first argument:

```
attr_name = 'cordsys';
attr_value = 'polar';

status = hdfsd('setattr',sds_id,attr_name,attr_value);
```

The HDF4 SD API also includes specialized functions for writing and reading the predefined attributes. These specialized functions, such as `SDsetdatastrs`, are sometimes easier to use, especially when you are reading or writing multiple related predefined attributes. You must use specialized functions to read or write the predefined dimension attributes.

You can associate multiple attributes with a single HDF4 object. HDF4 maintains an attribute index for each object. The attribute index is zero-based. The first attribute has index value 0, the second has index value 1, and so on. You access an attribute by its index value.

Each attribute has the format `name=value`, where `name` (called `label` in HDF4 terminology) is a text string up to 256 characters in length and `value` contains one or more entries of the same data type. A single attribute can have multiple values.

Step 5: Closing HDF4 Data Sets. After writing data to a data set in an HDF4 file, you must close access to the data set. In the HDF4 SD API, you use the `SDendaccess` routine to close a data set. In MATLAB, use the `hdfsd` function, specifying `endaccess` as the first argument. As the only other argument, specify a valid HDF4 SD data set identifier, `sds_id` in this example:

```
stat = hdfsd('endaccess',sds_id);
```

Step 6: Closing an HDF4 File. After writing data to a data set and closing the data set, you must also close the HDF4 file. In the HDF4 SD API, you use the `SDend` routine. In MATLAB, use the `hdfsd` function, specifying `end` as the first argument. As the only other argument, specify a valid HDF4 SD file identifier, `sd_id` in this example:

```
stat = hdfsd('end',sd_id);
```

You must close access to all the data sets in an HDF4 file before closing it.

Note Closing an HDF4 file executes all the write operations that have been queued using `SDwritedata`. As a convenience, the MATLAB HDF Utility API provides a function that can close all open data set and file identifiers with a single call. See "Using the MATLAB HDF4 Utility API" on page 7-71 for more information.

Using the MATLAB HDF4 Utility API

In addition to the standard HDF4 APIs, listed in the `hdf`reference page, MATLAB supports utility functions that are designed to make it easier to use HDF4 in the MATLAB environment.

For example, using the gateway function to the MATLAB HDF4 utility API, `hdfml`, and specifying the name of the `listinfo` routine as an argument, you can view all the currently open HDF4 identifiers. MATLAB updates this list whenever HDF identifiers are created or closed. In the following example only two identifiers are open.

```
hdfml('listinfo')
No open RI identifiers
No open GR identifiers
No open grid identifiers
No open grid file identifiers
No open annotation identifiers
No open AN identifiers
Open scientific dataset identifiers:
 262144
```

```
Open scientific data file identifiers:
 393216
No open Vdata identifiers
No open Vgroup identifiers
No open Vfile identifiers
No open point identifiers
No open point file identifiers
No open swath identifiers
No open swath file identifiers
No open access identifiers
No open file identifiers
```

Closing All Open HDF4 Identifiers. To close all the currently open HDF4 identifiers in a single call, use the gateway function to the MATLAB HDF4 utility API, `hdfml`, specifying the name of the `closeall` routine as an argument. The following example closes all the currently open HDF4 identifiers.

```
hdfml('closeall')
```

8

Error Handling

Error Reporting in MATLAB

In this section...

Overview

No matter how carefully you plan and test the programs you write, they may not always run as smoothly as expected when executed under different conditions. It is always a good idea to include error checking in programs to ensure reliable operation under all conditions.

In MATLAB, you can decide how your programs respond to different types of errors. You may want to prompt the user for more input, display extended error or warning information, or perhaps repeat a calculation using default values. The error-handling capabilities in MATLAB help your programs check for particular error conditions and execute the appropriate code depending on the situation.

When MATLAB detects a severe fault in the command or program it is running, it collects information about what was happening at the time of the error, displays a message to help the user understand what went wrong, and terminates the command or program. This is called *throwing an exception*. You can get an exception while entering commands at the MATLAB command prompt or while executing your program code.

Getting an Exception at the Command Line

If you get an exception at the MATLAB prompt, you have several options on how to deal with it as described below.

Determine the Fault from the Error Message

Evaluate the error message MATLAB has displayed. Most error messages attempt to explain at least the immediate cause of the program failure. There

is often sufficient information to determine the cause and what you need to do to remedy the situation.

Review the Failing Code

If the function in which the error occurred is implemented as an M-file, the error message should include a line that looks something like this:

```
surf
```

```
??? Error using ==> surf at 50
Not enough input arguments.
```

The underlined text to the right names the function that threw the error (`surf`, in this case) and shows the failing line number within that function's M-file. Click the underlined text; MATLAB opens the M-file and positions the cursor at the location in the file where the error originated. You may be able to determine the cause of the error by examining this line and the code that precedes it.

Step Through the Code in the Debugger

You can use the MATLAB Debugger to step through the failing code. Click the underlined error text to open the M-file in the MATLAB Editor at or near the point of the error. Next, click the hyphen at the beginning of that line to set a breakpoint at that location. When you rerun your program, MATLAB pauses execution at the breakpoint and enables you to step through the program code. The command `dbstop on error` is also helpful in finding the point of error.

See the documentation on "Editing and Debugging M-Files" for more information.

Getting an Exception in Your Program Code

When you are writing your own program in an M-file, you can *catch* exceptions and attempt to handle or resolve them instead of allowing your program to terminate. When you catch an exception, you interrupt the normal termination process and enter a block of code that deals with the faulty situation. This block of code is called a *catch block*.

Some of the things you might want to do in the catch block are:

- Examine information that has been captured about the error.
- Gather further information to report to the user.
- Try to accomplish the task at hand in some other way.
- Clean up any unwanted side effects of the error.

When you reach the end of the catch block, you can either continue executing the program, if possible, or terminate it.

The documentation on “Capturing Information About the Error” on page 8-5 describes how to acquire information about what caused the error, and “Responding to an Exception” on page 8-17 presents some ideas on how to respond to it.

Generating a New Exception

When your program code detects a condition that will either make the program fail or yield unacceptable results, it should throw an exception. This procedure

- Saves information about what went wrong and what code was executing at the time of the error.
- Gathers any other pertinent information about the error.
- Instructs MATLAB to throw the exception.

The documentation on “Capturing Information About the Error” on page 8-5 describes how to use an `MException` object to capture information about the error, and “Throwing an Exception” on page 8-16 explains how to initiate the exception process.

Capturing Information About the Error

In this section...

Overview

When MATLAB throws an exception, it captures information about what caused the error in a data structure called an `MException` object. This object is an instance of the MATLAB `MException` class. You can obtain access to the `MException` object by *catching* the exception before your program aborts and accessing the object constructed for this particular error via the `catch` command. When throwing an exception in response to an error in your own M-file code, you will have to create a new `MException` object and store information about the error in that object.

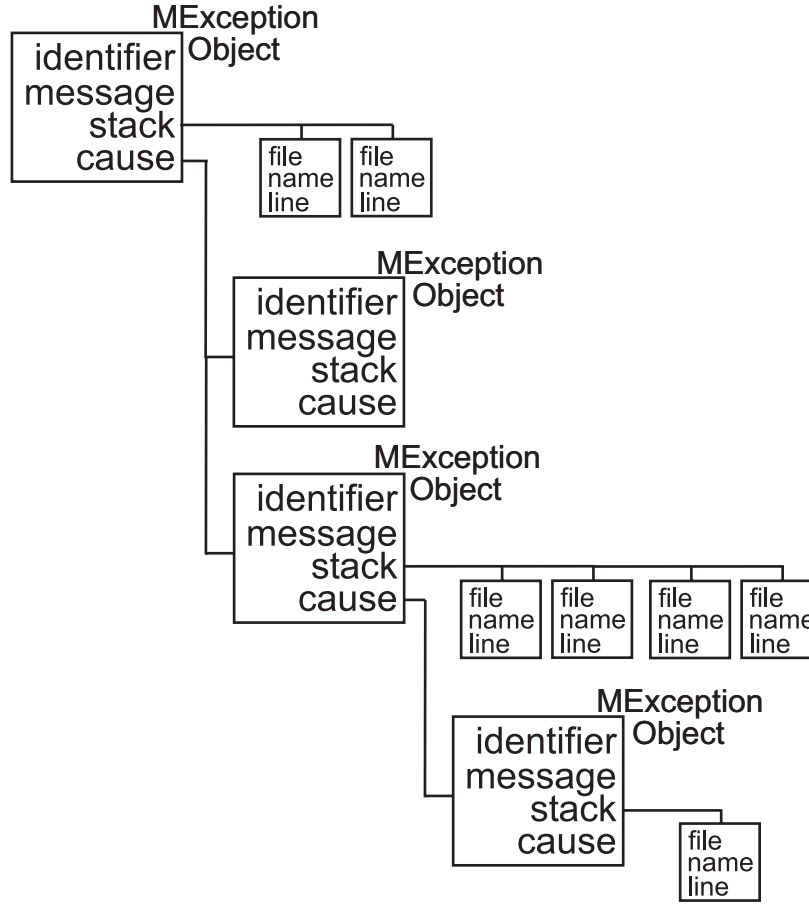
This section describes the `MException` class and objects constructed from that class:

Information on how to use this class is presented in later sections on "Responding to an Exception" on page 8-17 and "Throwing an Exception" on page 8-16.

The MException Class

The figure shown below illustrates one possible configuration of an object of the `MException` class. The object has four properties: `identifier`, `message`, `stack`, and `cause`. Each of these properties is implemented as a field of the structure that represents the `MException` object. The `stack` field is an N-by-1 array of additional structures, each one identifying an M-file, function, and line number from the call stack. The `cause` field is an M-by-1 cell array of `MException` objects, each representing an exception that is related to the current one.

See “Properties of the MException Class” on page 8-7 for a full description of these properties.



Object Constructor

Any code that detects an error and throws an exception must also construct an `MException` object in which to record and transfer information about the error. The syntax of the `MException` constructor is

```
ME = MException(identifier, message)
```

where `identifier` is a MATLAB message identifier of the form

```
component:mnemonic
```

that is enclosed in single quotes, and `message` is a text string, also enclosed in single quotes, that describes the error. The output `ME` is the resulting `MException` object.

If you are responding to an exception rather than throwing one, you do not have to construct an `MException` object. The object has already been constructed and populated by the code that originally detected the error.

Properties of the MException Class

The `MException` class has four properties. Each of these properties is implemented as a field of the structure that represents the `MException` object. Each of these properties is described in the sections below and referenced in the sections on "Responding to an Exception" on page 8-17 and "Throwing an Exception" on page 8-16:

- `identifier`
- `message`
- `stack`
- `cause`

Repeating the `surf` example shown above, but this time catching the exception, you can see the four properties of the `MException` object structure. (This example uses `try-catch` in an atypical fashion. See the section on "The try-catch Statement" on page 8-17 for more information on using `try-catch`).

```
try
    surf
catch ME
    ME
end
```

Run this at the command line and MATLAB returns the contents of the `MException` object:

```
ME =
 MException object with properties:

    identifier: 'MATLAB:nargchk:notEnoughInputs'
       message: 'Not enough input arguments.'
         stack: [1x1 struct]
         cause: {}
```

The `stack` field shows the filename, function, and line number where the exception was thrown:

```
ME.stack
ans =
    file: 'matlabroot\toolbox\matlab\graph3d\surf.m'
    name: 'surf'
    line: 54
```

The `cause` field is empty in this case. Each field is described in more detail in the sections that follow.

Message Identifiers

A message identifier is a tag that you attach to an error or warning statement that makes that error or warning uniquely recognizable by MATLAB. You can use message identifiers with error reporting to better identify the source of an error, or with warnings to control any selected subset of the warnings in your programs.

The message identifier is a read-only character string that specifies a *component* and a *mnemonic* label for an error or warning. The format of a simple identifier is

```
component:mnemonic
```

A colon separates the two parts of the identifier: `component` and `mnemonic`. If the identifier uses more than one `mnemonic`, then additional colons are required to separate them. A message identifier must always contain at least one colon.

Some examples of message identifiers are

```
MATLAB:divideByZero
Simulink:actionNotTaken
TechCorp:OpenFile:notFoundInPath
```

Both the `component` and `mnemonic` fields must adhere to the following syntax rules:

- No white space (space or tab characters) is allowed anywhere in the identifier.
- The first character must be alphabetic, either uppercase or lowercase.
- The remaining characters can be alphanumeric or an underscore.

There is no length limitation to either the `component` or `mnemonic`. The identifier can also be an empty string.

Component Field. The `component` field specifies a broad category under which various errors and warnings can be generated. Common components are a particular product or toolbox name, such as `MATLAB` or `Control`, or perhaps the name of your company, such as `TechCorp` in the preceding example.

You can also use this field to specify a multilevel component. The following statement has a three-level component followed by a mnemonic label:

```
TechCorp:TestEquipDiv:Waveform:obsoleteSyntax
```

The component field enables you to guarantee the uniqueness of each identifier. Thus, while MATLAB uses the identifier `MATLAB:divideByZero` for its `'Divide by zero'` warning, you can reuse the `divideByZero` mnemonic by using your own unique component. For example,

```
warning('TechCorp:divideByZero', ...
        'A sprocket value was divided by zero.')
```

Mnemonic Field. The `mnemonic` field is a string normally used as a tag relating to the particular message. For example, when reporting an error resulting from the use of ambiguous syntax, a simple component and mnemonic such as the following might be appropriate:

```
MATLAB:ambiguousSyntax
```

Message Identifiers in an MException Object. When throwing an exception, create an appropriate identifier and save it to the `MException` object at the time you construct the object using the syntax

```
ME = MException(identifier, string)
```

For example,

```
ME = MException('AcctError:Incomplete', ...
      'Client name not recognized.');

ME.identifier
ans =
    AcctError:NoClient
```

When responding to an exception, you can extract the message identifier from the `MException` object as shown here:

```
try
    surf
catch ME
    id = ME.identifier
end

id =
    MATLAB:nargchk:notEnoughInputs
```

Text of the Error Message

An error message in MATLAB is a read-only character string issued by the program code and returned in the `MException` object. This message can assist the user in determining the cause, and possibly the remedy, of the failure.

When throwing an exception, compose an appropriate error message and save it to the `MException` object at the time you construct the object using the syntax

```
ME = MException(identifier, string)
```

If your message string requires formatting specifications, like those available with the `sprintf` function, use this syntax for the `MException` constructor:

```
ME = MException(identifier, formatstring, arg1, arg2, ...)
```

For example,

```
S = 'Accounts';  f1 = 'ClientName';
ME = MException('AcctError:Incomplete', ...
      'Field ''%s.%s'' is not defined.', S, f1);

ME.message
ans =
    Field 'Accounts.ClientName' is not defined.
```

When responding to an exception, you can extract the error message from the `MException` object as follows:

```
try
    surf
catch ME
    msg = ME.message
end

msg =
    Not enough input arguments.
```

The Call Stack

The `stack` field of the `MException` object identifies the line number, function, and filename where the error was detected. If the error occurs in a called function, as in the following example, the `stack` field contains the line number, function name, and filename not only for the location of the immediate error, but also for each of the calling functions. In this case, `stack` is an N-by-1 array, where N represents the depth of the call stack. That is, the stack field displays the M-file function name and line number where the exception occurred, the name and line number of the M-file caller, the caller's caller, etc., until the top-most M-file function is reached.

When throwing an exception, MATLAB stores call stack information in the `stack` field. You cannot write to this field; access is read-only.

For example, suppose you have three functions that reside in two separate M-files:

```
 mfileA.m
=========================
        .
        .
42 function A1(x, y)
43 B1(x, y);

 mfileB.m
=========================
        .
        .
 8 function B1(x, y)
 9 B2(x, y)
        .
        .
26 function B2(x, y)
27      .
28      .
29      .
30      .
31 %  Throw exception here
```

Catch the exception in variable `ME` and then examine the `stack` field:

```
for k=1:length(ME.stack)
    ME.stack(k)
end

ans =
    file: 'C:\matlab\test\mfileB.m'
    name: 'B2'
    line: 31
```

```
ans =
    file: 'C:\matlab\test\mfileB.m'
    name: 'B1'
    line: 9
ans =
    file: 'C:\matlab\test\mfileA.m'
    name: 'A1'
    line: 43
```

The Cause Array

In some situations, it can be important to record information about not only the one command that caused execution to stop, but also other exceptions that your code caught. You can save these additional `MException` objects in the `cause` field of the primary exception.

The `cause` field of an `MException` is an optional cell array of related `MException` objects. You must use the following syntax when adding objects to the `cause` cell array:

```
primaryException = addCause(primaryException, secondaryException)
```

This example attempts to assign an array `D` to variable `X`. If the `D` array does not exist, the code attempts to load it from a MAT-file and then retries assigning it to `X`. If the load fails, a new `MException` object (`ME3`) is constructed to store the cause of the first two errors (`ME1` and `ME2`):

```
try
    X = D(1:25)
catch ME1
    try
        filename = 'test200';
        load(filename);
        X = D(1:25)
    catch ME2
        ME3 = MException('MATLAB:LoadErr', ...
               'Unable to load from file %s', filename);
        ME3 = addCause(ME3, ME1);
        ME3 = addCause(ME3, ME2);
    end
end
```

There are two exceptions in the cause field of ME3:

```
ME3.cause
ans =
    [1x1 MException]
    [1x1 MException]
```

Examine the cause field of ME3 to see the related errors:

```
ME3.cause{:}
ans =

 MException object with properties:

    identifier: 'MATLAB:UndefinedFunction'
       message: 'Undefined function or method 'D' for input
arguments of type 'double'.'
         stack: [0x1 struct]
         cause: {}
ans =

 MException object with properties:

    identifier: 'MATLAB:load:couldNotReadFile'
       message: 'Unable to read file test204: No such file or
directory.'
         stack: [0x1 struct]
         cause: {}
```

Methods of the MException Class

There are ten methods that you can use with the MException class. The names of these methods are case-sensitive. See the MATLAB function reference pages for more information.

Method Name	Description
addCause	Append an MException to the cause field of another MException.
disp	Display an MException object.

Method Name	Description
`eq`	Compare `MException` objects for equality.
`getReport`	Return a formatted message based on the current exception.
`isequal`	Compare `MException` objects for equality.
`last`	Return the last uncaught exception. This is a static method.
`ne`	Compare `MException` objects for inequality.
`rethrow`	Reissue an exception that has previously been caught.
`throw`	Issue an exception.
`throwAsCaller`	Issue an exception, but omit the current stack frame from the `stack` field.

Throwing an Exception

When your program detects a fault that will keep it from completing as expected or will generate erroneous results, you should halt further execution and report the error by throwing an exception. The basic steps to take are

- Detect the error. This is often done with some type of conditional statement, such as an `if` statement that checks the output of the current operation.
- Construct an `MException` object to represent the error. Add a message identifier string and error message string to the object when calling the constructor.
- If there are other exceptions that may have contributed to the current error, you can store the `MException` object for each in the `cause` field of a single `MException` that you intend to throw. Use the `addCause` method for this.
- Use the `throw` or `throwAsCaller` function to have MATLAB issue the exception. At this point, MATLAB stores call stack information in the `stack` field of the `MException`, exits the currently running function, and returns control to either the keyboard or an enclosing catch block in a calling function.

Responding to an Exception

In this section...

Overview

As stated earlier, MATLAB by default, terminates the currently running program when an exception is thrown. If you catch the exception in your program, however, you can capture information about what went wrong, and deal with the situation in a way that is appropriate for the particular condition. This requires a `try-catch` statement.

This section covers the following topics:

The try-catch Statement

When you have statements in your code that could generate undesirable results, put those statements into a `try-catch` block that catches any errors and handles them appropriately.

A `try-catch` statement looks something like the following pseudocode. It consists of two parts:

- A `try` block that includes all lines between the `try` and `catch` statements.
- A `catch` block that includes all lines of code between the `catch` and `end` statements.

```
    try
       Perform one ...
          or more operations
A   catch ME
       Examine error info in exception object ME
       Attempt to figure out what went wrong
       Either attempt to recover, or clean up and abort
```

```
    end

B   Program continues
```

The program executes the statements in the `try` block. If it encounters an error, it skips any remaining statements in the `try` block and jumps to the start of the `catch` block (shown here as point `A`). If all operations in the `try` block succeed, then execution skips the `catch` block entirely and goes to the first line following the `end` statement (point `B`).

Specifying the `try`, `catch`, and `end` commands and also the code of the `try` and `catch` blocks on separate lines is recommended. If you combine any of these components on the same line, separate them with commas:

```
try, surf, catch ME, ME.stack, end
ans =
    file: 'matlabroot\toolbox\matlab\graph3d\surf.m'
    name: 'surf'
    line: 54
```

The Try Block

On execution, your code enters the `try` block and executes each statement as if it were part of the regular program. If no errors are encountered, MATLAB skips the `catch` block entirely and continues execution following the `end` statement. If any of the `try` statements fail, MATLAB immediately exits the `try` block, leaving any remaining statements in that block unexecuted, and enters the `catch` block.

The Catch Block

The `catch` command marks the start of a `catch` block and provides access to a data structure that contains information about what caused the exception. This is shown as the variable `ME` in the preceding pseudocode. This data structure is an object of the MATLAB `MException` class. When an exception occurs, MATLAB constructs an instance of this class and returns it in the `catch` statement that handles that error.

You are not required to specify any argument with the `catch` statement. If you do not need any of the information or methods provided by the `MException` object, just specify the `catch` keyword alone.

The `MException` object is constructed by internal code in the program that fails. The object has properties that contain information about the error that can be useful in determining what happened and how to proceed. The `MException` object also provides access to methods that enable you to respond to the exception. See the section on"The MException Class" on page 8-5 to find out more about the `MException` class.

Having entered the `catch` block, MATLAB executes the statements in sequence. These statements can attempt to

- Attempt to resolve the error.
- Capture more information about the error.
- Switch on information found in the `MException` object and respond appropriately.
- Clean up the environment that was left by the failing code.

The `catch` block often ends with a `rethrow` command. The `rethrow` causes MATLAB to exit the current function, keeping the call stack information as it was when the exception was first thrown. If this function is at the highest level, that is, it was not called by another function, the program terminates. If the failing function was called by another function, it returns to that function. Program execution continues to return to higher level functions, unless any of these calls were made within a higher-level `try` block, in which case the program executes the respective catch block.

More information about the `MException` class is provided in the section "Capturing Information About the Error" on page 8-5.

Suggestions on How to Handle an Exception

The following example reads the contents of an image file. The `try` block attempts to open and read the file. If either the open or read fails, the program catches the resulting exception and saves the `MException` object in the variable `ME1`.

The `catch` block in the example checks to see if the specified file could not be found. If so, the program allows for the possibility that a common variation of the filename extension (e.g., `jpeg` instead of `jpg`) was used by retrying

the operation with a modified extension. This is done using a `try-catch` statement nested within the original `try-catch`.

```
function d_in = read_image(filename)
file_format = regexp(filename, '(?<=\.)\w+$', 'match');

try
   fid = fopen(filename, 'r');
   d_in = fread(fid);
catch ME1
   % Get last segment of the error message identifier.
   idSegLast = regexp(ME1.identifier, '(?<=:)\w+$', 'match');

   % Did the read fail because the file could not be found?
   if strcmp(idSegLast, 'InvalidFid') && ...
      ~exist(filename, 'file')

      % Yes. Try modifying the filename extension.
      switch file_format
      case 'jpg'    % Change jpg to jpeg
         filename = regexprep(filename, '(?<=\.)\w+$', 'jpeg');
      case 'jpeg'   % Change jpeg to jpg
         filename = regexprep(filename, '(?<=\.)\w+$', 'jpg');
      case 'tif'    % Change tif to tiff
         filename = regexprep(filename, '(?<=\.)\w+$', 'tiff');
      case 'tiff'   % Change tiff to tif
         filename = regexprep(filename, '(?<=\.)\w+$', 'tif');
      otherwise
         rethrow(ME1);
      end

      % Try again, with modifed filenames.
      try
         fid = fopen(filename, 'r');
         d_in = fread(fid);
      catch ME2
         ME2 = addCause(ME2, ME1);
         rethrow(ME2)
      end
   end
```

```
end
```

This example illustrates some of the actions that you can take in response to an exception:

- Compare the `identifier` field of the `MException` object against possible causes of the error.
- Use a nested `try-catch` statement to retry the open and read operations using a known variation of the filename extension.
- Display an appropriate message in the case that the file truly does not exist and then rethrow the exception.
- Add the first `MException` object to the `cause` field of the second.
- Rethrow the exception. This stops program execution and displays the error message.

Cleaning up any unwanted results of the error is also advisable. For example, your program may have allocated a significant amount of memory that it no longer needs.

Warnings

In this section...

Reporting a Warning

Like `error`, the `warning` function alerts the user of unexpected conditions detected when running a program. However, `warning` does not halt the execution of the program. It displays the specified warning message and then continues.

Use `warning` in your code to generate a warning message during execution. Specify the message string as the input argument to `warning`. For example,

```
warning('Input must be a string')
```

Warnings also differ from errors in that you can disable any warnings that you do not want to see. You do this by invoking `warning` with certain control parameters. See “Warning Control” on page 8-24 for more information.

Formatted Message Strings

The warning message string you specify can contain formatting conversion characters, such as those used with the MATLAB `sprintf` function. Make the warning string the first argument, and add any variables used by the conversion as subsequent arguments.

```
warning('formatted_warningmsg', arg1, arg2, ...)
```

For example, if your program cannot process a given parameter, you might report a warning with

```
warning('Ambiguous parameter name, "%s".', param)
```

MATLAB converts special characters like `%d` and `%s` in the warning message string only when you specify more than one input argument with `warning`. See “Formatted Message Strings” on page 8-22 for information.

Message Identifiers

Use a message identifier argument with `warning` to attach a unique tag to a warning message. MATLAB uses this tag to better identify the source of a warning. The first argument in this example is the message identifier.

```
warning('MATLAB:paramAmbiguous', ...
        'Ambiguous parameter name, "%s".', param)
```

See “Warning Control Statements” on page 8-26 for more information on how to use identifiers with warnings.

Identifying the Cause

The `lastwarn` function returns a string containing the last warning message issued by MATLAB. Use this to enable your program to identify the cause of a warning that has just been issued. To return the most recent warning message to the variable `warnmsg`, type

```
warnmsg = lastwarn;
```

You can also change the text of the last warning message with a new message or with an empty string as shown here:

```
lastwarn('newwarnmsg');   % Replace last warning with new string
lastwarn('');           % Replace last warning with empty string
```

Warning Control

In this section...

Overview

MATLAB gives you the ability to control what happens when a warning is encountered during M-file program execution. Options that are available include

- Display selected warnings.
- Ignore selected warnings.
- Stop in the debugger when a warning is invoked.
- Display an M-stack trace after a warning is invoked.

Depending on how you set your warning controls, you can have these actions affect all warnings in your code, specific warnings that you select, or just the most recently invoked warning.

Setting up this system of warning control involves several steps.

1. Start by determining the scope of the control you need for the warnings generated by your code. Do you want the control operations to affect all the warnings in your code at once, or do you want to be able to control certain warnings separately?

2. If the latter is true, you will need to identify those warnings you want to selectively control. This requires going through your code and attaching unique *message identifiers* to each of those warnings. If, on the other

hand, you do not require that fine a granularity of control, the warning statements in your code need no message identifiers.

3 When you are ready to run your programs, use the MATLAB warning control statements to exercise the desired controls on all or selected warnings. Include message identifiers in these control statements when selecting specific warnings to act upon.

Warning Statements

The warning statements you put into your M-file code must contain the string to be displayed when the warning is incurred, and may also contain a message identifier. If you are not planning to use warning control or if you do not need to single out certain warnings for control, you need to specify only the message string. Use the syntax shown in "Warnings" on page 8-22. Valid formats are

```
warning('warnmsg')
warning('formatted_warnmsg', arg1, arg2, ...)
```

Attaching an Identifier to the Warning Statement

If you want to be able to apply control statements to specific warnings, you need to include a message identifier in the warning statements you wish to control. The message identifier must be the first argument in the statement. Valid formats are

```
warning('msg_id', 'warnmsg')
warning('msg_id', 'formatted_warnmsg', arg1, arg2, ...)
```

See "Message Identifiers" on page 8-8 for information on how to specify the `msg_id` argument.

Note When you specify more than one input argument with `warning`, MATLAB treats the `warnmsg` string as if it were a `formatted_warnmsg`. This is explained in "Formatted Message Strings" on page 8-22.

Warning Control Statements

Once you have the warning statements in your M-file and are ready to execute it, you tell MATLAB how to act on these warnings by issuing control statements. These statements place the specified warning(s) into a desired state and have the format

```
warning state msg_id
```

Control statements can return information on the state of selected warnings if you assign the output to a variable, as shown below. See “Output from Control Statements” on page 8-28.

```
s = warning('state', 'msg_id');
```

Warning States

There are three possible values for the `state` argument of a warning control statement.

State	Description
`on`	Enable the display of selected warning message.
`off`	Disable the display of selected warning message.
`query`	Display the current state of selected warning.

Message Identifiers

In addition to the message identifiers already discussed, there are three other identifiers that you can use in control statements only.

Identifier	Description
`msg_id string`	Set selected warning to the specified state.
`all`	Set all warnings to the specified state.
`last`	Set only the last displayed warning to the specified state.

Note MATLAB starts up with all warnings enabled, except for those displayed in response to the command, `warning('query', 'all')`.

Example 1 — Enabling a Selected Warning

Enable just the `actionNotTaken` warning from Simulink by first turning off all warnings and then setting just that warning to `on`.

```
warning off all
warning on Simulink:actionNotTaken
```

Next, use `query` to determine the current state of all warnings. It reports that you have set all warnings to `off`, with the exception of `Simulink:actionNotTaken`.

```
warning query all
The default warning state is 'off'. Warnings not set to the
default are

  State  Warning Identifier

     on  Simulink:actionNotTaken
```

Example 2 — Disabling the Most Recent Warning

Evaluating `inv` on zero displays a warning message. Turn off the most recently invoked warning with `warning off last`.

```
inv(0)
Warning: Matrix is singular to working precision.
ans =
   Inf

warning off last

inv(0)              % No warning is displayed this time
ans =
   Inf
```

Output from Control Statements

The `warning` function, when used in a control statement, returns a MATLAB structure array containing the previous state of the selected warning(s). Use the following syntax to return this information in structure array `s`:

```
s = warning('state', 'msg_id');
```

You must type the command using the MATLAB function format; parentheses and quotation marks are required.

Note MATLAB does not display `warning` output if you do not assign the output to a variable.

The next example turns off `divideByZero` warnings for the MATLAB component, and returns the `identifier` and previous `state` in a 1-by-1 structure array.

```
s = warning('off','MATLAB:divideByZero')
s =
    identifier: 'MATLAB:divideByZero'
         state: 'on'
```

You can use output variables with any type of warning control statement. If you just want to collect the information but do not want to change state, simply perform a `query` on the warning(s). MATLAB returns the current state of those warnings selected by the message identifier.

```
s = warning('query', 'msg_id');
```

If you want to change state, but save the former state so you can restore it later, use the return structure array to save that state. The following example does an implicit `query`, returning state information in `s`, and then turns on all warnings.

```
s = warning('on', 'all');
```

See “Saving and Restoring State” on page 8-30, for more information on restoring the former state of warnings.

Output Structure Array

Each element of the structure array returned by `warning` contains two fields.

Field Name	Description
`identifier`	Message identifier string, `'all'`, or `'last'`
`state`	State of warning(s) prior to invoking this control statement

If you query for the state of just one warning, using a message identifier or `'last'` in the command, MATLAB returns a one-element structure array. The `identifier` field contains the selected message identifier, and the `state` field holds the current state of that warning:

```
s = warning('query','last')
s =
   identifier: 'MATLAB:divideByZero'
        state: 'on'
```

If you query for the state of all warnings, using `'all'` in the command, MATLAB returns a structure array having one or more elements:

- The first element of the array always represents the default state. (This is the state set by the last `warning on|off all` command.)
- Each other element of the array represents a warning that is in a state different from the default.

```
warning off all
warning on MATLAB:divideByZero
warning on MATLAB:fileNotFound

s = warning('query', 'all')
s =
   3x1 struct array with fields:
       identifier
       state

s(1)
ans =
```

```
   identifier: 'all'
        state: 'off'

s(2)
ans =
   identifier: 'MATLAB:divideByZero'
        state: 'on'

s(3)
ans =
   identifier: 'MATLAB:fileNotFound'
        state: 'on'
```

Saving and Restoring State

To temporarily change the state of some warnings and then later return to your original settings, save the original state in a structure array and then restore it from that array. You can save and restore the state of all of your warnings or just one that you select with a message identifier.

To save the current warning state, assign the output of a warning control statement, as discussed in “Output from Control Statements” on page 8-28. The following statement saves the current state of all warnings in structure array `s`:

```
s = warning('query', 'all');
```

To restore state from `s`, use the syntax shown below. Note that the MATLAB function format (enclosing arguments in parentheses) is required.

```
warning(s)
```

Example 1 — Performing an Explicit Query

Perform a query of all warnings to save the current state in structure array `s`:

```
s = warning('query', 'all');
```

Then, after doing some work that includes making changes to the state of some warnings, restore the original state of all warnings:

```
warning(s)
```

Example 2 — Performing an Implicit Query

Turn on one particular warning, saving the previous state of this warning in `s`. Remember that this nonquery syntax (where `state` equals `on` or `off`) performs an implicit query prior to setting the new state:

```
s = warning('on', 'Control:parameterNotSymmetric');
```

Restore the state of that one warning when you are ready, with

```
warning(s)
```

Backtrace and Verbose Modes

In addition to warning messages, there are two *modes* that can be enabled or disabled with a warning control statement. These modes are shown here.

Mode	Description	Default
`backtrace`	Display an M-stack trace after a warning is invoked.	`on (enabled)`
`verbose`	Display a message on how to suppress the warning.	`off (terse)`

The syntax for this type of control statement is as follows, where `state`, in this case, can be only `on`, `off`, or `query`:

```
warning state mode
```

Note that there is no need to include a message identifier with this type of control statement. All enabled warnings are affected by the this type of control statement.

Note You cannot save and restore the current state of the `backtrace` or `verbose` modes as you can with other states.

Example 1 — Displaying a Stack Trace on a Specific Warning

It can be difficult to locate the source of a warning when it is generated from code buried in several levels of function calls. This example generates

a warning within a function that is nested several levels deep within the primary function in file `f1.m`:

```
function f1(a, b)
   for k = a:-1:b
       f2(k)
   end
   function f2(x)
       f3(x-1)
       function f3(y)
           x = log(y);
       end
   end
end
```

After enabling all warnings, run the M-file. The code generates a `Log of zero` warning. In an M-file of this size, it is not difficult to find the cause of the warning, but in an M-file of several hundred lines, this could take some time:

```
warning on all

f1(50,1)
Warning: Log of zero.
```

To simplify the debug process, enable backtrace mode. In this mode, MATLAB reports which function generated the warning (`f3`), the line number of the attempted operation (line `8`), the sequence of function calls that led up to the execution of the function (`f1>f2/f3`), and the line at which each of these function call was made (`3` and `6`):

```
warning on backtrace
f1(50,1)
Warning: Log of zero.
> In f1>f2/f3 at 8
  In f1>f2 at 6
  In f1 at 3
```

Example 2 — Enabling Verbose Warnings

When you enable verbose warnings, MATLAB displays an extra line of information with each warning that tells you how to suppress it:

Turn on all warnings, disable backtrace (if you have just run the previous example), and enable verbose warnings:

```
warning on all
warning off backtrace
warning on verbose
```

Call the function described in Example 1 to find out how to suppress any warnings generated by that function:

```
f1(50,1)
Warning: Log of zero.
(Type "warning off MATLAB:log:logOfZero" to suppress this warning.)
```

Use the message identifier `MATLAB:log:logOfZero` to disable only this warning, and run the function again. This time the warning message is not displayed:

```
warning off MATLAB:log:logOfZero

f1(50,1)
```

Debugging Errors and Warnings

You can direct MATLAB to temporarily stop the execution of an M-file in the event of a run-time error or warning, at the same time opening a debug window paused at the M-file line that generated the error or warning. This enables you to examine values internal to the program and determine the cause of the error.

Use the `dbstop` function to have MATLAB stop execution and enter debug mode when any M-file you subsequently run produces a run-time error or warning. There are three types of such breakpoints that you can set.

Command	Description
`dbstop if all error`	Stop on any error.
`dbstop if error`	Stop on any error not detected within a `try-catch` block.
`dbstop if warning`	Stop on any warning.

In all three cases, the M-file you are trying to debug must be in a directory that is on the search path or in the current directory.

You cannot resume execution after an error; use `dbquit` to exit from the Debugger. To resume execution after a warning, use `dbcont` or `dbstep`.

9

Classes and Objects

Classes and Objects: An Overview

In this section...

Overview

You can view classes as new data types having specific behaviors defined for the class. For example, a polynomial class might redefine the addition operator (+) so that it correctly performs the operation of addition on polynomials. Operations defined to work with objects of a particular class are known as *methods* of that class.

You can also view classes as new items that you can treat as single entities. An example is an arrow object that MATLAB can display on graphs (perhaps composed of MATLAB line and patch objects) and that has properties like a Handle Graphics object. You can create an arrow simply by instantiating the arrow class.

You can add classes to your MATLAB environment by specifying a MATLAB structure that provides data storage for the object and creating a class directory containing M-files that operate on the object. These M-files contain the methods for the class. The class directory can also include functions that define the way various MATLAB operators, including arithmetic operations,

subscript referencing, and concatenation, apply to the objects. Redefining how a built-in operator works for your class is known as *overloading* the operator.

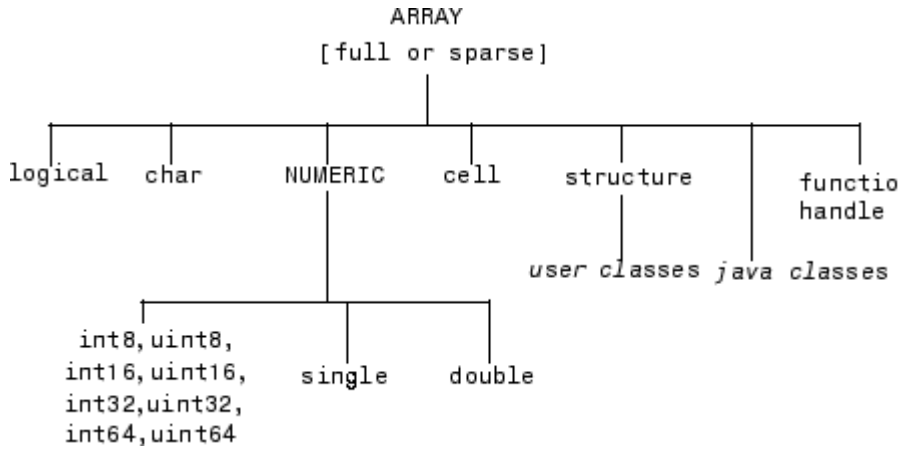
Features of Object-Oriented Programming

When using well-designed classes, object-oriented programming can significantly increase code reuse and make your programs easier to maintain and extend. Programming with classes and objects differs from ordinary structured programming in these important ways:

- **Function and operator overloading**. You can create methods that override existing MATLAB functions. When you call a function with a user-defined object as an argument, MATLAB first checks to see if there is a method defined for the object's class. If there is, MATLAB calls it, rather than the normal MATLAB function.
- **Encapsulation of data and methods**. Object properties are not visible from the command line; you can access them only with class methods. This protects the object properties from operations that are not intended for the object's class.
- **Inheritance**. You can create class hierarchies of parent and child classes in which the child class inherits data fields and methods from the parent. A child class can inherit from one parent (*single inheritance*) or many parents (*multiple inheritance*). Inheritance can span one or more generations. Inheritance enables sharing common parent functions and enforcing common behavior amongst all child classes.
- **Aggregation**. You can create classes using *aggregation*, in which an object contains other objects. This is appropriate when an object type is part of another object type. For example, a savings account object might be a part of a financial portfolio object.

MATLAB Data Class Hierarchy

All MATLAB data types are designed to function as classes in object-oriented programming. The diagram below shows the fifteen fundamental data types (or classes) defined in MATLAB. You can add new data types to MATLAB by extending the class hierarchy.



The diagram shows a *user class* that inherits from the structure class. All classes that you create are structure based since this is the point in the class hierarchy where you can insert your own classes. (For more information about MATLAB data types, see Chapter 2, “Data Types”)

Creating Objects

You create an object by calling the class constructor and passing it the appropriate input arguments. In MATLAB, constructors have the same name as the class name. For example, the statement,

```
p = polynom([1 0 -2 -5]);
```

creates an object named `p` belonging to the class `polynom`. Once you have created a polynom object, you can operate on the object using methods that are defined for the `polynom` class. See “Example — A Polynomial Class” on page 9-26 for a description of the `polynom` class.

Invoking Methods on Objects

Class methods are M-file functions that take an object as one of the input arguments. The methods for a specific class must be placed in the class directory for that class (the `@classname` directory). This is the first place that MATLAB looks to find a class method.

The syntax for invoking a method on an object is similar to a function call. Generally, it looks like

```
[out1,out2,...] = methodName(object,arg1,arg2, ...);
```

For example, suppose a user-defined class called `polynom` has a `char` method defined for the class. This method converts a polynom object to a character string and returns the string. This statement calls the `char` method on the polynom object `p`.

```
s = char(p);
```

Using the `class` function, you can confirm that the returned value `s` is a character string.

```
class(s)
ans =
    char

s
s =
    x^3-2*x-5
```

You can use the `methods` command to produce a list of all of the methods that are defined for a class.

Private Methods

Private methods can be called only by other methods of their class. You define private methods by placing the associated M-files in a `private` subdirectory of the `@`*`classname`* directory. In the example,

```
@classname/private/updateObj.m
```

the method `updateObj` has scope only within the *`classname`* class. This means that `updateObj` can be called by any method that is defined in the `@`*`classname`* directory, but it cannot be called from the MATLAB command line or by methods outside of the class directory, including parent methods.

Private methods and private functions differ in that private methods (in fact all methods) have an object as one of their input arguments and private

functions do not. You can use private functions as helper functions, such as described in the next section.

Helper Functions

In designing a class, you may discover the need for functions that perform support tasks for the class, but do not directly operate on an object. These functions are called *helper functions*. A helper function can be a subfunction in a class method file or a private function. When determining which version of a particular function to call, MATLAB looks for these functions in the order listed above. For more information about the order in which MATLAB calls functions and methods, see "How MATLAB Determines Which Method to Call" on page 9-72.

Debugging Class Methods

You can use the MATLAB debugging commands with object methods in the same way that you use them with other M-files. The only difference is that you need to include the class directory name before the method name in the command call, as shown in this example using `dbstop`.

```
dbstop @polynom/char
```

While debugging a class method, you have access to all methods defined for the class, including inherited methods, private methods, and private functions.

Changing Class Definition

If you change the class definition, such as the number or names of fields in a class, you must issue a

```
clear classes
```

command to propagate the changes to your MATLAB session. This command also clears all objects from the workspace. See the `clear` command help entry for more information.

Setting Up Class Directories

The M-files defining the methods for a class are collected together in a directory referred to as the class directory. The directory name is formed with

the class name preceded by the character @. For example, one of the examples used in this chapter is a class involving polynomials in a single variable. The name of the class, and the name of the class constructor, is `polynom`. The M-files defining a polynomial class would be located in directory with the name `@polynom`.

The class directories are subdirectories of directories on the MATLAB search path, but are not themselves on the path. For instance, the new `@polynom` directory could be a subdirectory of the MATLAB working directory or your own personal directory that has been added to the search path.

Adding the Class Directory to the MATLAB Path

After creating the class directory, you need to update the MATLAB path so that MATLAB can locate the class source files. The class directory should not be directly on the MATLAB path. Instead, you should add the parent directory to the MATLAB path. For example, if the `@polynom` class directory is located at

```
c:\myClasses\@polynom
```

you add the class directory to the MATLAB path with the `addpath` command

```
addpath c:\myClasses;
```

Using Multiple Class Directories

A MATLAB class can access methods in multiple *@classname* directories if all such directories are visible to MATLAB (i.e., the parent directories are on the MATLAB path or in the current directory). When you attempt to use a method of the class, MATLAB searches all the visible directories named *@classname* for the appropriate method.

For more information, see “How MATLAB Determines Which Method to Call” on page 9-72.

Data Structure

One of the first steps in the design of a new class is the choice of the data structure to be used by the class. Objects are stored in MATLAB structures. The fields of the structure, and the details of operations on the fields, are

visible only within the methods for the class. The design of the appropriate data structure can affect the performance of the code.

Tips for C++ and Java Programmers

If you are accustomed to programming in other object-oriented languages, such as C++ or Java, you will find that the MATLAB programming language differs from these languages in some important ways:

- In MATLAB, method dispatching is not syntax based, as it is in C++ and Java. When the argument list contains objects of equal precedence, MATLAB uses the left-most object to select the method to call.
- In MATLAB, there is no equivalent to a destructor method. To remove an object from the workspace, use the `clear` function.
- Construction of MATLAB data types occurs at runtime rather than compile time. You register an object as belonging to a class by calling the `class` function.
- When using inheritance in MATLAB, the inheritance relationship is established in the child class by creating the parent object, and then calling the `class` function. For more information on writing constructors for inheritance relationships, see “Building on Other Classes” on page 9-38.
- When using inheritance in MATLAB, the child object contains a parent object in a property with the name of the parent class.
- In MATLAB, there is no passing of variables by reference. When writing methods that update an object, you must pass back the updated object and use an assignment statement. For instance, this call to the `set` method updates the `name` field of the object `A` and returns the updated object.

  ```
  A = set(A,'name','John Smith');
  ```

- In MATLAB, there is no equivalent to an abstract class.
- In MATLAB, there is no equivalent to the C++ scoping operator.
- In MATLAB, there is no virtual inheritance or virtual base classes.
- In MATLAB, there is no equivalent to C++ templates.

Designing User Classes in MATLAB

In this section...

The MATLAB Canonical Class

When you design a MATLAB class, you should include a standard set of methods that enable the class to behave in a consistent and logical way within the MATLAB environment. Depending on the nature of the class you are defining, you may not need to include all of these methods and you may include a number of other methods to realize the class's design goals.

This table lists the basic methods included in MATLAB classes.

Class Method	Description
class constructor	Creates an object of the class.

Class Method	Description
`display`	Called whenever MATLAB displays the contents of an object (e.g., when an expression is entered without terminating with a semicolon).
`set` and `get`	Accesses class properties.
`subsref` and `subsasgn`	Enables indexed reference and assignment for user objects.
`end`	Supports `end` syntax in indexing expressions using an object; e.g., `A(1:end)`.
`subsindex`	Supports using an object in indexing expressions.
converters like `double` and `char`	Methods that convert an object to a MATLAB data type.

The following sections discuss the implementation of each type of method, as well as providing references to examples used in this chapter.

The Class Constructor Method

The @ directory for a particular class must contain an M-file known as the *constructor* for that class. The name of the constructor is the same as the name of the directory (excluding the @ prefix and `.m` extension) that defines the name of the class. The constructor creates the object by initializing the data structure and instantiating an object of the class.

Guidelines for Writing a Constructor

Class constructors must perform certain functions so that objects behave correctly in the MATLAB environment. In general, a class constructor must handle three possible combinations of input arguments:

- No input arguments
- An object of the same class as an input argument
- The input arguments used to create an object of the class (typically data of some kind)

No Input Arguments. If there are no input arguments, the constructor should create a default object. Since there are no inputs, you have no data from which to create the object, so you simply initialize the object's data structures with empty or default values, call the `class` function to instantiate the object, and return the object as the output argument. Support for this syntax is required for two reasons:

- When loading objects into the workspace, the `load` function calls the class constructor with no arguments.
- When creating arrays of objects, MATLAB calls the class constructor to add objects to the array.

Object Input Argument. If the first input argument in the argument list is an object of the same class, the constructor should simply return the object. Use the `isa` function to determine if an argument is a member of a class. See "Overloading the + Operator" on page 9-32 for an example of a method that uses this constructor syntax.

Data Input Arguments. If the input arguments exist and are not objects of the same class, then the constructor creates the object using the input data. Of course, as in any function, you should perform proper argument checking in your constructor function. A typical approach is to use a `varargin` input argument and a `switch` statement to control program flow. This provides an easy way to accommodate the three cases: no inputs, object input, or the data inputs used to create an object.

It is in this part of the constructor that you assign values to the object's data structure, call the `class` function to instantiate the object, and return the object as the output argument. If necessary, place the object in an object hierarchy using the `superiorto` and `inferiorto` functions.

Using the class Function in Constructors

Within a constructor method, you use the `class` function to associate an object structure with a particular class. This is done using an internal class tag that is only accessible using the `class` and `isa` functions. For example, this call to the `class` function identifies the object `p` to be of type `polynom`.

```
p = class(p,'polynom');
```

Examples of Constructor Methods

See the following sections for examples of constructor methods:

- "The Polynom Constructor Method" on page 9-27
- "The Asset Constructor Method" on page 9-43
- "The Stock Constructor Method" on page 9-50
- "The Portfolio Constructor Method" on page 9-59

Identifying Objects Outside the Class Directory

The `class` and `isa` functions used in constructor methods can also be used outside of the class directory. The expression

```
isa(a,'classname');
```

checks whether `a` is an object of the specified class. For example, if `p` is a polynom object, each of the following expressions is true.

```
isa(pi,'double');
isa('hello','char');
isa(p,'polynom');
```

Outside of the class directory, the `class` function takes only one argument (it is only within the constructor that `class` can have more than one argument).

The expression

```
class(a)
```

returns a string containing the class name of `a`. For example,

```
class(pi),
class('hello'),
class(p)
```

return

```
'double',
'char',
'polynom'
```

Use the whos function to see what objects are in the MATLAB workspace.

```
whos

  Name      Size          Bytes  Class
  p         1x1           156 polynom object
```

The display Method

MATLAB calls a method named display whenever an object is the result of a statement that is not terminated by a semicolon. For example, creating the variable a, which is a double, calls the MATLAB display method for doubles.

```
a = 5
a =
     5
```

You should define a display method so MATLAB can display values on the command line when referencing objects from your class. In many classes, display can simply print the variable name, and then use the char converter method to print the contents or value of the variable, since MATLAB displays output as strings. You must define the char method to convert the object's data to a character string.

Examples of display Methods

See the following sections for examples of display methods:

- "The Polynom display Method" on page 9-30
- "The Asset display Method" on page 9-48
- "The Stock display Method" on page 9-57
- "The Portfolio display Method" on page 9-61

Accessing Object Data

You need to write methods for your class that provide access to an object's data. Accessor methods can use a variety of approaches, but all methods that change object data always accept an object as an input argument and return a new object with the data changed. This is necessary because MATLAB does

not support passing arguments by reference (i.e., pointers). Functions can change only their private, temporary copy of an object. Therefore, to change an existing object, you must create a new one, and then replace the old one.

The following sections provide more detail about implementation techniques for the `set`, `get`, `subsasgn`, and `subsref` methods.

The set and get Methods

The `set` and `get` methods provide a convenient way to access object data in certain cases. For example, suppose you have created a class that defines an arrow object that MATLAB can display on graphs (perhaps composed of existing MATLAB line and patch objects).

To produce a consistent interface, you could define `set` and `get` methods that operate on arrow objects the way the MATLAB `set` and `get` functions operate on built-in graphics objects. The `set` and `get` verbs convey what operations they perform, but insulate the user from the internals of the object.

Examples of set and get Methods

See the following sections for examples of `set` and `get` methods:

- "The Asset get Method" on page 9-44 and "The Asset set Method" on page 9-45
- "The Stock get Method" on page 9-52 and "The Stock set Method" on page 9-53

Property Name Methods

As an alternative to a general `set` method, you can write a method to handle the assignment of an individual property. The method should have the same name as the property name.

For example, if you defined a class that creates objects representing employee data, you might have a field in an employee object called `salary`. You could then define a method called `salary.m` that takes an employee object and a value as input arguments and returns the object with the specified value set.

Indexed Reference Using subsref and subsasgn

User classes implement new data types in MATLAB. It is useful to be able to access object data via an indexed reference, as is possible with the MATLAB built-in data types. For example, if `A` is an array of class `double`, `A(i)` returns the i^{th} element of `A`.

As the class designer, you can decide what an index reference to an object means. For example, suppose you define a class that creates polynomial objects and these objects contain the coefficients of the polynomial.

An indexed reference to a polynomial object,

```
p(3)
```

could return the value of the coefficient of x^3, the value of the polynomial at $x = 3$, or something different depending on the intended design.

You define the behavior of indexing for a particular class by creating two class methods - `subsref` and `subsasgn`. MATLAB calls these methods whenever a subscripted reference or assignment is made on an object from the class. If you do not define these methods for a class, indexing is undefined for objects of this class.

In general, the rules for indexing objects are the same as the rules for indexing structure arrays. For details, see “Structures” on page 2-74.

Behavior Within Class Methods

If `A` is an array of one of the fundamental MATLAB data types, then referencing a value of `A` using an indexed reference calls the built-in MATLAB `subsref` method. It does not call any `subsref` method that you might have overloaded for that data type.

For example, if `A` is an array of type double, and there is an `@double/subsref` method on your MATLAB path, the statement `B = A(I)` does not call this method, but calls the MATLAB built-in `subsref` method instead.

The same is true for user-defined classes. Whenever a class method requires the functionality of the overloaded `subsref` or `subsassign`, it must call the

overloaded methods with function calls rather than using operators like '()', '{}', or '.'.

For example, suppose you define a polynomial class that defines a subsref method that causes the polynomial to be evaluated with the value of the independent variable equal to the subscript. Therefore,

```
p = polynom([1 0 -2 -5]);
```

The following subscripted expression returns the value of the polynomial at

```
x = 3 and x = 4.
p([3 4])
ans =
    16   51
```

Now suppose that you want to use this feature in one of the class methods. To do so, you must call the subsref function directly:

```
y = polyval(p,x);
 subs.type = '()';
 subs.subs = {x};
 y = subsref(p, subs);  % Need to call subsref here
```

Handling Subscripted Reference

The use of a subscript or field designator with an object on the right-hand side of an assignment statement is known as a *subscripted reference*. MATLAB calls a method named subsref in these situations.

Object subscripted references can be of three forms — an array index, a cell array index, and a structure field name:

```
A(I)
A{I}
A.field
```

Each of these results in a call by MATLAB to the subsref method in the class directory. MATLAB passes two arguments to subsref.

```
B = subsref(A,S)
```

The first argument is the object being referenced. The second argument, `S`, is a structure array with two fields:

- `S.type` is a string containing `'()'`, `'{}'`, or `'.'` specifying the subscript type. The parentheses represent a numeric array; the curly braces, a cell array; and the dot, a structure array.
- `S.subs` is a cell array or string containing the actual subscripts. A colon used as a subscript is passed as a cell array containing the string `':'`.

For instance, the expression

```
A(1:2,:)
```

causes MATLAB to call `subsref(A,S)`, where `S` is a 1-by-1 structure with

```
S.type = '()'
S.subs = {1:2,':'}
```

Similarly, the expression

```
A{1:2}
```

uses

```
S.type ='{}'
S.subs = {1:2}
```

The expression

```
A.field
```

calls `subsref(A,S)` where

```
S.type = '.'
S.subs = 'field'
```

These simple calls are combined for more complicated subscripting expressions. In such cases, `length(S)` is the number of subscripting levels. For example,

```
A(1,2).name(3:4)
```

calls `subsref(A,S)`, where `S` is a 3-by-1 structure array with the values:

```
S(1).type = '()'    S(2).type = '.'      S(3).type = '()'
S(1).subs = {1,2}   S(2).subs = 'name'   S(3).subs = {3:4}
```

How to Write subsref

The `subsref` method must interpret the subscripting expressions passed in by MATLAB. A typical approach is to use the `switch` statement to determine the type of indexing used and to obtain the actual indices. The following three code fragments illustrate how to interpret the input arguments. In each case, the function must return the value `B`.

For an array index:

```
switch S.type
case '()'
   B = A(S.subs{:});
end
```

For a cell array:

```
switch S.type
case '{}'
   B = A(S.subs{:});          % A is a cell array
end
```

For a structure array:

```
switch S.type
case '.'
   switch S.subs
   case 'field1'
      B = A.field1;
   case 'field2'
      B = A.field2;
   end
end
```

Examples of the subsref Method

See the following sections for examples of the `subsref` method:

- "The Polynom subsref Method" on page 9-31
- "The Asset subsref Method" on page 9-46
- "The Stock subsref Method" on page 9-54
- "The Portfolio subsref Method" on page 9-68

Handling Subscripted Assignment

The use of a subscript or field designator with an object on the left-hand side of an assignment statement is known as a *subscripted assignment*. MATLAB calls a method named `subsasgn` in these situations. Object subscripted assignment can be of three forms - an array index, a cell array index, and a structure field name.

```
A(I) = B
A{I} = B
A.field = B
```

Each of these results in a call to `subsasgn` of the form

```
A = subsasgn(A,S,B)
```

The first argument, `A`, is the object being referenced. The second argument, `S`, has the same fields as those used with `subsref`. The third argument, `B`, is the new value.

Examples of the subsasgn Method

See the following sections for examples of the `subsasgn` method:

- "The Asset subsasgn Method" on page 9-47
- "The Stock subsasgn Method" on page 9-55

Object Indexing Within Methods

If a subscripted reference is made within a class method, MATLAB uses its built-in `subsref` function to access data within the method's own class. If the method accesses data from another class, MATLAB calls the overloaded `subsref` function in that class. The same holds true for subscripted assignment and `subsasgn`.

The following example shows a method, `testref`, that is defined in the class, `employee`. This method makes a reference to a field, `address`, in an object of its own class. For this, MATLAB uses the built-in `subsref` function. It also references the same field in another class, this time using the overloaded `subsref` of that class.

```
% ---- EMPLOYEE class method: testref.m ----
function testref(myclass,otherclass)

myclass.address                % use built-in subsref
otherclass.address             % use overloaded subsref
```

The example creates an `employee` object and a `company` object.

```
empl = employee('Johnson','Chicago');
comp = company('The MathWorks','Natick');
```

The `employee` class method, `testref`, is called. MATLAB uses an overloaded `subsref` only to access data outside of the method's own class.

```
testref(empl,comp)
ans =                           % built-in subsref was called
   Chicago

ans =                           % @company\subsref was called
Executing @company\subsref ...
   Natick
```

Defining end Indexing for an Object

When you use `end` in an object indexing expression, MATLAB calls the object's `end` class method. If you want to be able to use `end` in indexing expressions involving objects of your class, you must define an `end` method for your class.

The `end` method has the calling sequence

```
end(a,k,n)
```

where `a` is the user object, `k` is the index in the expression where the `end` syntax is used, and `n` is the total number of indices in the expression.

For example, consider the expression

```
A(end-1,:)
```

MATLAB calls the `end` method defined for the object `A` using the arguments

```
end(A,1,2)
```

That is, the `end` statement occurs in the first index element and there are two index elements. The class method for `end` must then return the index value for the last element of the first dimension. When you implement the `end` method for your class, you must ensure it returns a value appropriate for the object.

Indexing an Object with Another Object

When MATLAB encounters an object as an index, it calls the `subsindex` method defined for the object. For example, suppose you have an object `a` and you want to use this object to index into another object `b`.

```
c = b(a);
```

A `subsindex` method might do something as simple as convert the object to double format to be used as an index, as shown in this sample code.

```
function d = subsindex(a)
%SUBSINDEX
% convert the object a to double format to be used
% as an index in an indexing expression
d = double(a);
```

`subsindex` values are 0-based, not 1-based.

Converter Methods

A converter method is a class method that has the same name as another class, such as `char` or `double`. Converter methods accept an object of one class as input and return an object of another class. Converters enable you to

- Use methods defined for another class
- Ensure that expressions involving objects of mixed class types execute properly

A converter function call is of the form

```
b = classname(a)
```

where `a` is an object of a class other than *`classname`*. In this case, MATLAB looks for a method called *`classname`* in the class directory for object `a`. If the input object is already of type *`classname`*, then MATLAB calls the constructor, which just returns the input argument.

Examples of Converter Methods

See the following sections for examples of converter methods:

- "The Polynom to Double Converter" on page 9-28
- "The Polynom to Char Converter" on page 9-29

Overloading Operators and Functions

In this section...

Overloading Operators

In many cases, you may want to change the behavior of the MATLAB operators and functions for cases when the arguments are objects. You can accomplish this by overloading the relevant functions. Overloading enables a function to handle different types and numbers of input arguments and perform whatever operation is appropriate for the highest-precedence object. See "Object Precedence" on page 9-70 for more information on object precedence.

Each built-in MATLAB operator has an associated function name (e.g., the + operator has an associated `plus.m` function). You can overload any operator by creating an M-file with the appropriate name in the class directory. For example, if either `p` or `q` is an object of type `classname`, the expression

```
p + q
```

generates a call to a function `@classname/plus.m`, if it exists. If `p` and `q` are both objects of different classes, then MATLAB applies the rules of precedence to determine which method to use.

Examples of Overloaded Operators

See the following sections for examples of overloaded operators:

- "Overloading the + Operator" on page 9-32
- "Overloading the - Operator" on page 9-33
- "Overloading the * Operator" on page 9-33

The following table lists the function names for most of the MATLAB operators.

Operation	M-File	Description
`a + b`	`plus(a,b)`	Binary addition
`a - b`	`minus(a,b)`	Binary subtraction
`-a`	`uminus(a)`	Unary minus
`+a`	`uplus(a)`	Unary plus
`a.*b`	`times(a,b)`	Element-wise multiplication
`a*b`	`mtimes(a,b)`	Matrix multiplication
`a./b`	`rdivide(a,b)`	Right elementwise division
`a.\b`	`ldivide(a,b)`	Left elementwise division
`a/b`	`mrdivide(a,b)`	Matrix right division
`a\b`	`mldivide(a,b)`	Matrix left division
`a.^b`	`power(a,b)`	Element-wise power
`a^b`	`mpower(a,b)`	Matrix power
`a < b`	`lt(a,b)`	Less than
`a > b`	`gt(a,b)`	Greater than
`a <= b`	`le(a,b)`	Less than or equal to
`a >= b`	`ge(a,b)`	Greater than or equal to
`a ~= b`	`ne(a,b)`	Not equal to
`a == b`	`eq(a,b)`	Equality
`a & b`	`and(a,b)`	Logical AND
`a | b`	`or(a,b)`	Logical OR
`~a`	`not(a)`	Logical NOT
`a:d:b` `a:b`	`colon(a,d,b)` `colon(a,b)`	Colon operator
`a'`	`ctranspose(a)`	Complex conjugate transpose
`a.'`	`transpose(a)`	Matrix transpose
`command window output`	`display(a)`	Display method

Operation	M-File	Description
`[a b]`	`horzcat(a,b,...)`	Horizontal concatenation
`[a; b]`	`vertcat(a,b,...)`	Vertical concatenation
`a(s1,s2,...sn)`	`subsref(a,s)`	Subscripted reference
`a(s1,...,sn) = b`	`subsasgn(a,s,b)`	Subscripted assignment
`b(a)`	`subsindex(a)`	Subscript index

Overloading Functions

You can overload any function by creating a function of the same name in the class directory. When a function is invoked on an object, MATLAB always looks in the class directory before any other location on the search path. To overload the `plot` function for a class of objects, for example, simply place your version of `plot.m` in the appropriate class directory.

Examples of Overloaded Functions

See the following sections for examples of overloaded functions:

- "Overloading Functions for the Polynom Class" on page 9-34
- "The Portfolio pie3 Method" on page 9-61

Example — A Polynomial Class

In this section...

Polynom Data Structure

This example implements a MATLAB data type for polynomials by defining a new class called `polynom`. The polynom class represents a polynomial with a row vector containing the coefficients of powers of the variable, in decreasing order. Therefore, a polynom object `p` is a structure with a single field, `p.c`, containing the coefficients. This field is accessible only within the methods in the `@polynom` directory.

Polynom Methods

To create a class that is well behaved within the MATLAB environment and provides useful functionality for a polynomial data type, the polynom class implements the following methods:

- A constructor method `polynom.m`
- A polynom to double converter
- A polynom to char converter
- A `display` method
- A `subsref` method

- Overloaded +, -, and * operators
- Overloaded `roots`, `polyval`, `plot`, and `diff` functions

The Polynom Constructor Method

Here is the polynom class constructor, `@polynom/polynom.m`.

```
function p = polynom(a)
%POLYNOM Polynomial class constructor.
%   p = POLYNOM(v) creates a polynomial object from vector v,
%   containing the coefficients of descending powers of x.
if nargin == 0
   p.c = [];
   p = class(p,'polynom');
elseif isa(a,'polynom')
   p = a;
else
   p.c = a(:).';
   p = class(p,'polynom');
end
```

Constructor Calling Syntax

You can call the polynom constructor method with one of three different arguments:

- No input argument — If you call the constructor function with no arguments, it returns a polynom object with empty fields.
- Input argument is an object — If you call the constructor function with an input argument that is already a polynom object, MATLAB returns the input argument. The `isa` function (pronounced “is a”) checks for this situation.
- Input argument is a coefficient vector — If the input argument is a variable that is not a polynom object, reshape it to be a row vector and assign it to the `.c` field of the object’s structure. The `class` function creates the `polynom` object, which is then returned by the constructor.

An example use of the `polynom` constructor is the statement

```
p = polynom([1 0 -2 -5])
```

This creates a polynomial with the specified coefficients.

Converter Methods for the Polynom Class

A converter method converts an object of one class to an object of another class. Two of the most important converter methods contained in MATLAB classes are `double` and `char`. Conversion to `double` produces the MATLAB traditional matrix, although this may not be appropriate for some classes. Conversion to `char` is useful for producing printed output.

The Polynom to Double Converter

The double converter method for the polynom class is a very simple M-file, `@polynom/double.m`, which merely retrieves the coefficient vector.

```
function c = double(p)
% POLYNOM/DOUBLE  Convert polynom object to coefficient vector.
%   c = DOUBLE(p) converts a polynomial object to the vector c
%   containing the coefficients of descending powers of x.
c = p.c;
```

On the object `p`,

```
p = polynom([1 0 -2 -5])
```

the statement

```
double(p)
```

returns

```
 ans =
 1 0 -2 -5
```

Having implemented the `double` method, you can use it to call MATLAB functions on polynom objects that require double values as inputs. For example,

```
size(double(p))
 ans =
 1  4
```

The Polynom to Char Converter

The converter to char is a key method because it produces a character string involving the powers of an independent variable, `x`. Therefore, once you have specified `x`, the string returned is a syntactically correct MATLAB expression, which you can then evaluate.

Here is `@polynom/char.m`.

```
function s = char(p)
% POLYNOM/CHAR
% CHAR(p) is the string representation of p.c
if all(p.c == 0)
   s = '0';
else
   d = length(p.c) - 1;
   s = [];
   for a = p.c;
      if a ~= 0;
         if ~isempty(s)
            if a > 0
               s = [s ' + '];
            else
               s = [s ' - '];
               a = -a;
            end
         end
         if a ~= 1 | d == 0
            s = [s num2str(a)];
            if d > 0
               s = [s '*'];
            end
         end
         if d >= 2
            s = [s 'x^' int2str(d)];
         elseif d == 1
            s = [s 'x'];
         end
      end
      d = d - 1;
   end
```

```
end
```

Evaluating the Output

If you create the polynom object `p`

```
p = polynom([1 0 -2 -5]);
```

and then call the `char` method on `p`

```
char(p)
```

MATLAB produces the result

```
ans =
    x^3 - 2*x - 5
```

The value returned by `char` is a string that you can pass to `eval` once you have defined a scalar value for `x`. For example,

```
x = 3;

eval(char(p))
ans =
    16
```

See “The Polynom subsref Method” on page 9-31 for a better method to evaluate the polynomial.

The Polynom display Method

Here is `@polynom/display.m`. This method relies on the `char` method to produce a string representation of the polynomial, which is then displayed on the screen. This method produces output that is the same as standard MATLAB output. That is, the variable name is displayed followed by an equal sign, then a blank line, then a new line with the value.

```
function display(p)
% POLYNOM/DISPLAY Command window display of a polynom
disp(' ');
disp([inputname(1),' = '])
disp(' ');
```

```
disp(['   ' char(p)])
disp(' ');
```

The statement

```
p = polynom([1 0 -2 -5])
```

creates a polynom object. Since the statement is not terminated with a semicolon, the resulting output is

```
p =
    x^3 - 2*x - 5
```

The Polynom subsref Method

Suppose the design of the polynom class specifies that a subscripted reference to a `polynom` object causes the polynomial to be evaluated with the value of the independent variable equal to the subscript. That is, for a polynom object `p`,

```
p = polynom([1 0 -2 -5]);
```

the following subscripted expression returns the value of the polynomial at `x = 3` and `x = 4`.

```
p([3 4])
ans =
    16   51
```

subsref Implementation Details

This implementation takes advantage of the `char` method already defined in the polynom class to produce an expression that can then be evaluated.

```
function b = subsref(a,s)
% SUBSREF
switch s.type
case '()'
   ind = s.subs{:};
   for k = 1:length(ind)
      b(k) = eval(strrep(char(a), 'x', ...
             ['(' num2str(ind(k)) ')']));
   end
otherwise
```

```
    error('Specify value for x as p(x)')
end
```

Once the polynomial expression has been generated by the `char` method, the `strrep` function is used to swap the passed in value for the character `x`. The `eval` function then evaluates the expression and returns the value in the output argument.

Note that if you perform an indexed reference from within other class methods, MATLAB calls the built-in `subsref` or `subsassign`. See "Behavior Within Class Methods" on page 9-15 for more information.

Overloading Arithmetic Operators for polynom

Several arithmetic operations are meaningful on polynomials and should be implemented for the polynom class. When overloading arithmetic operators, keep in mind what data types you want to operate on. In this section, the `plus`, `minus`, and `mtimes` methods are defined for the polynom class to handle addition, subtraction, and multiplication on polynom/polynom and polynom/double combinations of operands.

Overloading the + Operator

If either `p` or `q` is a polynom, the expression

```
p + q
```

generates a call to a function `@polynom/plus.m`, if it exists (unless `p` or `q` is an object of a higher precedence, as described in "Object Precedence" on page 9-70).

The following M-file redefines the + operator for the polynom class.

```
function r = plus(p,q)
% POLYNOM/PLUS  Implement p + q for polynoms.
p = polynom(p);
q = polynom(q);
k = length(q.c) - length(p.c);
r = polynom([zeros(1,k) p.c] + [zeros(1,-k) q.c]);
```

The function first makes sure that both input arguments are polynomials. This ensures that expressions such as

```
p + 1
```

that involve both a polynom and a double, work correctly. The function then accesses the two coefficient vectors and, if necessary, pads one of them with zeros to make them the same length. The actual addition is simply the vector sum of the two coefficient vectors. Finally, the function calls the `polynom` constructor a third time to create the properly typed result.

Overloading the - Operator

You can implement the overloaded minus operator (`-`) using the same approach as the plus (`+`) operator. MATLAB calls `@polynom/minus.m` to compute `p-q`.

```
function r = minus(p,q)
% POLYNOM/MINUS Implement p - q for polynoms.
p = polynom(p);
q = polynom(q);
k = length(q.c) - length(p.c);
r = polynom([zeros(1,k) p.c] - [zeros(1,-k) q.c]);
```

Overloading the * Operator

MATLAB calls the method `@polynom/mtimes.m` to compute the product `p*q`. The letter `m` at the beginning of the function name comes from the fact that it is overloading the MATLAB *matrix* multiplication. Multiplication of two polynomials is simply the convolution of their coefficient vectors.

```
function r = mtimes(p,q)
% POLYNOM/MTIMES   Implement p * q for polynoms.
p = polynom(p);
q = polynom(q);
r = polynom(conv(p.c,q.c));
```

Using the Overloaded Operators

Given the polynom object

```
p = polynom([1 0 -2 -5])
```

MATLAB calls these two functions `@polynom/plus.m` and `@polynom/mtimes.m` when you issue the statements

```
q = p+1
r = p*q
```

to produce

```
q =
     x^3 - 2*x - 4

r =
     x^6 - 4*x^4 - 9*x^3 + 4*x^2 + 18*x + 20
```

Overloading Functions for the Polynom Class

MATLAB already has several functions for working with polynomials represented by coefficient vectors. They should be overloaded to also work with the new polynom object. In many cases, the overloading methods can simply apply the original function to the coefficient field.

Overloading roots for the Polynom Class

The method `@polynom/roots.m` finds the roots of polynom objects.

```
function r = roots(p)
% POLYNOM/ROOTS.  ROOTS(p) is a vector containing the roots of p.
r = roots(p.c);
```

The statement

```
roots(p)
```

results in

```
ans =
     2.0946
    -1.0473 + 1.1359i
    -1.0473 - 1.1359i
```

Overloading polyval for the Polynom Class

The function `polyval` evaluates a polynomial at a given set of points. `@polynom/polyval.m` uses nested multiplication, or Horner's method to reduce the number of multiplication operations used to compute the various powers of x.

```
function y = polyval(p,x)
% POLYNOM/POLYVAL  POLYVAL(p,x) evaluates p at the points x.
y = 0;
for a = p.c
   y = y.*x + a;
end
```

Overloading plot for the Polynom Class

The overloaded `plot` function uses both `root` and `polyval`. The function selects the domain of the independent variable to be slightly larger than an interval containing the roots of the polynomial. Then `polyval` is used to evaluate the polynomial at a few hundred points in the domain.

```
function plot(p)
% POLYNOM/PLOT  PLOT(p) plots the polynom p.
r = max(abs(roots(p)));
x = (-1.1:0.01:1.1)*r;
y = polyval(p,x);
plot(x,y);
title(char(p))
grid on
```

Overloading diff for the Polynom Class

`The method @polynom/diff.m` differentiates a polynomial by reducing the degree by 1 and multiplying each coefficient by its original degree.

```
function q = diff(p)
% POLYNOM/DIFF  DIFF(p) is the derivative of the polynom p.
c = p.c;
d = length(c) - 1;  % degree
q = polynom(p.c(1:d).*(d:-1:1));
```

Listing Class Methods

The function call

```
methods('classname')
```

or its command form

```
methods classname
```

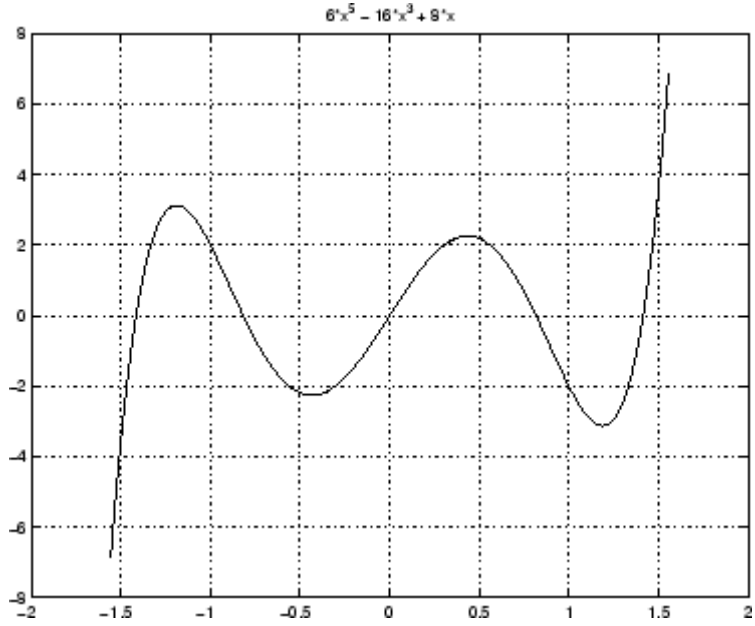
shows all the methods available for a particular class. For the `polynom` example, the output is

```
methods polynom
Methods for class polynom:

char       display    minus      plot       polynom    roots
diff       double     mtimes     plus       polyval    subsref
```

Plotting the two polynom objects x and p calls most of these methods.

```
x = polynom([1 0]);
p = polynom([1 0 -2 -5]);
plot(diff(p*p + 10*p + 20*x) - 20)
```



Building on Other Classes

In this section...

Overview

A MATLAB classes can *inherit* properties and behavior from another MATLAB class. When one object (of the derived class) inherits from another (of the base class), the derived class object includes all the fields of the base class object and can call the base class methods. The base class methods can access those fields that the derived class object inherited from the base class, but not fields new to the derived class.

Inheritance is a key feature of object-oriented programming. It makes it easy to reuse code by allowing derived class objects to take advantage of code that exists for base class objects. Inheritance enables a derived class object to behave exactly like a base class object, which facilitates the development of related classes that behave similarly, but are implemented differently.

There are two kinds of inheritance:

- Simple inheritance, in which a derived class object inherits characteristics from one base class.
- Multiple inheritance, in which a derived class object inherits characteristics from more than one parent class.

This section also discusses a related topic, aggregation. Aggregation allows one object to contain another object as one of its fields.

Simple Inheritance

A class that inherits attributes from a single base class, and adds new attributes of its own, uses simple inheritance. Inheritance implies that objects

belonging to the derived class have the same fields as the base class, as well as any fields added by the derived class.

Base class methods can operate on objects belonging to the derived class. However, derived class methods cannot operate on objects belonging to the base class. You cannot access the base class object's fields directly from the derived class; you must use access methods defined for the base class.

Derived Class Constructor

The constructor function for a derived class has two special characteristics:

- It calls the constructor function for the base class to create the inherited fields.
- It requires a special calling syntax for the `class` function, specifying both the derived class and the base class.

The syntax for establishing simple inheritance using the `class` function is:

```
derivedObj = class(derivedObj, 'derivedClass', baseObj);
```

Simple inheritance can span more than one generation. If a base class is itself an inherited class, the derived class object automatically inherits from the original base class.

Visibility of Class Properties and Methods

The base class does not have access to the derived class properties. The derived class cannot access the base class properties directly, but must use base class access methods (e.g., `get` or `subsref` method) to access the base class properties. From the derived class methods, this access is accomplished via the base class field in the derived class structure. For example, when a constructor creates a derived class object `c`,

```
c = class(c, 'derivedClassname', baseObject);
```

MATLAB automatically creates a field, `c.`*`baseClassname`*, in the object's structure that contains the base object. You could then have a statement in the derived class display method that calls the base class display method.

```
display(c.baseClassname)
```

See “Designing the Stock Class” on page 9-49 for examples that use simple inheritance.

Multiple Inheritance

In the multiple inheritance case, a class of objects inherits attributes from more than one base class. The derived class object gets fields from all the base classes, as well as fields of its own.

Multiple inheritance can encompass more than one generation. For example, each of the base class objects could have inherited fields from multiple base class objects, and so on. Multiple inheritance is implemented in the constructors by calling `class` with more than three arguments.

```
obj = class(structure,'classname',baseclass1,baseclass2,...)
```

You can append as many base class arguments as desired to the class input list.

Nonunique Method Names in Base Classes

Multiple base classes can have associated methods of the same name. In this case, MATLAB calls the method associated with the base class that appears first in the `class` function call in the constructor function. There is no way to access subsequent base class functions of this name.

Aggregation

In addition to standard inheritance, MATLAB objects support containment or *aggregation*. That is, one object can contain (embed) another object as one of its fields. For example, a rational object might use two polynom objects, one for the numerator and one for the denominator.

You can call a method for the contained object only from within a method for the outer object. When determining which version of a function to call, MATLAB considers only the outermost containing class of the objects passed as arguments; the classes of any contained objects are ignored.

See “Example — The Portfolio Container” on page 9-58 for an example of aggregation.

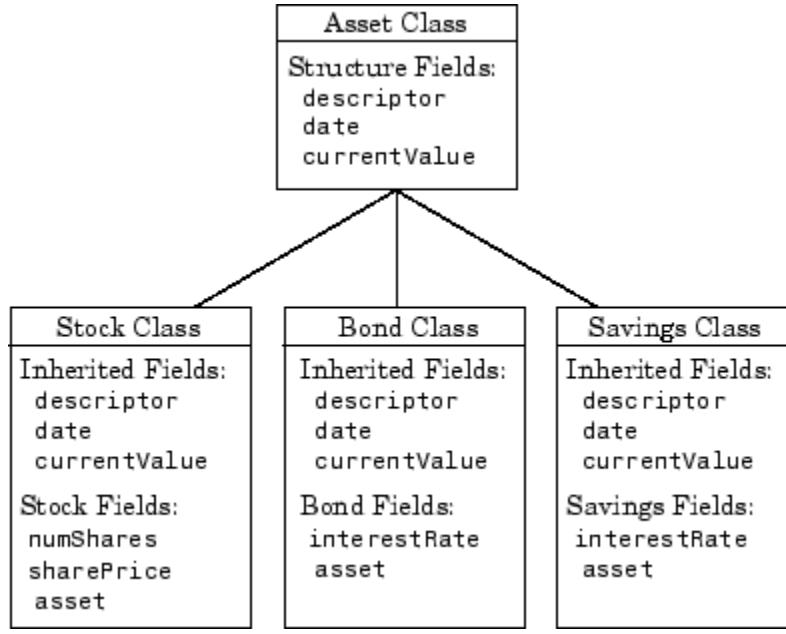
Example — Assets and Asset Subclasses

In this section...

Inheritance Model for the Asset Class

As an example of simple inheritance, consider a general `asset` class that can be used to represent any item that has monetary value. Some examples of an asset are: stocks, bonds, savings accounts, and any other piece of property. In designing this collection of classes, the `asset` class holds the data that is common to all of the specialized asset subclasses. The individual asset subclasses, such as the `stock` class, inherit the `asset` properties and contribute additional properties. The subclasses are "kinds of" assets.

An example of a simple inheritance relationship using an asset base class is shown in this diagram.



As shown in the diagram, the `stock`, `bond`, and `savings` classes inherit structure fields from the `asset` class. In this example, the `asset` class is used to provide storage for data common to all subclasses and to share asset methods with these subclasses. This example shows how to implement the asset and stock classes. The `bond` and `savings` classes can be implemented in a way that is very similar to the `stock` class, as would other types of asset subclasses.

Asset Class Design

The asset class provides storage and access for information common to all asset children. It is not intended to be instantiated directly, so it does not require an extensive set of methods. To serve its purpose, the class needs to contain the following methods:

- Constructor

- `get` and `set`
- `subsref` and `subsasgn`
- `display`

Other Asset Methods

The asset class provides inherited data storage for its child classes, but is not instanced directly. The `set`, `get`, and `display` methods provide access to the stored data. It is not necessary to implement the full complement of methods for asset objects (such as converters, `end`, and `subsindex`) since only the child classes access the data.

The Asset Constructor Method

The asset class is based on a structure array with four fields:

- `descriptor` — Identifier of the particular asset (e.g., stock name, savings account number, etc.)
- `date` — The date the object was created (calculated by the `date` command)
- `type` — The type of asset (e.g., savings, bond, stock)
- `currentValue` — The current value of the asset (calculated from subclass data)

This information is common to asset child objects (stock, bond, and savings), so it is handled from the parent object to avoid having to define the same fields in each child class. This is particularly helpful as the number of child classes increases.

```
function a = asset(varargin)
% ASSET Constructor function for asset object
% a = asset(descriptor, type, currentValue)
switch nargin
case 0
% if no input arguments, create a default object
   a.descriptor = 'none';
   a.date = date;
   a.type = 'none';
   a.currentValue = 0;
```

```
   a = class(a,'asset');
case 1
% if single argument of class asset, return it
   if (isa(varargin{1},'asset'))
      a = varargin{1};
   else
      error('Wrong argument type')
   end
case 3
% create object using specified values
   a.descriptor = varargin{1};
   a.date = date;
   a.type = varargin{2};
   a.currentValue = varargin{3};
   a = class(a,'asset');
otherwise
   error('Wrong number of input arguments')
end
```

The function uses a `switch` statement to accommodate three possible scenarios:

- Called with no arguments, the constructor returns a default asset object.
- Called with one argument that is an asset object, the object is simply returned.
- Called with three arguments (subclass descriptor, type, and current value), the constructor returns a new asset object.

The asset constructor method is not intended to be called directly; it is called from the child constructors since its purpose is to provide storage for common data.

The Asset get Method

The asset class needs methods to access the data contained in asset objects. The following function implements a `get` method for the class. It uses capitalized property names rather than literal field names to provide an interface similar to other MATLAB objects.

```
function val = get(a, propName)
% GET Get asset properties from the specified object
% and return the value
switch propName
case 'Descriptor'
   val = a.descriptor;
case 'Date'
   val = a.date;
case 'CurrentValue'
   val = a.currentValue;
otherwise
   error([propName,' Is not a valid asset property'])
end
```

This function accepts an object and a property name and uses a `switch` statement to determine which field to access. This method is called by the subclass `get` methods when accessing the data in the inherited properties. See "The Stock get Method" on page 9-52 for an example.

The Asset set Method

The asset class `set` method is called by subclass `set` methods. This method accepts an asset object and variable length argument list of property name/property value pairs and returns the modified object.

```
function a = set(a,varargin)
% SET Set asset properties and return the updated object
propertyArgIn = varargin;
while length(propertyArgIn) >= 2,
   prop = propertyArgIn{1};
   val = propertyArgIn{2};
   propertyArgIn = propertyArgIn(3:end);
   switch prop
   case 'Descriptor'
      a.descriptor = val;
   case 'Date'
      a.date = val;
   case 'CurrentValue'
      a.currentValue = val;
   otherwise
```

```
        error('Asset properties: Descriptor, Date, CurrentValue')
    end
end
```

Subclass `set` methods call the asset `set` method and require the capability to return the modified object since MATLAB does not support passing arguments by reference. See "The Stock set Method" on page 9-53 for an example.

The Asset subsref Method

The `subsref` method provides access to the data contained in an asset object using one-based numeric indexing and structure field name indexing. The outer `switch` statement determines if the index is a numeric or field name syntax. The inner `switch` statements map the index to the appropriate value.

MATLAB calls `subsref` whenever you make a subscripted reference to an object (e.g., `A(i)`, `A{i}`, or `A.fieldname`).

```
function b = subsref(a,index)
%SUBSREF Define field name indexing for asset objects
switch index.type
case '()'
   switch index.subs{:}
   case 1
      b = a.descriptor;
   case 2
      b = a.date;
   case 3
      b = a.currentValue;
   otherwise
      error('Index out of range')
   end
case '.'
   switch index.subs
   case 'descriptor'
      b = a.descriptor;
   case 'date'
      b = a.date;
   case 'currentValue'
      b = a.currentValue;
```

```
    otherwise
       error('Invalid field name')
    end
 case '{}'
    error('Cell array indexing not supported by asset objects')
 end
```

See the "The Stock subsref Method" on page 9-54 for an example of how the child `subsref` method calls the parent `subsref` method.

The Asset subsasgn Method

The `subsasgn` method is the assignment equivalent of the `subsref` method. This version enables you to change the data contained in an object using one-based numeric indexing and structure field name indexing. The outer `switch` statement determines if the index is a numeric or field name syntax. The inner `switch` statements map the index value to the appropriate value in the stock structure.

MATLAB calls `subsasgn` whenever you execute an assignment statement (e.g., `A(i) = val`, `A{i} = val`, or `A.fieldname = val`).

```
function a = subsasgn(a,index,val)
% SUBSASGN Define index assignment for asset objects
switch index.type
case '()'
   switch index.subs{:}
   case 1
      a.descriptor = val;
   case 2
      a.date = val;
   case 3
      a.currentValue = val;
   otherwise
      error('Index out of
   end
case '.'
   switch index.subs
   case 'descriptor'
      a.descriptor = val;
```

```
      case 'date'
         a.date = val;
      case 'currentValue'
         a.currentValue = val;
      otherwise
         error('Invalid field name')
      end
   end
```

The `subsasgn` method enables you to assign values to the asset object data structure using two techniques. For example, suppose you have a child stock object `s`. (If you want to run this statement, you first need to create a stock constructor method.)

```
s = stock('XYZ',100,25);
```

Within stock class methods, you could change the `descriptor` field with either of the following statements

```
s.asset(1) = 'ABC';
```

or

```
s.asset.descriptor = 'ABC';
```

See the "The Stock subsasgn Method" on page 9-55 for an example of how the child `subsasgn` method calls the parent `subsasgn` method.

The Asset display Method

The asset `display` method is designed to be called from child-class `display` methods. Its purpose is to display the data it stores for the child object. The method simply formats the data for display in a way that is consistent with the formatting of the child's display method.

```
function display(a)
% DISPLAY(a) Display an asset object
stg = sprintf(...
   'Descriptor: %s\nDate: %s\nType: %s\nCurrent Value:%9.2f',...
   a.descriptor,a.date,a.type,a.currentValue);
disp(stg)
```

The stock class display method can now call this method to display the data stored in the parent class. This approach isolates the stock `display` method from changes to the asset class. See "The Stock display Method" on page 9-57 for an example of how this method is called.

The Asset fieldcount Method

The asset `fieldcount` method returns the number of fields in the asset object data structure. `fieldcount` enables asset child methods to determine the number of fields in the asset object during execution, rather than requiring the child methods to have knowledge of the asset class. This allows you to make changes to the number of fields in the asset class data structure without having to change child-class methods.

```
function numFields = fieldcount(assetObj)
% Determines the number of fields in an asset object
% Used by asset child class methods
numFields = length(fieldnames(assetObj));
```

The `struct` function converts an object to its equivalent data structure, enabling access to the structure's contents.

Designing the Stock Class

A stock object is designed to represent one particular asset in a person's investment portfolio. This object contains two properties of its own and inherits three properties from its parent asset object.

Stock properties:

- `NumberShares` — The number of shares for the particular stock object.
- `SharePrice` — The value of each share.

Asset properties:

- `Descriptor` — The identifier of the particular asset (e.g., stock name, savings account number, etc.).
- `Date` — The date the object was created (calculated by the `date` command).
- `CurrentValue` — The current value of the asset.

Note that the property names are not actually the same as the field names of the structure array used internally by stock and asset objects. The property name interface is controlled by the stock and asset `set` and `get` methods and is designed to resemble the interface of other MATLAB object properties.

The `asset` field in the stock object structure contains the parent asset object and is used to access the inherited fields in the parent structure.

Stock Class Methods

The stock class implements the following methods:

- Constructor
- `get` and `set`
- `subsref` and `subsasgn`
- `display`

The Stock Constructor Method

The stock constructor creates a stock object from three input arguments:

- The stock name
- The number of shares
- The share price

The constructor must create an asset object from within the stock constructor to be able to specify it as a parent to the stock object. The stock constructor must, therefore, call the asset constructor. The `class` function, which is called to create the stock object, defines the asset object as the parent.

Keep in mind that the asset object is created in the temporary workspace of the stock constructor function and is stored as a field (`.asset`) in the stock structure. The stock object inherits the asset fields, but the asset object is not returned to the base workspace.

```
function s = stock(varargin)
% STOCK Stock class constructor.
% s = stock(descriptor, numShares, sharePrice)
```

```
switch nargin
case 0
   % if no input arguments, create a default object
   s.numShares = 0;
   s.sharePrice = 0;
   a = asset('none',0);
   s = class(s,'stock',a);
case 1
   % if single argument of class stock, return it
   if (isa(varargin{1},'stock'))
      s = varargin{1};
   else
      error('Input argument is not a stock object')
   end
case 3
   % create object using specified values
   s.numShares = varargin{2};
   s.sharePrice = varargin{3};
   a = asset(varargin{1},'stock',varargin{2} * varargin{3});
   s = class(s,'stock',a);
otherwise
   error('Wrong number of input arguments')
end
```

Constructor Calling Syntax

The stock constructor method can be called in one of three ways:

- No input argument — If called with no arguments, the constructor returns a default object with empty fields.
- Input argument is a stock object — If called with a single input argument that is a stock object, the constructor returns the input argument. A single argument that is not a stock object generates an error.
- Three input arguments — If there are three input arguments, the constructor uses them to define the stock object.

Otherwise, if none of the above three conditions are met, return an error.

For example, this statement creates a stock object to record the ownership of 100 shares of XYZ corporation stocks with a price per share of 25 dollars.

```
XYZStock = stock('XYZ',100,25);
```

The Stock get Method

The `get` method provides a way to access the data in the stock object using a "property name" style interface, similar to Handle Graphics. While in this example the property names are similar to the structure field name, they can be quite different. You could also choose to exclude certain fields from access via the `get` method or return the data from the same field for a variety of property names, if such behavior suits your design.

```
function val = get(s,propName)
% GET Get stock property from the specified object
% and return the value. Property names are: NumberShares
% SharePrice, Descriptor, Date, CurrentValue
switch propName
case 'NumberShares'
   val = s.numShares;
case 'SharePrice'
   val = s.sharePrice;
case 'Descriptor'
   val = get(s.asset,'Descriptor'); % call asset get method
case 'Date'
   val = get(s.asset,'Date');
case 'CurrentValue'
   val = get(s.asset,'CurrentValue');
otherwise
   error([propName ,'Is not a valid stock property'])
end
```

Note that the asset object is accessed via the stock object's asset field (`s.asset`). MATLAB automatically creates this field when the `class` function is called with the parent argument.

The Stock set Method

The `set` method provides a "property name" interface like the `get` method. It is designed to update the number of shares, the share value, and the descriptor. The current value and the date are automatically updated.

```
function s = set(s,varargin)
% SET Set stock properties to the specified values
% and return the updated object
propertyArgIn = varargin;
while length(propertyArgIn) >= 2,
   prop = propertyArgIn{1};
   val = propertyArgIn{2};
   propertyArgIn = propertyArgIn(3:end);
   switch prop
   case 'NumberShares'
      s.numShares = val;
   case 'SharePrice'
      s.sharePrice = val;
   case 'Descriptor'
      s.asset = set(s.asset,'Descriptor',val);
   otherwise
      error('Invalid property')
   end
end
s.asset = set(s.asset,'CurrentValue',...
   s.numShares * s.sharePrice,'Date',date);
```

Note that this function creates and returns a new stock object with the new values, which you then copy over the old value. For example, given the stock object,

```
s = stock('XYZ',100,25);
```

the following `set` command updates the share price.

```
s = set(s,'SharePrice',36);
```

It is necessary to copy over the original stock object (i.e., assign the output to `s`) because MATLAB does not support passing arguments by reference. Hence the `set` method actually operates on a copy of the object.

The Stock subsref Method

The `subsref` method defines subscripted indexing for the stock class. In this example, `subsref` is implemented to enable numeric and structure field name indexing of stock objects.

```
function b = subsref(s,index)
% SUBSREF Define field name indexing for stock objects
fc = fieldcount(s.asset);
switch index.type
case '()'
   if (index.subs{:} <= fc)
      b = subsref(s.asset,index);
   else
      switch index.subs{:} - fc
      case 1
         b = s.numShares;
      case 2
         b = s.sharePrice;
      otherwise
         error(['Index must be in the range 1 to ', ...
            num2str(fc + 2)])
      end
   end
case '.'
   switch index.subs
   case 'numShares'
      b = s.numShares;
   case 'sharePrice'
      b = s.sharePrice;
   otherwise
      b = subsref(s.asset,index);
   end
end
```

The outer `switch` statement determines if the index is a numeric or field name syntax.

The `fieldcount` asset method determines how many fields there are in the asset structure, and the `if` statement calls the asset `subsref` method for

indices 1 to `fieldcount`. See "The Asset fieldcount Method" on page 9-49 and "The Asset subsref Method" on page 9-46 for a description of these methods.

Numeric indices greater than the number returned by `fieldcount` are handled by the inner `switch` statement, which maps the index value to the appropriate field in the stock structure.

Field name indexing assumes field names other than `numShares` and `sharePrice` are asset fields, which eliminates the need for knowledge of asset fields by child methods. The asset `subsref` method performs field-name error checking.

See the `subsref` help entry for general information on implementing this method.

The Stock subsasgn Method

The `subsasgn` method enables you to change the data contained in a stock object using numeric indexing and structure field name indexing. MATLAB calls `subsasgn` whenever you execute an assignment statement (e.g., `A(i) = val`, `A{i} = val`, or `A.fieldname = val`).

```
function s = subsasgn(s,index,val)
% SUBSASGN Define index assignment for stock objects
fc = fieldcount(s.asset);
switch index.type
case '()'
   if (index.subs{:} <= fc)
      s.asset = subsasgn(s.asset,index,val);
   else
      switch index.subs{:}-fc
      case 1
         s.numShares = val;
      case 2
         s.sharePrice = val;
      otherwise
         error(['Index must be in the range 1 to ', ...
            num2str(fc + 2)])
      end
   end
```

```
case '.'
   switch index.subs
   case 'numShares'
      s.numShares = val;
   case 'sharePrice'
      s.sharePrice = val;
   otherwise
      s.asset = subsasgn(s.asset,index,val);
   end
end
```

The outer `switch` statement determines if the index is a numeric or field name syntax.

The `fieldcount` asset method determines how many fields there are in the asset structure and the `if` statement calls the asset `subsasgn` method for indices `1` to `fieldcount`. See "The Asset fieldcount Method" on page 9-49 and "The Asset subsasgn Method" on page 9-47 for a description of these methods.

Numeric indices greater than the number returned by `fieldcount` are handled by the inner `switch` statement, which maps the index value to the appropriate field in the stock structure.

Field name indexing assumes field names other than `numShares` and `sharePrice` are asset fields, which eliminates the need for knowledge of asset fields by child methods. The asset `subsasgn` method performs field-name error checking.

The `subsasgn` method enables you to assign values to stock object data structure using two techniques. For example, suppose you have a stock object

```
s = stock('XYZ',100,25)
```

You could change the `descriptor` field with either of the following statements

```
s(1) = 'ABC';
```

or

```
s.descriptor = 'ABC';
```

See the subsasgn help entry for general information on assignment statements in MATLAB.

The Stock display Method

When you issue the statement (without terminating with a semicolon)

```
XYZStock = stock('XYZ',100,25)
```

MATLAB looks for a method in the @stock directory called display. The display method for the stock class produces this output.

```
Descriptor: XYZ
Date: 17-Nov-1998
Type: stock
Current Value:  2500.00
Number of shares: 100
Share price: 25.00
```

Here is the stock display method.

```
function display(s)
% DISPLAY(s) Display a stock object
display(s.asset)
stg = sprintf('Number of shares: %g\nShare price: %3.2f\n',...
   s.numShares,s.sharePrice);
disp(stg)
```

First, the parent asset object is passed to the asset display method to display its fields (MATLAB calls the asset display method because the input argument is an asset object). The stock object's fields are displayed in a similar way using a formatted text string.

Note that if you did not implement a stock class display method, MATLAB would call the asset display method. This would work, but would display only the descriptor, date, type, and current value.

Example — The Portfolio Container

In this section...

Overview

Aggregation is the containment of one class by another class. The basic relationship is: each contained class "is a part of" the container class.

For example, consider a financial portfolio class as a container for a set of assets (stocks, bonds, savings, etc.). Once the individual assets are grouped, they can be analyzed, and useful information can be returned. The contained objects are not accessible directly, but only via the portfolio class methods.

See "Example — Assets and Asset Subclasses" on page 9-41 for information about the assets collected by this portfolio class.

Designing the Portfolio Class

The portfolio class is designed to contain the various assets owned by a given individual and provide information about the status of his or her investment portfolio. This example implements a somewhat over-simplified portfolio class that

- Contains an individual's assets
- Displays information about the portfolio contents
- Displays a 3-D pie chart showing the relative mix of asset types in the portfolio

Required Portfolio Methods

The portfolio class implements only three methods:

- `portfolio` — The portfolio constructor.
- `display` — Displays information about the portfolio contents.
- `pie3` — Overloaded version of `pie3` function designed to take a single portfolio object as an argument.

Since a portfolio object contains other objects, the portfolio class methods can use the methods of the contained objects. For example, the portfolio `display` method calls the stock class `display` method, and so on.

The Portfolio Constructor Method

The portfolio constructor method takes as input arguments a client's name and a variable length list of asset subclass objects (stock, bond, and savings objects in this example). The portfolio object uses a structure array with the following fields:

- `name` — The client's name.
- `indAssets` — The array of asset subclass objects (stock, bond, savings).
- `totalValue` — The total value of all assets. The constructor calculates this value from the objects passed in as arguments.
- `accountNumber` — The account number. This field is assigned a value only when you save a portfolio object (see "Saving and Loading Objects" on page 9-64).

```
function p = portfolio(name,varargin)
% PORTFOLIO Create a portfolio object containing the
% client's name and a list of assets
switch nargin
case 0
   % if no input arguments, create a default object
   p.name = 'none';
   p.totalValue = 0;
   p.indAssets = {};
```

```
        p.accountNumber = '';
        p = class(p,'portfolio');
    case 1
        % if single argument of class portfolio, return it
        if isa(name,'portfolio')
            p = name;
        else
            disp([inputname(1) ' is not a portfolio object'])
            return
        end
    otherwise
        % create object using specified arguments
        p.name = name;
        p.totalValue = 0;
        for k = 1:length(varargin)
            p.indAssets(k) = {varargin{k}};
            assetValue = get(p.indAssets{k},'CurrentValue');
            p.totalValue = p.totalValue + assetValue;
        end
        p.accountNumber = '';
        p = class(p,'portfolio');
    end
```

Constructor Calling Syntax

The portfolio constructor method can be called in one of three different ways:

- No input arguments — If called with no arguments, it returns an object with empty fields.
- Input argument is an object — If the input argument is already a portfolio object, MATLAB returns the input argument. The `isa` function checks for this case.
- More than two input arguments — If there are more than two input arguments, the constructor assumes the first is the client's name and the rest are asset subclass objects. A more thorough implementation would perform more careful input argument checking, for example, using the `isa` function to determine if the arguments are the correct class of objects.

The Portfolio display Method

The portfolio `display` method lists the contents of each contained object by calling the object's `display` method. It then lists the client name and total asset value.

```
function display(p)
% DISPLAY Display a portfolio object
for k = 1:length(p.indAssets)
   display(p.indAssets{k})
end
stg = sprintf('\nAssets for Client: %s\nTotal Value: %9.2f\n',...
p.name,p.totalValue);
disp(stg)
```

The Portfolio pie3 Method

The portfolio class overloads the MATLAB `pie3` function to accept a portfolio object and display a 3-D pie chart illustrating the relative asset mix of the client's portfolio. MATLAB calls the `@portfolio/pie3.m` version of `pie3` whenever the input argument is a single portfolio object.

```
function pie3(p)
% PIE3 Create a 3-D pie chart of a portfolio
stockAmt = 0; bondAmt = 0; savingsAmt = 0;
for k = 1:length(p.indAssets)
   if isa(p.indAssets{k}, 'stock')
      stockAmt = stockAmt + ...
         get(p.indAssets{k}, 'CurrentValue');
   elseif isa(p.indAssets{k}, 'bond')
      bondAmt = bondAmt + ...
         get(p.indAssets{k}, 'CurrentValue');
   elseif isa(p.indAssets{k}, 'savings')
      savingsAmt = savingsAmt + ...
         get(p.indAssets{k}, 'CurrentValue');
   end
end
i = 1;
if stockAmt ~= 0
   label(i) = {'Stocks'};
   pieVector(i) = stockAmt;
   i = i + 1;
```

```
end
if bondAmt ~= 0
   label(i) = {'Bonds'};
   pieVector(i) = bondAmt;
   i = i + 1;
end
if savingsAmt ~= 0
   label(i) = {'Savings'};
   pieVector(i) = savingsAmt;
end
pie3(pieVector, label)
set(gcf, 'Renderer', 'zbuffer')
set(findobj(gca, 'Type', 'Text'), 'FontSize', 14)
cm = gray(64);
colormap(cm(48:end, :))
stg(1) = {['Portfolio Composition for ', p.name]};
stg(2) = {['Total Value of Assets: $', num2str(p.totalValue)]};
title(stg, 'FontSize', 12)
```

There are three parts in the overloaded `pie3` method.

- The first uses the asset subclass `get` methods to access the `CurrentValue` property of each contained object. The total value of each class is summed.
- The second part creates the pie chart labels and builds a vector of graph data, depending on which objects are present.
- The third part calls the MATLAB `pie3` function, makes some font and colormap adjustments, and adds a title.

Creating a Portfolio

Suppose you have implemented a collection of asset subclasses in a manner similar to the stock class. You can then use a portfolio object to present the individual's financial portfolio. For example, given the following assets

```
XYZStock = stock('XYZ', 200, 12);
SaveAccount = savings('Acc # 1234', 2000, 3.2);
Bonds = bond('U.S. Treasury', 1600, 12);
```

create a portfolio object:

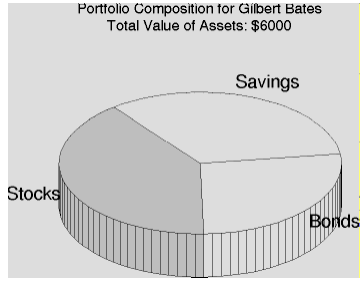
```
p = portfolio('Gilbert Bates',XYZStock,SaveAccount,Bonds)
```

The portfolio `display` method summarizes the portfolio contents (because this statement is not terminated by a semicolon).

```
Descriptor: XYZ
Date: 24-Nov-1998
Current Value:   2400.00
Type: stock
Number of shares: 200
Share price: 12.00
Descriptor: Acc # 1234
Date: 24-Nov-1998
Current Value:   2000.00
Type: savings
Interest Rate: 3.2%
Descriptor: U.S. Treasury
Date: 24-Nov-1998
Current Value:   1600.00
Type: bond
Interest Rate: 12%
Assets for Client: Gilbert Bates
Total Value:   6000.00
```

The portfolio `pie3` method displays the relative mix of assets using a pie chart.

```
pie3(p)
```



Saving and Loading Objects

You can use the MATLAB `save` and `load` commands to save and retrieve user-defined objects to and from `.mat` files, just like any other variables.

When you load objects, MATLAB calls the object's class constructor to register the object in the workspace. The constructor function for the object class you are loading must be able to be called with no input arguments and return a default object. See "Guidelines for Writing a Constructor" on page 9-10 for more information.

When you issue a `save` or `load` command on objects, MATLAB looks for class methods called `saveobj` and `loadobj` in the class directory. You can overload these methods to modify the object before the save or load operation. For example, you could define a `saveobj` method that saves related data along with the object or you could write a `loadobj` method that updates objects to a newer version when this type of object is loaded into the MATLAB workspace.

Example — Defining saveobj and loadobj for Portfolio

In this section...

Methods Executed by Save and Load

In the section "Example — The Portfolio Container" on page 9-58, portfolio objects are used to collect information about a client's investment portfolio. Suppose you decide to add an account number to each portfolio object that is saved. You can define a portfolio `saveobj` method to carry out this task automatically during the save operation.

Suppose further that you have already saved a number of portfolio objects without the account number. You want to update these objects during the load operation so that they are still valid portfolio objects. You can do this by defining a `loadobj` method for the portfolio class.

Summary of Code Changes

To implement the account number scenario, you need to add or change the following functions:

- `portfolio` — The portfolio constructor method needs to be modified to create a new field, `accountNumber`, which is initialized to the empty string when an object is created.
- `saveobj` — A new portfolio method designed to add an account number to a portfolio object during the save operation, only if the object does not already have one.

- `loadobj` — A new portfolio method designed to update older versions of portfolio objects that were saved before the account number structure field was added.
- `subsref` — A new portfolio method that enables subscripted reference to portfolio objects outside of a portfolio method.
- `getAccountNumber` — a MATLAB function that returns an account number that consists of the first three letters of the client's name.

New Portfolio Class Behavior

With the additions and changes made in this example, the portfolio class now

- Includes a field for an account number
- Adds the account number when a portfolio object is saved for the first time
- Automatically updates the older version of portfolio objects when you load them into the MATLAB workspace

The saveobj Method

MATLAB looks for the portfolio `saveobj` method whenever the `save` command is passed a portfolio object. If `@portfolio/saveobj` exists, MATLAB passes the portfolio object to `saveobj`, which must then return the modified object as an output argument. The following implementation of `saveobj` determines if the object has already been assigned an account number from a previous save operation. If not, `saveobj` calls `getAccountNumber` to obtain the number and assigns it to the `accountNumber` field.

```
function b = saveobj(a)
if isempty(a.accountNumber)
   a.accountNumber = getAccountNumber(a);
end
b = a;
```

The loadobj Method

MATLAB looks for the portfolio `loadobj` method whenever the `load` command detects portfolio objects in the `.mat` file being loaded. If `loadobj` exists, MATLAB passes the portfolio object to `loadobj`, which must then return the modified object as an output argument. The output argument is then loaded into the workspace.

If the input object does not match the current definition as specified by the constructor function, then MATLAB converts it to a structure containing the same fields and the object's structure with all the values intact (that is, you now have a structure, not an object).

The following implementation of `loadobj` first uses `isa` to determine whether the input argument is a portfolio object or a structure. If the input is an object, it is simply returned since no modifications are necessary. If the input argument has been converted to a structure by MATLAB, then the new `accountNumber` field is added to the structure and is used to create an updated portfolio object.

```
function b = loadobj(a)
% loadobj for portfolio class
if isa(a,'portfolio')
   b = a;
else % a is an old version
   a.accountNumber = getAccountNumber(a);
   b = class(a,'portfolio');
end
```

Changing the Portfolio Constructor

The portfolio structure array needs an additional field to accommodate the account number. To create this field, add the line

```
p.accountNumber = '';
```

to `@portfolio/portfolio.m` in both the zero argument and variable argument sections.

The getAccountNumber Function

In this example, `getAccountNumber` is a MATLAB function that returns an account number composed of the first three letters of the client name prepended to a series of digits. To illustrate implementation techniques, `getAccountNumber` is not a portfolio method so it cannot access the portfolio object data directly. Therefore, it is necessary to define a portfolio `subsref` method that enables access to the name field in a portfolio object's structure.

For this example, `getAccountNumber` simply generates a random number, which is formatted and concatenated with elements `1` to `3` from the portfolio `name` field.

```
function n = getAccountNumber(p)
% provides a account number for object p
n = [upper(p.name(1:3)) strcat(num2str(round(rand(1,7)*10))')'];
```

Note that the portfolio object is indexed by field name, and then by numerical subscript to extract the first three letters. The `subsref` method must be written to support this form of subscripted reference.

The Portfolio subsref Method

When MATLAB encounters a subscripted reference, such as that made in the `getAccountNumber` function

```
p.name(1:3)
```

MATLAB calls the portfolio `subsref` method to interpret the reference. If you do not define a `subsref` method, the above statement is undefined for portfolio objects (recall that here `p` is an object, not just a structure).

The portfolio `subsref` method must support field-name and numeric indexing for the `getAccountNumber` function to access the portfolio `name` field.

```
function b = subsref(p,index)
% SUBSREF Define field name indexing for portfolio objects
switch index(1).type
case '.'
   switch index(1).subs
   case 'name'
      if length(index)== 1
         b = p.name;
      else
         switch index(2).type
         case '()'
            b = p.name(index(2).subs{:});
         end
      end
   end
```

```
end
```

Note that the portfolio implementation of `subsref` is designed to provide access to specific elements of the `name` field; it is not a general implementation that provides access to all structure data, such as the stock class implementation of `subsref`.

See the `subsref` help entry for more information about indexing and objects.

Object Precedence

In this section...

How MATLAB Determines Precedence

Object precedence is a means to resolve the question of which of possibly many versions of an operator or function to call in a given situation. Object precedence enables you to control the behavior of expressions containing different classes of objects. For example, consider the expression

```
objectA + objectB
```

Ordinarily, MATLAB assumes that the objects have equal precedence and calls the method associated with the leftmost object. However, there are two exceptions:

- User-defined classes have precedence over MATLAB built-in classes.
- User-defined classes can specify their relative precedence with respect to other user-defined classes using the `inferiorto` and `superiorto` functions.

For example, in the section "Example — A Polynomial Class" on page 9-26 the polynom class defines a `plus` method that enables addition of polynom objects. Given the polynom object `p`

```
p = polynom([1 0 -2 -5])
p =
    x^3-2*x-5
```

The expression,

```
1 + p
ans =
    x^3-2*x-4
```

calls the polynom `plus` method (which converts the double, 1, to a polynom object, and then adds it to `p`). The user-defined polynom class has precedence over the MATLAB double class.

Specifying Precedence of User-Defined Classes

You can specify the relative precedence of user-defined classes by calling the `inferiorto` or `superiorto` function in the class constructor.

The `inferiorto` function places a class below other classes in the precedence hierarchy. The calling syntax for the `inferiorto` function is

```
inferiorto('class1','class2',...)
```

You can specify multiple classes in the argument list, placing the class below many other classes in the hierarchy.

Similarly, the `superiorto` function places a class above other classes in the precedence hierarchy. The calling syntax for the `superiorto` function is

```
superiorto('class1','class2',...)
```

Location in the Hierarchy

If *`objectA`* is above *`objectB`* in the precedence hierarchy, then the expression

```
objectA + objectB
```

calls `@`*`classA`*`/plus.m`. Conversely, if *`objectB`* is above *`objectA`* in the precedence hierarchy, then MATLAB calls `@`*`classB`*`/plus.m`.

See “How MATLAB Determines Which Method to Call” on page 9-72 for related information.

How MATLAB Determines Which Method to Call

In this section...

Overview

In MATLAB, functions exist in directories in the computer's file system. A directory may contain many functions (M-files). Function names are unique only within a single directory (e.g., more than one directory may contain a function called `pie3`). When you type a function name on the command line, MATLAB must search all the directories it is aware of to determine which function to call. This list of directories is called the *MATLAB path*.

When looking for a function, MATLAB searches the directories in the order they are listed in the path, and calls the first function whose name matches the name of the specified function.

If you write an M-file called `pie3.m` and put it in a directory that is searched before the `specgraph` directory that contains the MATLAB `pie3` function, then MATLAB uses your `pie3` function instead.

Object-oriented programming allows you to have many methods (MATLAB functions located in class directories) with the same name and enables MATLAB to determine which method to use based on the type or class of the variables passed to the function. For example, if `p` is a portfolio object, then

```
pie3(p)
```

calls `@portfolio/pie3.m` because the argument is a portfolio object.

Selecting a Method

When you call a method for which there are multiple versions with the same name, MATLAB determines the method to call by:

- Looking at the classes of the objects in the argument list to determine which argument has the highest object precedence; the class of this object controls the method selection and is called the *dispatch type*.
- Applying the *function precedence order* to determine which of possibly several implementations of a method to call. This order is determined by the location and type of function.

Determining the Dispatch Type

MATLAB first determines which argument controls the method selection. The class type of this argument then determines the class in which MATLAB searches for the method. The controlling argument is either

- The argument with the highest precedence, or
- The leftmost of arguments having equal precedence

User-defined objects take precedence over the MATLAB built-in classes such as `double` or `char`. You can set the relative precedence of user-defined objects with the `inferiorto` and `superiorto` functions, as described in "Object Precedence" on page 9-70.

MATLAB searches for functions by name. When you call a function, MATLAB knows the name, number of arguments, and the type of each argument. MATLAB uses the dispatch type to choose among multiple functions of the same name, but does not consider the number of arguments.

Function Precedence Order

The function precedence order determines the precedence of one function over another based on the type of function and its location on the MATLAB path. MATLAB selects the correct function for a given context by applying the following function precedence rules, in the order given:

1 Subfunctions

Subfunctions take precedence over all other M-file functions and overloaded methods that are on the path and have the same name. Even if the function is called with an argument of type matching that of an overloaded method, MATLAB uses the subfunction and ignores the overloaded method.

2 Private functions

   Private functions are called if there is no subfunction of the same name within the current scope. As with subfunctions, even if the function is called with an argument of type matching that of an overloaded method, MATLAB uses the private function and ignores the overloaded method.

3 Class constructor functions

   Constructor functions (functions having names that are the same as the @ directory, for example `@polynom/polynom.m`) take precedence over other MATLAB functions. Therefore, if you create an M-file called `polynom.m` and put it on your path before the constructor `@polynom/polynom.m` version, MATLAB will always call the constructor version.

4 Overloaded methods

   MATLAB calls an overloaded method if it is not masked by a subfunction or private function.

5 Current directory

   A function in the current working directory is selected before one elsewhere on the path.

6 Elsewhere on path

   Finally, a function anywhere else on the path is selected.

Selecting Methods from Multiple Directories

There may be a number of directories on the path that contain methods with the same name. MATLAB stops searching when it finds the first implementation of the method on the path, regardless of the implementation type (MEX-file, P-code, M-file).

Selecting Methods from Multiple Implementation Types

There are five file precedence types. MATLAB uses file precedence to select between identically named functions in the same directory. The order of precedence for file types is

1. Built-in file
2. MEX-files
3. MDL (Simulink model) file
4. P-code file
5. M-file

For example, if MATLAB finds a P-code and an M-file version of a method in a class directory, then the P-code version is used. It is, therefore, important to regenerate the P-code version whenever you edit the M-file.

Querying Which Method MATLAB Will Call

You can determine which method MATLAB will call using the `which` command. For example,

```
which pie3
your_matlab_path/toolbox/matlab/specgraph/pie3.m
```

However, if `p` is a portfolio object,

```
which pie3(p)
dir_on_your_path/@portfolio/pie3.m      % portfolio method
```

The `which` command determines which version of `pie3` MATLAB will call if you passed a portfolio object as the input argument. To see a list of all versions of a particular function that are on your MATLAB path, use the `-all` option. See the `which` reference page for more information on this command.

10

Scheduling Program Execution with Timers

Using a MATLAB Timer Object

In this section...

Overview

MATLAB includes a timer object that you can use to schedule the execution of MATLAB commands. This section describes how you can create timer objects, start a timer running, and specify the processing that you want performed when a timer fires. A timer is said to *fire* when the amount of time specified by the timer object elapses and the timer object executes the commands you specify.

To use a timer, perform these steps:

1. Create a timer object.

   You use the `timer` function to create a timer object. See "Creating Timer Objects" on page 10-5 for more information.

2. Specify which MATLAB commands you want executed when the timer fires and control other aspects of timer object behavior.

   You use timer object properties to specify this information. To learn about all the properties supported by the timer object, see "Working with Timer Object Properties" on page 10-7. (You can also set timer object properties when you create them, in step 1.)

3. Start the timer object.

   After you create the timer object, you must start it, using either the `start` or `startat` function. See "Starting and Stopping Timers" on page 10-10 for more information.

4. Delete the timer object when you are done with it.

After you are finished using a timer object, you should delete it from memory. See “Deleting Timer Objects from Memory” on page 10-23 for more information.

Note The specified execution time and the actual execution of a timer can vary because timer objects work in the MATLAB single-threaded execution environment. The length of this time lag is dependent on what other processing MATLAB is performing. To force the execution of the callback functions in the event queue, include a call to the `drawnow` function in your code. The `drawnow` function flushes the event queue.

Example: Displaying a Message

The following example sets up a timer object that executes a MATLAB command string after 10 seconds elapse. The example creates a timer object, specifying the values of two timer object properties, `TimerFcn` and `StartDelay`. `TimerFcn` specifies the timer callback function. This is the MATLAB command string or M-file that you want to execute when the timer fires. In the example, the timer callback function sets the value of the MATLAB workspace variable `stat` and executes the MATLAB `disp` command. The `StartDelay` property specifies how much time elapses before the timer fires.

After creating the timer object, the example uses the `start` function to start the timer object. (The additional commands in this example are included to illustrate the timer but are not required for timer operation.)

```
t = timer('TimerFcn', 'stat=false; disp(''Timer!'')',...
                  'StartDelay',10);
start(t)

stat=true;
while(stat==true)
  disp('.')
  pause(1)
end
```

When you execute this code, it produces this output:

```
.
.
.
.
.
.
.
.
.
Timer!

delete(t) % Always delete timer objects after using them.
```

Creating Timer Objects

In this section...

Creating the Object

To use a timer in MATLAB, you must create a timer object. The timer object represents the timer in MATLAB, supporting various properties and functions that control its behavior.

To create a timer object, use the `timer` function. This creates a valid timer object with default values for most properties. The following shows an example of the default timer object and its summary display:

```
t = timer
Timer Object: timer-1

   Timer Settings
      ExecutionMode: singleShot
              Period: 1
           BusyMode: drop
            Running: off

   Callbacks
           TimerFcn: ''
           ErrorFcn: ''
           StartFcn: ''
            StopFcn: ''
```

MATLAB names the timer object `timer-1`. (See “Naming the Object” on page 10-6 for more information.)

To specify the value of timer object properties after you create it, you can use the `set` function. This example sets the value of the `TimerFcn` property and the `StartDelay` property. For more information about timer object properties, see “Working with Timer Object Properties” on page 10-7.

```
set(t,'TimerFcn','disp(''Hello World!'')','StartDelay',5)
```

You can also set timer object properties when you create the timer object by specifying property name and value pairs as arguments to the `timer` function. The following example sets the same properties at object creation time:

```
t = timer('TimerFcn', 'disp(''Hello World!'')','StartDelay',5);
```

Always delete timer objects when you are done using them. See "Deleting Timer Objects from Memory" on page 10-23 for more information.

Naming the Object

MATLAB assigns a name to each timer object you create. This name has the form `'timer-`*`i`*`'`, where *`i`* is a number representing the total number of timer objects created this session.

For example, the first time you call the timer function to create a timer object, MATLAB names the object `timer-1`. If you call the timer function again to create another timer object, MATLAB names the object `timer-2`.

MATLAB keeps incrementing the number associated with each timer object it creates, even if you delete the timer objects you already created. For example, if you delete the first two timer objects and create a new object, MATLAB names it `timer-3`, even though the other two timer objects no longer exist in memory. To reset the numeric part of timer object names to 1, execute the `clear classes` command.

Working with Timer Object Properties

In this section...

To get information about timer object properties, see the `timer` function reference page.

Retrieving the Value of Timer Object Properties

The timer object supports many properties that provide information about the current state of the timer object and control aspects of its functioning. To retrieve the value of a timer object property, you can use the `get` function or use subscripts (dot notation) to access the field.

The following example uses the `set` function to retrieve the value of the `ExecutionMode` property:

```
t = timer;

tmode = get(t,'ExecutionMode')

tmode =

singleShot
```

The following example uses dot notation to retrieve the value of the `ExecutionMode` property:

```
tmode = t.ExecutionMode

tmode =

singleShot
```

To view a list of all the properties of a timer object, use the `get` function, specifying the timer object as the only argument:

```
get(t)
       AveragePeriod: NaN
            BusyMode: 'drop'
            ErrorFcn: ''
       ExecutionMode: 'singleShot'
       InstantPeriod: NaN
                Name: 'timer-4'
    ObjectVisibility: 'on'
              Period: 1
             Running: 'off'
          StartDelay: 0
            StartFcn: ''
             StopFcn: ''
                 Tag: ''
       TasksExecuted: 0
      TasksToExecute: Inf
            TimerFcn: ''
                Type: 'timer'
            UserData: []
```

Setting the Value of Timer Object Properties

To set the value of a timer object property, use the `set` function or subscripted assignment (dot notation). You can also set timer object properties when you create the timer object. For more information, see "Creating Timer Objects" on page 10-5.

The following example uses both methods to assign values to timer object properties. The example creates a timer that, once started, displays a message every second until you stop it with the `stop` command.

1 Create a timer object.

```
t = timer;
```

2 Assign values to timer object properties using the `set` function.

```
set(t,'ExecutionMode','fixedRate','BusyMode','drop','Period',1);
```

3 Assign a value to the timer object `TimerFcn` property using dot notation.

```
t.TimerFcn = 'disp(''Processing...'')'
```

4 Start the timer object. It displays a message at 1-second intervals.

```
start(t)
```

5 Stop the timer object.

```
stop(t)
```

6 Delete timer objects after you are done using them.

```
delete(t)
```

Viewing a List of All Settable Properties

To view a list of all timer object properties that can have values assigned to them (in contrast to the read-only properties), use the `set` function, specifying the timer object as the only argument.

The display includes the values you can use to set the property if, like the `BusyMode` property, the property accepts an enumerated list of values.

```
t = timer;

set(t)
   BusyMode: [ {drop} | queue | error ]
   ErrorFcn: string -or- function handle -or- cell array
   ExecutionMode: [{singleShot} | fixedSpacing | fixedDelay | fixedRate]
   Name
   ObjectVisibility: [ {on} | off ]
   Period
   StartDelay
   StartFcn: string -or- function handle -or- cell array
   StopFcn: string -or- function handle -or- cell array
   Tag
   TasksToExecute
   TimerFcn: string -or- function handle -or- cell array
   UserData
```

Starting and Stopping Timers

In this section...

Note Because the timer works within the MATLAB single-threaded environment, it cannot guarantee execution times or execution rates.

Starting a Timer

To start a timer object, call the `start` function, specifying the timer object as the only argument. The `start` function starts a timer object running; the amount of time the timer runs is specified in seconds in the `StartDelay` property.

This example creates a timer object that displays a greeting after 5 seconds elapse.

1 Create a timer object, specifying values for timer object properties.

```
t = timer('TimerFcn','disp(''Hello World!'')','StartDelay', 5);
```

2 Start the timer object.

```
start(t)
```

3 Delete the timer object after you are finished using it.

```
delete(t);
```

Starting a Timer at a Specified Time

To start a timer object and specify a date and time for the timer to fire, (rather than specifying the number of seconds to elapse), use the `startat` function. This function starts a timer object and allows you to specify the date, hour,

minute, and second when you want to the timer to execute. You specify the time as a MATLAB serial date number or as a specially formatted date text string.

This example creates a timer object that displays a message after an hour has elapsed. The `startat` function starts the timer object running and calculates the value of the `StartDelay` property based on the time you specify.

```
t2=timer('TimerFcn','disp(''It has been an hour now.'')');

startat(t2,now+1/24);
```

Stopping Timer Objects

Once started, the timer object stops running if one of the following conditions apply:

- The timer function callback (`TimerFcn`) has been executed the number of times specified in the `TasksToExecute` property.
- An error occurred while executing a timer function callback (`TimerFcn`).

You can also stop a timer object by using the `stop` function, specifying the timer object as the only argument. The following example illustrates stopping a timer object:

1 Create a timer object.

```
t = timer('TimerFcn','disp(''Hello World!'')', ...
          'StartDelay', 100);
```

2 Start it running.

```
start(t)
```

3 Check the state of the timer object after starting it.

```
get(t,'Running')

ans =

on
```

4 Stop the timer using the `stop` command and check the state again. When a timer stops, the value of the `Running` property of the timer object is set to `'off'`.

```
stop(t)

get(t,'Running')

ans =

off
```

5 Delete the timer object when you are finished using it.

```
delete(t)
```

Note The timer object can execute a callback function that you specify when it starts or stops. See "Creating and Executing Callback Functions" on page 10-14.

Blocking the MATLAB Command Line

By default, when you use the `start` or `startat` function to start a timer object, the function returns control to the command line immediately. For some applications, you might prefer to block the command line until the timer fires. To do this, call the `wait` function right after calling the `start` or `startat` function.

1 Create a timer object.

```
t = timer('StartDelay', 5,'TimerFcn', ...
          'disp(''Hello World!'')');
```

2 Start the timer object running.

```
start(t)
```

3 After the `start` function returns, call the `wait` function immediately. The `wait` function blocks the command line until the timer object fires.

```
wait(t)
```

4 Delete the timer object after you are finished using it.

```
delete(t)
```

Creating and Executing Callback Functions

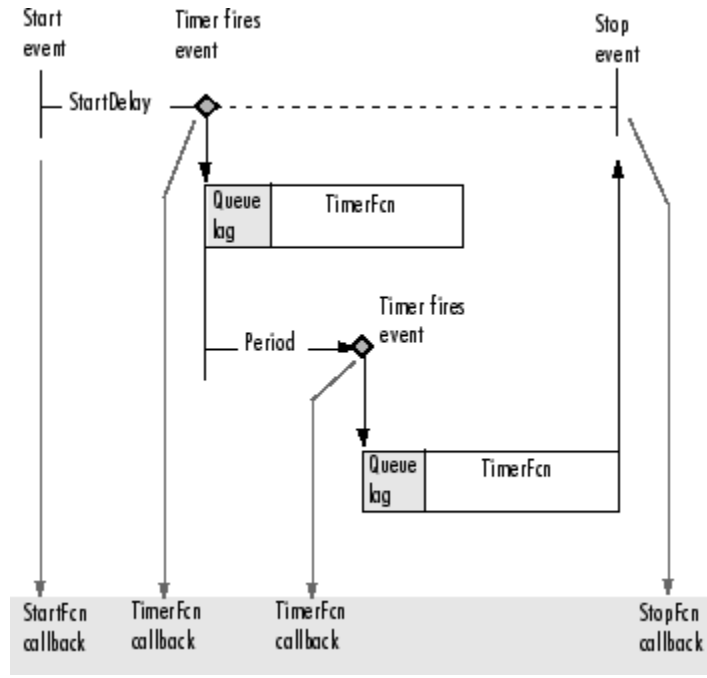
In this section...

Note Callback function execution might be delayed if the callback involves a CPU-intensive task such as updating a figure.

Associating Commands with Timer Object Events

The timer object supports properties that let you specify the MATLAB commands that execute when a timer fires, and for other timer object events, such as starting, stopping, or when an error occurs. These are called *callbacks*. To associate MATLAB commands with a timer object event, set the value of the associated timer object callback property.

The following diagram shows when the events occur during execution of a timer object and give the names of the timer object properties associated with each event. For example, to associate MATLAB commands with a start event, assign a value to the `StartFcn` callback property. Error callbacks can occur at any time.



Timer Object Events and Related Callback Function

Creating Callback Functions

When the time period specified by a timer object elapses, the timer object executes one or more MATLAB functions of your choosing. You can specify the functions directly as the value of the callback property. You can also put the commands in an M-file function and specify the M-file function as the value of the callback property.

Specifying Callback Functions Directly

This example creates a timer object that displays a greeting after 5 seconds. The example specifies the value of the `TimerFcn` callback property directly, putting the commands in a text string.

```
t = timer('TimerFcn','disp(''Hello World!'')','StartDelay',5);
```

Note When you specify the callback commands directly as the value of the callback function property, the commands are evaluated in the MATLAB workspace.

Putting Commands in a Callback Function

Instead of specifying MATLAB commands directly as the value of a callback property, you can put the commands in an M-file and specify the M-file as the value of the callback property.

When you create a callback function, the first two arguments must be a handle to the timer object and an event structure. An event structure contains two fields: `Type` and `Data`. The `Type` field contains a text string that identifies the type of event that caused the callback. The value of this field can be any of the following strings: `'StartFcn'`, `'StopFcn'`, `'TimerFcn'`, or `'ErrorFcn'`. The `Data` field contains the time the event occurred.

In addition to these two required input arguments, your callback function can accept application-specific arguments. To receive these input arguments, you must use a cell array when specifying the name of the function as the value of a callback property. For more information, see “Specifying the Value of Callback Function Properties” on page 10-17.

Example: Writing a Callback Function

This example implements a simple callback function that displays the type of event that triggered the callback and the time the callback occurred. To illustrate passing application-specific arguments, the example callback function accepts as an additional argument a text string and includes this text string in the display output. To see this function used with a callback property, see “Specifying the Value of Callback Function Properties” on page 10-17.

```
function my_callback_fcn(obj, event, string_arg)

txt1 = ' event occurred at ';
txt2 = string_arg;

event_type = event.Type;
event_time = datestr(event.Data.time);
```

```
msg = [event_type txt1 event_time];
disp(msg)
disp(txt2)
```

Specifying the Value of Callback Function Properties

You associate a callback function with a specific event by setting the value of the appropriate callback property. You can specify the callback function as a text string, cell array, or function handle. To access the object and event arguments, you must specify the function as a cell array or as a function handle. If your callback function accepts additional arguments, you must use a cell array.

The following table shows the syntax for several sample callback functions and describes how you call them.

Callback Function Syntax	How to Specify as a Property Value
`function myfile`	`set(h, 'StartFcn', 'myfile')`
`function myfile(obj, event)`	`set(h, 'StartFcn', @myfile)`
`function myfile(obj, event, arg1, arg2)`	`set(h, 'StartFcn', {'myfile', 5, 6})`
`function myfile(obj, event, arg1, arg2)`	`set(h, 'StartFcn', {@myfile, 5, 6})`

This example illustrates several ways you can specify the value of timer object callback function properties, some with arguments and some without. To see the code of the callback function, `my_callback_fcn`, see “Example: Writing a Callback Function” on page 10-16.

1 Create a timer object.

```
t = timer('StartDelay', 4,'Period', 4,'TasksToExecute', 2,...
          'ExecutionMode','fixedRate');
```

2. Specify the value of the `StartFcn` callback. Note that the example specifies the value in a cell array because the callback function needs to access arguments passed to it.

```
t.StartFcn = {'my_callback_fcn', 'My start message'};
```

3. Specify the value of the `StopFcn` callback. The example specifies the callback function by its handle, rather than as a text string. Again, the value is specified in a cell array because the callback function needs to access the arguments passed to it.

```
t.StopFcn = { @my_callback_fcn, 'My stop message'};
```

4. Specify the value of the `TimerFcn` callback. The example specifies the MATLAB commands in a text string.

```
t.TimerFcn = 'disp(''Hello World!'')';
```

5. Start the timer object.

```
start(t)
```

   The example outputs the following.

```
StartFcn event occurred at 10-Mar-2004 17:16:59
Start message
Hello World!
Hello World!
StopFcn event occurred at 10-Mar-2004 17:16:59
Stop message
```

6. Delete the timer object after you are finished with it.

```
delete(t)
```

Timer Object Execution Modes

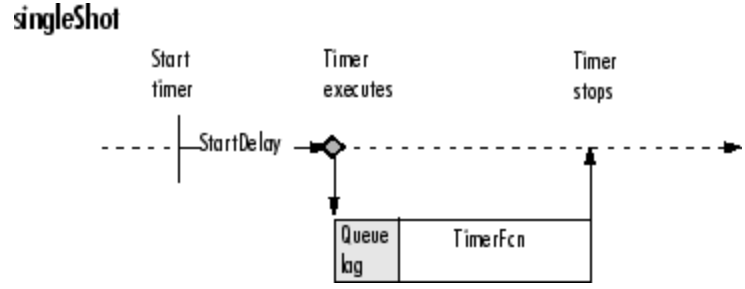
In this section...

Executing a Timer Callback Function Once

The timer object supports several execution modes that determine how it schedules the timer callback function (`TimerFcn`) for execution. You specify the execution mode by setting the value of the `ExecutionMode` property.

To execute a timer callback function once, set the `ExecutionMode` property to `'singleShot'`. This is the default execution mode. In this mode, the timer object starts the timer and, after the time period specified in the `StartDelay` property elapses, adds the timer callback function (`TimerFcn`) to the MATLAB execution queue. When the timer callback function finishes, the timer stops.

The following figure graphically illustrates the parts of timer callback execution for a `singleShot` execution mode. The shaded area in the figure, labelled queue lag, represents the indeterminate amount of time between when the timer adds a timer callback function to the MATLAB execution queue and when the function starts executing. The duration of this lag is dependent on what other processing MATLAB happens to be doing at the time.



Timer Callback Execution (singleShot Execution Mode)

Executing a Timer Callback Function Multiple Times

The timer object supports three multiple-execution modes:

- `'fixedRate'`
- `'fixedDelay'`
- `'fixedSpacing'`

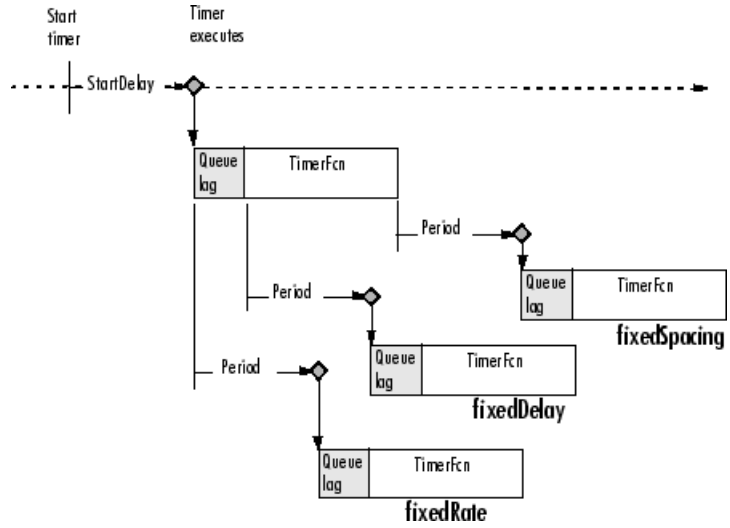
In many ways, these execution modes operate the same:

- The `TasksToExecute` property specifies the number of times you want the timer to execute the timer callback function (`TimerFcn`).
- The `Period` property specifies the amount of time between executions of the timer callback function.
- The `BusyMode` property specifies how the timer object handles queuing of the timer callback function when the previous execution of the callback function has not completed. See "Handling Callback Function Queuing Conflicts" on page 10-21 for more information.

The execution modes differ only in where they start measuring the time period between executions. The following table describes these differences.

Execution Mode	Description
`'fixedRate'`	Time period between executions begins immediately after the timer callback function is added to the MATLAB execution queue.
`'fixedDelay'`	Time period between executions begins when the timer function callback actually starts executing, after any time lag due to delays in the MATLAB execution queue.
`'fixedSpacing'`	Time period between executions begins when the timer callback function finishes executing.

The following figure illustrates the difference between these modes. Note that the amount of time between executions (specified by the `Period` property) remains the same. Only the point at which execution begins is different.



Differences Between Execution Modes

Handling Callback Function Queuing Conflicts

At busy times, in multiple-execution scenarios, the timer may need to add the timer callback function (`TimerFcn`) to the MATLAB execution queue before the previously queued execution of the callback function has completed. You can determine how the timer object handles this scenario by using the `BusyMode` property.

If you specify `'drop'` as the value of the `BusyMode` property, the timer object skips the execution of the timer function callback if the previously scheduled callback function has not already completed.

If you specify `'queue'`, the timer object waits until the currently executing callback function finishes before queuing the next execution of the timer callback function.

Note In `'queue'` mode, the timer object tries to make the average time between executions equal the amount of time specified in the `Period` property. If the timer object has to wait longer than the time specified in the `Period` property between executions of the timer function callback, it shortens the time period for subsequent executions to make up the time.

If the `BusyMode` property is set to `'error'`, the timer object stops and executes the timer object error callback function (`ErrorFcn`), if one is specified.

Deleting Timer Objects from Memory

In this section...

Deleting One or More Timer Objects

When you are finished with a timer object, delete it from memory using the `delete` function:

```
delete(t)
```

When you delete a timer object, workspace variables that referenced the object remain. Deleted timer objects are invalid and cannot be reused. Use the `clear` command to remove workspace variables that reference deleted timer objects.

To remove all timer objects from memory, enter

```
delete(timerfind)
```

For information about the `timerfind` function, see "Finding Timer Objects in Memory" on page 10-24.

Testing the Validity of a Timer Object

To test if a timer object has been deleted, use the `isvalid` function. The `isvalid` function returns logical `0` (`false`) for deleted timer objects:

```
isvalid(t)
ans =

     0
```

Finding Timer Objects in Memory

In this section...

Finding All Timer Objects

To find all the timer objects that exist in memory, use the `timerfind` function. This function returns an array of timer objects. If you leave off the semicolon, and there are multiple timer objects in the array, `timerfind` displays summary information in a table:

```
t1 = timer;
t2 = timer;
t3 = timer;
t_array = timerfind

Timer Object Array

   Index:  ExecutionMode:  Period:  TimerFcn:    Name:
   1       singleShot      1        ''           timer-3
   2       singleShot      1        ''           timer-4
   3       singleShot      1        ''           timer-5
```

Using `timerfind` to determine all the timer objects that exist in memory can be helpful when deleting timer objects.

Finding Invisible Timer Objects

If you set the value of a timer object's `ObjectVisibility` property to `'off'`, the timer object does not appear in listings of existing timer objects returned by `timerfind`. The `ObjectVisibility` property provides a way for application developers to prevent end-user access to the timer objects created by their application.

Objects that are not visible are still valid. If you have access to the object (for example, from within the M-file that created it), you can set its properties. To

retrieve a list of all the timer objects in memory, including invisible ones, use the `timerfindall` function.

11

Improving Performance and Memory Usage

Analyzing Your Program's Performance

In this section...

Overview

The M-file Profiler graphical user interface and the stopwatch timer functions enable you to get back information on how your program is performing and help you identify areas that need improvement. The Profiler can be more useful in measuring relative execution time and in identifying specific performance bottlenecks in your code, while the stopwatch functions tend to be more useful for providing absolute time measurements.

The M-File Profiler Utility

A good first step to speeding up your programs is to find out where the bottlenecks are. This is where you need to concentrate your attention to optimize your code.

MATLAB provides the M-file Profiler, a graphical user interface that shows you where your program is spending its time during execution. Use the Profiler to help you determine where you can modify your code to make performance improvements.

To start the Profiler, type `profile viewer` or select **Desktop > Profiler** in the MATLAB Command Window. See Profiling for Improving Performance in the MATLAB Desktop Tools and Development Environment documentation, and the `profile` function reference page.

Stopwatch Timer Functions

If you just need to get an idea of how long your program (or a portion of it) takes to run, or to compare the speed of different implementations of a program, you can use the stopwatch timer functions, `tic` and `toc`. Invoking

`tic` starts the timer, and the first subsequent `toc` stops it and reports the time elapsed between the two.

Use `tic` and `toc` as shown here:

```
tic
   -- run the program section to be timed --
toc
```

Keep in mind that `tic` and `toc` measure overall elapsed time. Make sure that no other applications are running in the background on your system that could affect the timing of your MATLAB programs.

Measuring Smaller Programs

Shorter programs sometimes run too fast to get useful data from `tic` and `toc`. When this is the case, try measuring the program running repeatedly in a loop, and then average to find the time for a single run:

```
tic
   for k = 1:100
      -- run the program --
   end
toc
```

Using tic and toc Versus the cputime Function

Although it is possible to measure performance using the `cputime` function, it is recommended that you use the `tic` and `toc` functions for this purpose exclusively. It has been the general rule for CPU-intensive calculations run on Windows machines that the elapsed time using `cputime` and the elapsed time using `tic` and `toc` are close in value, ignoring any first time costs. There are cases however that show a significant difference between these two methods. For example, in the case of a Pentium 4 with hyperthreading running Windows, there can be a significant difference between the values returned by `cputime` versus `tic` and `toc`.

Techniques for Improving Performance

In this section...

Vectorizing Loops

MATLAB is a matrix language, which means it is designed for vector and matrix operations. You can often speed up your M-file code by using vectorizing algorithms that take advantage of this design. *Vectorization* means converting `for` and `while` loops to equivalent vector or matrix operations.

Simple Example of Vectorizing

Here is one way to compute the sine of 1001 values ranging from 0 to 10:

```
i = 0;
for t = 0:.01:10
    i = i + 1;
    y(i) = sin(t);
```

```
end
```

A vectorized version of the same code is

```
t = 0:.01:10;
y = sin(t);
```

The second example executes much faster than the first and is the way MATLAB is meant to be used. Test this on your system by creating M-file scripts that contain the code shown, and then using the `tic` and `toc` functions to time the M-files.

Advanced Example of Vectorizing

`repmat` is an example of a function that takes advantage of vectorization. It accepts three input arguments: an array `A`, a row dimension `M`, and a column dimension `N`.

`repmat` creates an output array that contains the elements of array `A`, replicated and "tiled" in an `M`-by-`N` arrangement:

```
A = [1 2 3; 4 5 6];

B = repmat(A,2,3);
B =
    1    2    3    1    2    3    1    2    3
    4    5    6    4    5    6    4    5    6
    1    2    3    1    2    3    1    2    3
    4    5    6    4    5    6    4    5    6
```

`repmat` uses vectorization to create the indices that place elements in the output array:

```
function B = repmat(A, M, N)

% Step 1 Get row and column sizes
[m,n] = size(A);

% Step 2 Generate vectors of indices from 1 to row/column size
mind = (1:m)';
nind = (1:n)';
```

```
% Step 3 Create index matrices from vectors above
mind = mind(:,ones(1, M));
nind = nind(:,ones(1, N));

% Step 4 Create output array
B = A(mind,nind);
```

Step 1, above, obtains the row and column sizes of the input array.

Step 2 creates two column vectors. `mind` contains the integers from 1 through the row size of `A`. The `nind` variable contains the integers from 1 through the column size of `A`.

Step 3 uses a MATLAB vectorization trick to replicate a single column of data through any number of columns. The code is

```
B = A(:,ones(1,nCols))
```

where `nCols` is the desired number of columns in the resulting matrix.

Step 4 uses array indexing to create the output array. Each element of the row index array, `mind`, is paired with each element of the column index array, `nind`, using the following procedure:

1. The first element of `mind`, the row index, is paired with each element of `nind`. MATLAB moves through the `nind` matrix in a columnwise fashion, so `mind(1,1)` goes with `nind(1,1)`, and then `nind(2,1)`, and so on. The result fills the first row of the output array.
2. Moving columnwise through `mind`, each element is paired with the elements of `nind` as above. Each complete pass through the `nind` matrix fills one row of the output array.

Caution While `repmat` can take advantage of vectorization, it can do so at the expense of memory usage. When this is the case, you might find the `bsxfun` function be more appropriate in this respect.

Functions Used in Vectorizing

Some of the most commonly used functions for vectorizing are as follows

Function	Description
`all`	Test to determine if all elements are nonzero
`any`	Test for any nonzeros
`cumsum`	Find cumulative sum
`diff`	Find differences and approximate derivatives
`find`	Find indices and values of nonzero elements
`ind2sub`	Convert from linear index to subscripts
`ipermute`	Inverse permute dimensions of a multidimensional array
`logical`	Convert numeric values to logical
`ndgrid`	Generate arrays for multidimensional functions and interpolation
`permute`	Rearrange dimensions of a multidimensional array
`prod`	Find product of array elements
`repmat`	Replicate and tile an array
`reshape`	Change the shape of an array
`shiftdim`	Shift array dimensions
`sort`	Sort array elements in ascending or descending order
`squeeze`	Remove singleton dimensions from an array
`sub2ind`	Convert from subscripts to linear index
`sum`	Find the sum of array elements

Preallocating Arrays

`for` and `while` loops that incrementally increase, or *grow*, the size of a data structure each time through the loop can adversely affect performance and memory use. Repeatedly resizing arrays often requires that MATLAB spend extra time looking for larger contiguous blocks of memory and then moving the array into those blocks. You can often improve on code execution time by

preallocating the maximum amount of space that would be required for the array ahead of time.

The following code creates a scalar variable `x`, and then gradually increases the size of `x` in a `for` loop instead of preallocating the required amount of memory at the start:

```
x = 0;
for k = 2:1000
   x(k) = x(k-1) + 5;
end
```

Change the first line to preallocate a 1-by-1000 block of memory for `x` initialized to zero. This time there is no need to repeatedly reallocate memory and move data as more values are assigned to `x` in the loop:

```
x = zeros(1, 1000);
for k = 2:1000
   x(k) = x(k-1) + 5;
end
```

Preallocation Functions

Preallocation makes it unnecessary for MATLAB to resize an array each time you enlarge it. Use the appropriate preallocation function for the kind of array you are working with.

Array Type	Function	Examples
Numeric	`zeros`	`y = zeros(1, 100);`

Cell	`cell`	`B = cell(2, 3);`
		`B{1,3} = 1:3;`
		`B{2,2} = 'string';`

Preallocating a Nondouble Matrix

When you preallocate a block of memory to hold a matrix of some type other than `double`, avoid using the method

```
A = int8(zeros(100));
```

This statement preallocates a 100-by-100 matrix of `int8` first by creating a full matrix of `doubles`, and then converting each element to `int8`. This costs time and uses memory unnecessarily.

The next statement shows how to do this more efficiently:

```
A = zeros(100, 'int8');
```

Use Distributed Arrays for Large Datasets

This topic is described in the "Parallel Math" section of the Distributed Computing Toolbox documentation.

When Possible, Replace for with parfor (Parallel for)

This topic is described in the "Parallel for-Loops" section of the Distributed Computing Toolbox documentation.

Multithreading Capabilities in MATLAB

See "Implicit Multiprocessing" on page 11-14 to learn more about making use of multithreaded computation.

Limiting M-File Size and Complexity

Running programs that are unusually large or complex can put a strain on your system's resources. For example, a program that nearly exceeds memory capacity may work some of the time and sometimes not, depending on the commands it uses and on what other applications are running at the time. An example of unnecessary complexity might be having a large number of `if` and `else` statements where `switch` and `case` might be more suitable. This can also lead to performance and space problems.

If you have an M-file that includes thousands of variables or functions, tens of thousands of statements, or hundreds of language keyword pairs (e.g., `if-else`, or `try-catch`), then making some of the changes suggested here is likely to not only boost its performance and reliability, but should make your program code easier to understand and maintain as well.

Here are a few suggestions on how to make your programs less resource-intensive:

- Split large script files into smaller ones, having the first file call the second if necessary.
- Take your larger chunks of program code and make separate functions (or subfunctions and nested functions) of them.
- If you have functions or expressions by that seem overly complicated, make smaller and simpler functions or expressions of them. Simpler functions are also more likely to be made into utility functions that you can share with others.

Coding Loops in a MEX-File

If there are instances where you cannot vectorize and must use a `for` or `while` loop, consider coding the loop in a MEX-file. In this way, the loop executes much more quickly since the instructions in the loop do not have to be interpreted each time they execute.

See “Introducing MEX-Files” in the External Interfaces documentation.

Assigning to Variables

For best performance, keep the following suggestions in mind when assigning values to variables.

Changing a Variable’s Data Type or Dimension

Changing the data type or array shape of an existing variable slows MATLAB down as it must take extra time to process this. When you need to store data of a different type, it is advisable to create a new variable.

This code changes the type for `X` from `double` to `char`, which has a negative impact on performance:

```
X = 23;
     .
-- other code  --
     .
X = 'A';                  % X changed from type double to char
     .
-- other code  --
```

Assigning Real and Complex Numbers

Assigning a complex number to a variable that already holds a real number impacts the performance of your program. Similarly, you should not assign a real value to a variable that already holds a complex value.

Operating on Real Data

When operating on real (i.e., noncomplex) numbers, it is more efficient to use MATLAB functions that have been designed specifically for real numbers. The following functions return numeric values that are real.

Function	Description
`reallog`	Find natural logarithm for nonnegative real arrays
`realpow`	Find array power for real-only output
`realsqrt`	Find square root for nonnegative real arrays

Using Appropriate Logical Operators

When performing a logical AND or OR operation, you have a choice of two operators of each type.

Operator	Description
`&, |`	Perform logical AND and OR on arrays element by element
`&&, ||`	Perform logical AND and OR on scalar values with short-circuiting

In `if` and `while` statements, it is more efficient to use the short-circuiting operators, `&&` for logical AND and `||` for logical OR. This is because these operators often don't have to evaluate the entire logical expression. For example, MATLAB evaluates only the first part of this expression whenever the number of input arguments is less than three:

```
if (nargin >= 3) && (ischar(varargin{3}))
```

See Short-Circuit Operators in the MATLAB documentation for a discussion on short-circuiting with `&&` and `||`.

Overloading Built-In Functions

Overloading MATLAB built-in functions on any of the standard MATLAB data types can negatively affect performance. For example, if you overload the `plus` function to handle any of the integer data types differently, you may hinder certain optimizations in the MATLAB built-in function code for `plus`, and thus may slow down any programs that make use of this overload.

Functions Are Generally Faster Than Scripts

Your code executes more quickly if it is implemented in a function rather than a script.

Load and Save Are Faster Than File I/O Functions

If you have a choice of whether to use `load` and `save` instead of the low-level MATLAB file I/O routines such as `fread` and `fwrite`, choose the former. `load` and `save` have been optimized to run faster and reduce memory fragmentation.

Avoid Large Background Processes

Avoid running large processes in the background at the same time you are executing your program in MATLAB. This frees more CPU time for your MATLAB session.

Multiprocessing in MATLAB

In this section...

Overview

MATLAB supports two types of multiprocessing: *implicit* and *explicit*.

Implicit Multiprocessing

Characteristics of implicit multiprocessing:

- Runs multiple threads on a single machine, most often using one thread per processing unit.
- Requires a multiple CPU (multiprocessor or multicore) system.
- Speeds up elementwise computations such as those done by the `sin` and `log` functions, and computations that use the Basic Linear Algebra Subroutines (BLAS) library, such as matrix multiply.
- Does *not* require any changes to your MATLAB code.
- Works behind the scenes to take advantage of the processing units available to you. It does this by multithreading the computationally-intensive math library functions that you use in the course of your MATLAB session.

Enable implicit multiprocessing with the MATLAB Preferences Panel to enable or disable, or to set the number of threads to be used. You can change the maximum number of threads programmatically using the `maxNumCompThreads` function.

Explicit Multiprocessing

Characteristics of explicit multiprocessing:

- Runs separate processes on one or many machines.

- Requires installation of Distributed Computing Toolbox (DCT).
- Speeds up execution of large MATLAB jobs. Enables you to run jobs simultaneously on a cluster of computers, or as several processes on a single machine.
- Requires that you modify your MATLAB code.
- DCT supports programming constructs for distributed arrays and parallel `for` (`parfor`) loops. It also supports both interactive and batch execution.

Enable explicit multiprocessing by installing Distributed Computing Toolbox.

Implicit Multiprocessing

Multithreaded computation runs in a single instance of MATLAB and generates simultaneous instruction streams on a multiple CPU (multiprocessor or multicore) system. The multiple processors share the memory of a single computer. The work to be processed is implicitly partitioned for execution on multiple threads. In particular, multithreaded computation in MATLAB speeds up elementwise computations such as those done by the `sin` and `log` functions, and computations that use the Basic Linear Algebra Subroutines (BLAS) library, such as matrix multiply.

If you are using a multiple-CPU system, you can run a demo to see the performance impact—see Multithreaded Computation in the Help browser **Demos** pane, under MATLAB Mathematics.

For information regarding specific functions, search for “What MATLAB Functions Support Multithreaded Computation” on The MathWorks online Support page.

Platform Differences and Multithreaded Computation

The BLAS library used for multithreaded computation differs according to which platform you are using:

Platform	BLAS Used
Windows with Intel processors	Intel MKL BLAS
Windows with AMD processors	AMD ACML BLAS
Linux with Intel processors	Intel MKL BLAS
Linux with AMD processors	AMD ACML BLAS
Macintosh Intel-based	Intel MKL BLAS
MacIntosh PowerPC	Mac Accelerate BLAS
Solaris	Sun Performance Library BLAS

Note On Macintosh PowerPC platforms, multithreaded computation is always enabled for the Accelerate BLAS. To enable multithreaded computation for elementwise operations, use MATLAB preferences.

Enabling Multithreaded Computation

The preference automatically detects the number of CPUs on your system and recommends the number of threads based on that.

Multithreaded computation in MATLAB is disabled by default. To enable it and set the maximum number of threads to use, follow these steps:

1. Select **File > Preferences > General > Multithreading**.

   The **General Multithreading Preferences** panel opens.

2. On the **General Multithreading Preferences** panel, select **Enable multithreaded computation**.

3. Specify the **Maximum number of computational threads**. Accepting the **Automatic** option is recommended—MATLAB automatically sets the value to the actual number of computational cores on your system. Note

that if your system uses hyperthreading (where one processor is logically configured as two), MATLAB sets the value to 1.

If you choose **Manual**, enter the maximum number of threads you want to set; use a positive integer not greater than 16. (Selecting a number other than the recommended value might increase performance for some computations, but might decrease performance for others.)

Note You may find that, at certain times, a library function uses a number of threads smaller than what you have specified. This can happen if the function finds the specified number of threads to be inappropriate.

In the event of an abnormal termination with multithreaded computation enabled, MATLAB behaves differently than when multithreaded computation is not enabled. For details, see .

Making this setting in the **Preferences** panel not only affects your current MATLAB session, but future sessions as well. To disable multithreaded computation, clear the **Enable multithreaded computation** selection and click **OK**.

Note For Macintosh PowerPC platforms, BLAS multithreaded computation cannot be disabled.

Setting the Number of Threads Programmatically

To set or retrieve the maximum number of computational threads from within an M-file program, use the `maxNumCompThreads` function. You can either set the maximum number of computational threads to a specific number, or indicate that you want the setting to be done automatically by MATLAB.

To set the maximum number of computational threads to a specific number `N`, use

```
maxNumCompThreads(N)
```

To have MATLAB set the maximum number of threads, use:

```
maxNumCompThreads('automatic')
```

`maxNumCompThreads` also returns the current maximum number of threads if you call it with an output value:

```
old_N = MaxNumCompThreads(new_N)
```

MATLAB keeps the settings you make using `maxNumCompThreads` synchronous with your **Preferences** settings. If you change the maximum number of computational threads by means of the `maxNumCompThreads` function, MATLAB updates the **Preferences** panel to agree with the new setting.

Note Setting the maximum number of computational threads using `maxNumCompThreads` does not propagate to your next MATLAB session. To make this setting carry over to future sessions, use the **Preferences** panel instead.

Crash Recovery and Multithreading

If MATLAB experiences a segmentation violation or other serious problem when multithreaded computation is enabled, it cannot try to return control to the Command Window. You do not have an opportunity to view a segmentation violation message in the Command Window as you might when multithreaded computation is *not* enabled. Instead, your platform's vendor, for example, Microsoft or Apple, provides an error dialog box. MATLAB then terminates.

Upon the next MATLAB startup after a fatal problem, the "Error Log Reporter" prompts you to e-mail the log to The MathWorks.

Explicit Multiprocessing

See the Distributed Computing Toolbox documentation for information regarding explicit multiprocessing in MATLAB.

Memory Allocation in MATLAB

In this section...

For more information on memory management, see Technical Note 1106: "Memory Management Guide" at the following URL:

```
http://www.mathworks.com/support/tech-notes/1100/1106.html
```

Memory Allocation for Arrays

The topics below provide information on how MATLAB allocates memory when working with arrays and variables. The purpose is to help you use memory more efficiently when writing code. Most of the time, however, you should not need to be concerned with these internal operations as MATLAB handles data storage for you automatically.

Note Any information on how data is handled internally by MATLAB is subject to change in future releases.

Creating and Modifying Arrays

When you assign any type of data (a numeric, string, or structure array, for example) to a variable, MATLAB allocates a contiguous block of memory and stores the array data in that block. It also stores information about the array data, such as its data type and dimensions, in a separate, small block of memory called a header. The variable that you assign this data to is actually a *pointer* to the data; it does not *contain* the data.

If you add new elements to an existing array, MATLAB expands the existing array in memory in a way that keeps its storage contiguous. This might require finding a new block of memory large enough to hold the expanded array, and then copying the contents of the array from its original location to the new block in memory, adding the new elements to the array in this block, and freeing up the original array location in memory.

If you remove elements from an existing array, MATLAB keeps the memory storage contiguous by removing the deleted elements, and then compacting its storage in the original memory location.

Working with Large Data Sets. If you are working with large data sets, you need to be careful when increasing the size of an array to avoid getting errors caused by insufficient memory. If you expand the array beyond the available contiguous memory of its original location, MATLAB has to make a copy of the array in a new location in memory, as explained above, and then set this array to its new value. During this operation, there are two copies of the original array in memory, thus temporarily doubling the amount of memory required for the array and increasing the risk of your program running out of memory during execution. It is better to preallocate sufficient memory for the array at the start. See “Preallocating Arrays” on page 11-7.

Copying Arrays

Internally, multiple variables can point to the same block of data, thus sharing that array’s value. When you copy a variable to another variable (e.g., `B = A`), MATLAB makes a copy of the pointer, not the array. For example, the following code creates a single 500-by-500 matrix and two pointers to it, `A` and `B`:

```
A = magic(500);
B = A;
```

As long as the contents of the array are not modified, there is no need to store two copies of it. If you modify the array, then MATLAB does create a separate array to hold the new values.

If you modify the array shown above by referencing it with variable `A` (e.g., `A(400,:) = 0`), then MATLAB creates a copy of the array, modifies it accordingly, and stores a pointer to the new array in `A`. Variable `B` continues

to point to the original array. If you modify the array by referencing it with variable `B` (e.g., `B(400,:) = 0`), the same thing happens except that it is `B` that points to the new array.

Array Headers

When you assign an array to a variable, MATLAB also stores information about the array (such as data type and dimensions) in a separate piece of memory called a header. For most arrays, the memory required to store the header is insignificant. There is a small advantage though to storing large data sets in a small number of large arrays as opposed to a large number of small arrays, as the former configuration requires fewer array headers.

Structure and Cell Arrays. For structures and cell arrays, MATLAB creates a header not only for each array, but also for each field of the structure and for each cell of a cell array. Because of this, the amount of memory required to store a structure or cell array depends not only on how much data it holds, but also how it is constructed.

For example, a scalar structure array `S1` having fields `R`, `G`, and `B`, each field of size 100-by-50, requires one array header to describe the overall structure, and one header to describe each of the three field arrays, making a total of 4 array headers for the entire data structure:

```
S1.R(1:100,1:50)
S1.G(1:100,1:50)
S1.B(1:100,1:50)
```

On the other hand, a 100-by-50 structure array `S2` in which each element has scalar fields `R`, `G`, and `B` requires one array header to describe the overall structure, and one array header per field for each of the 5,000 elements of the structure, making a total of 15,001 array headers for the entire data structure:

```
S2(1:100,1:50).R
S2(1:100,1:50).G
S2(1:100,1:50).B
```

Thus, even though `S1` and `S2` contain the same amount of data, S1 uses significantly less space in memory. Not only is less memory required, but there is a corresponding speed benefit to using the `S1` format as well.

Memory Usage Reported By the whos Function. The `whos` function displays the amount of memory consumed by any variable. For reasons of simplicity, `whos` reports only the memory used to store the actual data. It does not report storage for the variable itself or the array header.

Function Arguments

MATLAB handles arguments passed in function calls in a similar way. When you pass a variable to a function, you are actually passing a pointer to the data that the variable represents. As long as the input data is not modified by the function being called, the variable in the calling function and the variable in the called function point to the same location in memory. If the called function modifies the value of the input data, then MATLAB makes a copy of the original array in a new location in memory, updates that copy with the modified value, and points the input variable in the called function to this new array.

In the example below, function `myfun` modifies the value of the array passed into it. MATLAB makes a copy in memory of the array pointed to by `A`, sets variable `X` as a pointer to this new array, and then sets one row of `X` to zero. The array referenced by `A` remains unchanged:

```
A = magic(500);
myfun(A);

function myfun(X)
X(400,:) = 0;
```

If the calling function needs the modified value of the array it passed to `myfun`, you will need to return the updated array as an output of the called function, as shown here for variable `A`:

```
A = magic(500);
A = myfun(A);
sprintf('The new value of A is %d', A)

function Y = myfun(X)
X(400,:) = 0;
Y = X;
```

Working with Large Data Sets. Again, when working with large data sets, you should be aware that MATLAB makes a temporary copy of `A` if the called function modifies its value. This temporarily doubles the memory required to store the array, which causes MATLAB to generate an error if sufficient memory is not available.

One way to avoid running out of memory in this situation is to use nested functions. A nested function shares the workspace of all outer functions, giving the nested function access to data outside of its usual scope. In the example shown here, nested function `setrowval` has direct access to the workspace of the outer function `myfun`, making it unnecessary to pass a copy of the variable in the function call. When `setrowval` modifies the value of `A`, it modifies it in the workspace of the calling function. There is no need to use additional memory to hold a separate array for the function being called, and there also is no need to return the modified value of `A`:

```
function myfun
A = magic(500);

   function setrowval(row, value)
   A(row,:) = value;
   end

setrowval(400, 0);
disp('The new value of A(399:401,1:10) is')
A(399:401,1:10)
end
```

Data Structures and Memory

Memory requirements differ for the various types of MATLAB data structures. You may be able to reduce the amount of memory used for these structures by considering how MATLAB stores them.

Numeric Arrays

MATLAB requires 1, 2, 4, or 8 bytes to store 8-bit, 16-bit, 32-bit, and 64-bit signed and unsigned integers respectively. For floating-point numbers, MATLAB uses 4 or 8 bytes for `single` and `double` types. To conserve memory, The MathWorks recommends that you use the smallest integer or floating-point type that will contain your data without overflowing. For more

information, see "Numeric Types" in the MATLAB Programming section on Data Types.

Complex Arrays

MATLAB stores complex data as separate real and imaginary parts. If you make a copy of a complex array variable, and then modify only the real or imaginary part of the array, MATLAB creates a new array containing both real and imaginary parts.

Sparse Matrices

It is best to store matrices with values that are mostly zero in sparse format. Sparse matrices can use less memory and may also be faster to manipulate than full matrices. You can convert a full matrix to sparse format using the `sparse` function.

Compare two 1000-by-1000 matrices: `X`, a matrix of doubles with 2/3 of its elements equal to zero; and `Y`, a sparse copy of `X`. As shown below, approximately half as much memory is required for the sparse matrix:

```
whos
  Name      Size                    Bytes  Class

  X      1000x1000                8000000  double array
  Y      1000x1000                4004000  double array (sparse)
```

Memory Management Functions

The following functions can help you to manage memory use in MATLAB:

- `whos` shows how much memory has been allocated for variables in the workspace.
- `pack` saves existing variables to disk, and then reloads them contiguously. This reduces the chances of running into problems due to memory fragmentation.

  See "Compressing Data in Memory" on page 11-28.
- `clear` removes variables from memory. One way to increase the amount of available memory is to periodically clear variables from memory that you no longer need.

  If you use `pack` and there is still not enough free memory to proceed, you probably need to remove some of the variables you are no longer using from memory. Use `clear` to do this.
- `save` selectively stores variables to the disk. This is a useful technique when you are working with large amounts of data. Save data to the disk periodically, and then use the `clear` function to remove the saved data from memory.
- `load` reloads a data file saved with the `save` function.
- `quit` exits MATLAB and returns all allocated memory to the system. This can be useful on UNIX systems as UNIX does not free up memory allocated to an application (e.g., MATLAB) until the application exits.

You can use the `save` and `load` functions in conjunction with the `quit` command to free memory by:

1. Saving any needed variables with the `save` function.
2. Quitting MATLAB to free all memory allocated to MATLAB.
3. Starting a new MATLAB session and loading the saved variables back into the clean MATLAB workspace.

Strategies for Efficient Use of Memory

In this section...

To conserve memory when creating variables,

- Avoid creating large temporary variables, and clear temporary variables when they are no longer needed.
- When working with arrays of fixed size, preallocate them rather than having MATLAB resize the array each time you enlarge it.
- Allocate your larger matrices first, as explained in .
- Set variables equal to the empty matrix `[]` to free memory, or clear the variables using the `clear` function.
- Reuse variables as much as possible, but keeping in mind the guidelines stated in “Assigning to Variables” on page 11-10.

Preallocating Arrays to Reduce Fragmentation

In the course of a MATLAB session, memory can become fragmented due to dynamic memory allocation and deallocation. `for` and `while` loops that incrementally increase, or *grow*, the size of a data structure each time through the loop can add to this fragmentation as they have to repeatedly find and allocate larger blocks of memory to store the data.

To make more efficient use of your memory, preallocate a block of memory large enough to hold the matrix at its final size before entering the loop. When you preallocate memory for a potentially large array, MATLAB “grabs” sufficient contiguous space for the data at the beginning of the computation. Once you have this space, you can add elements to the array without having to continually allocate new space for it in memory.

For more information on preallocation, see “Preallocating Arrays” on page 11-7.

Allocating Large Matrices Earlier

MATLAB uses a heap method of memory management. It requests memory from the operating system when there is not enough memory available in the MATLAB heap to store the current variables. It reuses memory as long as the size of the memory segment required is available in the MATLAB heap.

For example, on one machine these statements use approximately 15.4 MB of RAM:

```
a = rand(1e6,1);
b = rand(1e6,1);
```

This statement uses approximately 16.4 MB of RAM:

```
c = rand(2.1e6,1);
```

The following statements can use approximately 32.4 MB of RAM. This is because MATLAB may not be able to reuse the space previously occupied by two 1MB arrays when allocating space for a 2.1 MB array:

```
a = rand(1e6,1);
b = rand(1e6,1);
clear
c = rand(2.1e6,1);
```

The simplest way to prevent overallocation of memory is to allocate the largest vectors first. These statements use only about 16.4 MB of RAM:

```
c = rand(2.1e6,1);
clear
a = rand(1e6,1);
b = rand(1e6,1);
```

Working with Large Amounts of Data

If your program generates very large amounts of data, consider writing the data to disk periodically. After saving that portion of the data, use the `clear` function to remove the variable from memory and continue with the data generation.

Resolving "Out of Memory" Errors

In this section...

For more information on this topic, search for "Avoiding Out of Memory Errors" on The MathWorks online "Support" page.

General Suggestions for Reclaiming Memory

MATLAB generates an `Out of Memory` message whenever it requests a segment of memory from the operating system that is larger than what is currently available. When you see the `Out of Memory` message, use any of the techniques discussed under "Memory Allocation in MATLAB" on page 11-18 to help optimize the available memory. If the `Out of Memory` message still appears, you can try any of the following:

- Compress data to reduce memory fragmentation
- If possible, break large matrices into several smaller matrices so that less memory is used at any one time.
- If possible, reduce the size of your data.
- Make sure that there are no external constraints on the memory accessible to MATLAB. (On UNIX systems, use the `limit` command to check).
- Increase the size of the swap file. We recommend that your machine be configured with twice as much swap space as you have RAM. See "Increasing System Swap Space" on page 11-28, below.
- Add more memory to the system.

On machines running Windows 2000 Advanced Server or Windows 2000 Datacenter Server, the amount of virtual memory space reserved by the

operating system can be reduced by using the /3GB switch in the `boot.ini` file. More documentation on this option can be found at the following URL:

`http://support.microsoft.com/support/kb/articles/Q291/9/88.ASP`

Similarly, on machines running Windows Vista, you can achieve the same effect by using the command:

```
BCDEdit /set increaseuserva 3072
```

More documentation on this option can be found at the following URL:

`http://msdn2.microsoft.com/en-us/library/aa906211.aspx`

Compressing Data in Memory

Since MATLAB uses a heap method of memory management, extended MATLAB sessions may cause memory to become fragmented. When memory is fragmented, there may be plenty of free space, but not enough contiguous memory to store a new large variable. If you get the `Out of Memory` message from MATLAB, the `pack` function may be able to compress some of your data in memory, thus freeing up larger contiguous blocks.

Note Because of time considerations, you should not use `pack` within loops or M-file functions.

Increasing System Swap Space

How you set the swap space for your computer depends on what operating system you are running on.

UNIX

Information about swap space can be procured by typing `pstat -s` at the UNIX command prompt. For detailed information on changing swap space, ask your system administrator.

Linux

Swap space can be changed by using the `mkswap` and `swapon` commands. For more information on the above commands, type `man` followed by the command name at the Linux prompt.

Windows 2000

Follow the steps shown here:

1. Right-click the **My Computer** icon, and select **Properties**.
2. Select the **Advanced** tab and click the **Performance Options** button.
3. Click the **Change** button to change the amount of virtual memory.

Windows XP

Follow the steps shown here:

1. Right-click the **My Computer** icon, and select **Properties**.
2. In the **System Properties** GUI, select the **Advanced** tab. In the section labeled **Performance**, click the **Settings** button.
3. In the **Performance Options** GUI, click **Advanced**. In the section labeled **Virtual Memory**, click the **Change** button
4. In the **Virtual Memory** GUI, under **Paging file size for selected drive**, you can change the amount of virtual memory.

Freeing Up System Resources on Windows Systems

There are no functions implemented to manipulate the way MATLAB handles Microsoft Windows system resources. Windows uses system resources to track fonts, windows, and screen objects. Resources can be depleted by using multiple figure windows, multiple fonts, or several UI controls. One way to free up system resources is to close all inactive windows. Windows icons still use resources.

Reloading Variables on UNIX Systems

On UNIX systems, MATLAB does not return memory to the operating system even after variables have been cleared. This is due to the manner in which UNIX manages memory. UNIX does not accept memory back from a program until the program has terminated. So, the amount of memory used in a MATLAB session is not returned to the operating system until you exit MATLAB.

To free up the memory used in your MATLAB session, save your workspace variables, exit MATLAB, and then load your variables back in.

12

Programming Tips

Introduction

This section is a categorized compilation of tips for the MATLAB® programmer. Each item is relatively brief to help you browse through them and find information that is useful. Many of the tips include a reference to specific MATLAB documentation that gives you more complete coverage of the topic. You can find information on the following topics:

For suggestions on how to improve the performance of your MATLAB programs, and how to write programs that use memory more efficiently, see Chapter 11, “Improving Performance and Memory Usage”

Command and Function Syntax

In this section...

Syntax Help

For help about the general syntax of MATLAB functions and commands, type

```
help syntax
```

Command and Function Syntaxes

You can enter MATLAB commands using either a *command* or *function* syntax. It is important to learn the restrictions and interpretation rules for both.

```
functionname arg1 arg2 arg3               % Command syntax
functionname('arg1','arg2','arg3')        % Function syntax
```

For more information: See “Calling Functions” on page 4-52in the MATLAB Programming documentation.

Command Line Continuation

You can continue most statements to one or more additional lines by terminating each incomplete line with an ellipsis (`...`). Breaking down a statement into a number of lines can sometimes result in a clearer programming style.

```
sprintf ('Example %d shows a command coded on %d lines.\n', ...
          exampleNumber, ...
```

```
            numberOfLines)
```

Note that you cannot continue an incomplete string to another line.

```
disp 'This statement attempts to continue a string ...
      to another line, resulting in an error.'
```

For more information: See Entering Long Lines in the MATLAB Desktop Tools and Development Environment documentation.

Completing Commands Using the Tab Key

You can save some typing when entering commands by entering only the first few letters of the command, variable, property, etc. followed by the **Tab** key. Typing the second line below (with **T** representing **Tab**) yields the expanded, full command shown in the third line:

```
f = figure;
set(f, 'papTuT,'cT)                    % Type this line.
set(f, 'paperunits','centimeters')     % This is what you get.
```

If there are too many matches for the string you are trying to complete, you will get no response from the first **Tab**. Press **Tab** again to see all possible choices:

```
set(f, 'paTT
PaperOrientation   PaperPositionMode  PaperType     Parent
PaperPosition      PaperSize          PaperUnits
```

For more information: See Tab Completion in the MATLAB Desktop Tools and Development Environment documentation

Recalling Commands

Use any of the following methods to simplify recalling previous commands to the screen:

- To recall an earlier command to the screen, press the up arrow key one or more times, until you see the command you want. If you want to modify the recalled command, you can edit its text before pressing **Enter** or **Return** to execute it.

- To recall a specific command by name without having to scroll through your earlier commands one by one, type the starting letters of the command, followed by the up arrow key.
- Open the Command History window (**View > Command History**) to see all previous commands. Double-click the command you want to execute.

For more information: See Recalling Previous Lines and Command History in the MATLAB Desktop Tools and Development Environment documentation.

Clearing Commands

If you have typed a command that you then decide not to execute, you can clear it from the Command Window by pressing the Escape (**Esc**) key.

Suppressing Output to the Screen

To suppress output to the screen, end statements with a semicolon. This can be particularly useful when generating large matrices.

```
A = magic(100);     % Create matrix A, but do not display it.
```

Help

In this section...

Using the Help Browser

Open the Help browser from the MATLAB Command Window using one of the following:

- Click the question mark symbol in the toolbar.
- Select **Help > Product Help** from the menu.
- Type the word `doc` at the command prompt.

Some of the features of the Help browser are listed below.

Feature	Description
Product Filter	Establish which products to find help on.
Contents	Look up topics in the Table of Contents.
Index	Look up help using the documentation Index.
Search	Search the documentation for one or more words.
Demos	See what demos are available; run selected demos.
Favorites	Save bookmarks for frequently used Help pages.

For more information: See Finding Information with the Help Browser in the MATLAB Desktop Tools and Development Environment documentation.

Help on Functions from the Help Browser

To find help on any function from the Help browser, do either of the following:

- Select the **Contents** tab of the Help browser, open the **Contents** entry labeled `MATLAB`, and find the two subentries shown below. Use one of these to look up the function you want help on.
  - Functions — Categorical List
  - Functions — Alphabetical List
- Type `doc functionname` at the command line.

Help on Functions from the Command Window

Several types of help on functions are available from the Command Window:

- To list all categories that you can request help on from the Command Window, just type

  ```
  help
  ```

- To see a list of functions for one of these categories, along with a brief description of each function, type `help` *`category`*. For example,

  ```
  help datafun
  ```

- To get help on a particular function, type `help functionname`. For example,

  ```
  help sortrows
  ```

Topical Help

In addition to the help on individual functions, you can get help on any of the following topics by typing `help topicname` at the command line.

Topic Name	Description
`arith`	Arithmetic operators
`relop`	Relational and logical operators
`punct`	Special character operators
`slash`	Arithmetic division operators
`paren`	Parentheses, braces, and bracket operators
`precedence`	Operator precedence
`datatypes`	MATLAB data types, their associated functions, and operators that you can overload
`lists`	Comma separated lists
`strings`	Character strings
`function_handle`	Function handles and the `@` operator
`debug`	Debugging functions
`java`	Using Java from within MATLAB
`fileformats`	A list of readable file formats
`changeNotification`	Windows directory change notification

Paged Output

Before displaying a lengthy section of help text or code, put MATLAB into its paged output mode by typing `more on`. This breaks up any ensuing display into pages for easier viewing. Turn off paged output with `more off`.

Page through the displayed text using the space bar key. Or step through line by line using **Enter** or **Return**. Discontinue the display by pressing the **Q** key or **Ctrl+C**.

Writing Your Own Help

Start each program you write with a section of text providing help on how and when to use the function. If formatted properly, the MATLAB `help` function displays this text when you enter

```
help functionname
```

MATLAB considers the first group of consecutive lines immediately following the function definition line that begin with `%` to be the help section for the function. The first line without `%` as the left-most character ends the help.

For more information: See Help Text in the MATLAB Desktop Tools and Development Environment documentation.

Help for Subfunctions and Private Functions

You can write help for subfunctions using the same rules that apply to main functions. To display the help for the subfunction `mysubfun` in file `myfun.m`, type

```
help myfun>mysubfun
```

To display the help for a private function, precede the function name with `private/`. To get help on private function `myprivfun`, type

```
help private/myprivfun
```

Help for Methods and Overloaded Functions

You can write help text for object-oriented class methods implemented with M-files. Display help for the method by typing

```
help classname/methodname
```

where the file `methodname.m` resides in subdirectory `@classname`.

For example, if you write a `plot` method for a class named `polynom`, (where the `plot` method is defined in the file `@polynom/plot.m`), you can display this help by typing

```
help polynom/plot
```

You can get help on overloaded MATLAB functions in the same way. To display the help text for the `eq` function as implemented in `matlab/iofun/@serial`, type

```
help serial/eq
```

Development Environment

In this section...

Workspace Browser

The Workspace browser is a graphical interface to the variables stored in the MATLAB base and function workspaces. You can view, modify, save, load, and create graphics from workspace data using the browser. Select **View > Workspace** to open the browser.

To view function workspaces, you need to be in debug mode.

For more information: See MATLAB Workspace in the MATLAB Desktop Tools and Development Environment documentation.

Using the Find and Replace Utility

Find any word or phrase in a group of files using the Find and Replace utility. Click **View > Current Directory**, and then click the binoculars icon at the top of the **Current Directory** window.

When entering search text, you do not need to put quotes around a phrase. In fact, parts of words, like `win` for `windows`, will not be found if enclosed in quotes.

For more information: See Finding and Replacing a String in the MATLAB Desktop Tools and Development Environment documentation.

Commenting Out a Block of Code

To comment out a block of text or code within the MATLAB editor,

1. Highlight the block of text you would like to comment out.
2. Holding the mouse over the highlighted text, select **Text > Comment** (or **Uncomment**, to do the reverse) from the toolbar. (You can also get these options by right-clicking the mouse.)

For more information: See Commenting in the MATLAB Desktop Tools and Development Environment documentation.

Creating M-Files from Command History

If there is part of your current MATLAB session that you would like to put into an M-file, this is easily done using the Command History window:

1. Open this window by selecting **View > Command History**.
2. Use **Shift+Click** or **Ctrl+Click** to select the lines you want to use. MATLAB highlights the selected lines.
3. Right-click once, and select **Create M-File** from the menu that appears. MATLAB creates a new Editor window displaying the selected code.

Editing M-Files in EMACS

If you use Emacs, you can download editing modes for editing M-files with GNU-Emacs or with early versions of Emacs from the MATLAB Central Web site:

```
http://www.mathworks.com/matlabcentral/
```

At this Web site, select **File Exchange**, and then **Utilities > Emacs**.

For more information: See General Preferences for the Editor/Debugger in the MATLAB Desktop Tools and Development Environment documentation.

M-File Functions

In this section...

M-File Structure

An M-File consists of the components shown here:

```
function [x, y] = myfun(a, b, c)   % Function definition line
% H1 line -- A one-line summary of the function's purpose.
% Help text -- One or more lines of help text that explain
%   how to use the function. This text is displayed when
%   the user types "help functionname".

% The Function body normally starts after the first blank line.
% Comments -- Description (for internal use) of what the
%   function does, what inputs are expected, what outputs
%   are generated. Typing "help functionname" does not display
%   this text.

x = prod(a, b);                    % Start of Function code
```

For more information: See “Basic Parts of an M-File” on page 4-8 in the MATLAB Programming documentation.

Using Lowercase for Function Names

Function names appear in uppercase in MATLAB help text only to make the help easier to read. In practice, however, it is usually best to use lowercase when calling functions.

For M-file functions, case requirements depend on the case sensitivity of the operating system you are using. As a rule, naming and calling functions using lowercase generally makes your M-files more portable from one operating system to another.

Getting a Function's Name and Path

To obtain the name of an M-file that is currently being executed, use the following function in your M-file code.

```
mfilename
```

To include the path along with the M-file name, use

```
mfilename('fullpath')
```

For more information: See the `mfilename` function reference page.

What M-Files Does a Function Use?

For a simple display of all M-files referenced by a particular function, follow the steps below:

1. Type `clear functions` to clear all functions from memory (see Note below).
2. Execute the function you want to check. Note that the function arguments you choose to use in this step are important, since you can get different results when calling the same function with different arguments.
3. Type `inmem` to display all M-Files that were used when the function ran. If you want to see what MEX-files were used as well, specify an additional output, as shown here:

   ```
   [mfiles, mexfiles] = inmem
   ```

Note `clear functions` does not clear functions locked by `mlock`. If you have locked functions, (which you can check using `inmem`), unlock them with `munlock`, and then repeat step 1.

Dependent Functions, Built-Ins, Classes

For a much more detailed display of dependent function information, use the `depfun` function. In addition to M-files, `depfun` shows which built-ins and classes a particular function depends on.

Function Arguments

In this section...

Getting the Input and Output Arguments

Use `nargin` and `nargout` to determine the number of input and output arguments in a particular function call. Use `nargchk` and `nargoutchk` to verify that your function is called with the required number of input and output arguments.

```
function [x, y] = myplot(a, b, c, d)
disp(nargchk(2, 4, nargin))           % Allow 2 to 4 inputs
disp(nargoutchk(0, 2, nargout))       % Allow 0 to 2 outputs

x = plot(a, b);
if nargin == 4
   y = myfun(c, d);
end
```

Variable Numbers of Arguments

You can call functions with fewer input and output arguments than you have specified in the function definition, but not more. If you want to call a function with a variable number of arguments, use the `varargin` and `varargout` function parameters in the function definition.

This function returns the size vector and, optionally, individual dimensions:

```
function [s, varargout] = mysize(x)
nout = max(nargout, 1) - 1;
s = size(x);
for k = 1:nout
```

```
    varargout(k) = {s(k)};
end
```

Try calling it with

```
[s, rows, cols] = mysize(rand(4, 5))
```

String or Numeric Arguments

If you are passing only string arguments into a function, you can use MATLAB command syntax. All arguments entered in command syntax are interpreted as strings.

```
strcmp string1 string1
ans =
     1
```

When passing numeric arguments, it is best to use function syntax unless you want the number passed as a string. The right-hand example below passes the number `75` as the string, `'75'`.

```
isnumeric(75)
ans =
    1
```

```
isnumeric 75
ans =
    0
```

For more information: See “Passing Arguments with Command and Function Syntax” on page 4-57 in the MATLAB Programming documentation.

Passing Arguments in a Structure

Instead of requiring an additional argument for every value you want to pass in a function call, you can package them in a MATLAB structure and pass the structure. Make each input you want to pass a separate field in the structure argument, using descriptive names for the fields.

Structures allow you to change the number, contents, or order of the arguments without having to modify the function. They can also be useful when you have a number of functions that need similar information.

Passing Arguments in a Cell Array

You can also group arguments into cell arrays. The disadvantage over structures is that you do not have field names to describe each variable. The advantage is that cell arrays are referenced by index, allowing you to loop through a cell array and access each argument passed in or out of the function.

Program Development

In this section...

Planning the Program

When planning how to write a program, take the problem you are trying to solve and break it down into a series of smaller, independent tasks. Implement each task as a separate function. Try to keep functions fairly short, each having a single purpose.

Using Pseudo-Code

You may find it helpful to write the initial draft of your program in a structured format using your own natural language. This *pseudo-code* is often easier to think through, review, and modify than using a formal programming language, yet it is easily translated into a programming language in the next stage of development.

Selecting the Right Data Structures

Look at what data types and data structures are available to you in MATLAB and determine which of those best fit your needs in storing and passing your data.

For more information: See Data Types in the MATLAB Programming documentation.

General Coding Practices

A few suggested programming practices:

- Use descriptive function and variable names to make your code easier to understand.
- Order subfunctions alphabetically in an M-file to make them easier to find.
- Precede each subfunction with a block of help text describing what that subfunction does. This not only explains the subfunctions, but also helps to visually separate them.
- Do not extend lines of code beyond the 80th column. Otherwise, it will be hard to read when you print it out.
- Use full Handle Graphics® property and value names. Abbreviated names are often allowed, but can make your code unreadable. They also could be incompatible in future releases of MATLAB.

Naming a Function Uniquely

To avoid choosing a name for a new function that might conflict with a name already in use, check for any occurrences of the name using this command:

```
which -all functionname
```

For more information: See the `which` function reference page.

The Importance of Comments

Be sure to document your programs well to make it easier for you or someone else to maintain them. Add comments generously, explaining each major section and any smaller segments of code that are not obvious. You can add a block of comments as shown here.

```
%-----------------------------------------
% This function computes the ... <and so on>
%-----------------------------------------
```

For more information: See Comments in the MATLAB Programming documentation.

Coding in Steps

Do not try to write the entire program all at once. Write a portion of it, and then test that piece out. When you have that part working the way you want, then write the next piece, and so on. It's much easier to find programming errors in a small piece of code than in a large program.

Making Modifications in Steps

When making modifications to a working program, do not make widespread changes all at one time. It's better to make a few small changes, test and debug, make a few more changes, and so on. Tracking down a difficult bug in the small section that you've changed is much easier than trying to find it in a huge block of new code.

Functions with One Calling Function

If you have a function that is called by only one other function, put it in the same M-file as the calling function, making it a subfunction.

For more information: See Subfunctions in the MATLAB Programming documentation.

Testing the Final Program

One suggested practice for testing a new program is to step through the program in the MATLAB debugger while keeping a record of each line that gets executed on a printed copy of the program. Use different combinations of inputs until you have observed that every line of code is executed at least once.

Debugging

In this section...

The MATLAB Debug Functions

For a brief description of the main debug functions in MATLAB, type

```
help debug
```

For more information: See Debugging M-Files in the MATLAB Desktop Tools and Development Environment documentation.

More Debug Functions

Other functions you may find useful in debugging are listed below.

Function	Description
`echo`	Display function or script code as it executes.
`disp`	Display specified values or messages.
`sprintf`, `fprintf`	Display formatted data of different types.

Function	Description
`whos`	List variables in the workspace.
`size`	Show array dimensions.
`keyboard`	Interrupt program execution and allow input from keyboard.
`return`	Resume execution following a keyboard interruption.
`warning`	Display specified warning message.
`error`	Display specified error message.
`lasterr`	Return error message that was last issued.
`lasterror`	Return last error message and related information.
`lastwarn`	Return warning message that was last issued.

The MATLAB Graphical Debugger

Learn to use the MATLAB graphical debugger. You can view the function and its calling functions as you debug, set and clear breakpoints, single-step through the program, step into or over called functions, control visibility into all workspaces, and find and replace strings in your files.

Start out by opening the file you want to debug using **File > Open** or the `open` function. Use the debugging functions available on the toolbar and pull-down menus to set breakpoints, run or step through the program, and examine variables.

For more information: See Debugging M-Files and Using Debugging Features in the MATLAB Desktop Tools and Development Environment documentation.

A Quick Way to Examine Variables

To see the value of a variable from the Editor/Debugger window, hold the mouse cursor over the variable name for a second or two. You will see the value of the selected variable displayed.

Setting Breakpoints from the Command Line

You can set breakpoints with `dbstop` in any of the following ways:

- Break at a specific M-file line number.
- Break at the beginning of a specific subfunction.
- Break at the first executable line in an M-file.
- Break when a warning, or error, is generated.
- Break if any infinite or `NaN` values are encountered.

For more information: See Setting Breakpoints in the MATLAB Desktop Tools and Development Environment documentation.

Finding Line Numbers to Set Breakpoints

When debugging from the command line, a quick way to find line numbers for setting breakpoints is to use `dbtype`. The `dbtype` function displays all or part of an M-file, also numbering each line. To display delaunay`.m`, use

```
dbtype delaunay
```

To display only lines 35 through 41, use

```
dbtype delaunay 35:41
```

Stopping Execution on an Error or Warning

Use `dbstop if error` to stop program execution on any error and enter debug mode. Use `warning debug` to stop execution on any warning and enter debug mode.

For more information: See Debug, Backtrace, and Verbose Modes in the MATLAB Programming documentation.

Locating an Error from the Error Message

Click on the underlined text in an error message, and MATLAB opens the M-file being executed in its editor and places the cursor at the point of error.

For more information: See Types of Errors in the MATLAB Desktop Tools and Development Environment documentation.

Using Warnings to Help Debug

You can detect erroneous or unexpected behavior in your programs by inserting warning messages that MATLAB will display under the conditions you specify. See the section on "Warning Control" on page 8-24 in the MATLAB Programming documentation to find out how to selectively enable warnings.

For more information: See the `warning` function reference page.

Making Code Execution Visible

An easy way to see the end result of a particular line of code is to edit the program and temporarily remove the terminating semicolon from that line. Then, run your program and the evaluation of that statement is displayed on the screen.

For more information: See Finding Errors in the MATLAB Desktop Tools and Development Environment documentation.

Debugging Scripts

Scripts store their variables in a workspace that is shared with the caller of the script. So, when you debug a script from the command line, the script uses variables from the base workspace. To avoid errors caused by workspace sharing, type `clear all` before starting to debug your script to clear the base workspace.

Variables

In this section...

Rules for Variable Names

Although variable names can be of any length, MATLAB uses only the first N characters of the name, (where N is the number returned by the function `namelengthmax`), and ignores the rest. Hence, it is important to make each variable name unique in the first N characters to enable MATLAB to distinguish variables. Also note that variable names are case sensitive.

```
N = namelengthmax
N =
     63
```

For more information: See "Naming Variables" on page 3-6 in the MATLAB Programming documentation.

Making Sure Variable Names Are Valid

Before using a new variable name, you can check to see if it is valid with the `isvarname` function. Note that `isvarname` does not consider names longer than `namelengthmax` characters to be valid.

For example, the following name cannot be used for a variable since it begins with a number.

```
isvarname 8thColumn
ans =
     0
```

For more information: See “Naming Variables” on page 3-6 in the MATLAB Programming documentation.

Do Not Use Function Names for Variables

When naming a variable, make sure you are not using a name that is already used as a function name. If you do define a variable with a function name, you will not be able to call that function until you `clear` the variable from memory. (If it’s a MATLAB built-in function, then you will still be able to call that function but you must do so using `builtin`.)

To test whether a proposed variable name is already used as a function name, use

```
which -all name
```

For more information: See “Potential Conflict with Function Names” on page 3-7 in the MATLAB Programming documentation.

Checking for Reserved Keywords

MATLAB reserves certain keywords for its own use and does not allow you to override them. Attempts to use these words may result in any one of a number of error messages, some of which are shown here:

```
Error: Expected a variable, function, or constant, found "=".
Error: "End of Input" expected, "case" found.
Error: Missing operator, comma, or semicolon.
Error: "identifier" expected, "=" found.
```

Use the `iskeyword` function with no input arguments to list all reserved words.

Avoid Using i and j for Variables

MATLAB uses the characters `i` and `j` to represent imaginary units. Avoid using `i` and `j` for variable names if you intend to use them in complex arithmetic.

If you want to create a complex number without using `i` and `j`, you can use the `complex` function.

Avoid Overwriting Variables in Scripts

MATLAB scripts store their variables in a workspace that is shared with the caller of the script. When called from the command line, they share the base workspace. When called from a function, they share that function's workspace. If you run a script that alters a variable that already exists in the caller's workspace, that variable is overwritten by the script.

For more information: See "M-File Scripts" on page 4-17 in the MATLAB Programming documentation.

Persistent Variables

To get the equivalent of a static variable in MATLAB, use `persistent`. When you declare a variable to be `persistent` within a function, its value is retained in memory between calls to that function. Unlike `global` variables, `persistent` variables are known only to the function in which they are declared.

For more information: See "Persistent Variables" on page 3-5 in the MATLAB Programming documentation.

Protecting Persistent Variables

You can inadvertently clear `persistent` variables from memory by either modifying the function in which the variables are defined, or by clearing the function with one of the following commands:

```
clear all
clear functions
```

Locking the M-file in memory with `mlock` prevents any `persistent` variables defined in the file from being reinitialized.

Global Variables

Use global variables sparingly. The global workspace is shared by all of your functions and also by your interactive MATLAB session. The more global variables you use, the greater the chances of unintentionally reusing a variable name, thus leaving yourself open to having those variables change in value unexpectedly. This can be a difficult bug to track down.

For more information: See "Global Variables" on page 3-3 in the MATLAB Programming documentation.

Strings

In this section...

Creating Strings with Concatenation

Strings are often created by concatenating smaller elements together (e.g., strings, values, etc.). Two common methods of concatenating are to use the MATLAB concatenation operator (`[]`) or the `sprintf` function. The second and third line below illustrate both of these methods. Both lines give the same result:

```
numChars = 28;
s = ['There are ' int2str(numChars) ' characters here']
s = sprintf('There are %d characters here\n', numChars)
```

For more information: See “Creating Character Arrays” on page 2-37 and “Converting from Numeric to String” on page 2-59 in the MATLAB Programming documentation.

Comparing Methods of Concatenation

When building strings with concatenation, `sprintf` is often preferable to `[]` because

- It is easier to read, especially when forming complicated expressions
- It gives you more control over the output format
- It often executes more quickly

You can also concatenate using the `strcat` function, However, for simple concatenations, `sprintf` and `[]` are faster.

Store Arrays of Strings in a Cell Array

It is usually best to store an array of strings in a cell array instead of a character array, especially if the strings are of different lengths. Strings in a character array must be of equal length, which often requires padding the strings with blanks. This is not necessary when using a cell array of strings that has no such requirement.

The `cellRecord` below does not require padding the strings with spaces:

```
cellRecord = {'Allison Jones'; 'Development'; 'Phoenix'};
```

For more information: See "Cell Arrays of Strings" on page 2-39 in the MATLAB Programming documentation.

Converting Between Strings and Cell Arrays

You can convert between standard character arrays and cell arrays of strings using the `cellstr` and `char` functions:

```
charRecord = ['Allison Jones'; 'Development  '; ...
              'Phoenix      '];
cellRecord = cellstr(charRecord);
```

Also, a number of the MATLAB string operations can be used with either character arrays, or cell arrays, or both:

```
cellRecord2 = {'Brian Lewis'; 'Development'; 'Albuquerque'};
strcmp(charRecord, cellRecord2)
ans =
     0
     1
     0
```

For more information: See "Converting to a Cell Array of Strings" on page 2-40 and "String Comparisons" on page 2-55 in the MATLAB Programming documentation.

Search and Replace Using Regular Expressions

Using regular expressions in MATLAB offers a very versatile way of searching for and replacing characters or phrases within a string. See the help on these functions for more information.

Function	Description
`regexp`	Match regular expression.
`regexpi`	Match regular expression, ignoring case.
`regexprep`	Replace string using regular expression.

For more information: See “Regular Expressions” on page 3-30 in the MATLAB Programming documentation.

Evaluating Expressions

In this section...

Find Alternatives to Using eval

While the `eval` function can provide a convenient solution to certain programming challenges, it is best to limit its use. The main reason is that code that uses `eval` is often difficult to read and hard to debug. A second reason is that `eval` statements cannot always be translated into C or C++ code by the MATLAB Compiler.

If you are evaluating a function, it is more efficient to use `feval` than `eval`. The `feval` function is made specifically for this purpose and is optimized to provide better performance.

For more information: See MATLAB Technical Note 1103, "What Is the EVAL Function, When Should I Use It, and How Can I Avoid It?" at URL `http://www.mathworks.com/support/tech-notes/1100/1103.html`.

Assigning to a Series of Variables

One common pattern for creating variables is to use a variable name suffixed with a number (e.g., `phase1`, `phase2`, `phase3`, etc.). We recommend using a cell array to build this type of variable name series, as it makes code more readable and executes more quickly than some other methods. For example:

```
for k = 1:800
   phase{k} = expression;
end
```

Short-Circuit Logical Operators

MATLAB has logical `AND` and `OR` operators (`&&` and `||`) that enable you to partially evaluate, or *short-circuit*, logical expressions. Short-circuit operators are useful when you want to evaluate a statement only when certain conditions are satisfied.

In this example, MATLAB does not execute the function `myfun` unless its M-file exists on the current path.

```
comp = (exist('myfun.m') == 2) && (myfun(x) >= y)
```

For more information: See "Short-Circuit Operators" on page 3-24 in the MATLAB Programming documentation.

Changing the Counter Variable within a for Loop

You cannot change the value of the loop counter variable (e.g., the variable `k` in the example below) in the body of a `for` loop. For example, this loop executes just `10` times, even though `k` is set back to `1` on each iteration.

```
for k = 1:10
   fprintf('Pass %d\n', k)
   k = 1;
end
```

Although MATLAB does allow you to use a variable of the same name as the loop counter within a loop, this is not a recommended practice.

MATLAB Path

In this section...

Precedence Rules

When MATLAB is given a name to interpret, it determines its usage by checking the name against each of the entities listed below, and in the order shown:

1. Variable
2. Subfunction
3. Private function
4. Class constructor
5. Overloaded method
6. M-file in the current directory
7. M-file on the path, or MATLAB built-in function

If you have two or more M-files on the path that have the same name, MATLAB selects the function that has its M-file in the directory closest to the beginning of the path string.

For more information: See “Function Precedence Order” on page 9-73 in the MATLAB Programming documentation.

File Precedence

If you refer to a file by its filename only (leaving out the file extension), and there is more than one file of this name in the directory, MATLAB selects the file to use according to the following precedence:

1. MEX-file
2. MDL-file (Simulink® model)
3. P-Code file
4. M-file

For more information: See “Multiple Implementation Types” on page 4-55 in the MATLAB Programming documentation.

Adding a Directory to the Search Path

To add a directory to the search path, use either of the following:

- At the toolbar, select **File > Set Path**.
- At the command line, use the `addpath` function.

You can also add a directory and all of its subdirectories in one operation by either of these means. To do this from the command line, use `genpath` together with `addpath`. The online help for the `genpath` function shows how to do this.

This example adds `/control` and all of its subdirectories to the MATLAB path:

```
addpath(genpath('K:/toolbox/control'))
```

For more information: See Search Path in the MATLAB Desktop Tools and Development Environment documentation.

Handles to Functions Not on the Path

You cannot create function handles to functions that are not on the MATLAB path. But you can achieve essentially the same thing by creating the handles through a script file placed in the same off-path directory as the functions.

If you then run the script, using `run path/script`, you will have created the handles that you need.

For example,

1. Create a script in this off-path directory that constructs function handles and assigns them to variables. That script might look something like this:

```
File E:/testdir/createFhandles.m
   fhset = @setItems
   fhsort = @sortItems
   fhdel = @deleteItem
```

2. Run the script from your current directory to create the function handles:

```
run E:/testdir/createFhandles
```

3. You can now execute one of the functions by means of its handle.

```
fhset(item, value)
```

Making Toolbox File Changes Visible to MATLAB

Unlike functions in user-supplied directories, M-files (and MEX-files) in the *matlabroot*/toolbox directories are not time-stamp checked, so MATLAB does not automatically see changes to them. If you modify one of these files, and then rerun it, you may find that the behavior does not reflect the changes that you made. This is most likely because MATLAB is still using the previously loaded version of the file.

To force MATLAB to reload a function from disk, you need to explicitly clear the function from memory using `clear functionname`. Note that there are rare cases where `clear` will not have the desired effect, (for example, if the file is locked, or if it is a class constructor and objects of the given class exist in memory).

Similarly, MATLAB does not automatically detect the presence of new files in *matlabroot*/toolbox directories. If you add (or remove) files from these directories, use `rehash toolbox` to force MATLAB to see your changes. Note that if you use the MATLAB Editor to create files, these steps are unnecessary, as the Editor automatically informs MATLAB of such changes.

Making Nontoolbox File Changes Visible to MATLAB

For M-files outside of the toolbox directories, MATLAB sees the changes made to these files by comparing timestamps and reloads any file that has changed the next time you execute the corresponding function.

If MATLAB does not see the changes you make to one of these files, try clearing the old copy of the function from memory using `clear` *`functionname`*. You can verify that MATLAB has cleared the function using `inmem` to list all functions currently loaded into memory.

Change Notification on Windows

If MATLAB, running on Windows, is unable to see new files or changes you have made to an existing file, the problem may be related to operating system change notification handles.

Type the following for more information:

```
help changeNotification
help changeNotificationAdvanced
```

Program Control

In this section...

Using break, continue, and return

It's easy to confuse the `break`, `continue`, and `return` functions as they are similar in some ways. Make sure you use these functions appropriately.

Function	Where to Use It	Description
`break`	`for` or `while` loops	Exits the loop in which it appears. In nested loops, control passes to the next outer loop.
`continue`	`for` or `while` loops	Skips any remaining statements in the current loop. Control passes to next iteration of the same loop.
`return`	Anywhere	Immediately exits the function in which it appears. Control passes to the caller of the function.

Using switch Versus if

It is possible, but usually not advantageous, to implement `switch-case` statements using `if-elseif` instead. See pros and cons in the table.

switch-case Statements	if-elseif Statements
Easier to read.	Can be difficult to read.
Can compare strings of different lengths.	You need `strcmp` to compare strings of different lengths.
Test for equality only.	Test for equality or inequality.

MATLAB case Evaluates Strings

A useful difference between `switch-case` statements in MATLAB and C is that you can specify string values in MATLAB `case` statements, which you cannot do in C.

```
switch(method)
   case 'linear'
      disp('Method is linear')
   case 'cubic'
      disp('Method is cubic')
end
```

Multiple Conditions in a case Statement

You can test against more than one condition with `switch`. The first case below tests for either a `linear` or `bilinear` method by using a cell array in the case statement.

```
switch(method)
   case {'linear', 'bilinear'}
      disp('Method is linear or bilinear')
   case (<and so on>)
end
```

Implicit Break in switch-case

In C, if you do not end each `case` with a `break` statement, code execution falls through to the following `case`. In MATLAB, `case` statements do not fall

through; only one `case` may execute. Using `break` within a `case` statement is not only unnecessary, it is also invalid and generates a warning.

In this example, if `result` is `52`, only the first `disp` statement executes, even though the second is also a valid match:

```
switch(result)
   case 52
      disp('result is 52')
   case {52, 78}
      disp('result is 52 or 78')
end
```

Variable Scope in a switch

Since MATLAB executes only one `case` of any `switch` statement, variables defined within one `case` are not known in the other `cases` of that `switch` statement. The same holds true for `if-elseif` statements.

In these examples, you get an error when `choice` equals `2`, because `x` is undefined.

```
  -- SWITCH-CASE --
switch choice
   case 1
      x = -pi:0.01:pi;
   case 2
      plot(x, sin(x));
end
```

```
 -- IF-ELSEIF --

if choice == 1
   x = -pi:0.01:pi;
elseif choice == 2
   plot(x, sin(x));
end
```

Catching Errors with try-catch

When you have statements in your code that could possibly generate unwanted results, put those statements into a `try-catch` block that will catch any errors and handle them appropriately.

The example below shows a `try-catch` block within a function that multiplies two matrices. If a statement in the `try` segment of the block fails, control passes to the `catch` segment. In this case, the `catch` statements check the error message that was issued (returned by `lasterr`) and respond appropriately.

```
try
   X = A * B
catch
   errmsg = lasterr;
   if(strfind(errmsg, 'Inner matrix dimensions'))
      disp('** Wrong dimensions for matrix multiply')
end
```

For more information: See “The try-catch Statement” on page 8-17 in the MATLAB Programming documentation.

Nested try-catch Blocks

You can also nest `try-catch` blocks, as shown here. You can use this to attempt to recover from an error caught in the first `try` section:

```
try
   statement1                    % Try to execute statement1
catch
   try
      statement2                 % Attempt to recover from error
   catch
      disp 'Operation failed'    % Handle the error
   end
end
```

Forcing an Early Return from a Function

To force an early return from a function, place a `return` statement in the function at the point where you want to exit. For example,

```
if <done>
   return
end
```

Save and Load

In this section...

Saving Data from the Workspace

To save data from your workspace, you can do any of the following:

- Copy from the MATLAB Command Window and paste into a text file.
- Record part of your session in a `diary` file, and then edit the file in a text editor.
- Save to a binary or ASCII file using the `save` function.
- Save spreadsheet, scientific, image, or audio data with appropriate function.
- Save to a file using low-level file I/O functions (`fwrite`, `fprintf`, `...`).

For more information: See Saving the Current Workspace in the MATLAB Desktop Tools and Development Environment documentation, "Using the diary Function to Export Data" on page 6-87, and "Using Low-Level File I/O Functions" on page 6-104.

Loading Data into the Workspace

Similarly, to load new or saved data into the workspace, you can do any of the following:

- Enter or paste data at the command line.
- Create a script file to initialize large matrices or data structures.

- Read a binary or ASCII file using `load`.
- Load spreadsheet, scientific, image, or audio data with appropriate function.
- Load from a file using low-level file I/O functions (`fread`, `fscanf`, `...`).

For more information: See Loading a Saved Workspace and Importing Data in the MATLAB Development Environment documentation, and "Using Low-Level File I/O Functions" on page 6-104.

Viewing Variables in a MAT-File

To see what variables are saved in a MAT-file, use `who` or `whos` as shown here (the `.mat` extension is not required). `who` returns a cell array and `whos` returns a structure array.

```
mydataVariables = who('-file', 'mydata.mat');
```

Appending to a MAT-File

To save additional variables to an existing MAT-file, use

```
save matfilename -append
```

Any variables you save that do not yet exist in the MAT-file are added to the file. Any variables you save that already exist in the MAT-file overwrite the old values.

Note Saving with the `-append` switch does not append additional elements to an array that is already saved in a MAT-file. See the example below.

In this example, the second `save` operation does not concatenate new elements to vector `A`, (making `A` equal to `[1 2 3 4 5 6 7 8]`) in the MAT-file. Instead, it replaces the 5 element vector, `A`, with a 3 element vector, also retaining all other variables that were stored on the first `save` operation.

```
A = [1 2 3 4 5];   B = 12.5;   C = rand(4);
save savefile;
A = [6 7 8];
```

```
save savefile A -append;
```

Save and Load on Startup or Quit

You can automatically save your variables at the end of each MATLAB session by creating a `finish.m` file to `save` the contents of your base workspace every time you quit MATLAB. Load these variables back into your workspace at the beginning of each session by creating a `startup.m` file that uses the `load` function to load variables from your MAT-file.

For more information: See the `startup` and `finish` function reference pages.

Saving to an ASCII File

When you save matrix data to an ASCII file using `save -ascii`, MATLAB combines the individual matrices into one collection of numbers. Variable names are not saved. If this is not acceptable for your application, use `fprintf` to store your data instead.

For more information: See “Exporting Delimited ASCII Data Files” on page 6-86.

Files and Filenames

In this section...

Naming M-files

M-file names must start with an alphabetic character, may contain any alphanumeric characters or underscores, and must be no longer than the maximum allowed M-file name length (returned by the function `namelengthmax`).

```
N = namelengthmax
N =
    63
```

Since variables must obey similar rules, you can use the `isvarname` function to check whether a filename (minus its `.m` file extension) is valid for an M-file.

```
isvarname mfilename
```

Naming Other Files

The names of other files that MATLAB interacts with (e.g., MAT, MEX, and MDL-files) follow the same rules as M-files, but may be of any length.

Depending on your operating system, you may be able to include certain nonalphanumeric characters in your filenames. Check your operating system manual for information on valid filename restrictions.

Passing Filenames as Arguments

In MATLAB commands, you can specify a filename argument using the MATLAB command or function syntax. For example, either of the following are acceptable. (The `.mat` file extension is optional for `save` and `load`).

```
load mydata.mat           % Command syntax
load('mydata.mat')        % Function syntax
```

If you assign the output to a variable, you must use the function syntax.

```
savedData = load('mydata.mat')
```

Passing Filenames to ASCII Files

ASCII files are specified as follows. Here, the file extension is required.

```
load mydata.dat -ascii            % Command syntax
load('mydata.dat','-ascii')       % Function syntax
```

Determining Filenames at Run-Time

There are several ways that your function code can work on specific files without you having to hardcode their filenames into the program. You can

- Pass the filename in as an argument

  ```
  function myfun(datafile)
  ```

- Prompt for the filename using the `input` function

  ```
  filename = input('Enter name of file:  ', 's');
  ```

- Browse for the file using the `uigetfile` function

  ```
  [filename, pathname] =
     uigetfile('*.mat', 'Select MAT-file');
  ```

For more information: See the `input` and `uigetfile` function reference pages.

Returning the Size of a File

Two ways to have your program determine the size of a file are shown here.

```
  -- METHOD #1 --
s = dir('myfile.dat');
filesize = s.bytes
```

```
   -- METHOD #2 --
fid = fopen('myfile.dat');
fseek(fid, 0, 'eof');
filesize = ftell(fid)
fclose(fid);
```

The `dir` function also returns the filename (`s.name`), last modification date (`s.date`), and whether or not it's a directory (`s.isdir`).

(The second method requires read access to the file.)

For more information: See the `fopen`, `fseek`, `ftell`, and `fclose` function reference pages.

Input/Output

In this section...

For more information and examples on importing and exporting data, see Technical Note 1602:

http://www.mathworks.com/support/tech-notes/1600/1602.html

File I/O Function Overview

For a good overview of MATLAB file I/O functions, use the online "Functions — Categorical List" reference. In the Help browser **Contents**, select **MATLAB > Functions — Categorical List**, and then click **File I/O**.

Common I/O Functions

The most commonly used, high-level, file I/O functions in MATLAB are `save` and `load`. For help on these, type `doc save` or `doc load`.

Functions for I/O to text files with delimited values are `textread`, `dlmread`, `dlmwrite`. Functions for I/O to text files with comma-separated values are `csvread`, `csvwrite`.

For more information: See Text Files in the MATLAB "Functions — Categorical List" reference documentation.

Readable File Formats

Type `doc fileformats` to see a list of file formats that MATLAB can read, along with the associated MATLAB functions.

Using the Import Wizard

A quick method of importing text or binary data from a file (e.g., Excel files) is to use the MATLAB Import Wizard. Open the Import Wizard with the command, `uiimport filename` or by selecting **File > Import Data** at the Command Window.

Specify or browse for the file containing the data you want to import and you will see a preview of what the file contains. Select the data you want and click **Finish**.

For more information: See "Using the Import Wizard" on page 6-11 in the MATLAB Programming documentation.

Loading Mixed Format Data

To load data that is in mixed formats, use `textread` instead of `load`. The `textread` function lets you specify the format of each piece of data.

If the first line of file `mydata.dat` is

```
Sally    12.34 45
```

Read the first line of the file as a free format file using the % format:

```
[names, x, y] = textread('mydata.dat', '%s %f %d', 1)
```

returns

```
names =
    'Sally'
x =
  12.34000000000000
y =
    45
```

Reading Files with Different Formats

Attempting to read data from a file that was generated on a different platform may result in an error because the binary formats of the platforms may differ. Using the `fopen` function, you can specify a machine format when you open the file to avoid these errors.

Reading ASCII Data into a Cell Array

A common technique used to read an ASCII data file into a cell array is

```
[a,b,c,d] = textread('data.txt', '%s %s %s %s');
mydata = cellstr([a b c d]);
```

For more information: See the `textread` and `cellstr` function reference pages.

Interactive Input into Your Program

Your program can accept interactive input from users during execution. Use the `input` function to prompt the user for input, and then read in a response. When executed, `input` causes the program to display your prompt, pause while a response is entered, and then resume when the **Enter** key is pressed.

Starting MATLAB

Getting MATLAB to Start Up Faster

Here are some things that you can do to make MATLAB start up faster.

- Make sure toolbox path caching is enabled.
- Make sure that the system on which MATLAB is running has enough RAM.
- Choose only the windows you need in the MATLAB desktop.
- Close the Help browser before exiting MATLAB. When you start your next session, MATLAB will not open the Help browser, and thus will start faster.
- If disconnected from the network, check the `LM_LICENSE_FILE` variable. See http://www.mathworks.com/support/solutions/data/1-17VEB.html for a more detailed explanation.

For more information: See Reduced Startup Time with Toolbox Path Caching in the MATLAB Desktop Tools and Development Environment documentation.

Operating System Compatibility

In this section...

Executing O/S Commands from MATLAB

To execute a command from your operating system prompt without having to exit MATLAB, precede the command with the MATLAB `!` operator.

On Windows, you can add an ampersand (`&`) to the end of the line to make the output appear in a separate window.

For more information: See Running External Programs in the MATLAB Desktop Tools and Development Environment documentation, and the `system` and `dos` function reference pages.

Searching Text with grep

`grep` is a powerful tool for performing text searches in files on UNIX systems. To `grep` from within MATLAB, precede the command with an exclamation point (`!grep`).

For example, to search for the word `warning`, ignoring case, in all M-files of the current directory, you would use

```
!grep -i 'warning' *.m
```

Constructing Paths and Filenames

Use the `fullfile` function to construct path names and filenames rather than entering them as strings into your programs. In this way, you always get the correct path specification, regardless of which operating system you are using at the time.

Finding the MATLAB Root Directory

The `matlabroot` function returns the location of the MATLAB installation on your system. Use `matlabroot` to create a path to MATLAB and toolbox directories that does not depend on a specific platform or MATLAB version.

The following example uses `matlabroot` with `fullfile` to return a platform-independent path to the `general` toolbox directory:

```
fullfile(matlabroot,'toolbox','matlab','general')
```

Temporary Directories and Filenames

If you need to locate the directory on your system that has been designated to hold temporary files, use the `tempdir` function. `tempdir` returns a string that specifies the path to this directory.

To create a new file in this directory, use the `tempname` function. `tempname` returns a string that specifies the path to the temporary file directory, plus a unique filename.

For example, to store some data in a temporary file, you might issue the following command first.

```
fid = fopen(tempname, 'w');
```

Demos

Demos Available with MATLAB

MATLAB comes with a wide array of visual demonstrations to help you see the extent of what you can do with the product. To start running any of the demos, simply type `demo` at the MATLAB command prompt. Demos cover the following major areas:

- MATLAB
- Toolboxes
- Simulink
- Blocksets
- Real-Time Workshop®
- Stateflow®

For more information: See Demos in the Help Browser in the MATLAB Desktop Tools and Development Environment documentation, and the `demo` function reference page.

Programming Tips

Introduction

This section is a categorized compilation of tips for the MATLAB® programmer. Each item is relatively brief to help you browse through them and find information that is useful. Many of the tips include a reference to specific MATLAB documentation that gives you more complete coverage of the topic. You can find information on the following topics:

For suggestions on how to improve the performance of your MATLAB programs, and how to write programs that use memory more efficiently, see Improving Performance and Memory Usage

Command and Function Syntax

In this section...

Syntax Help

For help about the general syntax of MATLAB functions and commands, type

```
help syntax
```

Command and Function Syntaxes

You can enter MATLAB commands using either a *command* or *function* syntax. It is important to learn the restrictions and interpretation rules for both.

```
functionname arg1 arg2 arg3               % Command syntax
functionname('arg1','arg2','arg3')        % Function syntax
```

For more information: See Calling Functions in the MATLAB Programming documentation.

Command Line Continuation

You can continue most statements to one or more additional lines by terminating each incomplete line with an ellipsis (`...`). Breaking down a statement into a number of lines can sometimes result in a clearer programming style.

```
sprintf ('Example %d shows a command coded on %d lines.\n', ...
          exampleNumber, ...
```

```
            numberOfLines)
```

Note that you cannot continue an incomplete string to another line.

```
disp 'This statement attempts to continue a string ...
      to another line, resulting in an error.'
```

For more information: See Entering Long Statements in the MATLAB Desktop Tools and Development Environment documentation.

Completing Commands Using the Tab Key

You can save some typing when entering commands by entering only the first few letters of the command, variable, property, etc. followed by the **Tab** key. Typing the second line below (with **T** representing **Tab**) yields the expanded, full command shown in the third line:

```
f = figure;
set(f, 'papTuT,'cT)                    % Type this line.
set(f, 'paperunits','centimeters')     % This is what you get.
```

If there are too many matches for the string you are trying to complete, you will get no response from the first **Tab**. Press **Tab** again to see all possible choices:

```
set(f, 'paTT
PaperOrientation   PaperPositionMode  PaperType     Parent
PaperPosition      PaperSize          PaperUnits
```

For more information: See Tab Completion in the Command Window in the MATLAB Desktop Tools and Development Environment documentation

Recalling Commands

Use any of the following methods to simplify recalling previous commands to the screen:

- To recall an earlier command to the screen, press the up arrow key one or more times, until you see the command you want. If you want to modify the recalled command, you can edit its text before pressing **Enter** or **Return** to execute it.

- To recall a specific command by name without having to scroll through your earlier commands one by one, type the starting letters of the command, followed by the up arrow key.
- Open the Command History window (**View > Command History**) to see all previous commands. Double-click the command you want to execute.

For more information: See Recalling Previous Lines and Command History Window in the MATLAB Desktop Tools and Development Environment documentation.

Clearing Commands

If you have typed a command that you then decide not to execute, you can clear it from the Command Window by pressing the Escape (**Esc**) key.

Suppressing Output to the Screen

To suppress output to the screen, end statements with a semicolon. This can be particularly useful when generating large matrices.

```
A = magic(100);     % Create matrix A, but do not display it.
```

Help

In this section...

Using the Help Browser

Open the Help browser from the MATLAB Command Window using one of the following:

- Click the question mark symbol in the toolbar.
- Select **Help > Product Help** from the menu.
- Type the word `doc` at the command prompt.

Some of the features of the Help browser are listed below.

Feature	Description
Product Filter	Establish which products to find help on.
Contents	Look up topics in the Table of Contents.
Index	Look up help using the documentation Index.
Search	Search the documentation for one or more words.
Demos	See what demos are available; run selected demos.
Favorites	Save bookmarks for frequently used Help pages.

For more information: See Finding Information with the Help Browser in the MATLAB Desktop Tools and Development Environment documentation.

Help on Functions from the Help Browser

To find help on any function from the Help browser, do either of the following:

- Select the **Contents** tab of the Help browser, open the **Contents** entry labeled `MATLAB`, and find the two subentries shown below. Use one of these to look up the function you want help on.
  - Functions — Categorical List
  - Functions — Alphabetical List
- Type `doc functionname` at the command line.

Help on Functions from the Command Window

Several types of help on functions are available from the Command Window:

- To list all categories that you can request help on from the Command Window, just type

  ```
  help
  ```

- To see a list of functions for one of these categories, along with a brief description of each function, type `help` *`category`*. For example,

  ```
  help datafun
  ```

- To get help on a particular function, type `help functionname`. For example,

  ```
  help sortrows
  ```

Topical Help

In addition to the help on individual functions, you can get help on any of the following topics by typing `help topicname` at the command line.

Topic Name	Description
`arith`	Arithmetic operators
`relop`	Relational and logical operators
`punct`	Special character operators
`slash`	Arithmetic division operators
`paren`	Parentheses, braces, and bracket operators
`precedence`	Operator precedence
`datatypes`	MATLAB data types, their associated functions, and operators that you can overload
`lists`	Comma separated lists
`strings`	Character strings
`function_handle`	Function handles and the `@` operator
`debug`	Debugging functions
`java`	Using Java from within MATLAB
`fileformats`	A list of readable file formats
`changeNotification`	Windows directory change notification

Paged Output

Before displaying a lengthy section of help text or code, put MATLAB into its paged output mode by typing `more on`. This breaks up any ensuing display into pages for easier viewing. Turn off paged output with `more off`.

Page through the displayed text using the space bar key. Or step through line by line using **Enter** or **Return**. Discontinue the display by pressing the **Q** key or **Ctrl+C**.

Writing Your Own Help

Start each program you write with a section of text providing help on how and when to use the function. If formatted properly, the MATLAB `help` function displays this text when you enter

```
help functionname
```

MATLAB considers the first group of consecutive lines immediately following the function definition line that begin with `%` to be the help section for the function. The first line without `%` as the left-most character ends the help.

For more information: See Help Text in the MATLAB Desktop Tools and Development Environment documentation.

Help for Subfunctions and Private Functions

You can write help for subfunctions using the same rules that apply to main functions. To display the help for the subfunction `mysubfun` in file `myfun.m`, type

```
help myfun>mysubfun
```

To display the help for a private function, precede the function name with `private/`. To get help on private function `myprivfun`, type

```
help private/myprivfun
```

Help for Methods and Overloaded Functions

You can write help text for object-oriented class methods implemented with M-files. Display help for the method by typing

```
help classname/methodname
```

where the file `methodname.m` resides in subdirectory `@classname`.

For example, if you write a `plot` method for a class named `polynom`, (where the `plot` method is defined in the file `@polynom/plot.m`), you can display this help by typing

```
help polynom/plot
```

You can get help on overloaded MATLAB functions in the same way. To display the help text for the `eq` function as implemented in `matlab/iofun/@serial`, type

```
help serial/eq
```

Development Environment

In this section...

Workspace Browser

The Workspace browser is a graphical interface to the variables stored in the MATLAB base and function workspaces. You can view, modify, save, load, and create graphics from workspace data using the browser. Select **View > Workspace** to open the browser.

To view function workspaces, you need to be in debug mode.

For more information: See MATLAB Workspace in the MATLAB Desktop Tools and Development Environment documentation.

Using the Find and Replace Utility

Find any word or phrase in a group of files using the Find and Replace utility. Click **View > Current Directory**, and then click the binoculars icon at the top of the **Current Directory** window.

When entering search text, you do not need to put quotes around a phrase. In fact, parts of words, like `win` for `windows`, will not be found if enclosed in quotes.

For more information: See Finding and Replacing Text in the Current File in the MATLAB Desktop Tools and Development Environment documentation.

Commenting Out a Block of Code

To comment out a block of text or code within the MATLAB editor,

1. Highlight the block of text you would like to comment out.
2. Holding the mouse over the highlighted text, select **Text > Comment** (or **Uncomment**, to do the reverse) from the toolbar. (You can also get these options by right-clicking the mouse.)

For more information: See Adding Comments in the MATLAB Desktop Tools and Development Environment documentation.

Creating M-Files from Command History

If there is part of your current MATLAB session that you would like to put into an M-file, this is easily done using the Command History window:

1. Open this window by selecting **View > Command History**.
2. Use **Shift+Click** or **Ctrl+Click** to select the lines you want to use. MATLAB highlights the selected lines.
3. Right-click once, and select **Create M-File** from the menu that appears. MATLAB creates a new Editor window displaying the selected code.

Editing M-Files in EMACS

If you use Emacs, you can download editing modes for editing M-files with GNU-Emacs or with early versions of Emacs from the MATLAB Central Web site:

```
http://www.mathworks.com/matlabcentral/
```

At this Web site, select **File Exchange**, and then **Utilities > Emacs**.

For more information: See General Preferences for the Editor/Debugger in the MATLAB Desktop Tools and Development Environment documentation.

M-File Functions

In this section...

M-File Structure

An M-File consists of the components shown here:

```
function [x, y] = myfun(a, b, c)   % Function definition line
% H1 line -- A one-line summary of the function's purpose.
% Help text -- One or more lines of help text that explain
%   how to use the function. This text is displayed when
%   the user types "help functionname".

% The Function body normally starts after the first blank line.
% Comments -- Description (for internal use) of what the
%   function does, what inputs are expected, what outputs
%   are generated. Typing "help functionname" does not display
%   this text.

x = prod(a, b);                    % Start of Function code
```

For more information: See Basic Parts of an M-File in the MATLAB Programming documentation.

Using Lowercase for Function Names

Function names appear in uppercase in MATLAB help text only to make the help easier to read. In practice, however, it is usually best to use lowercase when calling functions.

For M-file functions, case requirements depend on the case sensitivity of the operating system you are using. As a rule, naming and calling functions using lowercase generally makes your M-files more portable from one operating system to another.

Getting a Function's Name and Path

To obtain the name of an M-file that is currently being executed, use the following function in your M-file code.

```
mfilename
```

To include the path along with the M-file name, use

```
mfilename('fullpath')
```

For more information: See the `mfilename` function reference page.

What M-Files Does a Function Use?

For a simple display of all M-files referenced by a particular function, follow the steps below:

1. Type `clear functions` to clear all functions from memory (see Note below).
2. Execute the function you want to check. Note that the function arguments you choose to use in this step are important, since you can get different results when calling the same function with different arguments.
3. Type `inmem` to display all M-Files that were used when the function ran. If you want to see what MEX-files were used as well, specify an additional output, as shown here:

   ```
   [mfiles, mexfiles] = inmem
   ```

Note `clear functions` does not clear functions locked by `mlock`. If you have locked functions, (which you can check using `inmem`), unlock them with `munlock`, and then repeat step 1.

Dependent Functions, Built-Ins, Classes

For a much more detailed display of dependent function information, use the `depfun` function. In addition to M-files, `depfun` shows which built-ins and classes a particular function depends on.

Function Arguments

In this section...

Getting the Input and Output Arguments

Use `nargin` and `nargout` to determine the number of input and output arguments in a particular function call. Use `nargchk` and `nargoutchk` to verify that your function is called with the required number of input and output arguments.

```
function [x, y] = myplot(a, b, c, d)
disp(nargchk(2, 4, nargin))           % Allow 2 to 4 inputs
disp(nargoutchk(0, 2, nargout))       % Allow 0 to 2 outputs

x = plot(a, b);
if nargin == 4
   y = myfun(c, d);
end
```

Variable Numbers of Arguments

You can call functions with fewer input and output arguments than you have specified in the function definition, but not more. If you want to call a function with a variable number of arguments, use the `varargin` and `varargout` function parameters in the function definition.

This function returns the size vector and, optionally, individual dimensions:

```
function [s, varargout] = mysize(x)
nout = max(nargout, 1) - 1;
s = size(x);
for k = 1:nout
```

```
    varargout(k) = {s(k)};
end
```

Try calling it with

```
[s, rows, cols] = mysize(rand(4, 5))
```

String or Numeric Arguments

If you are passing only string arguments into a function, you can use MATLAB command syntax. All arguments entered in command syntax are interpreted as strings.

```
strcmp string1 string1
ans =
     1
```

When passing numeric arguments, it is best to use function syntax unless you want the number passed as a string. The right-hand example below passes the number `75` as the string, `'75'`.

```
isnumeric(75)
ans =
    1
```

```
isnumeric 75
ans =
    0
```

For more information: See Passing Arguments with Command and Function Syntax in the MATLAB Programming documentation.

Passing Arguments in a Structure

Instead of requiring an additional argument for every value you want to pass in a function call, you can package them in a MATLAB structure and pass the structure. Make each input you want to pass a separate field in the structure argument, using descriptive names for the fields.

Structures allow you to change the number, contents, or order of the arguments without having to modify the function. They can also be useful when you have a number of functions that need similar information.

Passing Arguments in a Cell Array

You can also group arguments into cell arrays. The disadvantage over structures is that you do not have field names to describe each variable. The advantage is that cell arrays are referenced by index, allowing you to loop through a cell array and access each argument passed in or out of the function.

Program Development

In this section...

Planning the Program

When planning how to write a program, take the problem you are trying to solve and break it down into a series of smaller, independent tasks. Implement each task as a separate function. Try to keep functions fairly short, each having a single purpose.

Using Pseudo-Code

You may find it helpful to write the initial draft of your program in a structured format using your own natural language. This *pseudo-code* is often easier to think through, review, and modify than using a formal programming language, yet it is easily translated into a programming language in the next stage of development.

Selecting the Right Data Structures

Look at what data types and data structures are available to you in MATLAB and determine which of those best fit your needs in storing and passing your data.

For more information: See Data Types in the MATLAB Programming documentation.

General Coding Practices

A few suggested programming practices:

- Use descriptive function and variable names to make your code easier to understand.
- Order subfunctions alphabetically in an M-file to make them easier to find.
- Precede each subfunction with a block of help text describing what that subfunction does. This not only explains the subfunctions, but also helps to visually separate them.
- Do not extend lines of code beyond the 80th column. Otherwise, it will be hard to read when you print it out.
- Use full Handle Graphics® property and value names. Abbreviated names are often allowed, but can make your code unreadable. They also could be incompatible in future releases of MATLAB.

Naming a Function Uniquely

To avoid choosing a name for a new function that might conflict with a name already in use, check for any occurrences of the name using this command:

```
which -all functionname
```

For more information: See the `which` function reference page.

The Importance of Comments

Be sure to document your programs well to make it easier for you or someone else to maintain them. Add comments generously, explaining each major section and any smaller segments of code that are not obvious. You can add a block of comments as shown here.

```
%-------------------------------------------
% This function computes the ... <and so on>
%-------------------------------------------
```

For more information: See Comments in the MATLAB Programming documentation.

Coding in Steps

Do not try to write the entire program all at once. Write a portion of it, and then test that piece out. When you have that part working the way you want, then write the next piece, and so on. It's much easier to find programming errors in a small piece of code than in a large program.

Making Modifications in Steps

When making modifications to a working program, do not make widespread changes all at one time. It's better to make a few small changes, test and debug, make a few more changes, and so on. Tracking down a difficult bug in the small section that you've changed is much easier than trying to find it in a huge block of new code.

Functions with One Calling Function

If you have a function that is called by only one other function, put it in the same M-file as the calling function, making it a subfunction.

For more information: See Subfunctions in the MATLAB Programming documentation.

Testing the Final Program

One suggested practice for testing a new program is to step through the program in the MATLAB debugger while keeping a record of each line that gets executed on a printed copy of the program. Use different combinations of inputs until you have observed that every line of code is executed at least once.

Debugging

In this section...

The MATLAB Debug Functions

For a brief description of the main debug functions in MATLAB, type

```
help debug
```

For more information: See Debugging Process and Features in the MATLAB Desktop Tools and Development Environment documentation.

More Debug Functions

Other functions you may find useful in debugging are listed below.

Function	Description
`echo`	Display function or script code as it executes.
`disp`	Display specified values or messages.
`sprintf`, `fprintf`	Display formatted data of different types.

Function	Description
`whos`	List variables in the workspace.
`size`	Show array dimensions.
`keyboard`	Interrupt program execution and allow input from keyboard.
`return`	Resume execution following a keyboard interruption.
`warning`	Display specified warning message.
`error`	Display specified error message.
`lasterr`	Return error message that was last issued.
`lasterror`	Return last error message and related information.
`lastwarn`	Return warning message that was last issued.

The MATLAB Graphical Debugger

Learn to use the MATLAB graphical debugger. You can view the function and its calling functions as you debug, set and clear breakpoints, single-step through the program, step into or over called functions, control visibility into all workspaces, and find and replace strings in your files.

Start out by opening the file you want to debug using **File > Open** or the `open` function. Use the debugging functions available on the toolbar and pull-down menus to set breakpoints, run or step through the program, and examine variables.

For more information: See Debugging Process and Features in the MATLAB Desktop Tools and Development Environment documentation.

A Quick Way to Examine Variables

To see the value of a variable from the Editor/Debugger window, hold the mouse cursor over the variable name for a second or two. You will see the value of the selected variable displayed.

Setting Breakpoints from the Command Line

You can set breakpoints with `dbstop` in any of the following ways:

- Break at a specific M-file line number.
- Break at the beginning of a specific subfunction.
- Break at the first executable line in an M-file.
- Break when a warning, or error, is generated.
- Break if any infinite or `NaN` values are encountered.

For more information: See Setting Breakpoints in the MATLAB Desktop Tools and Development Environment documentation.

Finding Line Numbers to Set Breakpoints

When debugging from the command line, a quick way to find line numbers for setting breakpoints is to use `dbtype`. The `dbtype` function displays all or part of an M-file, also numbering each line. To display delaunay`.m`, use

```
dbtype delaunay
```

To display only lines 35 through 41, use

```
dbtype delaunay 35:41
```

Stopping Execution on an Error or Warning

Use `dbstop if error` to stop program execution on any error and enter debug mode. Use `warning debug` to stop execution on any warning and enter debug mode.

For more information: See Backtrace and Verbose Modes in the MATLAB Programming documentation.

Locating an Error from the Error Message

Click on the underlined text in an error message, and MATLAB opens the M-file being executed in its editor and places the cursor at the point of error.

For more information: See Finding Errors, Debugging, and Correcting M-Files in the MATLAB Desktop Tools and Development Environment documentation.

Using Warnings to Help Debug

You can detect erroneous or unexpected behavior in your programs by inserting warning messages that MATLAB will display under the conditions you specify. See the section on Warning Control in the MATLAB Programming documentation to find out how to selectively enable warnings.

For more information: See the `warning` function reference page.

Making Code Execution Visible

An easy way to see the end result of a particular line of code is to edit the program and temporarily remove the terminating semicolon from that line. Then, run your program and the evaluation of that statement is displayed on the screen.

For more information: See Finding Errors, Debugging, and Correcting M-Files in the MATLAB Desktop Tools and Development Environment documentation.

Debugging Scripts

Scripts store their variables in a workspace that is shared with the caller of the script. So, when you debug a script from the command line, the script uses variables from the base workspace. To avoid errors caused by workspace sharing, type `clear all` before starting to debug your script to clear the base workspace.

Variables

In this section...

Rules for Variable Names

Although variable names can be of any length, MATLAB uses only the first N characters of the name, (where N is the number returned by the function `namelengthmax`), and ignores the rest. Hence, it is important to make each variable name unique in the first N characters to enable MATLAB to distinguish variables. Also note that variable names are case sensitive.

```
N = namelengthmax
N =
     63
```

For more information: See Naming Variables in the MATLAB Programming documentation.

Making Sure Variable Names Are Valid

Before using a new variable name, you can check to see if it is valid with the `isvarname` function. Note that `isvarname` does not consider names longer than `namelengthmax` characters to be valid.

For example, the following name cannot be used for a variable since it begins with a number.

```
isvarname 8thColumn
ans =
     0
```

For more information: See Naming Variables in the MATLAB Programming documentation.

Do Not Use Function Names for Variables

When naming a variable, make sure you are not using a name that is already used as a function name. If you do define a variable with a function name, you will not be able to call that function until you `clear` the variable from memory. (If it's a MATLAB built-in function, then you will still be able to call that function but you must do so using `builtin`.)

To test whether a proposed variable name is already used as a function name, use

```
which -all name
```

For more information: See Potential Conflict with Function Names in the MATLAB Programming documentation.

Checking for Reserved Keywords

MATLAB reserves certain keywords for its own use and does not allow you to override them. Attempts to use these words may result in any one of a number of error messages, some of which are shown here:

```
Error: Expected a variable, function, or constant, found "=".
Error: "End of Input" expected, "case" found.
Error: Missing operator, comma, or semicolon.
Error: "identifier" expected, "=" found.
```

Use the `iskeyword` function with no input arguments to list all reserved words.

Avoid Using i and j for Variables

MATLAB uses the characters `i` and `j` to represent imaginary units. Avoid using `i` and `j` for variable names if you intend to use them in complex arithmetic.

If you want to create a complex number without using `i` and `j`, you can use the `complex` function.

Avoid Overwriting Variables in Scripts

MATLAB scripts store their variables in a workspace that is shared with the caller of the script. When called from the command line, they share the base workspace. When called from a function, they share that function's workspace. If you run a script that alters a variable that already exists in the caller's workspace, that variable is overwritten by the script.

For more information: See M-File Scripts in the MATLAB Programming documentation.

Persistent Variables

To get the equivalent of a static variable in MATLAB, use `persistent`. When you declare a variable to be `persistent` within a function, its value is retained in memory between calls to that function. Unlike `global` variables, `persistent` variables are known only to the function in which they are declared.

For more information: See Persistent Variables in the MATLAB Programming documentation.

Protecting Persistent Variables

You can inadvertently clear `persistent` variables from memory by either modifying the function in which the variables are defined, or by clearing the function with one of the following commands:

```
clear all
clear functions
```

Locking the M-file in memory with `mlock` prevents any `persistent` variables defined in the file from being reinitialized.

Global Variables

Use global variables sparingly. The global workspace is shared by all of your functions and also by your interactive MATLAB session. The more global variables you use, the greater the chances of unintentionally reusing a variable name, thus leaving yourself open to having those variables change in value unexpectedly. This can be a difficult bug to track down.

For more information: See Global Variables in the MATLAB Programming documentation.

Strings

In this section...

Creating Strings with Concatenation

Strings are often created by concatenating smaller elements together (e.g., strings, values, etc.). Two common methods of concatenating are to use the MATLAB concatenation operator (`[]`) or the `sprintf` function. The second and third line below illustrate both of these methods. Both lines give the same result:

```
numChars = 28;
s = ['There are ' int2str(numChars) ' characters here']
s = sprintf('There are %d characters here\n', numChars)
```

For more information: See Creating Character Arrays and Converting from Numeric to String in the MATLAB Programming documentation.

Comparing Methods of Concatenation

When building strings with concatenation, `sprintf` is often preferable to `[]` because

- It is easier to read, especially when forming complicated expressions
- It gives you more control over the output format
- It often executes more quickly

You can also concatenate using the `strcat` function, However, for simple concatenations, `sprintf` and `[]` are faster.

Store Arrays of Strings in a Cell Array

It is usually best to store an array of strings in a cell array instead of a character array, especially if the strings are of different lengths. Strings in a character array must be of equal length, which often requires padding the strings with blanks. This is not necessary when using a cell array of strings that has no such requirement.

The `cellRecord` below does not require padding the strings with spaces:

```
cellRecord = {'Allison Jones'; 'Development'; 'Phoenix'};
```

For more information: See Cell Arrays of Strings in the MATLAB Programming documentation.

Converting Between Strings and Cell Arrays

You can convert between standard character arrays and cell arrays of strings using the `cellstr` and `char` functions:

```
charRecord = ['Allison Jones'; 'Development  '; ...
              'Phoenix      '];
cellRecord = cellstr(charRecord);
```

Also, a number of the MATLAB string operations can be used with either character arrays, or cell arrays, or both:

```
cellRecord2 = {'Brian Lewis'; 'Development'; 'Albuquerque'};
strcmp(charRecord, cellRecord2)
ans =
     0
     1
     0
```

For more information: See Converting to a Cell Array of Strings and String Comparisons in the MATLAB Programming documentation.

Search and Replace Using Regular Expressions

Using regular expressions in MATLAB offers a very versatile way of searching for and replacing characters or phrases within a string. See the help on these functions for more information.

Function	Description
`regexp`	Match regular expression.
`regexpi`	Match regular expression, ignoring case.
`regexprep`	Replace string using regular expression.

For more information: See “Regular Expressions” in the MATLAB Programming documentation.

Evaluating Expressions

In this section...

Find Alternatives to Using eval

While the `eval` function can provide a convenient solution to certain programming challenges, it is best to limit its use. The main reason is that code that uses `eval` is often difficult to read and hard to debug. A second reason is that `eval` statements cannot always be translated into C or C++ code by the MATLAB Compiler.

If you are evaluating a function, it is more efficient to use `feval` than `eval`. The `feval` function is made specifically for this purpose and is optimized to provide better performance.

For more information: See MATLAB Technical Note 1103, "What Is the EVAL Function, When Should I Use It, and How Can I Avoid It?" at URL `http://www.mathworks.com/support/tech-notes/1100/1103.html`.

Assigning to a Series of Variables

One common pattern for creating variables is to use a variable name suffixed with a number (e.g., `phase1`, `phase2`, `phase3`, etc.). We recommend using a cell array to build this type of variable name series, as it makes code more readable and executes more quickly than some other methods. For example:

```
for k = 1:800
   phase{k} = expression;
end
```

Short-Circuit Logical Operators

MATLAB has logical `AND` and `OR` operators (`&&` and `||`) that enable you to partially evaluate, or *short-circuit*, logical expressions. Short-circuit operators are useful when you want to evaluate a statement only when certain conditions are satisfied.

In this example, MATLAB does not execute the function `myfun` unless its M-file exists on the current path.

```
comp = (exist('myfun.m') == 2) && (myfun(x) >= y)
```

For more information: See “Short-Circuit Operators” in the MATLAB Programming documentation.

Changing the Counter Variable within a for Loop

You cannot change the value of the loop counter variable (e.g., the variable `k` in the example below) in the body of a `for` loop. For example, this loop executes just `10` times, even though `k` is set back to `1` on each iteration.

```
for k = 1:10
   fprintf('Pass %d\n', k)
   k = 1;
end
```

Although MATLAB does allow you to use a variable of the same name as the loop counter within a loop, this is not a recommended practice.

MATLAB Path

In this section...

Precedence Rules

When MATLAB is given a name to interpret, it determines its usage by checking the name against each of the entities listed below, and in the order shown:

1. Variable
2. Subfunction
3. Private function
4. Class constructor
5. Overloaded method
6. M-file in the current directory
7. M-file on the path, or MATLAB built-in function

If you have two or more M-files on the path that have the same name, MATLAB selects the function that has its M-file in the directory closest to the beginning of the path string.

For more information: See Function Precedence Order in the MATLAB Programming documentation.

File Precedence

If you refer to a file by its filename only (leaving out the file extension), and there is more than one file of this name in the directory, MATLAB selects the file to use according to the following precedence:

1. MEX-file
2. MDL-file (Simulink® model)
3. P-Code file
4. M-file

For more information: See Multiple Implementation Types in the MATLAB Programming documentation.

Adding a Directory to the Search Path

To add a directory to the search path, use either of the following:

- At the toolbar, select **File > Set Path**.
- At the command line, use the `addpath` function.

You can also add a directory and all of its subdirectories in one operation by either of these means. To do this from the command line, use `genpath` together with `addpath`. The online help for the `genpath` function shows how to do this.

This example adds `/control` and all of its subdirectories to the MATLAB path:

```
addpath(genpath('K:/toolbox/control'))
```

For more information: See Search Path in the MATLAB Desktop Tools and Development Environment documentation.

Handles to Functions Not on the Path

You cannot create function handles to functions that are not on the MATLAB path. But you can achieve essentially the same thing by creating the handles through a script file placed in the same off-path directory as the functions.

If you then run the script, using `run path/script`, you will have created the handles that you need.

For example,

1. Create a script in this off-path directory that constructs function handles and assigns them to variables. That script might look something like this:

```
File E:/testdir/createFhandles.m
   fhset = @setItems
   fhsort = @sortItems
   fhdel = @deleteItem
```

2. Run the script from your current directory to create the function handles:

```
run E:/testdir/createFhandles
```

3. You can now execute one of the functions by means of its handle.

```
fhset(item, value)
```

Making Toolbox File Changes Visible to MATLAB

Unlike functions in user-supplied directories, M-files (and MEX-files) in the *matlabroot*/toolbox directories are not time-stamp checked, so MATLAB does not automatically see changes to them. If you modify one of these files, and then rerun it, you may find that the behavior does not reflect the changes that you made. This is most likely because MATLAB is still using the previously loaded version of the file.

To force MATLAB to reload a function from disk, you need to explicitly clear the function from memory using `clear functionname`. Note that there are rare cases where `clear` will not have the desired effect, (for example, if the file is locked, or if it is a class constructor and objects of the given class exist in memory).

Similarly, MATLAB does not automatically detect the presence of new files in *matlabroot*/toolbox directories. If you add (or remove) files from these directories, use `rehash toolbox` to force MATLAB to see your changes. Note that if you use the MATLAB Editor to create files, these steps are unnecessary, as the Editor automatically informs MATLAB of such changes.

Making Nontoolbox File Changes Visible to MATLAB

For M-files outside of the toolbox directories, MATLAB sees the changes made to these files by comparing timestamps and reloads any file that has changed the next time you execute the corresponding function.

If MATLAB does not see the changes you make to one of these files, try clearing the old copy of the function from memory using `clear` *`functionname`*. You can verify that MATLAB has cleared the function using `inmem` to list all functions currently loaded into memory.

Change Notification on Windows

If MATLAB, running on Windows, is unable to see new files or changes you have made to an existing file, the problem may be related to operating system change notification handles.

Type the following for more information:

```
help changeNotification
help changeNotificationAdvanced
```

Program Control

In this section...

Using break, continue, and return

It's easy to confuse the `break`, `continue`, and `return` functions as they are similar in some ways. Make sure you use these functions appropriately.

Function	Where to Use It	Description
`break`	`for` or `while` loops	Exits the loop in which it appears. In nested loops, control passes to the next outer loop.
`continue`	`for` or `while` loops	Skips any remaining statements in the current loop. Control passes to next iteration of the same loop.
`return`	Anywhere	Immediately exits the function in which it appears. Control passes to the caller of the function.

Using switch Versus if

It is possible, but usually not advantageous, to implement `switch-case` statements using `if-elseif` instead. See pros and cons in the table.

switch-case Statements	if-elseif Statements
Easier to read.	Can be difficult to read.
Can compare strings of different lengths.	You need `strcmp` to compare strings of different lengths.
Test for equality only.	Test for equality or inequality.

MATLAB case Evaluates Strings

A useful difference between `switch-case` statements in MATLAB and C is that you can specify string values in MATLAB `case` statements, which you cannot do in C.

```
switch(method)
   case 'linear'
      disp('Method is linear')
   case 'cubic'
      disp('Method is cubic')
end
```

Multiple Conditions in a case Statement

You can test against more than one condition with `switch`. The first case below tests for either a `linear` or `bilinear` method by using a cell array in the case statement.

```
switch(method)
   case {'linear', 'bilinear'}
      disp('Method is linear or bilinear')
   case (<and so on>)
end
```

Implicit Break in switch-case

In C, if you do not end each `case` with a `break` statement, code execution falls through to the following `case`. In MATLAB, `case` statements do not fall

through; only one `case` may execute. Using `break` within a `case` statement is not only unnecessary, it is also invalid and generates a warning.

In this example, if `result` is `52`, only the first `disp` statement executes, even though the second is also a valid match:

```
switch(result)
   case 52
      disp('result is 52')
   case {52, 78}
      disp('result is 52 or 78')
end
```

Variable Scope in a switch

Since MATLAB executes only one `case` of any `switch` statement, variables defined within one `case` are not known in the other `cases` of that `switch` statement. The same holds true for `if-elseif` statements.

In these examples, you get an error when `choice` equals `2`, because `x` is undefined.

```
  -- SWITCH-CASE --
switch choice
   case 1
      x = -pi:0.01:pi;
   case 2
      plot(x, sin(x));
end
```

```
 -- IF-ELSEIF --

if choice == 1
   x = -pi:0.01:pi;
elseif choice == 2
   plot(x, sin(x));
end
```

Catching Errors with try-catch

When you have statements in your code that could possibly generate unwanted results, put those statements into a `try-catch` block that will catch any errors and handle them appropriately.

The example below shows a `try-catch` block within a function that multiplies two matrices. If a statement in the `try` segment of the block fails, control passes to the `catch` segment. In this case, the `catch` statements check the error message that was issued (returned by `lasterr`) and respond appropriately.

```
try
   X = A * B
catch
   errmsg = lasterr;
   if(strfind(errmsg, 'Inner matrix dimensions'))
      disp('** Wrong dimensions for matrix multiply')
end
```

For more information: See “The try-catch Statement” in the MATLAB Programming documentation.

Nested try-catch Blocks

You can also nest `try-catch` blocks, as shown here. You can use this to attempt to recover from an error caught in the first `try` section:

```
try
   statement1                    % Try to execute statement1
catch
   try
      statement2                 % Attempt to recover from error
   catch
      disp 'Operation failed'    % Handle the error
   end
end
```

Forcing an Early Return from a Function

To force an early return from a function, place a `return` statement in the function at the point where you want to exit. For example,

```
if <done>
   return
end
```

Save and Load

In this section...

Saving Data from the Workspace

To save data from your workspace, you can do any of the following:

- Copy from the MATLAB Command Window and paste into a text file.
- Record part of your session in a `diary` file, and then edit the file in a text editor.
- Save to a binary or ASCII file using the `save` function.
- Save spreadsheet, scientific, image, or audio data with appropriate function.
- Save to a file using low-level file I/O functions (`fwrite`, `fprintf`, `...`).

For more information: See Saving the Current Workspace in the MATLAB Desktop Tools and Development Environment documentation, and "Using the diary Function to Export Data" and "Using Low-Level File I/O Functions" in the MATLAB Programming documentation.

Loading Data into the Workspace

Similarly, to load new or saved data into the workspace, you can do any of the following:

- Enter or paste data at the command line.
- Create a script file to initialize large matrices or data structures.

- Read a binary or ASCII file using `load`.
- Load spreadsheet, scientific, image, or audio data with appropriate function.
- Load from a file using low-level file I/O functions (`fread`, `fscanf`, `...`).

For more information: See Loading a Saved Workspace and Importing Data in the MATLAB Development Environment documentation, and "Using Low-Level File I/O Functions" in the MATLAB Programming documentation.

Viewing Variables in a MAT-File

To see what variables are saved in a MAT-file, use `who` or `whos` as shown here (the `.mat` extension is not required). `who` returns a cell array and `whos` returns a structure array.

```
mydataVariables = who('-file', 'mydata.mat');
```

Appending to a MAT-File

To save additional variables to an existing MAT-file, use

```
save matfilename -append
```

Any variables you save that do not yet exist in the MAT-file are added to the file. Any variables you save that already exist in the MAT-file overwrite the old values.

Note Saving with the `-append` switch does not append additional elements to an array that is already saved in a MAT-file. See the example below.

In this example, the second `save` operation does not concatenate new elements to vector `A`, (making `A` equal to `[1 2 3 4 5 6 7 8]`) in the MAT-file. Instead, it replaces the 5 element vector, `A`, with a 3 element vector, also retaining all other variables that were stored on the first `save` operation.

```
A = [1 2 3 4 5];   B = 12.5;   C = rand(4);
save savefile;
A = [6 7 8];
```

```
save savefile A -append;
```

Save and Load on Startup or Quit

You can automatically save your variables at the end of each MATLAB session by creating a `finish.m` file to `save` the contents of your base workspace every time you quit MATLAB. Load these variables back into your workspace at the beginning of each session by creating a `startup.m` file that uses the `load` function to load variables from your MAT-file.

For more information: See the `startup` and `finish` function reference pages.

Saving to an ASCII File

When you save matrix data to an ASCII file using `save -ascii`, MATLAB combines the individual matrices into one collection of numbers. Variable names are not saved. If this is not acceptable for your application, use `fprintf` to store your data instead.

For more information: See “Exporting Delimited ASCII Data Files”.

Files and Filenames

In this section...

Naming M-files

M-file names must start with an alphabetic character, may contain any alphanumeric characters or underscores, and must be no longer than the maximum allowed M-file name length (returned by the function `namelengthmax`).

```
N = namelengthmax
N =
     63
```

Since variables must obey similar rules, you can use the `isvarname` function to check whether a filename (minus its `.m` file extension) is valid for an M-file.

```
isvarname mfilename
```

Naming Other Files

The names of other files that MATLAB interacts with (e.g., MAT, MEX, and MDL-files) follow the same rules as M-files, but may be of any length.

Depending on your operating system, you may be able to include certain nonalphanumeric characters in your filenames. Check your operating system manual for information on valid filename restrictions.

Passing Filenames as Arguments

In MATLAB commands, you can specify a filename argument using the MATLAB command or function syntax. For example, either of the following are acceptable. (The `.mat` file extension is optional for `save` and `load`).

```
load mydata.mat           % Command syntax
load('mydata.mat')        % Function syntax
```

If you assign the output to a variable, you must use the function syntax.

```
savedData = load('mydata.mat')
```

Passing Filenames to ASCII Files

ASCII files are specified as follows. Here, the file extension is required.

```
load mydata.dat -ascii            % Command syntax
load('mydata.dat','-ascii')       % Function syntax
```

Determining Filenames at Run-Time

There are several ways that your function code can work on specific files without you having to hardcode their filenames into the program. You can

- Pass the filename in as an argument

  ```
  function myfun(datafile)
  ```

- Prompt for the filename using the `input` function

  ```
  filename = input('Enter name of file:  ', 's');
  ```

- Browse for the file using the `uigetfile` function

  ```
  [filename, pathname] =
     uigetfile('*.mat', 'Select MAT-file');
  ```

For more information: See the `input` and `uigetfile` function reference pages.

Returning the Size of a File

Two ways to have your program determine the size of a file are shown here.

```
  -- METHOD #1 --
s = dir('myfile.dat');
filesize = s.bytes
```

```
   -- METHOD #2 --
fid = fopen('myfile.dat');
fseek(fid, 0, 'eof');
filesize = ftell(fid)
fclose(fid);
```

The `dir` function also returns the filename (`s.name`), last modification date (`s.date`), and whether or not it's a directory (`s.isdir`).

(The second method requires read access to the file.)

For more information: See the `fopen`, `fseek`, `ftell`, and `fclose` function reference pages.

Input/Output

In this section...

For more information and examples on importing and exporting data, see Technical Note 1602:

http://www.mathworks.com/support/tech-notes/1600/1602.html

File I/O Function Overview

For a good overview of MATLAB file I/O functions, use the online "Functions — Categorical List" reference. In the Help browser **Contents**, select **MATLAB > Functions — Categorical List**, and then click **File I/O**.

Common I/O Functions

The most commonly used, high-level, file I/O functions in MATLAB are `save` and `load`. For help on these, type `doc save` or `doc load`.

Functions for I/O to text files with delimited values are `textread`, `dlmread`, `dlmwrite`. Functions for I/O to text files with comma-separated values are `csvread`, `csvwrite`.

For more information: See Text Files in the MATLAB "Functions — Categorical List" reference documentation.

Readable File Formats

Type `doc fileformats` to see a list of file formats that MATLAB can read, along with the associated MATLAB functions.

Using the Import Wizard

A quick method of importing text or binary data from a file (e.g., Excel files) is to use the MATLAB Import Wizard. Open the Import Wizard with the command, `uiimport filename` or by selecting **File > Import Data** at the Command Window.

Specify or browse for the file containing the data you want to import and you will see a preview of what the file contains. Select the data you want and click **Finish**.

For more information: See "Using the Import Wizard" in the MATLAB Programming documentation.

Loading Mixed Format Data

To load data that is in mixed formats, use `textread` instead of `load`. The `textread` function lets you specify the format of each piece of data.

If the first line of file `mydata.dat` is

```
Sally    12.34 45
```

Read the first line of the file as a free format file using the % format:

```
[names, x, y] = textread('mydata.dat', '%s %f %d', 1)
```

returns

```
names =
    'Sally'
x =
  12.34000000000000
y =
    45
```

Reading Files with Different Formats

Attempting to read data from a file that was generated on a different platform may result in an error because the binary formats of the platforms may differ. Using the `fopen` function, you can specify a machine format when you open the file to avoid these errors.

Reading ASCII Data into a Cell Array

A common technique used to read an ASCII data file into a cell array is

```
[a,b,c,d] = textread('data.txt', '%s %s %s %s');
mydata = cellstr([a b c d]);
```

For more information: See the `textread` and `cellstr` function reference pages.

Interactive Input into Your Program

Your program can accept interactive input from users during execution. Use the `input` function to prompt the user for input, and then read in a response. When executed, `input` causes the program to display your prompt, pause while a response is entered, and then resume when the **Enter** key is pressed.

Starting MATLAB

Getting MATLAB to Start Up Faster

Here are some things that you can do to make MATLAB start up faster.

- Make sure toolbox path caching is enabled.
- Make sure that the system on which MATLAB is running has enough RAM.
- Choose only the windows you need in the MATLAB desktop.
- Close the Help browser before exiting MATLAB. When you start your next session, MATLAB will not open the Help browser, and thus will start faster.
- If disconnected from the network, check the `LM_LICENSE_FILE` variable. See http://www.mathworks.com/support/solutions/data/1-17VEB.html for a more detailed explanation.

For more information: See Toolbox Path Caching in MATLAB in the MATLAB Desktop Tools and Development Environment documentation.

Operating System Compatibility

In this section...

Executing O/S Commands from MATLAB

To execute a command from your operating system prompt without having to exit MATLAB, precede the command with the MATLAB `!` operator.

On Windows, you can add an ampersand (`&`) to the end of the line to make the output appear in a separate window.

For more information: See Running External Programs in the MATLAB Desktop Tools and Development Environment documentation, and the `system` and `dos` function reference pages.

Searching Text with grep

`grep` is a powerful tool for performing text searches in files on UNIX systems. To `grep` from within MATLAB, precede the command with an exclamation point (`!grep`).

For example, to search for the word `warning`, ignoring case, in all M-files of the current directory, you would use

```
!grep -i 'warning' *.m
```

Constructing Paths and Filenames

Use the `fullfile` function to construct path names and filenames rather than entering them as strings into your programs. In this way, you always get the correct path specification, regardless of which operating system you are using at the time.

Finding the MATLAB Root Directory

The `matlabroot` function returns the location of the MATLAB installation on your system. Use `matlabroot` to create a path to MATLAB and toolbox directories that does not depend on a specific platform or MATLAB version.

The following example uses `matlabroot` with `fullfile` to return a platform-independent path to the `general` toolbox directory:

```
fullfile(matlabroot,'toolbox','matlab','general')
```

Temporary Directories and Filenames

If you need to locate the directory on your system that has been designated to hold temporary files, use the `tempdir` function. `tempdir` returns a string that specifies the path to this directory.

To create a new file in this directory, use the `tempname` function. `tempname` returns a string that specifies the path to the temporary file directory, plus a unique filename.

For example, to store some data in a temporary file, you might issue the following command first.

```
fid = fopen(tempname, 'w');
```

Demos

Demos Available with MATLAB

MATLAB comes with a wide array of visual demonstrations to help you see the extent of what you can do with the product. To start running any of the demos, simply type `demo` at the MATLAB command prompt. Demos cover the following major areas:

- MATLAB
- Toolboxes
- Simulink
- Blocksets
- Real-Time Workshop®
- Stateflow®

For more information: See Demos in the Help Browser in the MATLAB Desktop Tools and Development Environment documentation, and the `demo` function reference page.

Creating 3-D Graphs

A Typical 3-D Graph

This table illustrates typical steps involved in producing 3-D scenes containing either data graphs or models of 3-D objects. Example applications include pseudocolor surfaces illustrating the values of functions over specific regions and objects drawn with polygons and colored with light sources to produce realism. Usually, you follow either step 4 or step 5.

Step	Typical Code
1 Prepare your data.	`Z = peaks(20);`
2 Select window and position plot region within window.	`figure(1) subplot(2,1,2)`
3 Call 3-D graphing function.	`h = surf(Z);`

4 Set colormap and shading algorithm.	`colormap hot`
	`shading interp`
	`set(h,'EdgeColor','k')`

Step	Typical Code

5 Add lighting.	`light('Position',[-2,2,20])`
	`lighting phong`
	`material([0.4,0.6,0.5,30])`
	`set(h,'FaceColor',[0.7 0.7 0],...`
	`  'BackFaceLighting','lit')`

6 Set viewpoint.	`view([30,25])` `set(gca,'CameraViewAngleMode','Manual')`
7 Set axis limits and tick marks.	`axis([5 15 5 15 -8 8])` `set(gca,'ZTickLabel','Negative||Positive')`
8 Set aspect ratio.	`set(gca,'PlotBoxAspectRatio',[2.5 2.5 1])`

9 Annotate the graph with axis labels, legend, and text.	`xlabel('X Axis')`
	`ylabel('Y Axis')`
	`zlabel('Function Value')`
	`title('Peaks')`

10 Print graph.	`set(gcf,'PaperPositionMode','auto')` `print -dps2`

Line Plots of 3-D Data

In this section...

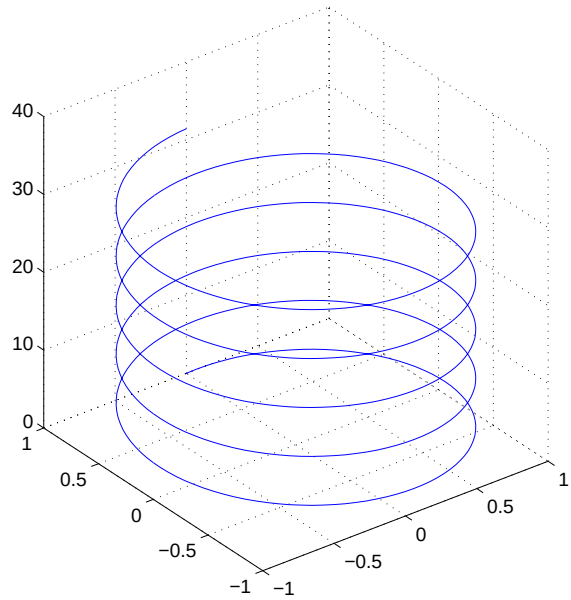
Basic 3-D Plotting: The plot3 function

The 3-D analog of the `plot` function is `plot3`. If `x`, `y`, and `z` are three vectors of the same length,

```
plot3(x,y,z)
```

generates a line in 3-D through the points whose coordinates are the elements of `x`, `y`, and `z` and then produces a 2-D projection of that line on the screen. For example, these statements produce a helix.

```
t = 0:pi/50:10*pi;
plot3(sin(t),cos(t),t)
axis square; grid on
```



Plotting Matrix Data

If the arguments to `plot3` are matrices of the same size, MATLAB© plots lines obtained from the columns of `X`, `Y`, and `Z`. For example,

```
[X,Y] = meshgrid([-2:0.1:2]);
Z = X.*exp(-X.^2-Y.^2);
plot3(X,Y,Z)
grid on
```

Notice how MATLAB cycles through line colors.

Representing a Matrix as a Surface

In this section...

Functions for Plotting Data Grids

MATLAB defines a surface by the *z*-coordinates of points above a rectangular grid in the *x*-*y* plane. The plot is formed by joining adjacent points with straight lines. Surface plots are useful for visualizing matrices that are too large to display in numerical form and for graphing functions of two variables.

MATLAB can create different forms of surface plots. Mesh plots are wire-frame surfaces that color only the lines connecting the defining points. Surface plots display both the connecting lines and the faces of the surface in color. This table lists the various forms.

Function	Used to Create
`mesh, surf`	Surface plot
`meshc, surfc`	Surface plot with contour plot beneath it
`meshz`	Surface plot with curtain plot (reference plane)
`pcolor`	Flat surface plot (value is proportional only to color)
`surfl`	Surface plot illuminated from specified direction
`surface`	Low-level function (on which high-level functions are based) for creating surface graphics objects

Mesh and Surface Plots

The `mesh` and `surf` commands create 3-D surface plots of matrix data. If `Z` is a matrix for which the elements `Z(i,j)` define the height of a surface over an underlying `(i,j)` grid, then

```
mesh(Z)
```

generates a colored, wire-frame view of the surface and displays it in a 3-D view. Similarly,

```
surf(Z)
```

generates a colored, faceted view of the surface and displays it in a 3-D view. Ordinarily, the facets are quadrilaterals, each of which is a constant color, outlined with black mesh lines, but the `shading` command allows you to eliminate the mesh lines (`shading flat`) or to select interpolated shading across the facet (`shading interp`).

Surface object properties provide additional control over the visual appearance of the surface. You can specify edge line styles, vertex markers, face coloring, lighting characteristics, and so on.

Visualizing Functions of Two Variables

The first step in displaying a function of two variables, $z = f(x,y)$, is to generate `X` and `Y` matrices consisting of repeated rows and columns, respectively, over the domain of the function. Then use these matrices to evaluate and graph the function.

The `meshgrid` function transforms the domain specified by two vectors, `x` and `y`, into matrices `X` and `Y`. You then use these matrices to evaluate functions of two variables. The rows of `X` are copies of the vector `x` and the columns of `Y` are copies of the vector `y`.

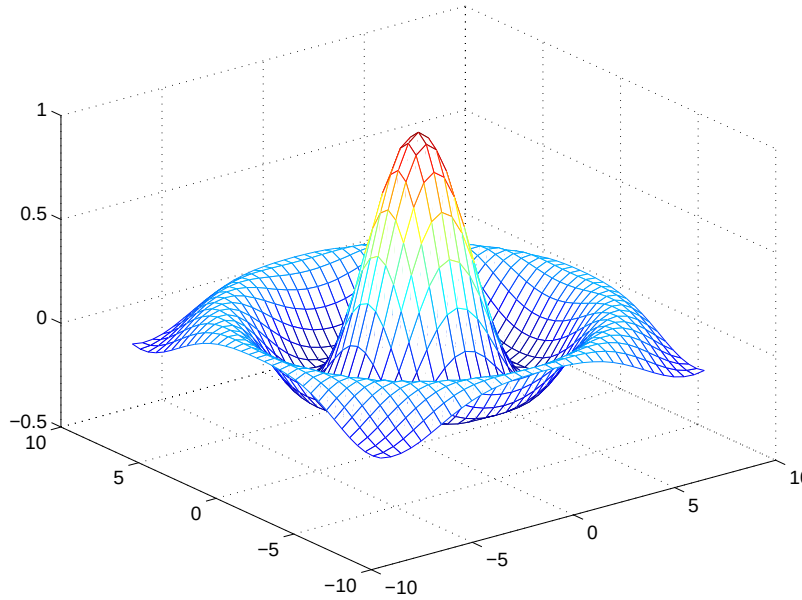
To illustrate the use of `meshgrid`, consider the `sin(r)/r` or `sinc` function. To evaluate this function between -8 and 8 in both x and y, you need pass only one vector argument to `meshgrid`, which is then used in both directions.

```
[X,Y] = meshgrid(-8:.5:8);
R = sqrt(X.^2 + Y.^2) + eps;
```

The matrix `R` contains the distance from the center of the matrix, which is the origin. Adding `eps` prevents the divide by zero (in the next step) that produces `Inf` values in the data.

Forming the `sinc` function and plotting `Z` with `mesh` results in the 3-D surface.

```
Z = sin(R)./R;
mesh(X,Y,Z)
```

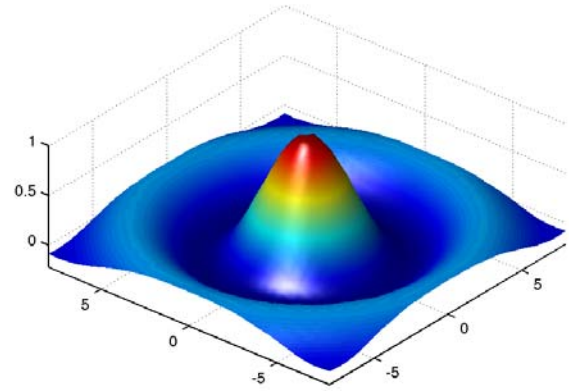


Emphasizing Surface Shape

MATLAB provides a number of techniques that can enhance the information content of your graphs. For example, this graph of the `sinc` function uses the same data as the previous graph, but employs lighting and view adjustment to emphasize the shape of the graphed function (`daspect`, `axis`, `view`, `camlight`).

```
surf(X,Y,Z,'FaceColor','interp',...
 'EdgeColor','none',...
 'FaceLighting','phong')
```

```
daspect([5 5 1])
axis tight
view(-50,30)
camlight left
```



See the `surf` function for more information on surface plots.

Surface Plots of Nonuniformly Sampled Data

You can use `meshgrid` to create a grid of uniformly sampled data points at which to evaluate and graph the `sinc` function. MATLAB then constructs the surface plot by connecting neighboring matrix elements to form a mesh of quadrilaterals.

To produce a surface plot from nonuniformly sampled data, first use `griddata` to interpolate the values at uniformly spaced points, and then use `mesh` and `surf` in the usual way.

Example — Displaying Nonuniform Data on a Surface

This example evaluates the `sinc` function at random points within a specific range and then generates uniformly sampled data for display as a surface plot. The process involves these tasks:

- Use `linspace` to generate evenly spaced values over the range of your unevenly sampled data.
- Use `meshgrid` to generate the plotting grid with the output of `linspace`.
- Use `griddata` to interpolate the irregularly sampled data to the regularly spaced grid returned by `meshgrid`.
- Use a plotting function to display the data.

1 First, generate unevenly sampled data within the range [-8, 8] and use it to evaluate the function.

```
x = rand(100,1)*16 - 8;
y = rand(100,1)*16 - 8;
r = sqrt(x.^2 + y.^2) + eps;
z = sin(r)./r;
```

2 The `linspace` function provides a convenient way to create uniformly spaced data with the desired number of elements. The following statements produce vectors over the range of the random data with the same resolution as that generated by the -8:.5:8 statement in the previous `sinc` example.

```
xlin = linspace(min(x),max(x),33);
ylin = linspace(min(y),max(y),33);
```

3 Now use these points to generate a uniformly spaced grid.

```
[X,Y] = meshgrid(xlin,ylin);
```

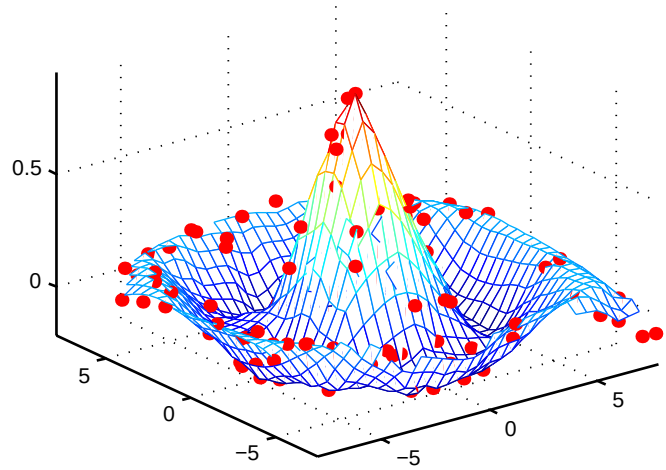
4 The key to this process is to use `griddata` to interpolate the values of the function at the uniformly spaced points, based on the values of the function at the original data points (which are random in this example). This statement uses a triangle-based cubic interpolation to generate the new data.

```
Z = griddata(x,y,z,X,Y,'cubic');
```

5 Plotting the interpolated and the nonuniform data produces

```
mesh(X,Y,Z) %interpolated
axis tight; hold on
```

```
plot3(x,y,z,'.','MarkerSize',15) %nonuniform
```



Parametric Surfaces

The functions that draw surfaces can take two additional vector or matrix arguments to describe surfaces with specific *x* and *y* data. If `Z` is an *m*-by-*n* matrix, `x` is an *n*-vector, and `y` is an *m*-vector, then

```
mesh(x,y,Z,C)
```

describes a mesh surface with vertices having color `C(i,j)` and located at the points

```
(x(j), y(i), Z(i,j))
```

where `x` corresponds to the columns of `Z` and `y` to its rows.

More generally, if `X`, `Y`, `Z`, and `C` are matrices of the same dimensions, then

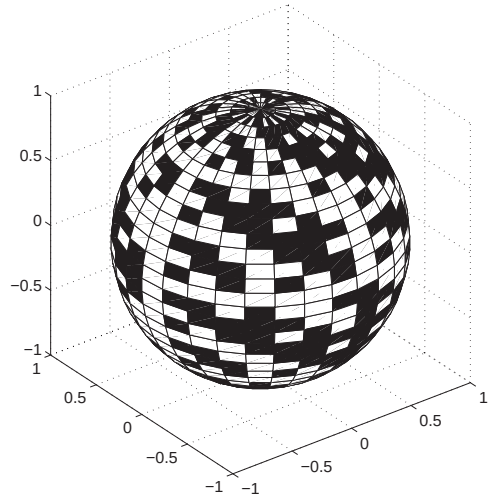
```
mesh(X,Y,Z,C)
```

describes a mesh surface with vertices having color `C(i,j)` and located at the points

```
(X(i,j), Y(i,j), Z(i,j))
```

This example uses spherical coordinates to draw a sphere and color it with the pattern of pluses and minuses in a Hadamard matrix, an orthogonal matrix used in signal processing coding theory. The vectors `theta` and `phi` are in the range $-\pi \le$ `theta` $\le \pi$ and $-\pi/2 \le$ `phi` $\le \pi/2$. Because `theta` is a row vector and `phi` is a column vector, the multiplications that produce the matrices `X`, `Y`, and `Z` are vector outer products.

```
k = 5;
n = 2^k-1;
theta = pi*(-n:2:n)/n;
phi = (pi/2)*(-n:2:n)'/n;
X = cos(phi)*cos(theta);
Y = cos(phi)*sin(theta);
Z = sin(phi)*ones(size(theta));
colormap([0 0 0;1 1 1])
C = hadamard(2^k);
surf(X,Y,Z,C)
axis square
```



Hidden Line Removal

By default, MATLAB removes lines that are hidden from view in mesh plots, even though the faces of the plot are not colored. You can disable hidden line removal and allow the faces of a mesh plot to be transparent with the command

```
hidden off
```

This is the surface plot with `hidden` set to `off`.

Coloring Mesh and Surface Plots

In this section...

Coloring Techniques

You can enhance the information content of surface plots by controlling the way MATLAB applies color to these plots. MATLAB can map particular data values to colors specified explicitly or can map the entire range of data to a predefined range of colors called a *colormap*.

You can apply three different coloring techniques:

- Indexed Color -- MATLAB colors the surface plot by assigning each data point an index into the figure's colormap. The way MATLAB applies these colors depends on the type of shading used (faceted, flat, or interpolated).
- Truecolor — MATLAB colors the surface plot using the explicitly specified colors (i.e., the RGB triplets). The way MATLAB applies these colors depends on the type of shading used (faceted, flat, or interpolated). To be rendered accurately, truecolor requires computers with 24-bit displays; however, MATLAB simulates truecolor on indexed systems. See the `shading` command for information on the types of shading.
- Texture Mapping -- Texture mapping displays a 2-D image mapped onto a 3-D surface.

Types of Color Data

The type of color data you specify (i.e., single values or RGB triplets) determines how MATLAB interprets it. When you create a surface plot, you can

- Provide no explicit color data, in which case MATLAB generates colormap indices from the *z*-data.
- Specify an array of color data that is equal in size to the *z*-data and is used for indexed colors.
- Specify an *m*-by-*n*-by-3 array of color data that defines an RGB triplet for each element in the *m*-by-*n* *z*-data array and is used for truecolor.

Colormaps

Each MATLAB figure window has a colormap associated with it. A colormap is simply a three-column matrix whose length is equal to the number of colors it defines. Each row of the matrix defines a particular color by specifying three values in the range 0 to 1. These values define the RGB components (i.e., the intensities of the red, green, and blue video components).

The `colormap` function, with no arguments, returns the current figure's colormap.

For example, the MATLAB default colormap contains 64 colors and the 57th color is red.

```
cm = colormap;
cm(57,:)
ans =
      1  0  0
```

RGB Color Components

This table lists some representative RGB color definitions.

Red	Green	Blue	Color
0	0	0	Black
1	1	1	White
1	0	0	Red
0	1	0	Green
0	0	1	Blue
1	1	0	Yellow
1	0	1	Magenta
0	1	1	Cyan
0.5	0.5	0.5	Gray
0.5	0	0	Dark red
1	0.62	0.40	Copper
0.49	1	0.83	Aquamarine

You can create colormaps with MATLAB array operations or you can use any of several functions that generate useful maps, including `hsv`, `hot`, `cool`, `summer`, and `gray`. Each function has an optional parameter that specifies the number of rows in the resulting map.

For example,

```
hot(m)
```

creates an *m*-by-3 matrix whose rows specify the RGB intensities of a map that varies from black, through shades of red, orange, and yellow, to white.

If you do not specify the colormap length, MATLAB creates a colormap the same length as the current colormap. The default colormap is `jet(64)`.

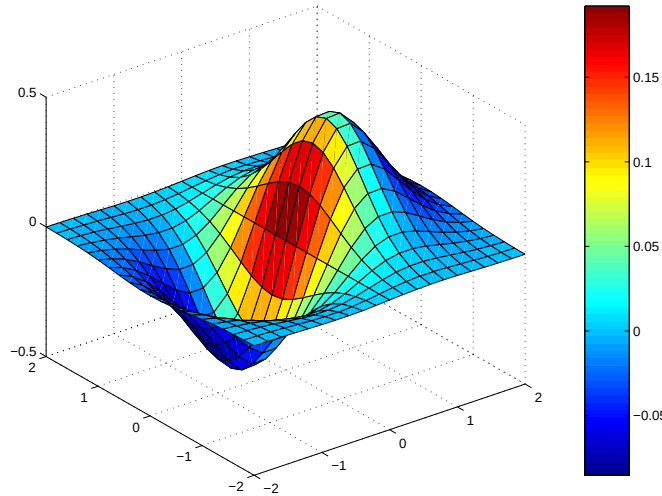
If you use long colormaps (> 64 colors) in each of several figure windows, it might become necessary for the operating system to swap in different color lookup tables as the active focus is moved among the windows.

Displaying Colormaps

The `colorbar` function displays the current colormap, either vertically or horizontally, in the figure window along with your graph. For example, the statements

```
[x,y] = meshgrid([-2:.2:2]);
Z = x.*exp(-x.^2-y.^2);
surf(x,y,Z,gradient(Z))
colorbar
```

produce a surface plot and a vertical strip of color corresponding to the colormap. Note how the colorbar indicates the mapping of data value to color with the axis labels.



Indexed Color Surfaces — Direct and Scaled Color Mapping

MATLAB can use two different methods to map indexed color data to the colormap — direct and scaled.

Direct Mapping

Direct mapping uses the color data directly as indices into the colormap. For example, a value of 1 points to the first color in the colormap, a value of 2 points to the second color, and so on. If the color data is noninteger, MATLAB rounds it toward zero. Values greater than the number of colors in the colormap are set equal to the last color in the colormap (i.e., the number `length(colormap)`). Values less than 1 are set to 1.

Scaled Mapping

Scaled mapping uses a two-element vector `[cmin cmax]` (specified with the `caxis` command) to control the mapping of color data to the figure colormap. `cmin` specifies the data value to map to the first color in the colormap and `cmax` specifies the data value to map to the last color in the colormap. Data values in between are linearly transformed from the second to the next-to-last color, using the expression

```
colormap_index = fix((color_data-cmin)/(cmax-cmin)*cm_length)+1
```

`cm_length` is the length of the colormap.

By default, MATLAB sets `cmin` and `cmax` to span the range of the color data of all graphics objects within the axes. However, you can set these limits to any range of values. This enables you to display multiple axes within a single figure window and use different portions of the figure's colormap for each one. See Calculating Color Limits in Axes Properties of the Using MATLAB Graphics documentation for an example that uses color limits.

By default, MATLAB uses scaled mapping. To use direct mapping, you must turn off scaling when you create the plot. For example,

```
surf(Z,C,'CDataMapping','direct')
```

See `surface` for more information on specifying color data.

Specifying Indexed Colors

When creating a surface plot with a single matrix argument, `surf(Z)` for example, the argument `Z` specifies both the height and the color of the surface. MATLAB transforms `Z` to obtain indices into the current colormap.

With two matrix arguments, the statement

```
surf(Z,C)
```

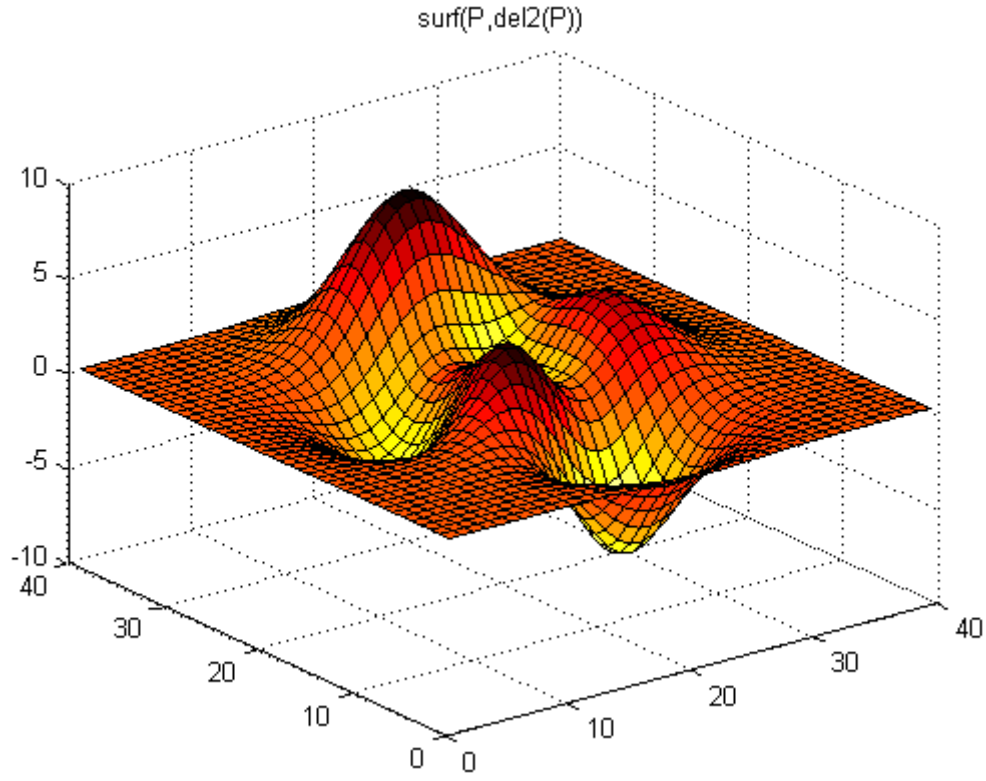
independently specifies the color using the second argument.

Example — Mapping Surface Curvature to Color

The Laplacian of a surface plot is related to its curvature; it is positive for functions shaped like `i^2 + j^2` and negative for functions shaped like `-(i^2 + j^2)`. The function `del2` computes the discrete Laplacian of any matrix. For example, use `del2` to determine the color for the data returned by `peaks`.

```
P = peaks(40);
C = del2(P);
surf(P,C)
colormap hot
```

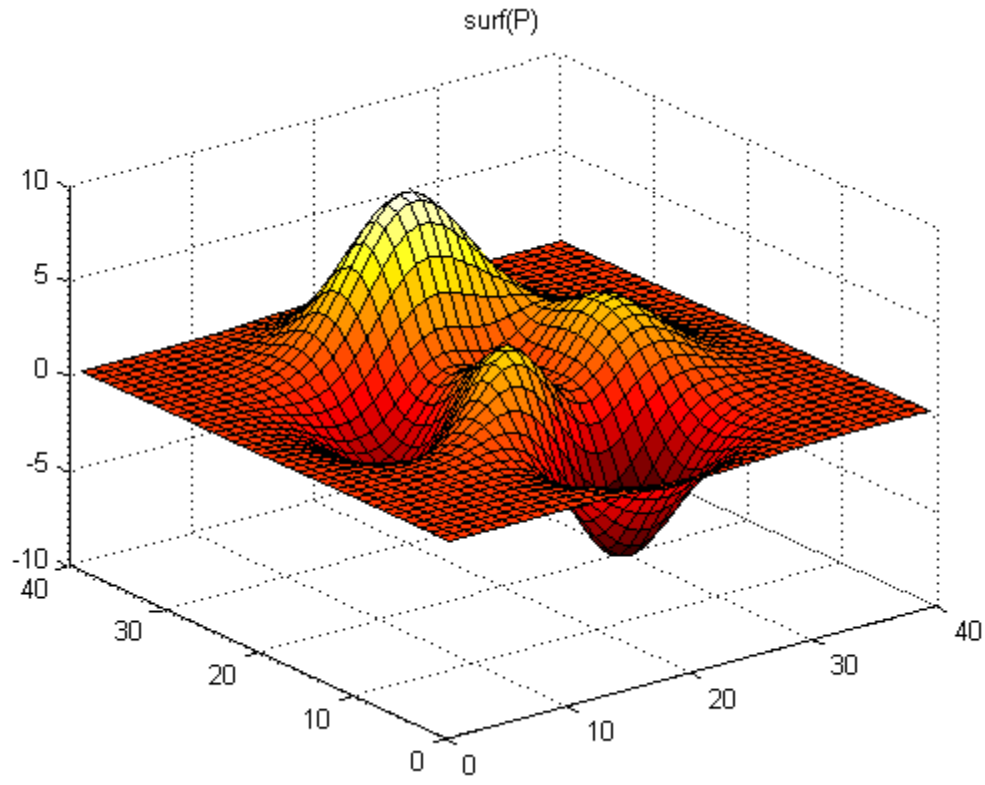
Creating a color array by applying the Laplacian to the data is useful because it causes regions with similar curvature to be drawn in the same color.



Compare this surface coloring with that produced by the statements

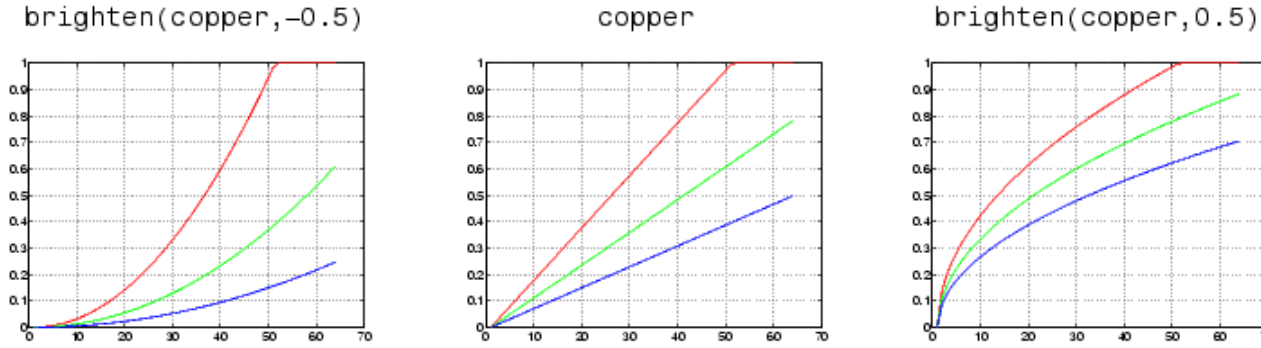
```
surf(P)
colormap hot
```

which use the same colormap, but map regions with similar z value (height above the x-y plane) to the same color.



Altering Colormaps

Because colormaps are matrices, you can manipulate them like other arrays. The `brighten` function takes advantage of this fact to increase or decrease the intensity of the colors. Plotting the values of the R, G, and B components of a colormap using `rgbplot` illustrates the effects of `brighten`.



NTSC Color Encoding

The brightness component of television signals uses the NTSC color encoding scheme.

```
b = .30*red + .59*green + .11*blue
  = sum(diag([.30 .59 .11])*map')';
```

Using the nonlinear greyscale map,

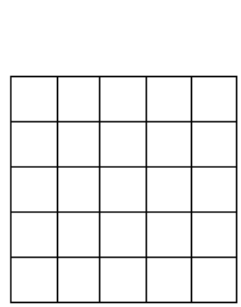
```
colormap([b b b])
```

effectively converts a color image to its NTSC black-and-white equivalent.

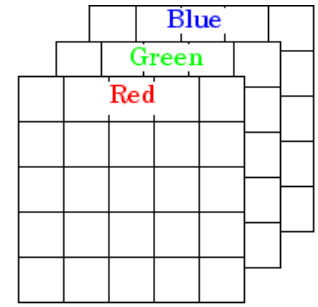
Truecolor Surfaces

Computer systems with 24-bit displays are capable of displaying over 16 million (2^{24}) colors, as opposed to the 256 colors available on 8-bit displays. You can take advantage of this capability by defining color data directly as RGB values and eliminating the step of mapping numerical values to locations in a colormap.

Specify truecolor using an *m*-by-*n*-by-3 array, where the size of `Z` is *m*-by-*n*.



m-by-*n* matrix defining surface plot

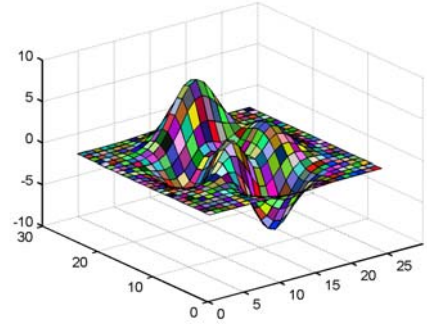


Corresponding *m*-by-*n*-by-3 matrix specifying truecolor for the surface plot

For example, the statements

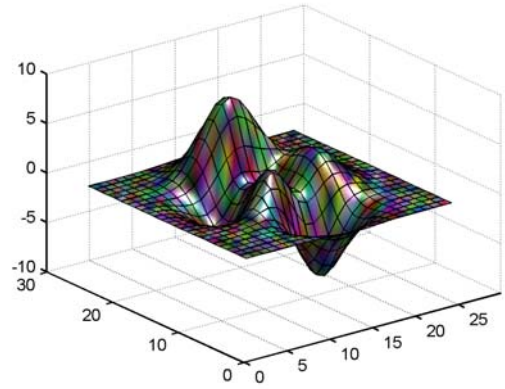
```
Z = peaks(25);
C(:,:,1) = rand(25);
C(:,:,2) = rand(25);
C(:,:,3) = rand(25);
surf(Z,C)
```

create a plot of the `peaks` matrix with random coloring.



You can set surface properties as with indexed color.

```
surf(Z,C,'FaceColor','interp','FaceLighting','phong')
camlight right
```



Rendering Methods for Truecolor

MATLAB always uses either OpenGL or the Z-buffer rendering method when displaying truecolor. If the figure `RendererMode` property is set to `auto`, MATLAB automatically switches the value of the `Renderer` property to `zbuffer` whenever you specify truecolor data.

If you explicitly set `Renderer` to `painters` (this sets `RendererMode` to `manual`) and attempt to define an image, patch, or surface object using truecolor, MATLAB returns a warning and does not render the object.

See the `image`, `patch`, and `surface` functions for information on defining truecolor for these objects.

Texture Mapping

Texture mapping is a technique for mapping a 2-D image onto a 3-D surface by transforming color data so that it conforms to the surface plot. It allows you to apply a "texture," such as bumps or wood grain, to a surface without performing the geometric modeling necessary to create a surface with these features. The color data can also be any image, such as a scanned photograph.

Texture mapping allows the dimensions of the color data array to be different from the data defining the surface plot. You can apply an image of arbitrary

size to any surface. MATLAB interpolates texture color data so that it is mapped to the entire surface.

Example — Texture Mapping a Surface

This example creates a spherical surface using the `sphere` function and texture maps it with an image of the earth taken from space. Because the earth image is a view of earth from one side, this example maps the image to only one side of the sphere, padding the image data with 1s In this case, the image data is a 257-by-250 matrix, so it is padded equally on each side with two 257-by-125 matrices of 1s by concatenating the three matrices.

To use texture mapping, set the `FaceColor` to `texturemap` and assign the image to the surface's `CData`.

```
load earth % Load image data, X, and colormap, map
sphere; h = findobj('Type','surface');
hemisphere = [ones(257,125),...
              X,...
              ones(257,125)];
set(h,'CData',flipud(hemisphere),'FaceColor','texturemap')
colormap(map)
axis equal
view([90 0])
set(gca,'CameraViewAngleMode','manual')
view([65 30])
```

Defining the View

Viewing Overview

In this section...

Viewing 3-D Graphs and Scenes

The *view* is the particular orientation you select to display your graph or graphical scene. The term *viewing* refers to the process of displaying a graphical scene from various directions, zooming in or out, changing the perspective and aspect ratio, flying by, and so on.

This section describes how to define the various viewing parameters to obtain the view you want. Generally, viewing is applied to 3-D graphs or models, although you might want to adjust the aspect ratio of 2-D views to achieve specific proportions or make a graph fit in a particular shape.

MATLAB viewing is composed of two basic areas:

- Positioning the viewpoint to orient the scene
- Setting the aspect ratio and relative axis scaling to control the shape of the objects being displayed

Positioning the Viewpoint

- Setting the Viewpoint -- Discusses how to specify the point from which you view a graph in terms of azimuth and elevation. This is conceptually simple, but does have limitations.
- Defining Scenes with Camera Graphics, View Control with the Camera Toolbar, and Camera Graphics Functions — How to compose complex scenes using the MATLAB camera viewing model.
- Dollying the Camera and Moving the Camera Through a Scene -- Programming techniques for moving the view around and through scenes.

- Low-Level Camera Properties — The graphics properties that control the camera and illustrates the effects they cause.

Setting the Aspect Ratio

- View Projection Types -- Describes orthographic and perspective projection types and illustrates their use.
- Understanding Axes Aspect Ratio and Axes Aspect Ratio Properties — How MATLAB sets the aspect ratio of the axes and how you can select the most appropriate setting for your graphs.

Default Views

MATLAB automatically sets the view when you create a graph. The actual view that MATLAB selects depends on whether you are creating a 2- or 3-D graph. See “Default Viewpoint Selection” on page 2-31 and “Default Aspect Ratio Selection” on page 2-48 for a description of how MATLAB defines the standard view.

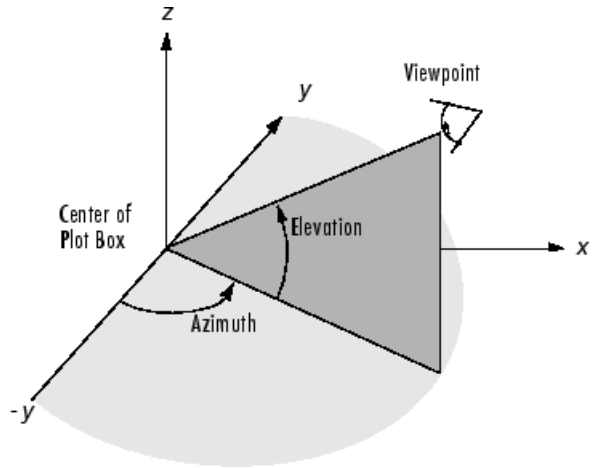
Setting the Viewpoint with Azimuth and Elevation

Azimuth and Elevation

MATLAB enables you to control the orientation of the graphics displayed in an axes. You can specify the viewpoint, view target, orientation, and extent of the view displayed in a figure window. These viewing characteristics are controlled by a set of graphics properties. You can specify values for these properties directly or you can use the `view` command and rely on MATLAB automatic property selection to define a reasonable view.

The `view` command specifies the viewpoint by defining azimuth and elevation with respect to the axis origin. Azimuth is a polar angle in the *x*-*y* plane, with positive angles indicating counterclockwise rotation of the viewpoint. Elevation is the angle above (positive angle) or below (negative angle) the *x*-*y* plane.

This diagram illustrates the coordinate system. The arrows indicate positive directions.



Default 2-D and 3-D Views

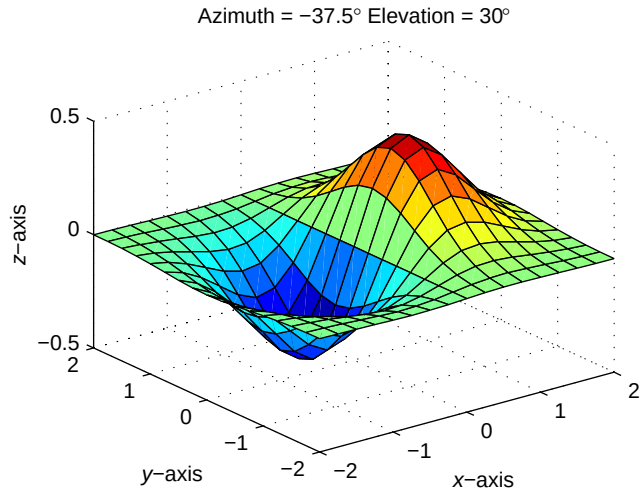
MATLAB automatically selects a viewpoint that is determined by whether the plot is 2-D or 3-D:

- For 2-D plots, the default is azimuth = 0° and elevation = 90°.
- For 3-D plots, the default is azimuth = -37.5° and elevation = 30°.

Examples of Views Specified with Azimuth and Elevation

For example, these statements create a 3-D surface plot and display it in the default 3-D view.

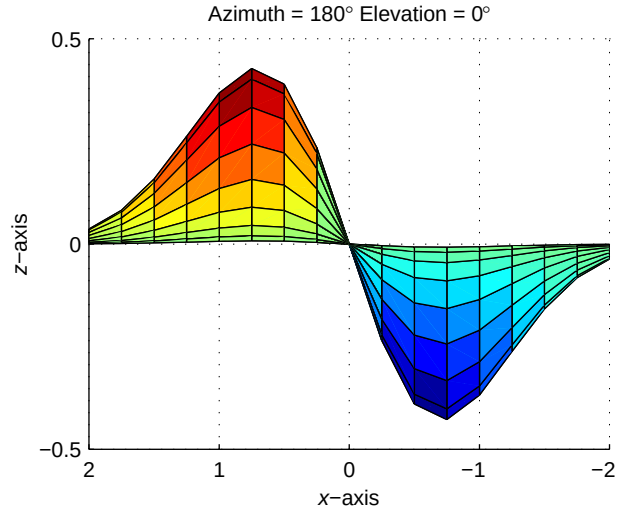
```
[X,Y] = meshgrid([-2:.25:2]);
Z = X.*exp(-X.^2 -Y.^2);
surf(X,Y,Z)
```



The statement

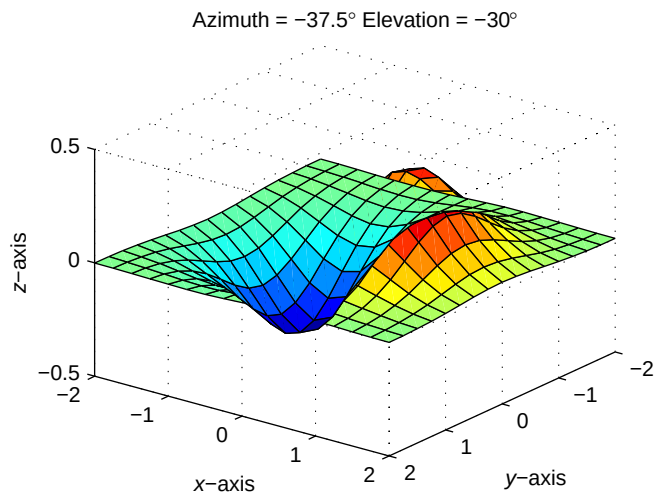
```
view([180 0])
```

sets the viewpoint so you are looking in the negative *y*-direction with your eye at the $z = 0$ elevation.



You can move the viewpoint to a location below the axis origin using a negative elevation.

```
view([-37.5 -30])
```



Limitations of Azimuth and Elevation

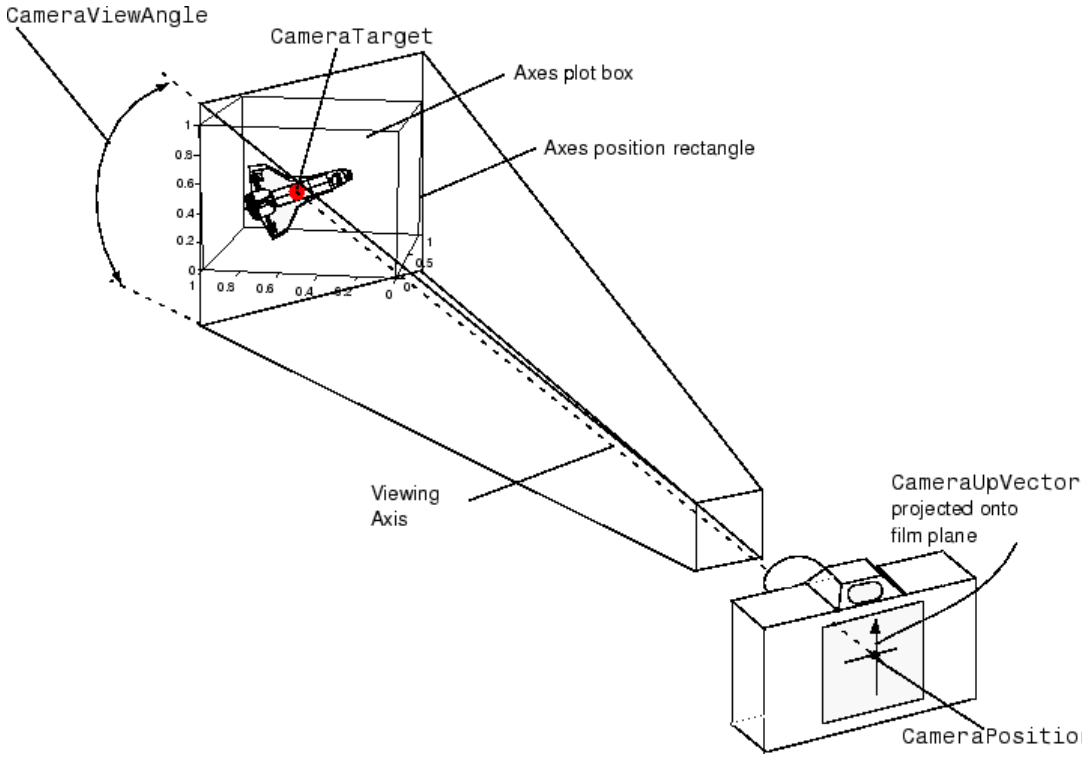
Specifying the viewpoint in terms of azimuth and elevation is conceptually simple, but it has limitations. It does not allow you to specify the actual position of the viewpoint, just its direction, and the *z*-axis is always pointing up. It does not allow you to zoom in and out on the scene or perform arbitrary rotations and translations.

MATLAB camera graphics provides greater control than the simple adjustments allowed with azimuth and elevation. The following sections discuss how to use camera properties to control the view.

Defining Scenes with Camera Graphics

When you look at the graphics objects displayed in an axes, you are viewing a scene from a particular location in space that has a particular orientation with regard to the scene. MATLAB provides functionality, analogous to that of a camera with a zoom lens, that enables you to control the view of the scene created by MATLAB.

This picture illustrates how the camera is defined in terms of properties of the axes.



View Control with the Camera Toolbar

In this section...

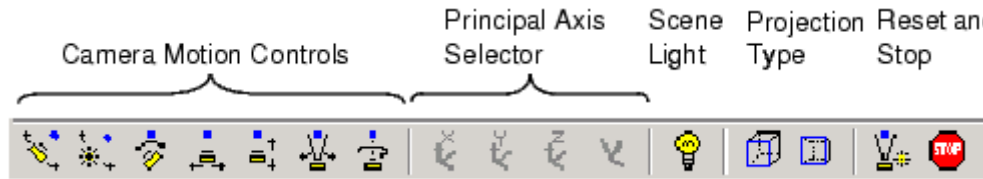
Camera Toolbar

The Camera toolbar enables you to perform a number of viewing operations interactively. To use the Camera toolbar,

- Display the toolbar by selecting **Camera Toolbar** from the figure window’s **View** menu.
- Select the type of camera motion control you want to use.
- Position the cursor over the figure window and click, hold down the right mouse button, then move the cursor in the desired direction.

MATLAB updates the display immediately as you move the mouse.

The toolbar contains the following parts:



- Camera Motion Controls — These tools select which camera motion function to enable. You can also access the camera motion controls from the **Tools** menu.
- Principal Axis Selector — Some camera controls operate with respect to a particular axis. These selectors enable you to select the principal axis or to select nonaxis constrained motion. The selectors are grayed out when not applicable to the currently selected function. You can also access the principal axis selector from the **Tools** menu.
- Scene Light — The scene light button toggles a light source on or off in the scene (one light per axes).
- Projection Type — You can select orthographic or perspective projection types.
- Reset and Stop — Reset returns the scene to the standard 3-D view. Stop causes the camera to stop moving (this can be useful if you apply too much cursor movement). You can also access an expanded set of reset functions from the **Tools** menu.

Principal Axes

The principal axis of a scene defines the direction that is oriented upward on the screen. For example, a MATLAB surface plot aligns the up direction along the positive *z*-axis.

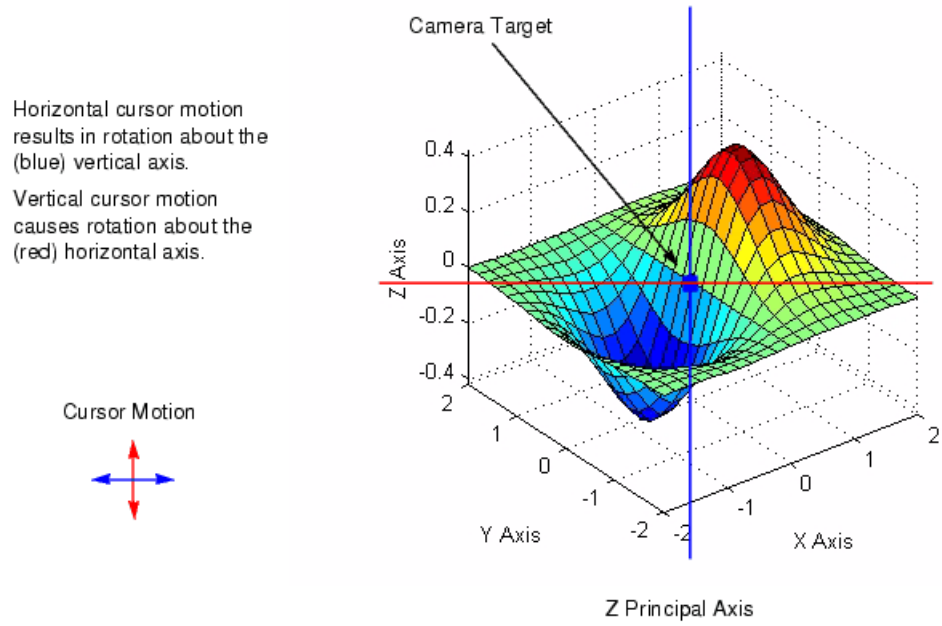
Principal axes constrain camera-tool motion along axes that are (on the screen) parallel and perpendicular to the principal axis that you select. Specifying a principal axis is useful if your data is defined with respect to a specific axis. Z is the default principal axis, because this matches the MATLAB default 3-D view.

Two of the camera tools (Orbit and Pan/Tilt) allow you to select a principal axis as well as axis-free motion. On the screen, the axes of rotation are determined by a vertical and a horizontal line, both of which pass through the point defined by the `CameraTarget` property and are parallel and perpendicular to the principal axis.

For example, when the principal axis is z, movement occurs about

- A vertical line that passes through the camera target and is parallel to the *z*-axis
- A horizontal line that passes through the camera target and is perpendicular to the *z*-axis

This means the scene (or camera, as the case may be) moves in an arc whose center is at the camera target. The following picture illustrates the rotation axes for a *z* principal axis.

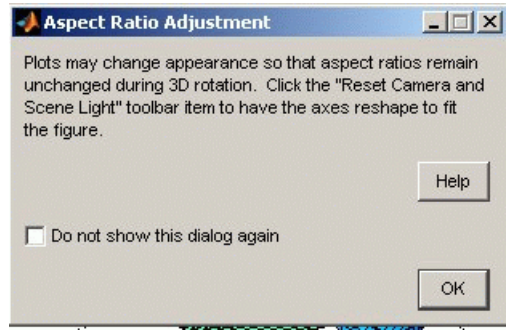


The axes of rotation always pass through the camera target.

Optimizing for 3-D Camera Motion

When you create a plot, MATLAB displays it with an aspect ratio that fits the figure window. This behavior might not create an optimum situation for the manipulation of 3-D graphics, as it can lead to distortion as you move the camera around the scene. To avoid possible distortion, it is best to switch to a 3-D visualization mode (enabled from the command line with the command

`axis vis3d`). When using the Camera toolbar, MATLAB automatically switches to the 3-D visualization mode, but warns you first with the following dialog box.



This dialog box appears only once per MATLAB session.

For more information about the underlying effects of related camera properties, see “Understanding Axes Aspect Ratio” on page 2-42. The next section, “Camera Motion Controls” on page 2-13, discusses how to use each tool.

Camera Motion Controls

This section discusses the individual camera motion functions selectable from the toolbar.

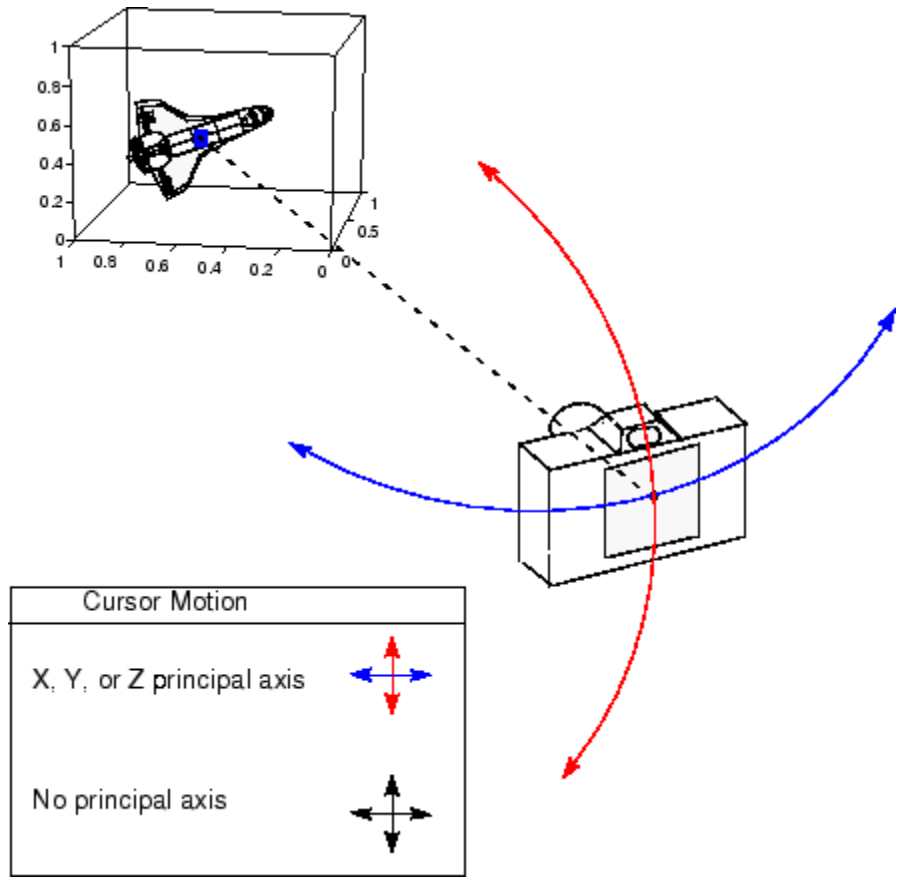
Note When interpreting the following diagrams, keep in mind that the camera always points towards the camera target. See “Defining Scenes with Camera Graphics” on page 2-9 for an illustration of the graphics properties involved in camera motion.

Orbit Camera

Orbit Camera rotates the camera about the *z*-axis (by default). You can select *x*-, *y*-, *z*-, or free-axis rotation using the Principal Axis Selectors. When using no principal axis, you can rotate about an arbitrary axis.

Graphics Properties

Orbit Camera changes the `CameraPosition` property while keeping the `CameraTarget` fixed.



Orbit Scene Light

The scene light is a light source that is placed with respect to the camera position. By default, the scene light is positioned to the right of the camera (i.e., `camlight right`). Orbit Scene Light changes the light's offset from the camera position. There is only one scene light; however, you can add other lights using the `light` command.

Toggle the scene light on and off by clicking the yellow light bulb icon.

Graphics Properties

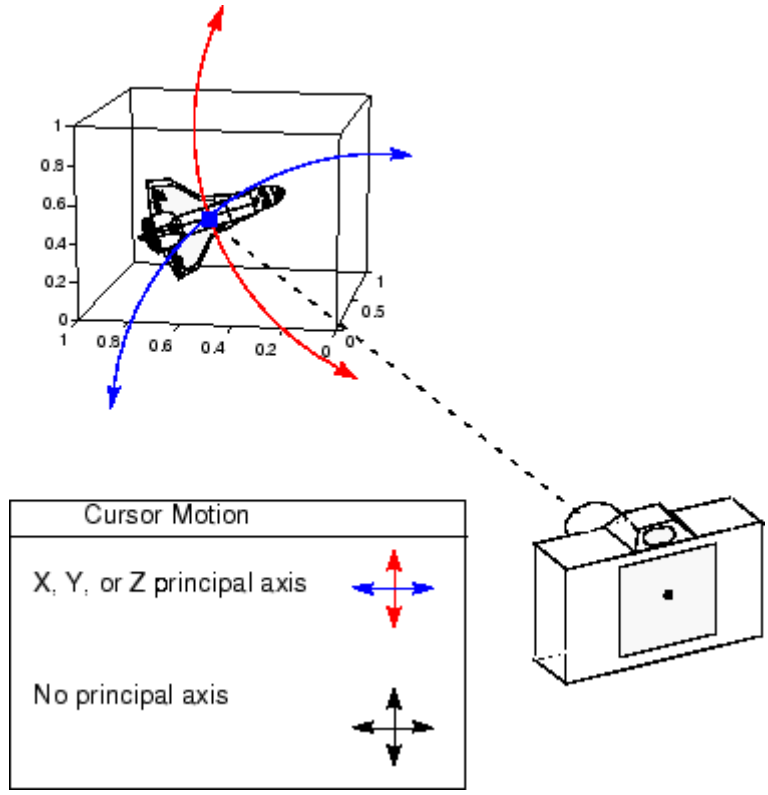
Orbit Scene Light moves the scene light by changing the light's `Position` property.

Pan/Tilt Camera

Pan/Tilt Camera moves the point in the scene that the camera points to while keeping the camera fixed. The movement occurs in an arc about the *z*-axis by default. You can select *x*-, *y*-, *z*-, or free-axis rotation using the Principal Axes Selectors.

Graphics Properties

Pan/Tilt Camera moves the point in the scene that the camera is pointing to by changing the `CameraTarget` property.

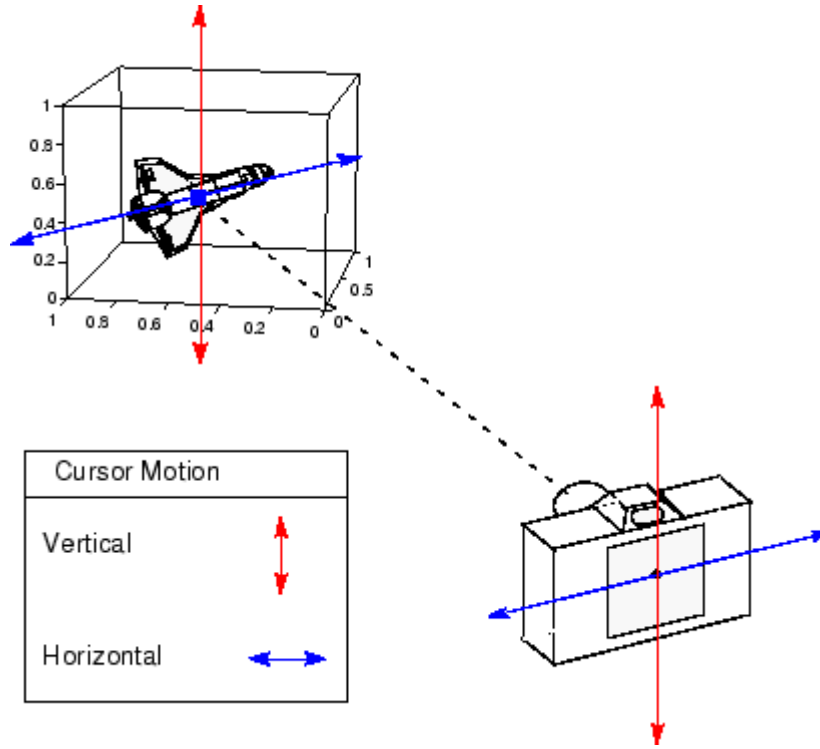


Move Camera Horizontally/Vertically

Moving the cursor horizontally or vertically (or any combination of the two) moves the scene in the same direction.

Graphics Properties

The horizontal and vertical movement is achieved by moving the `CameraPosition` and the `CameraTarget` in unison along parallel lines.

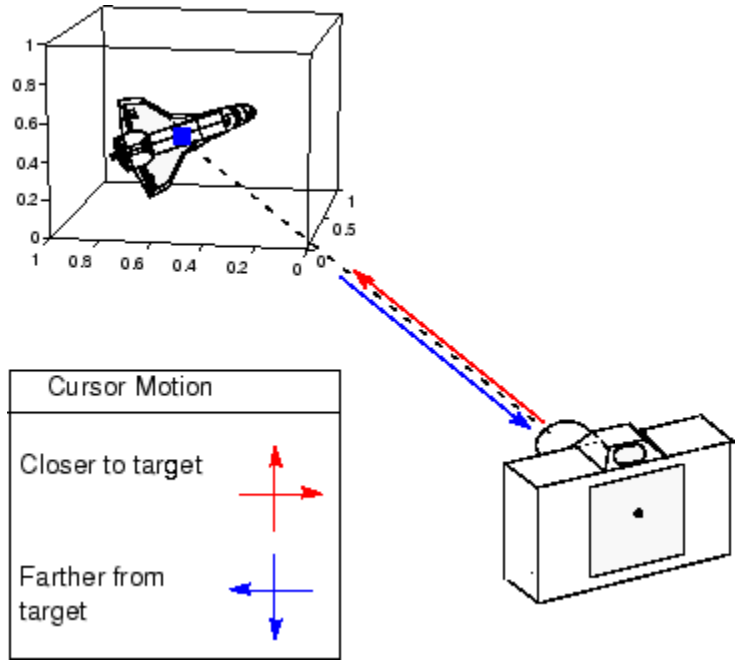


Move Camera Forward and Backward

Moving the cursor up or to the right moves the camera toward the scene. Moving the cursor down or to the left moves the camera away from the scene. It is possible to move the camera through objects in the scene and to the other side of the camera target.

Graphics Properties

This function moves the `CameraPosition` along the line connecting the camera position and the camera target.

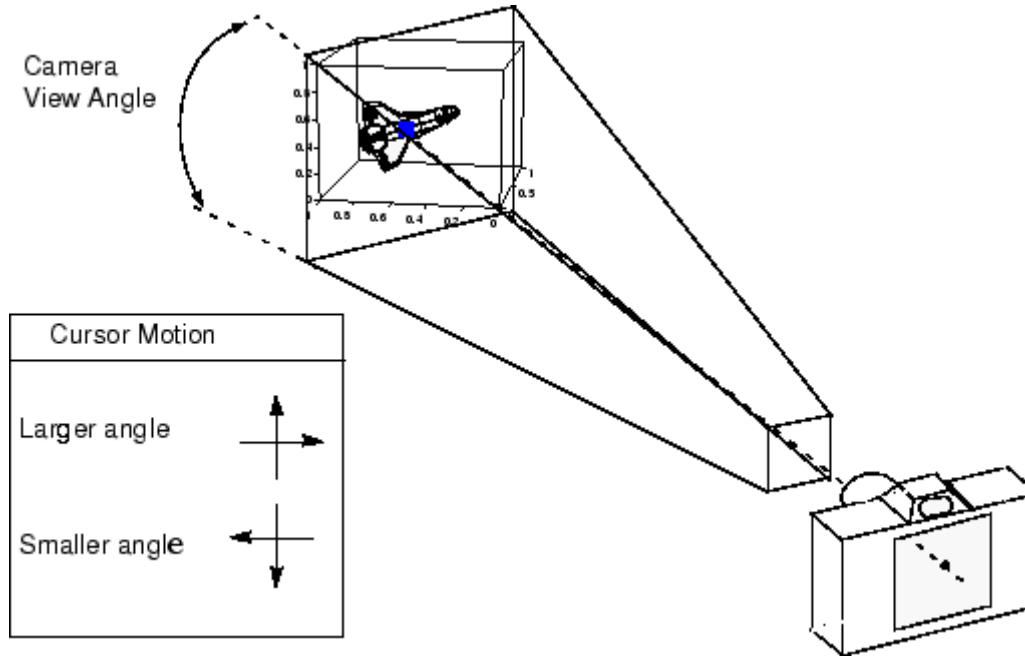


Zoom Camera

Zoom Camera makes the scene larger as you move the cursor up or to the right and smaller as you move the cursor down or to the left. Zooming does not move the camera and therefore cannot move the viewpoint through objects in the scene.

Graphics Properties

Zoom is implemented by changing the `CameraViewAngle`. The larger the angle, the smaller the scene appears, and vice versa.

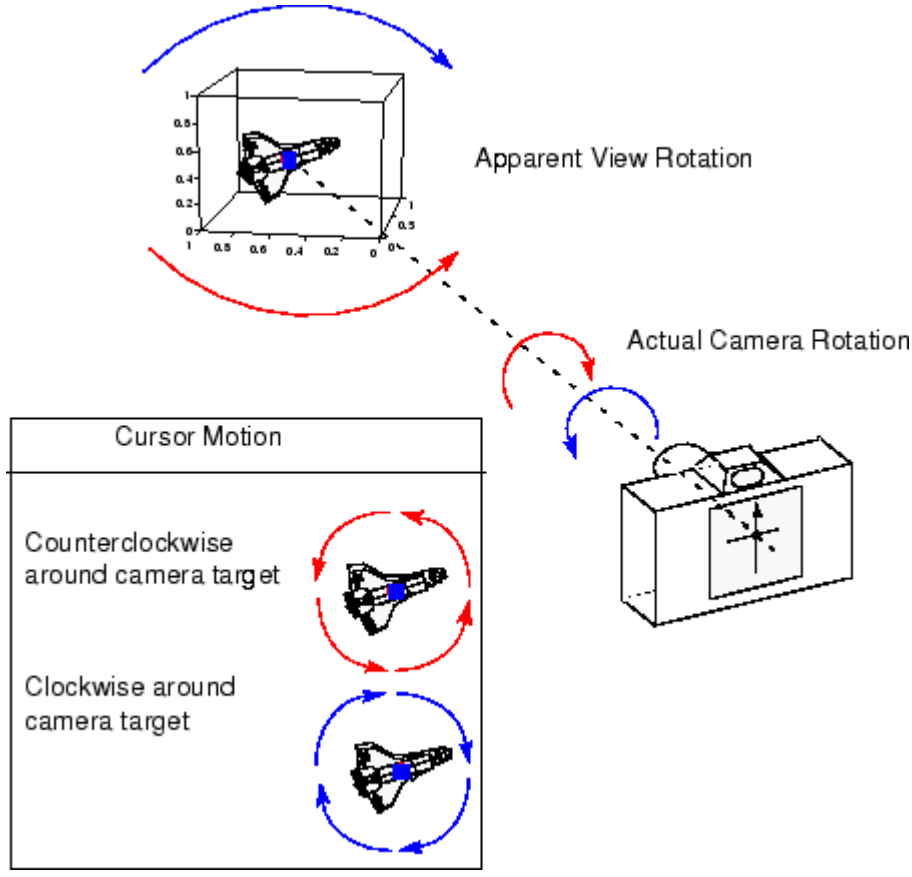


Camera Roll

Camera Roll rotates the camera about the viewing axis, thereby rotating the view on the screen.

Graphics Properties

Camera Roll changes the `CameraUpVector`.



Apparent View Rotation
Actual Camera Rotation
Cursor Motion
Counterclockwise around camera target
Clockwise around camera target

Camera Graphics Functions

The following table lists MATLAB functions that enable you to perform a number of useful camera maneuvers. The individual command descriptions provide information on using each one.

Function	Purpose
`camdolly`	Move camera position and target
`camlookat`	View specific objects
`camorbit`	Orbit the camera about the camera target
`campan`	Rotate the camera target about the camera position
`campos`	Set or get the camera position
`camproj`	Set or get the projection type (orthographic or perspective)
`camroll`	Rotate the camera about the viewing axis
`camtarget`	Set or get the camera target location
`camup`	Set or get the value of the camera up vector
`camva`	Set or get the value of the camera view angle
`camzoom`	Zoom the camera in or out on the scene

Example — Dollying the Camera

In this section...

Summary of Techniques

In the camera metaphor, a dolly is a stage that enables movement of the camera from side to side with respect to the scene. The `camdolly` command implements similar behavior by moving both the position of the camera and the position of the camera target in unison (or just the camera position if you so desire).

This example illustrates how to use `camdolly` to explore different regions of an image. It shows how to use the following functions:

- `ginput` to obtain the coordinates of locations on the image
- The `camdolly` `data` coordinates option to move the camera and target to the new position based on coordinates obtained from `ginput`
- `camva` to zoom in and to fix the camera view angle, which is otherwise under automatic control

Implementation

First load the Cape Cod image and zoom in by setting the camera view angle (using `camva`).

```
load cape
image(X)
colormap(map)
axis image
camva(camva/2.5)
```

Then use `ginput` to select the *x*- and *y*-coordinates of the camera target and camera position.

```
while 1
```

```
  [x,y] = ginput(1);
  if ~strcmp(get(gcf,'SelectionType'),'normal')
    break
  end
  ct = camtarget;
  dx = x - ct(1);
  dy = y - ct(2);
  camdolly(dx,dy,ct(3),'movetarget','data')
  drawnow
end
```

Example — Moving the Camera Through a Scene

In this section...

Summary of Techniques

A fly-through is an effect created by moving the camera through three-dimensional space, giving the impression that you are flying along with the camera as if in an aircraft. You can fly through regions of a scene that might be otherwise obscured by objects in the scene or you can fly by a scene by keeping the camera focused on a particular point.

To accomplish these effects you move the camera along a particular path, the *x*-axis for example, in a series of steps. To produce a fly-through, move both the camera position and the camera target at the same time.

The following example makes use of the fly-though effect to view the interior of an isosurface drawn within a volume defined by a vector field of wind velocities. This data represents air currents over North America.

This example employs a number of visualization techniques. It uses

- Isosurfaces and cone plots to illustrate the flow through the volume
- Lighting to illuminate the isosurface and cones in the volume
- Stream lines to define a path for the camera through the volume
- Coordinated motion of the camera position, camera target, and light

See `coneplot` for a fixed visualization of the same data.

Graphing the Volume Data

The first step is to draw the isosurface and plot the air flow using cone plots.

See `isosurface`, `isonormals`, `reducepatch`, and `coneplot` for information on using these commands.

Setting the data aspect ratio (`daspect`) to `[1,1,1]` before drawing the cone plot enables MATLAB to calculate the size of the cones correctly for the final view.

```
load wind
wind_speed = sqrt(u.^2 + v.^2 + w.^2);

hpatch = patch(isosurface(x,y,z,wind_speed,35));
isonormals(x,y,z,wind_speed,hpatch)
set(hpatch,'FaceColor','red','EdgeColor','none');

[f vt] = reducepatch(isosurface(x,y,z,wind_speed,45),0.05);
daspect([1,1,1]);
hcone = coneplot(x,y,z,u,v,w,vt(:,1),vt(:,2),vt(:,3),2);
set(hcone,'FaceColor','blue','EdgeColor','none');
```

Setting Up the View

You need to define viewing parameters to ensure the scene is displayed correctly:

- Selecting a perspective projection provides the perception of depth as the camera passes through the interior of the isosurface (`camproj`).
- Setting the camera view angle to a fixed value prevents MATLAB from automatically adjusting the angle to encompass the entire scene as well as zooming in the desired amount (`camva`).

  ```
  camproj perspective
  camva(25)
  ```

Specifying the Light Source

Positioning the light source at the camera location and modifying the reflectance characteristics of the isosurface and cones enhances the realism of the scene:

- Creating a light source at the camera position provides a "headlight" that moves along with the camera through the isosurface interior (`camlight`).
- Setting the reflection properties of the isosurface gives the appearance of a dark interior (`AmbientStrength` set to 0.1) with highly reflective material (`SpecularStrength` and `DiffuseStrength` set to 1).
- Setting the `SpecularStrength` of the cones to 1 makes them highly reflective.

```
hlight = camlight('headlight');
set(hpatch,'AmbientStrength',.1,...
      'SpecularStrength',1,...
      'DiffuseStrength',1);
set(hcone,'SpecularStrength',1);
set(gcf,'Color','k')
```

Selecting a Renderer

Because this example uses lighting, MATLAB must use either `zbuffer` or, if available, `OpenGL` renderer settings. The `OpenGL` renderer is likely to be much faster displaying the animation; however, you need to use `gouraud` lighting with OpenGL, which is not as smooth as Phong lighting, which you can use with the `zbuffer` renderer. The two choices are

```
lighting gouraud
set(gcf,'Renderer','OpenGL')
```

or for `zbuffer`

```
lighting phong
set(gcf,'Renderer','zbuffer')
```

Defining the Camera Path as a Stream Line

Stream lines indicate the direction of flow in the vector field. This example uses the *x*-, *y*-, and *z*-coordinate data of a single stream line to map a path

through the volume. The camera is then moved along this path. The tasks include

- Create a stream line starting at the point x = 80, y = 30, z = 11.
- Get the *x*-, *y*-, and *z*-coordinate data of the stream line.
- Delete the stream line (note that you could also use `stream3` to calculate the stream line data without actually drawing the stream line).

```
hsline = streamline(x,y,z,u,v,w,80,30,11);
xd = get(hsline,'XData');
yd = get(hsline,'YData');
zd = get(hsline,'ZData');
delete(hsline)
```

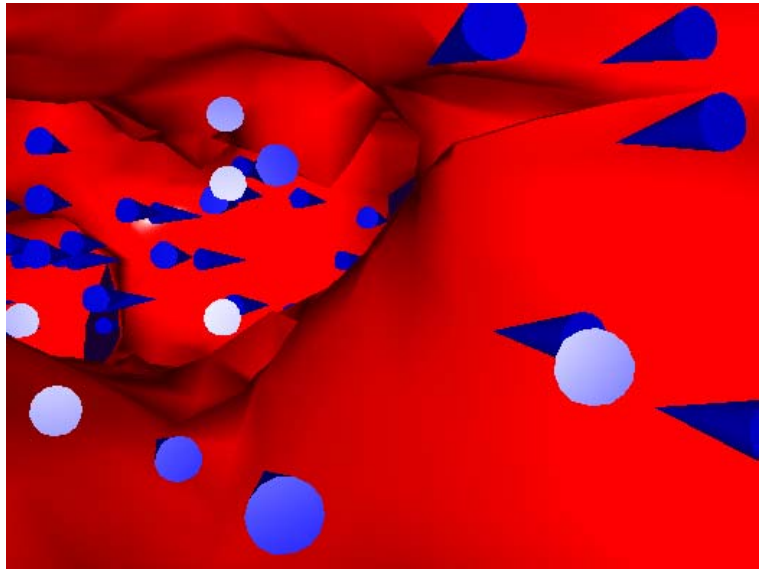
Implementing the Fly-Through

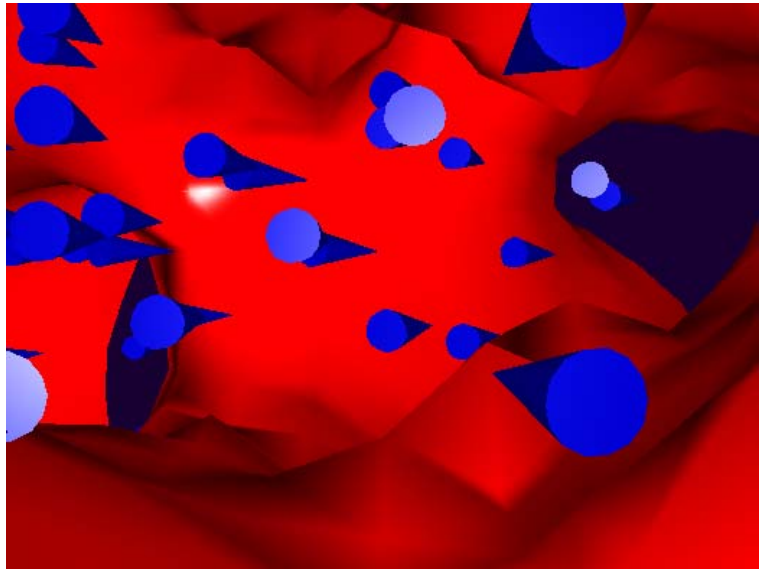
To create a fly-through, move the camera position and camera target along the same path. In this example, the camera target is placed five elements further along the *x*-axis than the camera. A small value is added to the camera target x position to prevent the position of the camera and target from becoming the same point if the condition `xd(n) = xd(n+5)` should occur:

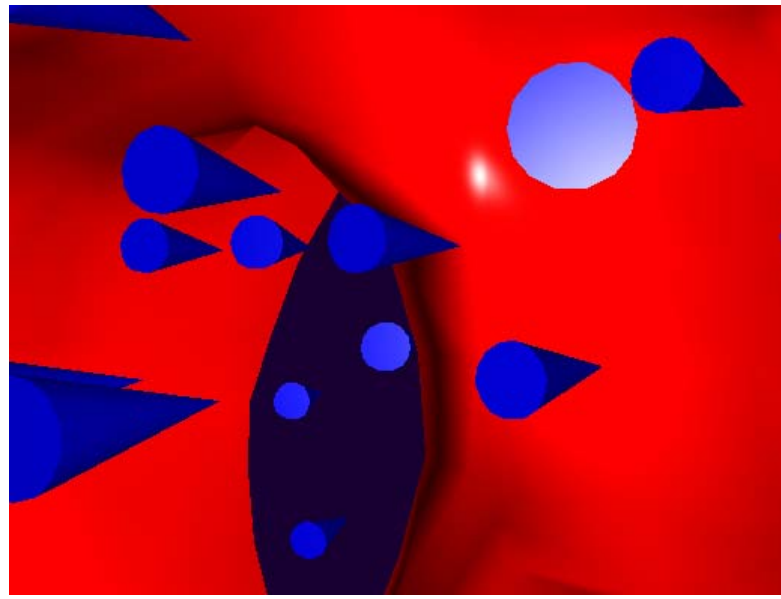
- Update the camera position and camera target so that they both move along the coordinates of the stream line.
- Move the light along with the camera.
- Call `drawnow` to display the results of each move.

```
for i=1:length(xd)-50
  campos([xd(i),yd(i),zd(i)])
  camtarget([xd(i+5)+min(xd)/100,yd(i),zd(i)])
  camlight(hlight,'headlight')
  drawnow
end
```

These snapshots illustrate the view at values of `i` equal to `10`, `110`, and `185`.







Low-Level Camera Properties

In this section...

Camera Properties You Can Set

Camera graphics is based on a group of axes properties that control the position and orientation of the camera. In general, the camera commands make it unnecessary to access these properties directly.

Property	Description
`CameraPosition`	Specifies the location of the viewpoint in axes units.
`CameraPositionMode`	In `automatic` mode, MATLAB determines the position based on the scene. In `manual` mode, you specify the viewpoint location.
`CameraTarget`	Specifies the location in the axes pointed to by the camera. Together with the `CameraPosition`, it defines the viewing axis.
`CameraTargetMode`	In `automatic` mode, MATLAB specifies the `CameraTarget` as the center of the axes plot box. In `manual` mode, you specify the location.
`CameraUpVector`	The rotation of the camera around the viewing axis is defined by a vector indicating the direction taken as up.
`CameraUpVectorMode`	In `automatic` mode, MATLAB orients the up vector along the positive *y*-axis for 2-D views and along the positive *z*-axis for 3-D views. In `manual` mode, you specify the direction.

Property	Description
`CameraViewAngle`	Specifies the field of view of the "lens." If you specify a value for CameraViewAngle, MATLAB overrides stretch-to-fill behavior (see “Understanding Axes Aspect Ratio” on page 2-42).
`CameraViewAngleMode`	In `automatic` mode, MATLAB adjusts the view angle to the smallest angle that captures the entire scene. In `manual` mode, you specify the angle. Setting `CameraViewAngleMode` to `manual` overrides stretch-to-fill behavior.
`Projection`	Selects either an orthographic or perspective projection.

Default Viewpoint Selection

When all the camera mode properties are set to `auto` (the default), MATLAB automatically controls the view, selecting appropriate values based on the assumption that you want the scene to fill the position rectangle (which is defined by the width and height components of the axes `Position` property).

By default, MATLAB

- Sets the `CameraPosition` so the orientation of the scene is the standard MATLAB 2-D or 3-D view (see the `view` command)
- Sets the `CameraTarget` to the center of the plot box
- Sets the `CameraUpVector` so the *y*-direction is up for 2-D views and the *z*-direction is up for 3-D views
- Sets the `CameraViewAngle` to the minimum angle that makes the scene fill the position rectangle (the rectangle defined by the axes `Position` property)
- Uses orthographic projection

This default behavior generally produces desirable results. However, you can change these properties to produce useful effects.

Moving In and Out on the Scene

You can move the camera anywhere in the 3-D space defined by the axes. The camera continues to point towards the target regardless of its position. When the camera moves, MATLAB varies the camera view angle to ensure the scene fills the position rectangle.

Moving Through a Scene

You can create a fly-by effect by moving the camera through the scene. To do this, continually change `CameraPosition` property, moving it toward the target. Because the camera is moving through space, it turns as it moves past the camera target. Override the MATLAB automatic resizing of the scene each time you move the camera by setting the `CameraViewAngleMode` to `manual`.

If you update the `CameraPosition` and the `CameraTarget`, the effect is to pass through the scene while continually facing the direction of movement.

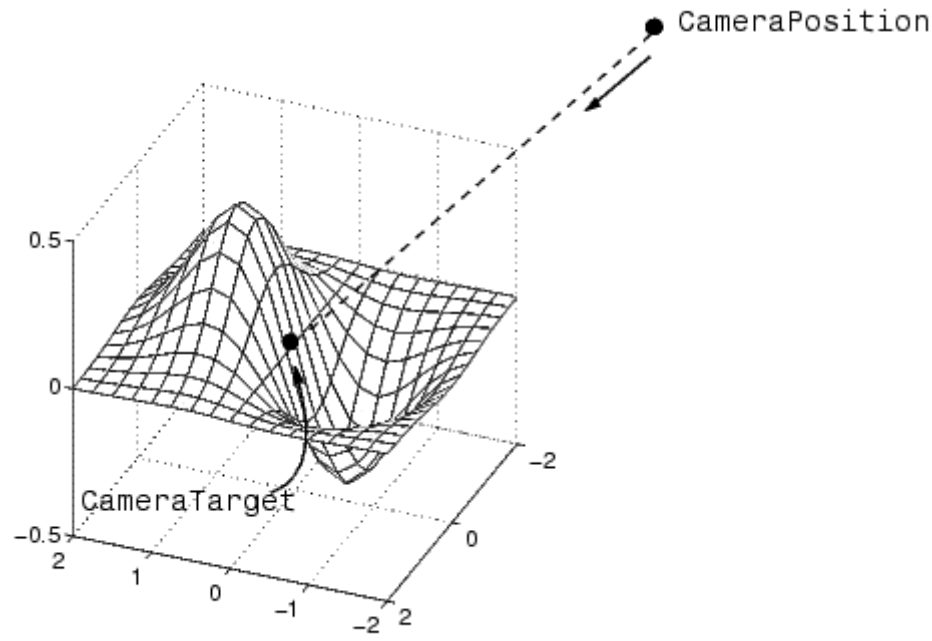
If the `Projection` is set to `perspective`, the amount of perspective distortion increases as the camera gets closer to the target and decreases as it gets farther away.

Example — Moving Toward or Away from the Target

To move the camera along the viewing axis, you need to calculate new coordinates for the `CameraPosition` property. This is accomplished by subtracting (to move closer to the target) or adding (to move away from the target) some fraction of the total distance between the camera position and the camera target.

The function `movecamera` calculates a new `CameraPosition` that moves in on the scene if the argument `dist` is positive and moves out if `dist` is negative.

```
function movecamera(dist) %dist in the range [-1 1]
set(gca,'CameraViewAngleMode','manual')
newcp = cpos - dist * (cpos - ctarg);
set(gca,'CameraPosition',newcp)
function out = cpos
out = get(gca,'CameraPosition');
function out = ctarg
out = get(gca,'CameraTarget');
```



Note that setting the `CameraViewAngleMode` to `manual` overrides MATLAB stretch-to-fill behavior and can cause an abrupt change in the aspect ratio. See “Understanding Axes Aspect Ratio” on page 2-42 for more information on stretch-to-fill.

Making the Scene Larger or Smaller

Adjusting the `CameraViewAngle` property makes the view of the scene larger or smaller. Larger angles cause the view to encompass a larger area, thereby making the objects in the scene appear smaller. Similarly, smaller angles make the objects appear larger.

Changing `CameraViewAngle` makes the scene larger or smaller without affecting the position of the camera. This is desirable if you want to zoom in without moving the viewpoint past objects that will then no longer be in the scene (as could happen if you changed the camera position). Also, changing

the CameraViewAngle does not affect the amount of perspective applied to the scene, as changing CameraPosition does when the figure Projection property is set to perspective.

Revolving Around the Scene

You can use the view command to revolve the viewpoint about the *z*-axis by varying the azimuth, and about the azimuth by varying the elevation. This has the effect of moving the camera around the scene along the surface of a sphere whose radius is the length of the viewing axis. You could create the same effect by changing the CameraPosition, but doing so requires you to perform calculations that MATLAB performs for you when you call view.

For example, the function orbit moves the camera around the scene.

```
function orbit(deg)
[az el] = view;
rotvec = 0:deg/10:deg;
for i = 1:length(rotvec)
    view([az+rotvec(i) el])
    drawnow
end
```

Rotation Without Resizing of Graphics Objects

When CameraViewAngleMode is auto, MATLAB calculates the CameraViewAngle so that the scene is as large as can fit in the axes position rectangle. This causes an apparent size change during rotation of the scene. To prevent resizing during rotation, you need to set the CameraViewAngleMode to manual (which happens automatically when you specify a value for the CameraViewAngle property). To do this in the orbit function, add the statement

```
set(gca,'CameraViewAngleMode','manual')
```

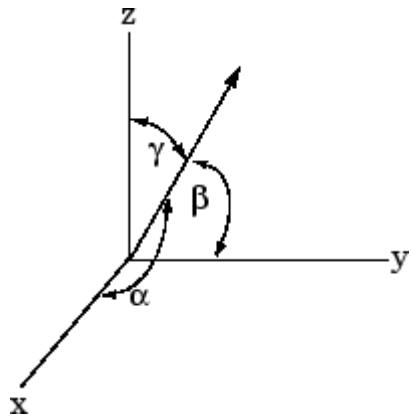
Rotation About the Viewing Axis

You can change the orientation of the scene by specifying the direction defined as up. By default, MATLAB defines *up* as the *y*-axis in 2-D views (the CameraUpVector is [0 1 0]) and the *z*-axis for 3-D views (the

`CameraUpVector` is `[0 0 1]`). However, you can specify up as any arbitrary direction.

The vector defined by the `CameraUpVector` property forms one axis of the camera's coordinate system. Internally, MATLAB determines the actual orientation of the camera up vector by projecting the specified vector onto the plane that is normal to the camera direction (i.e., the viewing axis). This simplifies the specification of the `CameraUpVector` property, because it need not lie in this plane.

In many cases, you might find it convenient to visualize the desired up vector in terms of angles with respect to the axes *x*-, *y*-, and *z*-axis. You can then use *direction cosines* to convert from angles to vector components. For a unit vector, the expression simplifies to



where the angles α, β, and γ are specified in degrees.

```
XComponent = cos(α x (pi   180));
YComponent = cos(β x (pi   180));
ZComponent = cos([[GAMMA]] x (pi   180));
```

(Consult a mathematics book on vector analysis for a more detailed explanation of direction cosines.)

Example — Calculating a Camera Up Vector

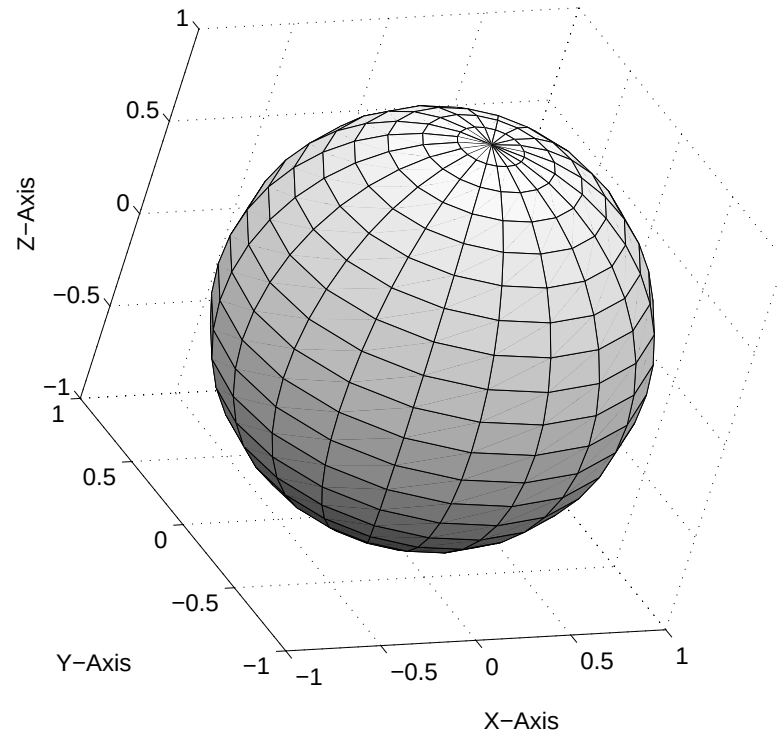
To specify an up vector that makes an angle of 30° with the z-axis and lies in the y-z plane, use the expression

```
upvec = [cos(90*(pi/180)),cos(60*(pi/180)),cos(30*(pi/180))];
```

and then set the `CameraUpVector` property.

```
set(gca,'CameraUpVector',upvec)
```

Drawing a sphere with this orientation produces



Understanding View Projections

In this section...

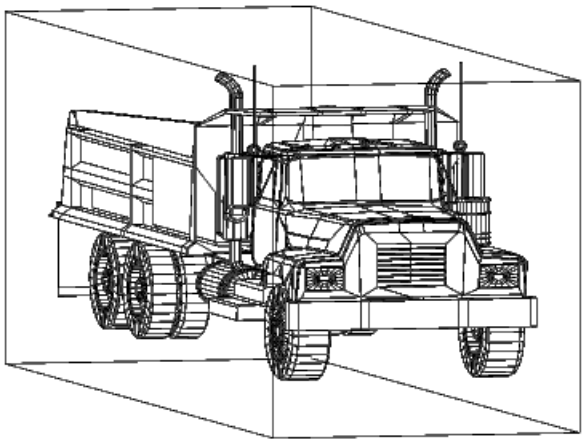
The Two Types of Projections

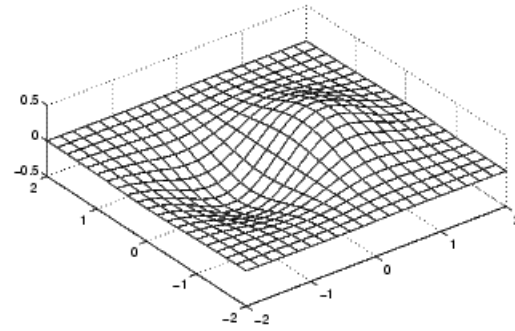
MATLAB supports both orthographic and perspective projection types for displaying 3-D graphics. The one you select depends on the type of graphics you are displaying:

- `orthographic` projects the viewing volume as a rectangular parallelepiped (i.e., a box whose opposite sides are parallel). Relative distance from the camera does not affect the size of objects. This projection type is useful when it is important to maintain the actual size of objects and the angles between objects.
- `perspective` projects the viewing volume as the frustum of a pyramid (a pyramid whose apex has been cut off parallel to the base). Distance causes foreshortening; objects further from the camera appear smaller. This projection type is useful when you want to display realistic views of real objects.

By default, MATLAB displays objects using orthographic projection. You can set the projection type using the `camproj` command.

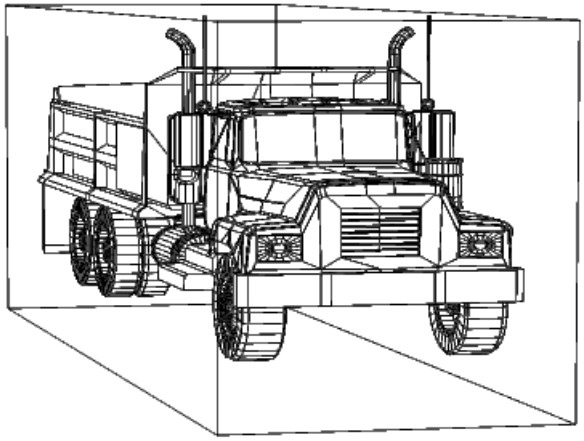
These pictures show a drawing of a dump truck (created with `patch`) and a surface plot of a mathematical function, both using orthographic projection.

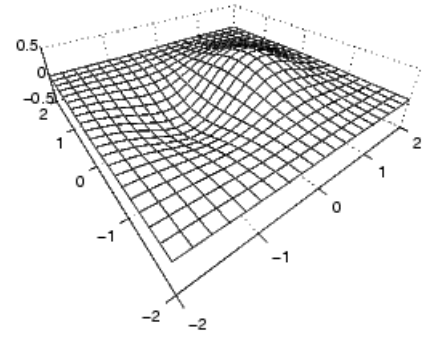




If you measure the width of the front and rear faces of the box enclosing the dump truck, you'll see they are the same size. This picture looks unnatural because it lacks the apparent perspective you see when looking at real objects with depth. On the other hand, the surface plot accurately indicates the values of the function within rectangular space.

Now look at the same graphics objects with perspective added. The dump truck looks more natural because portions of the truck that are farther from the viewer appear smaller. This projection mimics the way human vision works. The surface plot, on the other hand, looks distorted.



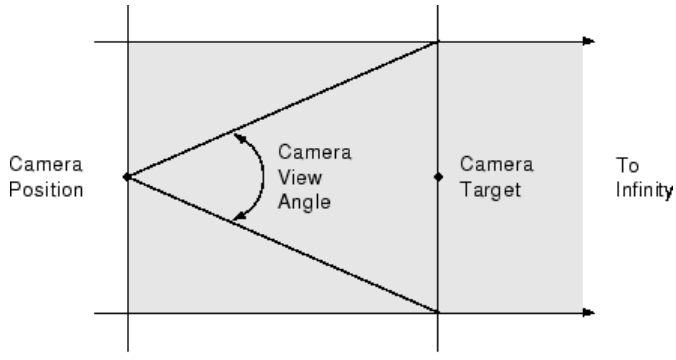


Projection Types and Camera Location

By default, MATLAB adjusts the `CameraPosition`, `CameraTarget`, and `CameraViewAngle` properties to point the camera at the center of the scene and to include all graphics objects in the axes. If you position the camera so that there are graphics objects behind the camera, the scene displayed can be affected by both the axes `Projection` property and the figure `Renderer` property. The following summarizes the interactions between projection type and rendering method.

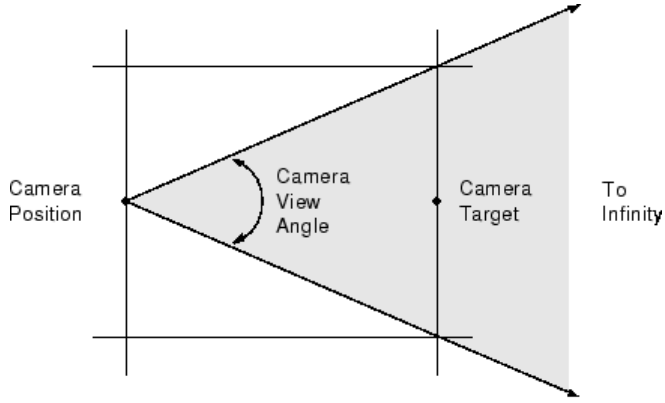
	Orthographic	**Perspective**
Z-buffer	`CameraViewAngle` determines extent of scene at `CameraTarget`.	`CameraViewAngle` determines extent of scene from `CameraPosition` to infinity.
Painters	All objects are displayed regardless of `CameraPosition`.	Not recommended if graphics objects are behind the `CameraPosition`.

This diagram illustrates what you see (gray area) when using orthographic projection and Z-buffer. Anything in front of the camera is visible.



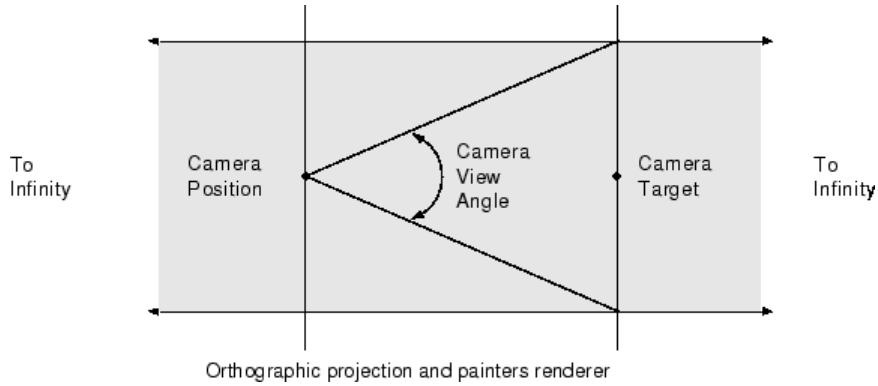
Orthographic projection and Z-buffer renderer

In perspective projection, you see only what is visible in the cone of the camera view angle.



Perspective projection and Z-buffer renderer

Painters rendering method is less suited to moving the camera in 3-D space because MATLAB does not clip along the viewing axis. Orthographic projection in painters method results in all objects contained in the scene being visible regardless of the camera position.



Orthographic projection and painters renderer

Printing 3-D Scenes

The same effects described in the previous section occur in hardcopy output. However, because of the differences in the process of rendering to the screen and to a printing format, MATLAB might render using Z-buffer and generate printed output using painters. You might need to specify Z-buffer printing explicitly to obtain the results displayed on the screen (use the `-zbuffer` option with the `print` command).

Additional Information

See Basic Printing and Exporting and Selecting a Renderer in Figure Properties in the Using MATLAB Graphics documentation for information on printing and rendering methods.

Understanding Axes Aspect Ratio

In this section...

Stretch-to-Fill

Axes shape graphics objects by setting the scaling and limits of each axis. When you create a graph, MATLAB automatically determines axis scaling based on the values or size of the plotted data, and then draws the axes to fit the space available for display. Axes aspect ratio properties control how MATLAB performs the scaling required to create a graph.

By default, the size of the axes MATLAB creates for plotting is normalized to the size of the figure window (but is slightly smaller to allow for borders). If you resize the figure, the size and possibly the aspect ratio (the ratio of width to height) of the axes changes proportionally. This enables the axes to always fill the available space in the window. MATLAB also sets the *x*-, *y*-, and *z*-axis limits to provide the greatest resolution in each direction, again optimizing the use of available space.

This stretch-to-fill behavior is generally desirable; however, you might want to control this process to produce specific results. For example, images need to be displayed in correct proportions regardless of the aspect ratio of the figure window, or you might want graphs always to be a particular size on a printed page.

Specifying Axis Scaling

The `axis` command enables you to adjust the scaling of graphs. By default, MATLAB finds the maxima and minima of the plotted data and chooses appropriate axes ranges. You can override the defaults by setting axis limits.

```
axis([xmin xmax ymin ymax zmin zmax])
```

You can control how MATLAB scales the axes with predefined `axis` options:

- `axis auto` returns the axis scaling to its default, automatic mode. `v = axis` saves the scaling of the axes of the current plot in vector `v`. For subsequent graphics commands to have these same axis limits, follow them with `axis(v)`.
- `axis manual` freezes the scaling at the current limits. If you then set `hold on`, subsequent plots use the current limits. Specifying values for axis limits also sets axis scaling to manual.
- `axis tight` sets the axis limits to the range of the data.
- `axis ij` places MATLAB into its "matrix" axes mode. The coordinate system origin is at the upper left corner. The *i*-axis is vertical and is numbered from top to bottom. The *j*-axis is horizontal and is numbered from left to right.
- `axis xy` places MATLAB into its default Cartesian axes mode. The coordinate system origin is at the lower left corner. The *x*-axis is horizontal and is numbered from left to right. The *y*-axis is vertical and is numbered from bottom to top.

Specifying Aspect Ratio

The `axis` command enables you to adjust the aspect ratio of graphs. Normally MATLAB stretches the axes to fill the window. In many cases, it is more useful to specify the aspect ratio of the axes based on a particular characteristic such as the relative length or scaling of each axis. The `axis` command provides a number of useful options for adjusting the aspect ratio:

- `axis equal` changes the current axes scaling so that equal tick mark increments on the *x*-, *y*-, and *z*-axis are equal in length. This makes the surface displayed by `sphere` look like a sphere instead of an ellipsoid. `axis equal` overrides stretch-to-fill behavior.
- `axis square` makes each axis the same length and overrides stretch-to-fill behavior.
- `axis vis3d` freezes aspect ratio properties to enable rotation of 3-D objects and overrides stretch-to-fill. Use this option after other `axis` options to keep settings from changing while you rotate the scene.

- `axis image` makes the aspect ratio of the axes the same as the image.
- axis auto returns the *x*-, *y*-, and *z*-axis limits to automatic selection mode.
- `axis normal` restores the current axis box to full size and removes any restrictions on the scaling of the units. It undoes the effects of `axis square`. Used in conjunction with `axis auto`, it undoes the effects of `axis equal`.

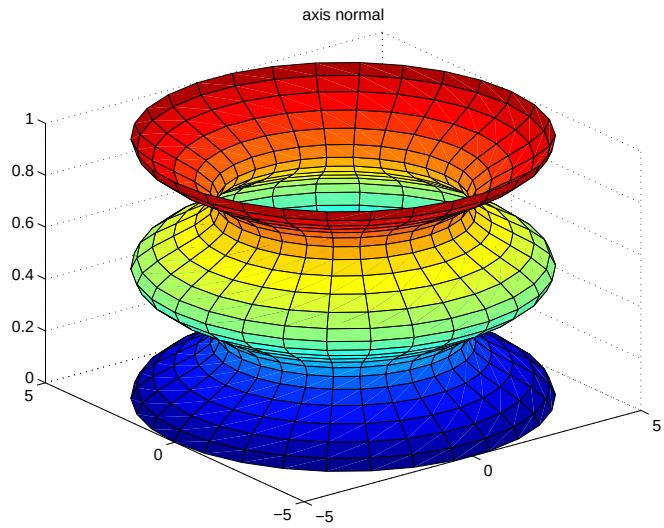
The `axis` command works by manipulating axes graphics object properties.

Example — axis Command Options

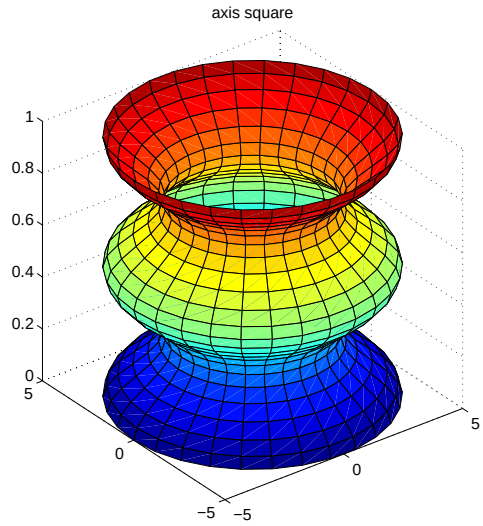
The following three pictures illustrate the effects of three `axis` options on a cylindrical surface created with the statements

```
t = 0:pi/6:4*pi;
[x,y,z] = cylinder(4+cos(t),30);
surf(x,y,z)
```

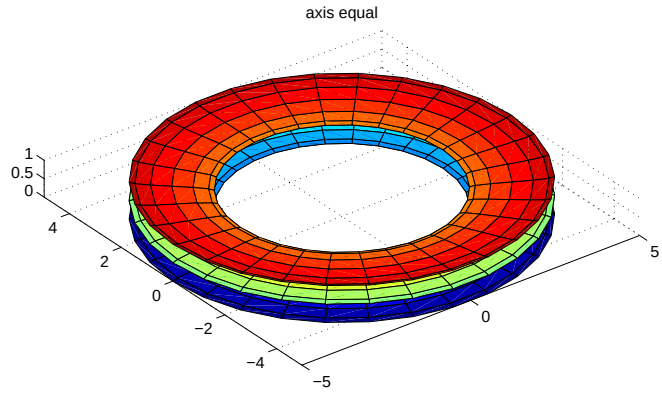
`axis normal` is the default behavior. MATLAB automatically sets the axis limits to span the data range along each axis and stretches the plot to fit the figure window.



`axis square` creates an axes that is square regardless of the shape of the figure window. The cylindrical surface is no longer distorted because it is not warped to fit the window. However, the size of one data unit is not equal along all axes (the *z*-axis spans only one unit while the *x*-axes and *y*-axes span 10 units each).



`axis equal` makes the length of one data unit equal along each axis while maintaining a nearly square plot box. It also prevents warping of the axis to fill the window's shape.



Additional Commands for Setting Aspect Ratio

You can control the aspect ratio of your graph in three ways:

- Specifying the relative scales of the *x*-, *y*-, and *z*-axes (data aspect ratio)
- Specifying the shape of the space defined by the axes (plot box aspect ratio)
- Specifying the axis limits

The following commands enable you to set these values.

Command	Purpose
`daspect`	Set or query the data aspect ratio
`pbaspect`	Set or query the plot box aspect ratio
`xlim`	Set or query *x*-axis limits
`ylim`	Set or query *y*-axis limits
`zlim`	Set or query *z*-axis limits

See “Manipulating Axes Aspect Ratio” on page 2-47 for a list of the axes properties that control aspect ratio.

Manipulating Axes Aspect Ratio

In this section...

Axes Aspect Ratio Properties

The `axis` command works by setting various axes object properties. You can set these properties directly to achieve precisely the effect you want.

Property	Description
`DataAspectRatio`	Sets the relative scaling of the individual axis data values. Set `DataAspectRatio` to `[1 1 1]` to display real-world objects in correct proportions. Specifying a value for DataAspectRatio overrides stretch-to-fill behavior.
`DataAspectRatioMode`	In `auto`, MATLAB selects axis scales that provide the highest resolution in the space available.
`PlotBoxAspectRatio`	Sets the proportions of the axes plot box (set `box` to `on` to see the box). Specifying a value for PlotBoxAspectRatio overrides stretch-to-fill behavior.
`PlotBoxAspectRatioMode`	In `auto`, MATLAB sets the `PlotBoxAspectRatio` to `[1 1 1]` unless you explicitly set the `DataAspectRatio` and/or the axis limits.
`Position`	Defines the location and size of the axes with a four-element vector: [*left offset*, *bottom offset*, *width*, *height*].
`XLim, YLim, ZLim`	Sets the minimum and maximum limits of the respective axes.
`XLimMode, YLimMode, ZLimMode`	In `auto`, MATLAB selects the axis limits.

By default, MATLAB automatically determines values for all of these properties (i.e., all the modes are auto) and then applies stretch-to-fill. You can override any property's automatic operation by specifying a value for the property or setting its mode to manual. The value you select for a particular property depends primarily on what type of data you want to display.

Much of the data visualized with MATLAB is either

- Numerical data displayed as line or mesh plots
- Representations of real-world objects (e.g., a dump truck or a section of the earth's topography)

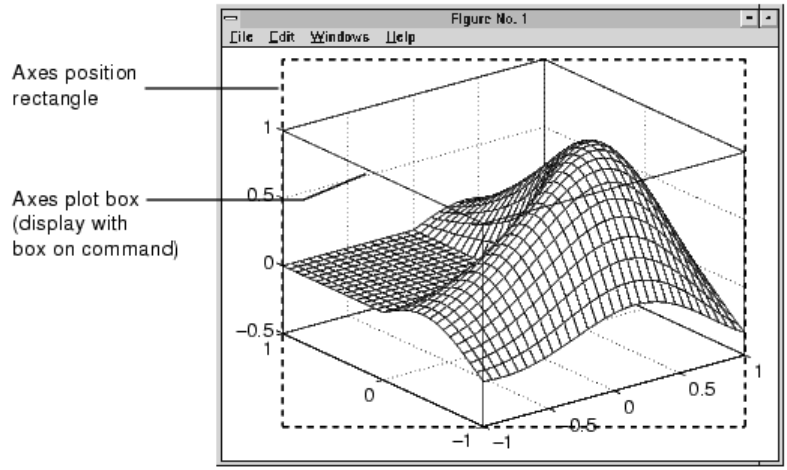
In the first case, it is generally desirable to select axis limits that provide good resolution in each axis direction and to fill the available space. Real-world objects, on the other hand, need to be represented accurately in proportion, regardless of the angle of view.

Default Aspect Ratio Selection

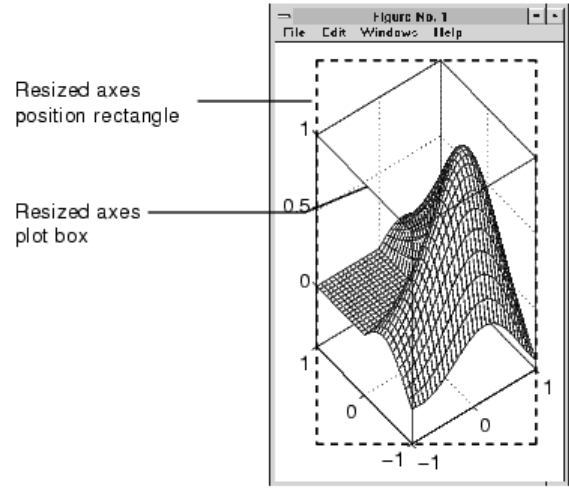
There are two key elements to MATLAB default behavior — normalizing the axes size to the window size and stretch-to-fill.

The axes `Position` property specifies the location and dimensions of the axes. The third and fourth elements of the `Position` vector (`width` and `height`) define a rectangle in which MATLAB draws the axes (indicated by the dotted line in the following pictures). MATLAB stretches the axes to fill this rectangle.

The default value for the axes `Units` property is `normalized` to the parent figure dimensions. This means the shape of the figure window determines the shape of the position rectangle. As you change the size of the window, MATLAB reshapes the position rectangle to fit it.



The view is the 2-D projection of the plot box onto the screen.



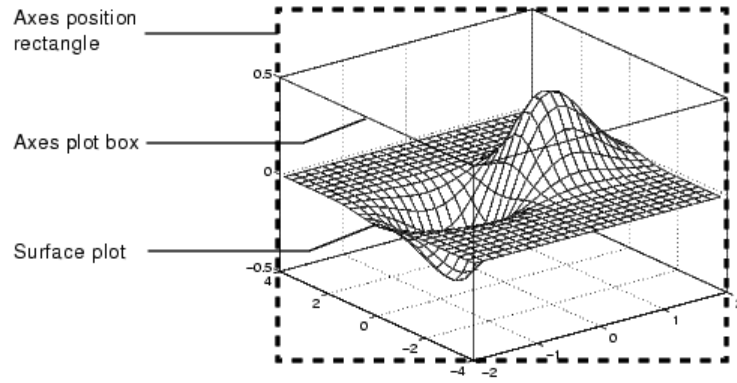
As you can see, reshaping the axes to fit into the figure window can change the aspect ratio of the graph. MATLAB applies stretch-to-fill so the axes fill the position rectangle and in the process can distort the shape. This is

generally desirable for graphs of numeric data, but not for displaying objects realistically.

Example — MATLAB Defaults

MATLAB surface plots are well suited for visualizing mathematical functions of two variables. For example, to display a mesh plot of the function $z = xe^{(-x^2 - y^2)}$ evaluated over the range $-2 \le x \le 2$, $-4 \le y \le 4$, use the statements

```
[X,Y] = meshgrid([-2:.15:2],[-4:.3:4]);
Z = X.*exp(-X.^2 - Y.^2);
mesh(X,Y,Z)
```



The MATLAB default property values are designed to

- Select axis limits to span the range of the data (`XLimMode`, `YLimMode`, and `ZLimMode` are set to `auto`).
- Provide the highest resolution in the available space by setting the scale of each axis independently (`DataAspectRatioMode` and the `PlotBoxAspectRatioMode` are set to `auto`).
- Draw axes that fit the position rectangle by adjusting the `CameraViewAngle` and then stretch-to-fill the axes if necessary.

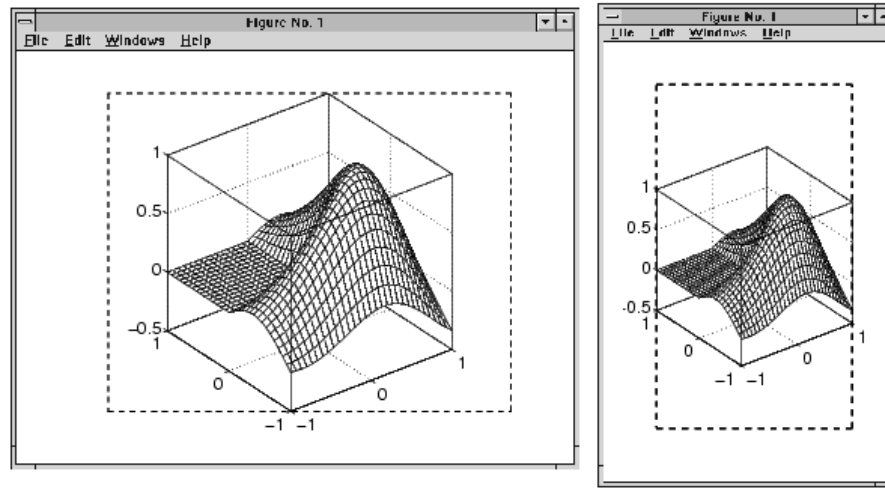
Overriding Stretch-to-Fill

To maintain a particular shape, you can specify the size of the axes in absolute units such as inches, which are independent of the figure window size. However, this is not a good approach if you are writing an M-file that you want to work with a figure window of any size. A better approach is to specify the aspect ratio of the axes and override automatic stretch-to-fill.

In cases where you want a specific aspect ratio, you can override stretching by specifying a value for these axes properties:

- `DataAspectRatio` or `DataAspectRatioMode`
- `PlotBoxAspectRatio` or `PlotBoxAspectRatioMode`
- `CameraViewAngle` or `CameraViewAngleMode`

The first two sets of properties affect the aspect ratio directly. Setting either of the mode properties to `manual` simply disables stretch-to-fill while maintaining all current property values. In this case, MATLAB enlarges the axes until one dimension of the position rectangle constrains it.



Setting the `CameraViewAngle` property disables stretch-to-fill, and also prevents MATLAB from readjusting the size of the axes if you change the view.

Effects of Setting Aspect Ratio Properties

It is important to understand how properties interact with each other, in order to obtain the results you want. The `DataAspectRatio`, `PlotBoxAspectRatio`, and the *x*-, *y*-, and *z*-axis limits (`XLim`, `YLim`, and `ZLim` properties) all place constraints on the shape of the axes.

Data Aspect Ratio

The `DataAspectRatio` property controls the ratio of the axis scales. For a mesh plot of the function $z = xe^{(-x^2 - y^2)}$ evaluated over the range $-2 \le x \le 2$, $-4 \le y \le 4$

```
[X,Y] = meshgrid([-2:.15:2],[-4:.3:4]);
Z = X.*exp(-X.^2 - Y.^2);
mesh(X,Y,Z)
```

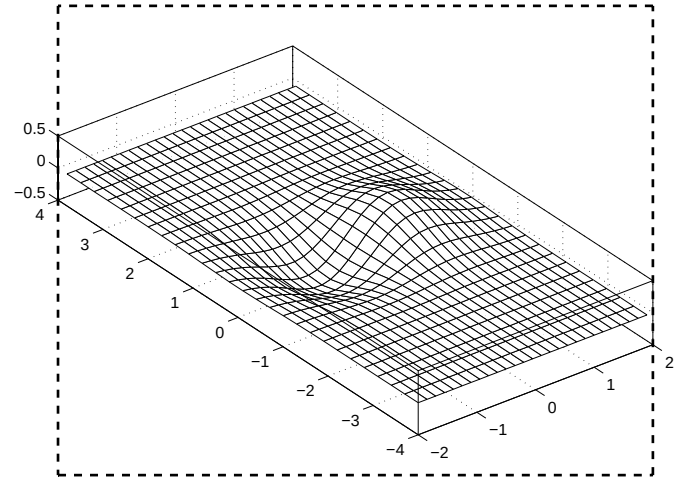
the values are

```
get(gca,'DataAspectRatio')
ans =
     4 8 1
```

This means that four units in length along the *x*-axis cover the same data values as eight units in length along the *y*-axis and one unit in length along the *z*-axis. The axes fill the plot box, which has an aspect ratio of [1 1 1] by default.

If you want to view the mesh plot so that the relative magnitudes along each axis are equal with respect to each other, you can set the `DataAspectRatio` to `[1 1 1]`.

```
set(gca,'DataAspectRatio',[1 1 1])
```



Setting the value of the `DataAspectRatio` property also sets the `DataAspectRatioMode` to `manual` and overrides stretch-to-fill so the specified aspect ratio is achieved.

Plot Box Aspect Ratio

Looking at the value of the `PlotBoxAspectRatio` for the graph in the previous section shows that it has now taken on the former value of the `DataAspectRatio`.

```
get(gca,'PlotBoxAspectRatio')
ans =
     4 8 1
```

MATLAB has rescaled the plot box to accommodate the graph using the specified `DataAspectRatio`.

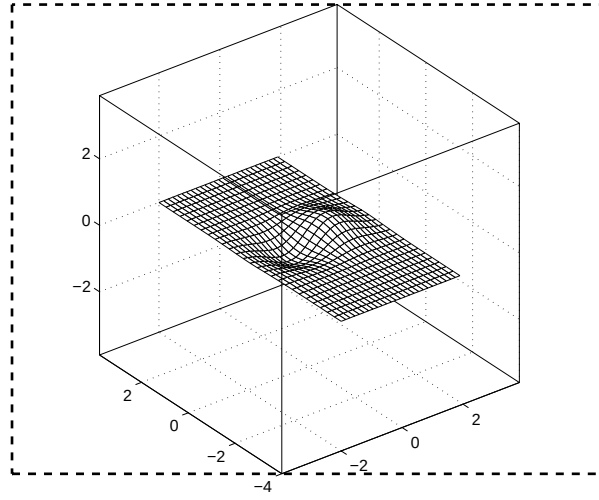
The `PlotBoxAspectRatio` property controls the shape of the axes plot box. MATLAB sets this property to `[1 1 1]` by default and adjusts the `DataAspectRatio` property so that graphs fill the plot box if stretching is on, or until reaching a constraint if stretch-to-fill has been overridden.

When you set the value of the DataAspectRatio and thereby prevent it from changing, MATLAB varies the PlotBoxAspectRatio instead. If you specify both the DataAspectRatio and the PlotBoxAspectRatio, MATLAB is forced to change the axis limits to obey the two constraints you have already defined.

Continuing with the mesh example, if you set both properties,

```
set(gca,'DataAspectRatio',[1 1 1],...
        'PlotBoxAspectRatio',[1 1 1])
```

MATLAB changes the axis limits to satisfy the two constraints placed on the axes.



Adjusting Axis Limits

MATLAB enables you to set the axis limits to the values you want. However, specifying a value for DataAspectRatio, PlotBoxAspectRatio, and the axis limits overconstrains the axes definition. For example, it is not possible for MATLAB to draw the axes if you set these values:

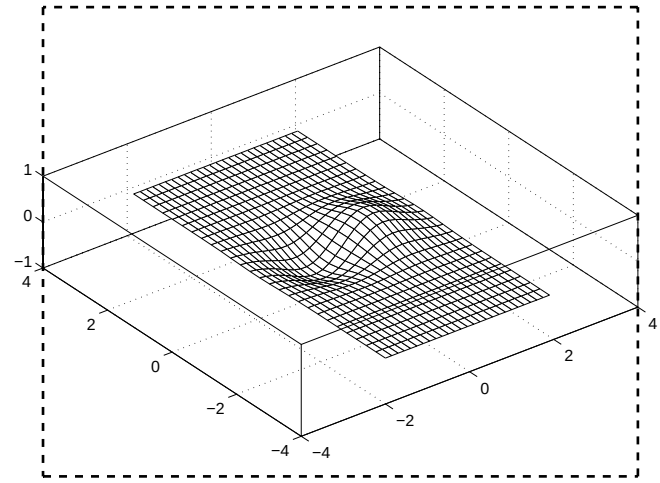
```
set(gca,'DataAspectRatio',[1 1 1],...
        'PlotBoxAspectRatio',[1 1 1],...
```

```
        'XLim',[-4 4],...
        'YLim',[-4 4],...
        'ZLim',[-1 1])
```

In this case, MATLAB ignores the setting of the `PlotBoxAspectRatio` and determines its value automatically. These particular values cause the `PlotBoxAspectRatio` to return to its calculated value.

```
get(gca,'PlotBoxAspectRatio')
ans =
      4 8 1
```

MATLAB can now draw the axes using the specified `DataAspectRatio` and axis limits.



Example — Displaying Cross-Sections of Surfaces

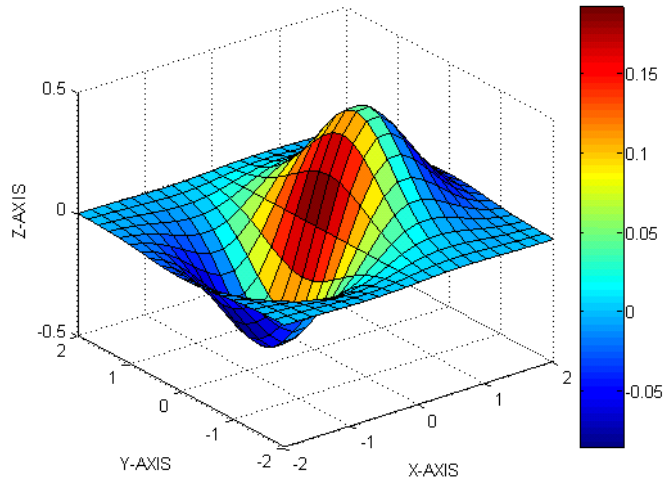
Sometimes projecting a 3-D surface onto an *x*-, *y*-, or *z*-axis can aid visualization. To do this, you might change the aspect ratio, in order to make space for the projection. The following example illustrates how to do this:

1 Create an *x*-*y* grid and *z*-values for it:

```
[x,y] = meshgrid([-2:.2:2]);
Z = x.*exp(-x.^2-y.^2);
```

2 Plot the surface in 3-D; annotate with a colorbar and axis labels:

```
surf(x,y,Z,gradient(Z))
colorbar
xlabel('X-AXIS')
ylabel('Y-AXIS')
zlabel('Z-AXIS')
```



3 Use `axis` to change the `Ymax` value in to 3, stretching the plot in one direction:

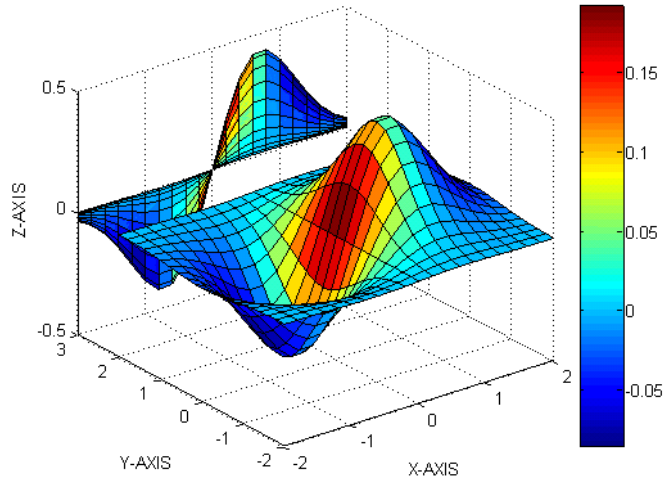
```
axis([-2 2 -2 3 -0.5 0.5]) %
```

4 Regrid the surface, setting all Y-values equal to 3:

```
y = 3*ones(21);
```

5 Plaster a plot of the surface onto the Y-axis:

```
hold on
surf(x,y,Z,gradient(Z))
```



Example — Displaying Real Objects

If you want to display an object so that it looks realistic, you need to change MATLAB defaults. For example, this data defines a wedge-shaped patch object.

```
vertex_list =

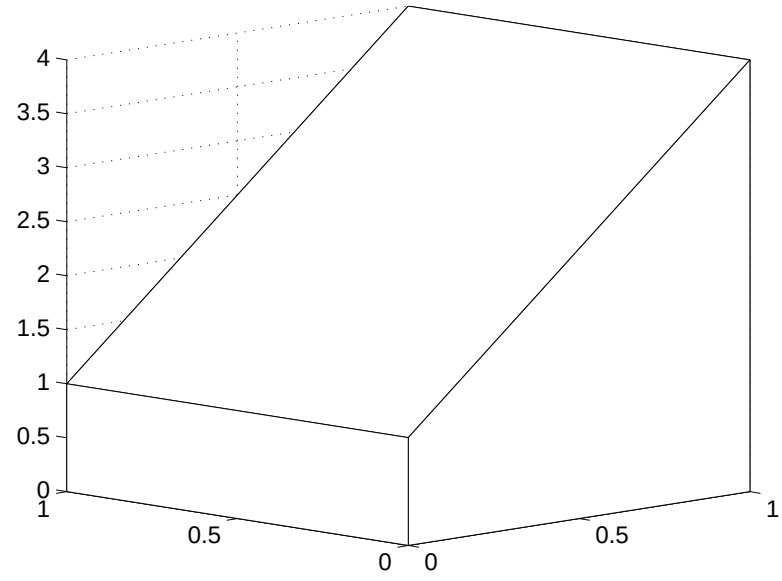
     0     0     0
     0     1     0
     1     1     0
     1     0     0
     0     0     1
     0     1     1
     1     1     4
     1     0     4
```

```
vertex_connection =

     1     2     3     4
     2     6     7     3
     4     3     7     8
     1     5     8     4
     1     2     6     5
     5     6     7     8
```

```
patch('Vertices',vertex_list,'Faces',vertex_connection,...
```

```
 'FaceColor','w','EdgeColor','k')
view(3)
```



However, this axes distorts the actual shape of the solid object defined by the data. To display it in correct proportions, set the `DataAspectRatio`.

```
set(gca,'DataAspectRatio',[1 1 1])
```

The units are now equal in the *x*-, *y*-, and *z*-directions and the axes is not being stretched to fill the position rectangle, revealing the true shape of the object.

Lighting as a Visualization Tool

Lighting Overview

In this section...

Lighting Commands

MATLAB provides commands that enable you to position light sources and adjust the characteristics of lit objects. These commands include the following.

Command	Purpose
`camlight`	Create or move a light with respect to the camera position
`lightangle`	Create or position a light in spherical coordinates
`light`	Create a light object
`lighting`	Select a lighting method
`material`	Set the reflectance properties of lit objects

You might find it useful to set light or lit-object properties directly to achieve specific results. In addition to the material in this topic area, you can explore the following lighting examples as an introduction to lighting for visualization.

Light Objects

You create a light object using the `light` function. Three important light object properties are

- `Color` — Color of the light cast by the light object
- `Style` — Either infinitely far away (the default) or local
- `Position` — Direction (for infinite light sources) or the location (for local light sources)

The `Color` property determines the color of the directional light from the light source. The color of an object in a scene is determined by the color of the object and the light source.

The `Style` property determines whether the light source is a point source (`Style` set to `local`), which radiates from the specified position in all directions, or a light source placed at infinity (`Style` set to `infinite`), which shines from the direction of the specified position with parallel rays.

The `Position` property specifies the location of the light source in axes data units. In the case of a light source at infinity, `Position` specifies the direction to the light source.

Lights affect surface and patch objects that are in the same axes as the light. These objects have a number of properties that alter the way they look when illuminated by lights.

Properties That Affect Lighting

You cannot see light objects themselves, but you can see their effects on any patch and surface objects present in the axes containing the light. A number of functions create these objects, including `surf`, `mesh`, `pcolor`, `fill`, and `fill3` as well as the `surface` and `patch` functions.

You control lighting effects by setting various axes, light, patch, and surface object properties. All properties have default values that generally produce desirable results. However, you can achieve the specific effect you want by adjusting the values of these properties.

Property	Effect
`AmbientLightColor`	An axes property that specifies the color of the background light in the scene, which has no direction and affects all objects uniformly. Ambient light effects occur only when there is a visible light object in the axes.
`AmbientStrength`	A patch and surface property that determines the intensity of the ambient component of the light reflected from the object.
`DiffuseStrength`	A patch and surface property that determines the intensity of the diffuse component of the light reflected from the object.

Property	Effect
`SpecularStrength`	A patch and surface property that determines the intensity of the specular component of the light reflected from the object.
`SpecularExponent`	A patch and surface property that determines the size of the specular highlight.
`SpecularColorReflectance`	A patch and surface property that determines the degree to which the specularly reflected light is colored by the object color or the light source color.
`FaceLighting`	A patch and surface property that determines the method used to calculate the effect of the light on the faces of the object. Choices are either no lighting, or flat, Gouraud, or Phong lighting algorithms.
`EdgeLighting`	A patch and surface property that determines the method used to calculate the effect of the light on the edges of the object. Choices are either no lighting, or flat, Gouraud, or Phong lighting algorithms.
`BackFaceLighting`	A patch and surface property that determines how faces are lit when their vertex normals point away from the camera. This property is useful for discriminating between the internal and external surfaces of an object.
`FaceColor`	A patch and surface property that specifies the color of the object faces.
`EdgeColor`	A patch and surface property that specifies the color of the object edges.
`VertexNormals`	A patch and surface property that contains normal vectors for each vertex of the object. MATLAB uses vertex normal vectors to perform lighting calculations. While MATLAB automatically generates this data, you can also specify your own vertex normals.
`NormalMode`	A patch and surface property that determines whether MATLAB recalculates vertex normals if you change object data (`auto`) or uses the current values of the `VertexNormals` property (`manual`). If you specify values for `VertexNormals`, MATLAB sets this property to `manual`.

For more information, see descriptions of `axes`, `surface`, and `patch` object properties.

Examples of Lighting Control

Lighting is a technique for adding realism to a graphical scene. It does this by simulating the highlights and dark areas that occur on objects under natural lighting (e.g., the directional light that comes from the sun). To create lighting effects, MATLAB defines a graphics object called a light. MATLAB applies lighting to surface and patch objects.

These examples illustrate the use of lighting in a visualization context.

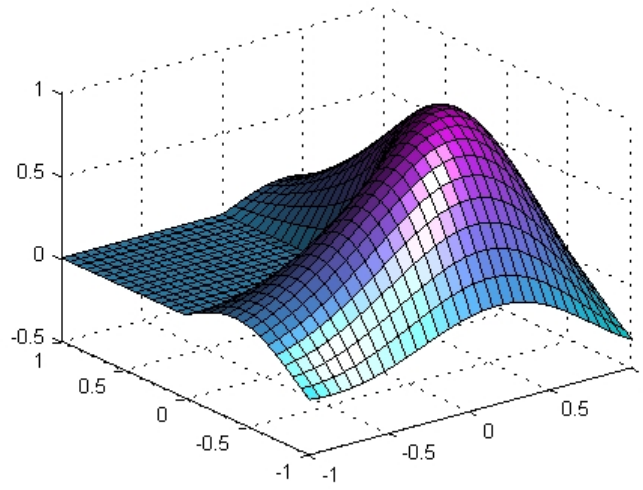
- Tracing a stream line through a volume — Sets properties of surfaces, patches, and lights (MATLAB Graphics documentation).
- Using slice planes and cone plots — Sets lighting characteristics of objects in a scene independently to achieve a desired result (MATLAB `coneplot` function).
- Lighting multiple slice planes independently to visualize fluid flow (MATLAB Graphics documentation).
- Combining single-color lit surfaces with interpolated coloring. See "Example — Visualizing MRI Data" (3–D Visualization documentation).
- Employing lighting to reveal surface shape. The fluid flow isosurface example and the surface plot of the `sinc` function examples illustrate this technique (3–D Visualization documentation).

Example — Adding Lights to a Scene

This example displays the membrane surface and illuminates it with a light source emanating from the direction defined by the position vector `[0 -2 1]`. This vector defines a direction from the axes origin passing through the point with the coordinates 0, -2, 1. The light shines from this direction toward the axes origin.

```
membrane
light('Position',[0 -2 1])
```

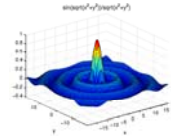
Creating a light activates a number of lighting-related properties controlling characteristics such as the ambient light and reflectance properties of objects. It also switches to Z-buffer renderer if not already in that mode.



Example — Illuminating Mathematical Functions

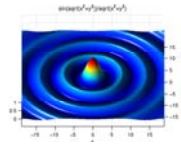
Lighting can enhance surface graphs of mathematical functions. For example, use the `ezsurf` command to evaluate the expression $\sin(\sqrt{x^2+y^2}) \div \sqrt{x^2+y^2}$ over the region -6π to 6π.

```
ezsurf('sin(sqrt(x^2+y^2))/sqrt(x^2+y^2)',[-6*pi,6*pi])
```



Now add lighting using the `lightangle` command, which accepts the light position in terms of azimuth and elevation.

```
view(0,75)
shading interp
lightangle(-45,30)
set(gcf,'Renderer','zbuffer')
set(findobj(gca,'type','surface'),...
    'FaceLighting','phong',...
    'AmbientStrength',.3,'DiffuseStrength',.8,...
    'SpecularStrength',.9,'SpecularExponent',25,...
    'BackFaceLighting','unlit')
```



After obtaining the surface object's handle using `findobj`, you can set properties that affect how the light reflects from the surface. See for more detailed descriptions of these properties.

Selecting a Lighting Method

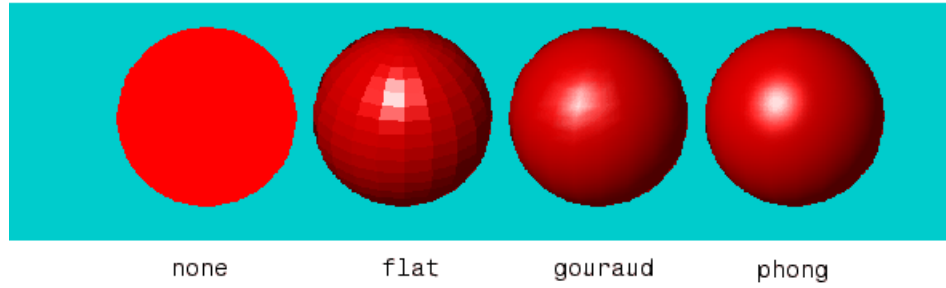
Face and Edge Lighting Methods

When you add lights to an axes, MATLAB determines the effects these lights have on the patch and surface objects that are displayed in that axes. There are different methods used to calculate the face and edge coloring of lit objects, and the one you select depends on the results you want to obtain.

MATLAB supports three different algorithms for lighting calculations, selected by setting the `FaceLighting` and `EdgeLighting` properties of each patch and surface object in the scene. Each algorithm produces somewhat different results:

- Flat lighting — Produces uniform color across each of the faces of the object. Select this method to view faceted objects.
- Gouraud lighting — Calculates the colors at the vertices and then interpolates colors across the faces. Select this method to view curved surfaces.
- Phong lighting — Interpolates the vertex normals across each face and calculates the reflectance at each pixel. Select this choice to view curved surfaces. Phong lighting generally produces better results than Gouraud lighting, but takes longer to render.

This illustration shows how a red sphere looks using each of the lighting methods with one white light source.



The `lighting` command (as opposed to the `light` function) provides a convenient way to set the lighting method.

Reflectance Characteristics of Graphics Objects

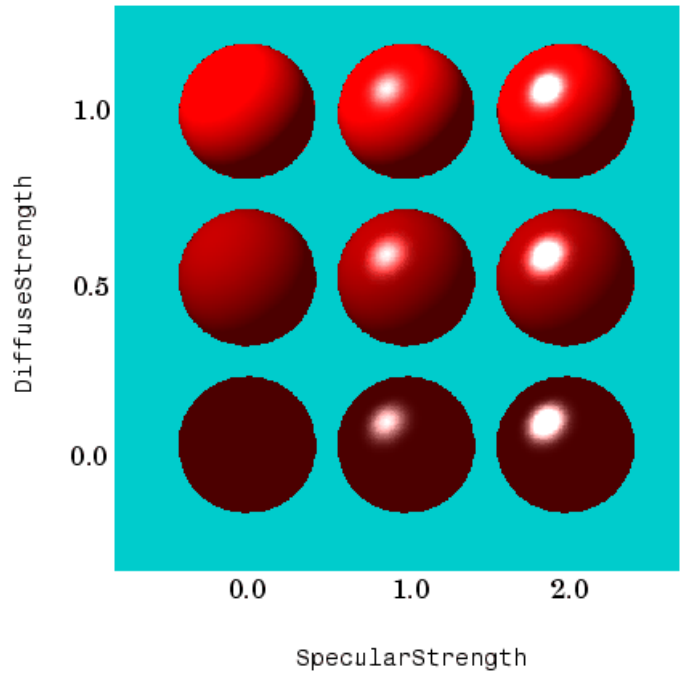
In this section...

Specular and Diffuse Reflection

You can specify the reflectance characteristics of patch and surface objects and thereby affect the way they look when lights are applied to the scene. It is likely you will adjust these characteristics in combination to produce particular results.

Also see the `material` command for a convenient way to produce certain lighting effects.

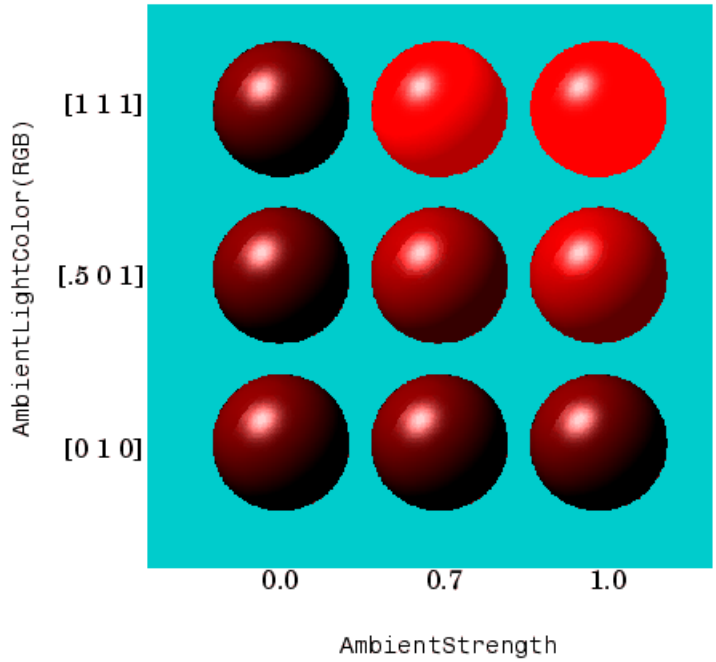
You can control the amount of specular and diffuse reflection from the surface of an object by setting the `SpecularStrength` and `DiffuseStrength` properties. This picture illustrates various settings.



Ambient Light

Ambient light is a directionless light that shines uniformly on all objects in the scene. Ambient light is visible only when there are light objects in the axes. There are two properties that control ambient light — `AmbientLightColor` is an axes property that sets the color, and `AmbientStrength` is a property of patch and surface objects that determines the intensity of the ambient light on the particular object.

This illustration shows three different ambient light colors at various intensities. The sphere is red and there is a white light object present.

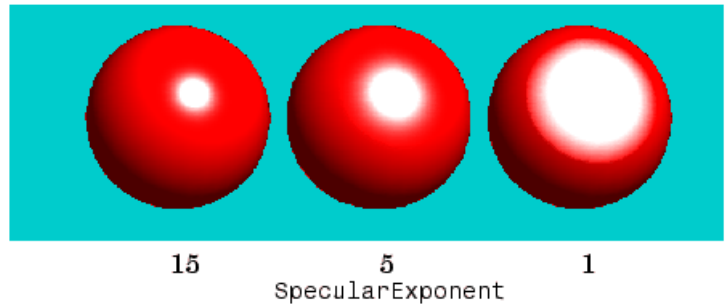


The green [0 1 0] ambient light does not affect the scene because there is no red component in green light. However, the color defined by the RGB values [.5 0 1] does have a red component, so it contributes to the light on the sphere (but less than the white [1 1 1] ambient light).

Specular Exponent

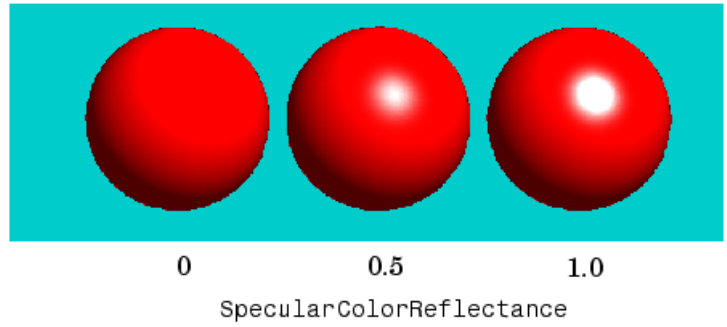
The size of the specular highlight spot depends on the value of the patch and surface object's `SpecularExponent` property. Typical values for this property range from 1 to 500, with normal objects having values in the range 5 to 20.

This illustration shows a red sphere illuminated by a white light with three different values for the `SpecularExponent` property.



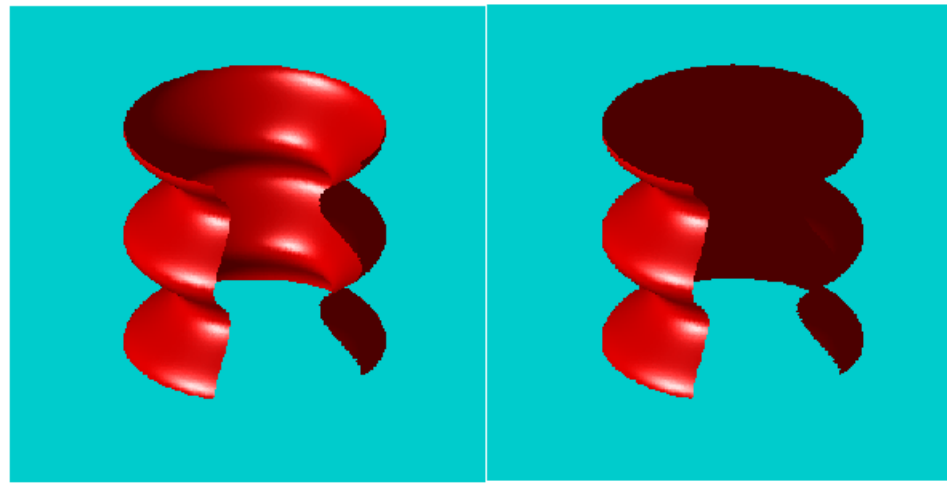
Specular Color Reflectance

The color of the specularly reflected light can range from a combination of the color of the object and the color of the light source to the color of the light source only. The patch and surface `SpecularColorReflectance` property controls this color. This illustration shows a red sphere illuminated by a white light. The values of the `SpecularColorReflectance` property range from 0 (object and light color) to 1 (light color).



Back Face Lighting

Back face lighting is useful for showing the difference between internal and external faces. These pictures of cut-away cylindrical surfaces illustrate the effects of back face lighting.

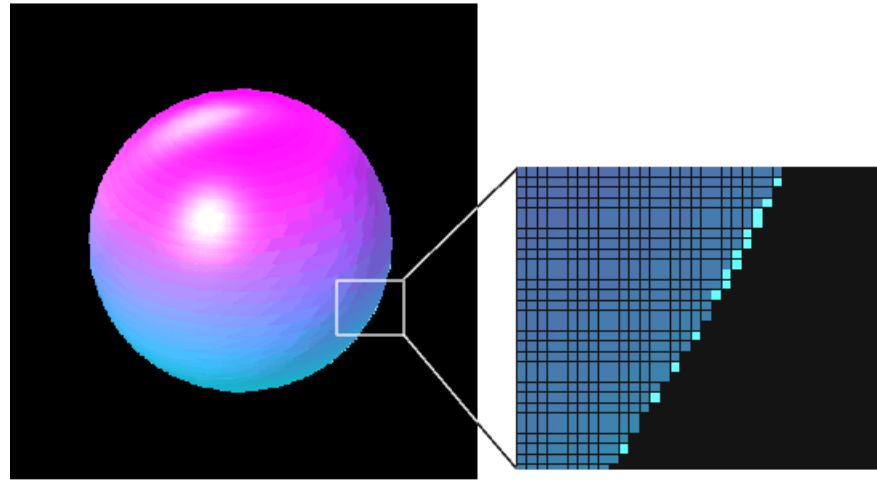


`BackFaceLighting = reverselit` `BackFaceLighting = unlit`

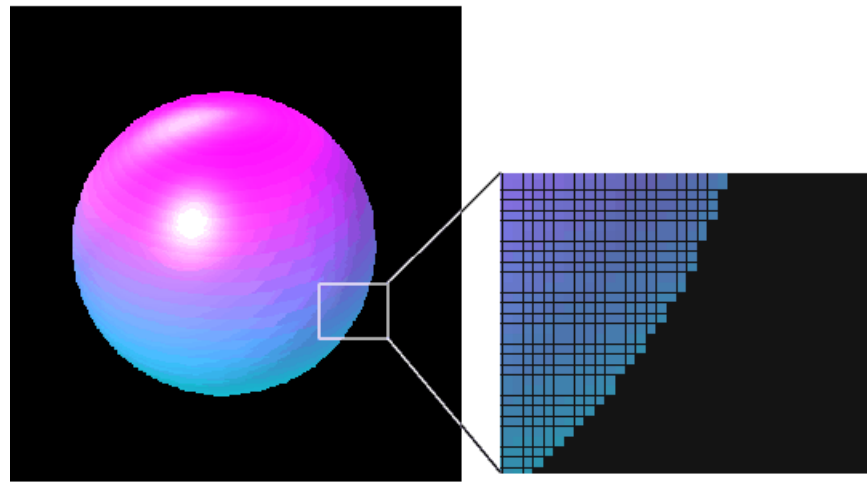
The default value for `BackFaceLighting` is `reverselit`. This setting reverses the direction of the vertex normals that face away from the camera, causing the interior surface to reflect light towards the camera. Setting `BackFaceLighting` to `unlit` disables lighting on faces with normals that point away from the camera.

You can also use `BackFaceLighting` to remove edge effects for closed objects. These effects occur when `BackFaceLighting` is set to `reverselit` and pixels along the edge of a closed object are lit as if their vertex normals faced the camera. This produces an improperly lit pixel because the pixel is visible but is really facing away from the camera.

To illustrate this effect, the next picture shows a blowup of the edge of a lit sphere. Setting `BackFaceLighting` to `lit` prevents the improper lighting of pixels.



BackFaceLighting = reverselit



BackFaceLighting = lit

Positioning Lights in Data Space

This example creates a sphere and a cube to illustrate the effects of various properties on lighting. The variables `vert` and `fac` define the cube using the `patch` function.

```
vert =                          fac =

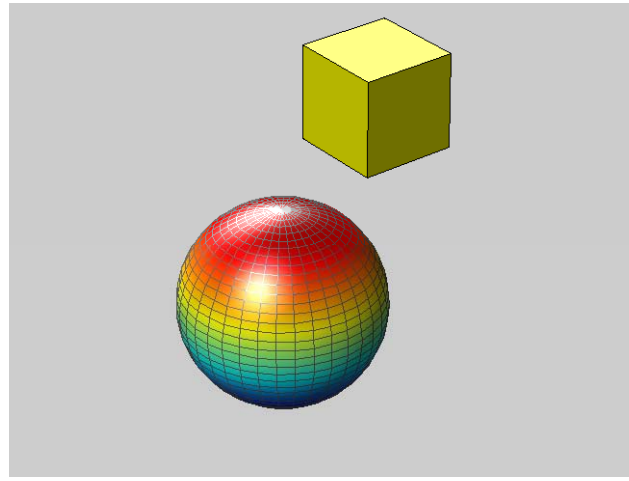
     1     1     1                1     2     3     4
     1     2     1                2     6     7     3
     2     2     1                4     3     7     8
     2     1     1                1     5     8     4
     1     1     2                1     2     6     5
     1     2     2                5     6     7     8
     2     2     2
     2     1     2
```

```
sphere(36);
h = findobj('Type','surface');
set(h,'FaceLighting','phong',...
      'FaceColor','interp',...
      'EdgeColor',[.4 .4 .4],...
      'BackFaceLighting','lit')
hold on
patch('faces',fac,'vertices',vert,'FaceColor','y');
light('Position',[1 3 2]);
light('Position',[-3 -1 3]);
material shiny
axis vis3d off
hold off
```

All faces of the cube have `FaceColor` set to yellow. The `sphere` function creates a spherical surface and the handle of this surface is obtained using `findobj` to search for the object whose `Type` property is `surface`. The `light` functions define two white (the default color) light objects located at infinity in the direction specified by the `Position` vectors. These vectors are defined in axes coordinates [*x*, *y*, *z*].

The patch uses `flat` `FaceLighting` (the default) to enhance the visibility of each side. The surface uses `phong` `FaceLighting` because it produces the smoothest interpolation of lighting effects. The `material shiny` command affects the reflectance properties of both the cube and sphere (although its effects are noticeable only on the sphere because of the cube's flat shading).

Because the sphere is closed, the `BackFaceLighting` property is changed from its default setting, which reverses the direction of vertex normals that face away from the camera, to normal lighting, which removes undesirable edge effects.



Examining the code in the `lighting` and `material` M-files can help you understand how various properties affect lighting.

4

Transparency

Making Objects Transparent

In this section...

About Transparency

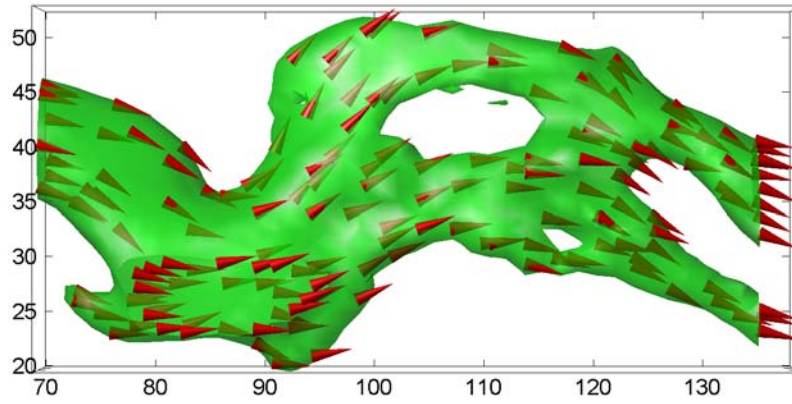
Making graphics objects semitransparent is a useful technique in 3-D visualization to make it possible to see an object, while at the same time, see what information the object would obscure if it was completely opaque. You can also use transparency as another dimension for displaying data, much the way color is used in MATLAB.

The transparency of a graphics object determines the degree to which you can see through the object. You can specify a continuous range of transparency varying from completely transparent (i.e., invisible) to completely opaque (i.e., no transparency).

Objects that support transparency are

- Image
- Patch
- Surface

The following picture illustrates the effect of transparency. The green isosurface (patch object) reveals the cone plot that lies in the interior.



Note You must have OpenGL available on your system to use transparency. When rendering transparency MATLAB automatically uses OpenGL if it is available. If it is not available, transparency does not display. See the figure property `RendererMode` for more information.

Specifying Transparency

Transparency values, which range from [0 1], are referred to as *alpha* values. An alpha value of 0 means completely transparent (i.e., invisible); an alpha value of 1 means completely opaque (i.e., no transparency).

MATLAB treats transparency in a way that is analogous to how it treats color for the respective objects:

- Patches and surfaces can define a single face and edge alpha value or use flat or interpolated transparency based on values in the figure's alphamap.
- Images, patches, and surfaces can define alpha data that is used as indices into the alphamap or directly as alpha values.
- Axes define alpha limits that control the mapping of object data to alpha values.
- Figures contain alphamaps, which are m-by-1 arrays of alpha values.

See the following sections for more information on color:

- "Specifying Patch Coloring" on page 5-14 in Creating 3-D Models with Patches in the Using MATLAB Graphics documentation
- "Coloring Mesh and Surface Plots" on page 1-16 in Creating 3-D Graphs in the Using MATLAB Graphics documentation

Transparency Properties

The following table summarizes the object properties that control transparency.

Property	Purpose
`AlphaData`	Transparency data for image and surface objects
`AlphaDataMapping`	Transparency data mapping method
`FaceAlpha`	Transparency of the faces (patch and surface only)
`EdgeAlpha`	Transparency of the edges (patch and surface only)
`FaceVertexAlphaData`	Patch only alpha data property
`ALim`	Alpha axis limits
`ALimMode`	Alpha axis limits mode
`Alphamap`	Figure alphamap

Transparency Functions

There are three functions that simplify the process of setting alpha properties.

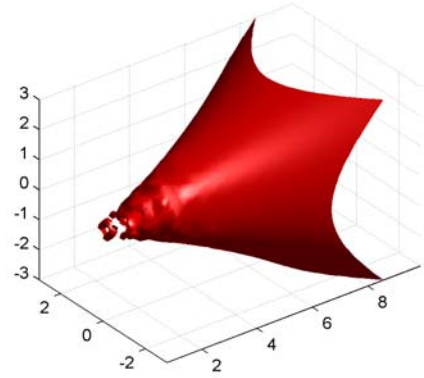
Function	Purpose
`alpha`	Set or query transparency properties for objects in current axes
`alphamap`	Specify the figure alphamap
`alim`	Set or query the axes alpha limits

Example — A Transparent Isosurface

Specifying a single transparency value for graphics objects is useful when you want to reveal structure that is obscured with opaque objects. For patches and surfaces, use the `FaceAlpha` and `EdgeAlpha` properties to specify the transparency of faces and edges. The following example illustrates this.

This example uses the `flow` function to generate data for the speed profile of a submerged jet within an infinite tank. One way to visualize this data is by creating an isosurface illustrating where the rate of flow is equal to a specified value.

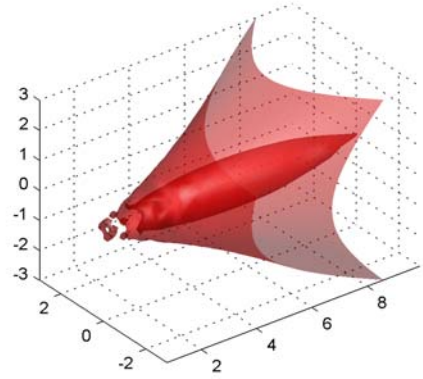
```
[x y z v] = flow;
p = patch(isosurface(x,y,z,v,-3));
isonormals(x,y,z,v,p);
set(p,'facecolor','red','edgecolor','none');
daspect([1 1 1]);
view(3); axis tight; grid on;
camlight; lighting gouraud;
```



Adding transparency to the isosurface reveals that there is greater complexity in the fluid flow than is visible using the opaque surface. The statement

```
alpha(.5)
```

sets the `FaceAlpha` value for the isosurface face to .5.



Setting a Single Transparency Value for Images

For images, the statement

```
alpha(.5)
```

sets `AlphaData` to .5. When the `AlphaDataMapping` property is set to `none` (the default), setting `AlphaData` on an image causes the entire image to be rendered with the specified alpha value.

Mapping Data to Transparency — Alpha Data

In this section...

What Is Alpha Data?

Alpha data is analogous to color data (e.g., the `CData` property of surfaces). When you create a surface, MATLAB maps each element in the color data array to a color in the colormap. Similarly, each element in the alpha data maps to a transparency value in the alphamap.

Specify surface and image alpha data with the `AlphaData` property. For patch objects, use the `FaceVertexAlphaData` property.

You can control how MATLAB interprets alpha data with the following properties:

- `FaceAlpha` and `EdgeAlpha` — Enable you to select flat or interpolated transparency rendering. If set to a single transparency value, MATLAB applies this value to all faces or edges and does not use the alpha data.
- `AlphaDataMapping` and `ALim` — Determine how MATLAB maps the alpha data to the alphamap. By default, MATLAB scales the alpha data to be within the range [0 1].
- `Alphamap` — Contains the actual transparency values to which the data is to be mapped.

Note that there are differences between the default values of equivalent color and alpha properties because, in contrast to color, transparency is not displayed by default. The following table highlights these differences.

Color Property	Default	Alpha Property	Default
`FaceColor`	Flat	`FaceAlpha`	1 (opaque)
`CData`	Equal to `ZData`	`AlphaData` and `FaceVertexAlphaData`	1 (scalar)

By default, objects have single-valued alpha data. Therefore you cannot specify `flat` or `interp` `FaceAlpha` or `EdgeAlpha` without first setting `AlphaData` to an array of the appropriate size.

The sections that follow illustrate how to use these properties to display object data as degrees of transparency.

Size of the Alpha Data Array

In order to use nonscalar alpha data, you need to specify the alpha data as an array equal in size to

- `CData` of images and surfaces
- The number of faces (flat) or the number of vertices (interpolated) defined in the `FaceVertexAlphaData` property of patches

Once you have specified an alpha data array of the proper size, you can select the face and edge rendering you want to use. Flat uses one transparency value per face, while interpolated performs bilinear interpolation of the values at each vertex.

Mapping Alpha Data to the Alphamap

You can control how MATLAB maps the alpha data to the alphamap using the `AlphaDataMapping` property. There are three possible mappings:

- `none` — Interpret the values in alpha data as transparency values (data values must be between 0 and 1, or will be clamped to 0 or 1). This is the default mapping.

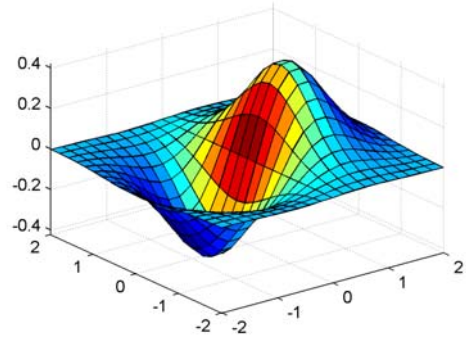
- `scaled` — Transform the alpha data to span the portion of the alphamap indicated by the axes `ALim` property, linearly mapping data values to alpha values. This is the same way color data is mapped to the colormap.
- `direct` — Use the alpha data directly as indices into the figure alphamap.

By default, objects have scalar alpha data (`AlphaData` and `FaceVertexAlphaData`) set to the value 1.

Example — Mapping Data to Color or Transparency

This example displays a surface plot of a function of two variables. The color is mapped to the gradient of the `z` data.

```
[x,y] = meshgrid([-2:.2:2]);
z = x.*exp(-x.^2-y.^2);
surf(x,y,z,gradient(z)); axis tight
```



You can map transparency to the gradient of `z` in a similar way.

```
surf(x,y,z,'FaceAlpha','flat',...
 'AlphaDataMapping','scaled',...
 'AlphaData',gradient(z),...
 'FaceColor','blue');
axis tight
```

0
1
2

Selecting an Alphamap

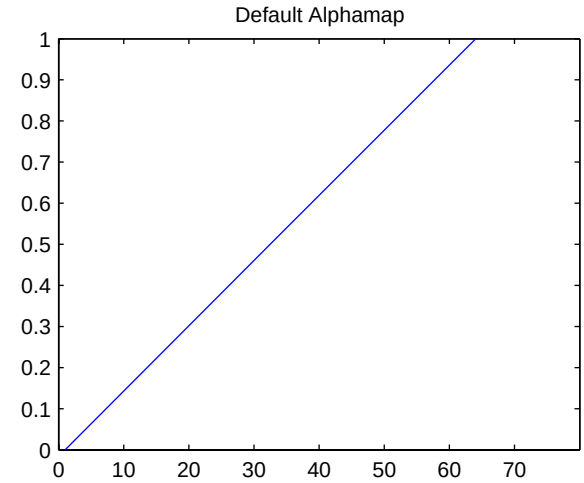
In this section...

What Is an Alphamap?

An alphamap is simply an array of values ranging from 0 to 1. The size of the array can be either m-by-1 or 1-by-m.

The default alphamap contains 64 values ranging linearly from 0 to 1, as you can see in the following plot.

```
plot(get(gcf,'Alphamap'))
```

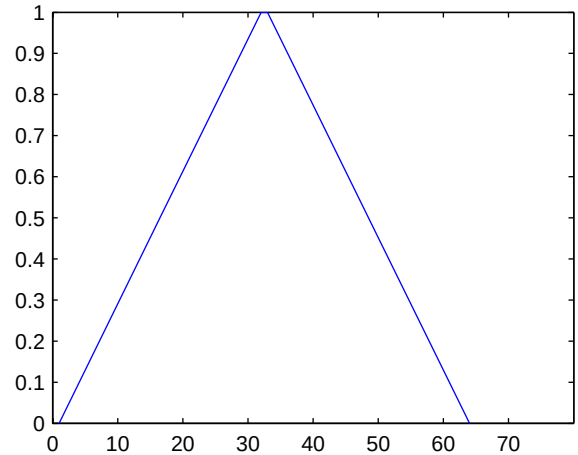


This alphamap displays the lowest alpha data values as completely transparent and the highest alpha data values as opaque.

The `alphamap` function creates some useful predefined alphamaps and also enables you to modify existing maps. For example,

```
plot(alphamap('vup'))
```

produces the following alphamap.

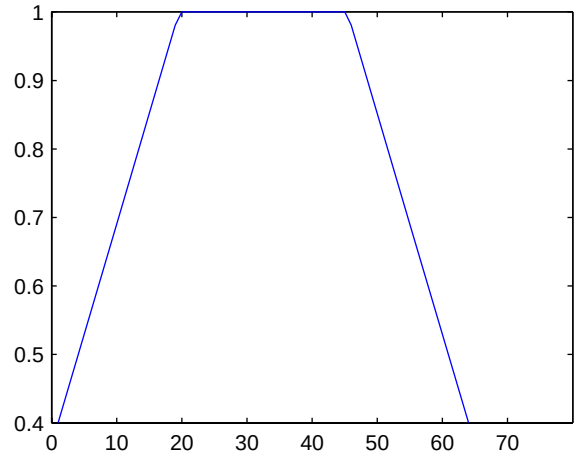


You can shift the values using the `increase` or `decrease` options. For example,

```
alphamap('increase',.4)
```

adds the value .4 to all values in the current figure's alphamap. Replotting the `'vup'` alphamap illustrates the change. Note how the values are clamped to the range [0 1].

```
plot(get(gcf,'Alphamap'))
```



Example — Modifying the Alphamap

This example uses slice planes to examine volume data. The slice planes use the color data for alpha data and employ a rampdown alphamap (the values range from 1 to 0):

1. Create the volume data by evaluating a function of three variables.

```
[x,y,z] = meshgrid(-1.25:.1:-.25,-2:.2:2,-2:.1:2);
v = x.*exp(-x.^2-y.^2-z.^2);
```

2. Create the slice planes, set the alpha data equal to the color data, and specify interpolated `FaceAlpha`.

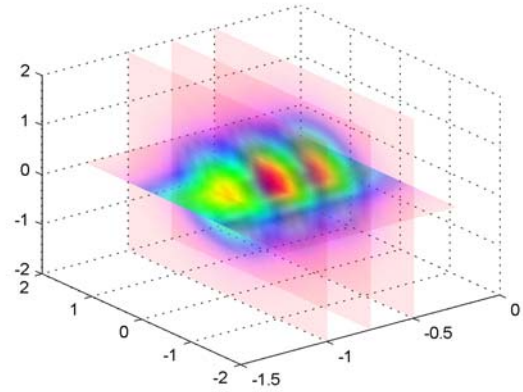
```
h = slice(x,y,z,v,[-1 -.75 -.5],[],[0]);
alpha('color')
set(h,'EdgeColor','none','FaceColor','interp',...
 'FaceAlpha','interp')
```

3. Install the rampdown alphamap and increase each value in the alphamap by .1 to achieve the desired degree of transparency. Specify the `hsv` colormap.

```
alphamap('rampdown')
```

```
alphamap('increase',.1)
colormap(hsv)
```

This alphamap causes the smallest values of the function (around zero) to be displayed with the least transparency and the greatest values to display with the most transparency. This enables you to see through the slice planes, while at the same time preserving the data around zero.



5

Creating 3-D Models with Patches

Introduction to Patch Objects

In this section...

What Are Patch Objects?

A patch graphics object is composed of one or more polygons that may or may not be connected. Patches are useful for modeling real-world objects such as airplanes or automobiles, and for drawing 2- or 3-D polygons of arbitrary shape.

In contrast, surface objects are rectangular grids of quadrilaterals and are better suited for displaying planar topographies such as the values of mathematical functions of two variables, the contours of data in a rectangular plane, or parameterized surfaces such as spheres.

A number of MATLAB functions create patch objects — `fill`, `fill3`, `isosurface`, `isocaps`, some of the `contour` functions, and `patch`. This section concentrates on use of the `patch` function.

You define a patch by specifying the coordinates of its vertices and some form of color data. Patches support a variety of coloring options that are useful for visualizing data superimposed on geometric shapes.

There are two ways to specify a patch:

- By specifying the coordinates of the vertices of each polygon, which MATLAB connects to form the patch
- By specifying the coordinates of each *unique* vertex and a matrix that specifies how to connect these vertices to form the faces

The second technique is preferred for multifaceted patches because it generally requires less data to define the patch; vertices shared by more than

one face need be defined only once. This section provides examples of both techniques.

Behavior of the patch Function

There are two forms of the `patch` function -- high-level syntax and low-level syntax. The behavior of the `patch` function differs somewhat depending on which syntax you use.

High-Level Syntax

When you use the high-level syntax, MATLAB automatically determines how to color each face based on the color data you specify. The high-level syntax enables you to omit the property names for the *x*-, *y*-, and *z*-coordinates and the color data, as long as you specify these arguments in the correct order.

```
patch(x-coordinates,y-coordinates,z-coordinates,colordata)
```

However, you must specify color data so MATLAB can determine what type of coloring to use. If you do not specify color data, MATLAB returns an error.

```
patch(sin(t),cos(t))
??? Error using ==> patch
Not enough input arguments.
```

Low-Level Syntax

The low-level syntax accepts only property name/property value pairs as arguments and does not automatically color the faces unless you also change the value of the `FaceColor` property. For example, the statement

```
patch('XData',sin(t),'YData',cos(t)) % Low-level syntax
```

draws a patch with white face color because the factory default value for the `FaceColor` property is the color white.

```
get(0,'FactoryPatchFaceColor')
ans =
      1     1     1
```

See the list of patch properties in the MATLAB Function Reference and the `get` command for information on how to obtain the factory and user default values for properties.

Interpreting the Color Argument

When you use the low-level syntax, MATLAB interprets the third (or fourth if there are *z*-coordinates) argument as color data. If you intend to define a patch with *x*-, *y*-, and *z*-coordinates, but leave out the color, MATLAB interprets the *z*-coordinates as color data, and then draws a 2-D patch. For example,

```
h = patch(sin(t),cos(t),1:length(t))
```

draws a patch with all vertices at z = 0, colored by interpolating the vertex colors (since there is one color for each vertex), whereas

```
h = patch(sin(t),cos(t),1:length(t),'y')
```

draws a patch with vertices at increasing values of *z*, colored yellow.

"Specifying Patch Coloring" on page 5-14 provides more information on options for coloring patches.

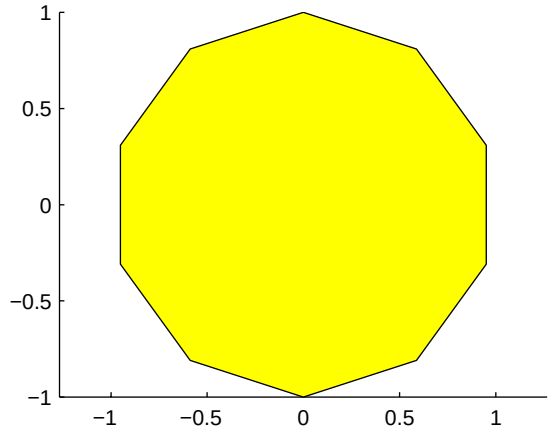
Creating a Single Polygon

A polygon is simply a patch with one face. To create a polygon, specify the coordinates of the vertices and color data with a statement of the form

```
patch(x-coordinates,y-coordinates,[z-coordinates],colordata)
```

For example, these statements display a 10-sided polygon with a yellow face enclosed by a black edge. The `axis equal` command produces a correctly proportioned polygon.

```
t = 0:pi/5:2*pi;
patch(sin(t),cos(t),'y')
axis equal
```

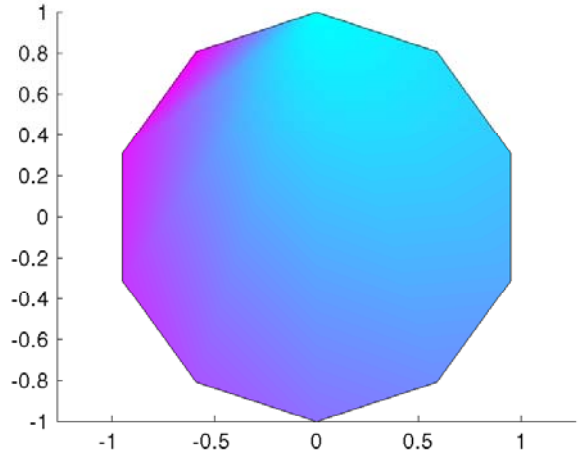


The first and last vertices need not coincide; MATLAB automatically closes each polygonal face of the patch. In fact, it is generally better to define each vertex only once, particularly if you are using interpolated face coloring.

Interpolated Face Colors

You can control many aspects of the patch coloring. For example, instead of specifying a single color, you can provide a range of numerical values that map the color at each vertex to a color in the figure colormap.

```
a = t(1:length(t)-1); %remove redundant vertex definition
patch(sin(a),cos(a),1:length(a),'FaceColor','interp')
colormap cool;
axis equal
```



MATLAB now interpolates the colors across the face of the patch. You can color the edges of the patch the same way, by setting the edge colors to be interpolated. The command is

```
patch(sin(t),cos(t),1:length(t),'EdgeColor','interp')
```

“Specifying Patch Coloring” on page 5-14 provides more information on options for coloring patches.

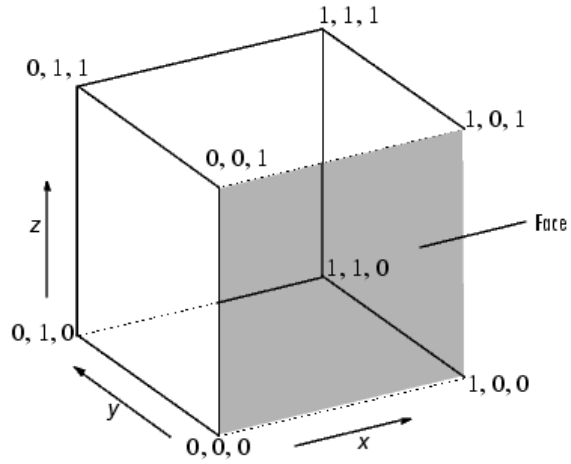
Multifaceted Patches

Example — Defining a Cube

A cube is defined by eight vertices that form six sides. This illustration shows the *x*-, *y*-, and *z*-coordinates of the vertices defining a cube in which the sides are one unit in length.

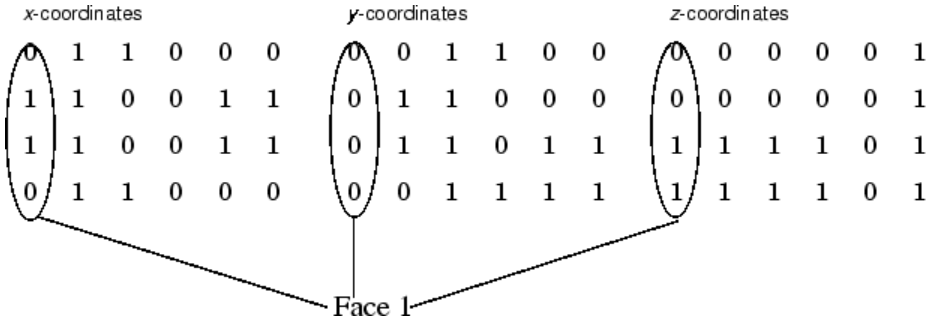
If you specify the *x*-, *y*-, and *z*-coordinate arguments as vectors, MATLAB draws a single polygon by connecting the points. If the arguments are matrices, MATLAB draws one polygon per column, producing a single patch with multiple faces. These faces need not be connected and can be self-intersecting.

Alternatively, you can specify the coordinates of each unique vertex and the order in which to connect them to form the faces. The examples in this section illustrate both techniques.



Specifying X, Y, and Z Coordinates

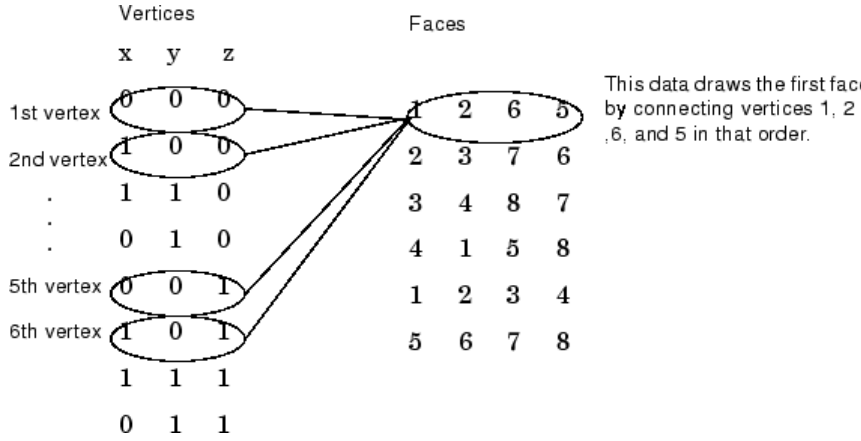
Each of the six faces has four vertices. Because you do not need to close each polygon (i.e., the first and last vertices do not need to be the same), you can define this cube using a 4-by-6 matrix for each of the *x*-, *y*-, and *z*-coordinates.



Each column of the matrices specifies a different face. Note that while there are only eight vertices, you must specify 24 vertices to define all six faces. Since each face shares vertices with four other faces, you can define the patch more efficiently by defining each vertex only once and then specifying the order in which to connect these vertices to form each face. The patch `Vertices` and `Faces` properties define patches in just this way.

Specifying Faces and Vertices

These matrices specify the cube using `Vertices` and `Faces`.



Using the vertices/faces technique can save a considerable amount of computer memory when patches contain a large number of faces. This technique requires the formal `patch` function syntax, which entails assigning values to the `Vertices` and `Faces` properties explicitly. For example,

```
patch('Vertices',vertex_matrix,'Faces',faces_matrix)
```

Because the high-level syntax does not automatically assign face or edge colors, you must set the appropriate properties to produce patches with colors other than the default white face color and black edge color.

Flat Face Color

Flat face color is the result of specifying one color per face. For example, using the vertices/faces technique and the `FaceVertexCData` property to define color, this statement specifies one color per face and sets the `FaceColor` property to `flat`.

```
patch('Vertices',vertex_matrix,'Faces',faces_matrix,...
      'FaceVertexCData',hsv(6),'FaceColor','flat')
```

Because truecolor specified with the `FaceVertexCData` property has the same format as a MATLAB colormap (i.e., an *n*-by-3 array of RGB values), this example uses the `hsv` colormap to generate the six colors required for flat shading.

Interpolated Face Color

Interpolated face color means the vertex colors of each face define a transition of color from one vertex to the next. To interpolate the colors between vertices, you must specify a color for each vertex and set the `FaceColor` property to `interp`.

```
patch('Vertices',vertex_matrix,'Faces',faces_matrix,...
      'FaceVertexCData',hsv(8),'FaceColor','interp')
```

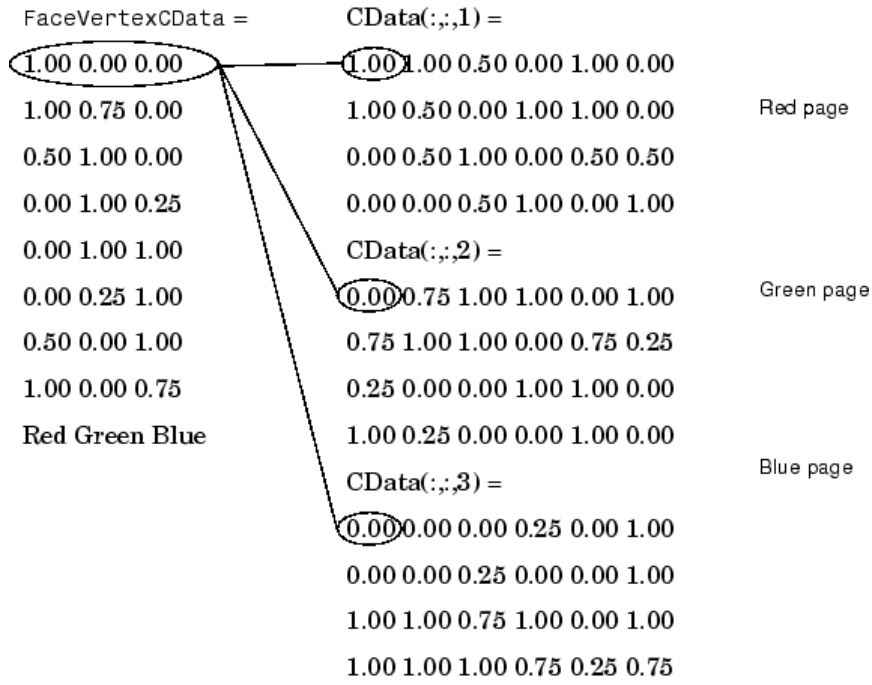
Changing to the standard 3-D view and making the axis square,

```
view(3); axis square
```

produces a cube with each face colored by interpolating the vertex colors.

To specify the same coloring using the x, y, z, c technique, c must be an *m*-by-*n*-by-3 array, where the dimensions of x, y, and z are *m*-by-*n*.

This diagram shows the correspondence between the `FaceVertexCData` and `CData` properties.



"Specifying Patch Coloring" on page 5-14 discusses coloring techniques in more detail.

Modifying Data on Existing Patch Objects

In this section...

Specifying Patch Data

In general, if you define a patch with `Faces` and `Vertices` data and then want to modify its data, you should continue to use these same properties. Do not switch modes and modify the `XData`, `YData`, `ZData`, or `CData` properties.

Handling Mixed Data Specification

When you create a patch specified with `Faces` and `Vertices` data, MATLAB constructs arrays of data for the `XData`, `YData`, `ZData` and `CData` properties when you query them. However, these arrays contain only enough data to define the same number of vertices as there are referred to in the `Faces` property. If the number of vertices in the `Vertices` property is greater than the number of vertices used by the `Faces` property, then MATLAB cannot generate complete x, y, and z data from the faces and vertex data.

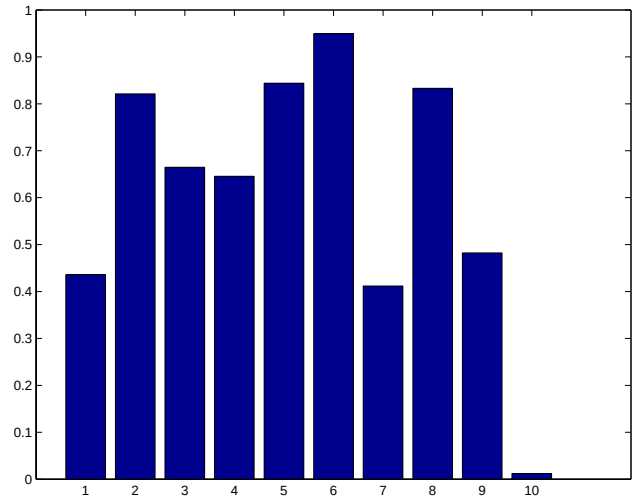
While you should not use mixed data specification when defining patch objects directly, you might need to modify patch data when using functions that themselves create patch objects. For example, the `bar` function creates patch objects to implement the bars in a graph.

Note The barseries `YData` property enables you to modify the bar graph without the need to use the following steps. See the `bar` function for more information on working with bar graphs.

The function uses y-data values to determine the height of each bar, but creates each bar as the face of a patch specified by faces and vertices. For example,

```
rand('state',4)
```

```
h = bar(rand(10,1));   % y data for each bar
p = get(h,'children'); % get the handle of the patch
cl = get(gca,'CLim');
```



Before you can change the patch `YData` property, you must switch the patch to x, y, and z data as follows:

```
xd = get(p,'XData');
yd = get(p,'YData');
zd = get(p,'ZData');
cd = get(p,'CData');
set(p,'XData',xd,'YData',yd,'ZData',zd,'CData',cd);
set(gca,'CLim',cl)
```

This setting of the `XData`, `YData`, `ZData` and `CData` properties causes the `patch` function to match the faces and vertex data with x, y, and z data. Note that because there is a change in the patch data, the color limits change, so you must use the original values for the axes `CLim` property.

You can now modify the y data values to change your graph. For example, the value of bar at x = 10 is 0.0122:

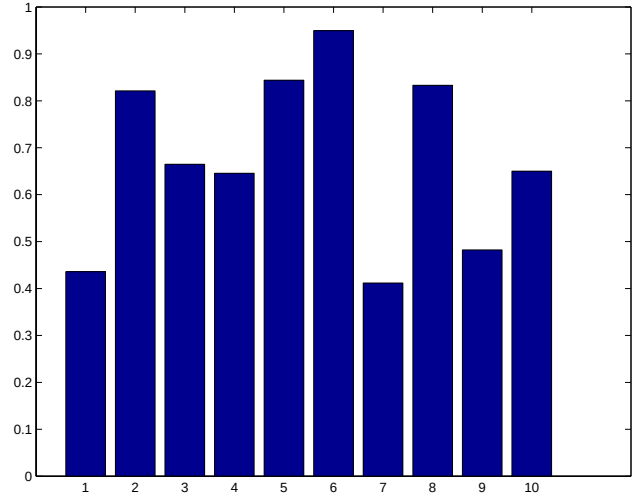
```
yd(:,10)
ans =
         0
    0.0122
    0.0122
         0
```

You can change this bar by changes rows 2 and 3:

```
yd(2:3,10) = [.65 .65];
```

Now reset the patch `YData` property:

```
set(p,'YData',yd)
```



Another reason you might want to modify face-vertex data for bar graphs or other objects is to modify their `CData` to customize how they are colored. Techniques for doing this for 2–D and 3–D bar graphs are explained in "Coloring 2-D Bars According to Height" and "Coloring 3-D Bars According to Height" in the MATLAB Graphics documentation.

Specifying Patch Coloring

In this section...

Patch Color Properties

Patch coloring is defined differently from surface object coloring in that patches do not automatically generate color data based on the value of the *z*-coordinate at each vertex. You must explicitly specify patch coloring, or MATLAB uses the default white face color and black edge color.

You can specify patch face coloring by defining

- A single color for all faces
- One color for each face, which is used for flat coloring
- One color for each vertex, which is used for interpolated coloring

Specify the face color using either the `CData` property, if you are using *x*-, *y*-, and *z*-coordinates, or the `FaceVertexCData` property, if you are specifying vertices and faces.

This table summarizes the patch properties that control color (exclusive of those used when light sources are present).

Property	Purpose
`CData`	Specify single, per face, or per vertex colors in conjunction with x, y, and z data
`CDataMapping`	Specifies whether color data is scaled or used directly as indices into the figure colormap
`FaceVertexCData`	Specify single, per face, or per vertex colors in conjunction with faces and vertices data

Property	Purpose
`EdgeColor`	Specifies whether edges are invisible, a single color, a flat color determined by vertex colors, or interpolated colors determined by vertex colors
`FaceColor`	Specifies whether faces are invisible, a single color, a flat color determined by vertex colors, or interpolated colors determined by vertex colors
`MarkerEdgeColor`	Specifies the color of the marker, or the edge color for filled markers
`MarkerFaceColor`	Specifies the fill color for markers that are closed shapes

Patch Edge Coloring

Each patch face has a bounding edge, which you can color as

- A single color for all edges
- A flat color defined by the color of the vertex that precedes the edge
- Interpolated colors determined by the two vertices that bound the edge

Note that patch edge colors can be flat or interpolated only when you specify a color for each vertex. For flat edge coloring, MATLAB uses the color of the vertex preceding the edge to determine the color of the edge. The order in which you specify the vertices establishes which vertex colors a particular edge.

The following examples illustrate patch edge coloring:

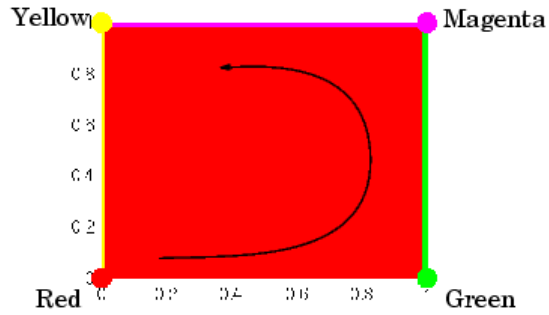
-
- “Coloring Edges with Shared Vertices” on page 5-17

Example — Specifying Flat Edge and Face Coloring

These statements create a square patch.

```
v  = [0 0 0;1 0 0;1 1 0;0 1 0];
```

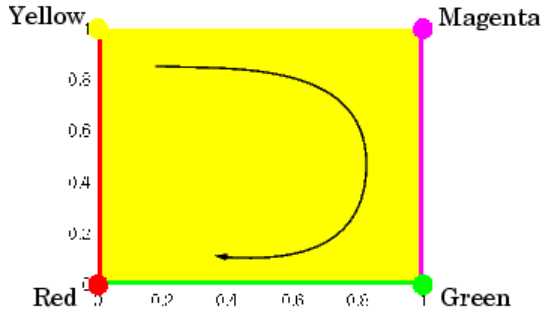
```
f = [1 2 3 4];
fvc = [1 0 0;0 1 0;1 0 1;1 1 0];
patch('Vertices',v,'Faces',f,'FaceVertexCData',fvc,...
      'FaceColor','flat','EdgeColor','flat',...
      'Marker','o','MarkerFaceColor','flat')
```



The `Faces` property value, `[1 2 3 4]`, determines the order in which MATLAB connects the vertices. In this case, the order is red, green, magenta, and yellow. If you change this order, the results can be quite different. For example, specifying the `Faces` property as

```
f = [4 3 2 1];
```

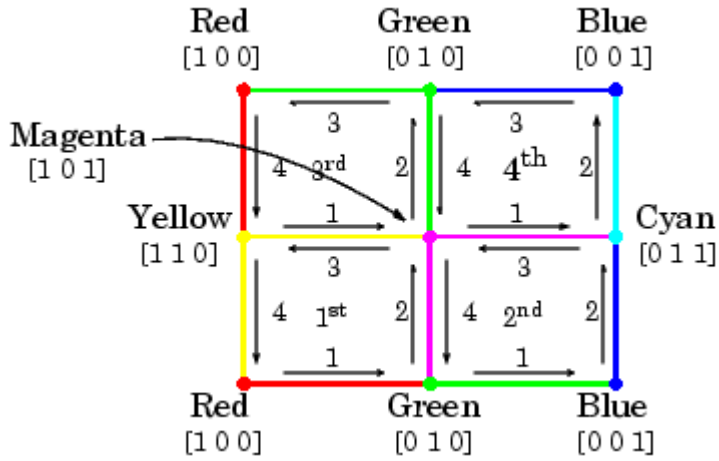
changes the order to yellow, magenta, green, and red. Note that changing the order not only changes the color of the edges, but also the color of the face, which is the color of the first vertex specified.



Coloring Edges with Shared Vertices

Each patch face is bound by edges, which are line segments that connect the vertices. When patches have multiple faces that share vertices, some of the edges might overlap. In such cases, the edges of the most recently drawn face overlie previously drawn edges.

For example, this illustration shows a patch with four faces and flat colored edges (`FaceColor` set to `none`, `EdgeColor` set to `flat`).



The arrows indicate the order in which each edge is drawn in the first, second, third, and fourth face. The color at each vertex determines the color of the edge that follows it. Notice how the second edge in the first face would be green except that the second face drew its fourth edge from the magenta vertex. You can see similar effects in all shared edges.

For `EdgeColor` set to `interp`, MATLAB interpolates colors between adjacent vertices. In this case, the order in which you specify the vertices does not affect the edge color.

Interpreting Indexed and Truecolor Data

In this section...

Introduction

MATLAB interprets the patch color data in either of two ways:

- Indexed Color Data — Numerical values that are mapped to colors defined in the figure colormap
- Truecolor Data — RGB triples that define colors explicitly and do not make use of the figure colormap

The dimensions of the color data (`CData` or `FaceVertexCData`) determine how MATLAB interprets it. If you specify only one numeric value per patch, per face, or per vertex, then MATLAB interprets the data as indexed. If there are three numeric values per patch, face, or vertex, then MATLAB interprets the data as RGB values.

Indexed Color Data

MATLAB interprets indexed color data as either values to scale before mapping to the colormap, or directly as indices into the colormap. You control the interpretation by setting the `CDataMapping` property. The default is to scale the data.

Scaled Color

By default, MATLAB scales the color data so that the minimum value maps to the first color in the colormap, the maximum value maps to the last color in the colormap, and values in between are linearly transformed to span the colormap. This enables you to use colormaps of different sizes without

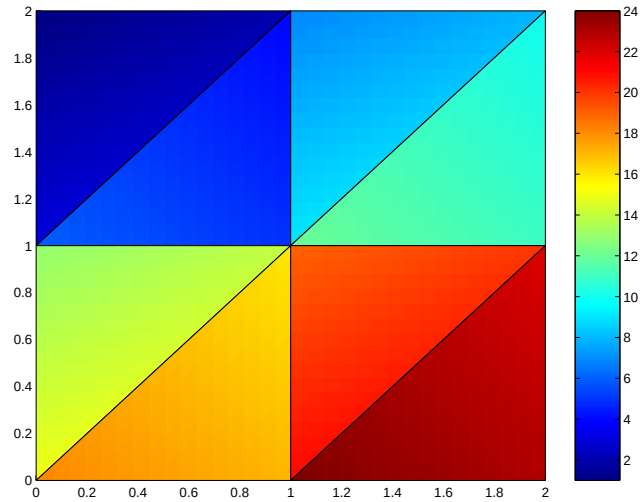
changing your data and to use data in any range of values without changing the colormap.

For example, the following patch has eight triangular faces with a total of 24 (nonunique) vertices. The color data are integers that range from one to 24, but could be any values.

The variable `c` contains the color data. It is a 3-by-8 matrix, with each column specifying the colors for the three vertices of each face.

```
c =
     1     4     7    10    13    16    19    22
     2     5     8    11    14    17    20    23
     3     6     9    12    15    18    21    24
```

The color bar (`colorbar`) on the right side of the patch illustrates the colormap used and indicates with the vertical axis which color is mapped to the respective data value.



You can alter the mapping of color data to colormap entry using the `caxis` command. This command uses a two-element vector `[cmin cmax]` to specify

what data values map to the beginning and end of the colormap, thereby shifting the color mapping.

By default, MATLAB sets `cmin` to the minimum value and `cmax` to the maximum value of the color data of all graphics objects within the axes. However, you can set these limits to span any range of values and thereby shift the color mapping. See Calculating Color Limits in "Axes Properties" in the Using MATLAB Graphics documentation for more information.

The color data does not need to be a sequential list of integers; it can be any matrix with dimensions matching the coordinate data. For example,

```
patch(x,y,z,rand(size(z)))
```

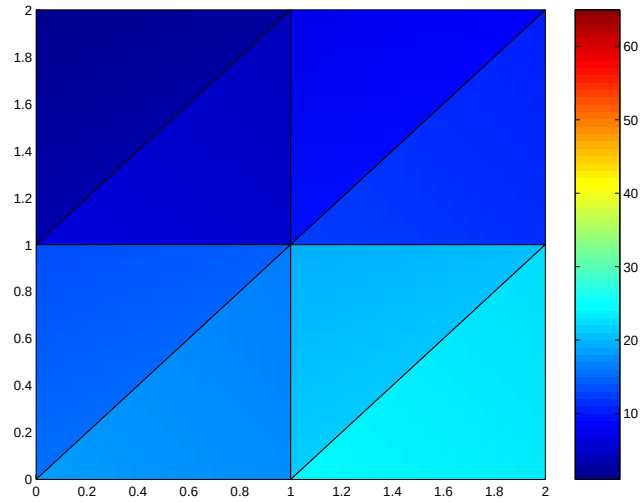
Direct Color

If you set the patch `CDataMapping` property to `direct`,

```
set(patch_handle,'CDataMapping','direct')
```

MATLAB interprets each color data value as a direct index into the colormap. That is, a value of 1 maps to the first color, a value of 2 maps to the second color, and so on.

The patch from the previous example would then use only the first 24 colors in the colormap.



This example uses integer color data. However, if the values are not integers, MATLAB converts them according to these rules:

- If value is < 1, it maps to the first color in the colormap.
- If value is not an integer, it is rounded to the nearest integer toward zero.
- If value > `length(colormap)`, it maps to the last color in the colormap.

Unscaled color data is more commonly used for images where there is typically a colormap associated with a particular image.

Truecolor Patches

Truecolor is a means to specify a color explicitly with RGB values rather than pointing to an entry in the figure colormap. Truecolor generally provides a greater range of colors than can be defined in a colormap.

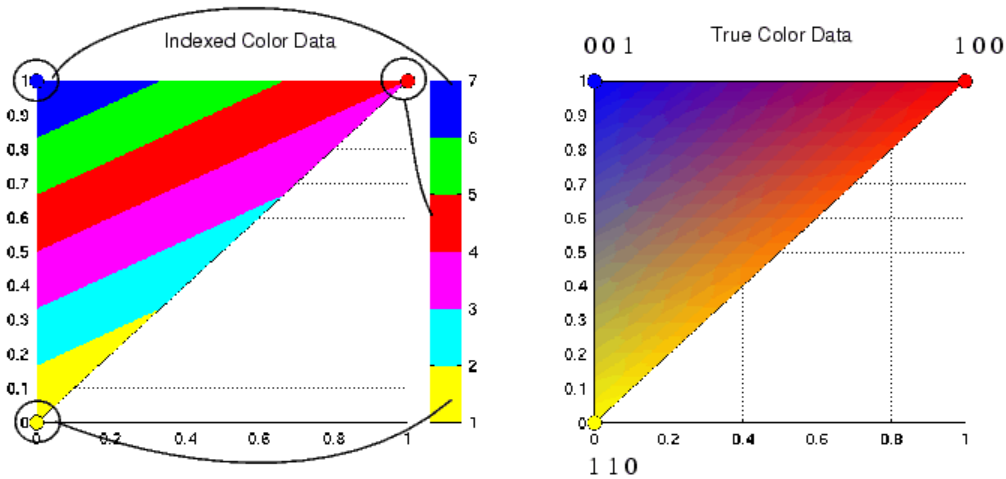
Using truecolor eliminates the mapping of data to colormap entries. On the other hand, you cannot change the coloring of the patch without redefining the color data (as opposed to just changing the colormap).

Interpolating in Indexed Color Versus Truecolor

When you specify interpolated face coloring, MATLAB determines the color of each face by interpolating the vertex colors. The method of interpolation depends on whether you specified truecolor data or indexed color data.

With truecolor data, MATLAB interpolates the numeric RGB values defined for the vertices. This generally produces a smooth variation of color across the face. In contrast, indexed color interpolation uses only colors that are defined in the colormap. With certain colormaps, the results can be quite different.

To illustrate this difference, these two patches are defined with the same vertex colors. Circular markers indicate the yellow, red, and blue vertex colors.



The patch on the left uses indexed colors obtained from the six-element colormap shown next to it. The color data maps the vertex colors to the colormap elements indicated in the picture. With this colormap, interpolating from the cyan vertex to the blue vertex can include only the colors green, red, yellow, and magenta, hence the banding.

Interpolation in RGB space makes no use of the colormap. It is simply the gradual transition from one numeric value to another. For example,

interpolating from the cyan vertex to the blue vertex follows a progression similar to these values.

```
0 1 1, 0 0.9 1, 0 0.8 1, ... 0 0.2 1, 0 0.1 1, 0 0 1
```

In reality each pixel would be a different color so the incremental change would be much smaller than illustrated here.

6

Volume Visualization Techniques

Overview of Volume Visualization

In this section...

Examples of Volume Data

Volume visualization is the creation of graphical representations of data sets that are defined on three-dimensional grids. Volume data sets are characterized by multidimensional arrays of scalar or vector data. These data are typically defined on lattice structures representing values sampled in 3-D space. There are two basic types of volume data:

- *Scalar volume data* contains single values for each point.
- *Vector volume data* contains two or three values for each point, defining the components of a vector.

An example of scalar volume data is that produced by the `flow` M-file. The flow data represents the speed profile of a submerged jet within an infinite tank. Typing

```
[x,y,z,v] = flow;
```

produces four 3-D arrays. The `x`, `y`, and `z` arrays specify the coordinates of the scalar values in the array `v`.

The `wind` data set is an example of vector volume data that represents air currents over North America. You can load this data in the MATLAB workspace with the command

```
load wind
```

This data set comprises six 3-D arrays: `x`, `y`, and `z` are the coordinate data for the arrays `u`, `v`, and `w`, which are the vector components for each point in the volume.

Selecting Visualization Techniques

The techniques you select to visualize volume data depend on what type of data you have and what you want to learn. In general,

- Scalar data is best viewed with isosurfaces, slice planes, and contour slices.
- Vector data represents both a magnitude and direction at each point, which is best displayed by stream lines (particles, ribbons, and tubes), cone plots, and arrow plots. Most visualizations, however, employ a combination of techniques to best reveal the content of the data.

The material in these sections describes how to apply a variety of techniques to typical volume data.

Steps to Create a Volume Visualization

Creating an effective visualization requires a number of steps to compose the final scene. These steps fall into four basic categories:

1. Determine the characteristics of your data. Graphing volume data usually requires knowledge of the range of both the coordinates and the data values.
2. Select an appropriate plotting routine. The information in this section helps you select the right methods.
3. Define the view. The information conveyed by a complex three-dimensional graph can be greatly enhanced through careful composition of the scene. Viewing techniques include adjusting camera position, specifying aspect ratio and project type, zooming in or out, and so on.
4. Add lighting and specify coloring. Lighting is an effective means to enhance the visibility of surface shape and to provide a three-dimensional perspective to volume graphs. Color can convey data values, both constant and varying.

Volume Visualization Functions

MATLAB provides functions that enable you to apply a variety of volume visualization techniques. The following tables group these functions into two categories based on the type of data (scalar or vector) that each is designed to work with. The reference page for each function provides examples of the intended use.

Functions for Scalar Data

Function	Purpose
`contourslice`	Draw contours in volume slice planes
`isocaps`	Compute isosurface end-cap geometry
`isocolors`	Compute the colors of isosurface vertices
`isonormals`	Compute normals of isosurface vertices
`isosurface`	Extract isosurface data from volume data
`patch`	Create a patch (multipolygon) graphics object
`reducepatch`	Reduce the number of patch faces
`reducevolume`	Reduce the number of elements in a volume data set
`shrinkfaces`	Reduce the size of each patch face
`slice`	Draw slice planes in volume
`smooth3`	Smooth 3-D data
`surf2patch`	Convert surface data to patch data
`subvolume`	Extract subset of volume data set

Functions for Vector Data

Function	Purpose
`coneplot`	Plot velocity vectors as cones in 3-D vector fields
`curl`	Compute the curl and angular velocity of a 3-D vector field

Function	Purpose
`divergence`	Compute the divergence of a 3-D vector field
`interpstreamspeed`	Interpolate streamline vertices from vector-field magnitudes
`streamline`	Draw stream lines from 2-D or 3-D vector data
`streamparticles`	Draw stream particles from vector volume data
`streamribbon`	Draw stream ribbons from vector volume data
`streamslice`	Draw well-spaced stream lines from vector volume data
`streamtube`	Draw stream tubes from vector volume data
`stream2`	Compute 2-D stream line data
`stream3`	Compute 3-D stream line data
`volumebounds`	Return coordinate and color limits for volume (scalar and vector)

Techniques for Visualizing Scalar Volume Data

In this section...

What Is Scalar Volume Data?

Typical scalar volume data is composed of a 3-D array of data and three coordinate arrays of the same dimensions. The coordinate arrays specify the *x*-, *y*-, and *z*-coordinates for each data point.

The units of the coordinates depend on the type of data. For example, flow data might have coordinate units of inches and data units of psi.

MATLAB supports a number of functions that are useful for visualizing scalar data:

- Slice planes provide a way to explore the distribution of data values within the volume by mapping values to colors. You can orient slice planes at arbitrary angles, as well as use nonplanar slices. (For illustrations of how to use slice planes, see `slice`, a volume slicing example, and slice planes used to show context.) You can specify the data used to color isosurfaces, enabling you to display different information in color and surface shape (see `isocolors`).
- Contour slices are contour plots drawn at specific coordinates within the volume. Contour plots enable you to see where in a given plane the data values are equal. See `contourslice` for an example
- Isosurfaces are surfaces constructed by using points of equal value as the vertices of `patch` graphics objects.

Example — Ways to Display MRI Data

An example of scalar data includes Magnetic Resonance Imaging (MRI) data. This data typically contains a number of slice planes taken through a volume, such as the human body. MATLAB includes an MRI data set that contains 27 image slices of a human head. This example illustrate the following techniques applied to MRI data:

- A series of 2-D images representing slices through the head
- 2-D and 3-D contour slices taken at arbitrary locations within the data
- An isosurface with isocaps showing a cross section of the interior

Changing the Data Format

The MRI data, `D`, is stored as a 128-by-128-by-1-by-27 array. The third array dimension is used typically for the image color data. However, since these are indexed images (a colormap, `map`, is also loaded) there is no information in the third dimension, which you can remove using the `squeeze` command. The result is a 128-by-128-by-27 array.

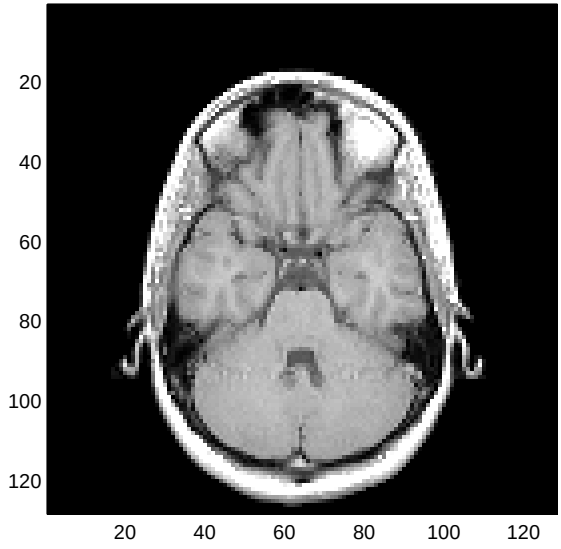
The first step is to load the data and transform the data array from 4-D to 3-D.

```
load mri
D = squeeze(D);
```

Displaying Images of MRI Data

To display one of the MRI images, use the `image` command, indexing into the data array to obtain the eighth image. Then adjust `axis` scaling, and install the MRI `colormap`, which was loaded along with the data.

```
image_num = 8;
image(D(:,:,image_num))
axis image
colormap(map)
```



Save the *x*- and *y*-axis limits for use in the next part of the example.

```
x = xlim;
y = ylim;
```

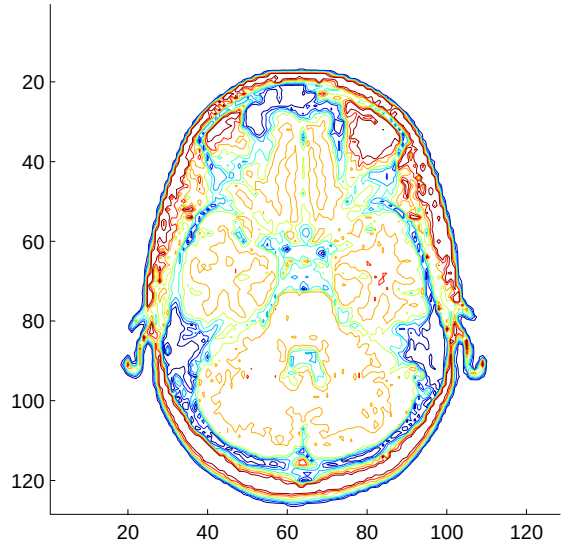
Displaying a 2-D Contour Slice

You can treat this MRI data as a volume because it is a collection of slices taken progressively through the 3-D object. Use `contourslice` to display a contour plot of a slice of the volume. To create a contour plot with the same

orientation and size as the image created in the first part of this example, adjust the *y*-axis direction (`axis`), set the limits (`xlim`, `ylim`), and set the data aspect ratio (`daspect`).

```
contourslice(D,[],[],image_num)
axis ij
xlim(x)
ylim(y)
daspect([1,1,1])
colormap('default')
```

This contour plot uses the figure colormap to map color to contour value.

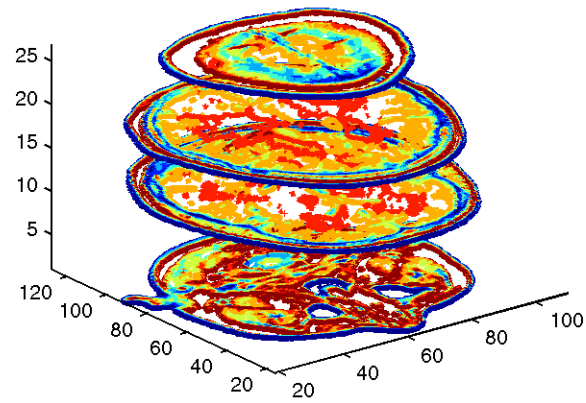


Displaying 3-D Contour Slices

Unlike images, which are 2-D objects, contour slices are 3-D objects that you can display in any orientation. For example, you can display four contour slices in a 3-D view. To improve the visibility of the contour line, increase the `LineWidth` to 2 points (one point equals 1/72 of an inch).

```
phandles = contourslice(D,[],[],[1,12,19,27],8);
```

```
view(3); axis tight
set(phandles,'LineWidth',2)
```



Displaying an Isosurface

You can use isosurfaces to display the overall structure of a volume. When combined with isocaps, this technique can reveal information about data on the interior of the isosurface.

First, smooth the data with `smooth3`; then use `isosurface` to calculate the isodata. Use `patch` to display this data as a graphics object.

```
Ds = smooth3(D);
hiso = patch(isosurface(Ds,5),...
 'FaceColor',[1,.75,.65],...
 'EdgeColor','none');
```

Adding an Isocap to Show a Cutaway Surface

Use `isocaps` to calculate the data for another patch that is displayed at the same isovalue (`5`) as the surface. Use the unsmoothed data (`D`) to show details of the interior. You can see this as the sliced-away top of the head.

```
hcap = patch(isocaps(D,5),...
 'FaceColor','interp',...
 'EdgeColor','none');
colormap(map)
```

Defining the View

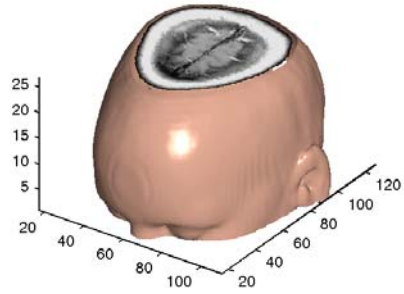
Define the view and set the aspect ratio (`view`, `axis`, `daspect`).

```
view(45,30)
axis tight
daspect([1,1,.4])
```

Add Lighting

Add lighting and recalculate the surface normals based on the gradient of the volume data, which produces smoother lighting (`camlight`, `lighting`, `isonormals`). Increase the `AmbientStrength` property of the isocap to brighten the coloring without affecting the isosurface. Set the `SpecularColorReflectance` of the isosurface to make the color of the specular reflected light closer to the color of the isosurface; then set the `SpecularExponent` to reduce the size of the specular spot.

```
lightangle(45,30);
set(gcf,'Renderer','zbuffer'); lighting phong
isonormals(Ds,hiso)
set(hcap,'AmbientStrength',.6)
set(hiso,'SpecularColorReflectance',0,'SpecularExponent',50)
```



Example of an Isocap

The isocap uses interpolated face coloring, which means the figure colormap determines the coloring of the patch. This example uses the colormap supplied with the data.

To display isocaps at other data values, try changing the isosurface value or use the `subvolume` command. See the `isocaps` and `subvolume` reference pages for examples.

Exploring Volumes with Slice Planes

In this section...

Example — Slicing Fluid Flow Data

A slice plane (which does not have to be planar) is a surface that takes on coloring based on the values of the volume data in the region where the slice is positioned. Slice planes are useful for probing volume data sets to discover where interesting regions exist, which you can then visualize with other types of graphs (see the `slice` example). Slice planes are also useful for adding a visual context to the bound of the volume when other graphing methods are also used (see `coneplot` and "Example — Stream Line Plots of Vector Data" on page 6-32 for examples).

Use the `slice` function to create slice planes. This example slices through a volume generated by the `flow` M-file.

1. Investigate the Data

Generate the volume data with the command

```
[x,y,z,v] = flow;
```

Determine the range of the volume by finding the minimum and maximum of the coordinate data.

```
xmin = min(x(:));
ymin = min(y(:));
zmin = min(z(:));

xmax = max(x(:));
ymax = max(y(:));
zmax = max(z(:));
```

2. Create a Slice Plane at an Angle to the X-Axes

To create a slice plane that does not lie in an axes plane, first define a surface and rotate it to the desired orientation. This example uses a surface that has the same *x*- and *y*- coordinates as the volume.

```
hslice = surf(linspace(xmin,xmax,100),...
 linspace(ymin,ymax,100),...
 zeros(100));
```

Rotate the surface by -45 degrees about the *x*-axis and save the surface `XData`, `YData`, and `ZData` to define the slice plane; then delete the surface.

```
rotate(hslice,[-1,0,0],-45)
xd = get(hslice,'XData');
yd = get(hslice,'YData');
zd = get(hslice,'ZData');
delete(hslice)
```

3. Draw the Slice Planes

Draw the rotated slice plane, setting the `FaceColor` to `interp` so that it is colored by the figure colormap, and set the `EdgeColor` to `none`. Increase the `DiffuseStrength` to `.8` to make this plane shine more brightly after adding a light source.

```
h = slice(x,y,z,v,xd,yd,zd);
set(h,'FaceColor','interp',...
 'EdgeColor','none',...
 'DiffuseStrength',.8)
```

Set `hold` to on and add three more orthogonal slice planes at `xmax`, `ymax`, and `zmin` to provide a context for the first plane, which slices through the volume at an angle.

```
hold on
hx = slice(x,y,z,v,xmax,[],[]);
set(hx,'FaceColor','interp','EdgeColor','none')

hy = slice(x,y,z,v,[],ymax,[]);
set(hy,'FaceColor','interp','EdgeColor','none')
```

```
hz = slice(x,y,z,v,[],[],zmin);
set(hz,'FaceColor','interp','EdgeColor','none')
```

4. Define the View

To display the volume in correct proportions, set the data aspect ratio to `[1,1,1]` (`daspect`). Adjust the axis to fit tightly around the volume (`axis`) and turn on the `box` to provide a sense of a 3-D object. The orientation of the axes can be selected initially using `rotate3d` to determine the best `view`.

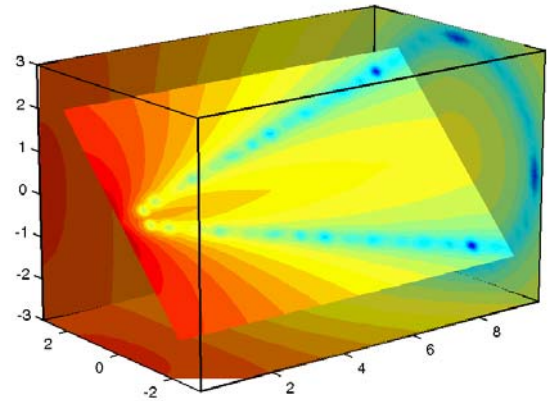
Zooming in on the scene provides a larger view of the volume (`camzoom`). Selecting a projection type of `perspective` gives the rectangular solid more natural proportions than the default orthographic projection (`camproj`).

```
daspect([1,1,1])
axis tight
box on
view(-38.5,16)
camzoom(1.4)
camproj perspective
```

5. Add Lighting and Specify Colors

Adding a light to the scene makes the boundaries between the four slice planes more obvious because each plane forms a different angle with the light source (`lightangle`). Selecting a colormap with only 24 colors (the default is 64) creates visible gradations that help indicate the variation within the volume.

```
lightangle(-45,45)
colormap (jet(24))
set(gcf,'Renderer','zbuffer')
```



The “Modifying the Color Mapping” on page 6-17 section shows how to modify how the data is mapped to color.

Modifying the Color Mapping

The current colormap determines the coloring of the slice planes. This enables you to change the slice plane coloring by

- Changing the colormap
- Changing the mapping of data value to color

Suppose, for example, you are interested in data values only between -5 and 2.5 and would like to use a colormap that mapped lower values to reds and higher values to blues (that is, the opposite of the default `jet` colormap).

Customizing the Colormap

The first step is to flip the colormap (`colormap`, `flipud`).

```
colormap (flipud(jet(24)))
```

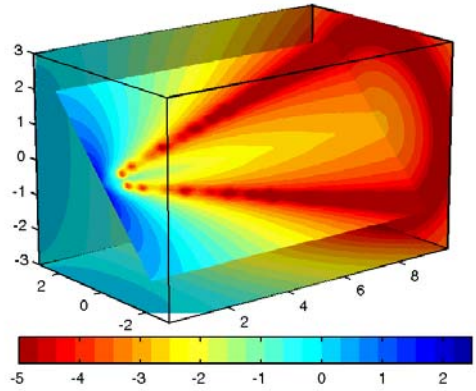
Adjusting the Color Limits

Adjusting the color limits enables you to emphasize any particular data range of interest. Adjust the color limits to range from -5 to 2.4832 so that any value lower than the value -5 (the original data ranged from -11.5417 to 2.4832) is mapped into the same color. (See `caxis` and Axis Color Limits - The CLim Property in Axes Properties in the MATLAB documentation for an explanation of color mapping.)

```
caxis([-5,2.4832])
```

Adding a color bar provides a key for the data-to-color mapping.

```
colorbar('horiz')
```



Connecting Equal Values with Isosurfaces

Example — Isosurfaces in Fluid Flow Data

Isosurfaces are constructed by creating a surface within the volume that has the same value at each vertex. Isosurface plots are similar to contour plots in that they both indicate where values are equal.

Isosurfaces are useful to determine where in a volume a certain threshold value is reached or to observe the spatial distribution of data by selecting various isovalues at which to generate a plot. The isovalue must lie within the range of the volume data.

Create isosurfaces with the `isosurface` and `patch` commands.

This example creates isosurfaces in a volume generated by the `flow` M-file. Generate the volume data with the command

```
[x,y,z,v] = flow;
```

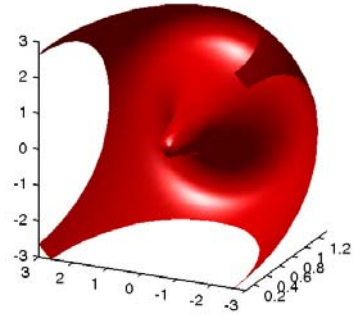
To select the isovalue, determine the range of values in the volume data.

```
min(v(:))
ans =
 -11.5417
max(v(:))
ans =
 2.4832
```

Through exploration, you can select isovalues that reveal useful information about the data. Once selected, use the isovalue to create the isosurface:

- Use `isosurface` to generate data that you can pass directly to `patch`.
- Recalculate the surface normals from the gradient of the volume data to produce better lighting characteristics (`isonormals`).
- Set the patch `FaceColor` to `red` and the `EdgeColor` to `none` to produce a smoothly lit surface.
- Adjust the view and add lighting (`daspect`, `view`, `camlight`, `lighting`).

```
hpatch = patch(isosurface(x,y,z,v,0));
isonormals(x,y,z,v,hpatch)
set(hpatch,'FaceColor','red','EdgeColor','none')
daspect([1,4,4])
view([-65,20])
axis tight
camlight left;
set(gcf,'Renderer','zbuffer'); lighting phong
```



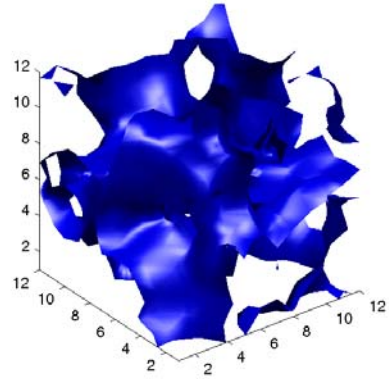
Isocaps Add Context to Visualizations

In this section...

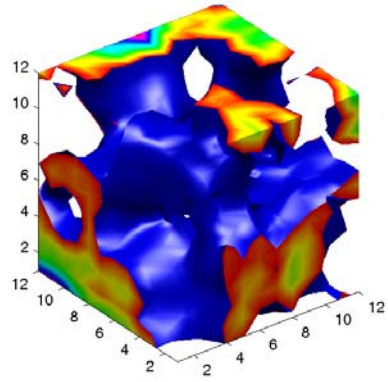
What Are Isocaps?

Isocaps are planes that are fitted to the limits of an isosurface to provide a visual context for the isosurface. Isocaps show a cross-sectional view of the interior of the isosurface for which the isocap provides an *end cap*.

The following two pictures illustrate the use of isocaps. The first is an isosurface without isocaps.



The second picture shows the effect of adding isocaps to the same isosurface.



Other Isocap Applications

Some additional applications of isocaps are shown in the following examples.

- Isocaps show the interior of a cut-away volume.
- Isocaps cap the end of a volume that would otherwise appear empty.
- Isocaps enhance the visibility of the isosurface limits.

Defining Isocaps

Isocaps, like isosurfaces, are created as `patch` graphics objects. Use the `isocaps` command to generate the data to pass to `patch`. For example,

```
patch(isocaps(voldata,isoval),...
 'FaceColor','interp',...
 'EdgeColor','none')
```

creates isocaps for the scalar volume data `voldata` at the value `isoval`. You should create the isosurface using the same volume data and isovalue to ensure that the edges of the isocaps *fit* the isosurface.

Setting the patch `FaceColor` property to `interp` results in a coloring that maps the data values spanned by the isocap to colormap entries. You can also set other patch properties to control the effects of lighting and coloring on the isocaps.

Example — Adding Isocaps to an Isosurface

This example illustrates how to set coloring and lighting characteristics when working with isocaps. There are five basic steps:

- Generate and process your volume data.
- Create the isosurface and isocaps and set patch properties to control the coloring and lighting.
- Create the isocaps and set properties.
- Specify the view.
- Add lights to the scene.

1. Prepare the Data

This example uses a 3-D array of random (`rand`) data to define the volume data. The data is then smoothed (`smooth3`).

```
data = rand(12,12,12);
data = smooth3(data,'box',5);
```

2. Create the Isosurface and Set Properties

Use `isosurface` and `patch` to create the isosurface and set coloring and lighting properties. Reduce the `AmbientStrength`, `SpecularStrength`, and `DiffuseStrength` of the reflected light to compensate for the brightness of the two light sources used to provide more uniform lighting.

Recalculate the vertex normals of the isosurface to produce smoother lighting (`isonormals`).

```
isoval = .5;
h = patch(isosurface(data,isoval),...
 'FaceColor','blue',...
 'EdgeColor','none',...
 'AmbientStrength',.2,...
 'SpecularStrength',.7,...
 'DiffuseStrength',.4);
isonormals(data,h)
```

3. Create the Isocaps and Set Properties

Define the `isocaps` using the same data and isovalue as the isosurface. Specify interpolated coloring and select a colormap that provides better contrasting colors with the blue isosurface than those in the default colormap (`colormap`).

```
patch(isocaps(data,isoval),...
 'FaceColor','interp',...
 'EdgeColor','none')
colormap hsv
```

4. Define the View

Set the data aspect ratio to `[1,1,1]` so that the display is in correct proportions (`daspect`). Eliminate white space within the axes and set the view to 3-D (`axis tight`, `view`).

```
daspect([1,1,1])
axis tight
view(3)
```

5. Add Lighting

To add fairly uniform lighting, but still take advantage of the ability of light sources to make visible subtle variations in shape, this example uses two lights, one to the left and one to the right of the camera (`camlight`). Use Phong lighting to produce the smoothest variation of color (`lighting`). Phong lighting requires the `zbuffer` renderer.

```
camlight right
camlight left
set(gcf,'Renderer','zbuffer');
lighting phong
```

Visualizing Vector Volume Data

In this section...

Lines, Particles, Ribbons, Streams, Tubes, and Cones

Vector volume data contains more information than scalar data because each coordinate point in the data set has three values associated with it. These values define a vector that represents both a magnitude and a direction. The velocity of fluid flow is an example of vector data.

MATLAB supports a number of techniques that are useful for visualizing vector data:

- Stream lines trace the path that a massless particle immersed in the vector field would follow.
- Stream particles are markers that trace stream lines and are useful for creating stream line animations.
- Stream ribbons are similar to stream lines, except that the width of the ribbons enables them to indicate twist. Stream ribbons are useful to indicate curl angular velocity.
- Stream tubes are similar to stream lines, but you can also control the width of the tube. Stream tubes are useful for displaying the divergence of a vector field.
- Cone plots represent the magnitude and direction of the data at each point by displaying a conical arrowhead or an arrow.

It is typically the case that these functions best elucidate the data when used in conjunction with other visualization techniques, such as contours, slice planes, and isosurfaces. The examples in this section illustrate some of these techniques.

Using Scalar Techniques with Vector Data

Visualization techniques such as contour slices, slice planes, and isosurfaces require scalar volume data. You can use these techniques with vector data by taking the magnitude of the vectors. For example, the `wind` data set returns three coordinate arrays and three vector component arrays, `u`, `v`, `w`. In this case, the magnitude of the velocity vectors equals the wind speed at each corresponding coordinate point in the volume.

```
wind_speed = sqrt(u.^2 + v.^2 + w.^2);
```

The array `wind_speed` contains scalar values for the volume data. The usefulness of the information produced by this approach, however, depends on what physical phenomenon is represented by the magnitude of your vector data.

Specifying Starting Points for Stream Plots

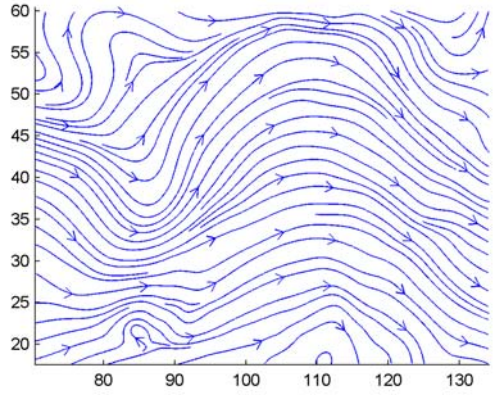
Stream plots (stream lines, ribbons, tubes, and cones or arrows) illustrate the flow of a 3-D vector field. The MATLAB stream plotting routines (`streamline`, `streamribbon`, `streamtube`, `coneplot`, `stream2`, `stream3`) all require you to specify the point at which you want to begin each stream trace.

Determining the Starting Points

Generally, knowledge of your data's characteristics helps you select the starting points. Information such as the primary direction of flow and the range of the data coordinates helps you decide where to evaluate the data.

The `streamslice` function is useful for exploring your data. For example, these statements draw a slice through the vector field at a z value midway in the range.

```
load wind
zmax = max(z(:)); zmin = min(z(:));
streamslice(x,y,z,u,v,w,[],[],(zmax-zmin)/2)
```



This stream slice plot indicates that the flow is in the positive *x* direction and also enables you to select starting points in both *x* and *y*. You could create similar plots that slice the volume in the *x*-*z* plane or the *y*-*z* plane to gain further insight into your data's range and orientation.

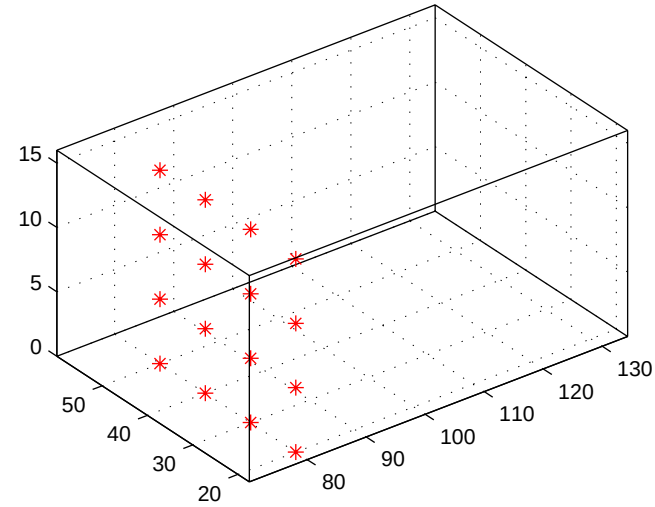
Specifying Arrays of Starting-Point Coordinates

To specify the starting point for one stream line, you need the *x*-, *y*-, and *z*-coordinates of the point. The `meshgrid` command provides a convenient way to create arrays of starting points. For example, you could select the following starting points from the wind data displayed in the previous stream slice.

```
[sx,sy,sz] = meshgrid(80,20:10:50,0:5:15);
```

This statement defines the starting points as all lying on x = 80, y ranging from 20 to 50, and z ranging from 0 to 15. You can use `plot3` to display the locations.

```
plot3(sx(:),sy(:),sz(:),'*r');
axis(volumebounds(x,y,z,u,v,w))
grid; box; daspect([2 2 1])
```



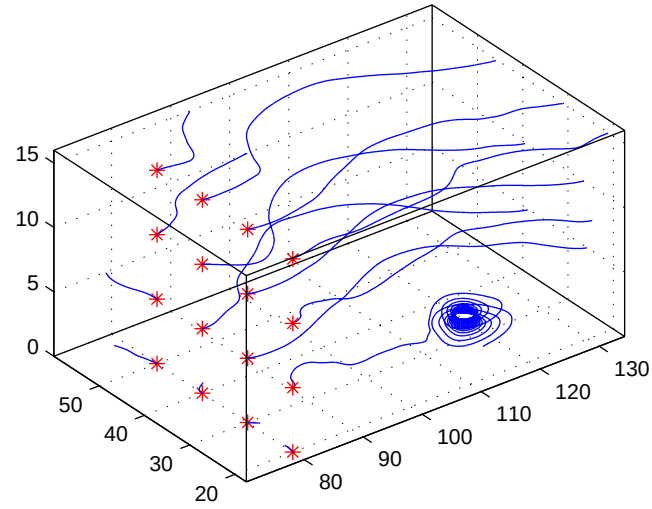
You do not need to use 3-D arrays, such as those returned by `meshgrid`, but the size of each array must be the same, and `meshgrid` provides a convenient way to generate arrays when you do not have an equal number of unique values in each coordinate. You can also define starting-point arrays as column vectors. For example, `meshgrid` returns 3-D arrays.

```
[sx,sy,sz] = meshgrid(80,20:10:50,0:5:15);
whos
Name      Size          Bytes  Class
sx        4x1x4           128  double array
sy        4x1x4           128  double array
sz        4x1x4           128  double array
```

In addition, you could use 16-by-1 column vectors with the corresponding elements of the three arrays composing the coordinates of each starting point. (This is the equivalent of indexing the values returned by `meshgrid` as `sx(:)`, `sy(:)`, and `sz(:)`.)

For example, adding the stream lines produces

```
streamline(x,y,z,u,v,w,sx(:),sy(:),sz(:))
```



Accessing Subregions of Volume Data

The `subvolume` function provides a simple way to access subregions of a volume data set. `subvolume` enables you to select regions of interest based on limits rather than using the colon operator to index into the 3-D arrays that define volumes. Consider the following two approaches to creating the data for a subvolume — indexing with the colon operator and using `subvolume`.

Indexing with the Colon Operator

When you index the arrays, you work with values that specify the elements in each dimension of the array.

```
load wind
xsub = x(1:10,20:30,1:7);
ysub = y(1:10,20:30,1:7);
zsub = z(1:10,20:30,1:7);
usub = u(1:10,20:30,1:7);
vsub = v(1:10,20:30,1:7);
wsub = w(1:10,20:30,1:7);
```

Using the subvolume Function

`subvolume` enables you to use coordinate values that you can read from the axes. For example,

```
lims = [100.64 116.67 17.25 28.75 -0.02 6.86];
[xsub,ysub,zsub,usub,vsub,wsub] = subvolume(x,y,z,u,v,w,lims);
```

You can then use the subvolume data as inputs to any function requiring vector volume data.

Example — Stream Line Plots of Vector Data

In this section...

Wind Mapping Data

MATLAB includes a vector data set called `wind` that represents air currents over North America. This example uses a combination of techniques:

- Stream lines to trace the wind velocity
- Slice planes to show cross-sectional views of the data
- Contours on the slice planes to improve the visibility of slice-plane coloring

1. Determine the Range of the Coordinates

Load the data and determine minimum and maximum values to locate the slice planes and contour plots (`load`, `min`, `max`).

```
load wind
xmin = min(x(:));
xmax = max(x(:));
ymax = max(y(:));
zmin = min(z(:));
```

2. Add Slice Planes for Visual Context

Calculate the magnitude of the vector field (which represents wind speed) to generate scalar data for the `slice` command. Create slice planes along the *x*-axis at `xmin`, `100`, and `xmax`, along the *y*-axis at `ymax`, and along the *z*-axis at `zmin`. Specify interpolated face coloring so the slice coloring indicates wind speed, and do not draw edges (`sqrt`, `slice`, `FaceColor`, `EdgeColor`).

```
wind_speed = sqrt(u.^2 + v.^2 + w.^2);
hsurfaces = slice(x,y,z,wind_speed,[xmin,100,xmax],ymax,zmin);
set(hsurfaces,'FaceColor','interp','EdgeColor','none')
```

3. Add Contour Lines to the Slice Planes

Draw light gray contour lines on the slice planes to help quantify the color mapping (`contourslice`, `EdgeColor`, `LineWidth`).

```
hcont = ...
contourslice(x,y,z,wind_speed,[xmin,100,xmax],ymax,zmin);
set(hcont,'EdgeColor',[.7,.7,.7],'LineWidth',.5)
```

4. Define the Starting Points for the Stream Lines

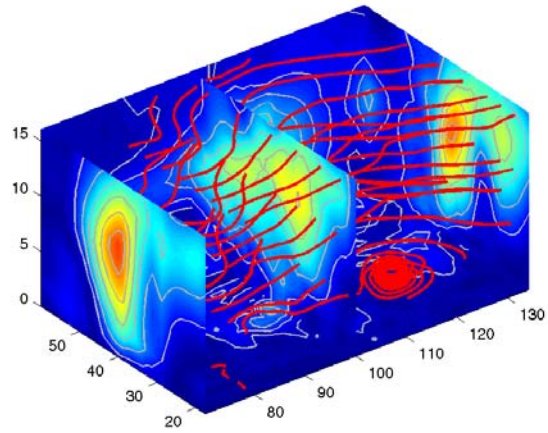
In this example, all stream lines start at an *x*-axis value of 80 and span the range 20 to 50 in the *y* direction and 0 to 15 in the *z* direction. Save the handles of the stream lines and set the line width and color (`meshgrid`, `streamline`, `LineWidth`, `Color`).

```
[sx,sy,sz] = meshgrid(80,20:10:50,0:5:15);
hlines = streamline(x,y,z,u,v,w,sx,sy,sz);
set(hlines,'LineWidth',2,'Color','r')
```

5. Define the View

Set up the view, expanding the *z*-axis to make it easier to read the graph (`view`, `daspect`, `axis`).

```
view(3)
daspect([2,2,1])
axis tight
```



See `coneplot` for an example of the same data plotted with cones.

Example — Displaying Curl with Stream Ribbons

In this section...

What Stream Ribbons Can Show

Stream ribbons illustrate direction of flow, similar to stream lines, but can also show rotation about the flow axis by twisting the ribbon-shaped flow line. The `streamribbon` function enables you to specify a twist angle (in radians) for each vertex in the stream ribbons.

When used in conjunction with the `curl` function, `streamribbon` is useful for displaying the curl angular velocity of a vector field. The following example illustrates this technique:

1. Select a Subset of Data to Plot

Load and select a region of interest in the `wind` data set using `subvolume`. Plotting the full data set first can help you select a region of interest.

```
load wind
lims = [100.64 116.67 17.25 28.75 -0.02 6.86];
[x,y,z,u,v,w] = subvolume(x,y,z,u,v,w,lims);
```

2. Calculate Curl Angular Velocity and Wind Speed

Calculate the `curl` angular velocity and the wind speed.

```
cav = curl(x,y,z,u,v,w);
wind_speed = sqrt(u.^2 + v.^2 + w.^2);
```

3. Create the Stream Ribbons

- Use `meshgrid` to create arrays of starting points for the stream ribbons. See "Starting Points for Stream Plots" in this chapter for information on specifying the arrays of starting points.
- `stream3` calculates the stream line vertices with a step size of `.5`.
- `streamribbon` scales the width of the ribbon by a factor of `2` to enhance the visibility of the twisting (which indicates curl angular velocity).
- `streamribbon` returns the handles of the surface objects it creates, which are then used to set the color to red (`FaceColor`), the color of the surface edges to light gray (`EdgeColor`), and slightly increase the brightness of the ambient light reflected when lighting is applied (`AmbientStrength`).

```
[sx sy sz] = meshgrid(110,20:5:30,1:5);
verts = stream3(x,y,z,u,v,w,sx,sy,sz,.5);
h = streamribbon(verts,x,y,z,cav,wind_speed,2);
set(h,'FaceColor','r',...
 'EdgeColor',[.7 .7 .7],...
 'AmbientStrength',.6)
```

4. Define the View and Add Lighting

- The `volumebounds` command provides a convenient way to set `axis` and color limits.
- Add a `grid` and set the `view` for 3-D (`streamribbon` does not change the current view).
- `camlight` creates a light positioned to the right of the viewpoint and `lighting` sets the lighting method to Phong (which requires the Z-buffer renderer).

```
axis(volumebounds(x,y,z,wind_speed))
grid on
view(3)
camlight right;
set(gcf,'Renderer','zbuffer'); lighting phong
```

Example — Displaying Divergence with Stream Tubes

In this section...

What Stream Tubes Can Show

Stream tubes are similar to stream lines, except the tubes have width, providing another dimension that you can use to represent information.

By default, MATLAB indicates the divergence of the vector field by the width of the tube. You can also define widths for each tube vertex and thereby map other data to width.

This example uses the following techniques:

- Stream tubes to indicate flow direction and divergence of the vector field in the `wind` data set
- Slice planes colored to indicate the speed of the wind currents overlaid with contour line to enhance visibility

Inputs include the coordinates of the volume, vector field components, and starting locations for the stream tubes.

1. Load Data and Calculate Required Values

The first step is to load the data and calculate values needed to make the plots. These values include

- The location of the slice planes (maximum `x`, minimum `y`, and a value for the altitude)

- The minimum `x` value for the start of the stream tubes
- The speed of the wind (magnitude of the vector field)

```
load wind
xmin = min(x(:));
xmax = max(x(:));
ymin = min(y(:));
alt = 7.356; % z-value for slice and streamtube plane
wind_speed = sqrt(u.^2 + v.^2 + w.^2);
```

2. Draw the Slice Planes

Draw the slice planes (`slice`) and set `surface` properties to create a smoothly colored slice. Use 16 colors from the `hsv colormap`.

```
hslice = slice(x,y,z,wind_speed,xmax,ymin,alt);
set(hslice,'FaceColor','interp','EdgeColor','none')
colormap hsv(16)
```

3. Add Contour Lines to Slice Planes

Add contour lines (`contourslice`) to the slice planes. Adjust the contour interval so the lines match the color boundaries in the slice planes:

- Call `caxis` to get the current color limits.
- Set the interpolation method used by `contourslice` to `linear` to match the default used by `slice`.

```
color_lim = caxis;
cont_intervals = linspace(color_lim(1),color_lim(2),17);
hcont = contourslice(x,y,z,wind_speed,xmax,ymin,...
 alt,cont_intervals,'linear');
set(hcont,'EdgeColor',[.4 .4 .4],'LineWidth',1)
```

4. Create the Stream Tubes

Use `meshgrid` to create arrays for the starting points for the stream tubes, which begin at the minimum `x` value, range from 20 to 50 in `y`, and lie in a single plane in `z` (corresponding to one of the slice planes).

The stream tubes (`streamtube`) are drawn at the specified locations and scaled to be 1.25 times the default width to emphasize the variation in divergence (width). The second element in the vector [1.25 30] specifies the number of points along the circumference of the tube (the default is 20). You might want to increase this value as the tube size increases, to maintain a smooth-looking tube.

Set the data aspect ratio (`daspect`) before calling `streamtube`.

Stream tubes are surface objects, therefore you can control their appearance by setting surface properties. This example sets surface properties to give a brightly lit, red surface.

```
[sx,sy,sz] = meshgrid(xmin,20:3:50,alt);
daspect([1,1,1]) % set DAR before calling streamtube
htubes = streamtube(x,y,z,u,v,w,sx,sy,sz,[1.25 30]);
set(htubes,'EdgeColor','none','FaceColor','r',...
 'AmbientStrength',.5)
```

5. Define the View

The final step is to define the view and add lighting (`view`, `axis volumebounds`, `Projection`, `camlight`).

```
view(-100,30)
axis(volumebounds(x,y,z,wind_speed))
set(gca,'Projection','perspective')
camlight left
```

Example — Creating Stream Particle Animations

In this section...

What Particle Animations Can Show

A stream particle animation is useful for visualizing the flow direction and speed of a vector field. The "particles" (represented by any of the line markers) trace the flow along a particular stream line. The speed of each particle in the animation is proportional to the magnitude of the vector field at any given point along the stream line:

1. Specify the Starting Points of the Data Range to Plot

This example determines the region of the volume to plot by specifying the appropriate starting points. In this case, the stream plots begin at x = 100, y spans 20 to 50 and in the z = 5 plane. Note that this is not the full volume bounds.

```
load wind
[sx sy sz] = meshgrid(100,20:2:50,5);
```

2. Create Stream Lines to Indicate the Particle Paths

This example uses stream lines (`stream3`, `streamline`) to trace the path of the animated particles. This adds a visual context for the animation. Another possibility is to set the `EraseMode` property of the stream particle to none, which would be useful for a single trace through the volume.

```
verts = stream3(x,y,z,u,v,w,sx,sy,sz);
sl = streamline(verts);
```

3. Define the View

While all the stream lines start in the z = 5 plane, the values of some spiral down to lower values. The following settings provide a clear view of the animation:

- The viewpoint (`view`) selected shows both the plane containing most stream lines and the spiral.
- Selecting a data aspect ratio (`daspect`) of `[2 2 0.125]` provides greater resolution in the *z* direction to make the stream particles more easily visible in the spiral.
- Set the axes limits to match the data limits (`axis`) and draw the axis box (`box`).

```
view(-10.5,18)
daspect([2 2 0.125])
axis tight; box on
```

4. Calculate the Stream Particle Vertices

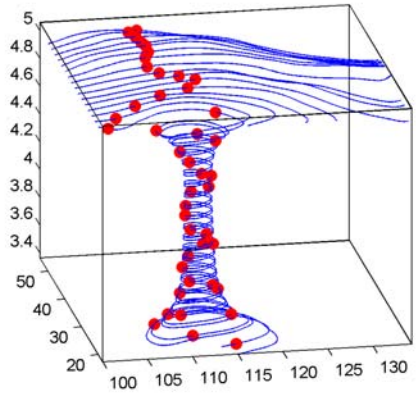
The first step is to determine the vertices along the stream line where a particle should be drawn. The `interpstreamspeed` function returns this data based on the stream line vertices and the speed of the vector data. This example scales the velocities by 0.05 to increase the number of interpolated vertices.

Setting the axes `DrawMode` property to `fast` enables the animation to run faster.

The `streamparticles` function sets the following properties:

- `Animate` to `10` to run the animation 10 times
- `ParticleAlignment` to `on` to start all particle traces together
- `MarkerEdgeColor` to `none` to draw only the face of the circular marker. Animations usually run faster when marker edges are not drawn.
- MarkerFaceColor to `red`
- `Marker` to `o`, which draws a circular marker. You can use other line markers as well.

```
iverts = interpstreamspeed(x,y,z,u,v,w,verts,0.05);
set(gca,'drawmode','fast');
streamparticles(iverts,15,...
 'Animate',10,...
 'ParticleAlignment','on',...
 'MarkerEdgeColor','none',...
 'MarkerFaceColor','red',...
 'Marker','o');
```



Example — Vector Field Displayed with Cone Plots

In this section...

What Cone Plots Can Show

This example plots the velocity vector cones for the `wind` data. The graph produced employs a number of visualization techniques:

- An isosurface is used to provide visual context for the cone plots and to provide means to select a specific data value for a set of cones.
- Lighting enables the shape of the isosurface to be clearly visible.
- The use of perspective projection, camera positioning, and view angle adjustments composes the final view.

1. Create an Isosurface

Displaying an isosurface within the rectangular space of the data provides a visual context for the cone plot. Creating the isosurface requires a number of steps:

- Calculate the magnitude of the vector field, which represents the speed of the wind.
- Use `isosurface` and `patch` to draw an isosurface illustrating where in the rectangular space the wind speed is equal to a particular value. Regions inside the isosurface have higher wind speeds, regions outside the isosurface have lower wind speeds.

- Use `isonormals` to compute vertex normals of the isosurface from the volume data rather than calculate the normals from the triangles used to render the isosurface. These normals generally produce more accurate results.
- Set visual properties of the isosurface, making it red and without drawing edges (`FaceColor`, `EdgeColor`).

```
load wind
wind_speed = sqrt(u.^2 + v.^2 + w.^2);
hiso = patch(isosurface(x,y,z,wind_speed,40));
isonormals(x,y,z,wind_speed,hiso)
set(hiso,'FaceColor','red','EdgeColor','none');
```

2. Add Isocaps to the Isosurface

Isocaps are similar to slice planes in that they show a cross section of the volume. They are designed to be the end caps of isosurfaces. Using interpolated face color on an isocap causes a mapping of data value to color in the current colormap. To create isocaps for the isosurface, define them at the same isovalue (`isocaps`, `patch`, `colormap`).

```
hcap = patch(isocaps(x,y,z,wind_speed,40),...
    'FaceColor','interp',...
    'EdgeColor','none');
colormap hsv
```

3. Create First Set of Cones

- Use `daspect` to set the data aspect ratio of the axes before calling `coneplot` so MATLAB can determine the proper size of the cones.
- Determine the points at which to place cones by calculating another isosurface that has a smaller isovalue (so the cones are displayed outside the first isosurface) and use `reducepatch` to reduce the number of faces and vertices (so there are not too many cones on the graph).
- Draw the cones and set the face color to blue and the edge color to none.

```
daspect([1,1,1]);
[f verts] = reducepatch(isosurface(x,y,z,wind_speed,30),0.07);
h1 = coneplot(x,y,z,u,v,w,verts(:,1),verts(:,2),verts(:,3),3);
```

```
set(h1,'FaceColor','blue','EdgeColor','none');
```

4. Create Second Set of Cones

- Create a second set of points at values that span the data range (`linspace`, `meshgrid`).
- Draw a second set of cones and set the face color to green and the edge color to none.

```
xrange = linspace(min(x(:)),max(x(:)),10);
yrange = linspace(min(y(:)),max(y(:)),10);
zrange = 3:4:15;
[cx,cy,cz] = meshgrid(xrange,yrange,zrange);
h2 = coneplot(x,y,z,u,v,w,cx,cy,cz,2);
set(h2,'FaceColor','green','EdgeColor','none');
```

5. Define the View

- Use the `axis` command to set the axis limits equal to the minimum and maximum values of the data and enclose the graph in a box to improve the sense of a volume (`box`).
- Set the projection type to perspective to create a more natural view of the volume. Set the viewpoint and zoom in to make the scene larger (`camproj`, `camzoom`, `view`).

```
axis tight
box on
camproj perspective
camzoom(1.25)
view(65,45)
```

6. Add Lighting

Add a light source and use Phong lighting for the smoothest lighting of the isosurface (Phong lighting requires the Z-buffer renderer). Increase the strength of the background lighting on the isocaps to make them brighter (`camlight`, `lighting`, `AmbientStrength`).

```
camlight(-45,45)
```

```
set(gcf,'Renderer','zbuffer');
lighting phong
set(hcap,'AmbientStrength',.6)
```

Revision History

December 1996	First Printing	New for MATLAB 5 (Release 8)
May 1997	Online only	Revised for MATLAB 5.1 (Release 9)
January 1998	Online Only	Revised for MATLAB 5.2 (Release 10)
January 1999	Online Only	Revised for MATLAB 5.3 (Release 11)
September 2000	Online Only	Revised for MATLAB 6.0 (Release 12)
June 2001	Online only	Revised for MATLAB 6.1 (Release 12.1)
July 2002	Online only	Revised for MATLAB 6.5 (Release 13)
January 2003	Online only	Revised for MATLAB 6.5.1 (Release 13SP1)
June 2004	Online only	Revised for MATLAB 7.0 (Release 14)
October 2004	Online only	Revised for MATLAB 7.0.1 (Release 14SP1)
March 2005	Online only	Revised for MATLAB 7.0.4 (Release 14SP2)
September 2005	Online only	Revised for MATLAB 7.1 (Release 14SP3)
March 2006	Online only	Revised for MATLAB 7.2 (Release 2006a)
September 2006	Online only	Revised for MATLAB 7.3 (Release 2006b)
March 2007	Online only	Revised and renamed for MATLAB 7.4 (Release 2007a)
September 2007	Online only	Revised and renamed for MATLAB 7.5 (Release 2007b)

API — By Category

MAT-File Access (p. 1-2)	Incorporate and use MATLAB® data in C and Fortran programs
MX Array Manipulation (p. 1-2)	Create and manipulate MATLAB arrays from C and Fortran MEX and engine routines
MEX-Files (p. 1-9)	Perform operations in MATLAB environment from C and Fortran MEX-files
MATLAB Engine (p. 1-11)	Call MATLAB from C and Fortran programs

See also “External Interfaces” in MATLAB Function Reference for MATLAB interfaces to DLLs, Java, COM and ActiveX, Web services, and serial port devices.

MAT-File Access

matClose (C and Fortran)	Close MAT-file
matDeleteVariable (C and Fortran)	Delete named mxArray from MAT-file
MATFile (C and Fortran)	Type for a MAT-file
matGetDir (C and Fortran)	Get directory of mxArrays in MAT-file
matGetFp (C)	Get file pointer to MAT-file
matGetNextVariable (C and Fortran)	Read next mxArray from MAT-file
matGetNextVariableInfo (C and Fortran)	Load array header information only
matGetVariable (C and Fortran)	Read mxArrays from MAT-files
matGetVariableInfo (C and Fortran)	Load array header information only
matOpen (C and Fortran)	Open MAT-file
matPutVariable (C and Fortran)	Write mxArrays to MAT-files
matPutVariableAsGlobal (C and Fortran)	Put mxArrays into MAT-files as originating from global workspace

MX Array Manipulation

mwIndex (C and Fortran)	Type for index values
mwPointer (Fortran)	Declare appropriate pointer type for platform
mwSize (C and Fortran)	Type for size values
mxAddField (C and Fortran)	Add field to structure array
mxArray (C and Fortran)	Type for a MATLAB array
mxArrayToString (C)	Convert array to string

mxAssert (C)	Check assertion value for debugging purposes
mxAssertS (C)	Check assertion value without printing assertion text
mxCalcSingleSubscript (C and Fortran)	Offset from first element to desired element
mxCalloc (C and Fortran)	Allocate dynamic memory for array using MATLAB memory manager
mxChar (C)	Type for string mxArray
mxClassID (C)	Enumerated value identifying class of mxArray
mxClassIDFromClassName (Fortran)	Identifier corresponding to class
mxComplexity (C)	Flag specifying whether mxArray has imaginary components
mxCopyCharacterToPtr (Fortran)	Copy character values from Fortran array to pointer array
mxCopyComplex16ToPtr (Fortran)	Copy COMPLEX*16 values from Fortran array to pointer array
mxCopyComplex8ToPtr (Fortran)	Copy COMPLEX*8 values from Fortran array to pointer array
mxCopyInteger1ToPtr (Fortran)	Copy INTEGER*1 values from Fortran array to pointer array
mxCopyInteger2ToPtr (Fortran)	Copy INTEGER*2 values from Fortran array to pointer array
mxCopyInteger4ToPtr (Fortran)	Copy INTEGER*4 values from Fortran array to pointer array
mxCopyPtrToCharacter (Fortran)	Copy character values from pointer array to Fortran array
mxCopyPtrToComplex16 (Fortran)	Copy COMPLEX*16 values from pointer array to Fortran array

mxCopyPtrToComplex8 (Fortran)	Copy COMPLEX*8 values from pointer array to Fortran array
mxCopyPtrToInteger1 (Fortran)	Copy INTEGER*1 values from pointer array to Fortran array
mxCopyPtrToInteger2 (Fortran)	Copy INTEGER*2 values from pointer array to Fortran array
mxCopyPtrToInteger4 (Fortran)	Copy INTEGER*4 values from pointer array to Fortran array
mxCopyPtrToPtrArray (Fortran)	Copy pointer values from pointer array to Fortran array
mxCopyPtrToReal4 (Fortran)	Copy REAL*4 values from pointer array to Fortran array
mxCopyPtrToReal8 (Fortran)	Copy REAL*8 values from pointer array to Fortran array
mxCopyReal4ToPtr (Fortran)	Copy REAL*4 values from Fortran array to pointer array
mxCopyReal8ToPtr (Fortran)	Copy REAL*8 values from Fortran array to pointer array
mxCreateCellArray (C and Fortran)	Create unpopulated N-D cell mxArray
mxCreateCellMatrix (C and Fortran)	Create unpopulated 2-D cell mxArray
mxCreateCharArray (C and Fortran)	Create unpopulated N-D string mxArray
mxCreateCharMatrixFromStrings (C and Fortran)	Create unpopulated 2-D string mxArray
mxCreateDoubleMatrix (C and Fortran)	Create 2-D, double-precision, floating-point mxArray initialized to 0
mxCreateDoubleScalar (C and Fortran)	Create scalar, double-precision array initialized to specified value
mxCreateLogicalArray (C)	Create N-D logical mxArray initialized to false

`mxCreateLogicalMatrix (C)`	Create 2-D, logical `mxArray` initialized to `false`
`mxCreateLogicalScalar (C)`	Create scalar, logical `mxArray` initialized to `false`
`mxCreateNumericArray (C and Fortran)`	Create unpopulated N-D numeric `mxArray`
`mxCreateNumericMatrix (C and Fortran)`	Create numeric matrix and initialize data elements to 0
`mxCreateSparse (C and Fortran)`	Create 2-D unpopulated sparse `mxArray`
`mxCreateSparseLogicalMatrix (C)`	Create unpopulated 2-D, sparse, logical `mxArray`
`mxCreateString (C and Fortran)`	Create 1-by-N string `mxArray` initialized to specified string
`mxCreateStructArray (C and Fortran)`	Create unpopulated N-D structure `mxArray`
`mxCreateStructMatrix (C and Fortran)`	Create unpopulated 2-D structure `mxArray`
`mxDestroyArray (C and Fortran)`	Free dynamic memory allocated by `mxCreate*` functions
`mxDuplicateArray (C and Fortran)`	Make deep copy of array
`mxFree (C and Fortran)`	Free dynamic memory allocated by `mxCalloc`, `mxMalloc`, or `mxRealloc`
`mxGetCell (C and Fortran)`	Get contents of `mxArray` cell
`mxGetChars (C)`	Get pointer to character array data
`mxGetClassID (C and Fortran)`	Get class of `mxArray`
`mxGetClassName (C and Fortran)`	Get class of `mxArray` as string
`mxGetData (C and Fortran)`	Get pointer to data
`mxGetDimensions (C andFortran)`	Get pointer to dimensions array

mxGetElementSize (C and Fortran)	Get number of bytes required to store each data element
mxGetEps (C and Fortran)	Get value of eps
mxGetField (C and Fortran)	Get field value, given field name and index into structure array
mxGetFieldByNumber (C and Fortran)	Get field value, given field number and index into structure array
mxGetFieldNameByNumber (C and Fortran)	Get field name, given field number in structure array
mxGetFieldNumber (C and Fortran)	Get field number, given field name in structure array
mxGetImagData (C and Fortran)	Get pointer to imaginary data of mxArray
mxGetInf (C and Fortran)	Get value of infinity
mxGetIr (C and Fortran)	Get ir array of sparse matrix
mxGetJc (C and Fortran)	Get jc array of sparse matrix
mxGetLogicals (C)	Get pointer to logical array data
mxGetM (C and Fortran)	Get number of rows in mxArray
mxGetN (C and Fortran)	Get number of columns in mxArray
mxGetNaN (C and Fortran)	Get value of NaN (Not-a-Number)
mxGetNumberOfDimensions (C and Fortran)	Get number of dimensions in mxArray
mxGetNumberOfElements (C and Fortran)	Get number of elements in mxArray
mxGetNumberOfFields (C and Fortran)	Get number of fields in structure mxArray
mxGetNzmax (C and Fortran)	Get number of elements in ir, pr, and pi arrays
mxGetPi (C and Fortran)	Get imaginary data elements in mxArray
mxGetPr (C and Fortran)	Get real data elements in mxArray

`mxGetScalar (C and Fortran)`	Get real component of first data element in `mxArray`
`mxGetString (C and Fortran)`	Copy string `mxArray` to C-style string
`mxIsCell (C and Fortran)`	Determine whether input is cell `mxArray`
`mxIsChar (C and Fortran)`	Determine whether input is string `mxArray`
`mxIsClass (C and Fortran)`	Determine whether `mxArray` is member of specified class
`mxIsComplex (C and Fortran)`	Determine whether data is complex
`mxIsDouble (C and Fortran)`	Determine whether `mxArray` represents data as double-precision, floating-point numbers
`mxIsEmpty (C and Fortran)`	Determine whether `mxArray` is empty
`mxIsFinite (C and Fortran)`	Determine whether input is finite
`mxIsFromGlobalWS (C and Fortran)`	Determine whether `mxArray` was copied from MATLAB global workspace
`mxIsInf (C and Fortran)`	Determine whether input is infinite
`mxIsInt16 (C and Fortran)`	Determine whether `mxArray` represents data as signed 16-bit integers
`mxIsInt32 (C and Fortran)`	Determine whether `mxArray` represents data as signed 32-bit integers
`mxIsInt64 (C and Fortran)`	Determine whether `mxArray` represents data as signed 64-bit integers
`mxIsInt8 (C and Fortran)`	Determine whether `mxArray` represents data as signed 8-bit integers

`mxIsLogical (C and Fortran)`	Determine whether `mxArray` is of type `mxLogical`
`mxIsLogicalScalar (C)`	Determine whether scalar `mxArray` is of type `mxLogical`
`mxIsLogicalScalarTrue (C)`	Determine whether scalar `mxArray` of type `mxLogical` is `true`
`mxIsNaN (C and Fortran)`	Determine whether input is `NaN` (Not-a-Number)
`mxIsNumeric (C and Fortran)`	Determine whether `mxArray` is numeric
`mxIsSingle (C and Fortran)`	Determine whether `mxArray` represents data as single-precision, floating-point numbers
`mxIsSparse (C and Fortran)`	Determine whether input is sparse `mxArray`
`mxIsStruct (C and Fortran)`	Determine whether input is structure `mxArray`
`mxIsUint16 (C and Fortran)`	Determine whether `mxArray` represents data as unsigned 16-bit integers
`mxIsUint32 (C and Fortran)`	Determine whether `mxArray` represents data as unsigned 32-bit integers
`mxIsUint64 (C and Fortran)`	Determine whether `mxArray` represents data as unsigned 64-bit integers
`mxIsUint8 (C and Fortran)`	Determine whether `mxArray` represents data as unsigned 8-bit integers
`mxLogical (C)`	Type for logical `mxArray`
`mxMalloc (C and Fortran)`	Allocate dynamic memory using MATLAB memory manager
`mxRealloc (C and Fortran)`	Reallocate memory

`mxRemoveField (C and Fortran)`	Remove field from structure array
`mxSetCell (C and Fortran)`	Set value of one cell of `mxArray`
`mxSetClassName (C)`	Convert structure array to MATLAB object array
`mxSetData (C and Fortran)`	Set pointer to data
`mxSetDimensions (C and Fortran)`	Modify number of dimensions and size of each dimension
`mxSetField (C and Fortran)`	Set structure array field, given field name and index
`mxSetFieldByNumber (C and Fortran)`	Set structure array field, given field number and index
`mxSetImagData (C and Fortran)`	Set imaginary data pointer for `mxArray`
`mxSetIr (C and Fortran)`	Set `ir` array of sparse `mxArray`
`mxSetJc (C and Fortran)`	Set `jc` array of sparse `mxArray`
`mxSetM (C and Fortran)`	Set number of rows in `mxArray`
`mxSetN (C and Fortran)`	Set number of columns in `mxArray`
`mxSetNzmax (C and Fortran)`	Set storage space for nonzero elements
`mxSetPi (C and Fortran)`	Set new imaginary data for `mxArray`
`mxSetPr (C and Fortran)`	Set new real data for `mxArray`

MEX-Files

`mexAtExit (C and Fortran)`	Register function to call when MEX-function is cleared or MATLAB terminates
`mexCallMATLAB (C and Fortran)`	Call MATLAB function or user-defined M-file or MEX-file

`mexErrMsgIdAndTxt (C and Fortran)`	Issue error message with identifier and return to MATLAB prompt
`mexErrMsgTxt (C and Fortran)`	Issue error message and return to MATLAB prompt
`mexEvalString (C and Fortran)`	Execute MATLAB command in caller's workspace
`mexFunction (C and Fortran)`	Entry point to C MEX-file
`mexFunctionName (C and Fortran)`	Name of current MEX-function
`mexGet (C)`	Get value of specified Handle Graphics® property
`mexGetVariable (C and Fortran)`	Get copy of variable from specified workspace
`mexGetVariablePtr (C and Fortran)`	Get read-only pointer to variable from another workspace
`mexIsGlobal (C and Fortran)`	Determine whether `mxArray` has global scope
`mexIsLocked (C and Fortran)`	Determine whether MEX-file is locked
`mexLock (C and Fortran)`	Prevent MEX-file from being cleared from memory
`mexMakeArrayPersistent (C and Fortran)`	Make `mxArray` persist after MEX-file completes
`mexMakeMemoryPersistent (C and Fortran)`	Make allocated memory MATLAB persist after MEX-function completes
`mexPrintf (C and Fortran)`	ANSI C `printf`-style output routine
`mexPutVariable (C and Fortran)`	Copy `mxArray` from MEX-function into specified workspace
`mexSet (C)`	Set value of specified Handle Graphics property

`mexSetTrapFlag (C and Fortran)`	Control response of `mexCallMATLAB` to errors
`mexUnlock (C and Fortran)`	Allow MEX-file to be cleared from memory
`mexWarnMsgIdAndTxt (C and Fortran)`	Issue warning message with identifier
`mexWarnMsgTxt (C and Fortran)`	Issue warning message

MATLAB Engine

`engClose (C and Fortran)`	Quit MATLAB engine session
`engEvalString (C and Fortran)`	Evaluate expression in string
`engGetVariable (C and Fortran)`	Copy variable from MATLAB engine workspace
`engGetVisible (C)`	Determine visibility of MATLAB engine session
`Engine (C)`	Type for a MATLAB engine
`engOpen (C and Fortran)`	Start MATLAB engine session
`engOpenSingleUse (C)`	Start MATLAB engine session for single, nonshared use
`engOutputBuffer (C and Fortran)`	Specify buffer for MATLAB output
`engPutVariable (C and Fortran)`	Put variables into MATLAB engine workspace
`engSetVisible (C)`	Show or hide MATLAB engine session

2

API — Alphabetical List

engClose (C and Fortran)

Purpose

Quit MATLAB engine session

C Syntax

```
#include "engine.h"
int engClose(Engine *ep);
```

Fortran Syntax

```
integer*4 engClose(ep)
mwPointer ep
```

Arguments

`ep`

Engine pointer

Returns

`0` on success, and `1` otherwise. Possible failure includes attempting to terminate a MATLAB engine session that was already terminated.

Description

This routine sends a quit command to the MATLAB engine session and closes the connection.

C Examples

UNIX

See `engdemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program.

Windows

See `engwindemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program for Windows.

Fortran Examples

See `fengdemo.F` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a Fortran program.

See Also

`engOpen`

Purpose

Evaluate expression in string

C Syntax

```
#include "engine.h"
int engEvalString(Engine *ep,const char *string);
```

Fortran Syntax

```
integer*4 engEvalString(ep, string)
mwPointer ep
character*(*) string
```

Arguments

`ep`
Engine pointer

`string`
String to execute

Returns

`0` if the command was evaluated by the MATLAB engine session, and nonzero otherwise. Possible reasons for failure include the MATLAB engine session is no longer running or the engine pointer is invalid or `NULL`.

Description

`engEvalString` evaluates the expression contained in `string` for the MATLAB engine session, `ep`, previously started by `engOpen`.

UNIX

On UNIX systems, `engEvalString` sends commands to MATLAB by writing down a pipe connected to the MATLAB *`stdin`*. Any output resulting from the command that ordinarily appears on the screen is read back from *`stdout`* into the buffer defined by `engOutputBuffer`.

To turn off output buffering in C, use

```
engOutputBuffer(ep, NULL, 0);
```

To turn off output buffering in Fortran, use

```
engOutputBuffer(ep, '')
```

Windows

On a PC, `engEvalString` communicates with MATLAB using a Component Object Model (COM) interface.

C Examples

UNIX

See `engdemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program.

Windows

See `engwindemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program for Windows.

Fortran Examples

See `fengdemo.F` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a Fortran program.

See Also

`engOpen`, `engOutputBuffer`

Purpose

Copy variable from MATLAB engine workspace

C Syntax

```
#include "engine.h"
mxArray *engGetVariable(Engine *ep, const char *name);
```

Fortran Syntax

```
mwPointer engGetVariable(ep, name)
mwPointer ep
character*(*) name
```

Arguments

`ep`
: Engine pointer

`name`
: Name of `mxArray` to get from MATLAB

Returns

A pointer to a newly allocated `mxArray` structure, or `NULL` if the attempt fails. `engGetVariable` fails if the named variable does not exist.

Description

`engGetVariable` reads the named `mxArray` from the MATLAB engine session associated with `ep`.

Be careful in your code to free the `mxArray` created by this routine when you are finished with it.

C Examples

UNIX

See `engdemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program.

Windows

See `engwindemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program for Windows.

See Also

`engPutVariable`

engGetVisible (C)

Purpose

Determine visibility of MATLAB engine session

C Syntax

```
#include "engine.h"
int engGetVisible(Engine *ep, bool *value);
```

Arguments

`ep`
Engine pointer

`value`
Pointer to value returned from `engGetVisible`

Returns

Windows Only

`0` on success, and `1` otherwise.

Description

`engGetVisible` returns the current visibility setting for MATLAB engine session, `ep`. A *visible* engine session runs in a window on the Windows desktop, thus making the engine available for user interaction. An invisible session is hidden from the user by removing it from the desktop.

Examples

The following code opens engine session `ep` and disables its visibility.

```
Engine *ep;
bool vis;

ep = engOpen(NULL);
engSetVisible(ep, 0);
```

To determine the current visibility setting, use

```
engGetVisible(ep, &vis);
```

See Also

`engSetVisible`

Purpose

Type for a MATLAB engine

Description

A handle to a MATLAB engine object.

`Engine` is a C language opaque type.

You can call MATLAB as a computational engine by writing C and Fortran programs that use the MATLAB engine library, described in "MATLAB Engine" on page 1-11. `Engine` is the link between your program and the separate MATLAB engine process.

The header file containing this type is

```
#include "engine.h"
```

Examples

The example `engwindemo.c` (in your *`matlabroot`*`/extern/examples/eng_mat` directory) shows how to plot position versus time for a falling object in a MATLAB figure window.

The `engOpen` function starts the MATLAB process, returning an `Engine` variable. You use this handle for all calls to MATLAB.

The `mxCreateDoubleMatrix` function creates an `mxArray` named `T`. The C function `memcpy` copies your `time` data (initialized in `engwindemo.c`) into `T`.

The `engPutVariable` function puts `T` into MATLAB. Now you can use this variable to calculate distance `D`. The `engEvalString` function evaluates the expression `D = .5.*(-9.8).*T.^2`.

Next, various MATLAB plot functions, like `plot(T,D)`, display the graph.

Calls to the `engClose` and `mxDestroyArray` functions complete the procedure.

Other sample programs, also found in your *`matlabroot`*`\extern\examples\eng_mat` directory, that show you how to use `Engine` are:

- `engdemo.c` shows how to call the MATLAB engine functions from a C program.
- `engwindemo.c` show how to call the MATLAB engine functions from a C program for Windows.
- `fengdemo.F` shows how to call the MATLAB engine functions from a Fortran program.

See Also

`engOpen`

Purpose

Start MATLAB engine session

C Syntax

```
#include "engine.h"
Engine *engOpen(const char *startcmd);
```

Fortran Syntax

```
mwPointer engOpen(startcmd)
character*(*) startcmd
```

Arguments

`startcmd`
: String to start the MATLAB process. On Windows, the `startcmd` string must be `NULL`.

Returns

A pointer to an engine handle or `NULL` if the open fails.

Description

This routine allows you to start a MATLAB process for the purpose of using MATLAB as a computational engine.

`engOpen` starts a MATLAB process using the command specified in the string `startcmd`, establishes a connection, and returns a unique engine identifier, or `NULL` if the open fails.

On UNIX systems, if `startcmd` is `NULL` or the empty string, `engOpen` starts MATLAB on the current host using the command `matlab`. If `startcmd` is a `hostname`, `engOpen` starts MATLAB on the designated host by embedding the specified `hostname` string into the larger string:

```
"rsh hostname \"/bin/csh -c 'setenv DISPLAY\
 hostname:0; matlab'\""
```

If `startcmd` is any other string (has white space in it, or nonalphanumeric characters), the string is executed literally to start MATLAB.

On UNIX systems, `engOpen` performs the following steps:

1. Creates two pipes.

2 Forks a new process and sets up the pipes to pass *stdin* and *stdout* from MATLAB (parent) to two file descriptors in the engine program (child).

3 Executes a command to run MATLAB (`rsh` for remote execution).

Under Windows on a PC, `engOpen` opens a COM channel to MATLAB. This starts the MATLAB that was registered during installation. If you did not register during installation, on the command line you can enter the command

```
matlab /regserver
```

See "Introducing MATLAB COM Integration" for additional details.

C Examples

UNIX

See `engdemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program.

Windows

See `engwindemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program for Windows.

Fortran Examples

See `fengdemo.F` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a Fortran program.

Purpose

Start MATLAB engine session for single, nonshared use

C Syntax

```
#include "engine.h"
Engine *engOpenSingleUse(const char *startcmd, void *dcom,
  int *retstatus);
```

Arguments

`startcmd`
: String to start MATLAB process. On Windows, the `startcmd` string must be `NULL`.

`dcom`
: Reserved for future use; must be `NULL`.

`retstatus`
: Return status; possible cause of failure.

Returns

Windows Only

A pointer to an engine handle or `NULL` if the open fails.

UNIX

This routine is not supported and simply returns.

Description

This routine allows you to start multiple MATLAB processes for the purpose of using MATLAB as a computational engine. `engOpenSingleUse` starts a MATLAB process, establishes a connection, and returns a unique engine identifier, or `NULL` if the open fails. `engOpenSingleUse` starts a new MATLAB process each time it is called.

`engOpenSingleUse` opens a COM channel to MATLAB. This starts the MATLAB that was registered during installation. If you did not register during installation, on the command line you can enter the command

```
matlab /regserver
```

`engOpenSingleUse` allows single-use instances of a MATLAB engine server. `engOpenSingleUse` differs from `engOpen`, which allows multiple users to use the same MATLAB engine server.

See “Introducing MATLAB COM Integration” for additional details.

Purpose

Specify buffer for MATLAB output

C Syntax

```
#include "engine.h"
int engOutputBuffer(Engine *ep, char *p, int n);
```

Fortran Syntax

```
integer*4 engOutputBuffer(ep, p)
mwPointer ep
character*n p
```

Arguments

`ep`
: Engine pointer

`p`
: Pointer to character buffer

`n`
: Length of buffer `p`

Returns

`1` if you pass it a NULL engine pointer. Otherwise, it returns `0`.

Description

`engOutputBuffer` defines a character buffer for `engEvalString` to return any output that ordinarily appears on the screen.

The default behavior of `engEvalString` is to discard any standard output caused by the command it is executing. A call to `engOutputBuffer` with a buffer of nonzero length tells any subsequent calls to `engEvalString` to save output in the character buffer pointed to by `p`.

To turn off output buffering in C, use

```
engOutputBuffer(ep, NULL, 0);
```

To turn off output buffering in Fortran, use

```
engOutputBuffer(ep, '')
```

Note The buffer returned by `engEvalString` is not guaranteed to be `NULL` terminated.

C Examples

UNIX

See `engdemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program.

Windows

See `engwindemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program for Windows.

Fortran Examples

See `fengdemo.F` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a Fortran program.

See Also

`engOpen`, `engEvalString`

Purpose

Put variables into MATLAB engine workspace

C Syntax

```
#include "engine.h"
int engPutVariable(Engine *ep, const char *name, const mxArray
     *pm);
```

Fortran Syntax

```
integer*4 engPutVariable(ep, name, pm)
mwPointer ep, pm
character*(*) name
```

Arguments

`ep`
: Engine pointer

`name`
: Name given to the `mxArray` in the engine's workspace

`pm`
: `mxArray` pointer

Returns

`0` if successful and `1` if an error occurs.

Description

`engPutVariable` writes `mxArray` `pm` to the engine `ep`, giving it the variable name `name`. If the `mxArray` does not exist in the workspace, it is created. If an `mxArray` with the same name already exists in the workspace, the existing `mxArray` is replaced with the new `mxArray`.

C Examples

UNIX

See `engdemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program.

Windows

See `engwindemo.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to call the MATLAB engine functions from a C program for Windows.

See Also

engGetVariable

Purpose

Show or hide MATLAB engine session

C Syntax

```
#include "engine.h"
int engSetVisible(Engine *ep, bool value);
```

Arguments

`ep`
: Engine pointer

`value`
: Value to set the `Visible` property to. Set `value` to `1` to make the engine window visible, or to `0` to make it invisible.

Returns

Windows Only

`0` on success, and `1` otherwise.

Description

`engSetVisible` makes the window for the MATLAB engine session, `ep`, either visible or invisible on the Windows desktop. You can use this function to enable or disable user interaction with the MATLAB engine session.

Examples

The following code opens engine session `ep` and disables its visibility.

```
Engine *ep;
bool vis;

ep = engOpen(NULL);
engSetVisible(ep, 0);
```

To determine the current visibility setting, use

```
engGetVisible(ep, &vis);
```

See Also

`engGetVisible`

matClose (C and Fortran)

Purpose

Close MAT-file

C Syntax

```
#include "mat.h"
int matClose(MATFile *mfp);
```

Fortran Syntax

```
integer*4 matClose(mfp)
mwPointer mfp
```

Arguments

`mfp`
Pointer to MAT-file information

Returns

`EOF` in C (`-1` in Fortran) for a write error, and `0` if successful.

Description

`matClose` closes the MAT-file associated with `mfp`.

C Examples

See `matcreat.c` and `matdgns.c` in the `eng_mat` subdirectory of the `examples` directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a C program.

Fortran Examples

See `matdemo1.F` and `matdemo2.F` in the `eng_mat` subdirectory of the `examples` directory for sample programs that illustrate how to use this MAT-file routine in a Fortran program.

Purpose

Delete named mxArray from MAT-file

C Syntax

```
#include "mat.h"
int matDeleteVariable(MATFile *mfp, const char *name);
```

Fortran Syntax

```
integer*4 matDeleteVariable(mfp, name)
mwPointer mfp
character*(*) name
```

Arguments

`mfp`
: Pointer to MAT-file information

`name`
: Name of mxArray to delete

Returns

0 if successful, and nonzero otherwise.

Description

matDeleteVariable deletes the named mxArray from the MAT-file pointed to by mfp.

C Examples

See matcreat.c and matdgns.c in the eng_mat subdirectory of the examples directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a C program.

MATFile (C and Fortran)

Purpose

Type for a MAT-file

Description

A handle to a MAT-file object. A MAT-file is the data file format MATLAB uses for saving data to your disk.

`MATFile` is a C language opaque type.

The MAT-file interface library contains routines for reading and writing MAT-files. These routines are listed in "MAT-File Access" on page 1-2. You call these routines from your own C and Fortran programs, using `MATFile` to access your data file.

The header file containing this type is

```
#include "mat.h"
```

Examples

The example `matcreat.c` in your *`matlabroot`*`/extern/examples/eng_mat` directory shows how to create and use a MAT-file.

The `matOpen` function creates the file `mattest.mat`.

The `mxCreateDoubleMatrix` and `mxCreateString` functions create `mxArrays` `pa1`, `pa2`, and `pa3`. `mxCreateString` also initializes `pa3` using the literal string `"MATLAB: the language of technical computing"`. The C function `memcpy` copies `data` (initialized in `matcreat.c`) into `pa2`.

The `matPutVariable` and `matPutVariableAsGlobal` functions write the data to `mattest.mat`.

Calls to the `matClose` and `mxDestroyArray` functions complete the procedure.

Other examples, also found in your *`matlabroot`*`\extern\examples\eng_mat` directory, that show you how to use `MATFile` are:

- `matdgns.c` shows how to use MAT-file routines in a C program.
- `matdemo1.F` and `matdemo2.F` show how to use MAT-file routines in a Fortran program.

See Also

matOpen, matClose, matPutVariable, matGetVariable, mxDestroyArray

matGetDir (C and Fortran)

Purpose

Get directory of mxArrays in MAT-file

C Syntax

```
#include "mat.h"
char **matGetDir(MATFile *mfp, int *num);
```

Fortran Syntax

```
mwPointer matGetDir(mfp, num)
mwPointer mfp
integer*4 num
```

Arguments

mfp
: Pointer to MAT-file information

num
: Address of the variable to contain the number of mxArrays in the MAT-file

Returns

A pointer to an internal array containing pointers to the names of the mxArrays in the MAT-file pointed to by mfp. In C, each name is a NULL-terminated string. The length of the internal array (number of mxArrays in the MAT-file) is placed into num. If num is zero, mfp contains no arrays.

matGetDir returns NULL in C (0 in Fortran) and sets num to a negative number if it fails.

Description

This routine allows you to get a list of the names of the mxArrays contained within a MAT-file.

The internal array of strings that matGetDir returns is allocated using a single mxCalloc and must be freed using mxFree when you are finished with it.

MATLAB variable names can be up to length mxMAXNAM, where mxMAXNAM is defined in the C header file matrix.h.

C Examples

See matcreat.c and matdgns.c in the eng_mat subdirectory of the examples directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a C program.

Fortran Examples

See `matdemo2.F` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to use this MAT-file routine in a Fortran program.

matGetFp (C)

Purpose

Get file pointer to MAT-file

C Syntax

```
#include "mat.h"
FILE *matGetFp(MATFile *mfp);
```

Arguments

`mfp`
Pointer to MAT-file information

Returns

A C file handle to the MAT-file with handle `mfp`. Returns `NULL` if `mfp` is a handle to a MAT-file in HDF5-based format.

Description

Use `matGetFp` to obtain a C file handle to a MAT-file. This can be useful for using standard C library routines like `ferror` and `feof` to investigate error situations.

Examples

See `matcreat.c` and `matdgns.c` in the `eng_mat` subdirectory of the `examples` directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a C program.

Purpose

Read next mxArray from MAT-file

C Syntax

```
#include "mat.h"
mxArray *matGetNextVariable(MATFile *mfp, const char **name);
```

Fortran Syntax

```
mwPointer matGetNextVariable(mfp, name)
mwPointer mfp
character*(*) name
```

Arguments

mfp
: Pointer to MAT-file information

name
: Address of the variable to contain the mxArray name

Returns

A pointer to a newly allocated mxArray structure representing the next mxArray from the MAT-file pointed to by mfp. The function returns the name of the mxArray in name.

matGetNextVariable returns NULL in C (0 in Fortran) when the end-of-file is reached or if there is an error condition. In C, use feof and ferror from the Standard C Library to determine status.

Description

matGetNextVariable allows you to step sequentially through a MAT-file and read all the mxArrays in a single pass. The function reads and returns the next mxArray from the MAT-file pointed to by mfp.

Use matGetNextVariable immediately after opening the MAT-file with matOpen and not in conjunction with other MAT-file routines. Otherwise, the concept of the *next* mxArray is undefined.

Free the memory used by the mxArray created by this routine when you are finished with it.

The order of variables returned from successive calls to matGetNextVariable is not guaranteed to be the same order in which the variables were written.

C Examples

See `matdgns.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to use the MATLAB MAT-file routines in a C program.

Purpose

Load array header information only

C Syntax

```
#include "mat.h"
mxArray *matGetNextVariableInfo(MATFile *mfp, const char **name);
```

Fortran Syntax

```
mwPointer matGetNextVariableInfo(mfp, name)
mwPointer mfp
character*(*) name
```

Arguments

`mfp`
: Pointer to MAT-file information

`name`
: Address of the variable to contain the `mxArray` name

Returns

A pointer to a newly allocated `mxArray` structure representing header information for the next `mxArray` from the MAT-file pointed to by `mfp`. The function returns the name of the `mxArray` in `name`.

`matGetNextVariableInfo` returns `NULL` in C (`0` in Fortran) when the end-of-file is reached or if there is an error condition. In C, use `feof` and `ferror` from the Standard C Library to determine status.

Description

`matGetNextVariableInfo` loads only the array header information, including everything except `pr`, `pi`, `ir`, and `jc`, from the file's current file offset.

If `pr`, `pi`, `ir`, and `jc` are set to nonzero values when loaded with `matGetVariable`, `matGetNextVariableInfo` sets them to `-1` instead. These headers are for informational use only and should *never* be passed back to MATLAB or saved to MAT-files.

Free the memory used by the `mxArray` created by this routine when you are finished with it.

The order of variables returned from successive calls to `matGetNextVariableInfo` is not guaranteed to be the same order in which the variables were written.

C Examples

See `matdgns.c` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to use the MATLAB MAT-file routines in a C program.

See Also

`matGetNextVariable`, `matGetVariableInfo`

Purpose

Read mxArrays from MAT-files

C Syntax

```
#include "mat.h"
mxArray *matGetVariable(MATFile *mfp, const char *name);
```

Fortran Syntax

```
mwPointer matGetVariable(mfp, name)
mwPointer mfp
character*(*) name
```

Arguments

`mfp`
: Pointer to MAT-file information

`name`
: Name of `mxArray` to get from MAT-file

Returns

A pointer to a newly allocated `mxArray` structure representing the `mxArray` named by `name` from the MAT-file pointed to by `mfp`.

`matGetVariable` returns `NULL` in C (`0` in Fortran) if the attempt to return the `mxArray` named by `name` fails.

Description

This routine allows you to copy an `mxArray` out of a MAT-file.

Free the memory used by the `mxArray` created by this routine when you are finished with it.

C Examples

See `matcreat.c` and `matdgns.c` in the `eng_mat` subdirectory of the `examples` directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a C program.

matGetVariableInfo (C and Fortran)

Purpose

Load array header information only

C Syntax

```
#include "mat.h"
mxArray *matGetVariableInfo(MATFile *mfp, const char *name);
```

Fortran Syntax

```
mwPointer matGetVariableInfo(mfp, name);
mwPointer mfp
character*(*) name
```

Arguments

`mfp`
: Pointer to MAT-file information

`name`
: Name of `mxArray` to get from MAT-file

Returns

A pointer to a newly allocated `mxArray` structure representing header information for the `mxArray` named by `name` from the MAT-file pointed to by `mfp`.

`matGetVariableInfo` returns `NULL` in C (`0` in Fortran) if the attempt to return header information for the `mxArray` named by `name` fails.

Description

`matGetVariableInfo` loads only the array header information, including everything except `pr`, `pi`, `ir`, and `jc`. It recursively creates the cells and structures through their leaf elements, but does not include `pr`, `pi`, `ir`, and `jc`.

If `pr`, `pi`, `ir`, and `jc` are set to nonzero values when loaded with `matGetVariable`, `matGetVariableInfo` sets them to `-1` instead. These headers are for informational use only and should *never* be passed back to MATLAB or saved to MAT-files.

Free the memory used by the `mxArray` created by this routine when you are finished with it.

C Examples

See `matcreat.c` and `matdgns.c` in the `eng_mat` subdirectory of the `examples` directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a C program.

See Also `matGetVariable`

matOpen (C and Fortran)

Purpose

Open MAT-file

C Syntax

```
#include "mat.h"
MATFile *matOpen(const char *filename, const char *mode);
```

Fortran Syntax

```
mwPointer matOpen(filename, mode)
character*(*) filename, mode
```

Arguments

`filename`

Name of file to open

`mode`

File opening mode. Valid values for `mode` are listed in the following table.

`r`	Opens file for reading only; determines the current version of the MAT-file by inspecting the files and preserves the current version.
`u`	Opens file for update, both reading and writing, but does not create the file if the file does not exist (equivalent to the `r+` mode of `fopen`); determines the current version of the MAT-file by inspecting the files and preserves the current version.
`w`	Opens file for writing only; deletes previous contents, if any.
`w4`	Creates a Level 4 MAT-file, compatible with MATLAB Versions 4 and earlier.
`wL`	Opens file for writing character data using the default character set for your system. The resulting MAT-file can be read with MATLAB Version 6 or 6.5. If you do not use the `wL` mode switch, MATLAB writes character data to the MAT-file using Unicode character encoding by default.

`wz`	Opens file for writing compressed data.
`w7.3`	Creates a MAT-file in an HDF5-based format that can store objects occupy more than 2 GB.

Returns

A file handle, or `NULL` in C (`0` in Fortran) if the open fails.

Description

This routine opens a MAT-file for reading and writing.

See "Writing Character Data" in the External Interfaces documentation for more information on how MATLAB uses character encodings.

C Examples

See `matcreat.c` and `matdgns.c` in the `eng_mat` subdirectory of the `examples` directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a C program.

Fortran Examples

See `matdemo1.F` and `matdemo2.F` in the `eng_mat` subdirectory of the `examples` directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a Fortran program.

matPutVariable (C and Fortran)

Purpose

Write mxArrays to MAT-files

C Syntax

```
#include "mat.h"
int matPutVariable(MATFile *mfp, const char *name, const mxArray
  *pm);
```

Fortran Syntax

```
integer*4 matPutVariable(mfp, name, pm)
mwPointer mfp, pm
character*(*) name
```

Arguments

`mfp`
: Pointer to MAT-file information

`name`
: Name of `mxArray` to put into MAT-file

`pm`
: `mxArray` pointer

Returns

`0` if successful and nonzero if an error occurs. In C, use `feof` and `ferror` from the Standard C Library along with `matGetFp` to determine status.

Description

This routine allows you to put an `mxArray` into a MAT-file.

`matPutVariable` writes `mxArray pm` to the MAT-file `mfp`. If the `mxArray` does not exist in the MAT-file, it is appended to the end. If an `mxArray` with the same name already exists in the file, the existing `mxArray` is replaced with the new `mxArray` by rewriting the file. The size of the new `mxArray` can be different from the existing `mxArray`.

C Examples

See `matcreat.c` and `matdgns.c` in the `eng_mat` subdirectory of the `examples` directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a C program.

Purpose

Put mxArrays into MAT-files as originating from global workspace

C Syntax

```
#include "mat.h"
int matPutVariableAsGlobal(MATFile *mfp, const char *name, const
  mxArray *pm);
```

Fortran Syntax

```
integer*4 matPutVariableAsGlobal(mfp, name, pm)
mwPointer mfp, pm
character*(*) name
```

Arguments

`mfp`
: Pointer to MAT-file information

`name`
: Name of `mxArray` to put into MAT-file

`pm`
: `mxArray` pointer

Returns

`0` if successful and nonzero if an error occurs. In C, use `feof` and `ferror` from the Standard C Library with `matGetFp` to determine status.

Description

This routine puts an `mxArray` into a MAT-file. `matPutVariableAsGlobal` is similar to `matPutVariable`, except that the array, when loaded by MATLAB, is placed into the global workspace and a reference to it is set in the local workspace. If you write to a MATLAB 4 format file, `matPutVariableAsGlobal` does not load it as global and has the same effect as `matPutVariable`.

`matPutVariableAsGlobal` writes `mxArray pm` to the MAT-file `mfp`. If the `mxArray` does not exist in the MAT-file, it is appended to the end. If an `mxArray` with the same name already exists in the file, the existing `mxArray` is replaced with the new `mxArray` by rewriting the file. The size of the new `mxArray` can be different from the existing `mxArray`.

C Examples

See `matcreat.c` and `matdgns.c` in the `eng_mat` subdirectory of the `examples` directory for sample programs that illustrate how to use the MATLAB MAT-file routines in a C program.

Purpose

Register function to call when MEX-function is cleared or MATLAB terminates

C Syntax

```
#include "mex.h"
int mexAtExit(void (*ExitFcn)(void));
```

Fortran Syntax

```
integer*4 mexAtExit(ExitFcn)
subroutine ExitFcn()
```

Arguments

`ExitFcn`
Pointer to function you want to run on exit

Returns

Always returns `0`.

Description

Use `mexAtExit` to register a function to be called just before the MEX-function is cleared or MATLAB is terminated. `mexAtExit` gives your MEX-function a chance to perform tasks such as freeing persistent memory and closing files. Typically, the named `ExitFcn` performs tasks like closing streams or sockets.

Each MEX-function can register only one active exit function at a time. If you call `mexAtExit` more than once, MATLAB uses the `ExitFcn` from the more recent `mexAtExit` call as the exit function.

If a MEX-function is locked, all attempts to clear the MEX-file will fail. Consequently, if a user attempts to clear a locked MEX-file, MATLAB does not call the `ExitFcn`.

In Fortran, you must declare the `ExitFcn` as `external` in the Fortran routine that calls `mexAtExit` if it is not within the scope of the file.

C Examples

See `mexatexit.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexLock`, `mexUnlock`, `mexSetTrapFlag`

mexCallMATLAB (C and Fortran)

Purpose

Call MATLAB function or user-defined M-file or MEX-file

C Syntax

```
#include "mex.h"
int mexCallMATLAB(int nlhs, mxArray *plhs[], int nrhs,
  mxArray *prhs[], const char *name);
```

Fortran Syntax

```
integer*4 mexCallMATLAB(nlhs, plhs, nrhs, prhs, name)
integer*4 nlhs, nrhs
mwPointer plhs(*), prhs(*)
character*(*) name
```

Arguments

`nlhs`

Number of desired output arguments. This value must be less than or equal to 50.

`plhs`

Array of pointers to `mxArrays`. The called command puts pointers to the resultant `mxArrays` into `plhs` and allocates dynamic memory to store the resultant `mxArrays`. By default, MATLAB automatically deallocates this dynamic memory when you clear the MEX-file. However, if heap space is at a premium, you may want to call `mxDestroyArray` as soon as you are finished with the `mxArrays` that `plhs` points to.

`nrhs`

Number of input arguments. This value must be less than or equal to `50`.

`prhs`

Array of pointers to input arguments.

`name`

Character string containing the name of the MATLAB built-in, operator, M-file, or MEX-file that you are calling. If `name` is an operator, just place the operator inside a pair of single quotes, for example, `'+'`.

Returns

`0` if successful, and a nonzero value if unsuccessful.

Description

Call `mexCallMATLAB` to invoke internal MATLAB numeric functions, MATLAB operators, M-files, or other MEX-files. See `mexFunction` for a complete description of the arguments.

By default, if `name` detects an error, MATLAB terminates the MEX-file and returns control to the MATLAB prompt. If you want a different error behavior, turn on the trap flag by calling `mexSetTrapFlag`.

It is possible to generate an object of type `mxUNKNOWN_CLASS` using `mexCallMATLAB`. For example, if you create an M-file that returns two variables but assigns only one of them a value,

```
function [a,b]=foo(c)
a=2*c;
```

you get this warning message in MATLAB:

```
Warning: One or more output arguments not assigned
during call to 'foo'.
```

MATLAB assigns output `b` to an empty matrix. If you then call `foo` using `mexCallMATLAB`, the unassigned output variable is given type `mxUNKNOWN_CLASS`.

C Examples

See `mexcallmatlab.c` in the `mex` subdirectory of the `examples` directory.

Additional examples:

- `sincall.c` in the `refbook` subdirectory of the `examples` directory
- `mexevalstring.c` and `mexsettrapflag.c` in the `mex` subdirectory of the `examples` directory
- `mxcreatecellmatrix.c` and `mxisclass.c` in the `mx` subdirectory of the `examples` directory

See Also

`mexFunction`, `mexSetTrapFlag`

mexErrMsgIdAndTxt (C and Fortran)

Purpose

Issue error message with identifier and return to MATLAB prompt

C Syntax

```
#include "mex.h"
void mexErrMsgIdAndTxt(const char *errorid,
const char *errormsg, ...);
```

Fortran Syntax

```
mexErrMsgIdAndTxt(errorid, errormsg)
character*(*) errorid, errormsg
```

Arguments

`errorid`
: String containing a MATLAB message identifier. See "Message Identifiers" in the MATLAB documentation for information on this topic.

`errormsg`
: String containing the error message to be displayed. In C, the string may include formatting conversion characters, such as those used with the ANSI C `sprintf` function.

`...`
: In C, any additional arguments needed to translate formatting conversion characters used in `errormsg`. Each conversion character in `errormsg` is converted to one of these values.

Description

Call `mexErrMsgIdAndTxt` to write an error message and its corresponding identifier to the MATLAB window. After the error message prints, MATLAB terminates the MEX-file and returns control to the MATLAB prompt.

Calling `mexErrMsgIdAndTxt` does not clear the MEX-file from memory. Consequently, `mexErrMsgIdAndTxt` does not invoke the function registered through `mexAtExit`.

If your application called `mxCalloc` or one of the `mxCreate*` routines to allocate memory, `mexErrMsgIdAndTxt` automatically frees the allocated memory.

Note If you get warnings when using `mexErrMsgIdAndTxt`, you may have a memory management compatibility problem. For more information, see "Memory Management Compatibility Issues" in the External Interfaces documentation.

Remarks

In addition to the `errorid` and `errormsg`, the `mexerrmsgtxt` function determines where the error occurred, and displays the following information. For example, in the function `foo`, `mexerrmsgtxt` displays:

```
??? Error using ==> foo
```

See Also

`mexErrMsgTxt`, `mexWarnMsgIdAndTxt`, `mexWarnMsgTxt`

mexErrMsgTxt (C and Fortran)

Purpose

Issue error message and return to MATLAB prompt

C Syntax

```
#include "mex.h"
void mexErrMsgTxt(const char *errormsg);
```

Fortran Syntax

```
mexErrMsgTxt(errormsg)
character*(*) errormsg
```

Arguments

`errormsg`
: String containing the error message to be displayed

Description

Call `mexErrMsgTxt` to write an error message to the MATLAB window. After the error message prints, MATLAB terminates the MEX-file and returns control to the MATLAB prompt.

Calling `mexErrMsgTxt` does not clear the MEX-file from memory. Consequently, `mexErrMsgTxt` does not invoke the function registered through `mexAtExit`.

If your application called `mxCalloc` or one of the `mxCreate*` routines to allocate memory, `mexErrMsgTxt` automatically frees the allocated memory.

Note If you get warnings when using `mexErrMsgTxt`, you may have a memory management compatibility problem. For more information, see "Memory Management Compatibility Issues".

Remarks

In addition to the `errormsg`, the `mexerrmsgtxt` function determines where the error occurred, and displays the following information. If an error labeled `Print my error message` occurs in the function `foo`, `mexerrmsgtxt` displays:

```
??? Error using ==> foo
Print my error message
```

C Examples

See `xtimesy.c` in the `refbook` subdirectory of the `examples` directory.

For additional examples, see `convec.c`, `findnz.c`, `fulltosparse.c`, `phonebook.c`, `revord.c`, and `timestwo.c` in the `refbook` subdirectory of the `examples` directory.

See Also

`mexErrMsgIdAndTxt`, `mexWarnMsgIdAndTxt`, `mexWarnMsgTxt`

mexEvalString (C and Fortran)

Purpose

Execute MATLAB command in caller's workspace

C Syntax

```
#include "mex.h"
int mexEvalString(const char *command);
```

Fortran Syntax

```
integer*4 mexEvalString(command)
character*(*) command
```

Arguments

`command`
A string containing the MATLAB command to execute

Returns

`0` if successful, and a nonzero value if unsuccessful.

Description

Call `mexEvalString` to invoke a MATLAB `command` in the workspace of the caller.

`mexEvalString` and `mexCallMATLAB` both execute MATLAB commands. However, `mexCallMATLAB` provides a mechanism for returning results (left-hand side arguments) back to the MEX-file; `mexEvalString` provides no way for return values to be passed back to the MEX-file.

All arguments that appear to the right of an equal sign in the `command` string must already be current variables of the caller's workspace.

Examples

See `mexevalstring.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexCallMATLAB`

Purpose

Entry point to C MEX-file

C Syntax

```
#include "mex.h"
void mexFunction(int nlhs, mxArray *plhs[], int nrhs,
     const mxArray *prhs[]);
```

Fortran Syntax

```
mexFunction(nlhs, plhs, nrhs, prhs)
integer*4 nlhs, nrhs
mwPointer plhs(*), prhs(*)
```

Arguments

`nlhs`
: The number of expected output `mxArrays`

`plhs`
: Array of pointers to the expected output `mxArrays`

`nrhs`
: The number of input `mxArrays`

`prhs`
: Array of pointers to the input `mxArrays`. These `mxArrays` are read only and should not be modified by your MEX-file. Changing the data in these `mxArrays` may produce undesired side effects.

Description

`mexFunction` is not a routine you call. Rather, `mexFunction` is the name of a function in C (subroutine in Fortran) that you must write in every MEX-file. When you invoke a MEX-function, MATLAB finds and loads the corresponding MEX-file of the same name. MATLAB then searches for a symbol named `mexFunction` within the MEX-file. If it finds one, it calls the MEX-function using the address of the `mexFunction` symbol. If MATLAB cannot find a routine named `mexFunction` inside the MEX-file, it issues an error message.

When you invoke a MEX-file, MATLAB automatically seeds `nlhs`, `plhs`, `nrhs`, and `prhs` with the caller's information. In the syntax of the MATLAB language, functions have the general form

```
[a,b,c,...] = fun(d,e,f,...)
```

where the ... denotes more items of the same format. The a,b,c... are left-hand side arguments, and the d,e,f... are right-hand side arguments. The arguments nlhs and nrhs contain the number of left-hand side and right-hand side arguments, respectively, with which the MEX-function is called. prhs is an array of mxArray pointers whose length is nrhs. plhs is an array whose length is nlhs, where your function must set pointers for the returned left-hand side mxArrays.

C Examples

See mexfunction.c in the mex subdirectory of the examples directory.

Purpose

Name of current MEX-function

C Syntax

```
#include "mex.h"
const char *mexFunctionName(void);
```

Fortran Syntax

```
character*(*) mexFunctionName()
```

Returns

The name of the current MEX-function.

Description

`mexFunctionName` returns the name of the current MEX-function.

C Examples

See `mexgetarray.c` in the `mex` subdirectory of the `examples` directory.

mexGet (C)

Purpose

Get value of specified Handle Graphics® property

C Syntax

```
#include "mex.h"
const mxArray *mexGet(double handle, const char *property);
```

Arguments

`handle`
Handle to a particular graphics object

`property`
A Handle Graphics property

Returns

The value of the specified property in the specified graphics object on success. Returns `NULL` on failure. The return argument from `mexGet` is declared as `constant`, meaning that it is read only and should not be modified. Changing the data in these `mxArrays` may produce undesired side effects.

Description

Call `mexGet` to get the value of the property of a certain graphics object. `mexGet` is the API equivalent of the MATLAB `get` function. To set a graphics property value, call `mexSet`.

Examples

See `mexget.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexSet`

Purpose

Get copy of variable from specified workspace

C Syntax

```
#include "mex.h"
mxArray *mexGetVariable(const char *workspace, const char
  *varname);
```

Fortran Syntax

```
mwPointer mexGetVariable(workspace, varname)
character*(*) workspace, varname
```

Arguments

`workspace`

Specifies where `mexGetVariable` should search in order to find array `varname`. The possible values are

`base`	Search for the variable in the base workspace.
`caller`	Search for the variable in the caller's workspace.
`global`	Search for the variable in the global workspace.

`varname`

Name of the variable to copy

Returns

A copy of the variable on success. Returns `NULL` in C (`0` on Fortran) on failure. A common cause of failure is specifying a variable that is not currently in the workspace. Perhaps the variable was in the workspace at one time but has since been cleared.

Description

Call `mexGetVariable` to get a copy of the specified variable. The returned `mxArray` contains a copy of all the data and characteristics that the variable had in the other workspace. Modifications to the returned `mxArray` do not affect the variable in the workspace unless you write the copy back to the workspace with `mexPutVariable`.

C Examples

See `mexgetarray.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexGetVariablePtr`, `mexPutVariable`

mexGetVariablePtr (C and Fortran)

Purpose

Get read-only pointer to variable from another workspace

C Syntax

```
#include "mex.h"
const mxArray *mexGetVariablePtr(const char *workspace,
  const char *varname);
```

Fortran Syntax

```
mwPointer mexGetVariablePtr(workspace, varname)
character*(*) workspace, varname
```

Arguments

`workspace`

Specifies which workspace you want `mexGetVariablePtr` to search. The possible values are

`base`	Search for the variable in the base workspace.
`caller`	Search for the variable in the caller's workspace.
`global`	Search for the variable in the global workspace.

`varname`

Name of a variable in another workspace. This is a variable name, not an `mxArray` pointer.

Returns

A read-only pointer to the `mxArray` on success. Returns `NULL` in C (`0` in Fortran) on failure.

Description

Call `mexGetVariablePtr` to get a read-only pointer to the specified variable, `varname`, into your MEX-file's workspace. This command is useful for examining an `mxArray`'s data and characteristics. If you need to change data or characteristics, use `mexGetVariable` (along with `mexPutVariable`) instead of `mexGetVariablePtr`.

If you simply need to examine data or characteristics, `mexGetVariablePtr` offers superior performance because the caller needs to pass only a pointer to the array.

C Examples

See `mxislogical.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mexGetVariable`

mexIsGlobal (C and Fortran)

Purpose

Determine whether mxArray has global scope

C Syntax

```
#include "matrix.h"
bool mexIsGlobal(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mexIsGlobal(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the mxArray has global scope, and logical 0 (false) otherwise.

Description

Use mexIsGlobal to determine whether the specified mxArray has global scope.

C Examples

See mxislogical.c in the mx subdirectory of the examples directory.

See Also

mexGetVariable, mexGetVariablePtr, mexPutVariable, global

Purpose

Determine whether MEX-file is locked

C Syntax

```
#include "mex.h"
bool mexIsLocked(void);
```

Fortran Syntax

```
integer*4 mexIsLocked()
```

Returns

Logical `1` (`true`) if the MEX-file is locked; logical `0` (`false`) if the file is unlocked.

Description

Call `mexIsLocked` to determine whether the MEX-file is locked. By default, MEX-files are unlocked, meaning that users can clear the MEX-file at any time.

To unlock a MEX-file, call `mexUnlock`.

C Examples

See `mexlock.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexLock`, `mexMakeArrayPersistent`, `mexMakeMemoryPersistent`, `mexUnlock`

mexLock (C and Fortran)

Purpose

Prevent MEX-file from being cleared from memory

C Syntax

```
#include "mex.h"
void mexLock(void);
```

Fortran Syntax

```
mexLock()
```

Description

By default, MEX-files are unlocked, meaning that a user can clear them at any time. Call `mexLock` to prohibit a MEX-file from being cleared.

To unlock a MEX-file, you must call `mexUnlock`. Do not use the `munlock` function.

`mexLock` increments a lock count. If you call `mexLock` `n` times, you must call `mexUnlock` `n` times to unlock your MEX-file.

C Examples

See `mexlock.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexIsLocked`, `mexMakeArrayPersistent`, `mexMakeMemoryPersistent`, `mexUnlock`

Purpose

Make mxArray persist after MEX-file completes

C Syntax

```
#include "mex.h"
void mexMakeArrayPersistent(mxArray *pm);
```

Fortran Syntax

```
mexMakeArrayPersistent(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray created by an mxCreate* function

Description

By default, mxArrays allocated by mxCreate* functions are not persistent. The MATLAB memory management facility automatically frees nonpersistent mxArrays when the MEX-function finishes. If you want the mxArray to persist through multiple invocations of the MEX-function, you must call mexMakeArrayPersistent.

Note If you create a persistent mxArray, you are responsible for destroying it when the MEX-file is cleared. If you do not destroy a persistent mxArray, MATLAB leaks memory. See mexAtExit to see how to register a function that gets called when the MEX-file is cleared. See mexLock to see how to lock your MEX-file so that it is never cleared.

See Also

mexAtExit, mexLock, mexMakeMemoryPersistent, and the mxCreate* functions

mexMakeMemoryPersistent (C and Fortran)

Purpose

Make allocated memory MATLAB persist after MEX-function completes

C Syntax

```
#include "mex.h"
void mexMakeMemoryPersistent(void *ptr);
```

Fortran Syntax

```
mexMakeMemoryPersistent(ptr)
mwPointer ptr
```

Arguments

`ptr`

Pointer to the beginning of memory allocated by one of the MATLAB memory allocation routines

Description

By default, memory allocated by MATLAB is nonpersistent, so it is freed automatically when the MEX-function finishes. If you want the memory to persist, you must call `mexMakeMemoryPersistent`.

Note If you create persistent memory, you are responsible for freeing it when the MEX-function is cleared. If you do not free the memory, MATLAB leaks memory. To free memory, use `mxFree`. See `mexAtExit` to see how to register a function that gets called when the MEX-function is cleared. See `mexLock` to see how to lock your MEX-function so that it is never cleared.

See Also

`mexAtExit`, `mexLock`, `mexMakeArrayPersistent`, `mxCalloc`, `mxFree`, `mxMalloc`, `mxRealloc`

Purpose

ANSI C `printf`-style output routine

C Syntax

```
#include "mex.h"
int mexPrintf(const char *message, ...);
```

Fortran Syntax

```
integer*4 mexPrintf(message)
character*(*) message
```

Arguments

`message`
: String to be displayed. In C, the string may include formatting conversion characters, such as those used with the ANSI C `printf` function.

`...`
: In C, any additional arguments needed to translate formatting conversion characters used in `message`. Each conversion character in `message` is converted to one of these values.

Returns

The number of characters printed. This includes characters specified with backslash codes, such as `\n` and `\b`.

Description

This routine prints a string on the screen and in the diary (if the diary is in use). It provides a callback to the standard C `printf` routine already linked inside MATLAB, and avoids linking the entire `stdio` library into your MEX-file.

In a C MEX-file, you must call `mexPrintf` instead of `printf` to display a string.

Note If you want the literal `%` in your message, you must use `%%` in your message string since `%` has special meaning to `mexPrintf`. Failing to do so causes unpredictable results.

C Examples

See

- `mexfunction.c` in the `mex` subdirectory of the `examples` directory
- `phonebook.c` in the `refbook` subdirectory of the `examples` directory.

See Also

`mexErrMsgIdAndTxt`, `mexErrMsgTxt`, `mexWarnMsgIdAndTxt`, `mexWarnMsgTxt`

Purpose

Copy mxArray from MEX-function into specified workspace

C Syntax

```
#include "mex.h"
int mexPutVariable(const char *workspace, const char *varname,
  const mxArray *pm);
```

Fortran Syntax

```
integer*4 mexPutVariable(workspace, varname, pm)
character*(*) workspace, varname
mwPointer pm
```

Arguments

workspace
: Specifies the scope of the array that you are copying. The possible values are

base	Copy mxArray to the base workspace.
caller	Copy mxArray to the caller's workspace.
global	Copy mxArray to the list of global variables.

varname
: Name given to the mxArray in the workspace

pm
: Pointer to the mxArray

Returns

0 on success; 1 on failure. A possible cause of failure is that pm is NULL in C (0 in Fortran).

Description

Call mexPutVariable to copy the mxArray, at pointer pm, from your MEX-function into the specified workspace. MATLAB gives the name, varname, to the copied mxArray in the receiving workspace.

mexPutVariable makes the array accessible to other entities, such as MATLAB, M-files, or other MEX-functions.

If a variable of the same name already exists in the specified workspace, mexPutVariable overwrites the previous contents of the variable with

the contents of the new `mxArray`. For example, suppose the MATLAB workspace defines variable `Peaches` as

```
Peaches
1     2     3     4
```

and you call `mexPutVariable` to copy `Peaches` into the same workspace:

```
mexPutVariable("base", "Peaches", pm)
```

Then the old value of `Peaches` disappears and is replaced by the value passed in by `mexPutVariable`.

C Examples

See `mexgetarray.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexGetVariable`

Purpose

Set value of specified Handle Graphics property

C Syntax

```
#include "mex.h"
int mexSet(double handle, const char *property,
           mxArray *value);
```

Arguments

`handle`
: Handle to a particular graphics object

`property`
: String naming a Handle Graphics property

`value`
: Pointer to an `mxArray` holding the new value to assign to the property

Returns

`0` on success; `1` on failure. Possible causes of failure include:

- Specifying a nonexistent property.
- Specifying an illegal value for that property, for example, specifying a string value for a numerical property.

Description

Call `mexSet` to set the value of the property of a certain graphics object. `mexSet` is the API equivalent of the MATLAB `set` function. To get the value of a graphics property, call `mexGet`.

Examples

See `mexget.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexGet`

mexSetTrapFlag (C and Fortran)

Purpose

Control response of `mexCallMATLAB` to errors

C Syntax

```
#include "mex.h"
void mexSetTrapFlag(int trapflag);
```

Fortran Syntax

```
mexSetTrapFlag(trapflag)
integer*4 trapflag
```

Arguments

`trapflag`
Control flag. Possible values are

`0`	On error, control returns to the MATLAB prompt.
`1`	On error, control returns to your MEX-file.

Description

Call `mexSetTrapFlag` to control the MATLAB response to errors in `mexCallMATLAB`.

If you do not call `mexSetTrapFlag`, then whenever MATLAB detects an error in a call to `mexCallMATLAB`, MATLAB automatically terminates the MEX-file and returns control to the MATLAB prompt. Calling `mexSetTrapFlag` with `trapflag` set to `0` is equivalent to not calling `mexSetTrapFlag` at all.

If you call `mexSetTrapFlag` and set the `trapflag` to `1`, then whenever MATLAB detects an error in a call to `mexCallMATLAB`, MATLAB does not automatically terminate the MEX-file. Rather, MATLAB returns control to the line in the MEX-file immediately following the call to `mexCallMATLAB`. The MEX-file is then responsible for taking an appropriate response to the error.

If you call `mexSetTrapFlag`, the value of the `trapflag` you set remains in effect until the next call to `mexSetTrapFlag` within that MEX-file or, if there are no more calls to `mexSetTrapFlag`, until the MEX-file exits. If a routine defined in a MEX-file calls another MEX-file,

1. The current value of the `trapflag` in the first MEX-file is saved.

2 The second MEX-file is called with the `trapflag` initialized to `0` within that file.

3 When the second MEX-file exits, the saved value of the `trapflag` in the first MEX-file is restored within that file.

C Examples

See `mexsettrapflag.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexAtExit`, `mexErrMsgTxt`

mexUnlock (C and Fortran)

Purpose

Allow MEX-file to be cleared from memory

C Syntax

```
#include "mex.h"
void mexUnlock(void);
```

Fortran Syntax

```
mexUnlock()
```

Description

By default, MEX-files are unlocked, meaning that a user can clear them at any time. Calling `mexLock` locks a MEX-file so that it cannot be cleared. Calling `mexUnlock` removes the lock so that the MEX-file can be cleared.

`mexLock` increments a lock count. If you called `mexLock` `n` times, you must call `mexUnlock` `n` times to unlock your MEX-file.

C Examples

See `mexlock.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mexIsLocked`, `mexLock`, `mexMakeArrayPersistent`, `mexMakeMemoryPersistent`

Purpose

Issue warning message with identifier

C Syntax

```
#include "mex.h"
void mexWarnMsgIdAndTxt(const char *warningid,
  const char *warningmsg, ...);
```

Fortran Syntax

```
mexWarnMsgIdAndTxt(warningid, warningmsg)
character*(*) warningid, warningmsg
```

Arguments

`warningid`
: String containing a MATLAB message identifier. See "Message Identifiers" in the MATLAB documentation for information on this topic.

`warningmsg`
: String containing the warning message to be displayed. In C, the string may include formatting conversion characters, such as those used with the ANSI C `sprintf` function.

`...`
: In C, any additional arguments needed to translate formatting conversion characters used in `warningmsg`. Each conversion character in `warningmsg` is converted to one of these values.

Description

Call `mexWarnMsgIdAndTxt` to write a warning message and its corresponding identifier to the MATLAB window.

Unlike `mexErrMsgIdAndTxt`, `mexWarnMsgIdAndTxt` does not cause the MEX-file to terminate.

See Also

`mexErrMsgTxt`, `mexErrMsgIdAndTxt`, `mexWarnMsgTxt`

mexWarnMsgTxt (C and Fortran)

Purpose

Issue warning message

C Syntax

```
#include "mex.h"
void mexWarnMsgTxt(const char *warningmsg);
```

Fortran Syntax

```
mexWarnMsgTxt(warningmsg)
character*(*) warningmsg
```

Arguments

`warningmsg`
String containing the warning message to be displayed

Description

`mexWarnMsgTxt` causes MATLAB to display the contents of `warningmsg`.

Unlike `mexErrMsgTxt`, `mexWarnMsgTxt` does not cause the MEX-file to terminate.

C Examples

See `yprime.c` in the `mex` subdirectory of the `examples` directory.

Additional examples:

- `explore.c` in the `mex` subdirectory of the `examples` directory
- `fulltosparse.c` in the `refbook` subdirectory of the `examples` directory
- `mxisfinite.c` and `mxsetnzmax.c` in the `mx` subdirectory of the `examples` directory

See Also

`mexErrMsgTxt`, `mexErrMsgIdAndTxt`, `mexWarnMsgIdAndTxt`

Purpose

Type for index values

Description

`mwIndex` is a type that represents index values, such as indices into arrays. This function is provided for purposes of cross-platform flexibility. By default, `mwIndex` is equivalent to `int` in C. When using the mex `-largeArrayDims` switch, `mwIndex` is equivalent to `size_t` in C. `mwIndex` is equivalent to `INTEGER*4` in Fortran. The C header file containing this type is

```
#include "matrix.h"
```

In Fortran, `mwIndex` is implemented as a preprocessor macro. The Fortran header file containing this type is

```
#include "fintrf.h"
```

See Also

`mex`, `mwSize`

mwPointer (Fortran)

Purpose

Declare appropriate pointer type for platform

Description

`mwPointer` is a preprocessor macro that declares the appropriate Fortran type representing a pointer to an `mxArray` or to other data that is not of a native Fortran type, such as memory allocated by `mxMalloc`. On 32-bit platforms, the Fortran type that represents a pointer is `INTEGER*4`; on 64-bit platforms, it is `INTEGER*8`. The Fortran preprocessor translates `mwPointer` to the Fortran declaration that is appropriate for the platform on which you compile your file.

If your Fortran compiler supports preprocessing, you can use `mwPointer` to declare functions, arguments, and variables that represent pointers. If you cannot use `mwPointer`, you must ensure that your declarations have the correct size for the platform on which you are compiling Fortran code.

The Fortran header file containing this type is

```
#include "fintrf.h"
```

Examples

This example declares the arguments for `mexFunction` in a Fortran MEX-file:

```
SUBROUTINE MEXFUNCTION(NLHS, PLHS, NRHS, PRHS)
MWPOINTER PLHS(*), PRHS(*)
INTEGER NLHS, NRHS
```

For additional examples, see the Fortran files with names ending in `.F` in the `$MATLAB/extern/examples` directory, where `$MATLAB` is the string returned by the `matlabroot` command.

Purpose

Type for size values

Description

`mwSize` is a type that represents size values, such as array dimensions. This function is provided for purposes of cross-platform flexibility. By default, `mwSize` is equivalent to `int` in C. When using the mex `-largeArrayDims` switch, `mwSize` is equivalent to `size_t` in C. `mwSize` is equivalent to `INTEGER*4` in Fortran.

In Fortran, `mwSize` is implemented as a preprocessor macro.

The C header file containing this type is

```
#include "matrix.h"
```

The Fortran header file containing this type is

```
#include "fintrf.h"
```

See Also

`mex`, `mwIndex`

mxAddField (C and Fortran)

Purpose

Add field to structure array

C Syntax

```
#include "matrix.h"
extern int mxAddField(mxArray pm, const char *fieldname);
```

Fortran Syntax

```
integer*4 mxAddField(pm, fieldname)
mwPointer pm
character*(*) fieldname
```

Arguments

`pm`
: Pointer to a structure `mxArray`

`fieldname`
: The name of the field you want to add

Returns

Field number on success or `-1` if inputs are invalid or an out-of-memory condition occurs.

Description

Call `mxAddField` to add a field to a structure array. You must then create the values with the `mxCreate*` functions and use `mxSetFieldByNumber` to set the individual values for the field.

See Also

`mxRemoveField`, `mxSetFieldByNumber`

Purpose

Type for a MATLAB array

Description

The fundamental type underlying MATLAB data. For information on how the MATLAB array works with MATLAB-supported variables, see "MATLAB Data" in the External Interfaces documentation.

`mxArray` is a C language opaque type.

All C and Fortran MEX-files start with a gateway routine, called `mexFunction`, which requires `mxArray` for both input and output parameters. A C MEX-file gateway routine is described in "C MEX-Files". The Fortran version is described in "Fortran MEX-Files".

Once you have MATLAB data in your MEX-file, you can use the array access library routines (listed in "MX Array Manipulation" on page 1-2) to manipulate the data, and the MEX library routines (listed in "MEX-Files" on page 1-9) to perform operations in the MATLAB environment. You use `mxArray` to pass data to and from these functions.

Use any of the `mxcreate*` functions when you need to create data, and the corresponding `mxDestroyArray` function to free memory.

The header file containing this type is

```
#include "matrix.h"
```

Example

See `mxcreatecharmatrixfromstr.c` in your *`matlabroot`*`/extern/examples/mx` directory.

The input argument `prhs` contains two or more strings, defined as `mxArray`. Use the `mxIsChar` function to validate the input. Create a C variable `str` of type `char` using the `mxArrayToString` function. Now you can manipulate your data in C.

To set the return values in `plhs`, use the `mxCreateCharMatrixFromStrings` function.

Before you exit your routine, be sure to free memory using the `mxFree` function on `str`.

See Also

mexFunction, mxClassID, mxCreateDoubleMatrix, mxCreateNumericArray, mxCreateString, mxDestroyArray, mxGetData, mxSetData

Purpose

Convert array to string

C Syntax

```
#include "matrix.h"
char *mxArrayToString(const mxArray *array_ptr);
```

Arguments

`array_ptr`
Pointer to a string `mxArray`; that is, a pointer to an `mxArray` having the `mxCHAR_CLASS` class.

Returns

A C-style string. Returns NULL on failure. Possible reasons for failure include out of memory and specifying an `mxArray` that is not a string `mxArray`.

Description

Call `mxArrayToString` to copy the character data of a string `mxArray` into a C-style string. The C-style string is always terminated with a `NULL` character.

If the string array contains several rows, they are copied, one column at a time, into one long string array. This function is similar to `mxGetString`, except that

- It does not require the length of the string as an input.
- It supports multibyte character sets.

`mxArrayToString` does not free the dynamic memory that the `char` pointer points to. Consequently, you should typically free the string (using `mxFree`) immediately after you have finished using it.

Examples

See `mexatexit.c` in the `mex` subdirectory of the `examples` directory.

For additional examples, see `mxcreatecharmatrixfromstr.c` and `mxislogical.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxCreateCharArray`, `mxCreateCharMatrixFromStrings`, `mxCreateString`, `mxGetString`

mxAssert (C)

Purpose

Check assertion value for debugging purposes

C Syntax

```
#include "matrix.h"
void mxAssert(int expr, char *error_message);
```

Arguments

`expr`
: Value of assertion

`error_message`
: Description of why assertion failed

Description

Similar to the ANSI C `assert` macro, `mxAssert` checks the value of an assertion, and continues execution only if the assertion holds. If `expr` evaluates to logical `1` (`true`), `mxAssert` does nothing. If `expr` evaluates to logical `0` (`false`), `mxAssert` prints an error to the MATLAB command window consisting of the failed assertion's expression, the filename and line number where the failed assertion occurred, and the `error_message` string. The `error_message` string allows you to specify a better description of why the assertion failed. Use an empty string if you don't want a description to follow the failed assertion message.

After a failed assertion, control returns to the MATLAB command line.

The `mex` script turns off these assertions when building optimized MEX-functions, so use this for debugging purposes only. Build the MEX-file using the syntax `mex -g filename` in order to use `mxAssert`.

Assertions are a way of maintaining internal consistency of logic. Use them to keep yourself from misusing your own code and to prevent logical errors from propagating before they are caught; do not use assertions to prevent users of your code from misusing it.

Assertions can be taken out of your code by the C preprocessor. You can use these checks during development and then remove them when the code works properly, letting you use them for troubleshooting during development without slowing down the final product.

Purpose

Check assertion value without printing assertion text

C Syntax

```
#include "matrix.h"
void mxAssertS(int expr, char *error_message);
```

Arguments

`expr`
Value of assertion

`error_message`
Description of why assertion failed

Description

`mxAssertS` is similar to `mxAssert`, except `mxAssertS` does not print the text of the failed assertion. `mxAssertS` checks the value of an assertion, and continues execution only if the assertion holds. If `expr` evaluates to logical `1` (`true`), `mxAssertS` does nothing. If `expr` evaluates to logical `0` (`false`), `mxAssertS` prints an error to the MATLAB command window consisting of the filename and line number where the assertion failed and the `error_message` string. The `error_message` string allows you to specify a better description of why the assertion failed. Use an empty string if you don't want a description to follow the failed assertion message.

After a failed assertion, control returns to the MATLAB command line.

Note that the `mex` script turns off these assertions when building optimized MEX-functions, so use this for debugging purposes only. Build the MEX-file using the syntax`mex -g filename` in order to use `mxAssertS`.

mxCalcSingleSubscript (C and Fortran)

Purpose

Offset from first element to desired element

C Syntax

```
#include "matrix.h"
mwIndex mxCalcSingleSubscript(const mxArray *pm, mwSize nsubs,
    mwIndex *subs);
```

Fortran Syntax

```
mwIndex mxCalcSingleSubscript(pm, nsubs, subs)
mwPointer pm
mwSize nsubs
mwIndex subs
```

Arguments

`pm`

Pointer to an `mxArray`

`nsubs`

The number of elements in the `subs` array. Typically, you set `nsubs` equal to the number of dimensions in the `mxArray` that `pm` points to.

subs

An array of integers. Each value in the array should specify that dimension's subscript. In C syntax, the value in `subs[0]` specifies the row subscript, and the value in `subs[1]` specifies the column subscript. Use zero-based indexing for subscripts. For example, to express the starting element of a two-dimensional `mxArray` in `subs`, set `subs[0]` to `0` and `subs[1]` to `0`.

In Fortran syntax, the value in `subs(1)` specifies the row subscript, and the value in `subs(2)` specifies the column subscript. Use 1-based indexing for subscripts. For example, to express the starting element of a two-dimensional `mxArray` in `subs`, set `subs(1)` to `1` and `subs(2)` to `1`.

Returns

The number of elements between the start of the `mxArray` and the specified subscript. This returned number is called an *index*; many `mx` routines (for example, `mxGetField`) require an index as an argument.

If subs describes the starting element of an mxArray, mxCalcSingleSubscript returns 0. If subs describes the final element of an mxArray, mxCalcSingleSubscript returns N-1 (where N is the total number of elements).

Description

Call mxCalcSingleSubscript to determine how many elements there are between the beginning of the mxArray and a given element of that mxArray. For example, given a subscript like (5,7), mxCalcSingleSubscript returns the distance from the first element of the array to the (5,7) element. Remember that the mxArray data type internally represents all data elements in a one-dimensional array no matter how many dimensions the MATLAB mxArray appears to have.

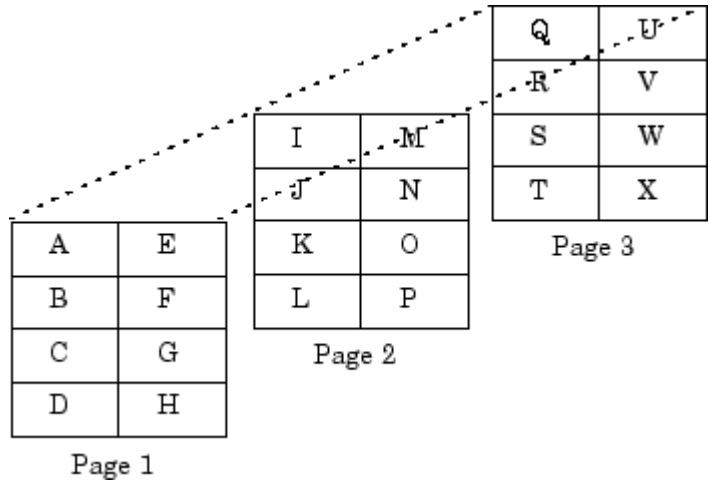
MATLAB uses a column-major numbering scheme to represent data elements internally. That means that MATLAB internally stores data elements from the first column first, then data elements from the second column second, and so on through the last column. For example, suppose you create a 4-by-2 variable. It is helpful to visualize the data as follows.

A	E
B	F
C	G
D	H

In fact, though, MATLAB internally represents the data as the following:

A	B	C	D	E	F	G	H
Index 0	Index 1	Index 2	Index 3	Index 4	Index 5	Index 6	Index 7

If an mxArray is N-dimensional, MATLAB represents the data in N-major order. For example, consider a three-dimensional array having dimensions 4-by-2-by-3. Although you can visualize the data as



MATLAB internally represents the data for this three-dimensional array in the following order:

A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P	Q	R	S	T	U	V	W	X
0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23

Avoid using `mxCalcSingleSubscript` to traverse the elements of an array. In C, it is more efficient to do this by finding the array's starting address and then using pointer auto-incrementing to access successive elements. For example, to find the starting address of a numerical array, call `mxGetPr` or `mxGetPi`.

C Examples

See `mxcalcsinglesubscript.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxGetCell`, `mxSetCell`

Purpose

Allocate dynamic memory for array using MATLAB memory manager

C Syntax

```
#include "matrix.h"
#include <stdlib.h>
void *mxCalloc(mwSize n, mwSize size);
```

Fortran Syntax

```
mwPointer mxCalloc(n, size)
mwSize n, size
```

Arguments

`n`

Number of elements to allocate. This must be a nonnegative number.

`size`

Number of bytes per element. (The C `sizeof` operator calculates the number of bytes per element.)

Returns

A pointer to the start of the allocated dynamic memory, if successful. If unsuccessful in a stand-alone (non-MEX-file) application, `mxCalloc` returns `NULL` in C (`0` in Fortran). If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt.

`mxCalloc` is unsuccessful when there is insufficient free heap space.

Description

MATLAB applications should always call `mxCalloc` rather than `calloc` to allocate memory. Note that `mxCalloc` works differently in MEX-files than in stand-alone MATLAB applications.

In MEX-files, `mxCalloc` automatically

- Allocates enough contiguous heap space to hold `n` elements.
- Initializes all `n` elements to `0`.
- Registers the returned heap space with the MATLAB memory management facility.

The MATLAB memory management facility maintains a list of all memory allocated by `mxCalloc`. The MATLAB memory management facility automatically frees (deallocates) all of a MEX-file's parcels when control returns to the MATLAB prompt.

In stand-alone MATLAB C applications, `mxCalloc` calls the ANSI C `calloc` function.

By default, in a MEX-file, `mxCalloc` generates nonpersistent `mxCalloc` data. In other words, the memory management facility automatically deallocates the memory as soon as the MEX-file ends. If you want the memory to persist after the MEX-file completes, call `mexMakeMemoryPersistent` after calling `mxCalloc`. If you write a MEX-file with persistent memory, be sure to register a `mexAtExit` function to free allocated memory in the event your MEX-file is cleared.

When you finish using the memory allocated by `mxCalloc`, call `mxFree`. `mxFree` deallocates the memory.

C Examples

See

- `explore.c` in the `mex` subdirectory of the `examples` directory
- `phonebook.c` and `revord.c` in the `refbook` subdirectory of the `examples` directory

For additional examples, see `mxcalcsinglesubscript.c` and `mxsetdimensions.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mexAtExit`, `mexMakeArrayPersistent`, `mexMakeMemoryPersistent`, `mxDestroyArray`, `mxFree`, `mxMalloc`, `mxRealloc`

Purpose

Type for string mxArray

Description

A string mxArray stores its data elements as mxChar rather than as char.

The header file containing this type is

```
#include "matrix.h"
```

Examples

See mxmalloc.c in the mx subdirectory of the examples directory.

Additional examples:

- explore.c in the mex subdirectory of the examples directory
- mxcreatecharmatrixfromstr.c in the mx subdirectory of the examples directory

See Also

mxCreateCharArray

mxClassID (C)

Purpose

Enumerated value identifying class of `mxArray`

C Syntax

```
typedef enum {
        mxUNKNOWN_CLASS,
        mxCELL_CLASS,
        mxSTRUCT_CLASS,
        mxLOGICAL_CLASS,
        mxCHAR_CLASS,
        mxDOUBLE_CLASS,
        mxSINGLE_CLASS,
        mxINT8_CLASS,
        mxUINT8_CLASS,
        mxINT16_CLASS,
        mxUINT16_CLASS,
        mxINT32_CLASS,
        mxUINT32_CLASS,
        mxINT64_CLASS,
        mxUINT64_CLASS,
        mxFUNCTION_CLASS
} mxClassID;
```

Constants

`mxUNKNOWN_CLASS`
: The class cannot be determined. You cannot specify this category for an `mxArray`; however, `mxGetClassID` can return this value if it cannot identify the class.

`mxCELL_CLASS`
: Identifies a cell `mxArray`.

`mxSTRUCT_CLASS`
: Identifies a structure `mxArray`.

`mxLOGICAL_CLASS`
: Identifies a logical `mxArray`, an `mxArray` whose data is represented as `mxLogical`.

`mxCHAR_CLASS`
: Identifies a string `mxArray`, an `mxArray` whose data is represented as `mxChar`.

`mxDOUBLE_CLASS`
: Identifies a numeric `mxArray` whose data is stored as double-precision, floating-point numbers.

`mxSINGLE_CLASS`
: Identifies a numeric `mxArray` whose data is stored as single-precision, floating-point numbers.

`mxINT8_CLASS`
: Identifies a numeric `mxArray` whose data is stored as signed 8-bit integers.

`mxUINT8_CLASS`
: Identifies a numeric `mxArray` whose data is stored as unsigned 8-bit integers.

`mxINT16_CLASS`
: Identifies a numeric `mxArray` whose data is stored as signed 16-bit integers.

`mxUINT16_CLASS`
: Identifies a numeric `mxArray` whose data is stored as unsigned 16-bit integers.

`mxINT32_CLASS`
: Identifies a numeric `mxArray` whose data is stored as signed 32-bit integers.

`mxUINT32_CLASS`
: Identifies a numeric `mxArray` whose data is stored as unsigned 32-bit integers.

`mxINT64_CLASS`
: Identifies a numeric `mxArray` whose data is stored as signed 64-bit integers.

`mxUINT64_CLASS`
: Identifies a numeric `mxArray` whose data is stored as unsigned 64-bit integers.

`mxFUNCTION_CLASS`
: Identifies a function handle `mxArray`.

mxClassID (C)

Description

Various `mx*` calls require or return an `mxClassID` argument. `mxClassID` identifies the way in which the `mxArray` represents its data elements.

Examples

See `explore.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mxGetClassID` , `mxCreateNumericArray`

Purpose

Identifier corresponding to class

Fortran Syntax

```
integer*4 mxClassIDFromClassName(classname)
character*(*) classname
```

Arguments

`classname`

A `character` array specifying a MATLAB class name. Use one of the strings from the following table.

Returns

A numeric identifier used internally by MATLAB to represent the MATLAB class, `classname`. Returns `unknown` if `classname` is not a recognized MATLAB class.

Description

Use `mxClassIDFromClassName` to obtain an identifier for any class that is recognized by MATLAB. This function is most commonly used to provide a `classid` argument to `mxCreateNumericArray` and `mxCreateNumericMatrix`.

Valid choices for `classname` are listed in the `mxIsClass` reference page.

See Also

`mxGetClassName`, `mxCreateNumericArray`, `mxCreateNumericMatrix`, `mxIsClass`

mxComplexity (C)

Purpose

Flag specifying whether `mxArray` has imaginary components

C Syntax

```
typedef enum mxComplexity {mxREAL=0, mxCOMPLEX};
```

Constants

`mxREAL`
: Identifies an `mxArray` with no imaginary components.

`mxCOMPLEX`
: Identifies an `mxArray` with imaginary components.

Description

Various `mx*` calls require an `mxComplexity` argument. You can set an `mxComplex` argument to either `mxREAL` or `mxCOMPLEX`.

Examples

See `mxcalcsinglesubscript.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxCreateNumericArray`, `mxCreateDoubleMatrix`, `mxCreateSparse`

Purpose

Copy character values from Fortran array to pointer array

Fortran Syntax

```
mxCopyCharacterToPtr(y, px, n)
character*(*) y
mwPointer px
mwSize n
```

Arguments

`y`
: `character` Fortran array

`px`
: Pointer to `character` or `name` array

`n`
: Number of elements to copy

Description

`mxCopyCharacterToPtr` copies `n` `character` values from the Fortran `character` array `y` into the MATLAB string array pointed to by `px`. This subroutine is essential for copying character data between MATLAB pointer arrays and ordinary Fortran `character` arrays.

See Also

`mxCopyPtrToCharacter`, `mxCreateCharArray`, `mxCreateString`, `mxCreateCharMatrixFromStrings`

mxCopyComplex16ToPtr (Fortran)

Purpose

Copy COMPLEX*16 values from Fortran array to pointer array

Fortran Syntax

```
mxCopyComplex16ToPtr(y, pr, pi, n)
complex*16 y(n)
mwPointer pr, pi
mwSize n
```

Arguments

`y`
: COMPLEX*16 Fortran array

`pr`
: Pointer to the real data of a double-precision MATLAB array

`pi`
: Pointer to the imaginary data of a double-precision MATLAB array

`n`
: Number of elements to copy

Description

`mxCopyComplex16ToPtr` copies `n` `COMPLEX*16` values from the Fortran `COMPLEX*16` array `y` into the MATLAB arrays pointed to by `pr` and `pi`. This subroutine is essential for use with Fortran compilers that do not support the `%VAL` construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

`mxCopyPtrToComplex16`, `mxCreateNumericArray`, `mxCreateNumericMatrix`, `mxGetData`, `mxGetImagData`

Purpose

Copy COMPLEX*8 values from Fortran array to pointer array

Fortran Syntax

```
mxCopyComplex8ToPtr(y, pr, pi, n)
complex*8 y(n)
mwPointer pr, pi
mwSize n
```

Arguments

`y`
: COMPLEX*8 Fortran array

`pr`
: Pointer to the real data of a single-precision MATLAB array

`pi`
: Pointer to the imaginary data of a single-precision MATLAB array

`n`
: Number of elements to copy

Description

`mxCopyComplex8ToPtr` copies `n` `COMPLEX*8` values from the Fortran `COMPLEX*8` array `y` into the MATLAB arrays pointed to by `pr` and `pi`. This subroutine is essential for use with Fortran compilers that do not support the `%VAL` construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

`mxCopyPtrToComplex8`, `mxCreateNumericArray`, `mxCreateNumericMatrix`, `mxGetData`, `mxGetImagData`

mxCopyInteger1ToPtr (Fortran)

Purpose

Copy INTEGER*1 values from Fortran array to pointer array

Fortran Syntax

```
mxCopyInteger1ToPtr(y, px, n)
integer*1 y(n)
mwPointer px
mwSize n
```

Arguments

`y`
: INTEGER*1 Fortran array

`px`
: Pointer to `ir` or `jc` array

`n`
: Number of elements to copy

Description

`mxCopyInteger1ToPtr` copies `n` INTEGER*1 values from the Fortran INTEGER*1 array `y` into the MATLAB array pointed to by `px`, either an `ir` or `jc` array. This subroutine is essential for use with Fortran compilers that do not support the `%VAL` construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

`mxCopyPtrToInteger1`, `mxCreateNumericArray`, `mxCreateNumericMatrix`

Purpose

Copy INTEGER*2 values from Fortran array to pointer array

Fortran Syntax

```
mxCopyInteger2ToPtr(y, px, n)
integer*2 y(n)
mwPointer px
mwSize n
```

Arguments

`y`
: INTEGER*2 Fortran array

`px`
: Pointer to `ir` or `jc` array

`n`
: Number of elements to copy

Description

`mxCopyInteger2ToPtr` copies `n` INTEGER*2 values from the Fortran INTEGER*2 array `y` into the MATLAB array pointed to by `px`, either an `ir` or `jc` array. This subroutine is essential for use with Fortran compilers that do not support the `%VAL` construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

`mxCopyPtrToInteger2`, `mxCreateNumericArray`, `mxCreateNumericMatrix`

mxCopyInteger4ToPtr (Fortran)

Purpose

Copy INTEGER*4 values from Fortran array to pointer array

Fortran Syntax

```
mxCopyInteger4ToPtr(y, px, n)
integer*4 y(n)
mwPointer px
mwSize n
```

Arguments

`y`
: INTEGER*4 Fortran array

`px`
: Pointer to `ir` or `jc` array

`n`
: Number of elements to copy

Description

`mxCopyInteger4ToPtr` copies `n` INTEGER*4 values from the Fortran INTEGER*4 array `y` into the MATLAB array pointed to by `px`, either an `ir` or `jc` array. This subroutine is essential for use with Fortran compilers that do not support the `%VAL` construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

`mxCopyPtrToInteger4`, `mxCreateNumericArray`, `mxCreateNumericMatrix`

Purpose

Copy character values from pointer array to Fortran array

Fortran Syntax

```
mxCopyPtrToCharacter(px, y, n)
mwPointer px
character*(*) y
mwSize n
```

Arguments

`px`
: Pointer to character or name array

`y`
: character Fortran array

`n`
: Number of elements to copy

Description

`mxCopyPtrToCharacter` copies `n` character values from the MATLAB array pointed to by `px` into the Fortran character array `y`. This subroutine is essential for copying character data from MATLAB pointer arrays into ordinary Fortran character arrays.

Examples

See `matdemo2.F` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to use this routine in a Fortran program.

See Also

`mxCopyCharacterToPtr`, `mxCreateCharArray`, `mxCreateString`, `mxCreateCharMatrixFromStrings`

mxCopyPtrToComplex16 (Fortran)

Purpose

Copy COMPLEX*16 values from pointer array to Fortran array

Fortran Syntax

```
mxCopyPtrToComplex16(pr, pi, y, n)
mwPointer pr, pi
complex*16 y(n)
mwSize n
```

Arguments

`pr`
: Pointer to the real data of a double-precision MATLAB array

`pi`
: Pointer to the imaginary data of a double-precision MATLAB array

`y`
: COMPLEX*16 Fortran array

`n`
: Number of elements to copy

Description

`mxCopyPtrToComplex16` copies `n` `COMPLEX*16` values from the MATLAB arrays pointed to by `pr` and `pi` into the Fortran `COMPLEX*16` array `y`. This subroutine is essential for use with Fortran compilers that do not support the `%VAL` construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

`mxCopyComplex16ToPtr`, `mxCreateNumericArray`, `mxCreateNumericMatrix`, `mxGetData`, `mxGetImagData`

Purpose

Copy COMPLEX*8 values from pointer array to Fortran array

Fortran Syntax

```
mxCopyPtrToComplex8(pr, pi, y, n)
mwPointer pr, pi
complex*8 y(n)
mwSize n
```

Arguments

`pr`
: Pointer to the real data of a single-precision MATLAB array

`pi`
: Pointer to the imaginary data of a single-precision MATLAB array

`y`
: COMPLEX*8 Fortran array

`n`
: Number of elements to copy

Description

mxCopyPtrToComplex8 copies n COMPLEX*8 values from the MATLAB arrays pointed to by pr and pi into the Fortran COMPLEX*8 array y. This subroutine is essential for use with Fortran compilers that do not support the %VAL construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

mxCopyComplex8ToPtr, mxCreateNumericArray, mxCreateNumericMatrix, mxGetData, mxGetImagData

mxCopyPtrToInteger1 (Fortran)

Purpose

Copy INTEGER*1 values from pointer array to Fortran array

Fortran Syntax

```
mxCopyPtrToInteger1(px, y, n)
mwPointer px
integer*1 y(n)
mwSize n
```

Arguments

px
: Pointer to ir or jc array

y
: INTEGER*1 Fortran array

n
: Number of elements to copy

Description

mxCopyPtrToInteger1 copies n INTEGER*1 values from the MATLAB array pointed to by px, either an ir or jc array, into the Fortran INTEGER*1 array y. This subroutine is essential for use with Fortran compilers that do not support the %VAL construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

mxCopyInteger1ToPtr, mxCreateNumericArray, mxCreateNumericMatrix

Purpose

Copy INTEGER*2 values from pointer array to Fortran array

Fortran Syntax

```
mxCopyPtrToInteger2(px, y, n)
mwPointer px
integer*2 y(n)
mwSize n
```

Arguments

`px`
: Pointer to `ir` or `jc` array

`y`
: `INTEGER*2` Fortran array

`n`
: Number of elements to copy

Description

`mxCopyPtrToInteger2` copies `n` `INTEGER*2` values from the MATLAB array pointed to by `px`, either an `ir` or `jc` array, into the Fortran `INTEGER*2` array `y`. This subroutine is essential for use with Fortran compilers that do not support the `%VAL` construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

`mxCopyInteger2ToPtr`, `mxCreateNumericArray`, `mxCreateNumericMatrix`

mxCopyPtrToInteger4 (Fortran)

Purpose

Copy INTEGER*4 values from pointer array to Fortran array

Fortran Syntax

```
mxCopyPtrToInteger4(px, y, n)
mwPointer px
integer*4 y(n)
mwSize n
```

Arguments

px
: Pointer to ir or jc array

y
: INTEGER*4 Fortran array

n
: Number of elements to copy

Description

mxCopyPtrToInteger4 copies n INTEGER*4 values from the MATLAB array pointed to by px, either an ir or jc array, into the Fortran INTEGER*4 array y. This subroutine is essential for use with Fortran compilers that do not support the %VAL construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

mxCopyInteger4ToPtr, mxCreateNumericArray, mxCreateNumericMatrix

Purpose

Copy pointer values from pointer array to Fortran array

Fortran Syntax

```
mxCopyPtrToPtrArray(px, y, n)
mwPointer px
mwPointer y(n)
mwSize n
```

Arguments

`px`
: Pointer to pointer array

`y`
: Fortran array of `mwPointer` values

`n`
: Number of pointers to copy

Description

`mxCopyPtrToPtrArray` copies `n` pointers from the MATLAB array pointed to by `px` into the Fortran array `y`. This subroutine is essential for copying the output of `matGetDir` into an array of pointers. After calling this function, each element of `y` contains a pointer to a string. You can convert these strings to Fortran character arrays by passing each element of `y` as the first argument to `mxCopyPtrToCharacter`.

Examples

See `matdemo2.F` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to use this routine in a Fortran program.

See Also

`matGetDir`, `mxCopyPtrToCharacter`

mxCopyPtrToReal4 (Fortran)

Purpose

Copy REAL*4 values from pointer array to Fortran array

Fortran Syntax

```
mxCopyPtrToReal4(px, y, n)
mwPointer px
real*4 y(n)
mwSize n
```

Arguments

px
: Pointer to the real or imaginary data of a single-precision MATLAB array

y
: REAL*4 Fortran array

n
: Number of elements to copy

Description

mxCopyPtrToReal4 copies n REAL*4 values from the MATLAB array pointed to by px, either a pr or pi array, into the Fortran REAL*4 array y. This subroutine is essential for use with Fortran compilers that do not support the %VAL construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

mxCopyReal4ToPtr, mxCreateNumericArray, mxCreateNumericMatrix, mxGetData, mxGetImagData

Purpose

Copy REAL*8 values from pointer array to Fortran array

Fortran Syntax

```
mxCopyPtrToReal8(px, y, n)
mwPointer px
real*8 y(n)
mwSize n
```

Arguments

px
: Pointer to the real or imaginary data of a double-precision MATLAB array

y
: REAL*8 Fortran array

n
: Number of elements to copy

Description

mxCopyPtrToReal8 copies n REAL*8 values from the MATLAB array pointed to by px, either a pr or pi array, into the Fortran REAL*8 array y. This subroutine is essential for use with Fortran compilers that do not support the %VAL construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

Examples

See fengdemo.F in the eng_mat subdirectory of the examples directory for a sample program that illustrates how to use this routine in a Fortran program.

See Also

mxCopyReal8ToPtr, mxCreateNumericArray, mxCreateNumericMatrix, mxGetData, mxGetImagData

mxCopyReal4ToPtr (Fortran)

Purpose

Copy REAL*4 values from Fortran array to pointer array

Fortran Syntax

```
mxCopyReal4ToPtr(y, px, n)
real*4 y(n)
mwPointer px
mwSize n
```

Arguments

y
: REAL*4 Fortran array

px
: Pointer to the real or imaginary data of a single-precision MATLAB array

n
: Number of elements to copy

Description

mxCopyReal4ToPtr copies n REAL*4 values from the Fortran REAL*4 array y into the MATLAB array pointed to by px, either a pr or pi array. This subroutine is essential for use with Fortran compilers that do not support the %VAL construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

See Also

mxCopyPtrToReal4, mxCreateNumericArray, mxCreateNumericMatrix, mxGetData, mxGetImagData

Purpose

Copy REAL*8 values from Fortran array to pointer array

Fortran Syntax

```
mxCopyReal8ToPtr(y, px, n)
real*8 y(n)
mwPointer px
mwSize n
```

Arguments

y
: REAL*8 Fortran array

px
: Pointer to the real or imaginary data of a double-precision MATLAB array

n
: Number of elements to copy

Description

mxCopyReal8ToPtr copies n REAL*8 values from the Fortran REAL*8 array y into the MATLAB array pointed to by px, either a pr or pi array. This subroutine is essential for use with Fortran compilers that do not support the %VAL construct in order to set up standard Fortran arrays for passing as arguments to the computation routine of a MEX-file.

Examples

See matdemo1.F and fengdemo.F in the eng_mat subdirectory of the examples directory for a sample program that illustrates how to use this routine in a Fortran program.

See Also

mxCopyPtrToReal8, mxCreateNumericArray, mxCreateNumericMatrix, mxGetData, mxGetImagData

mxCreateCellArray (C and Fortran)

Purpose

Create unpopulated N-D cell mxArray

C Syntax

```
#include "matrix.h"
mxArray *mxCreateCellArray(mwSize ndim, const mwSize *dims);
```

Fortran Syntax

```
mwPointer mxCreateCellArray(ndim, dims)
mwSize ndim, dims
```

Arguments

ndim

The desired number of dimensions in the created cell. For example, to create a three-dimensional cell mxArray, set ndim to 3.

dims

The dimensions array. Each element in the dimensions array contains the size of the mxArray in that dimension. For example, in C, setting dims[0] to 5 and dims[1] to 7 establishes a 5-by-7 mxArray. In Fortran, setting dims(1) to 5 and dims(2) to 7 establishes a 5-by-7 mxArray. In most cases, there should be ndim elements in the dims array.

Returns

A pointer to the created cell mxArray, if successful. If unsuccessful in a stand-alone (nonMEX-file) application, mxCreateCellArray returns NULL in C (0 in Fortran). If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt. The most common cause of failure is insufficient free heap space.

Description

Use mxCreateCellArray to create a cell mxArray whose size is defined by ndim and dims. For example, in C, to establish a three-dimensional cell mxArray having dimensions 4-by-8-by-7, set

```
ndim = 3;
dims[0] = 4; dims[1] = 8; dims[2] = 7;
```

In Fortran, to establish a three-dimensional cell mxArray having dimensions 4-by-8-by-7, set

```
ndim = 3;
```

```
dims(1) = 4; dims(2) = 8; dims(3) = 7;
```

The created cell `mxArray` is unpopulated; `mxCreateCellArray` initializes each cell to `NULL`. To put data into a cell, call `mxSetCell`.

Any trailing singleton dimensions specified in the `dims` argument are automatically removed from the resulting array. For example, if `ndim` equals `5` and `dims` equals `[4 1 7 1 1]`, the resulting array is given the dimensions 4-by-1-by-7.

C Examples

See `phonebook.c` in the `refbook` subdirectory of the `examples` directory.

See Also

`mxCreateCellMatrix`, `mxGetCell`, `mxSetCell`, `mxIsCell`

mxCreateCellMatrix (C and Fortran)

Purpose

Create unpopulated 2-D cell mxArray

C Syntax

```
#include "matrix.h"
mxArray *mxCreateCellMatrix(mwSize m, mwSize n);
```

Fortran Syntax

```
mwPointer mxCreateCellMatrix(m, n)
mwSize m, n
```

Arguments

m
: The desired number of rows

n
: The desired number of columns

Returns

A pointer to the created cell mxArray, if successful. If unsuccessful in a stand-alone (non-MEX-file) application, mxCreateCellMatrix returns NULL in C (0 in Fortran). If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt. Insufficient free heap space is the only reason for mxCreateCellMatrix to be unsuccessful.

Description

Use mxCreateCellMatrix to create an m-by-n two-dimensional cell mxArray. The created cell mxArray is unpopulated; mxCreateCellMatrix initializes each cell to NULL in C (0 in Fortran). To put data into cells, call mxSetCell.

mxCreateCellMatrix is identical to mxCreateCellArray except that mxCreateCellMatrix can create two-dimensional mxArrays only, but mxCreateCellArray can create mxArrays having any number of dimensions greater than 1.

C Examples

See mxcreatecellmatrix.c in the mx subdirectory of the examples directory.

See Also

mxCreateCellArray

Purpose

Create unpopulated N-D string mxArray

C Syntax

```
#include "matrix.h"
mxArray *mxCreateCharArray(mwSize ndim, const mwSize *dims);
```

Fortran Syntax

```
mwPointer mxCreateCharArray(ndim, dims)
mwSize ndim, dims
```

Arguments

`ndim`

The desired number of dimensions in the string mxArray. You must specify a positive number. If you specify 0, 1, or 2, mxCreateCharArray creates a two-dimensional mxArray.

`dims`

The dimensions array. Each element in the dimensions array contains the size of the array in that dimension. For example, in C, setting `dims[0]` to `5` and `dims[1]` to `7` establishes a 5-by-7 mxArray. In Fortran, setting `dims(1)` to `5` and `dims(2)` to `7` establishes a 5-by-7 character mxArray. The dims array must have at least ndim elements.

Returns

A pointer to the created string mxArray, if successful. If unsuccessful in a stand-alone (non-MEX-file) application, mxCreateCharArray returns `NULL` in C (`0` in Fortran). If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt. Insufficient free heap space is the only reason for mxCreateCharArray to be unsuccessful.

Description

Call mxCreateCharArray to create an N-dimensional string mxArray. The created mxArray is unpopulated; that is, mxCreateCharArray initializes each cell to `NULL` in C (`0` in Fortran).

Any trailing singleton dimensions specified in the dims argument are automatically removed from the resulting array. For example, if ndim equals `5` and dims equals `[4 1 7 1 1]`, the resulting array is given the dimensions 4-by-1-by-7.

C Examples

See `mxcreatecharmatrixfromstr.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxCreateCharMatrixFromStrings`, `mxCreateString`

Purpose

Create populated 2-D string mxArray

C Syntax

```
#include "matrix.h"
mxArray *mxCreateCharMatrixFromStrings(mwSize m, const char **str);
```

Fortran Syntax

```
mwPointer mxCreateCharMatrixFromStrings(m, str)
mwSize m
character*(*) str(m)
```

Arguments

`m`

The desired number of rows in the created string mxArray. The value you specify for m should equal the number of strings in str.

`str`

In C, an array of strings containing at least m strings. In Fortran, a character*n array of size m, where each element of the array is n bytes.

Returns

A pointer to the created string mxArray, if successful. If unsuccessful in a stand-alone (non-MEX-file) application, mxCreateCharMatrixFromStrings returns NULL in C (0 in Fortran). If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt. Insufficient free heap space is the primary reason for mxCreateCharMatrixFromStrings to be unsuccessful. Another possible reason for failure is that str contains fewer than m strings.

Description

Use mxCreateCharMatrixFromStrings to create a two-dimensional string mxArray, where each row is initialized to a string from str. In C, the created mxArray has dimensions m-by-max, where max is the length of the longest string in str. In Fortran, the created mxArray has dimensions m-by-n, where n is the number of characters in str(i).

Note that string mxArrays represent their data elements as mxChar rather than as C char.

C Examples

See `mxcreatecharmatrixfromstr.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxCreateCharArray`, `mxCreateString`, `mxGetString`

Purpose

Create 2-D, double-precision, floating-point mxArray initialized to 0

C Syntax

```
#include "matrix.h"
mxArray *mxCreateDoubleMatrix(mwSize m, mwSize n,
  mxComplexity ComplexFlag);
```

Fortran Syntax

```
mwPointer mxCreateDoubleMatrix(m, n, ComplexFlag)
mwSize m, n
integer*4 ComplexFlag
```

Arguments

m
: The desired number of rows

n
: The desired number of columns

ComplexFlag
: Specify either mxREAL or mxCOMPLEX. If the data you plan to put into the mxArray has no imaginary components, specify mxREAL in C (0 in Fortran). If the data has some imaginary components, specify mxCOMPLEX in C (1 in Fortran).

Returns

A pointer to the created mxArray, if successful. If unsuccessful in a stand-alone (non-MEX-file) application, mxCreateDoubleMatrix returns NULL in C (0 in Fortran). If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt. mxCreateDoubleMatrix is unsuccessful when there is not enough free heap space to create the mxArray.

Description

Use mxCreateDoubleMatrix to create an m-by-n mxArray. mxCreateDoubleMatrix initializes each element in the pr array to 0. If you set ComplexFlag to mxCOMPLEX in C (1 in Fortran), mxCreateDoubleMatrix also initializes each element in the pi array to 0.

If you set ComplexFlag to mxREAL in C (0 in Fortran), mxCreateDoubleMatrix allocates enough memory to hold m-by-n real elements. If you set ComplexFlag to mxCOMPLEX in C (1 in Fortran),

mxCreateDoubleMatrix allocates enough memory to hold m-by-n real elements and m-by-n imaginary elements.

Call mxDestroyArray when you finish using the mxArray. mxDestroyArray deallocates the mxArray and its associated real and complex elements.

C Examples

See convec.c, findnz.c, sincall.c, timestwo.c, timestwoalt.c, and xtimesy.c in the refbook subdirectory of the examples directory.

See Also

mxCreateNumericArray

Purpose

Create scalar, double-precision array initialized to specified value

C Syntax

```
#include "matrix.h"
mxArray *mxCreateDoubleScalar(double value);
```

Fortran Syntax

```
mwPointer mxCreateDoubleScalar(value)
real*8 value
```

Arguments

`value`
The desired value to which you want to initialize the array

Returns

A pointer to the created `mxArray`, if successful. `mxCreateDoubleScalar` is unsuccessful if there is not enough free heap space to create the `mxArray`. If `mxCreateDoubleScalar` is unsuccessful in a MEX-file, the MEX-file prints an "Out of Memory" message, terminates, and control returns to the MATLAB prompt. If `mxCreateDoubleScalar` is unsuccessful in a stand-alone (nonMEX-file) application, `mxCreateDoubleScalar` returns `NULL` in C (`0` in Fortran).

Description

Call `mxCreateDoubleScalar` to create a scalar double `mxArray`. `mxCreateDoubleScalar` is a convenience function that can be used in place of the following C code:

```
pa = mxCreateDoubleMatrix(1, 1, mxREAL);
*mxGetPr(pa) = value;
```

`mxCreateDoubleScalar` can be used in place of the following Fortran code:

```
pm = mxCreateDoubleMatrix(1, 1, 0)
mxCopyReal8ToPtr(value, mxGetPr(pm), 1)
```

When you finish using the `mxArray`, call `mxDestroyArray` to destroy it.

See Also

`mxGetPr`, `mxCreateDoubleMatrix`

mxCreateLogicalArray (C)

Purpose

Create N-D logical mxArray initialized to false

C Syntax

```
#include "matrix.h"
mxArray *mxCreateLogicalArray(mwSize ndim, const mwSize *dims);
```

Arguments

ndim

Number of dimensions. If you specify a value for ndim that is less than 2, mxCreateLogicalArray automatically sets the number of dimensions to 2.

dims

The dimensions array. Each element in the dimensions array contains the size of the array in that dimension. For example, setting dims[0] to 5 and dims[1] to 7 establishes a 5-by-7 mxArray. There should be ndim elements in the dims array.

Returns

A pointer to the created mxArray, if successful. If unsuccessful in a stand-alone (non-MEX-file) application, mxCreateLogicalArray returns NULL. If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt. mxCreateLogicalArray is unsuccessful when there is not enough free heap space to create the mxArray.

Description

Call mxCreateLogicalArray to create an N-dimensional mxArray of mxLogical elements. After creating the mxArray, mxCreateLogicalArray initializes all its elements to logical 0. mxCreateLogicalArray differs from mxCreateLogicalMatrix in that the latter can create two-dimensional arrays only.

mxCreateLogicalArray allocates dynamic memory to store the created mxArray. When you finish with the created mxArray, call mxDestroyArray to deallocate its memory.

Any trailing singleton dimensions specified in the dims argument are automatically removed from the resulting array. For example, if ndim equals 5 and dims equals [4 1 7 1 1], the resulting array is given the dimensions 4-by-1-by-7.

See Also

mxCreateLogicalMatrix, mxCreateSparseLogicalMatrix, mxCreateLogicalScalar

mxCreateLogicalMatrix (C)

Purpose

Create 2-D, logical mxArray initialized to false

C Syntax

```
#include "matrix.h"
mxArray *mxCreateLogicalMatrix(mwSize m, mwSize n);
```

Arguments

m
: The desired number of rows

n
: The desired number of columns

Returns

A pointer to the created mxArray, if successful. If unsuccessful in a stand-alone (non-MEX-file) application, mxCreateLogicalMatrix returns NULL. If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt. mxCreateLogicalMatrix is unsuccessful when there is not enough free heap space to create the mxArray.

Description

Use mxCreateLogicalMatrix to create an m-by-n mxArray of mxLogical elements. mxCreateLogicalMatrix initializes each element in the array to logical 0.

Call mxDestroyArray when you finish using the mxArray. mxDestroyArray deallocates the mxArray.

See Also

mxCreateLogicalArray, mxCreateSparseLogicalMatrix, mxCreateLogicalScalar

Purpose

Create scalar, logical mxArray initialized to false

C Syntax

```
#include "matrix.h"
mxArray *mxCreateLogicalScalar(mxLogical value);
```

Arguments

value
: The desired logical value to which you want to initialize the array

Returns

A pointer to the created mxArray, if successful. mxCreateLogicalScalar is unsuccessful if there is not enough free heap space to create the mxArray. If mxCreateLogicalScalar is unsuccessful in a MEX-file, the MEX-file prints an "Out of Memory" message, terminates, and control returns to the MATLAB prompt. If mxCreateLogicalScalar is unsuccessful in a stand-alone (non-MEX-file) application, the function returns NULL.

Description

Call mxCreateLogicalScalar to create a scalar logical mxArray. mxCreateLogicalScalar is a convenience function that can be used in place of the following code:

```
pa = mxCreateLogicalMatrix(1, 1);
*mxGetLogicals(pa) = value;
```

When you finish using the mxArray, call mxDestroyArray to destroy it.

See Also

mxCreateLogicalArray, mxCreateLogicalMatrix, mxIsLogicalScalar, mxIsLogicalScalarTrue, mxGetLogicals

mxCreateNumericArray (C and Fortran)

Purpose

Create unpopulated N-D numeric mxArray

C Syntax

```
#include "matrix.h"
mxArray *mxCreateNumericArray(mwSize ndim, const mwSize *dims,
         mxClassID classid, mxComplexity ComplexFlag);
```

Fortran Syntax

```
mwPointer mxCreateNumericArray(ndim, dims, classid,
  ComplexFlag)
mwSize ndim, dims
integer*4 classid, ComplexFlag
```

Arguments

`ndim`

Number of dimensions. If you specify a value for `ndim` that is less than 2, `mxCreateNumericArray` automatically sets the number of dimensions to 2.

`dims`

The dimensions array. Each element in the dimensions array contains the size of the array in that dimension. For example, in C, setting `dims[0]` to 5 and `dims[1]` to 7 establishes a 5-by-7 `mxArray`. In Fortran, setting `dims(1)` to `5` and `dims(2)` to `7` establishes a 5-by-7 `mxArray`. In most cases, there should be `ndim` elements in the `dims` array.

`classid`

An identifier for the class of the array, which determines the way the numerical data is represented in memory. For example, specifying `mxINT16_CLASS` in C causes each piece of numerical data in the `mxArray` to be represented as a 16-bit signed integer. In Fortran, use the function `mxClassIDFromClassName` to derive the `classid` value from a MATLAB class name. See the Description section for more information.

`ComplexFlag`

If the data you plan to put into the `mxArray` has no imaginary components, specify `mxREAL` in C (`0` in Fortran). If the data has some imaginary components, specify `mxCOMPLEX` in C (`1` in Fortran).

Returns

A pointer to the created `mxArray`, if successful. If unsuccessful in a stand-alone (non-MEX-file) application, `mxCreateNumericArray` returns `NULL` in C (`0` in Fortran). If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt. `mxCreateNumericArray` is unsuccessful when there is not enough free heap space to create the `mxArray`.

Description

Call `mxCreateNumericArray` to create an N-dimensional `mxArray` in which all data elements have the numeric data type specified by `classid`. After creating the `mxArray`, `mxCreateNumericArray` initializes all its real data elements to 0. If `ComplexFlag` equals `mxCOMPLEX` in C (`1` in Fortran), `mxCreateNumericArray` also initializes all its imaginary data elements to 0. `mxCreateNumericArray` differs from `mxCreateDoubleMatrix` in two important respects:

- All data elements in `mxCreateDoubleMatrix` are double-precision, floating-point numbers. The data elements in `mxCreateNumericArray` could be any numerical type, including different integer precisions.
- `mxCreateDoubleMatrix` can create two-dimensional arrays only; `mxCreateNumericArray` can create arrays of two or more dimensions.

`mxCreateNumericArray` allocates dynamic memory to store the created `mxArray`. When you finish with the created `mxArray`, call `mxDestroyArray` to deallocate its memory.

Any trailing singleton dimensions specified in the `dims` argument are automatically removed from the resulting array. For example, if `ndim` equals `5` and `dims` equals `[4 1 7 1 1]`, the resulting array is given the dimensions 4-by-1-by-7.

The following table shows the C `classid` values and the Fortran data types that are equivalent to MATLAB classes.

MATLAB Class Name	C classid Value	Fortran Type
int8	mxINT8_CLASS	BYTE
uint8	mxUINT8_CLASS	
int16	mxUINT16_CLASS	INTEGER*2
uint16	mxUINT16_CLASS	
int32	mxINT32_CLASS	INTEGER*4
uint32	mxUINT32_CLASS	
int64	mxINT64_CLASS	INTEGER*8
uint64	mxUINT64_CLASS	
single	mxSINGLE_CLASS	REAL*4
double	mxDOUBLE_CLASS	REAL*8
single, with imaginary components	mxSINGLE_CLASS	COMPLEX*8
double, with imaginary components	mxDOUBLE_CLASS	COMPLEX*16

C Examples

See phonebook.c and doubleelement.c in the refbook subdirectory of the examples directory. For an additional example, see mxisfinite.c in the mx subdirectory of the examples directory.

Fortran Examples

To create a 4-by-4-by-2 array of REAL*8 elements having no imaginary components, use

```
C       Create 4x4x2 mxArray of REAL*8
        data dims / 4, 4, 2 /
        mxCreateNumericArray(3, dims,
     +                mxClassIDFromClassName('double'), 0)
```

See Also

mxClassId, mxClassIdFromClassName, mxComplexity, mxCreateNumericMatrix

mxCreateNumericMatrix (C and Fortran)

Purpose

Create numeric matrix and initialize data elements to 0

C Syntax

```
#include "matrix.h"
mxArray *mxCreateNumericMatrix(mwSize m, mwSize n,
  mxClassID classid, mxComplexity ComplexFlag);
```

Fortran Syntax

```
mwPointer mxCreateNumericMatrix(m, n, classid,
  ComplexFlag)
mwSize m, n
integer*4 classid, ComplexFlag
```

Arguments

`m`
: The desired number of rows.

`n`
: The desired number of columns.

`classid`
: An identifier for the class of the array, which determines the way the numerical data is represented in memory. For example, specifying `mxINT16_CLASS` in C causes each piece of numerical data in the `mxArray` to be represented as a 16-bit signed integer. In Fortran, use the function `mxClassIDFromClassName` to derive the `classid` value from a MATLAB class name. See the Description section for more information.

`ComplexFlag`
: If the data you plan to put into the `mxArray` has no imaginary components, specify `mxREAL` in C (`0` in Fortran). If the data has some imaginary components, specify `mxCOMPLEX` in C (`1` in Fortran).

Returns

A pointer to the created `mxArray`, if successful. `mxCreateNumericMatrix` is unsuccessful if there is not enough free heap space to create the `mxArray`. If `mxCreateNumericMatrix` is unsuccessful in a MEX-file, the MEX-file prints an “Out of Memory” message, terminates, and control returns to the MATLAB prompt. If `mxCreateNumericMatrix`

is unsuccessful in a stand-alone (nonMEX-file) application, `mxCreateNumericMatrix` returns `NULL` in C (`0` in Fortran).

Description

Call `mxCreateNumericMatrix` to create a 2-D `mxArray` in which all data elements have the numeric data type specified by `classid`. After creating the `mxArray`, `mxCreateNumericMatrix` initializes all its real data elements to 0. If `ComplexFlag` equals `mxCOMPLEX` in C (`1` in Fortran), `mxCreateNumericMatrix` also initializes all its imaginary data elements to 0. `mxCreateNumericMatrix` allocates dynamic memory to store the created `mxArray`. When you finish using the `mxArray`, call `mxDestroyArray` to destroy it.

The following table shows the C `classid` values and the Fortran data types that are equivalent to MATLAB classes.

MATLAB Class Name	C `classid` Value	Fortran Type
int8	mxINT8_CLASS	BYTE
uint8	mxUINT8_CLASS	
int16	mxUINT16_CLASS	INTEGER*2
uint16	mxUINT16_CLASS	
int32	mxINT32_CLASS	INTEGER*4
uint32	mxUINT32_CLASS	
int64	mxINT64_CLASS	INTEGER*8
uint64	mxUINT64_CLASS	
single	mxSINGLE_CLASS	REAL*4
double	mxDOUBLE_CLASS	REAL*8

MATLAB Class Name	C classid Value	Fortran Type
single, with imaginary components	mxSINGLE_CLASS	COMPLEX*8
double, with imaginary components	mxDOUBLE_CLASS	COMPLEX*16

Fortran Examples

To create a 4-by-3 matrix of REAL*4 elements having no imaginary components, use

```
C      Create 4x3 mxArray of REAL*4
       mxCreateNumericMatrix(4, 3,
     +                mxClassIDFromClassName('single'), 0)
```

See Also

mxClassId, mxClassIdFromClassName, mxComplexity, mxCreateNumericArray

Purpose

Create 2-D unpopulated sparse mxArray

C Syntax

```
#include "matrix.h"
mxArray *mxCreateSparse(mwSize m, mwSize n, mwSize nzmax,
         mxComplexity ComplexFlag);
```

Fortran Syntax

```
mwPointer mxCreateSparse(m, n, nzmax, ComplexFlag)
mwSize m, n, nzmax
integer*4 ComplexFlag
```

Arguments

`m`
: The desired number of rows

`n`
: The desired number of columns

`nzmax`
: The number of elements that `mxCreateSparse` should allocate to hold the `pr`, `ir`, and, if `ComplexFlag` is `mxCOMPLEX` in C (`1` in Fortran), `pi` arrays. Set the value of `nzmax` to be greater than or equal to the number of nonzero elements you plan to put into the `mxArray`, but make sure that `nzmax` is less than or equal to `m*n`.

`ComplexFlag`
: If the `mxArray` you are creating is to contain imaginary data, set `ComplexFlag` to `mxCOMPLEX` in C (`1` in Fortran). Otherwise, set `ComplexFlag` to `mxREAL` in C (`0` in Fortran).

Returns

A pointer to the created sparse double `mxArray` if successful, and `NULL` in C (`0` in Fortran) otherwise. The most likely reason for failure is insufficient free heap space. If that happens, try reducing `nzmax`, `m`, or `n`.

Description

Call `mxCreateSparse` to create an unpopulated sparse double `mxArray`. The returned sparse `mxArray` contains no sparse information and cannot be passed as an argument to any MATLAB sparse functions. To make the returned sparse `mxArray` useful, you must initialize the `pr`, `ir`, `jc`, and (if it exists) `pi` arrays.

mxCreateSparse allocates space for

- A pr array of length nzmax.
- A pi array of length nzmax, but only if ComplexFlag is mxCOMPLEX in C (1 in Fortran).
- An ir array of length nzmax.
- A jc array of length n+1.

When you finish using the sparse mxArray, call mxDestroyArray to reclaim all its heap space.

C Examples

See fulltosparse.c in the refbook subdirectory of the examples directory.

See Also

mxDestroyArray, mxSetNzmax, mxSetPr, mxSetPi, mxSetIr, mxSetJc, mxComplexity

Purpose

Create unpopulated 2-D, sparse, logical mxArray

C Syntax

```
#include "matrix.h"
mxArray *mxCreateSparseLogicalMatrix(mwSize m, mwSize n,
  mwSize nzmax);
```

Arguments

m
: The desired number of rows

n
: The desired number of columns

nzmax
: The number of elements that mxCreateSparseLogicalMatrix should allocate to hold the data. Set the value of nzmax to be greater than or equal to the number of nonzero elements you plan to put into the mxArray, but make sure that nzmax is less than or equal to m*n.

Returns

A pointer to the created mxArray, if successful. If unsuccessful in a stand-alone (nonMEX-file) application, mxCreateSparseLogicalMatrix returns NULL. If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt. mxCreateSparseLogicalMatrix is unsuccessful when there is not enough free heap space to create the mxArray.

Description

Use mxCreateSparseLogicalMatrix to create an m-by-n mxArray of mxLogical elements. mxCreateSparseLogicalMatrix initializes each element in the array to logical 0.

Call mxDestroyArray when you finish using the mxArray. mxDestroyArray deallocates the mxArray and its elements.

See Also

mxCreateLogicalArray, mxCreateLogicalMatrix, mxCreateLogicalScalar, mxCreateSparse, mxIsLogical

mxCreateString (C and Fortran)

Purpose

Create 1-by-N string mxArray initialized to specified string

C Syntax

```
#include "matrix.h"
mxArray *mxCreateString(const char *str);
```

Fortran Syntax

```
mwPointer mxCreateString(str)
character*(*) str
```

Arguments

str

The string that is to serve as the mxArray's initial data

Returns

A pointer to the created string mxArray if successful, and NULL in C (0 in Fortran) otherwise. The most likely cause of failure is insufficient free heap space.

Description

Use mxCreateString to create a string mxArray initialized to str. Many MATLAB functions (for example, strcmp and upper) require string array inputs.

Free the string mxArray when you are finished using it. To free a string mxArray, call mxDestroyArray.

C Examples

See revord.c in the refbook subdirectory of the examples directory.

For additional examples, see mxcreatestructarray.c and mxisclass.c in the mx subdirectory of the examples directory.

Fortran Examples

See matdemo1.F in the eng_mat subdirectory of the examples directory for a sample program that illustrates how to use this routine in a Fortran program.

See Also

mxCreateCharMatrixFromStrings, mxCreateCharArray

Purpose

Create unpopulated N-D structure `mxArray`

C Syntax

```
#include "matrix.h"
mxArray *mxCreateStructArray(mwSize ndim, const mwSize *dims,
  int nfields, const char **fieldnames);
```

Fortran Syntax

```
mwPointer mxCreateStructArray(ndim, dims, nfields,
  fieldnames)
mwSize ndim, dims
integer*4 nfields
character*(*) fieldnames(nfields)
```

Arguments

`ndim`
: Number of dimensions. If you set `ndim` to be less than `2`, `mxCreateStructArray` creates a two-dimensional `mxArray`.

`dims`
: The dimensions array. Each element in the dimensions array contains the size of the array in that dimension. For example, in C, setting `dims[0]` to `5` and `dims[1]` to `7` establishes a 5-by-7 `mxArray`. In Fortran, setting `dims(1)` to `5` and `dims(2)` to `7` establishes a 5-by-7 `mxArray`. Typically, the `dims` array should have `ndim` elements.

`nfields`
: The desired number of fields in each element

`fieldnames`
: The desired list of field names

Each structure field name must begin with a letter and is case sensitive. The rest of the name may contain letters, numerals, and underscore characters. Use the `namelengthmax` function to determine the maximum length of a field name.

Returns

A pointer to the created structure `mxArray` if successful, and `NULL` in C (`0` in Fortran) otherwise. The most likely cause of failure is insufficient heap space to hold the returned `mxArray`.

Description

Call `mxCreateStructArray` to create an unpopulated structure `mxArray`. Each element of a structure `mxArray` contains the same number of fields (specified in `nfields`). Each field has a name; the list of names is specified in `fieldnames`. A structure `mxArray` in MATLAB is conceptually identical to an array of `structs` in the C language.

Each field holds one `mxArray` pointer. `mxCreateStructArray` initializes each field to `NULL` in C (`0` in Fortran). Call `mxSetField` or `mxSetFieldByNumber` to place a non-`NULL` `mxArray` pointer in a field.

When you finish using the returned structure `mxArray`, call `mxDestroyArray` to reclaim its space.

Any trailing singleton dimensions specified in the `dims` argument are automatically removed from the resulting array. For example, if `ndim` equals `5` and `dims` equals `[4 1 7 1 1]`, the resulting array is given the dimensions 4-by-1-by-7.

C Examples

See `mxcreatestructarray.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxDestroyArray`, `mxAddField`, `mxRemoveField`, `mxSetField`, `mxSetFieldByNumber`

Purpose

Create unpopulated 2-D structure mxArray

C Syntax

```
#include "matrix.h"
mxArray *mxCreateStructMatrix(mwSize m, mwSize n, int nfields,
         const char **fieldnames);
```

Fortran Syntax

```
mwPointer mxCreateStructMatrix(m, n, nfields, fieldnames)
mwSize m, n
integer*4 nfields
character*(*) fieldnames(nfields)
```

Arguments

`m`
: The desired number of rows. This must be a positive integer.

`n`
: The desired number of columns. This must be a positive integer.

`nfields`
: The desired number of fields in each element.

`fieldnames`
: The desired list of field names.

Each structure field name must begin with a letter and is case sensitive. The rest of the name may contain letters, numerals, and underscore characters. Use the `namelengthmax` function to determine the maximum length of a field name.

Returns

A pointer to the created structure `mxArray` if successful, and `NULL` in C (`0` in Fortran) otherwise. The most likely cause of failure is insufficient heap space to hold the returned `mxArray`.

Description

`mxCreateStructMatrix` and `mxCreateStructArray` are almost identical. The only difference is that `mxCreateStructMatrix` can create only two-dimensional `mxArrays`, while `mxCreateStructArray` can create `mxArrays` having two or more dimensions.

C Examples

See `phonebook.c` in the `refbook` subdirectory of the `examples` directory.

See Also

`mxCreateStructArray`

Purpose

Free dynamic memory allocated by mxCreate* functions

C Syntax

```
#include "matrix.h"
void mxDestroyArray(mxArray *pm);
```

Fortran Syntax

```
mxDestroyArray(pm)
mwPointer pm
```

Arguments

pm

Pointer to the mxArray you want to free

Description

mxDestroyArray deallocates the memory occupied by the specified mxArray. mxDestroyArray not only deallocates the memory occupied by the mxArray's characteristics fields (such as m and n), but also deallocates all the mxArray's associated data arrays, such as pr and pi for complex arrays, ir and jc for sparse arrays, fields of structure arrays, and cells of cell arrays. Do not call mxDestroyArray on an mxArray you are returning on the left-hand side.

C Examples

See sincall.c in the refbook subdirectory of the examples directory.

Additional examples:

- mexcallmatlab.c and mexgetarray.c in the mex subdirectory of the examples directory
- mxisclass.c in the mx subdirectory of the examples directory

See Also

mxCalloc, mxMalloc, mxFree, mexMakeArrayPersistent, mexMakeMemoryPersistent

mxDuplicateArray (C and Fortran)

Purpose

Make deep copy of array

C Syntax

```
#include "matrix.h"
mxArray *mxDuplicateArray(const mxArray *in);
```

Fortran Syntax

```
mwPointer mxDuplicateArray(in)
mwPointer in
```

Arguments

`in`

Pointer to the `mxArray` you want to copy

Returns

Pointer to a copy of the array.

Description

`mxDuplicateArray` makes a deep copy of an array, and returns a pointer to the copy. A deep copy refers to a copy in which all levels of data are copied. For example, a deep copy of a cell array copies each cell and the contents of each cell (if any), and so on.

C Examples

See

- `mexget.c` in the `mex` subdirectory of the `examples` directory
- `phonebook.c` in the `refbook` subdirectory of the `examples` directory

For additional examples, see `mxcreatecellmatrix.c`, `mxgetinf.c`, and `mxsetnzmax.c` in the `mx` subdirectory of the `examples` directory.

Purpose

Free dynamic memory allocated by `mxCalloc`, `mxMalloc`, or `mxRealloc`

C Syntax

```
#include "matrix.h"
void mxFree(void *ptr);
```

Fortran Syntax

```
mxFree(ptr)
mwPointer ptr
```

Arguments

`ptr`

Pointer to the beginning of any memory parcel allocated by `mxCalloc`, `mxMalloc`, or `mxRealloc`.

Description

`mxFree` deallocates heap space using the MATLAB memory management facility. This ensures correct memory management in error and abort (**Ctrl+C**) conditions.

To deallocate heap space, MATLAB applications in C should always call `mxFree` rather than the ANSI C `free` function.

The MATLAB memory management facility maintains a list of all memory allocated by `mxCalloc`, `mxMalloc`, `mxRealloc`, and the `mxCreate*` calls. The MATLAB memory management facility automatically deallocates all of a MEX-file's managed parcels when the MEX-file completes and control returns to the MATLAB prompt.

When `mxFree` appears in a stand-alone MATLAB application, `mxFree` simply deallocates the contiguous heap space that begins at address `ptr`. In a MEX-file, `mxFree` also removes the memory parcel from the MATLAB memory management facility's list of memory parcels.

In a MEX-file, your use of `mxFree` depends on whether the specified memory parcel is persistent or nonpersistent. By default, memory parcels created by `mxCalloc`, `mxMalloc`, and `mxRealloc` are nonpersistent. The MATLAB memory management facility automatically frees all nonpersistent memory whenever a MEX-file completes. Thus, even if you do not call `mxFree`, MATLAB takes care of freeing the memory for you. Nevertheless, it is good programming

practice to deallocate memory as soon as you are through using it. Doing so generally makes the entire system run more efficiently.

If an application calls `mexMakeMemoryPersistent`, the specified memory parcel becomes persistent. When a MEX-file completes, the MATLAB memory management facility does not free persistent memory parcels. Therefore, the only way to free a persistent memory parcel is to call `mxFree`. Typically, MEX-files call `mexAtExit` to register a cleanup handler. The cleanup handler calls `mxFree`.

C Examples

See `mxcalcsinglesubscript.c` in the `mx` subdirectory of the `examples` directory.

Additional examples:

- `phonebook.c` in the `refbook` subdirectory of the `examples` directory
- `explore.c` and `mexatexit.c` in the `mex` subdirectory of the `examples` directory
- `mxcreatecharmatrixfromstr.c`, `mxisfinite.c`, `mxmalloc.c`, and `mxsetdimensions.c` in the `mx` subdirectory of the `examples` directory

See Also

`mexAtExit`, `mexMakeArrayPersistent`, `mexMakeMemoryPersistent`, `mxCalloc`, `mxDestroyArray`, `mxMalloc`, `mxRealloc`

Purpose

Get contents of mxArray cell

C Syntax

```
#include "matrix.h"
mxArray *mxGetCell(const mxArray *pm, mwIndex index);
```

Fortran Syntax

```
mwPointer mxGetCell(pm, index)
mwPointer pm
mwIndex index
```

Arguments

`pm`
: Pointer to a cell mxArray

`index`
: The number of elements in the cell mxArray between the first element and the desired one. See mxCalcSingleSubscript for details on calculating an index in a multidimensional cell array.

Returns

A pointer to the ith cell mxArray if successful, and NULL in C (0 in Fortran) otherwise. Causes of failure include

- Specifying the index of a cell array element that has not been populated.
- Specifying a pm that does not point to a cell mxArray.
- Specifying an index greater than the number of elements in the cell.
- Insufficient free heap space to hold the returned cell mxArray.

Description

Call mxGetCell to get a pointer to the mxArray held in the indexed element of the cell mxArray.

Note Inputs to a MEX-file are constant read-only mxArrays and should not be modified. Using mxSetCell* or mxSetField* to modify the cells or fields of an argument passed from MATLAB causes unpredictable results.

C Examples

See `explore.c` in the `mex` subdirectory of the `examples` directory.

See Also

`mxCreateCellArray`, `mxIsCell`, `mxSetCell`

Purpose

Get pointer to character array data

C Syntax

```
#include "matrix.h"
mxChar *mxGetChars(const mxArray *array_ptr);
```

Arguments

`array_ptr`
Pointer to an `mxArray`

Returns

The address of the first character in the `mxArray`. Returns `NULL` if the specified array is not a character array.

Description

Call `mxGetChars` to determine the address of the first character in the `mxArray` that `array_ptr` points to. Once you have the starting address, you can access any other element in the `mxArray`.

See Also

`mxGetString`

mxGetClassID (C and Fortran)

Purpose

Get class of mxArray

C Syntax

```
#include "matrix.h"
mxClassID mxGetClassID(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxGetClassID(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

A numeric identifier of the class (category) of the mxArray that pm points to. The C-language class identifiers are listed in the mxClassID reference page.

Description

Use mxGetClassId to determine the class of an mxArray. The class of an mxArray identifies the kind of data the mxArray is holding. For example, if pm points to a logical mxArray, then mxGetClassId returns mxLOGICAL_CLASS (in C).

mxGetClassId is similar to mxGetClassName, except that the former returns the class as an integer identifier and the latter returns the class as a string.

C Examples

See

- phonebook.c in the refbook subdirectory of the examples directory
- explore.c in the mex subdirectory of the examples directory

See Also

mxClassID, mxGetClassName

Purpose

Get class of mxArray as string

C Syntax

```
#include "matrix.h"
const char *mxGetClassName(const mxArray *pm);
```

Fortran Syntax

```
character*(*) mxGetClassName(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

The class (as a string) of the mxArray pointed to by pm.

Description

Call mxGetClassName to determine the class of an mxArray. The class of an mxArray identifies the kind of data the mxArray is holding. For example, if pm points to a logical mxArray, mxGetClassName returns logical.

mxGetClassID is similar to mxGetClassName, except that the former returns the class as an integer identifier, as listed in the mxClassID reference page, and the latter returns the class as a string, as listed in the mxIsClass reference page.

C Examples

See mexfunction.c in the mex subdirectory of the examples directory. For an additional example, see mxisclass.c in the mx subdirectory of the examples directory.

See Also

mxGetClassID, mxIsClass

mxGetData (C and Fortran)

Purpose

Get pointer to data

C Syntax

```
#include "matrix.h"
void *mxGetData(const mxArray *pm);
```

Fortran Syntax

```
mwPointer mxGetData(pm)
mwPointer pm
```

Arguments

`pm`
Pointer to an `mxArray`

Returns

The address of the first element of the real data. Returns `NULL` in C (`0` in Fortran) if there is no real data.

Description

Similar to `mxGetPr`, except that in C, `mxGetData` returns a `void *`.

To copy values from the returned pointer to Fortran, use one of the `mxCopyPtrTo*` functions in the following manner:

```
C       Get the data in mxArray, pm
        mxCopyPtrToReal8(mxGetData(pm), data,
     +                       mxGetNumberOfElements(pm))
```

C Examples

See `phonebook.c` in the `refbook` subdirectory of the `examples` directory.

For additional examples, see `mxcreatecharmatrixfromstr.c` and `mxisfinite.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxGetImagData`, `mxGetPr`

Purpose

Get pointer to dimensions array

C Syntax

```
#include "matrix.h"
const mwSize *mxGetDimensions(const mxArray *pm);
```

Fortran Syntax

```
mwPointer mxGetDimensions(pm)
mwPointer pm
```

Arguments

`pm`
Pointer to an `mxArray`.

Returns

The address of the first element in the dimensions array. Each integer in the dimensions array represents the number of elements in a particular dimension. The array is not `NULL` terminated.

Description

Use `mxGetDimensions` to determine how many elements are in each dimension of the `mxArray` that `pm` points to. Call `mxGetNumberOfDimensions` to get the number of dimensions in the `mxArray`.

To copy the values to Fortran, use `mxCopyPtrToInteger4` in the following manner:

```
C      Get dimensions of mxArray, pm
       mxCopyPtrToInteger4(mxGetDimensions(pm), dims,
     +                     mxGetNumberOfDimensions(pm))
```

C Examples

See `mxcalcsinglesubscript.c` in the `mx` subdirectory of the `examples` directory.

Additional examples:

- `findnz.c` and `phonebook.c` in the `refbook` subdirectory of the `examples` directory
- `explore.c` in the `mex` subdirectory of the `examples` directory

- `mxgeteps.c` and `mxisfinite.c` in the `mx` subdirectory of the `examples` directory

See Also

`mxGetNumberOfDimensions`

Purpose

Get number of bytes required to store each data element

C Syntax

```
#include "matrix.h"
mwSize mxGetElementSize(const mxArray *pm);
```

Fortran Syntax

```
mwSize mxGetElementSize(pm)
mwPointer pm
```

Arguments

`pm`

Pointer to an `mxArray`

Returns

The number of bytes required to store one element of the specified `mxArray`, if successful. Returns 0 on failure. The primary reason for failure is that `pm` points to an `mxArray` having an unrecognized class. If `pm` points to a cell `mxArray` or a structure `mxArray`, `mxGetElementSize` returns the size of a pointer (not the size of all the elements in each cell or structure field).

Description

Call `mxGetElementSize` to determine the number of bytes in each data element of the `mxArray`. For example, if the MATLAB class of an `mxArray` is `int16`, the `mxArray` stores each data element as a 16-bit (2-byte) signed integer. Thus, `mxGetElementSize` returns `2`.

`mxGetElementSize` is particularly helpful when using a non-MATLAB routine to manipulate data elements. For example, the C function `memcpy` requires (for its third argument) the size of the elements you intend to copy.

C Examples

See `doubleelement.c` and `phonebook.c` in the `refbook` subdirectory of the `examples` directory.

See Also

`mxGetM`, `mxGetN`

mxGetEps (C and Fortran)

Purpose

Get value of eps

C Syntax

```
#include "matrix.h"
double mxGetEps(void);
```

Fortran Syntax

```
real*8 mxGetEps
```

Returns

The value of the MATLAB eps variable

Description

Call mxGetEps to return the value of the MATLAB eps variable. This variable holds the distance from 1.0 to the next largest floating-point number. As such, it is a measure of floating-point accuracy. The MATLAB PINV and RANK functions use eps as a default tolerance.

C Examples

See mxgeteps.c in the mx subdirectory of the examples directory.

See Also

mxGetInf, mxGetNan

Purpose

Get field value, given field name and index into structure array

C Syntax

```
#include "matrix.h"
mxArray *mxGetField(const mxArray *pm, mwIndex index,
         const char *fieldname);
```

Fortran Syntax

```
mwPointer mxGetField(pm, index, fieldname)
mwPointer pm
mwIndex index
character*(*) fieldname
```

Arguments

`pm`
: Pointer to a structure `mxArray`

`index`
: The desired element. In C, the first element of an `mxArray` has an `index` of `0`, the second element has an `index` of `1`, and the last element has an `index` of `N-1`, where `N` is the total number of elements in the structure `mxArray`. In Fortran, the first element of an `mxArray` has an `index` of `1`, the second element has an `index` of `2`, and the last element has an `index` of `N`, where N is the total number of elements in the structure `mxArray`.

`fieldname`
: The name of the field whose value you want to extract.

Returns

A pointer to the `mxArray` in the specified field at the specified `fieldname`, on success. Returns `NULL` in C (`0` in Fortran) if passed an invalid argument or if there is no value assigned to the specified field. Common causes of failure include

- Specifying an array pointer `pm` that does not point to a structure `mxArray`. To determine whether `pm` points to a structure `mxArray`, call `mxIsStruct`.
- Specifying an `index` to an element outside the bounds of the `mxArray`. For example, given a structure `mxArray` that contains 10 elements, you cannot specify an `index` greater than `9` in C (`10` in Fortran).

- Specifying a nonexistent `fieldname`. Call `mxGetFieldNameByNumber` or `mxGetFieldNumber` to get existing field names.
- Insufficient heap space to hold the returned `mxArray`.

Description

Call `mxGetField` to get the value held in the specified element of the specified field. In pseudo-C terminology, `mxGetField` returns the value at

```
pm[index].fieldname
```

`mxGetFieldByNumber` is similar to `mxGetField`. Both functions return the same value. The only difference is in the way you specify the field. `mxGetFieldByNumber` takes a field number as its third argument, and `mxGetField` takes a field name as its third argument.

Note Inputs to a MEX-file are constant read-only `mxArrays` and should not be modified. Using `mxSetCell*` or `mxSetField*` to modify the cells or fields of an argument passed from MATLAB causes unpredictable results.

In C, calling

```
mxGetField(pa, index, "field_name");
```

is equivalent to calling

```
field_num = mxGetFieldNumber(pa, "field_name");
mxGetFieldByNumber(pa, index, field_num);
```

where `index` is `0` if you have a 1-by-1 structure.

In Fortran, calling

```
mxGetField(pm, index, 'fieldname')
```

is equivalent to calling

```
fieldnum = mxGetFieldNumber(pm, 'fieldname')
mxGetFieldByNumber(pm, index, fieldnum)
```

where `index` is `1` if you have a 1-by-1 structure.

See Also

`mxGetFieldByNumber`, `mxGetFieldNameByNumber`, `mxGetFieldNumber`, `mxGetNumberOfFields`, `mxIsStruct`, `mxSetField`, `mxSetFieldByNumber`

mxGetFieldByNumber (C and Fortran)

Purpose

Get field value, given field number and index into structure array

C Syntax

```
#include "matrix.h"
mxArray *mxGetFieldByNumber(const mxArray *pm, mwIndex index,
         int fieldnumber);
```

Fortran Syntax

```
mwPointer mxGetFieldByNumber(pm, index, fieldnumber)
mwPointer pm
mwIndex index
integer*4 fieldnumber
```

Arguments

`pm`

Pointer to a structure `mxArray`

`index`

The desired element. In C, the first element of an `mxArray` has an `index` of `0`, the second element has an `index` of `1`, and the last element has an `index` of `N-1`, where `N` is the total number of elements in the structure `mxArray`. In Fortran, the first element of an `mxArray` has an `index` of `1`, the second element has an `index` of `2`, and the last element has an `index` of `N`, where `N` is the total number of elements in the structure `mxArray`. See `mxCalcSingleSubscript` for more details on calculating an `index`.

`fieldnumber`

The position of the field whose value you want to extract. In C, the first field within each element has a field number of `0`, the second field has a field number of `1`, and so on. The last field has a field number of `N-1`, where `N` is the number of fields. In Fortran, the first field within each element has a field number of `1`, the second field has a field number of `2`, and so on. The last field has a field number of `N`, where `N` is the number of fields.

Returns

A pointer to the `mxArray` in the specified field for the desired element, on success. Returns `NULL` in C (`0` in Fortran) if passed an invalid argument or if there is no value assigned to the specified field. Common causes of failure include

- Specifying an array pointer `pm` that does not point to a structure `mxArray`. Call `mxIsStructto` determine whether `pm` points to a structure `mxArray`.
- Specifying an `index` to an element outside the bounds of the `mxArray`. For example, given a structure `mxArray` that contains 10 elements, you cannot specify an `index` greater than `9` in C (`10` in Fortran).
- Specifying a nonexistent field number. Call `mxGetFieldNumber` to determine the field number that corresponds to a given field name.

Description

Call `mxGetFieldByNumber` to get the value held in the specified `fieldnumber` at the indexed element.

Note Inputs to a MEX-file are constant read-only `mxArrays` and should not be modified. Using `mxSetCell*` or `mxSetField*` to modify the cells or fields of an argument passed from MATLAB causes unpredictable results.

In C, calling

```
mxGetField(pa, index, "field_name");
```

is equivalent to calling

```
field_num = mxGetFieldNumber(pa, "field_name");
mxGetFieldByNumber(pa, index, field_num);
```

where `index` is `0` if you have a 1-by-1 structure.

In Fortran, calling

```
mxGetField(pm, index, 'fieldname')
```

is equivalent to calling

```
fieldnum = mxGetFieldNumber(pm, 'fieldname')
mxGetFieldByNumber(pm, index, fieldnum)
```

where `index` is `1` if you have a 1-by-1 structure.

C Examples

See `phonebook.c` in the `refbook` subdirectory of the `examples` directory.

Additional examples:

- `mxisclass.c` in the `mx` subdirectory of the `examples` directory
- `explore.c` in the `mex` subdirectory of the `examples` directory

See Also

`mxGetField`, `mxGetFieldNameByNumber`, `mxGetFieldNumber`, `mxGetNumberOfFields`, `mxIsStruct`, `mxSetField`, `mxSetFieldByNumber`

Purpose

Get field name, given field number in structure array

C Syntax

```
#include "matrix.h"
const char *mxGetFieldNameByNumber(const mxArray *pm,
            int fieldnumber);
```

Fortran Syntax

```
character*(*) mxGetFieldNameByNumber(pm, fieldnumber)
mwPointer pm
integer*4 fieldnumber
```

Arguments

`pm`

Pointer to a structure `mxArray`

`fieldnumber`

The position of the desired field. For instance, in C, to get the name of the first field, set `fieldnumber` to 0; to get the name of the second field, set `fieldnumber` to 1; and so on. In Fortran, to get the name of the first field, set `fieldnumber` to `1`; to get the name of the second field, set `fieldnumber` to `2`; and so on.

Returns

A pointer to the nth field name, on success. Returns `NULL` in C (`0` in Fortran) on failure. Common causes of failure include

- Specifying an array pointer `pm` that does not point to a structure `mxArray`. Call `mxIsStruct` to determine whether `pm` points to a structure `mxArray`.
- Specifying a value of `fieldnumber` outside the bounds of the number of fields in the structure `mxArray`. In C, `fieldnumber` 0 represents the first field, and `fieldnumber` `N-1` represents the last field, where `N` is the number of fields in the structure `mxArray`. In Fortran, `fieldnumber` `1` represents the first field, and `fieldnumber` `N` represents the last field.

Description

Call `mxGetFieldNameByNumber` to get the name of a field in the given structure `mxArray`. A typical use of `mxGetFieldNameByNumber` is to call

it inside a loop in order to get the names of all the fields in a given `mxArray`.

Consider a MATLAB structure initialized to

```
patient.name = 'John Doe';
patient.billing = 127.00;
patient.test = [79 75 73; 180 178 177.5; 220 210 205];
```

In C, the field number `0` represents the field `name`; field number `1` represents field `billing`; field number `2` represents field `test`. A field number other than `0`, `1`, or `2` causes `mxGetFieldNameByNumber` to return `NULL`.

In Fortran, the field number `1` represents the field `name`; field number `2` represents field `billing`; field number `3` represents field `test`. A field number other than `1`, `2`, or `3` causes `mxGetFieldNameByNumber` to return `0`.

C Examples

See `phonebook.c` in the `refbook` subdirectory of the `examples` directory.

Additional examples:

- `mxisclass.c` in the `mx` subdirectory of the `examples` directory
- `explore.c` in the `mex` subdirectory of the `examples` directory

See Also

`mxGetField`, `mxGetFieldByNumber`, `mxGetFieldNumber`, `mxGetNumberOfFields`, `mxIsStruct`, `mxSetField`, `mxSetFieldByNumber`

Purpose

Get field number, given field name in structure array

C Syntax

```
#include "matrix.h"
int mxGetFieldNumber(const mxArray *pm,
    const char *fieldname);
```

Fortran Syntax

```
integer*4 mxGetFieldNumber(pm, fieldname)
mwPointer pm
character*(*) fieldname
```

Arguments

`pm`
Pointer to a structure `mxArray`.

`fieldname`
The name of a field in the structure `mxArray`.

Returns

The field number of the specified `fieldname`, on success. In C, the first field has a field number of `0`, the second field has a field number of `1`, and so on. In Fortran, the first field has a field number of `1`, the second field has a field number of `2`, and so on. Returns `-1` in C (`0` in Fortran) on failure. Common causes of failure include

- Specifying an array pointer `pm` that does not point to a structure `mxArray`. Call `mxIsStruct` to determine whether `pm` points to a structure `mxArray`.
- Specifying the `fieldname` of a nonexistent field.

Description

If you know the name of a field but do not know its field number, call `mxGetFieldNumber`. Conversely, if you know the field number but do not know its field name, call `mxGetFieldNameByNumber`.

For example, consider a MATLAB structure initialized to

```
patient.name = 'John Doe';
patient.billing = 127.00;
patient.test = [79 75 73; 180 178 177.5; 220 210 205];
```

In C, the field `name` has a field number of `0`; the field `billing` has a field number of `1`; and the field `test` has a field number of `2`. If you call `mxGetFieldNumber` and specify a field name of anything other than `name`, `billing`, or `test`, `mxGetFieldNumber` returns `-1`.

Calling

```
mxGetField(pa, index, "field_name");
```

is equivalent to calling

```
field_num = mxGetFieldNumber(pa, "field_name");
mxGetFieldByNumber(pa, index, field_num);
```

where `index` is `0` if you have a 1-by-1 structure.

In Fortran, the field `name` has a field number of `1`; the field `billing` has a field number of `2`; and the field `test` has a field number of `3`. If you call `mxGetFieldNumber` and specify a field name of anything other than `name`, `billing`, or `test`, `mxGetFieldNumber` returns `0`.

Calling

```
mxGetField(pm, index, 'fieldname');
```

is equivalent to calling

```
fieldnum = mxGetFieldNumber(pm, 'fieldname');
mxGetFieldByNumber(pm, index, fieldnum);
```

where `index` is `1` if you have a 1-by-1 structure.

C Examples

See `mxcreatestructarray.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxGetField`, `mxGetFieldByNumber`, `mxGetFieldNameByNumber`, `mxGetNumberOfFields`, `mxIsStruct`, `mxSetField`, `mxSetFieldByNumber`

Purpose

Get pointer to imaginary data of `mxArray`

C Syntax

```
#include "matrix.h"
void *mxGetImagData(const mxArray *pm);
```

Fortran Syntax

```
mwPointer mxGetImagData(pm)
mwPointer pm
```

Arguments

`pm`

Pointer to an `mxArray`

Returns

The address of the first element of the imaginary data, on success. Returns `NULL` in C (`0` in Fortran) if there is no imaginary data or if there is an error.

Description

This function is similar to `mxGetPi`, except that in C it returns a `void *`.

C Examples

See `mxisfinite.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxGetData`, `mxGetPi`

mxGetInf (C and Fortran)

Purpose

Get value of infinity

C Syntax

```
#include "matrix.h"
double mxGetInf(void);
```

Fortran Syntax

```
real*8 mxGetInf
```

Returns

The value of infinity on your system.

Description

Call `mxGetInf` to return the value of the MATLAB internal `inf` variable. `inf` is a permanent variable representing IEEE arithmetic positive infinity. The value of `inf` is built into the system; you cannot modify it.

Operations that return infinity include

- Division by 0. For example, 5/0 returns infinity.
- Operations resulting in overflow. For example, `exp(10000)` returns infinity because the result is too large to be represented on your machine.

C Examples

See `mxgetinf.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxGetEps`, `mxGetNaN`

Purpose

Get ir array of sparse matrix

C Syntax

```
#include "matrix.h"
mwIndex *mxGetIr(const mxArray *pm);
```

Fortran Syntax

```
mwPointer mxGetIr(pm)
mwPointer pm
```

Arguments

pm

Pointer to a sparse mxArray

Returns

A pointer to the first element in the ir array, if successful, and NULL in C (0 in Fortran) otherwise. Possible causes of failure include

- Specifying a full (nonsparse) mxArray.
- Specifying a value for pm that is NULL in C (0 in Fortran). This usually means that an earlier call to mxCreateSparse failed.

Description

Use mxGetIr to obtain the starting address of the ir array. The ir array is an array of integers; the length of the ir array is typically nzmax values. For example, if nzmax equals 100, the ir array should contain 100 integers.

Each value in an ir array indicates a row (offset by 1) at which a nonzero element can be found. (The jc array is an index that indirectly specifies a column where nonzero elements can be found.)

For details on the ir and jc arrays, see mxSetIr and mxSetJc.

C Examples

See fulltosparse.c in the refbook subdirectory of the examples directory.

Additional examples:

- explore.c in the mex subdirectory of the examples directory

- `mxsetdimensions.c` and `mxsetnzmax.c` in the `mx` subdirectory of the `examples` directory

See Also

`mxGetJc`, `mxGetNzmax`, `mxSetIr`, `mxSetJc`, `mxSetNzmax`

Purpose

Get jc array of sparse matrix

C Syntax

```
#include "matrix.h"
mwIndex *mxGetJc(const mxArray *pm);
```

Fortran Syntax

```
mwPointer mxGetJc(pm)
mwPointer pm
```

Arguments

pm

Pointer to a sparse mxArray

Returns

A pointer to the first element in the jc array, if successful, and NULL in C (0 in Fortran) otherwise. Possible causes of failure include

- Specifying a full (nonsparse) mxArray.
- Specifying a value for pm that is NULL in C (0 in Fortran). This usually means that an earlier call to mxCreateSparse failed.

Description

Use mxGetJc to obtain the starting address of the jc array. The jc array is an integer array having n+1 elements, where n is the number of columns in the sparse mxArray. The values in the jc array indirectly indicate columns containing nonzero elements. For a detailed explanation of the jc array, see mxSetJc.

C Examples

See fulltosparse.c in the refbook subdirectory of the examples directory.

Additional examples:

- explore.c in the mex subdirectory of the examples directory
- mxgetnzmax.c, mxsetdimensions.c, and mxsetnzmax.c in the mx subdirectory of the examples directory

See Also

mxGetIr, mxGetNzmax, mxSetIr, mxSetJc, mxSetNzmax

mxGetLogicals (C)

Purpose

Get pointer to logical array data

C Syntax

```
#include "matrix.h"
mxLogical *mxGetLogicals(const mxArray *array_ptr);
```

Arguments

`array_ptr`
Pointer to an `mxArray`

Returns

The address of the first logical element in the `mxArray`. The result is unspecified if the `mxArray` is not a logical array.

Description

Call `mxGetLogicals` to determine the address of the first logical element in the `mxArray` that `array_ptr` points to. Once you have the starting address, you can access any other element in the `mxArray`.

See Also

`mxCreateLogicalArray`, `mxCreateLogicalMatrix`, `mxCreateLogicalScalar`, `mxIsLogical`, `mxIsLogicalScalar`, `mxIsLogicalScalarTrue`

Purpose

Get number of rows in mxArray

C Syntax

```
#include "matrix.h"
mwSize mxGetM(const mxArray *pm);
```

Fortran Syntax

```
mwSize mxGetM(pm)
mwPointer pm
```

Arguments

pm
: Pointer to an mxArray

Returns

The number of rows in the mxArray to which pm points.

Description

mxGetM returns the number of rows in the specified array. The term *rows* always means the first dimension of the array, no matter how many dimensions the array has. For example, if pm points to a four-dimensional array having dimensions 8-by-9-by-5-by-3, mxGetM returns 8.

C Examples

See convec.c in the refbook subdirectory of the examples directory.

Additional examples:

- fulltosparse.c, revord.c, timestwo.c, and xtimesy.c in the refbook subdirectory of the examples directory
- explore.c, mexget.c, mexlock.c, mexsettrapflag.c and yprime.c in the mex subdirectory of the examples directory
- mxmalloc.c, mxsetdimensions.c, mxgetnzmax.c, and mxsetnzmax.c in the mx subdirectory of the examples directory

Fortran Examples

See matdemo2.F in the eng_mat subdirectory of the examples directory for a sample program that illustrates how to use this routine in a Fortran program.

See Also

mxGetN, mxSetM, mxSetN

mxGetN (C and Fortran)

Purpose

Get number of columns in mxArray

C Syntax

```
#include "matrix.h"
mwSize mxGetN(const mxArray *pm);
```

Fortran Syntax

```
mwSize mxGetN(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

The number of columns in the mxArray.

Description

Call mxGetN to determine the number of columns in the specified mxArray.

If pm is an N-dimensional mxArray, mxGetN is the product of dimensions 2 through N. For example, if pm points to a four-dimensional mxArray having dimensions 13-by-5-by-4-by-6, mxGetN returns the value 120 (5 × 4 × 6). If the specified mxArray has more than two dimensions and you need to know exactly how many elements are in each dimension, call mxGetDimensions.

If pm points to a sparse mxArray, mxGetN still returns the number of columns, not the number of occupied columns.

C Examples

See convec.c in the refbook subdirectory of the examples directory.

Additional examples:

- fulltosparse.c, revord.c, timestwo.c, and xtimesy.c in the refbook subdirectory of the examples directory
- explore.c, mexget.c, mexlock.c, mexsettrapflag.c and yprime.c in the mex subdirectory of the examples directory
- mxmalloc.c, mxsetdimensions.c, mxgetnzmax.c, and mxsetnzmax.c in the mx subdirectory of the examples directory

Fortran Examples

See `matdemo2.F` in the `eng_mat` subdirectory of the `examples` directory for a sample program that illustrates how to use this routine in a Fortran program.

`mxGetM`, `mxGetDimensions`, `mxSetM`, `mxSetN`

mxGetNaN (C and Fortran)

Purpose

Get value of NaN (Not-a-Number)

C Syntax

```
#include "matrix.h"
double mxGetNaN(void);
```

Fortran Syntax

```
real*8 mxGetNaN
```

Returns

The value of NaN (Not-a-Number) on your system

Description

Call mxGetNaN to return the value of NaN for your system. NaN is the IEEE arithmetic representation for Not-a-Number. Certain mathematical operations return NaN as a result, for example,

- `0.0/0.0`
- `Inf-Inf`

The value of Not-a-Number is built in to the system. You cannot modify it.

C Examples

See `mxgetinf.c` in the `mx` subdirectory of the `examples` directory.

See Also

mxGetEps, mxGetInf

Purpose

Get number of dimensions in `mxArray`

C Syntax

```
#include "matrix.h"
mwSize mxGetNumberOfDimensions(const mxArray *pm);
```

Fortran Syntax

```
mwSize mxGetNumberOfDimensions(pm)
mwPointer pm
```

Arguments

`pm`

Pointer to an `mxArray`

Returns

The number of dimensions in the specified `mxArray`. The returned value is always `2` or greater.

Description

Use `mxGetNumberOfDimensions` to determine how many dimensions are in the specified array. To determine how many elements are in each dimension, call `mxGetDimensions`.

C Examples

See `explore.c` in the `mex` subdirectory of the `examples` directory.

Additional examples:

- `findnz.c`, `fulltosparse.c`, and `phonebook.c` in the `refbook` subdirectory of the `examples` directory
- `mxcalcsinglesubscript.c`, `mxgeteps.c`, and `mxisfinite.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxSetM`, `mxSetN`, `mxGetDimensions`

mxGetNumberOfElements (C and Fortran)

Purpose

Get number of elements in `mxArray`

C Syntax

```
#include "matrix.h"
mwSize mxGetNumberOfElements(const mxArray *pm);
```

Fortran Syntax

```
mwSize mxGetNumberOfElements(pm)
mwPointer pm
```

Arguments

`pm`
Pointer to an `mxArray`

Returns

Number of elements in the specified `mxArray`

Description

`mxGetNumberOfElements` tells you how many elements an array has. For example, if the dimensions of an array are 3-by-5-by-10, `mxGetNumberOfElements` returns the number `150`.

C Examples

See `findnz.c` and `phonebook.c` in the `refbook` subdirectory of the `examples` directory.

Additional examples:

- `explore.c` in the `mex` subdirectory of the `examples` directory
- `mxcalcsinglesubscript.c`, `mxgeteps.c`, `mxgetinf.c`, `mxisfinite.c`, and `mxsetdimensions.c` in the `mx` subdirectory of the `examples` directory

See Also

`mxGetDimensions`, `mxGetM`, `mxGetN`, `mxGetClassID`, `mxGetClassName`

Purpose

Get number of fields in structure mxArray

C Syntax

```
#include "matrix.h"
int mxGetNumberOfFields(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxGetNumberOfFields(pm)
mwPointer pm
```

Arguments

pm

Pointer to a structure mxArray

Returns

The number of fields, on success. Returns 0 on failure. The most common cause of failure is that pm is not a structure mxArray. Call mxIsStruct to determine whether pm is a structure.

Description

Call mxGetNumberOfFields to determine how many fields are in the specified structure mxArray.

Once you know the number of fields in a structure, you can loop through every field in order to set or to get field values.

C Examples

See phonebook.c in the refbook subdirectory of the examples directory.

Additional examples:

- mxisclass.c in the mx subdirectory of the examples directory
- explore.c in the mex subdirectory of the examples directory.

See Also

mxGetField, mxIsStruct, mxSetField

mxGetNzmax (C and Fortran)

Purpose

Get number of elements in `ir`, `pr`, and `pi` arrays

C Syntax

```
#include "matrix.h"
mwSize mxGetNzmax(const mxArray *pm);
```

Fortran Syntax

```
mwSize mxGetNzmax(pm)
mwPointer pm
```

Arguments

`pm`

Pointer to a sparse `mxArray`

Returns

The number of elements allocated to hold nonzero entries in the specified sparse `mxArray`, on success. Returns an indeterminate value on error. The most likely cause of failure is that `pm` points to a full (nonsparse) `mxArray`.

Description

Use `mxGetNzmax` to get the value of the `nzmax` field. The `nzmax` field holds an integer value that signifies the number of elements in the `ir`, `pr`, and, if it exists, the `pi` arrays. The value of `nzmax` is always greater than or equal to the number of nonzero elements in a sparse `mxArray`. In addition, the value of `nzmax` is always less than or equal to the number of rows times the number of columns.

As you adjust the number of nonzero elements in a sparse `mxArray`, MATLAB often adjusts the value of the `nzmax` field. MATLAB adjusts `nzmax` in order to reduce the number of costly reallocations and in order to optimize its use of heap space.

C Examples

See `mxgetnzmax.c` and `mxsetnzmax.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxSetNzmax`

Purpose

Get imaginary data elements in mxArray

C Syntax

```
#include "matrix.h"
double *mxGetPi(const mxArray *pm);
```

Fortran Syntax

```
mwPointer mxGetPi(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

The imaginary data elements of the specified mxArray, on success. Returns NULL in C (0 in Fortran) if there is no imaginary data or if there is an error.

Description

The pi field points to an array containing the imaginary data of the mxArray. Call mxGetPi to get the contents of the pi field, that is, to get the starting address of this imaginary data.

The best way to determine whether an mxArray is purely real is to call mxIsComplex.

The imaginary parts of all input matrices to a MATLAB function are allocated if any of the input matrices are complex.

C Examples

See convec.c, findnz.c, and fulltosparse.c in the refbook subdirectory of the examples directory.

Additional examples:

- explore.c and mexcallmatlab.c in the mex subdirectory of the examples directory
- mxcalcsinglesubscript.c, mxgetinf.c, mxisfinite.c, and mxsetnzmax.c in the mx subdirectory of the examples directory

See Also

mxGetPr, mxSetPi, mxSetPr

mxGetPr (C and Fortran)

Purpose

Get real data elements in mxArray

C Syntax

```
#include "matrix.h"
double *mxGetPr(const mxArray *pm);
```

Fortran Syntax

```
mwPointer mxGetPr(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

The address of the first element of the real data. Returns NULL in C (0 in Fortran) if there is no real data.

Description

Call mxGetPr to determine the starting address of the real data in the mxArray that pm points to. Once you have the starting address, you can access any other element in the mxArray.

C Examples

See convec.c, doubleelement.c, findnz.c, fulltosparse.c, sincall.c, timestwo.c, timestwoalt.c, and xtimesy.c in the refbook subdirectory of the examples directory.

See Also

mxGetPi, mxSetPi, mxSetPr

Purpose

Get real component of first data element in mxArray

C Syntax

```
#include "matrix.h"
double mxGetScalar(const mxArray *pm);
```

Fortran Syntax

```
real*8 mxGetScalar(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray; cannot be a cell mxArray, a structure mxArray, or an empty mxArray

Returns

The value of the first real (nonimaginary) element of the mxArray. Notice that in C, mxGetScalar returns a double. Therefore, if real elements in the mxArray are stored as something other than double, mxGetScalar automatically converts the scalar value into a double. To preserve the original data representation of the scalar, you must cast the return value to the desired data type.

mxGetScalar should only be called when pm points to a non-empty numeric, logical, or char mxArray. Use mx functions such as mxIsEmpty, mxIsLogical, mxIsNumeric, or mxIsChar to test for this condition before calling mxGetScalar.

If pm points to a sparse mxArray, mxGetScalar returns the value of the first nonzero real element in the mxArray.

Description

Call mxGetScalar to get the value of the first real (nonimaginary) element of the mxArray.

In most cases, you call mxGetScalar when pm points to an mxArray containing only one element (a scalar). However, pm can point to an mxArray containing many elements. If pm points to an mxArray containing multiple elements, mxGetScalar returns the value of the first real element. If pm points to a two-dimensional mxArray, mxGetScalar returns the value of the (1,1) element; if pm points to

a three-dimensional `mxArray`, `mxGetScalar` returns the value of the `(1,1,1)` element; and so on.

C Examples

See timestwoalt.c and xtimesy.c in the `refbook` subdirectory of the `examples` directory.

Additional examples:

- mxsetdimensions.c in the `mx` subdirectory of the `examples` directory
- mexlock.c and mexsettrapflag.c in the `mex` subdirectory of the `examples` directory

See Also

`mxGetM`, `mxGetN`

Purpose

Copy string mxArray to C-style string

C Syntax

```
#include "matrix.h"
int mxGetString(const mxArray *pm, char *str, mwSize strlen);
```

Fortran Syntax

```
integer*4 mxGetString(pm, str, strlen)
mwPointer pm
character*(*) str
mwSize strlen
```

Arguments

pm
: Pointer to a string mxArray; that is, a pointer to an mxArray having the mxCHAR_CLASS class.

str
: The starting location into which the string should be written. mxGetString writes the character data into str and then, in C, terminates the string with a NULL character (in the manner of C strings). str can point to either dynamic or static memory.

strlen
: Maximum number of characters to read into str. Typically, in C, you set strlen to 1 plus the number of elements in the string mxArray to which pm points. See the mxGetM and mxGetN reference pages to find out how to get the number of elements.

Returns

0 on success, and 1 on failure. Possible reasons for failure include

- Specifying an mxArray that is not a string mxArray.
- Specifying strlen with less than the number of characters needed to store the entire mxArray pointed to by pm. If this is the case, 1 is returned and the string is truncated.

Description

Call mxGetString to copy the character data of a string mxArray into a C-style string in C or a character array in Fortran. The copied string starts at str and contains no more than strlen-1 characters in C (no

more than strlen characters in Fortran). In C, the C-style string is always terminated with a NULL character.

If the string array contains several rows, they are copied—one column at a time—into one long string array.

Multibyte Character Sets

This function is for use only with strings that represent single-byte character sets. For strings that represent multibyte character sets, use the C function mxArrayToString. Fortran users must allocate sufficient space for the return string to avoid possible truncation.

```
strlen = (mxGetM(prhs[0]) * mxGetN(prhs[0]) * sizeof(mxChar)) + 1
```

C Examples

Examples:

- explore.c in the mex subdirectory of the examples directory
- mxmalloc.c in the mx subdirectory of the examples directory

See Also

mxArrayToString, mxCreateCharArray, mxCreateCharMatrixFromStrings, mxCreateString

Purpose

Determine whether input is cell mxArray

C Syntax

```
#include "matrix.h"
bool mxIsCell(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsCell(pm)
mwPointer pm
```

Arguments

pm
: Pointer to an mxArray

Returns

Logical 1 (true) if pm points to an array having the class mxCELL_CLASS, and logical 0 (false) otherwise.

Description

Use mxIsCell to determine whether the specified array is a cell array.

In C, calling mxIsCell is equivalent to calling

```
mxGetClassID(pm) == mxCELL_CLASS
```

In Fortran, calling mxIsCell is equivalent to calling

```
mxGetClassName(pm) .eq. 'cell'
```

Note mxIsCell does not answer the question "Is this mxArray a cell of a cell array?" An individual cell of a cell array can be of any type.

See Also

mxIsClass

mxIsChar (C and Fortran)

Purpose

Determine whether input is string mxArray

C Syntax

```
#include "matrix.h"
bool mxIsChar(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsChar(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if pm points to an array having the class mxCHAR_CLASS, and logical 0 (false) otherwise.

Description

Use mxIsChar to determine whether pm points to string mxArray.

In C, calling mxIsChar is equivalent to calling

```
mxGetClassID(pm) == mxCHAR_CLASS
```

In Fortran, calling mxIsChar is equivalent to calling

```
mxGetClassName(pm) .eq. 'char'
```

C Examples

See phonebook.c and revord.c in the refbook subdirectory of the examples directory.

For additional examples, see mxcreatecharmatrixfromstr.c, mxislogical.c, and mxmalloc.c in the mx subdirectory of the examples directory.

See Also

mxIsClass, mxGetClassID

Purpose

Determine whether mxArray is member of specified class

C Syntax

```
#include "matrix.h"
bool mxIsClass(const mxArray *pm, const char *classname);
```

Fortran Syntax

```
integer*4 mxIsClass(pm, classname)
mwPointer pm
character*(*) classname
```

Arguments

`pm`

Pointer to an mxArray

`classname`

The array category that you are testing. Specify classname as a string (not as an integer identifier). You can specify any one of the following predefined constants:

Value of classname	Corresponding Class
cell	mxCELL_CLASS
char	mxCHAR_CLASS
double	mxDOUBLE_CLASS
function_handle	mxFUNCTION_CLASS
int8	mxINT8_CLASS
int16	mxINT16_CLASS
int32	mxINT32_CLASS
int64	mxINT64_CLASS
logical	mxLOGICAL_CLASS
single	mxSINGLE_CLASS
struct	mxSTRUCT_CLASS
uint8	mxUINT8_CLASS

Value of classname	Corresponding Class
uint16	mxUINT16_CLASS
uint32	mxUINT32_CLASS
uint64	mxUINT64_CLASS
<class_name>	*<class_id>*
unknown	mxUNKNOWN_CLASS

In the table, *<class_name>* represents the name of a specific MATLAB custom object. You can also specify one of your own class names.

Returns

Logical `1` (`true`) if `pm` points to an array having category `classname`, and logical `0` (`false`) otherwise.

Description

Each `mxArray` is tagged as being a certain type. Call `mxIsClass` to determine whether the specified `mxArray` has this type.

In C,

```
mxIsClass("double");
```

is equivalent to calling either of these forms:

```
mxIsDouble(pm);
```

```
strcmp(mxGetClassName(pm), "double");
```

In Fortran,

```
mxIsClass(pm, 'double')
```

is equivalent to calling either one of the following

```
mxIsDouble(pm)
```

```
mxGetClassName(pm) .eq. 'double'
```

It is most efficient to use the `mxIsDouble` form.

C Examples

See `mxisclass.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxClassID`, `mxGetClassID`, `mxIsEmpty`, `mxGetClassName`

mxIsComplex (C and Fortran)

Purpose

Determine whether data is complex

C Syntax

```
#include "matrix.h"
bool mxIsComplex(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsComplex(pm)
mwPointer pm
```

Arguments

`pm`
Pointer to an `mxArray`

Returns

Logical `1` (`true`) if `pm` is a numeric array containing complex data, and logical `0` (`false`) otherwise. If `pm` points to a cell array or a structure array, `mxIsComplex` returns `false`.

Description

Use `mxIsComplex` to determine whether or not an imaginary part is allocated for an `mxArray`. The imaginary pointer `pi` is `NULL` in C (`0` in Fortran) if an `mxArray` is purely real and does not have any imaginary data. If an `mxArray` is complex, `pi` points to an array of numbers.

C Examples

See `mxisfinite.c` in the `mx` subdirectory of the `examples` directory.

Additional examples:

- `convec.c`, `phonebook.c`, `timestwo.c`, and `xtimesy.c` in the `refbook` subdirectory of the `examples` directory
- `explore.c`, `yprime.c`, `mexlock.c`, and `mexsettrapflag.c` in the `mex` subdirectory of the `examples` directory
- `mxcalcsinglesubscript.c`, `mxgeteps.c`, and `mxgetinf.c` in the `mx` subdirectory of the `examples` directory

See Also

`mxIsNumeric`

Purpose

Determine whether mxArray represents data as double-precision, floating-point numbers

C Syntax

```
#include "matrix.h"
bool mxIsDouble(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsDouble(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the mxArray stores its data as double-precision, floating-point numbers, and logical 0 (false) otherwise.

Description

Call mxIsDouble to determine whether or not the specified mxArray represents its real and imaginary data as double-precision, floating-point numbers.

Older versions of MATLAB store all mxArray data as double-precision, floating-point numbers. However, starting with MATLAB Version 5, MATLAB can store real and imaginary data in a variety of numerical formats.

In C, calling mxIsDouble is equivalent to calling

```
mxGetClassID(pm) == mxDOUBLE_CLASS
```

In Fortran, calling mxIsDouble is equivalent to calling

```
mxGetClassName(pm) .eq. 'double'
```

C Examples

See findnz.c, fulltosparse.c, timestwo.c, and xtimesy.c in the refbook subdirectory of the examples directory.

Additional examples:

- `mexget.c`, `mexlock.c`, `mexsettrapflag.c`, and `yprime.c` in the `mex` subdirectory of the `examples` directory
- `mxcalcsinglesubscript.c`, `mxgeteps.c`, `mxgetinf.c`, and `mxisfinite.c` in the `mx` subdirectory of the `examples` directory

See Also

`mxIsClass`, `mxGetClassID`

Purpose

Determine whether mxArray is empty

C Syntax

```
#include "matrix.h"
bool mxIsEmpty(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsEmpty(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the mxArray is empty, and logical 0 (false) otherwise.

Description

Use mxIsEmpty to determine whether an mxArray contains no data. An mxArray is empty if the size of any of its dimensions is 0.

C Examples

See mxisfinite.c in the mx subdirectory of the examples directory.

See Also

mxIsClass

mxIsFinite (C and Fortran)

Purpose

Determine whether input is finite

C Syntax

```
#include "matrix.h"
bool mxIsFinite(double value);
```

Fortran Syntax

```
integer*4 mxIsFinite(value)
real*8 value
```

Arguments

`value`
The double-precision, floating-point number that you are testing

Returns

Logical `1` (`true`) if `value` is finite, and logical `0` (`false`) otherwise.

Description

Call `mxIsFinite` to determine whether or not `value` is finite. A number is finite if it is greater than `-Inf` and less than `Inf`.

C Examples

See `mxisfinite.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxIsInf`, `mxIsNan`

Purpose

Determine whether mxArray was copied from MATLAB global workspace

C Syntax

```
#include "matrix.h"
bool mxIsFromGlobalWS(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsFromGlobalWS(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the array was copied out of the global workspace, and logical 0 (false) otherwise.

Description

mxIsFromGlobalWS is useful for stand-alone MAT programs. mexIsGlobal tells you whether the pointer you pass actually points into the global workspace.

C Examples

See matdgns.c and matcreat.c in the eng_mat subdirectory of the examples directory.

See Also

mexIsGlobal

mxIsInf (C and Fortran)

Purpose

Determine whether input is infinite

C Syntax

```
#include "matrix.h"
bool mxIsInf(double value);
```

Fortran Syntax

```
integer*4 mxIsInf(value)
real*8 value
```

Arguments

`value`
The double-precision, floating-point number that you are testing

Returns

Logical `1` (`true`) if value is infinite, and logical `0` (`false`) otherwise.

Description

Call `mxIsInf` to determine whether or not `value` is equal to infinity or minus infinity. MATLAB stores the value of infinity in a permanent variable named `Inf`, which represents IEEE arithmetic positive infinity. The value of the variable `Inf` is built into the system; you cannot modify it.

Operations that return infinity include

- Division by 0. For example, `5/0` returns infinity.
- Operations resulting in overflow. For example, `exp(10000)` returns infinity because the result is too large to be represented on your machine.

If `value` equals `NaN` (Not-a-Number), `mxIsInf` returns `false`. In other words, `NaN` is not equal to infinity.

C Examples

See `mxisfinite.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxIsFinite`, `mxIsNaN`

Purpose

Determine whether mxArray represents data as signed 16-bit integers

C Syntax

```
#include "matrix.h"
bool mxIsInt16(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsInt16(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the array stores its data as signed 16-bit integers, and logical 0 (false) otherwise.

Description

Use mxIsInt16 to determine whether or not the specified array represents its real and imaginary data as 16-bit signed integers.

In C, calling mxIsInt16 is equivalent to calling

```
mxGetClassID(pm) == mxINT16_CLASS
```

In Fortran, calling mxIsInt16 is equivalent to calling

```
mxGetClassName(pm) == 'int16'
```

See Also

mxIsClass, mxGetClassID, mxIsInt8, mxIsInt32, mxIsInt64, mxIsUint8, mxIsUint16, mxIsUint32, mxIsUint64

mxIsInt32 (C and Fortran)

Purpose

Determine whether mxArray represents data as signed 32-bit integers

C Syntax

```
#include "matrix.h"
bool mxIsInt32(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsInt32(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the array stores its data as signed 32-bit integers, and logical 0 (false) otherwise.

Description

Use mxIsInt32 to determine whether or not the specified array represents its real and imaginary data as 32-bit signed integers.

In C, calling mxIsInt32 is equivalent to calling

```
mxGetClassID(pm) == mxINT32_CLASS
```

In Fortran, calling mxIsInt32 is equivalent to calling

```
mxGetClassName(pm) == 'int32'
```

See Also

mxIsClass, mxGetClassID, mxIsInt8, mxIsInt16, mxIsInt64, mxIsUint8, mxIsUint16, mxIsUint32, mxIsUint64

Purpose

Determine whether mxArray represents data as signed 64-bit integers

C Syntax

```
#include "matrix.h"
bool mxIsInt64(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsInt64(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the array stores its data as signed 64-bit integers, and logical 0 (false) otherwise.

Description

Use mxIsInt64 to determine whether or not the specified array represents its real and imaginary data as 64-bit signed integers.

In C, calling mxIsInt64 is equivalent to calling

```
mxGetClassID(pm) == mxINT64_CLASS
```

In Fortran, calling mxIsInt64 is equivalent to calling

```
mxGetClassName(pm) == 'int64'
```

See Also

mxIsClass, mxGetClassID, mxIsInt8, mxIsInt16, mxIsInt32, mxIsUint8, mxIsUint16, mxIsUint32, mxIsUint64

mxIsInt8 (C and Fortran)

Purpose

Determine whether mxArray represents data as signed 8-bit integers

C Syntax

```
#include "matrix.h"
bool mxIsInt8(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsInt8(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the array stores its data as signed 8-bit integers, and logical 0 (false) otherwise.

Description

Use mxIsInt8 to determine whether or not the specified array represents its real and imaginary data as 8-bit signed integers.

In C, calling mxIsInt8 is equivalent to calling

```
mxGetClassID(pm) == mxINT8_CLASS
```

In Fortran, calling mxIsInt8 is equivalent to calling

```
mxGetClassName(pm) .eq. 'int8'
```

See Also

mxIsClass, mxGetClassID, mxIsInt16, mxIsInt32, mxIsInt64, mxIsUint8, mxIsUint16, mxIsUint32, mxIsUint64

Purpose

Determine whether `mxArray` is of type `mxLogical`

C Syntax

```
#include "matrix.h"
bool mxIsLogical(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsLogical(pm)
mwPointer pm
```

Arguments

`pm`

Pointer to an `mxArray`

Returns

Logical `1` (`true`) if `pm` points to a logical `mxArray`, and logical `0` (`false`) otherwise.

Description

Use `mxIsLogical` to determine whether MATLAB treats the data in the `mxArray` as Boolean (logical). If an `mxArray` is logical, MATLAB treats all zeros as meaning `false` and all nonzero values as meaning `true`. For additional information on the use of logical variables in MATLAB, type `help logical` at the MATLAB prompt.

C Examples

See `mxislogical.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxIsClass`

mxIsLogicalScalar (C)

Purpose

Determine whether scalar `mxArray` is of type `mxLogical`

C Syntax

```
#include "matrix.h"
bool mxIsLogicalScalar(const mxArray *array_ptr);
```

Arguments

`array_ptr`
Pointer to an `mxArray`

Returns

Logical `1` (`true`) if the `mxArray` is of class `mxLogical` and has 1-by-1 dimensions, and logical `0` (`false`) otherwise.

Description

Use `mxIsLogicalScalar` to determine whether MATLAB treats the scalar data in the `mxArray` as logical or numerical. For additional information on the use of logical variables in MATLAB, type `help logical` at the MATLAB prompt.

`mxIsLogicalScalar(pa)` is equivalent to

```
mxIsLogical(pa) && mxGetNumberOfElements(pa) == 1
```

See Also

`mxIsLogical`, `mxIsLogicalScalarTrue`, `mxGetLogicals`, `mxGetScalar`

Purpose

Determine whether scalar `mxArray` of type `mxLogical` is `true`

C Syntax

```
#include "matrix.h"
bool mxIsLogicalScalarTrue(const mxArray *array_ptr);
```

Arguments

`array_ptr`
Pointer to an `mxArray`

Returns

Logical `1` (`true`) if the value of the `mxArray`'s logical, scalar element is `true`, and logical `0` (`false`) otherwise.

Description

Use `mxIsLogicalScalarTrue` to determine whether the value of a scalar `mxArray` is true or false. For additional information on the use of logical variables in MATLAB, type `help logical` at the MATLAB prompt.

`mxIsLogicalScalarTrue(pa)` is equivalent to

```
mxIsLogical(pa) && mxGetNumberOfElements(pa) == 1 &&
mxGetLogicals(pa)[0] == true
```

See Also

`mxIsLogical`, `mxIsLogicalScalar`, `mxGetLogicals`, `mxGetScalar`

mxIsNaN (C and Fortran)

Purpose

Determine whether input is NaN (Not-a-Number)

C Syntax

```
#include "matrix.h"
bool mxIsNaN(double value);
```

Fortran Syntax

```
integer*4 mxIsNaN(value)
real*8 value
```

Arguments

`value`
The double-precision, floating-point number that you are testing

Returns

Logical `1` (`true`) if `value` is `NaN` (Not-a-Number), and logical `0` (`false`) otherwise.

Description

Call `mxIsNaN` to determine whether or not `value` is `NaN`. `NaN` is the IEEE arithmetic representation for Not-a-Number. A `NaN` is obtained as a result of mathematically undefined operations such as

- `0.0/0.0`
- `Inf-Inf`

The system understands a family of bit patterns as representing `NaN`. In other words, `NaN` is not a single value; rather, it is a family of numbers that MATLAB (and other IEEE-compliant applications) use to represent an error condition or missing data.

C Examples

See `mxisfinite.c` in the `mx` subdirectory of the `examples` directory.

For additional examples, see `findnz.c` and `fulltosparse.c` in the `refbook` subdirectory of the `examples` directory.

See Also

`mxIsFinite`, `mxIsInf`

Purpose

Determine whether mxArray is numeric

C Syntax

```
#include "matrix.h"
bool mxIsNumeric(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsNumeric(pm)
mwPointer pm
```

Arguments

pm
: Pointer to an mxArray

Returns

Logical 1 (true) if the array can contain numeric data. The following class IDs represent storage types for arrays that can contain numeric data:

- mxDOUBLE_CLASS
- mxSINGLE_CLASS
- mxINT8_CLASS
- mxUINT8_CLASS
- mxINT16_CLASS
- mxUINT16_CLASS
- mxINT32_CLASS
- mxUINT32_CLASS
- mxINT64_CLASS
- mxUINT64_CLASS

Logical 0 (false) if the array cannot contain numeric data.

Description

Call mxIsNumeric to determine whether the specified array contains numeric data. If the specified array has a storage type that represents

numeric data, `mxIsNumeric` returns logical `1` (`true`). Otherwise, `mxIsNumeric` returns logical `0` (`false`).

Call `mxGetClassID` to determine the exact storage type.

C Examples

See `phonebook.c` in the `refbook` subdirectory of the `examples` directory.

Fortran Examples

See `matdemo1.F` in the `eng_mat` subdirectory of the `examples` directory.

See Also

`mxGetClassID`

Purpose

Determine whether mxArray represents data as single-precision, floating-point numbers

C Syntax

```
#include "matrix.h"
bool mxIsSingle(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsSingle(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the array stores its data as single-precision, floating-point numbers, and logical 0 (false) otherwise.

Description

Use mxIsSingle to determine whether or not the specified array represents its real and imaginary data as single-precision, floating-point numbers.

In C, calling mxIsSingle is equivalent to calling

```
mxGetClassID(pm) == mxSINGLE_CLASS
```

In Fortran, calling mxIsSingle is equivalent to calling

```
mxGetClassName(pm) .eq. 'single'
```

See Also

mxIsClass, mxGetClassID

mxIsSparse (C and Fortran)

Purpose

Determine whether input is sparse mxArray

C Syntax

```
#include "matrix.h"
bool mxIsSparse(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsSparse(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if pm points to a sparse mxArray, and logical 0 (false) otherwise. A false return value means that pm points to a full mxArray or that pm does not point to a legal mxArray.

Description

Use mxIsSparse to determine whether pm points to a sparse mxArray. Many routines (for example, mxGetIr and mxGetJc) require a sparse mxArray as input.

C Examples

See phonebook.c in the refbook subdirectory of the examples directory.

For additional examples, see mxgetnzmax.c, mxsetdimensions.c, and mxsetnzmax.c in the mx subdirectory of the examples directory.

See Also

mxGetIr, mxGetJc, mxCreateSparse

Purpose

Determine whether input is structure mxArray

C Syntax

```
#include "matrix.h"
bool mxIsStruct(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsStruct(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if pm points to a structure mxArray, and logical 0 (false) otherwise.

Description

Use mxIsStruct to determine whether pm points to a structure mxArray. Many routines (for example, mxGetFieldName and mxSetField) require a structure mxArray as an argument.

C Examples

See phonebook.c in the refbook subdirectory of the examples directory.

See Also

mxCreateStructArray, mxCreateStructMatrix, mxGetNumberOfFields, mxGetField, mxSetField

mxIsUint16 (C and Fortran)

Purpose

Determine whether mxArray represents data as unsigned 16-bit integers

C Syntax

```
#include "matrix.h"
bool mxIsUint16(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsUint16(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the mxArray stores its data as unsigned 16-bit integers, and logical 0 (false) otherwise.

Description

Use mxIsUint16 to determine whether or not the specified mxArray represents its real and imaginary data as 16-bit unsigned integers.

In C, calling mxIsUint16 is equivalent to calling

```
mxGetClassID(pm) == mxUINT16_CLASS
```

In Fortran, calling mxIsUint16 is equivalent to calling

```
mxGetClassName(pm) .eq. 'uint16'
```

See Also

mxIsClass, mxGetClassID, mxIsInt8, mxIsInt16, mxIsInt32, mxIsInt64, mxIsUint8, mxIsUint32, mxIsUint64

Purpose

Determine whether mxArray represents data as unsigned 32-bit integers

C Syntax

```
#include "matrix.h"
bool mxIsUint32(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsUint32(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the mxArray stores its data as unsigned 32-bit integers, and logical 0 (false) otherwise.

Description

Use mxIsUint32 to determine whether or not the specified mxArray represents its real and imaginary data as 32-bit unsigned integers.

In C, calling mxIsUint32 is equivalent to calling

```
mxGetClassID(pm) == mxUINT32_CLASS
```

In Fortran, calling mxIsUint32 is equivalent to calling

```
mxGetClassName(pm) .eq. 'uint32'
```

See Also

mxIsClass, mxGetClassID, mxIsInt8, mxIsInt16, mxIsInt32, mxIsInt64, mxIsUint8, mxIsUint16, mxIsUint64

mxIsUint64 (C and Fortran)

Purpose

Determine whether mxArray represents data as unsigned 64-bit integers

C Syntax

```
#include "matrix.h"
bool mxIsUint64(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsUint64(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the mxArray stores its data as unsigned 64-bit integers, and logical 0 (false) otherwise.

Description

Use mxIsUint64 to determine whether or not the specified mxArray represents its real and imaginary data as 64-bit unsigned integers.

In C, calling mxIsUint64 is equivalent to calling

```
mxGetClassID(pm) == mxUINT64_CLASS
```

In Fortran, calling mxIsUint64 is equivalent to calling

```
mxGetClassName(pm) .eq. 'uint64'
```

See Also

mxIsClass, mxGetClassID, mxIsInt8, mxIsInt16, mxIsInt32, mxIsInt64, mxIsUint8, mxIsUint16, mxIsUint32

Purpose

Determine whether mxArray represents data as unsigned 8-bit integers

C Syntax

```
#include "matrix.h"
bool mxIsUint8(const mxArray *pm);
```

Fortran Syntax

```
integer*4 mxIsUint8(pm)
mwPointer pm
```

Arguments

pm

Pointer to an mxArray

Returns

Logical 1 (true) if the mxArray stores its data as unsigned 8-bit integers, and logical 0 (false) otherwise.

Description

Use mxIsUint8 to determine whether or not the specified mxArray represents its real and imaginary data as 8-bit unsigned integers.

In C, calling mxIsUint8 is equivalent to calling

```
mxGetClassID(pm) == mxUINT8_CLASS
```

In Fortran, calling mxIsUint8 is equivalent to calling

```
mxGetClassName(pm) .eq. 'uint8'
```

See Also

mxIsClass, mxGetClassID, mxIsInt8, mxIsInt16, mxIsInt32, mxIsInt64, mxIsUint16, mxIsUint32, mxIsUint64

mxLogical (C)

Purpose

Type for logical `mxArray`

Description

All logical `mxArrays` store their data elements as `mxLogical` rather than as `bool`.

The header file containing this type is

```
#include "matrix.h"
```

Examples

See `mxislogical.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxCreateLogicalArray`

Purpose

Allocate dynamic memory using MATLAB memory manager

C Syntax

```
#include "matrix.h"
#include <stdlib.h>
void *mxMalloc(mwSize n);
```

Fortran Syntax

```
mwPointer mxMalloc(n)
mwSize n
```

Arguments

`n`

Number of bytes to allocate

Returns

A pointer to the start of the allocated dynamic memory, if successful. If unsuccessful in a stand-alone (nonMEX-file) application, `mxMalloc` returns `NULL` in C (`0` in Fortran). If unsuccessful in a MEX-file, the MEX-file terminates and control returns to the MATLAB prompt.

`mxMalloc` is unsuccessful when there is insufficient free heap space.

Description

MATLAB applications should always call `mxMalloc` rather than `malloc` to allocate memory.

`mxMalloc` works differently in MEX-files than in stand-alone MATLAB applications. In MEX-files, `mxMalloc` automatically

- Allocates enough contiguous heap space to hold `n` bytes.
- Registers the returned heap space with the MATLAB memory management facility.

The MATLAB memory management facility maintains a list of all memory allocated by `mxMalloc`. The MATLAB memory management facility automatically frees (deallocates) all of a MEX-file's parcels when control returns to the MATLAB prompt.

In stand-alone MATLAB C applications, `mxMalloc` calls the ANSI C `malloc` function.

By default, in a MEX-file, `mxMalloc` generates nonpersistent `mxMalloc` data. In other words, the memory management facility automatically deallocates the memory as soon as the MEX-file ends. If you want the memory to persist after the MEX-file completes, call `mexMakeMemoryPersistent` after calling `mxMalloc`. If you write a MEX-file with persistent memory, be sure to register a `mexAtExit` function to free allocated memory in the event your MEX-file is cleared.

When you finish using the memory allocated by `mxMalloc`, call `mxFree`. `mxFree` deallocates the memory.

C Examples

See `mxmalloc.c` in the `mx` subdirectory of the `examples` directory. For an additional example, see `mxsetdimensions.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mexAtExit`, `mexMakeArrayPersistent`, `mexMakeMemoryPersistent`, `mxCalloc`, `mxDestroyArray`, `mxFree`, `mxRealloc`

Purpose

Reallocate memory

C Syntax

```
#include "matrix.h"
#include <stdlib.h>
void *mxRealloc(void *ptr, mwSize size);
```

Fortran Syntax

```
mwPointer mxRealloc(ptr, size)
mwPointer ptr
mwSize size
```

Arguments

ptr
: Pointer to a block of memory allocated by `mxCalloc`, `mxMalloc`, or `mxRealloc`

`size`
: New size of allocated memory, in bytes

Returns

A pointer to the reallocated block of memory, or `NULL` in C (`0` in Fortran) if `size` is `0`. In a stand-alone (non-MEX-file) application, if not enough memory is available to expand the block to the given size, `mxRealloc` returns `NULL` in C (`0` in Fortran). In a MEX-file, if not enough memory is available to expand the block to the given size, the MEX-file terminates and control returns to the MATLAB prompt.

Description

`mxRealloc` changes the size of a memory block that has been allocated with `mxCalloc`, `mxMalloc`, or `mxRealloc`.

If `size` is `0` and `ptr` is not `NULL` in C (`0` in Fortran), `mxRealloc` frees the memory pointed to by `ptr` and returns `NULL` in C (`0` in Fortran).

If `size` is greater than `0` and `ptr` is `NULL` in C (`0` in Fortran), `mxRealloc` behaves like `mxMalloc`, allocating a new block of memory of `size` bytes and returning a pointer to the new block.

Otherwise, `mxRealloc` changes the size of the memory block pointed to by `ptr` to `size` bytes. The contents of the reallocated memory are unchanged up to the smaller of the new and old sizes. The reallocated memory may be in a different location from the original memory, so

the returned pointer can be different from `ptr`. If the memory location changes, `mxRealloc` frees the original memory block pointed to by `ptr`.

In a stand-alone (non-MEX-file) application, if not enough memory is available to expand the block to the given size, `mxRealloc` returns `NULL` in C (`0` in Fortran) and leaves the original memory block unchanged. You must use `mxFree` to free the original memory block.

MATLAB maintains a list of all memory allocated by `mxRealloc`. By default, in a MEX-file, `mxRealloc` generates nonpersistent `mxRealloc` data. The memory management facility automatically deallocates the memory as soon as the MEX-file ends.

If you want the memory to persist after a MEX-file completes, call `mexMakeMemoryPersistent` after calling `mxRealloc`. If you write a MEX-file with persistent memory, be sure to register a `mexAtExit` function to free allocated memory when your MEX-file is cleared.

When you finish using the memory allocated by `mxRealloc`, call `mxFree`. `mxFree` deallocates the memory.

C Examples

See `mxsetnzmax.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mexAtExit`, `mexMakeArrayPersistent`, `mexMakeMemoryPersistent`, `mxCalloc`, `mxDestroyArray`, `mxFree`, `mxMalloc`

Purpose

Remove field from structure array

C Syntax

```
#include "matrix.h"
void mxRemoveField(mxArray pm, int fieldnumber);
```

Fortran Syntax

```
subroutine mxRemoveField(pm, fieldnumber)
mwPointer pm
integer*4 fieldnumber
```

Arguments

`pm`

Pointer to a structure `mxArray`

`fieldnumber`

The number of the field you want to remove. In C, to remove the first field, set `fieldnumber` to `0`; to remove the second field, set `fieldnumber` to `1`; and so on. In Fortran, to remove the first field, set `fieldnumber` to `1`; to remove the second field, set `fieldnumber` to `2`; and so on.

Description

Call `mxRemoveField` to remove a field from a structure array. If the field does not exist, nothing happens. This function does not destroy the field values. Use `mxDestroyArray` to destroy the actual field values.

Consider a MATLAB structure initialized to

```
patient.name = 'John Doe';
patient.billing = 127.00;
patient.test = [79 75 73; 180 178 177.5; 220 210 205];
```

In C, the field number `0` represents the field `name`; field number `1` represents field `billing`; field number `2` represents field `test`. In Fortran, the field number `1` represents the field `name`; field number `2` represents field `billing`; field number `3` represents field `test`.

See Also

`mxAddField`, `mxDestroyArray`, `mxGetFieldByNumber`

mxSetCell (C and Fortran)

Purpose

Set value of one cell of mxArray

C Syntax

```
#include "matrix.h"
void mxSetCell(mxArray *pm, mwIndex index, mxArray *value);
```

Fortran Syntax

```
mxSetCell(pm, index, value)
mwPointer pm, value
mwIndex index
```

Arguments

pm
: Pointer to a cell mxArray

index
: Index from the beginning of the mxArray. Specify the number of elements between the first cell of the mxArray and the cell you want to set. The easiest way to calculate index in a multidimensional cell array is to call mxCalcSingleSubscript.

value
: The new value of the cell. You can put any kind of mxArray into a cell. In fact, you can even put another cell mxArray into a cell.

Description

Call mxSetCell to put the designated value into a particular cell of a cell mxArray.

Note Inputs to a MEX-file are constant read-only mxArrays and should not be modified. Using mxSetCell* or mxSetField* to modify the cells or fields of an argument passed from MATLAB causes unpredictable results.

This function does not free any memory allocated for existing data that it displaces. To free existing memory, call mxFree on the pointer returned by mxGetCell before you call mxSetCell.

C Examples

See `phonebook.c` in the `refbook` subdirectory of the `examples` directory. For an additional example, see `mxcreatecellmatrix.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxCreateCellArray`, `mxCreateCellMatrix`, `mxGetCell`, `mxIsCell`, `mxFree`

mxSetClassName (C)

Purpose

Convert structure array to MATLAB object array

C Syntax

```
#include "matrix.h"
int mxSetClassName(mxArray *array_ptr, const char *classname);
```

Arguments

`array_ptr`
Pointer to an `mxArray` of class `mxSTRUCT_CLASS`

`classname`
The object class to which to convert `array_ptr`

Returns

`0` if successful, and nonzero otherwise. One cause of failure is that `array_ptr` is not a structure `mxArray`. Call `mxIsStruct` to determine whether `array_ptr` is a structure.

Description

`mxSetClassName` converts a structure array to an object array, to be saved subsequently to a MAT-file. The object is not registered or validated by MATLAB until it is loaded via the `LOAD` command. If the specified `classname` is an undefined class within MATLAB, `LOAD` converts the object back to a simple structure array.

See Also

`mxIsClass`, `mxGetClassID`

Purpose

Set pointer to data

C Syntax

```
#include "matrix.h"
void mxSetData(mxArray *pm, void *pr);
```

Fortran Syntax

```
mxSetData(pm, pr)
mwPointer pm, pr
```

Arguments

`pm`

Pointer to an `mxArray`

`pr`

Pointer to an array. Each element in the array contains the real component of a value. The array must be in dynamic memory; call `mxCalloc` to allocate this memory.

Description

`mxSetData` is similar to `mxSetPr`, except that in C, its second argument is a `void *`. Use this on numeric arrays with contents other than `double`.

This function does not free any memory allocated for existing data that it displaces. To free existing memory, call `mxFree` on the pointer returned by `mxGetData` before you call `mxSetData`.

See Also

`mxCalloc`, `mxFree`, `mxGetData`, `mxSetPr`

mxSetDimensions (C and Fortran)

Purpose

Modify number of dimensions and size of each dimension

C Syntax

```
#include "matrix.h"
int mxSetDimensions(mxArray *pm, const mwSize *dims,
  mwSize ndim);
```

Fortran Syntax

```
integer*4 mxSetDimensions(pm, dims, ndim)
mwPointer pm
mwSize dims, ndim
```

Arguments

`pm`
: Pointer to an `mxArray`

`dims`
: The dimensions array. Each element in the dimensions array contains the size of the array in that dimension. For example, in C, setting `dims[0]` to `5` and `dims[1]` to `7` establishes a 5-by-7 `mxArray`. In Fortran, setting `dims(1)` to `5` and `dims(2)` to `7` establishes a 5-by-7 `mxArray`. In most cases, there should be `ndim` elements in the `dims` array.

`ndim`
: The desired number of dimensions

Returns

`0` on success, and `1` on failure. `mxSetDimensions` allocates heap space to hold the input size array. So it is possible (though extremely unlikely) that increasing the number of dimensions can cause the system to run out of heap space.

Description

Call `mxSetDimensions` to reshape an existing `mxArray`. `mxSetDimensions` is similar to `mxSetM` and `mxSetN`; however, `mxSetDimensions` provides greater control for reshaping `mxArrays` that have more than two dimensions.

`mxSetDimensions` does not allocate or deallocate any space for the `pr` or `pi` arrays. Consequently, if your call to `mxSetDimensions` increases the number of elements in the `mxArray`, you must enlarge the `pr` (and `pi`, if it exists) arrays accordingly.

If your call to mxSetDimensions reduces the number of elements in the mxArray, you can optionally reduce the size of the pr and pi arrays using mxRealloc.

Any trailing singleton dimensions specified in the dims argument are automatically removed from the resulting array. For example, if ndim equals 5 and dims equals [4 1 7 1 1], the resulting array is given the dimensions 4-by-1-by-7.

C Examples

See mxsetdimensions.c in the mx subdirectory of the examples directory.

See Also

mxGetNumberOfDimensions, mxSetM, mxSetN, mxRealloc

mxSetField (C and Fortran)

Purpose

Set structure array field, given field name and index

C Syntax

```
#include "matrix.h"
void mxSetField(mxArray *pm, mwIndex index,
  const char *fieldname, mxArray *value);
```

Fortran Syntax

```
mxSetField(pm, index, fieldname, value)
mwPointer pm, value
mwIndex index
character*(*) fieldname
```

Arguments

`pm`

Pointer to a structure `mxArray`. Call `mxIsStruct` to determine whether `pm` points to a structure `mxArray`.

`index`

Index of the desired element. In C, the first element of an `mxArray` has an index of `0`, the second element has an index of `1`, and the last element has an index of `N-1`, where `N` is the total number of elements in the structure `mxArray`. In Fortran, the first element of an `mxArray` has an index of `1`, the second element has an index of `2`, and the last element has an index of `N`. See `mxCalcSingleSubscript` for details on calculating an index.

`fieldname`

The name of the field whose value you are assigning. Call `mxGetFieldNameByNumber` or `mxGetFieldNumber` to determine existing field names.

value

Pointer to the `mxArray` you are assigning.

Description

Use `mxSetField` to assign a `value` to the specified element of the specified field. In pseudo-C terminology, `mxSetField` performs the assignment

```
pm[index].fieldname = value;
```

Note Inputs to a MEX-file are constant read-only `mxArrays` and should not be modified. Using `mxSetCell*` or `mxSetField*` to modify the cells or fields of an argument passed from MATLAB causes unpredictable results.

In C, calling

```
mxSetField(pa, index, "fieldname", new_value_pa);
```

is equivalent to calling

```
field_num = mxGetFieldNumber(pa, "fieldname");
mxSetFieldByNumber(pa, index, field_num, new_value_pa);
```

In Fortran, calling

```
mxSetField(pm, index, 'fieldname', newvalue)
```

is equivalent to calling

```
fieldnum = mxGetFieldNumber(pm, 'fieldname')
mxSetFieldByNumber(pm, index, fieldnum, newvalue)
```

This function does not free any memory allocated for existing data that it displaces. To free existing memory, call `mxFree` on the pointer returned by `mxGetField` before you call `mxSetField`.

C Examples

See `mxcreatestructarray.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxCreateStructArray`, `mxCreateStructMatrix`, `mxGetField`, `mxGetFieldByNumber`, `mxGetFieldNameByNumber`, `mxGetFieldNumber`, `mxGetNumberOfFields`, `mxIsStruct`, `mxSetFieldByNumber`, `mxFree`

mxSetFieldByNumber (C and Fortran)

Purpose

Set structure array field, given field number and index

C Syntax

```
#include "matrix.h"
void mxSetFieldByNumber(mxArray *pm, mwIndex index,
  int fieldnumber, mxArray *value);
```

Fortran Syntax

```
mxSetFieldByNumber(pm, index, fieldnumber, value)
mwPointer pm, value
mwIndex index
integer*4 fieldnumber
```

Arguments

`pm`

Pointer to a structure `mxArray`. Call `mxIsStruct` to determine whether`pm` points to a structure `mxArray`.

`index`

The desired element. In C, the first element of an `mxArray` has an index of `0`, the second element has an index of `1`, and the last element has an index of `N-1`, where `N` is the total number of elements in the structure `mxArray`. In Fortran, the first element of an `mxArray` has an index of `1`, the second element has an index of `2`, and the last element has an index of `N`. See `mxCalcSingleSubscript` for details on calculating an index.

`fieldnumber`

The position of the field whose value you want to extract. In C, the first field within each element has a `fieldnumber` of `0`, the second field has a `fieldnumber` of `1`, and so on. The last field has a `fieldnumber` of `N-1`, where `N` is the number of fields. In Fortran, the first field within each element has a `fieldnumber` of `1`, the second field has a `fieldnumber` of `2`, and so on. The last field has a `fieldnumber` of `N`.

`value`

The value you are assigning.

Description

Use `mxSetFieldByNumber` to assign a `value` to the specified element of the specified field. `mxSetFieldByNumber` is almost identical to

mxSetField; however, the former takes a field number as its third argument and the latter takes a field name as its third argument.

Note Inputs to a MEX-file are constant read-only mxArrays and should not be modified. Using mxSetCell* or mxSetField* to modify the cells or fields of an argument passed from MATLAB causes unpredictable results.

In C, calling

```
mxSetField(pa, index, "field_name", new_value_pa);
```

is equivalent to calling

```
field_num = mxGetFieldNumber(pa, "field_name");
mxSetFieldByNumber(pa, index, field_num, new_value_pa);
```

In Fortran, calling

```
mxSetField(pm, index, 'fieldname', newvalue)
```

is equivalent to calling

```
fieldnum = mxGetFieldNumber(pm, 'fieldname')
mxSetFieldByNumber(pm, index, fieldnum, newvalue)
```

This function does not free any memory allocated for existing data that it displaces. To free existing memory, call mxFree on the pointer returned by mxGetFieldByNumber before you call mxSetFieldByNumber.

C Examples

See mxcreatestructarray.c in the mx subdirectory of the examples directory. For an additional example, see phonebook.c in the refbook subdirectory of the examples directory.

See Also

mxCreateStructArray, mxCreateStructMatrix, mxGetField, mxGetFieldByNumber, mxGetFieldNameByNumber, mxGetFieldNumber, mxGetNumberOfFields, mxIsStruct, mxSetField, mxFree

Purpose

Set imaginary data pointer for `mxArray`

C Syntax

```
#include "matrix.h"
void mxSetImagData(mxArray *pm, void *pi);
```

Fortran Syntax

```
mxSetImagData(pm, pi)
mwPointer pm, pi
```

Arguments

`pm`

Pointer to an `mxArray`

`pi`

Pointer to the first element of an array. Each element in the array contains the imaginary component of a value. The array must be in dynamic memory; call `mxCalloc` to allocate this dynamic memory. If `pi` points to static memory, memory errors will result when the array is destroyed.

Description

`mxSetImagData` is similar to `mxSetPi`, except that in C, its `pi` argument is a `void *`. Use this on numeric arrays with contents other than `double`.

This function does not free any memory allocated for existing data that it displaces. To free existing memory, call `mxFree` on the pointer returned by `mxGetImagData` before you call `mxSetImagData`.

C Examples

See `mxisfinite.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxCalloc`, `mxFree`, `mxGetImagData`, `mxSetPi`

mxSetIr (C and Fortran)

Purpose

Set ir array of sparse mxArray

C Syntax

```
#include "matrix.h"
void mxSetIr(mxArray *pm, mwIndex *ir);
```

Fortran Syntax

```
mxSetIr(pm, ir)
mwPointer pm, ir
```

Arguments

pm

Pointer to a sparse mxArray

ir

Pointer to the ir array. The ir array must be sorted in column-major order.

Description

Use mxSetIr to specify the ir array of a sparse mxArray. The ir array is an array of integers; the length of the ir array should equal the value of nzmax.

Each element in the ir array indicates a row (offset by 1) at which a nonzero element can be found. (The jc array is an index that indirectly specifies a column where nonzero elements can be found. See mxSetJc for more details on jc.)

For example, suppose you create a 7-by-3 sparse mxArray named Sparrow containing six nonzero elements by typing

```
Sparrow = zeros(7,3);
Sparrow(2,1) = 1;
Sparrow(5,1) = 1;
Sparrow(3,2) = 1;
Sparrow(2,3) = 2;
Sparrow(5,3) = 1;
Sparrow(6,3) = 1;
Sparrow = sparse(Sparrow);
```

The pr array holds the real data for the sparse matrix, which in Sparrow is the five 1s and the one 2. If there is any nonzero imaginary data, it is in a pi array.

Subscript	ir	pr	jc	Comments
(2,1)	1	1	0	Column 1; ir is 1 because row is 2.
(5,1)	4	1	2	Column 1; ir is 4 because row is 5.
(3,2)	2	1	3	Column 2; ir is 2 because row is 3.
(2,3)	1	2	6	Column 3; ir is 1 because row is 2.
(5,3)	4	1		Column 3; ir is 4 because row is 5.
(6,3)	5	1		Column 3; ir is 5 because row is 6.

Notice how each element of the ir array is always 1 less than the row of the corresponding nonzero element. For instance, the first nonzero element is in row 2; therefore, the first element in ir is 1 (that is, 2 – 1). The second nonzero element is in row 5; therefore, the second element in ir is 4 (5 – 1).

The ir array must be in column-major order. That means that the ir array must define the row positions in column 1 (if any) first, then the row positions in column 2 (if any) second, and so on through column N. Within each column, row position 1 must appear prior to row position 2, and so on.

mxSetIr does not sort the ir array for you; you must specify an ir array that is already sorted.

This function does not free any memory allocated for existing data that it displaces. To free existing memory, call mxFree on the pointer returned by mxGetIr before you call mxSetIr.

C Examples

See mxsetnzmax.c in the mx subdirectory of the examples directory. For an additional example, see explore.c in the mex subdirectory of the examples directory.

See Also mxCreateSparse, mxGetIr, mxGetJc, mxSetJc, mxFree

Purpose

Set jc array of sparse mxArray

C Syntax

```
#include "matrix.h"
void mxSetJc(mxArray *pm, mwIndex *jc);
```

Fortran Syntax

```
mxSetJc(pm, jc)
mwPointer pm, jc
```

Arguments

pm
: Pointer to a sparse mxArray

jc
: Pointer to the jc array

Description

Use mxSetJc to specify a new jc array for a sparse mxArray. The jc array is an integer array having n+1 elements, where n is the number of columns in the sparse mxArray.

If the jth column of the sparse mxArray has any nonzero elements:

- jc[j] is the index in ir, pr, and pi (if it exists) of the first nonzero element in the jth column.
- jc[j+1]-1 is the index of the last nonzero element in the jth column.

The number of nonzero elements in the jth column of the sparse mxArray is

```
jc[j+1] - jc[j];
```

For the jth column of the sparse mxArray, jc[j] is the total number of nonzero elements in all preceding columns. The last element of the jc array, jc[number of columns], is equal to nnz, which is the number of nonzero elements in the entire sparse mxArray.

For example, consider a 7-by-3 sparse mxArray named Sparrow containing six nonzero elements, created by typing

```
Sparrow = zeros(7,3);
```

```
Sparrow(2,1) = 1;
Sparrow(5,1) = 1;
Sparrow(3,2) = 1;
Sparrow(2,3) = 2;
Sparrow(5,3) = 1;
Sparrow(6,3) = 1;
Sparrow = sparse(Sparrow);
```

The contents of the `ir`, `jc`, and `pr` arrays are listed in this table.

Subscript	ir	pr	jc	Comment
(2,1)	1	1	0	Column 1 contains two nonzero elements, with rows designated by `ir[0]` and `ir[1]`
(5,1)	4	1	2	Column 2 contains one nonzero element, with row designated by `ir[2]`
(3,2)	2	1	3	Column 3 contains three nonzero elements, with rows designated by `ir[3]`,`ir[4]`, and `ir[5]`
(2,3)	1	2	6	There are six nonzero elements in all.
(5,3)	4	1		
(6,3)	5	1		

As an example of a much sparser `mxArray`, consider a 1,000-by-8 sparse `mxArray` named `Spacious` containing only three nonzero elements. The `ir`, `pr`, and `jc` arrays contain the values listed in this table.

Subscript	ir	pr	jc	Comment
(73,2)	72	1	0	Column 1 contains no nonzero elements.
(50,3)	49	1	0	Column 2 contains one nonzero element, with row designated by `ir[0]`.
(64,5)	63	1	1	Column 3 contains one nonzero element, with row designated by `ir[1]`.
			2	Column 4 contains no nonzero elements.
			2	Column 5 contains one nonzero element, with row designated by `ir[2]`.
			3	Column 6 contains no nonzero elements.
			3	Column 7 contains no nonzero elements.
			3	Column 8 contains no nonzero elements.
			3	There are three nonzero elements in all.

This function does not free any memory allocated for existing data that it displaces. To free existing memory, call `mxFree` on the pointer returned by `mxGetJc` before you call `mxSetJc`.

C Examples

See `mxsetdimensions.c` in the `mx` subdirectory of the `examples` directory. For an additional example, see `explore.c` in the `mex` subdirectory of the `examples` directory.

mxSetM (C and Fortran)

Purpose

Set number of rows in mxArray

C Syntax

```
#include "matrix.h"
void mxSetM(mxArray *pm, mwSize m);
```

Fortran Syntax

```
mxSetM(pm, m)
mwPointer pm
mwSize m
```

Arguments

pm
: Pointer to an mxArray

m
: The desired number of rows

Description

Call mxSetM to set the number of rows in the specified mxArray. The term *rows* means the first dimension of an mxArray, regardless of the number of dimensions. Call mxSetN to set the number of columns.

You typically use mxSetM to change the shape of an existing mxArray. Note that mxSetM does not allocate or deallocate any space for the pr, pi, ir, or jc arrays. Consequently, if your calls to mxSetM and mxSetN increase the number of elements in the mxArray, you must enlarge the pr, pi, ir, and/or jc arrays. Call mxRealloc to enlarge them.

If your calls to mxSetM and mxSetN end up reducing the number of elements in the mxArray, you may want to reduce the sizes of the pr, pi, ir, and/or jc arrays in order to use heap space more efficiently. However, reducing the size is not mandatory.

C Examples

See mxsetdimensions.c in the mx subdirectory of the examples directory. For an additional example, see sincall.c in the refbook subdirectory of the examples directory.

See Also

mxGetM, mxGetN, mxSetN

Purpose

Set number of columns in mxArray

C Syntax

```
#include "matrix.h"
void mxSetN(mxArray *pm, mwSize n);
```

Fortran Syntax

```
mxSetN(pm, n)
mwPointer pm
mwSize n
```

Arguments

pm
: Pointer to an mxArray

n
: The desired number of columns

Description

Call mxSetN to set the number of columns in the specified mxArray. The term *columns* always means the second dimension of a matrix. Calling mxSetN forces an mxArray to have two dimensions. For example, if pm points to an mxArray having three dimensions, calling mxSetN reduces the mxArray to two dimensions.

You typically use mxSetN to change the shape of an existing mxArray. Note that mxSetN does not allocate or deallocate any space for the pr, pi, ir, or jc arrays. Consequently, if your calls to mxSetN and mxSetM increase the number of elements in the mxArray, you must enlarge the pr, pi, ir, and/or jc arrays.

If your calls to mxSetM and mxSetN end up reducing the number of elements in the mxArray, you may want to reduce the sizes of the pr, pi, ir, and/or jc arrays in order to use heap space more efficiently. However, reducing the size is not mandatory.

C Examples

See mxsetdimensions.c in the mx subdirectory of the examples directory. For an additional example, see sincall.c in the refbook subdirectory of the examples directory.

See Also

mxGetM, mxGetN, mxSetM

mxSetNzmax (C and Fortran)

Purpose

Set storage space for nonzero elements

C Syntax

```
#include "matrix.h"
void mxSetNzmax(mxArray *pm, mwSize nzmax);
```

Fortran Syntax

```
mxSetNzmax(pm, nzmax)
mwPointer pm
mwSize nzmax
```

Arguments

`pm`

Pointer to a sparse `mxArray`.

`nzmax`

The number of elements that `mxCreateSparse` should allocate to hold the arrays pointed to by `ir`, `pr`, and `pi` (if it exists). Set `nzmax` greater than or equal to the number of nonzero elements in the `mxArray`, but set it to be less than or equal to the number of rows times the number of columns. If you specify an `nzmax` value of `0`, `mxSetNzmax` sets the value of `nzmax` to `1`.

Description

Use `mxSetNzmax` to assign a new value to the `nzmax` field of the specified sparse `mxArray`. The `nzmax` field holds the maximum possible number of nonzero elements in the sparse `mxArray`.

The number of elements in the `ir`, `pr`, and `pi` (if it exists) arrays must be equal to `nzmax`. Therefore, after calling `mxSetNzmax`, you must change the size of the `ir`, `pr`, and `pi` arrays. To change the size of one of these arrays:

1. Call `mxRealloc` with a pointer to the array, setting the size to the new value of `nzmax`.
2. Call the appropriate `mxSet` routine (`mxSetIr`, `mxSetPr`, or `mxSetPi`) to establish the new memory area as the current one.

Two ways of determining how big you should make `nzmax` are

- Set `nzmax` equal to or slightly greater than the number of nonzero elements in a sparse `mxArray`. This approach conserves precious heap space.
- Make `nzmax` equal to the total number of elements in an `mxArray`. This approach eliminates (or, at least reduces) expensive reallocations.

C Examples

See `mxsetnzmax.c` in the `mx` subdirectory of the `examples` directory.

See Also

`mxGetNzmax`, `mxRealloc`

mxSetPi (C and Fortran)

Purpose

Set new imaginary data for mxArray

C Syntax

```
#include "matrix.h"
void mxSetPi(mxArray *pm, double *pi);
```

Fortran Syntax

```
mxSetPi(pm, pi)
mwPointer pm, pi
```

Arguments

pm

Pointer to a full (nonsparse) mxArray

pi

Pointer to the first element of an array. Each element in the array contains the imaginary component of a value. The array must be in dynamic memory; call mxCalloc to allocate this dynamic memory. If pi points to static memory, memory leaks and other memory errors may result.

Description

Use mxSetPi to set the imaginary data of the specified mxArray.

Most mxCreate* functions optionally allocate heap space to hold imaginary data. If you tell an mxCreate* function to allocate heap space—for example, by setting the ComplexFlag to mxCOMPLEX in C (1 in Fortran) or by setting pi to a non-NULL value in C (a nonzero value in Fortran)—you do not ordinarily use mxSetPi to initialize the created mxArray's imaginary elements. Rather, you call mxSetPi to replace the initial imaginary values with new ones.

This function does not free any memory allocated for existing data that it displaces. To free existing memory, call mxFree on the pointer returned by mxGetPi before you call mxSetPi.

C Examples

See mxisfinite.c and mxsetnzmax.c in the mx subdirectory of the examples directory.

See Also

mxGetPi, mxGetPr, mxSetImagData, mxSetPr, mxFree

Purpose

Set new real data for mxArray

C Syntax

```
#include "matrix.h"
void mxSetPr(mxArray *pm, double *pr);
```

Fortran Syntax

```
mxSetPr(pm, pr)
mwPointer pm, pr
```

Arguments

pm

Pointer to a full (nonsparse) mxArray

pr

Pointer to the first element of an array. Each element in the array contains the real component of a value. The array must be in dynamic memory; call mxCalloc to allocate this dynamic memory. If pr points to static memory, memory leaks and other memory errors can result.

Description

Use mxSetPr to set the real data of the specified mxArray.

All mxCreate* calls allocate heap space to hold real data. Therefore, you do not ordinarily use mxSetPr to initialize the real elements of a freshly created mxArray. Rather, you call mxSetPr to replace the initial real values with new ones.

This function does not free any memory allocated for existing data that it displaces. To free existing memory, call mxFree on the pointer returned by mxGetPr before you call mxSetPr.

C Examples

See mxsetnzmax.c in the mx subdirectory of the examples directory.

1

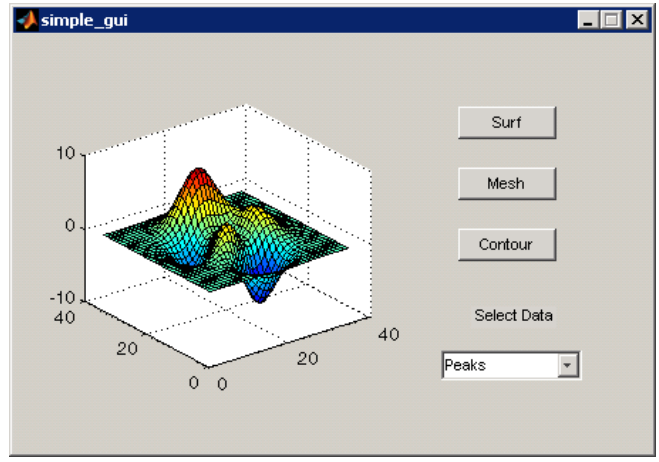
About GUIs in MATLAB

What Is a GUI?

A graphical user interface (GUI) is a graphical display that contains devices, or components, that enable a user to perform interactive tasks. To perform these tasks, the user of the GUI does not have to create a script or type commands at the command line. Often, the user does not have to know the details of the task at hand.

The GUI components can be menus, toolbars, push buttons, radio buttons, list boxes, and sliders—just to name a few. In MATLAB, a GUI can also display data in tabular form or as plots, and can group related components.

The following figure illustrates a simple GUI.



The GUI contains

- An axes component
- A pop-up menu listing three data sets that correspond to MATLAB functions: `peaks`, `membrane`, and `sinc`
- A static text component to label the pop-up menu
- Three buttons that provide different kinds of plots: surface, mesh, and contour

When you click a push button, the axes component displays the selected data set using the specified plot.

How Does a GUI Work?

Each component, and the GUI itself, is associated with one or more user-written routines known as callbacks. The execution of each callback is triggered by a particular user action such as a button push, mouse click, selection of a menu item, or the cursor passing over a component. You, as the creator of the GUI, provide these callbacks.

In the GUI described in “What Is a GUI?” on page 1-2, the user selects a data set from the pop-up menu, then clicks one of the plot type buttons. Clicking the button triggers the execution of a callback that plots the selected data in the axes.

This kind of programming is often referred to as event-driven programming. The event in the example is a button click. In event-driven programming, callback execution is asynchronous, controlled by events external to the software. In the case of MATLAB GUIs, these events usually take the form of user interactions with the GUI.

The writer of a callback has no control over the sequence of events that leads to its execution or, when the callback does execute, what other callbacks might be running simultaneously.

Where Do I Start?

First you have to design your GUI. You have to decide what you want it to do, how you want the user to interact with it, and what components you need. “Designing a GUI” on page 6-3 lists references that may be of help.

Next, you must decide what technique you want to use to create your GUI. MATLAB enables you to create GUIs programmatically or with GUIDE, an interactive GUI builder. It also provides functions that simplify the creation of standard dialog boxes. The technique you choose depends on your experience, your preferences, and the kind of GUI you want to create. This table outlines some possibilities.

GUI	Technique
Dialog box	MATLAB provides a selection of standard dialog boxes that you can create with a single function call. For links to these functions, see “Predefined Dialog Boxes” in the MATLAB Function Reference documentation.
GUI containing just a few components	It is often simpler to create GUIs that contain only a few components programmatically. Each component can be fully defined with a single function call.
Moderately complex GUIs	GUIDE simplifies the creation of such GUIs.
Complex GUIs with many components, and GUIs that require interaction with other GUIs	Creating such GUIs programmatically lets you control exact placement of the components and provides reproducibility.

Once you have decided which technique you want to use, you can continue to learn about creating GUIs in MATLAB by following the examples in these topics:

- Chapter 2, “Creating a Simple GUI with GUIDE”
- Chapter 3, “Creating a Simple GUI Programmatically”

2

Creating a Simple GUI with GUIDE

GUIDE: A Brief Introduction

In this section...

Laying Out a GUI

GUIDE, the MATLAB graphical user interface development environment, provides a set of tools for creating graphical user interfaces (GUIs). These tools simplify the process of laying out and programming GUIs.

The GUIDE Layout Editor enables you to populate a GUI by clicking and dragging GUI components — such as buttons, text fields, sliders, axes, and so on — into the layout area. It also enables you to create menus and context menus for the GUI.

Other tools, which are accessible from the Layout Editor, enable you to size the GUI, modify component look and feel, align components, set tab order, view a hierarchical list of the component objects, and set GUI options.

The following topic, "Laying Out a Simple GUI" on page 2-5, uses some of these tools to show you the basics of laying out a GUI. "GUIDE Tools Summary" on page 4-3 describes the tools.

Programming a GUI

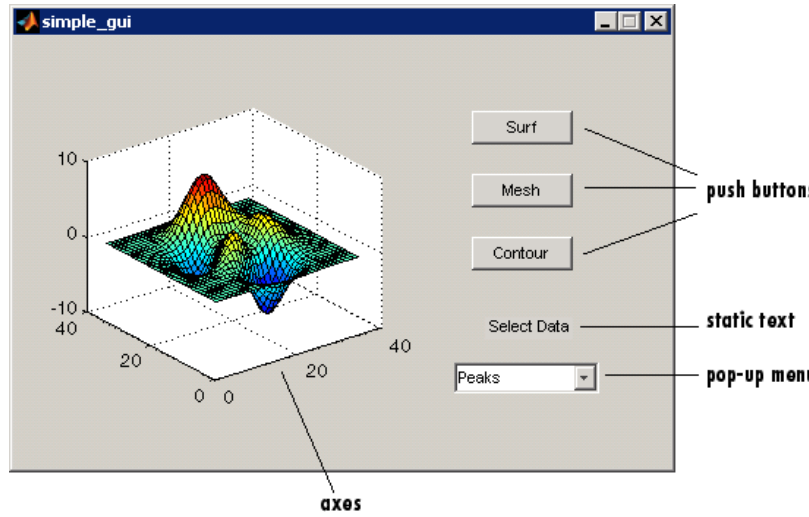
When you save your GUI layout, GUIDE automatically generates an M-file that you can use to control how the GUI works. This M-file provides code to initialize the GUI and contains a framework for the GUI callbacks—the routines that execute in response to user-generated events such as a mouse click. Using the M-file editor, you can add code to the callbacks to perform the functions you want. "Programming a Simple GUI" on page 2-21 shows you what code to add to the example M-file to make the GUI work.

Example: Simple GUI

In this section...

Simple GUI Overview

This section shows you how to use GUIDE to create the graphical user interface (GUI) shown in the following figure.



The GUI contains

- An axes component
- A pop-up menu listing three different data sets that correspond to MATLAB functions: `peaks`, `membrane`, and `sinc`
- A static text component to label the pop-up menu
- Three push buttons, each of which provides a different kind of plot: surface, mesh, and contour

To use the GUI, select a data set from the pop-up menu, then click one of the plot-type buttons. Clicking the button triggers the execution of a callback that plots the selected data in the axes.

Subsequent topics, starting with “Laying Out a Simple GUI” on page 2-5, guide you through the steps to create this GUI. We recommend that you create the GUI for yourself, as this is the best way to learn how to use GUIDE.

View Completed Layout and Its GUI M-File

If you are reading this in the MATLAB Help browser, you can click the following links to display the GUIDE Layout Editor and the MATLAB Editor with a completed version of this example.

Note The following links execute MATLAB commands and are designed to work within the MATLAB Help browser. If you are reading this online or in PDF, you should go to the corresponding section in the MATLAB Help Browser to use the links.

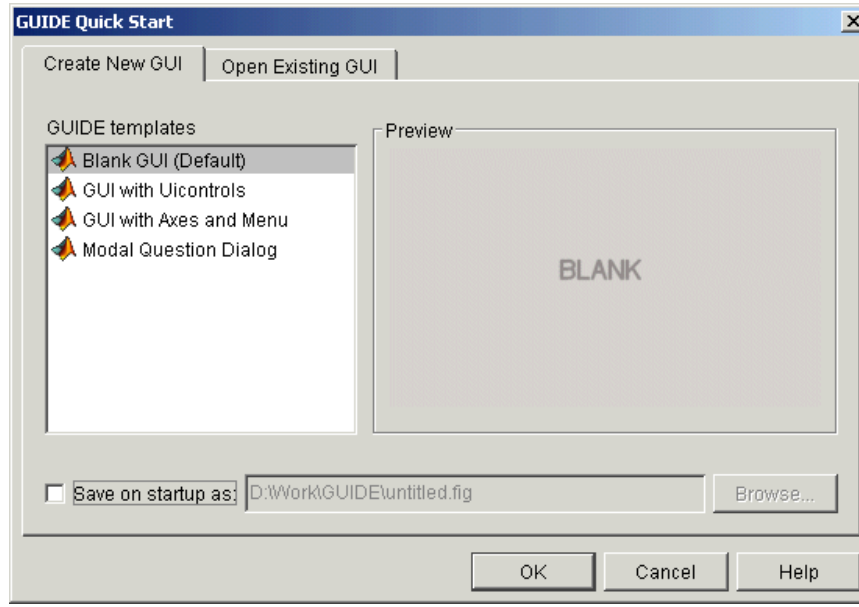
- Click here to display this GUI in the Layout Editor.
- Click here to display the GUI M-file in the MATLAB Editor.

Laying Out a Simple GUI

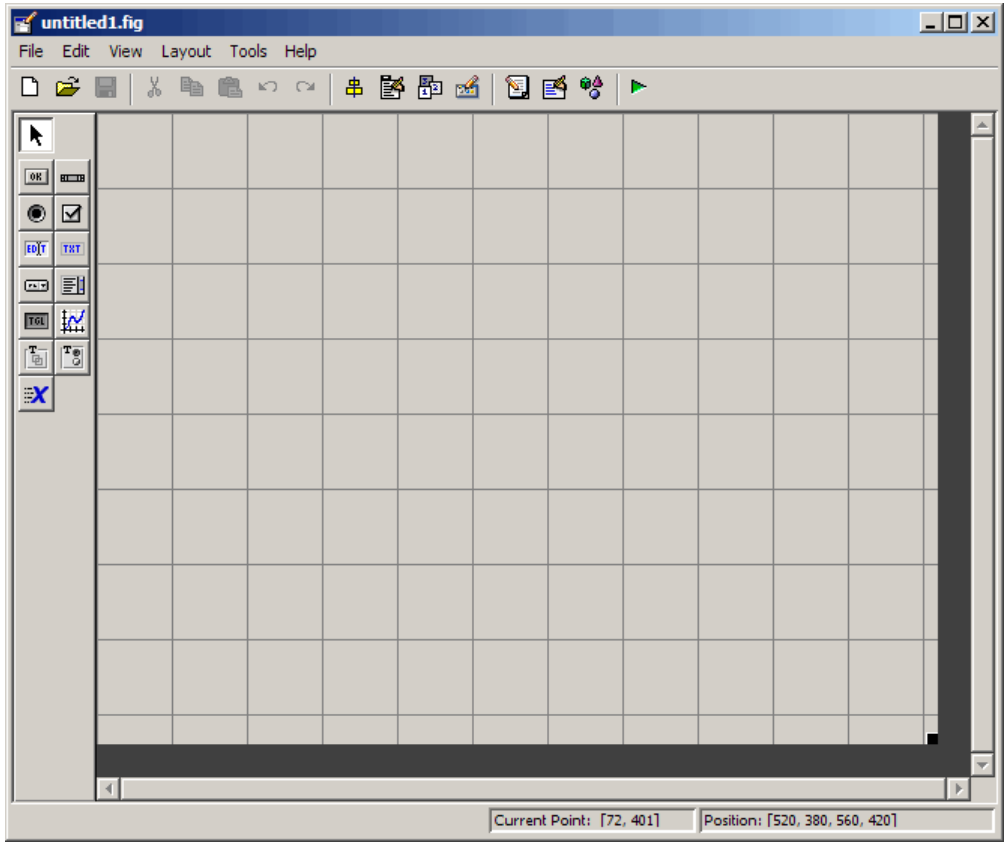
In this section...

Opening a New GUI in the Layout Editor

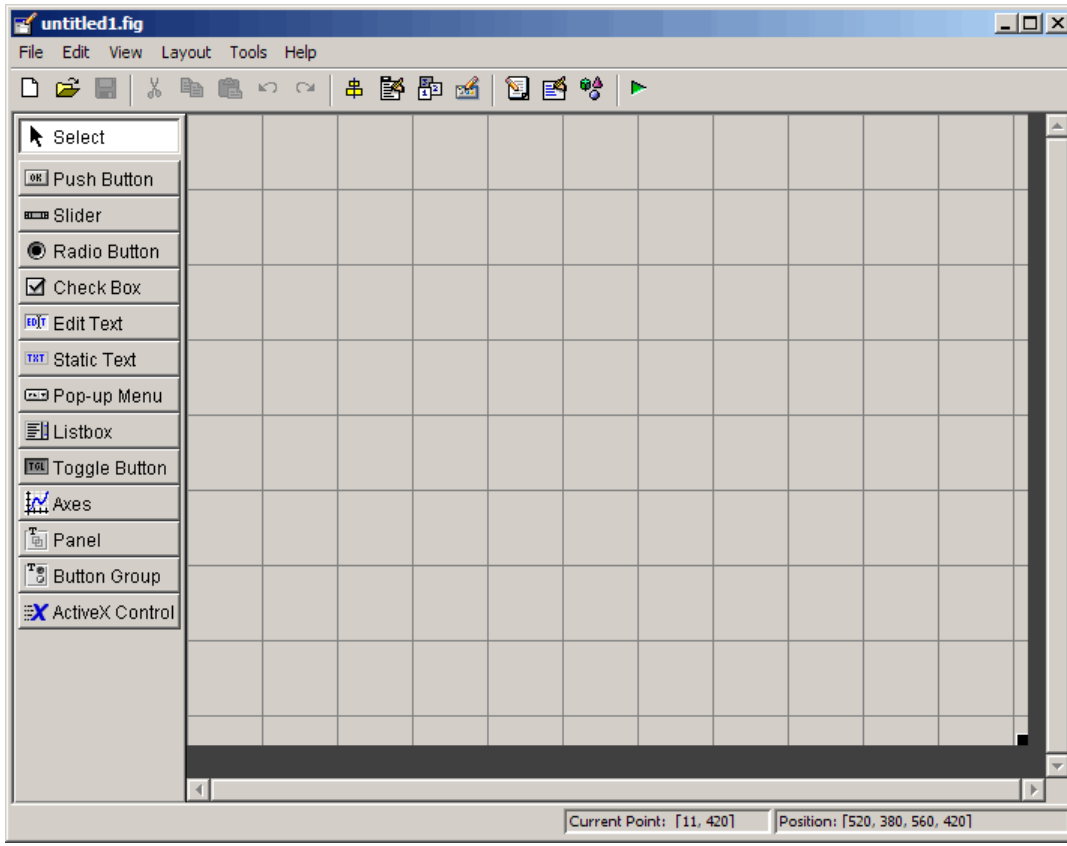
1 Start GUIDE by typing `guide` at the MATLAB prompt. This displays the GUIDE Quick Start dialog shown in the following figure.



2 In the Quick Start dialog, select the **Blank GUI (Default)** template. Click **OK** to display the blank GUI in the Layout Editor, as shown in the following figure.

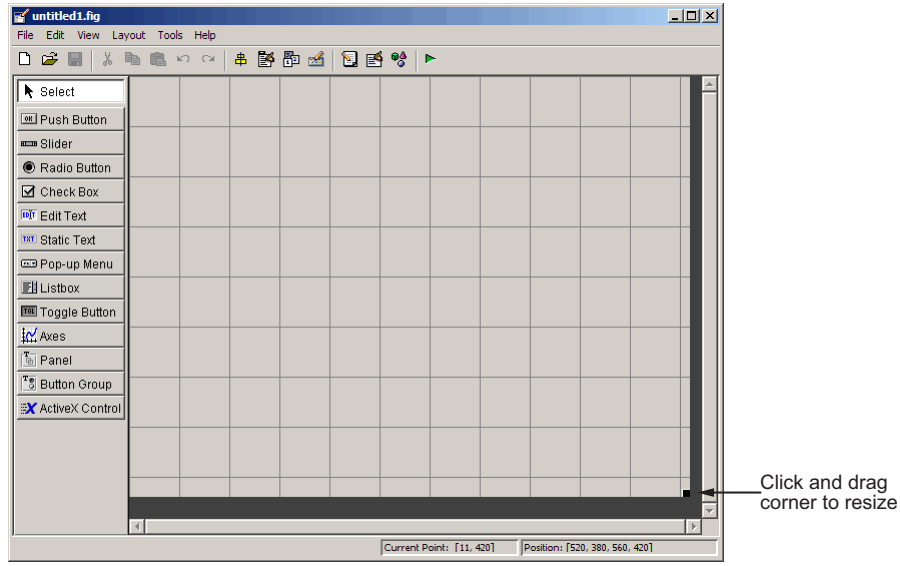


3 Display the names of the GUI components in the component palette. Select **Preferences** from the MATLAB **File** menu. Then select **GUIDE > Show names in component palette**, and click **OK**. The Layout Editor then appears as shown in the following figure.



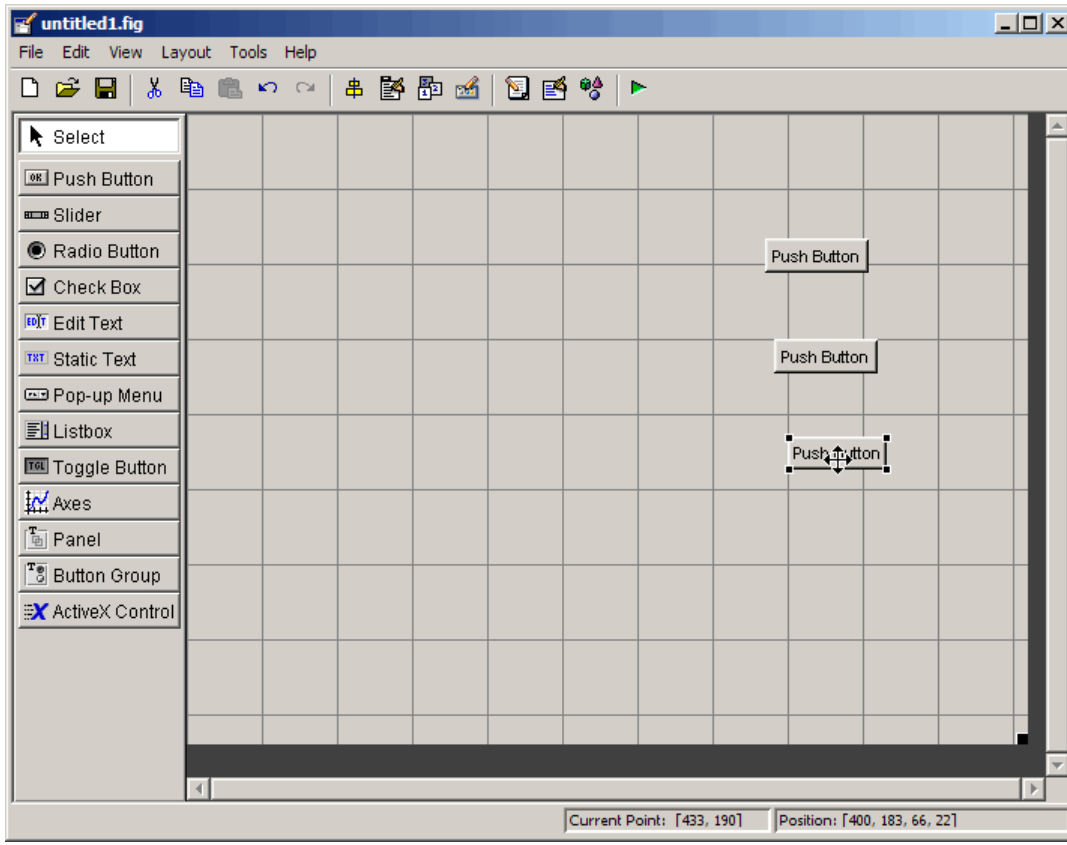
Setting the GUI Figure Size

Set the size of the GUI by resizing the grid area in the Layout Editor. Click the lower-right corner and drag it until the GUI is approximately 3 inches high and 4 inches wide. If necessary, make the window larger.



Adding the Components

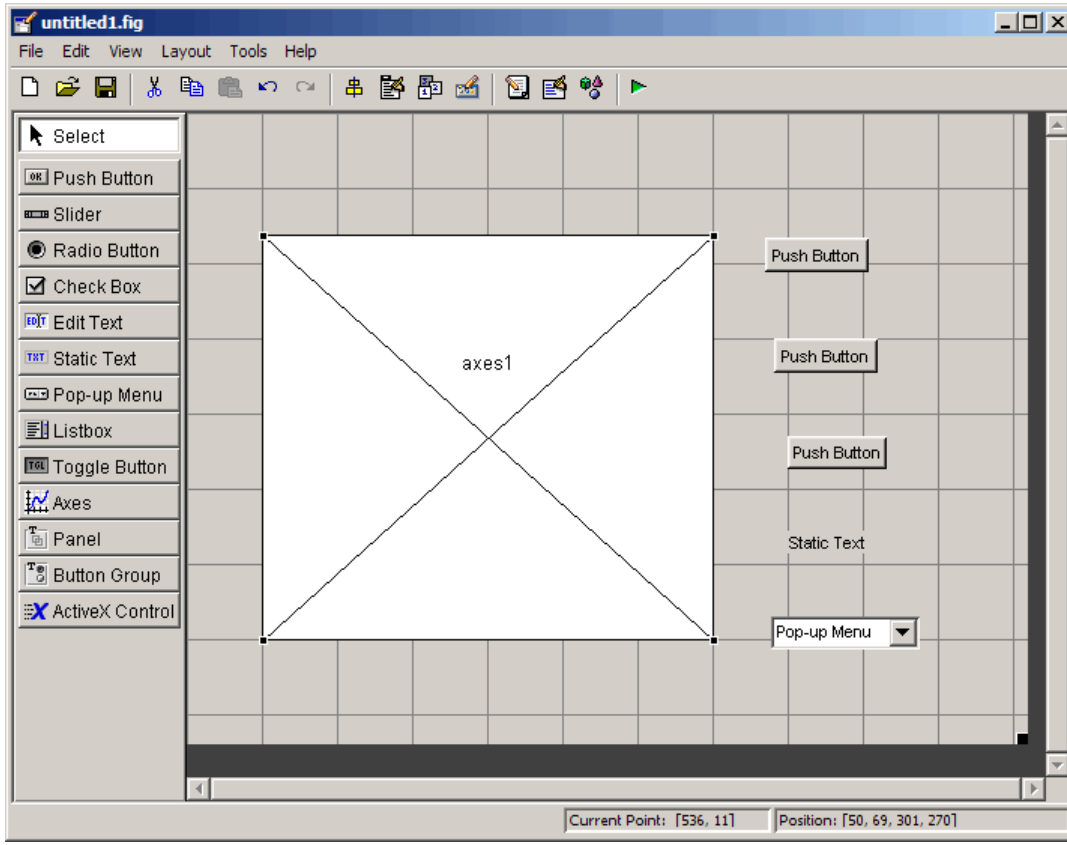
1 Add the three push buttons to the GUI. For each push button, select the push button from the component palette at the left of the Layout Editor and drag it into the layout area. Position them approximately as shown in the following figure.



2 Add the remaining components to the GUI.

- A static text area
- A pop-up menu
- An axes

Arrange the components as shown in the following figure. Resize the axes component to approximately 2-by-2 inches.



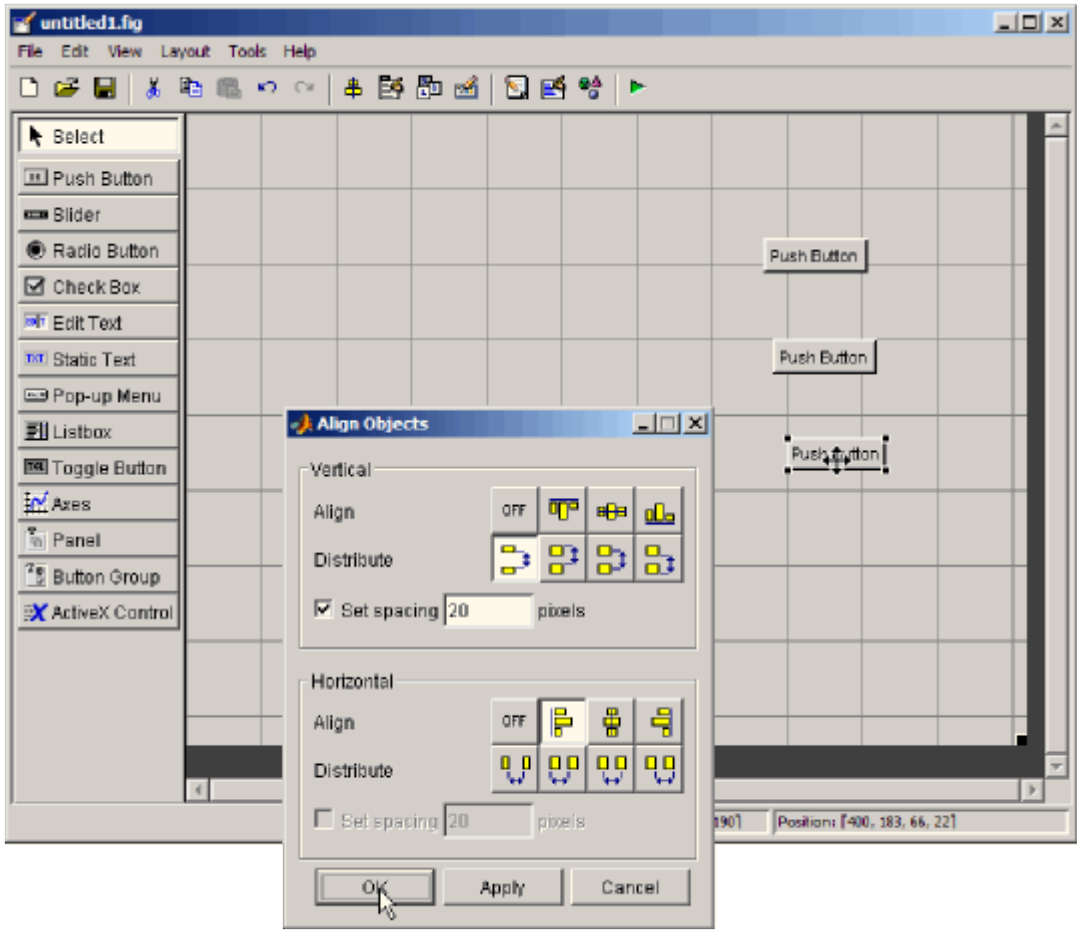
Aligning the Components

You can use the Alignment Tool to align components with respect to one another, if they have the same parent. To align the three push buttons:

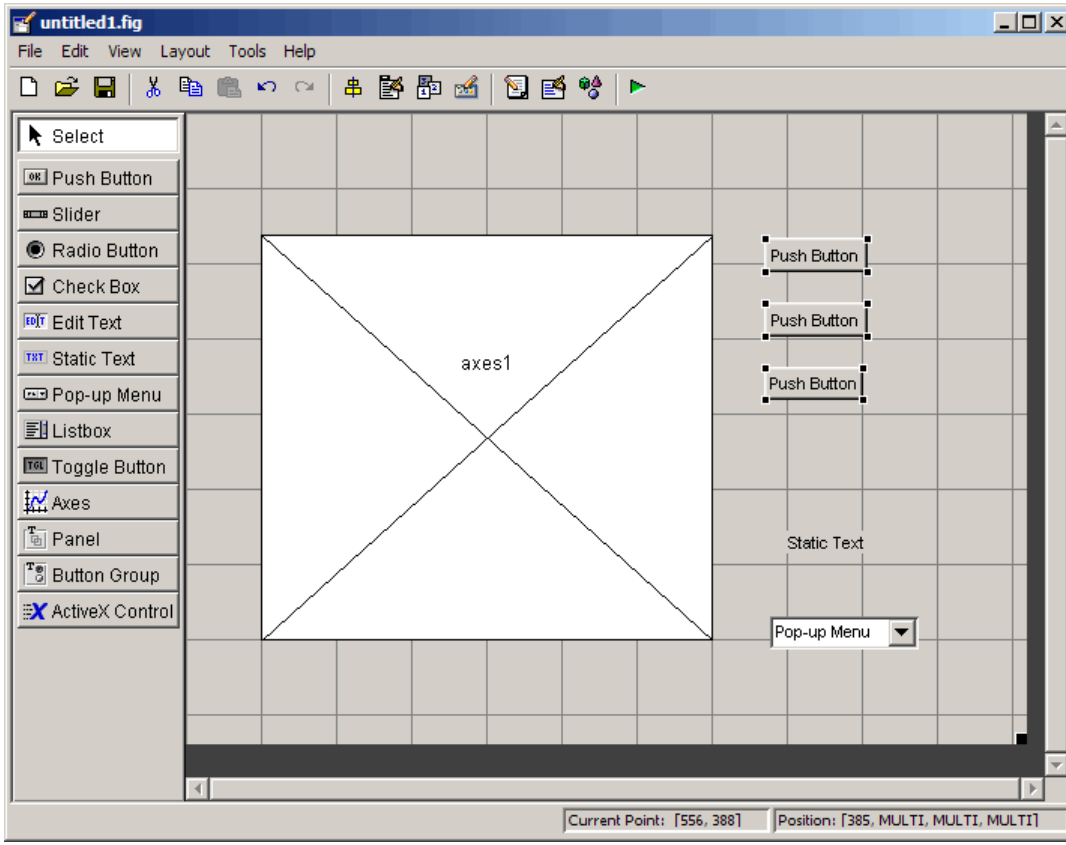
1. Select all three push buttons by pressing **Ctrl** and clicking them.
2. Select **Align Objects** from the **Tools** menu to display the Alignment Tool.

3 Make these settings in the Alignment Tool, as shown in the following figure:

- 20 pixels spacing between push buttons in the vertical direction.
- Left-aligned in the horizontal direction.



4 Click **OK**. Your GUI now looks like this in the Layout Editor.

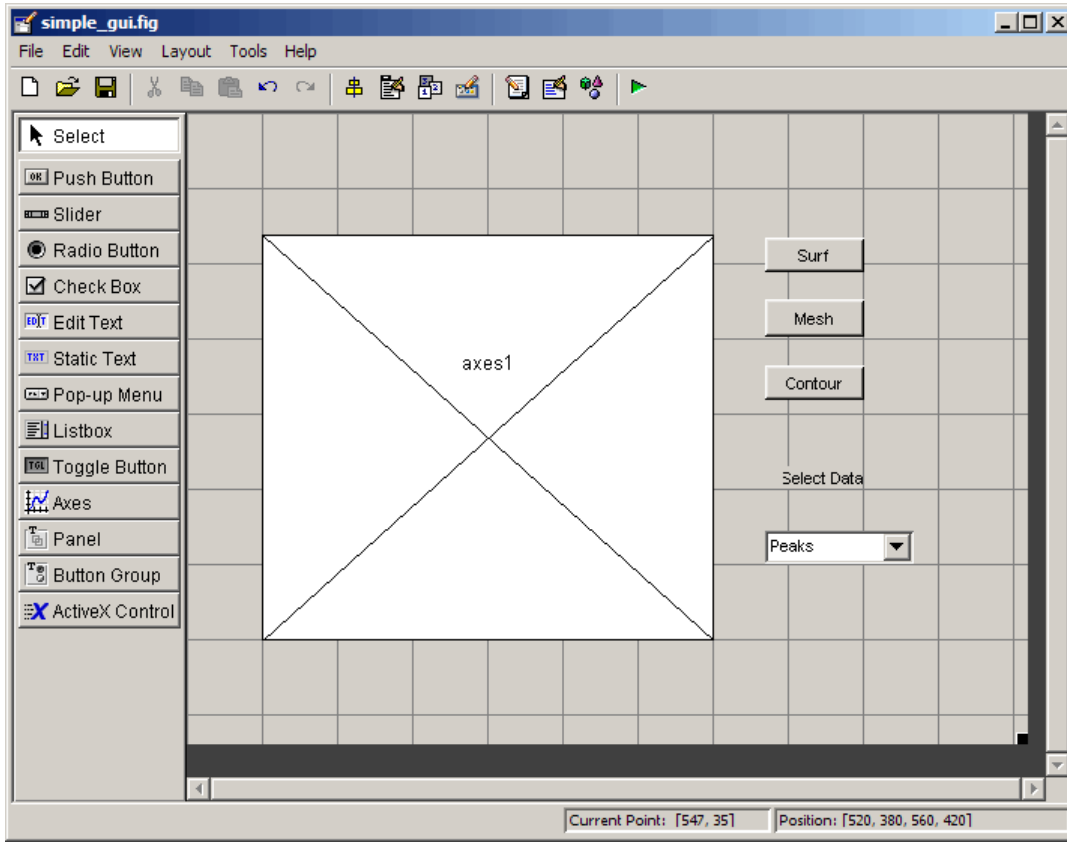


Adding Text to the Components

Although the push buttons, pop-up menu, and static text show some text in the Layout Editor, the text is not appropriate to the GUI being created. This topic shows you how to modify the default text.

- "Labeling the Push Buttons" on page 2-13
- "Entering Pop-Up Menu Items" on page 2-15
- "Modifying the Static Text" on page 2-17

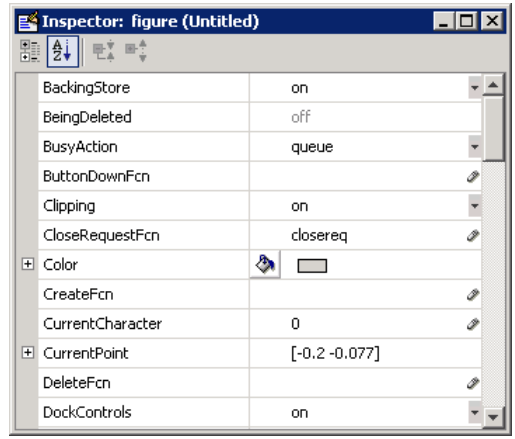
After you have added the appropriate text, the GUI will look like this in the Layout Editor.



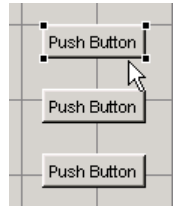
Labeling the Push Buttons

Each of the three push buttons lets the user choose a plot type: surf, mesh, and contour. This topic shows you how to label the buttons with those choices.

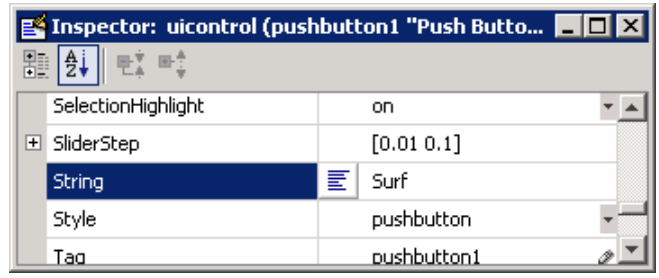
1 Select **Property Inspector** from the **View** menu.



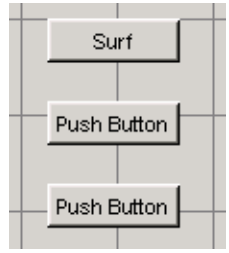
2 In the layout area, select the top push button by clicking it.



3 In the Property Inspector, select the `String` property and then replace the existing value with the word `Surf`.



4 Click outside the `String` field. The push button label changes to **Surf**.



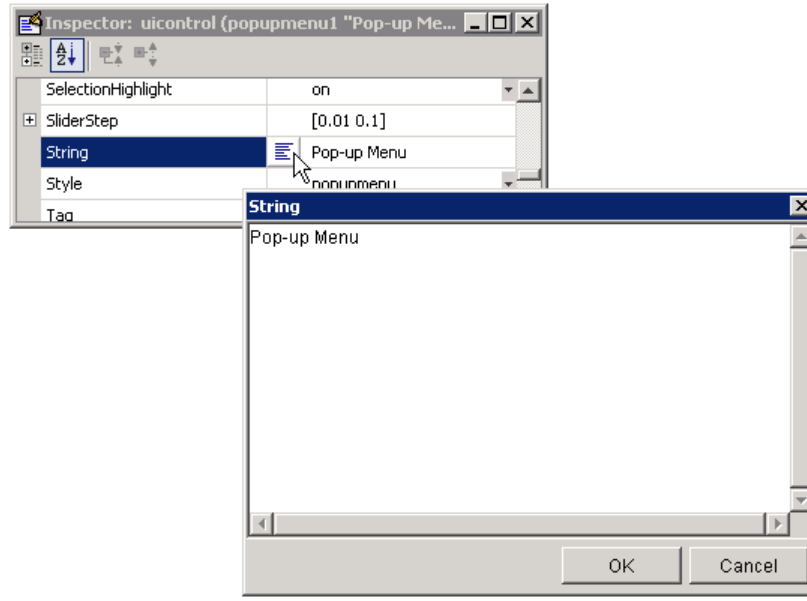
5 Select each of the remaining push buttons in turn and repeat steps 3 and 4. Label the middle push button **Mesh**, and the bottom button **Contour**.

Entering Pop-Up Menu Items

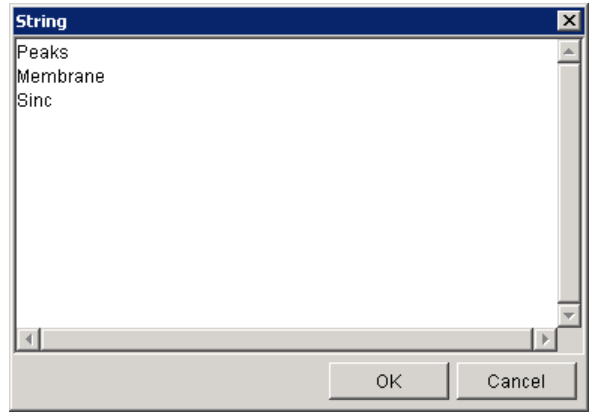
The pop-up menu provides a choice of three data sets: peaks, membrane, and sinc. These data sets correspond to MATLAB functions of the same name. This topic shows you how to list those data sets as choices in the pop-menu.

1 In the layout area, select the pop-up menu by clicking it.

2 In the Property Inspector, click the button next to `String`. The String dialog box displays.



3 Replace the existing text with the names of the three data sets: Peaks, Membrane, and Sinc. Press **Enter** to move to the next line.



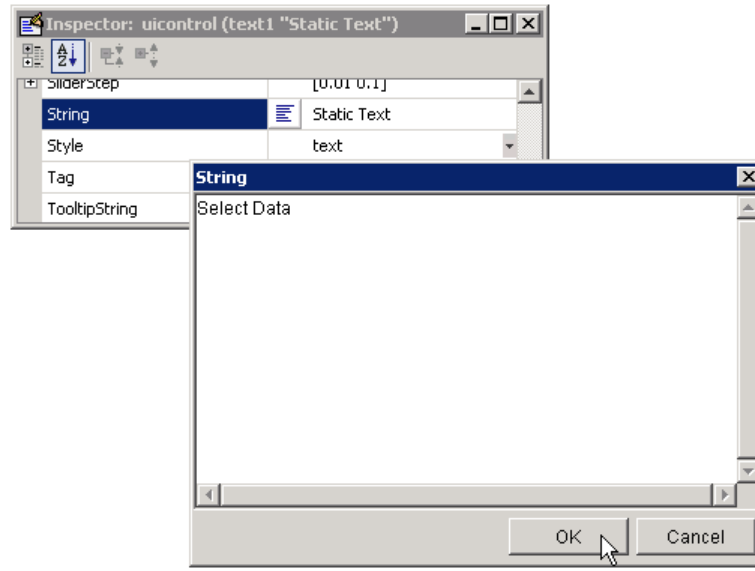
4 When you are done, click **OK**. The first item in your list, `Peaks`, appears in the pop-up menu in the layout area.

Modifying the Static Text

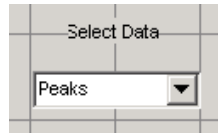
In this GUI, the static text serves as a label for the pop-up menu. The user cannot change this text. This topic shows you how to change the static text to read `Select Data`.

1 In the layout area, select the static text by clicking it.

2 In the Property Inspector, click the button next to `String`. In the String dialog box that displays, replace the existing text with the phrase `Select Data`.

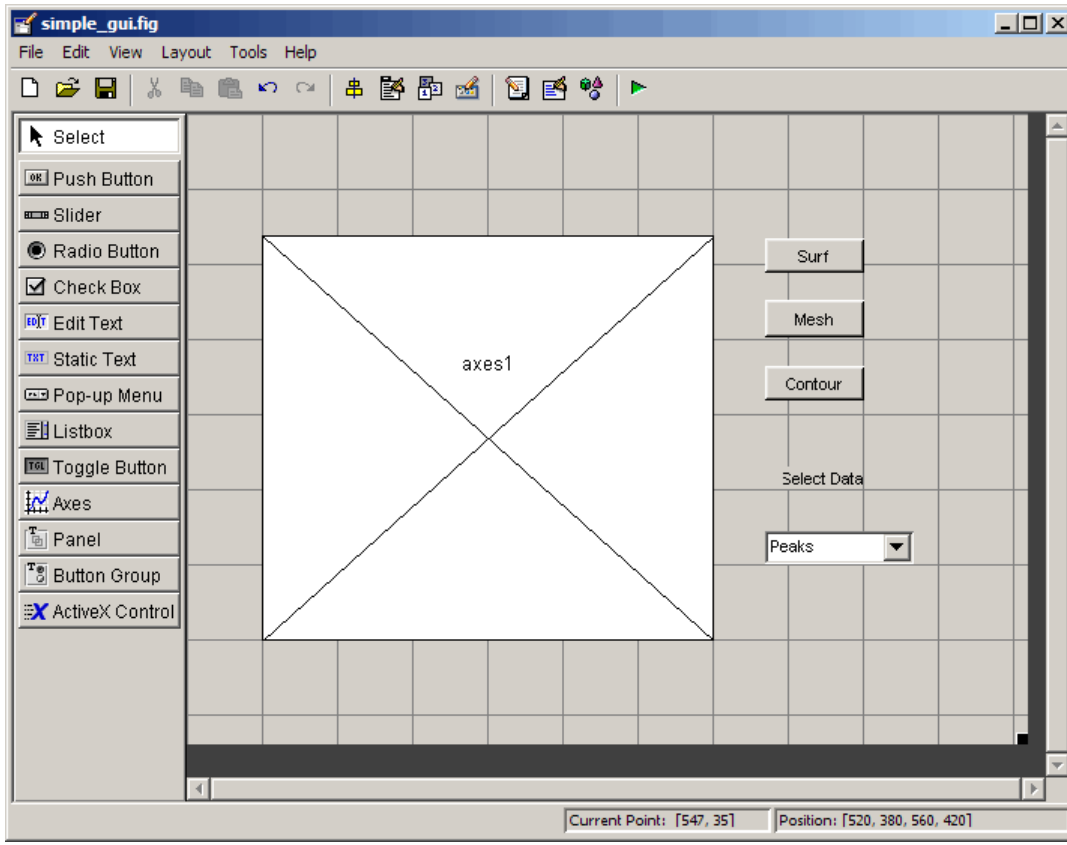


3 Click **OK**. The phrase `Select Data` appears in the static text component above the pop-up menu.



Completed Layout

In the Layout Editor, your GUI now looks like this and the next step is to save the layout. The next topic, “Saving the GUI Layout” on page 2-19, tells you how to do this.

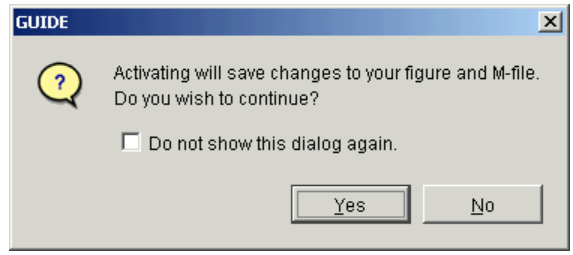


Saving the GUI Layout

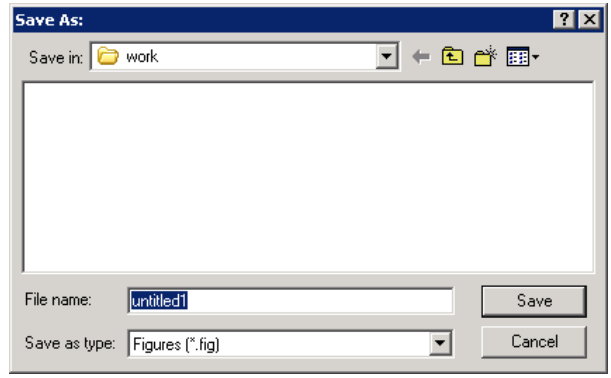
When you save a GUI, GUIDE creates two files, a FIG-file and an M-file. The FIG-file, with extension `.fig`, is a binary file that contains a description of the layout. The M-file, with extension `.m`, contains the code that controls the GUI.

1. Save and activate your GUI by selecting **Run** from the **Tools** menu.

2. GUIDE displays the following dialog box. Click **Yes** to continue.



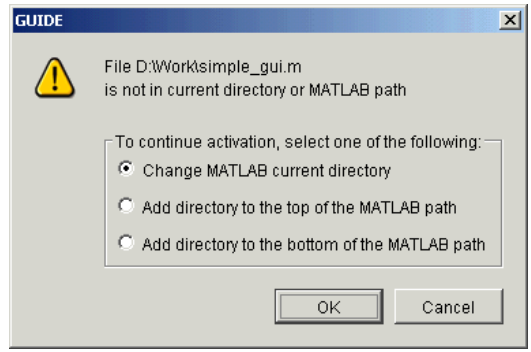
3. GUIDE opens a **Save As** dialog box in your current directory and prompts you for a FIG-file name.



4. Browse to any directory for which you have write privileges, and then enter the filename `simple_gui` for the FIG-file. GUIDE saves both the FIG-file and the M-file using this name.

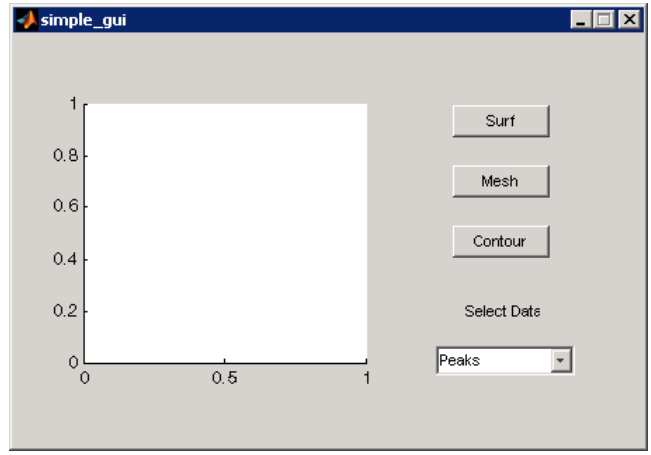
5. If the directory in which you save the GUI is not on the MATLAB path, GUIDE opens a dialog box, giving you the option of changing the current

working directory to the directory containing the GUI files, or adding that directory to the top or bottom of the MATLAB path.



6 GUIDE saves the files `simple_gui.fig` and `simple_gui.m` and activates the GUI. It also opens the GUI M-file in your default editor.

The GUI is active. You can select a data set in the pop-up menu and click the push buttons. But nothing happens. This is because there is no code in the M-file to service the pop-up menu and the buttons. The next step is to program the GUI. The next topic, “Programming a Simple GUI” on page 2-21, shows you how to do this.



Programming a Simple GUI

In this section...

Adding Code to the M-file

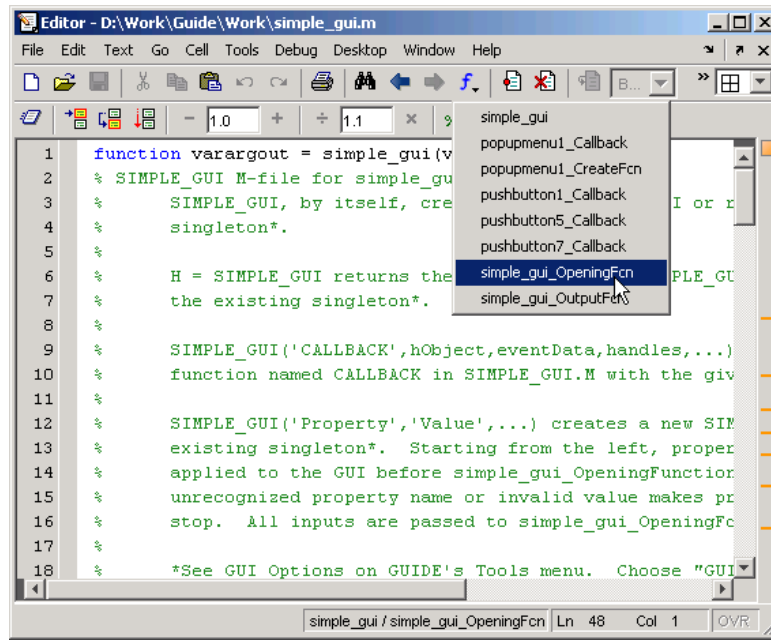
When you saved your GUI in the previous topic, “Saving the GUI Layout” on page 2-19, GUIDE created two files: a FIG-file `simple_gui.fig` that contains the GUI layout, and an M-file `simple_gui.m` that contains the code that controls the GUI. But the GUI didn’t do anything because there was no code in the M-file to make it work. This topic shows you how to add code to the M-file to make it work. There are three steps:

Generating Data to Plot

This topic shows you how to generate the data to be plotted when the user clicks a button. This data is generated in the *opening function*. The opening function is the first callback in every GUIDE-generated GUI M-file. You can use it to perform tasks that need to be done before the user has access to the GUI.

In this example, you add code that creates three data sets to the opening function. The code uses the MATLAB functions `peaks`, `membrane`, and `sinc`.

1. Display the opening function in the M-file editor. If the GUI M-file, `simple_gui.m`, is not already open in your editor, open it by selecting **M-file Editor** from the **View** menu. In the editor, click the function icon on the toolbar, then select **simple_gui_OpeningFcn** in the pop-up menu that displays.



The cursor moves to the opening function, which already contains this code:

```
% --- Executes just before simple_gui is made visible.
function simple_gui_OpeningFcn(hObject, eventdata, handles, varargin)
% This function has no output args, see OutputFcn.
% hObject    handle to figure
% eventdata  reserved - to be defined in a future version of MATLAB
% handles    structure with handles and user data (see GUIDATA)
% varargin   command line arguments to simple_gui (see VARARGIN)

% Choose default command line output for simple_gui
handles.output = hObject;

% Update handles structure
guidata(hObject, handles);

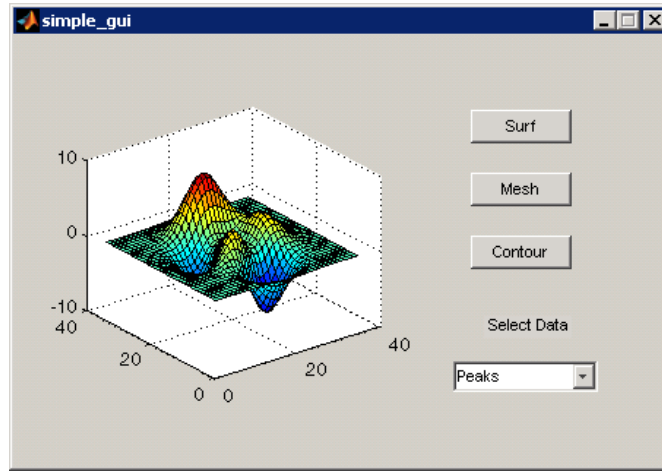
% UIWAIT makes simple_gui wait for user response (see UIRESUME)
% uiwait(handles.figure1);
```

2 Create data for the GUI to plot by adding the following code to the opening function immediately after the comment that begins `% varargin...`

```
% Create the data to plot.
handles.peaks=peaks(35);
handles.membrane=membrane;
[x,y] = meshgrid(-8:.5:8);
r = sqrt(x.^2+y.^2) + eps;
sinc = sin(r)./r;
handles.sinc = sinc;
% Set the current data value.
handles.current_data = handles.peaks;
surf(handles.current_data)
```

The first six executable lines create the data using the MATLAB functions `peaks`, `membrane`, and `sinc`. They store the data in the `handles` structure, which is passed as an argument to all callbacks. Callbacks for the push buttons can retrieve the data from the `handles` structure.

The last two lines create a current data value and set it to peaks, and then display the surf plot for peaks. The following figure shows how the GUI now looks when it first displays.



Programming the Pop-Up Menu

The pop-up menu enables the user to select the data to plot. When the GUI user selects one of the three plots, MATLAB sets the pop-up menu `Value` property to the index of the selected string. The pop-up menu callback reads the pop-up menu `Value` property to determine what item is currently displayed and sets `handles.current_data` accordingly.

1. Display the pop-up menu callback in the M-file editor. Right-click the pop-up menu component in the Layout Editor to display a context menu. From that menu, select **View Callbacks > Callback**.

   The GUI M-file opens in the editor if it is not already open, and the cursor moves to the pop-menu callback, which already contains this code:

```
% --- Executes on selection change in popupmenu1.
function popupmenu1_Callback(hObject, eventdata, handles)
% hObject    handle to popupmenu1 (see GCBO)
% eventdata  reserved - to be defined in a future version of MATLAB
% handles    structure with handles and user data (see GUIDATA)
```

2. Add the following code to the `popupmenu1_Callback` after the comment that begins `% handles...`

This code first retrieves two pop-up menu properties:

- `String` — a cell array that contains the menu contents
- `Value` — the index into the menu contents of the selected data set

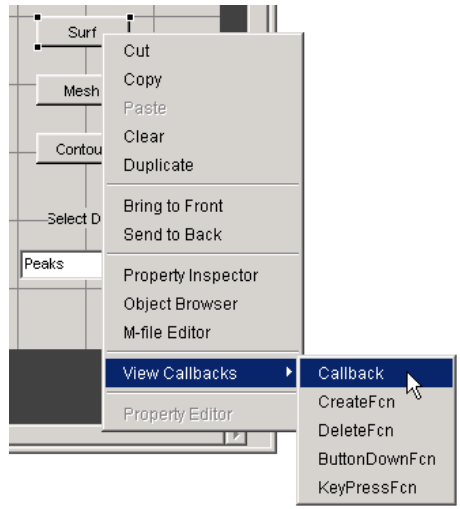
It then uses a `switch` statement to make the selected data set the current data. The last statement saves the changes to the `handles` structure.

```
% Determine the selected data set.
str = get(hObject, 'String');
val = get(hObject,'Value');
% Set current data to the selected data set.
switch str{val};
case 'Peaks' % User selects peaks.
   handles.current_data = handles.peaks;
case 'Membrane' % User selects membrane.
   handles.current_data = handles.membrane;
case 'Sinc' % User selects sinc.
   handles.current_data = handles.sinc;
end
% Save the handles structure.
guidata(hObject,handles)
```

Programming the Push Buttons

Each of the push buttons creates a different type of plot using the data specified by the current selection in the pop-up menu. The push button callbacks get data from the `handles` structure and then plot it.

1 Display the **Surf** push button callback in the M-file editor. Right-click the **Surf** push button in the Layout Editor to display a context menu. From that menu, select **View Callbacks > Callback**.



The GUI M-file opens in the editor if it is not already open, and the cursor moves to the **Surf** push button callback, which already contains this code:

```
% --- Executes on button press in pushbutton1.
function pushbutton1_Callback(hObject, eventdata, handles)
% hObject    handle to pushbutton1 (see GCBO)
% eventdata  reserved - to be defined in a future version of MATLAB
% handles    structure with handles and user data (see GUIDATA)
```

2 Add the following code to the callback immediately after the comment that begins `% handles...`

```
% Display surf plot of the currently selected data.
surf(handles.current_data);
```

3 Repeat steps 1 and 2 to add similar code to the **Mesh** and **Contour** push button callbacks.

- Add this code to the **Mesh** push button callback, `pushbutton2_Callback`:

```
% Display mesh plot of the currently selected data.
mesh(handles.current_data);
```

- Add this code to the **Contour** push button callback, `pushbutton3_Callback`:

```
% Display contour plot of the currently selected data.
contour(handles.current_data);
```

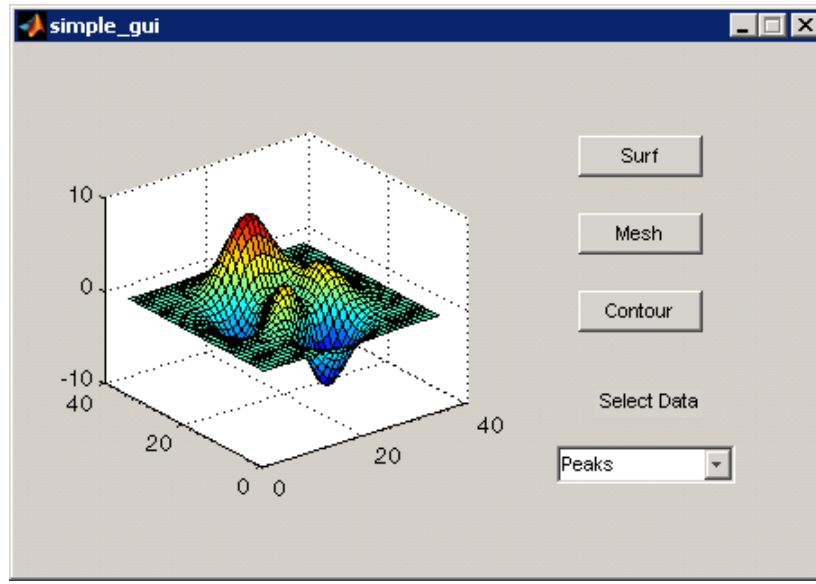
4 Save the M-file by selecting **Save** from the **File** menu.

Your GUI is ready to run. The next topic, “Running the GUI” on page 2-28, tells you how to do that.

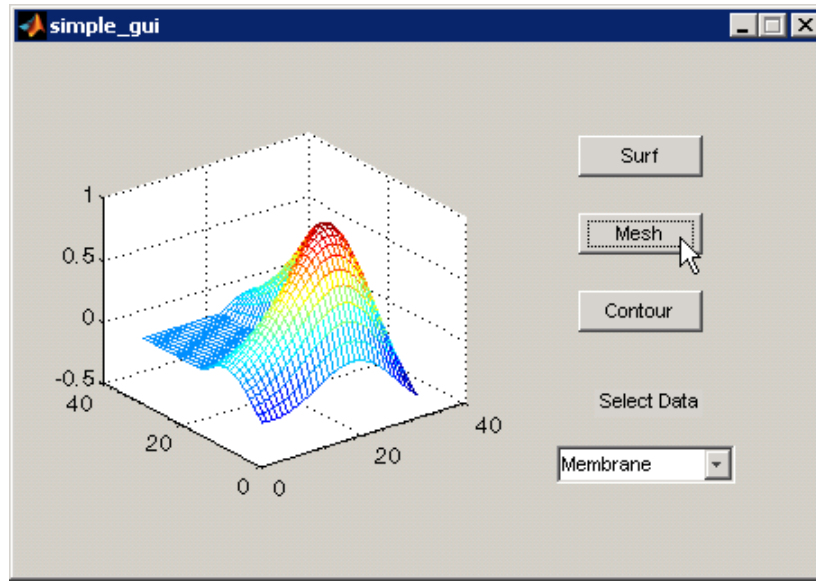
Running the GUI

In the previous topic, you programmed the pop-up menu and the push buttons. You also created data for them to use and initialized the display. Now you can run your GUI and see how it works.

1 Run your GUI by selecting **Run** from the Layout Editor **Tools** menu. If the GUI is on your MATLAB path or in your current directory, you can also run it by typing its name, `simple_gui`, at the prompt. The GUI looks like this when it first displays:



2 In the pop-up menu, select **Membrane**, then click the **Mesh** button. The GUI displays a mesh plot of the MATLAB logo.



3 Try other combinations before closing the GUI.

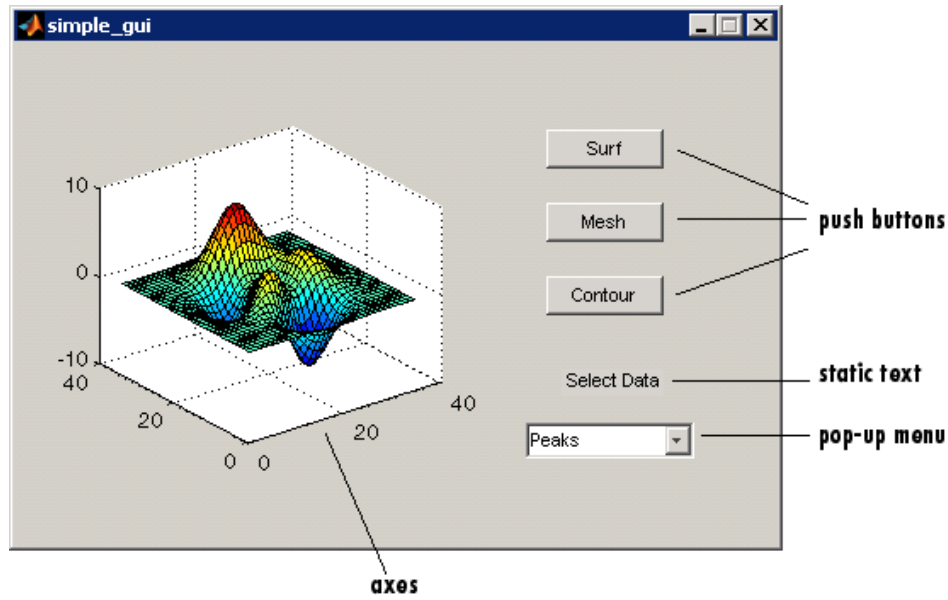
3

Creating a Simple GUI Programmatically

Example: Simple GUI

Simple GUI Overview

This section shows you how to write a script that creates the example graphical user interface (GUI) shown in the following figure.



The GUI contains

- An axes
- A pop-up menu listing three data sets that correspond to MATLAB functions: `peaks`, `membrane`, and `sinc`
- A static text component to label the pop-up menu
- Three push buttons, each of which provides a different kind of plot: surface, mesh, and contour

To use the GUI, the user selects a data set from the pop-up menu, then clicks one of the plot-type push buttons. Clicking the button triggers the execution of a callback that plots the selected data in the axes.

The next topic, “Function Summary” on page 3-4, summarizes the functions used to create this example GUI.

Subsequent topics guide you through the process of creating the GUI. This process begins with “Creating a GUI M-File” on page 3-5. We recommend that you create the GUI for yourself.

View Completed Example

If you are reading this in the MATLAB Help browser, you can click the following links to display the example GUI and its M-file.

Note The following links execute MATLAB commands and are designed to work within the MATLAB Help browser. If you are reading this online or in PDF, you should go to the corresponding section in the MATLAB Help Browser to use the links.

- Click here to display the example GUI.
- Click here to display the GUI M-file in the MATLAB Editor.

Function Summary

MATLAB provides a suite of functions for creating GUIs. This topic introduces you to the functions you need to create the example GUI.

Functions Used to Create the Simple GUI

Function	Description
`align`	Align GUI components such as user interface controls and axes.
`axes`	Create axes objects.
`figure`	Create figure objects. A GUI is a figure object.
`movegui`	Move GUI figure to specified location on screen.
`uicontrol`	Create user interface control objects, such as push buttons, static text, and pop-up menus.

Other MATLAB Functions Used to Program the GUI

Function	Description
`contour`	Contour graph of a matrix
`eps`	Floating point relative accuracy
`get`	Query object properties
`membrane`	Generate the MATLAB logo
`mesh`	Mesh plot
`meshgrid`	Generate X and Y arrays for 3-D plots
`peaks`	Example function of two variables.
`set`	Set object properties
`sin`	Sine; result in radians
`sqrt`	Square root
`surf`	3-D shaded surface plot

Creating a GUI M-File

Start by creating an M-file for the example GUI.

1. At the MATLAB prompt, type `edit`. MATLAB opens the editor.

2. Type or copy the following statement into the editor. This function statement is the first line in the file.

```
function simple_gui2
```

3. Add these comments to the M-file following the function statement. They are displayed at the command line in response to the `help` command. They must be followed by a blank line.

```
% SIMPLE_GUI2 Select a data set from the pop-up menu, then
% click one of the plot-type push buttons. Clicking the button
% plots the selected data in the axes.
(Leave a blank line here)
```

4. Add an `end` statement at the end of the file. This `end` statement matches the `function` statement. Your file now looks like this.

```
function simple_gui2
% SIMPLE_GUI2 Select a data set from the pop-up menu, then
% click one of the plot-type push buttons. Clicking the button
% plots the selected data in the axes.

end
```

Note You need the `end` statement because the example is written using nested functions. For information about using nested functions, see "Nested Functions" in the MATLAB Programming documentation.

---

5. Save the file in your current directory or at a location that is on your MATLAB path.

The next section, "Laying Out a Simple GUI" on page 3-6, shows you how to add components to your GUI.

Laying Out a Simple GUI

In this section...

Creating the Figure

In MATLAB, a GUI is a figure. This first step creates the figure and positions it on the screen. It also makes the GUI invisible so that the GUI user cannot see the components being added or initialized. When the GUI has all its components and is initialized, the example makes it visible.

```
%  Initialize and hide the GUI as it is being constructed.
f = figure('Visible','off','Position',[360,500,450,285]);
```

The call to the `figure` function uses two property/value pairs. The `Position` property is a four-element vector that specifies the location of the GUI on the screen and its size: [distance from left, distance from bottom, width, height]. Default units are pixels.

The next topic, "Adding the Components" on page 3-6, shows you how to add the push buttons, axes, and other components to the GUI.

Adding the Components

The example GUI has six components: three push buttons, one static text, one pop-up menu, and one axes. Start by writing statements that add these components to the GUI. Create the push buttons, static text, and pop-up menu with the `uicontrol` function. Use the `axes` function to create the axes.

1. Add the three push buttons to your GUI by adding these statements to your M-file following the call to `figure`.

```
% Construct the components.
hsurf    = uicontrol('Style','pushbutton',...
             'String','Surf','Position',[315,220,70,25]);
hmesh    = uicontrol('Style','pushbutton',...
             'String','Mesh','Position',[315,180,70,25]);
```

```
hcontour = uicontrol('Style','pushbutton',...
             'String','Countour','Position',[315,135,70,25]);
```

These statements use the `uicontrol` function to create the push buttons. Each statement uses a series of property/value pairs to define a push button.

Property	Description
`Style`	In the example, `pushbutton` specifies the component as a push button.
`String`	Specifies the label that appears on each push button. Here, there are three types of plots: `Surf`, `Mesh`, `Contour`.
`Position`	Uses a four-element vector to specify the location of each push button within the GUI and its size: [distance from left, distance from bottom, width, height]. Default units for push buttons are pixels.

Each call returns the handle of the component that is created.

2 Add the pop-up menu and its label to your GUI by adding these statements to the M-file following the push button definitions.

```
hpopup = uicontrol('Style','popupmenu',...
           'String',{'Peaks','Membrane','Sinc'},...
           'Position',[300,50,100,25]);
htext  = uicontrol('Style','text','String','Select Data',...
           'Position',[325,90,60,15]);
```

For the pop-up menu, the `String` property uses a cell array to specify the three items in the pop-up menu: `Peaks`, `Membrane`, `Sinc`. The static text component serves as a label for the pop-up menu. Its `String` property tells the GUI user to `Select Data`. Default units for these components are pixels.

3 Add the axes to the GUI by adding this statement to the M-file. Set the `Units` property to pixels so that it has the same units as the other components.

```
ha = axes('Units','pixels','Position',[50,60,200,185]);
```

4 Align all components except the axes along their centers with the following statement. Add it to the M-file following all the component definitions.

```
align([hsurf,hmesh,hcontour,htext,hpopup],'Center','None');
```

5 Make your GUI visible by adding this command following the `align` command.

```
set(f,'Visible','on')
```

6 This is what your M-file should now look like:

```
function simple_gui2
% SIMPLE_GUI2 Select a data set from the pop-up menu, then
% click one of the plot-type push buttons. Clicking the button
% plots the selected data in the axes.

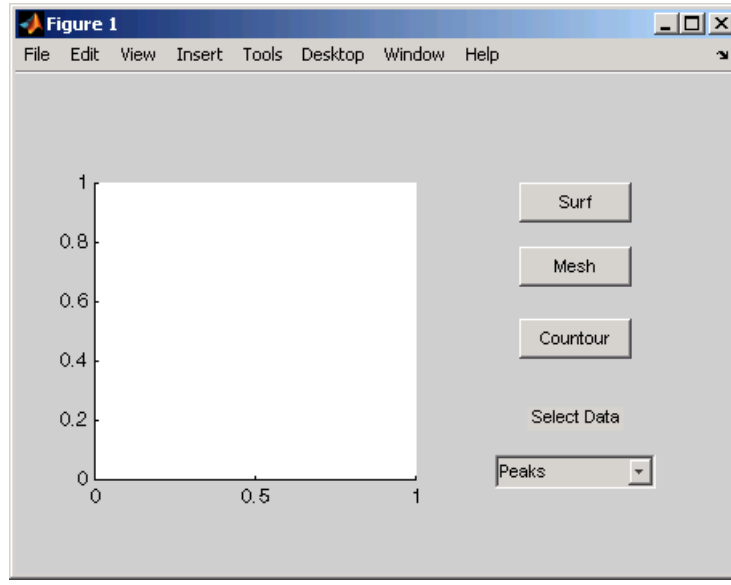
   %  Create and hide the GUI as it is being constructed.
   f = figure('Visible','off','Position',[360,500,450,285]);

   %  Construct the components.
   hsurf = uicontrol('Style','pushbutton','String','Surf',...
           'Position',[315,220,70,25]);
   hmesh = uicontrol('Style','pushbutton','String','Mesh',...
           'Position',[315,180,70,25]);
   hcontour = uicontrol('Style','pushbutton',...
           'String','Countour',...
           'Position',[315,135,70,25]);
   htext = uicontrol('Style','text','String','Select Data',...
           'Position',[325,90,60,15]);
   hpopup = uicontrol('Style','popupmenu',...
           'String',{'Peaks','Membrane','Sinc'},...
           'Position',[300,50,100,25]);
   ha = axes('Units','Pixels','Position',[50,60,200,185]);
   align([hsurf,hmesh,hcontour,htext,hpopup],'Center','None');

   %Make the GUI visible.
   set(f,'Visible','on')

end
```

7 Run your script by typing `simple_gui2` at the command line. This is what your GUI now looks like. Note that you can select a data set in the pop-up menu and click the push buttons. But nothing happens. This is because there is no code in the M-file to service the pop-up menu and the buttons.



8 Type `help simple_gui2` at the command line. MATLAB displays this help text.

```
help simple_gui2
  SIMPLE_GUI2 Select a data set from the pop-up menu, then
  click one of the plot-type push buttons. Clicking the button
  plots the selected data in the axes.
```

The next topic, “Initializing the GUI” on page 3-10, shows you how to initialize the GUI.

Initializing the GUI

When you make the GUI visible, it should be initialized so that it is ready for the user. This topic shows you how to

- Make the GUI behave properly when it is resized by changing the component and figure units to `normalized`. This causes the components to resize when the GUI is resized. Normalized units map the lower-left corner of the figure window to `(0,0)` and the upper-right corner to `(1.0, 1.0)`.
- Generate the data to plot. The example needs three sets of data: `peaks_data`, `membrane_data`, and `sinc_data`. Each set corresponds to one of the items in the pop-up menu.
- Create an initial plot in the axes
- Assign the GUI a name that appears in the window title
- Move the GUI to the center of the screen
- Make the GUI visible

1 Replace this code in your M-file:

```
% Make the GUI visible.
set(f,'Visible','on')
```

with this code:

```
% Initialize the GUI.
% Change units to normalized so components resize automatically.
set([f,hsurf,hmesh,hcontour,htext,hpopup],'Units','normalized');
% Generate the data to plot.
peaks_data = peaks(35);
membrane_data = membrane;
[x,y] = meshgrid(-8:.5:8);
r = sqrt(x.^2+y.^2) + eps;
sinc_data = sin(r)./r;
% Create a plot in the axes.
current_data = peaks_data;
surf(current_data);
% Assign the GUI a name to appear in the window title.
set(f,'Name','Simple GUI')
```

```
% Move the GUI to the center of the screen.
movegui(f,'center')
% Make the GUI visible.
set(f,'Visible','on');
```

2 Verify that your M-file now looks like this:

```
function simple_gui2
% SIMPLE_GUI2 Select a data set from the pop-up menu, then
% click one of the plot-type push buttons. Clicking the button
% plots the selected data in the axes.

   % Create and hide the GUI figure as it is being constructed.
   f = figure('Visible','off','Position',[360,500,450,285]);

   % Construct the components
   hsurf = uicontrol('Style','pushbutton','String','Surf',...
           'Position',[315,220,70,25]);
   hmesh = uicontrol('Style','pushbutton','String','Mesh',...
           'Position',[315,180,70,25]);
   hcontour = uicontrol('Style','pushbutton',...
           'String','Countour',...
           'Position',[315,135,70,25]);
   htext = uicontrol('Style','text','String','Select Data',...
           'Position',[325,90,60,15]);
   hpopup = uicontrol('Style','popupmenu',...
           'String',{'Peaks','Membrane','Sinc'},...
           'Position',[300,50,100,25]);
   ha = axes('Units','Pixels','Position',[50,60,200,185]);
   align([hsurf,hmesh,hcontour,htext,hpopup],'Center','None');

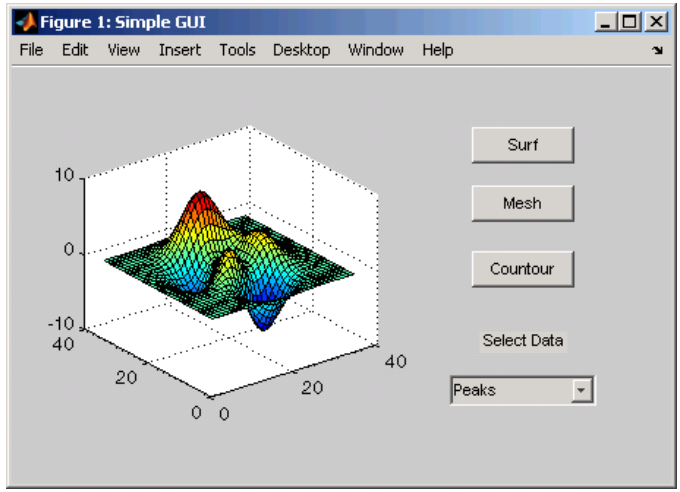
   % Create the data to plot
   peaks_data = peaks(35);
   membrane_data = membrane;
   [x,y] = meshgrid(-8:.5:8);
   r = sqrt(x.^2+y.^2) + eps;
   sinc_data = sin(r)./r;

   % Initialize the GUI.
   % Change units to normalized so components resize
```

```
    % automatically.
    set([f,hsurf,hmesh,hcontour,htext,hpopup],...
        'Units','normalized');
    %Create a plot in the axes.
    current_data = peaks_data;
    surf(current_data);
    % Assign the GUI a name to appear in the window title.
    set(f,'Name','Simple GUI')
    % Move the GUI to the center of the screen.
    movegui(f,'center')
    % Make the GUI visible.
    set(f,'Visible','on');

end
```

3 Run your script by typing `simple_gui2` at the command line. This is what your GUI should now look like:



The next topic, “Programming the GUI” on page 3-13, shows you how to program the push buttons and pop-up menu so you can interactively generate different plots in the axes.

Programming the GUI

In this section...

Programming the Pop-Up Menu

The pop-up menu enables users to select the data to plot. When a GUI user selects one of the three data sets, MATLAB sets the pop-up menu `Value` property to the index of the selected string. The pop-up menu callback reads the pop-up menu `Value` property to determine which item is currently displayed and sets `current_data` accordingly.

Add the following callback to your file following the initialization code and before the final `end` statement.

```
%  Pop-up menu callback. Read the pop-up menu Value property to
%  determine which item is currently displayed and make it the
%  current data. This callback automatically has access to
%  current_data because this function is nested at a lower level.
   function popup_menu_Callback(source,eventdata)
      % Determine the selected data set.
      str = get(source, 'String');
      val = get(source,'Value');
      % Set current data to the selected data set.
      switch str{val};
      case 'Peaks' % User selects Peaks.
         current_data = peaks_data;
      case 'Membrane' % User selects Membrane.
         current_data = membrane_data;
      case 'Sinc' % User selects Sinc.
         current_data = sinc_data;
      end
   end
```

The next topic, "Programming the Push Buttons" on page 3-14, shows you how to write callbacks for the three push buttons.

Programming the Push Buttons

Each of the three push buttons creates a different type of plot using the data specified by the current selection in the pop-up menu. The push button callbacks plot the data in `current_data`. They automatically have access to `current_data` because they are nested at a lower level.

Add the following callbacks to your file following the pop-up menu callback and before the final `end` statement.

```
% Push button callbacks. Each callback plots current_data in the
% specified plot type.

function surfbutton_Callback(source,eventdata)
% Display surf plot of the currently selected data.
     surf(current_data);
end

function meshbutton_Callback(source,eventdata)
% Display mesh plot of the currently selected data.
     mesh(current_data);
end

function contourbutton_Callback(source,eventdata)
% Display contour plot of the currently selected data.
     contour(current_data);
end
```

The next topic shows you how to associate each callback with its specific component.

Associating Callbacks with Their Components

When the GUI user selects a data set from the pop-up menu or clicks one of the push buttons, MATLAB executes the callback associated with that particular event. But how does MATLAB know which callback to execute?

You must use each component's `Callback` property to specify the name of the callback with which it is associated.

1. To the `uicontrol` statement that defines the **Surf** push button, add the property/value pair

   ```
   'Callback',{@surfbutton_Callback}
   ```

   so that the statement looks like this:

   ```
   hsurf = uicontrol('Style','pushbutton','String','Surf',...
           'Position',[315,220,70,25],...
           'Callback',{@surfbutton_Callback});
   ```

   `Callback` is the name of the property. `surfbutton_Callback` is the name of the callback that services the **Surf** push button.

2. Similarly, to the `uicontrol` statement that defines the **Mesh** push button, add the property/value pair

   ```
   'Callback',{@meshbutton_Callback}
   ```

3. To the `uicontrol` statement that defines the **Contour** push button, add the property/value pair

   ```
   'Callback',{@contourbutton_Callback}
   ```

4. To the `uicontrol` statement that defines the pop-up menu, add the property/value pair

   ```
   'Callback',{@popup_menu_Callback}
   ```

The next topic, "Running the Final GUI" on page 3-16, shows the final M-file and runs the GUI.

Running the Final GUI

In this section...

Final M-File

This is what your final M-file should now look like:

```
function simple_gui2
% SIMPLE_GUI2 Select a data set from the pop-up menu, then
% click one of the plot-type push buttons. Clicking the button
% plots the selected data in the axes.

   %  Create and then hide the GUI as it is being constructed.
   f = figure('Visible','off','Position',[360,500,450,285]);

   %  Construct the components.
   hsurf = uicontrol('Style','pushbutton','String','Surf',...
          'Position',[315,220,70,25],...
          'Callback',{@surfbutton_Callback});
   hmesh = uicontrol('Style','pushbutton','String','Mesh',...
          'Position',[315,180,70,25],...
          'Callback',{@meshbutton_Callback});
   hcontour = uicontrol('Style','pushbutton',...
          'String','Countour',...
          'Position',[315,135,70,25],...
          'Callback',{@contourbutton_Callback});
   htext = uicontrol('Style','text','String','Select Data',...
          'Position',[325,90,60,15]);
   hpopup = uicontrol('Style','popupmenu',...
          'String',{'Peaks','Membrane','Sinc'},...
          'Position',[300,50,100,25],...
          'Callback',{@popup_menu_Callback});
   ha = axes('Units','Pixels','Position',[50,60,200,185]);
   align([hsurf,hmesh,hcontour,htext,hpopup],'Center','None');
```

```
% Create the data to plot.
peaks_data = peaks(35);
membrane_data = membrane;
[x,y] = meshgrid(-8:.5:8);
r = sqrt(x.^2+y.^2) + eps;
sinc_data = sin(r)./r;

% Initialize the GUI.
% Change units to normalized so components resize
% automatically.
set([f,ha,hsurf,hmesh,hcontour,htext,hpopup],...
'Units','normalized');
%Create a plot in the axes.
current_data = peaks_data;
surf(current_data);
% Assign the GUI a name to appear in the window title.
set(f,'Name','Simple GUI')
% Move the GUI to the center of the screen.
movegui(f,'center')
% Make the GUI visible.
set(f,'Visible','on');

%  Callbacks for simple_gui2. These callbacks automatically
%  have access to component handles and initialized data
%  because they are nested at a lower level.

%  Pop-up menu callback. Read the pop-up menu Value property
%  to determine which item is currently displayed and make it
%  the current data.
   function popup_menu_Callback(source,eventdata)
      % Determine the selected data set.
      str = get(source, 'String');
      val = get(source,'Value');
      % Set current data to the selected data set.
      switch str{val};
      case 'Peaks' % User selects Peaks.
         current_data = peaks_data;
      case 'Membrane' % User selects Membrane.
         current_data = membrane_data;
      case 'Sinc' % User selects Sinc.
```

```
            current_data = sinc_data;
         end
      end

   % Push button callbacks. Each callback plots current_data in
   % the specified plot type.

   function surfbutton_Callback(source,eventdata)
   % Display surf plot of the currently selected data.
      surf(current_data);
   end

   function meshbutton_Callback(source,eventdata)
   % Display mesh plot of the currently selected data.
      mesh(current_data);
   end

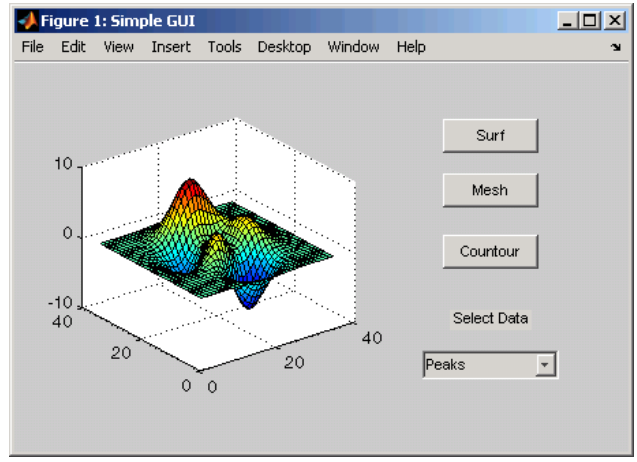
   function contourbutton_Callback(source,eventdata)
   % Display contour plot of the currently selected data.
      contour(current_data);
   end

end
```

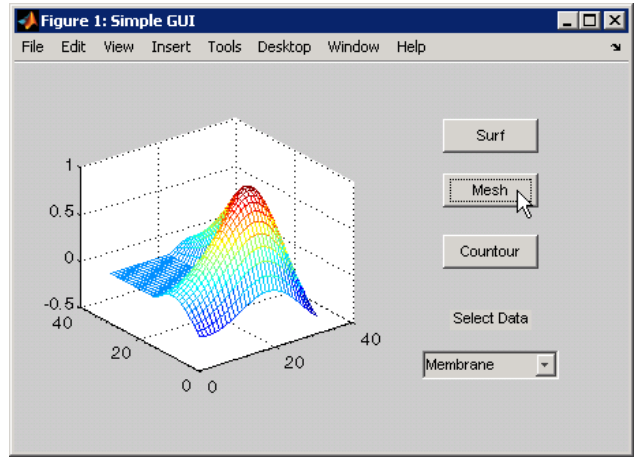
Running the GUI

1 Run the simple GUI by typing the name of the M-file at the command line.

```
simple_gui2
```



2 In the pop-up menu, select **Membrane**, and then click the **Mesh** button. The GUI displays a mesh plot of the MATLAB logo.



3 Try other combinations before closing the GUI.

Creating GUIs with GUIDE

Chapter 4, What Is GUIDE? (p. 4-1)	Introduces GUIDE
Chapter 5, GUIDE Preferences and Options (p. 5-1)	Describes briefly the available MATLAB preferences and GUI options.
Chapter 6, Laying Out a GUIDE GUI (p. 6-1)	Shows you how to start GUIDE and from there how to populate the GUI and create menus. Provides guidance in designing a GUI for cross-platform compatibility.
Chapter 7, Saving and Running a GUIDE GUI (p. 7-1)	Describes the files used to store the GUI. Steps you through the process for saving a GUI, and lists the different ways in which you can activate a GUI.
Chapter 8, Programming a GUIDE GUI (p. 8-1)	Explains how user-written callback routines control GUI behavior. Shows you how to associate callbacks with specific components and explains callback syntax and arguments. Provides simple programming examples for each kind of component.
Chapter 9, Managing and Sharing Application Data in GUIDE (p. 9-1)	Explains the mechanisms for managing application-defined data and explains how to share data among a GUIs callbacks.
Chapter 10, Examples of GUIDE GUIs (p. 10-1)	Illustrates techniques for programming various behaviors.

4

What Is GUIDE?

GUIDE: An Overview

In this section...

GUI Layout

GUIDE, the MATLAB graphical user interface development environment, provides a set of tools for creating graphical user interfaces (GUIs). These tools simplify the process of laying out and programming GUIs.

Using the GUIDE Layout Editor, you can populate a GUI by clicking and dragging GUI components—such as axes, panels, buttons, text fields, sliders, and so on—into the layout area. You can also create menus and context menus for the GUI. From the Layout Editor, you can size the GUI, modify component look and feel, align components, set tab order, view a hierarchical list of the component objects, and set GUI options.

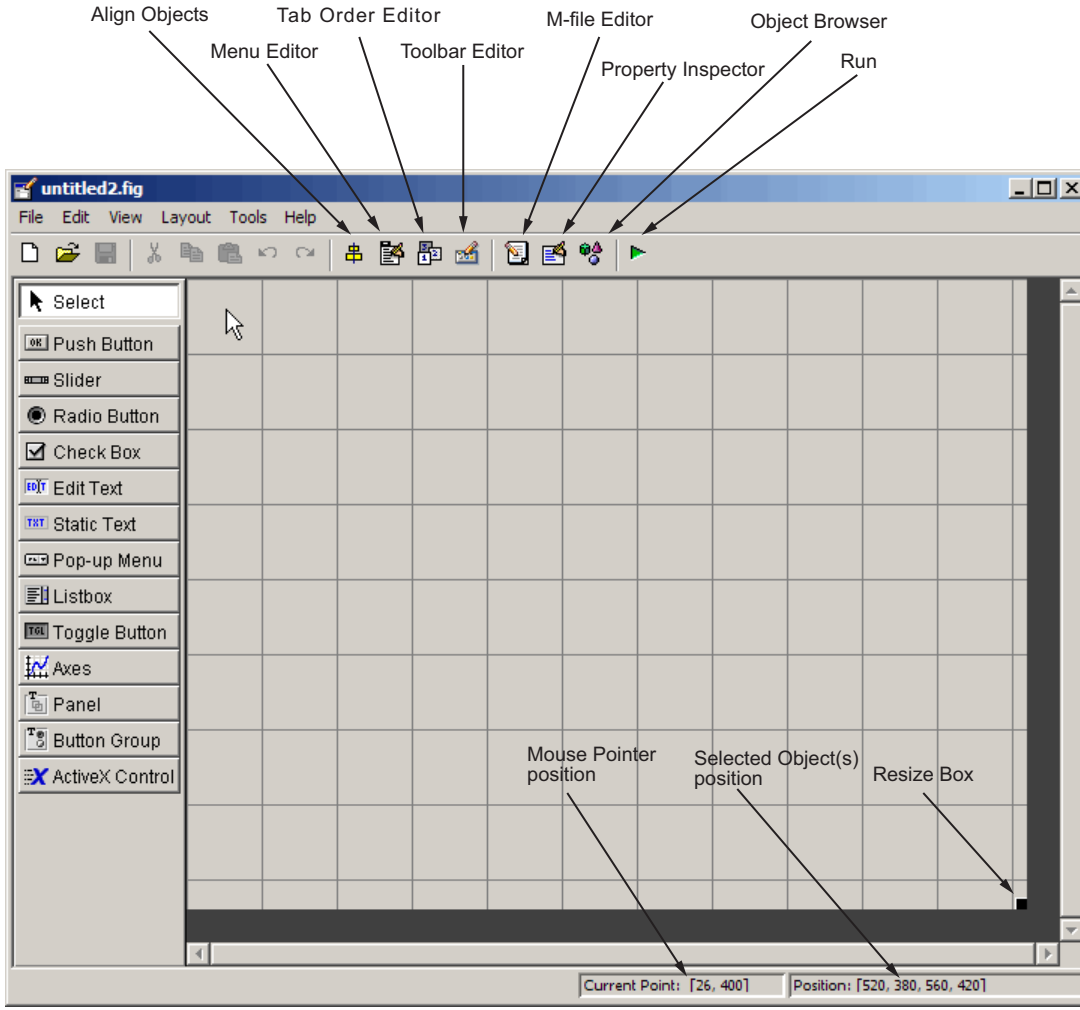
GUI Programming

GUIDE automatically generates an M-file that controls how the GUI operates. This M-file provides code to initialize the GUI and contains a framework for the GUI callbacks—the routines that execute when a user interacts with a GUI component. Using the M-file editor, you can add code to the callbacks to perform the functions you want.

Note MATLAB provides a selection of standard dialog boxes that you can create with a single function call. For information about these dialog boxes and the functions used to create them, see "Predefined Dialog Boxes" in the MATLAB Function Reference documentation.

GUIDE Tools Summary

The GUIDE tools are available from the Layout Editor shown in the figure below. The tools are called out in the figure and described briefly below. Subsequent sections show you how to use them.



Use This Tool...	To...
Layout Editor	Select components from the component palette, at the left side of the Layout Editor, and arrange them in the layout area. See “Adding Components to the GUI” on page 6-18 for more information.
Figure Resize Tab	Set the size at which the GUI is initially displayed when you run it. See “Setting the GUI Size” on page 6-16 for more information.
Menu Editor	Create menus and context, i.e., pop-up, menus. See “Creating Menus” on page 6-70 for more information.
Align Objects	Align and distribute groups of components. Grids and rulers also enable you to align components on a grid with an optional snap-to-grid capability. See “Aligning Components” on page 6-62 for more information.
Tab Order Editor	Set the tab and stacking order of the components in your layout. See “Setting Tab Order” on page 6-67 for more information.
Toolbar Editor	Create Toolbars containing predefined and custom push buttons and toggle buttons. See “Creating Toolbars” on page 6-84 for more information.
Icon Editor	Create and modify icons for tools in a toolbar. See “Creating Toolbars” on page 6-84 for more information.
Property Inspector	Set the properties of the components in your layout. It provides a list of all the properties you can set and displays their current values.
Object Browser	Display a hierarchical list of the objects in the GUI. See “Viewing the Object Hierarchy” on page 6-100 for more information.
Run	Save and run the current GUI. See Chapter 7, “Saving and Running a GUIDE GUI” for more information.

Use This Tool...	To...
M-File Editor	Display, in your default editor, the M-file associated with the GUI. See "GUI Files: An Overview" on page 8-5 for more information.
Position Readouts	Continuously display the mouse cursor position and the positions of selected objects

You can also set preferences that apply to all GUIs at creation, and options that are GUI-specific. See Chapter 5, "GUIDE Preferences and Options" for more information.

5

GUIDE Preferences and Options

GUIDE Preferences

In this section...

Setting Prefernces

You can set preferences for GUIDE by selecting **Preferences** from the **File** menu. These preferences apply to GUIDE and to all GUIs you create.

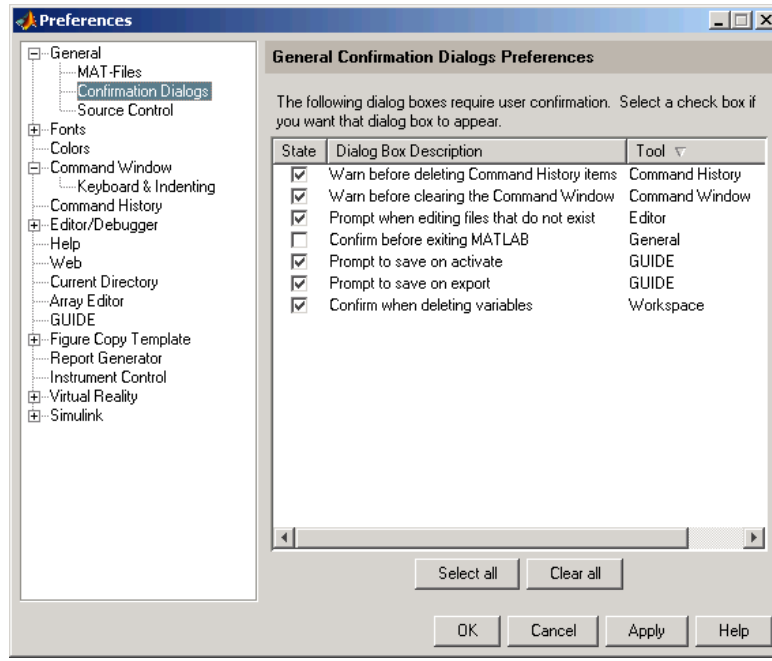
The preferences are in different locations within the Preferences dialog box:

Confirmation Preferences

GUIDE provides two confirmation preferences. You can choose whether you want to display a confirmation dialog box when you

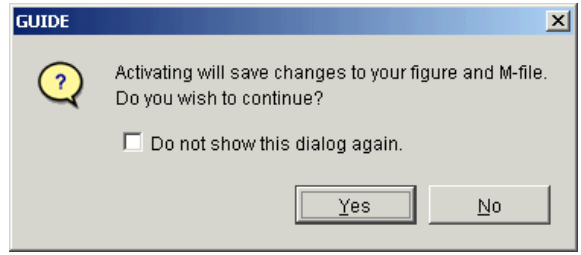
- Activate a GUI from GUIDE
- Export a GUI from GUIDE

In the Preferences dialog box, click **General > Confirmation Dialogs** to access the GUIDE confirmation preferences. Look for the word `GUIDE` in the **Tool** column.



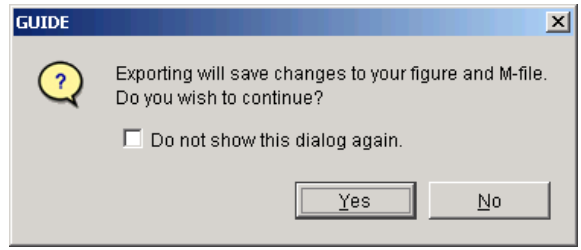
Prompt to Save on Activate

When you activate a GUI by clicking the **Run** button in the Layout Editor, a dialog box informs you of the impending save and lets you choose whether or not you want to continue.



Prompt to Save on Export

When you select **Export** from the Layout Editor **File** menu, a dialog box informs you of the impending save and lets you choose whether or not you want to continue.

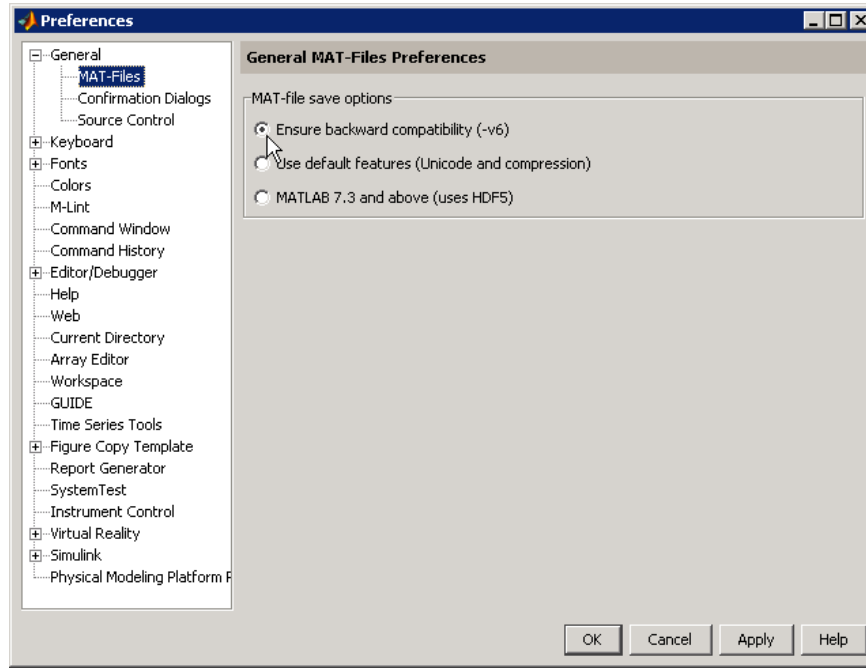


Backward Compatibility Preference

Ensure Backward Compatibility (-v6)

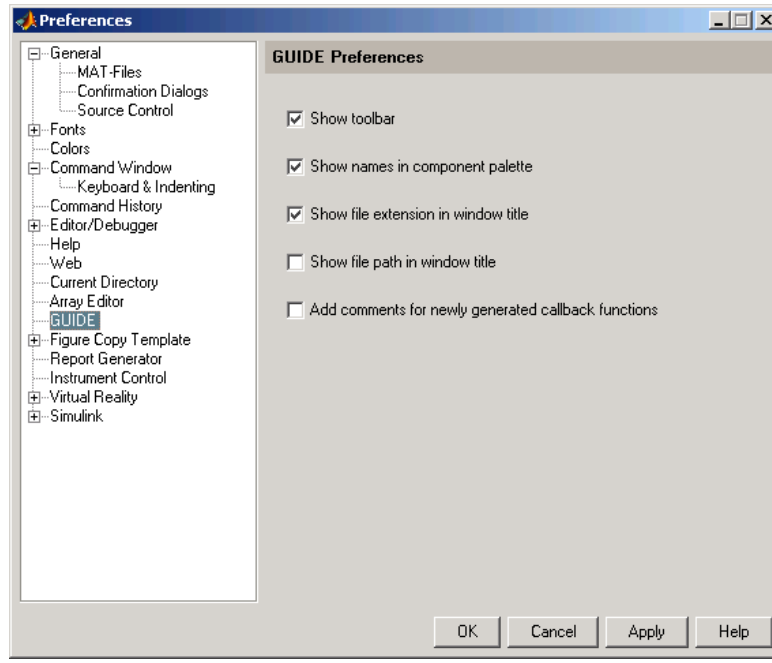
GUI FIG-files created or modified with MATLAB 7.0 or a later MATLAB version are not automatically compatible with Version 6.5 and earlier versions. GUIDE automatically generates FIG-files, which are a kind of MAT-file, to hold layout information for GUIs.

To make a FIG-file backward compatible, you must select **Ensure backward compatibility (-v6)** in the Preferences dialog box under **General > MAT-Files**. This is shown in the figure below.



All Other Preferences

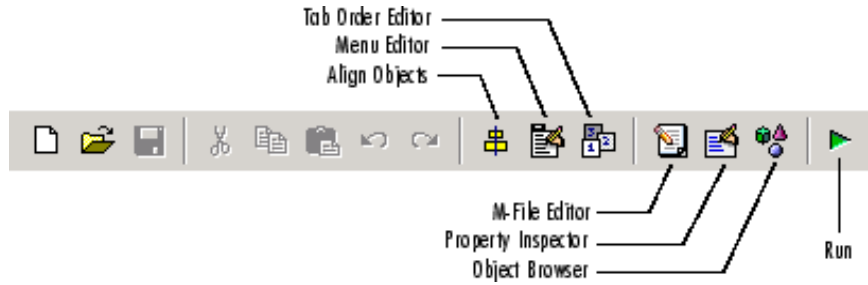
GUIDE provides several other preferences for the Layout Editor interface and M-file comments. In the Preferences dialog box, click **GUIDE** to access these preferences.



The following topics describe the preferences in this dialog:

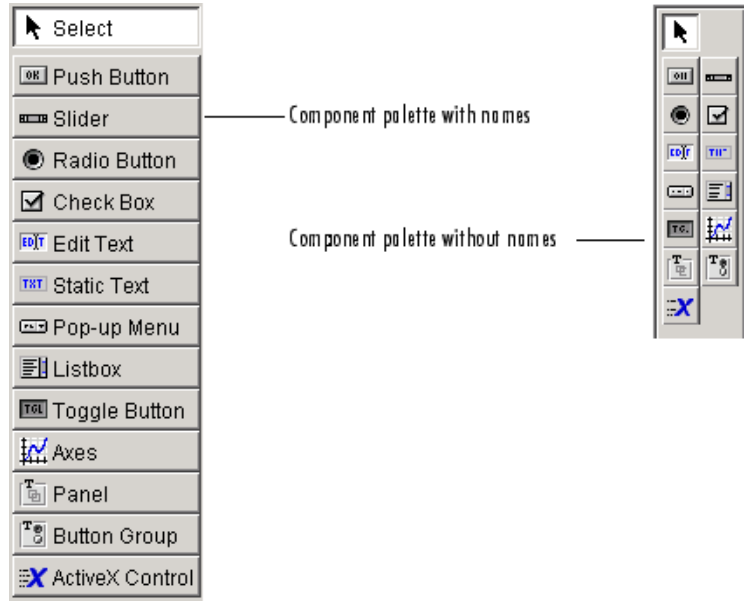
Show Toolbar

Displays the following toolbar in the Layout Editor window.



Show Names in Component Palette

Displays both icons and names in the component palette, as shown below. When unchecked, the icons alone are displayed in two columns.



Show File Extension in Window Title

Displays the GUI FIG-file filename with its file extension, `.fig`, in the Layout Editor window title. If unchecked, only the filename is displayed.

Show File Path in Window Title

Displays the full file path in the Layout Editor window title. If unchecked, the file path is not displayed.

Add Comments for Newly Generated Callback Functions

When this preference is checked, GUIDE includes the comment lines shown in the following example to all callbacks that are added to the M-file.

```
% --- Executes during object deletion, before destroying properties.
function figure1_DeleteFcn(hObject, eventdata, handles)
% hObject    handle to figure1 (see GCBO)
% eventdata  reserved - to be defined in a future version of MATLAB
% handles    structure with handles and user data (see GUIDATA)
```

Some callbacks are added automatically because their associated components are part of the original GUIDE template that you chose. Other commonly used callbacks are added automatically when you add components. You can also add callbacks explicitly by selecting them from **View Callbacks** on the **View** menu or on the component's context menu.

If this preference is unchecked, GUIDE includes comments only for callbacks that are automatically included to support the original GUIDE template. No comments are included for any other callbacks that are added to the M-file.

See "Callback Syntax and Arguments" on page 8-12 for more information about callbacks and about the arguments described in the comments above.

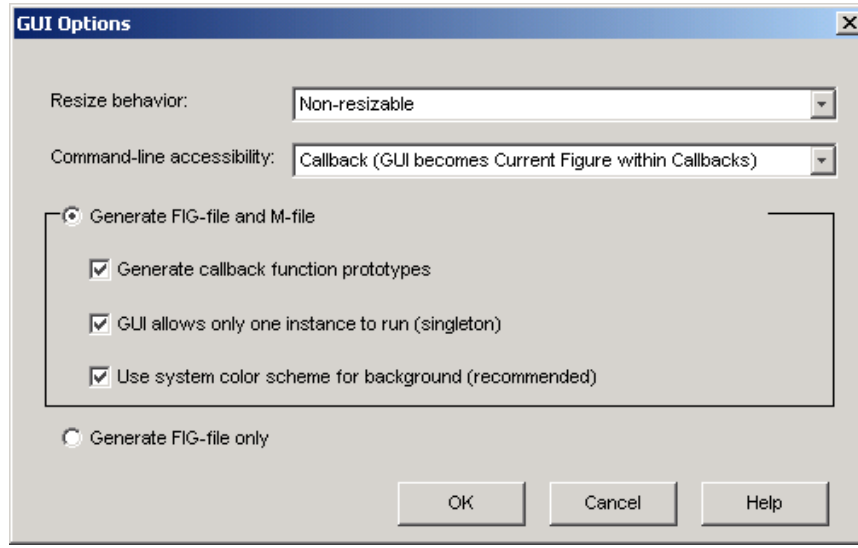
GUI Options

In this section...

The GUI Options Dialog Box

You can use the GUI Options dialog box to configure various behaviors that are specific to the GUI you are creating. These options take effect when you next save the GUI.

Access the dialog box by selecting **GUI Options** from the Layout Editor **Tools** menu.



The following sections describe the options in this dialog box:

Resize Behavior

You can control whether users can resize the figure window containing your GUI and how MATLAB handles resizing. GUIDE provides three options:

- **Non-resizable** — Users cannot change the window size (default).
- **Proportional** — MATLAB automatically rescales the components in the GUI in proportion to the new figure window size.
- **Other (Use ResizeFcn)** — Program the GUI to behave in a certain way when users resize the figure window.

The first two options set figure and component properties appropriately and require no other action. **Other (Use ResizeFcn)** requires you to write a callback routine that recalculates sizes and positions of the components based on the new figure size.

Command-Line Accessibility

You can restrict access to a GUI figure from the command line or from an M-file by using the GUIDE **Command-line accessibility** options.

Unless you explicitly specify a figure handle, many commands, such as `plot`, alter the current figure, i.e., the figure specified by the root `CurrentFigure` property and returned by the `gcf` command. The current figure is usually the figure that is most recently created or clicked in. However, a figure can also become the current figure with the statement

```
figure(h)
```

or by setting the `CurrentFigure` property to the figure's handle.

The `gcf` function returns the handle of the current figure.

```
h = gcf
```

For a GUI created in GUIDE, set the **Command-line accessibility** option to prevent users from inadvertently changing the appearance or content of a GUI by executing commands at the command line or from an M-file, such as `plot`. The following table briefly describes the four options for **Command-line accessibility**.

Option	Description
Callback (GUI becomes Current Figure within Callbacks)	The GUI can be accessed only from within a GUI callback. The GUI cannot be accessed from the command line or from an M-script. This is the default.
Off (GUI never becomes Current Figure)	The GUI can not be accessed from a callback, the command line, or an M-script, without the handle.
On (GUI may become Current Figure from Command Line)	The GUI can be accessed from a callback, from the command line, and from an M-script.
Other (Use settings from Property Inspector)	You control accessibility by setting the `HandleVisibility` and `IntegerHandle` properties from the Property Inspector.

Generate FIG-File and M-File

Select **Generate FIG-file and M-file** in the **GUI Options** dialog box if you want GUIDE to create both the FIG-file and the GUI M-file (this is the default). Once you have selected this option, you can select any of the following items in the frame to configure the M-file:

- "Generate Callback Function Prototypes" on page 5-11
- "GUI Allows Only One Instance to Run (Singleton)" on page 5-12
- "Use System Color Scheme for Background" on page 5-12

See "GUI Files: An Overview" on page 8-5 for information about these files.

Generate Callback Function Prototypes

If you select **Generate callback function prototypes** in the **GUI Options** dialog, GUIDE adds templates for the most commonly used callbacks to the GUI M-file for most components you add to the GUI. You must then write the code for these callbacks.

GUIDE also adds a callback whenever you edit a callback routine from the Layout Editor's right-click context menu and when you add menus to the GUI using the Menu Editor.

See "Callback Syntax and Arguments" on page 8-12 for general information about callbacks.

Note This option is available only if you first select the **Generate FIG-file and M-File** option.

GUI Allows Only One Instance to Run (Singleton)

This option allows you to select between two behaviors for the GUI figure:

- Allow MATLAB to display only one instance of the GUI at a time.
- Allow MATLAB to display multiple instances of the GUI.

If you allow only one instance, MATLAB reuses the existing GUI figure whenever the command to run the GUI is issued. If a GUI already exists, MATLAB brings it to the foreground rather than creating a new figure.

If you clear this option, MATLAB creates a new GUI figure whenever you issue the command to run the GUI.

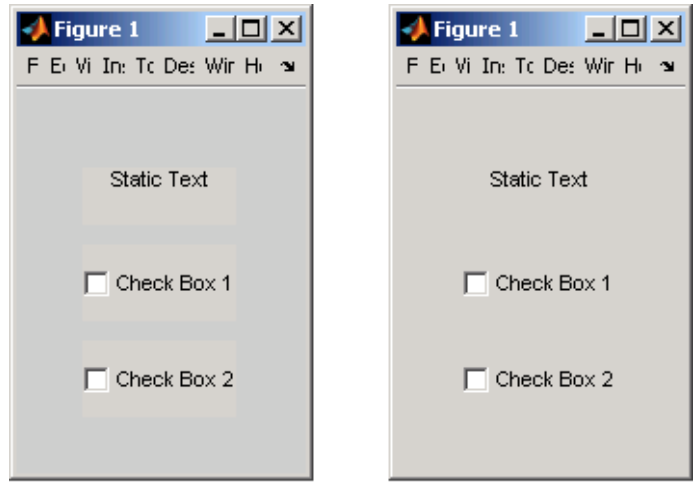
Note This option is available only if you first select the **Generate FIG-file and M-File** option.

Use System Color Scheme for Background

The default color used for GUI components is system dependent. This option enables you to make the figure background color the same as the default component background color.

If you select **Use system color scheme for background** (the default), GUIDE changes the figure background color to match the color of the GUI components.

The following figures illustrate the results with and without system color matching.



Without system color matching

With system color matching

Note This option is available only if you first select the **Generate FIG-file and M-File** option.

Generate FIG-File Only

The **Generate FIG-file only** option enables you to open figures and GUIs to perform limited editing. These can be any figures and need not be GUIs. GUIs need not have been generated using GUIDE. This mode provides limited editing capability and may be useful for GUIs generated in MATLAB Versions 5.3 and earlier. See the `guide` function for more information.

GUIDE selects **Generate FIG-file only** as the default if you do one of the following:

- Start GUIDE from the command line and provide one or more figure handles as arguments.

  ```
  guide(fh)
  ```

In this case, GUIDE selects **Generate FIG-file only** even though there may be a corresponding M-file in the same location.

- Start GUIDE from the command line and provide the name of a FIG-file for which no M-file with the same name exists in the same location.

```
guide('myfig.fig')
```

- Use the GUIDE **Open Existing GUI** tab to open a FIG-file for which no M-file with the same name exists in the same location.

When you save the figure or GUI with **Generate FIG-file only** selected, GUIDE saves only the FIG-file. You must update any corresponding M-files as appropriate.

If you want GUIDE to manage the GUI M-file for you, change the selection to **Generate FIG-file and M-file** before saving the GUI. If there is no corresponding M-file in the same location, GUIDE creates one. If an M-file with the same name as the original figure or GUI exists in the same location, GUIDE overwrites it. To prevent this, save the GUI using **Save As** from the **File** menu and select another filename. You must update the new M-file as appropriate.

6

Laying Out a GUIDE GUI

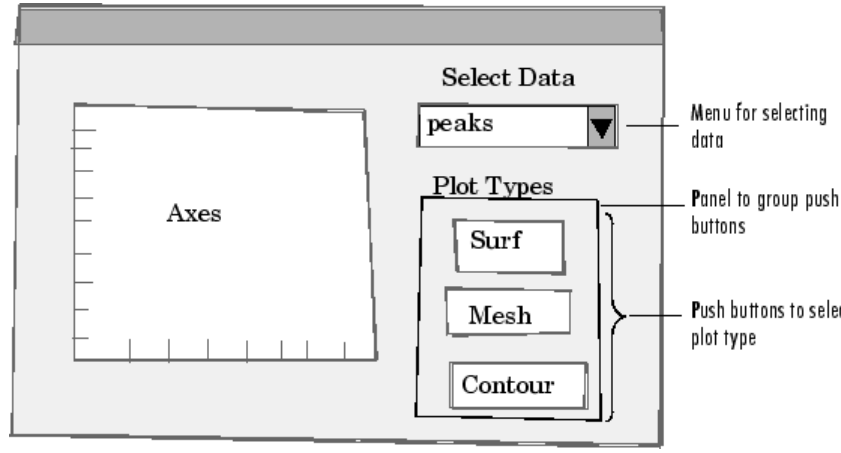
Viewing the Object Hierarchy (p. 6-100)	Describes use of the Object Browser to view the hierarchy of objects, including menus, in your GUI.
Designing for Cross-Platform Compatibility (p. 6-101)	Provides pointers for creating GUIs that behave more consistently when run on different platforms.

Designing a GUI

Before creating the actual GUI, it is important to decide what it is you want your GUI to do and how you want it to work. It is helpful to draw your GUI on paper and envision what the user sees and what actions the user takes.

Note MATLAB provides a selection of standard dialog boxes that you can create with a single function call. For information about these dialog boxes and the functions used to create them, see "Predefined Dialog Boxes" in the MATLAB Function Reference documentation.

The GUI used in this example contains an axes component that displays either a surface, mesh, or contour plot of data selected from the pop-up menu. The following picture shows a sketch that you might use as a starting point for the design.



A panel contains three push buttons that enable you to choose the type of plot you want. The pop-up menu contains three strings — `peaks`, `membrane`, and `sinc`, which correspond to MATLAB functions. You can select the data to plot from this menu.

Many Web sites and commercial publications such as the following provide guidelines for designing GUIs:

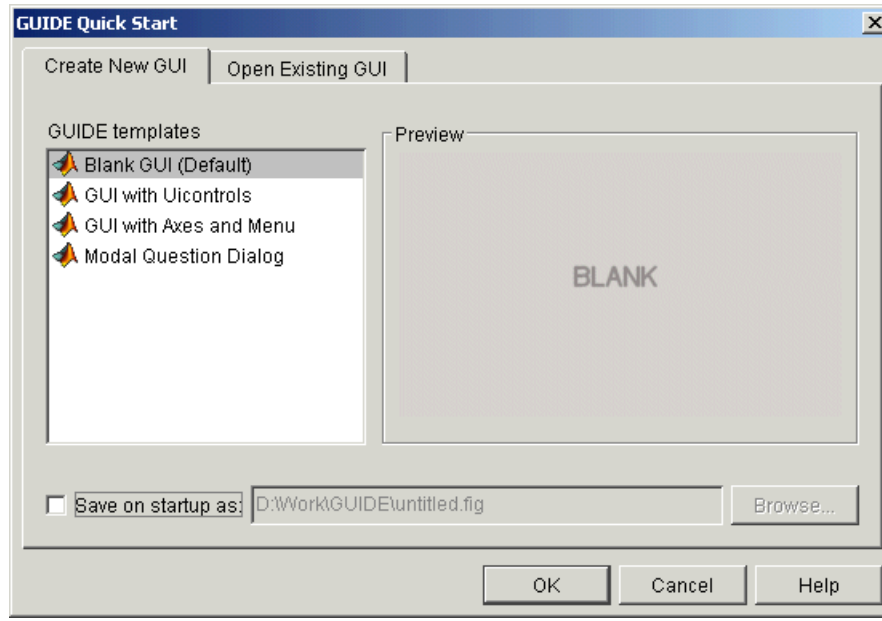
- AskTog — Essays on good design and a list of First Principles for good user interface design. The author, Tognazzini, is a well-respected user interface designer. `http://www.asktog.com/basics/firstPrinciples.html`.
- Galitz, Wilbert, O., *Essential Guide to User Interface Design*. Wiley, New York, NY, 2002.
- GUI Design Handbook — A detailed guide to the use of GUI controls. `http://www.fast-consulting.com/GUI%20Design%20Handbook/GDH_FRNTMTR.htm`.
- Johnson, J., *GUI Bloopers: Don'ts and Do's for Software Developers and Web Designers*. Morgan Kaufmann, San Francisco, CA, 2000.
- Usability Glossary — An extensive glossary of terms related to GUI design, usability, and related topics. `http://www.usabilityfirst.com/glossary/main.cgi`.
- UsabilityNet — Covers design principles, user-centered design, and other usability and design-related topics. `http://www.usabilitynet.org/management/b_design.htm`.

Starting GUIDE

There are many ways to start GUIDE. You can start GUIDE from the:

- Command line by typing `guide`
- **Start** menu by selecting **MATLAB > GUIDE (GUI Builder)**
- **MATLAB File** menu by selecting **New > GUI**
- MATLAB toolbar by clicking the **GUIDE** button 

However you start GUIDE, it displays the GUIDE Quick Start dialog box shown in the following figure.



The GUIDE Quick Start dialog box contains two tabs:

- **Create New GUI** — Asks you to start creating your new GUI by choosing a template for it. You can also specify the name by which the GUI is saved.

See “Selecting a GUI Template” on page 6-7 for information about the templates.

- **Open Existing GUI** — Enables you to open an existing GUI in GUIDE. You can choose a GUI from your current directory or browse other directories.

Selecting a GUI Template

In this section...

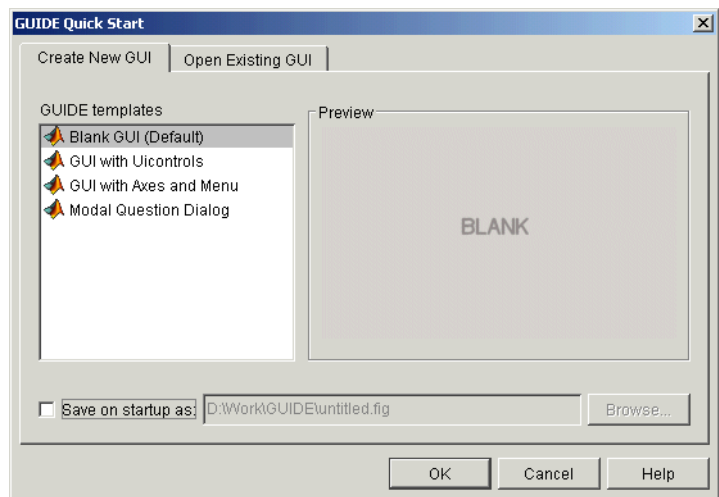
Accessing the Templates

GUIDE provides several templates that you can modify to create your own GUIs. The templates are fully functional GUIs; they are already programmed.

You can access the templates in two ways:

- Start GUIDE. See “Starting GUIDE” on page 6-5 for information.
- If GUIDE is already open, select **New** from the **File** menu in the Layout Editor.

In either case, GUIDE displays the **GUIDE Quick Start** dialog box with the **Create New GUI** tab selected as shown in the following figure. This tab contains a list of the available templates.



To use a template:

1. Select a template in the left pane. A preview displays in the right pane.
2. Optionally, name your GUI now by selecting **Save on startup as** and typing the name in the field to the right. GUIDE saves the GUI before opening it in the Layout Editor. If you choose not to name the GUI at this point, GUIDE prompts you to save it and give it a name the first time you run the GUI.
3. Click **OK** to open the GUI template in the Layout Editor.

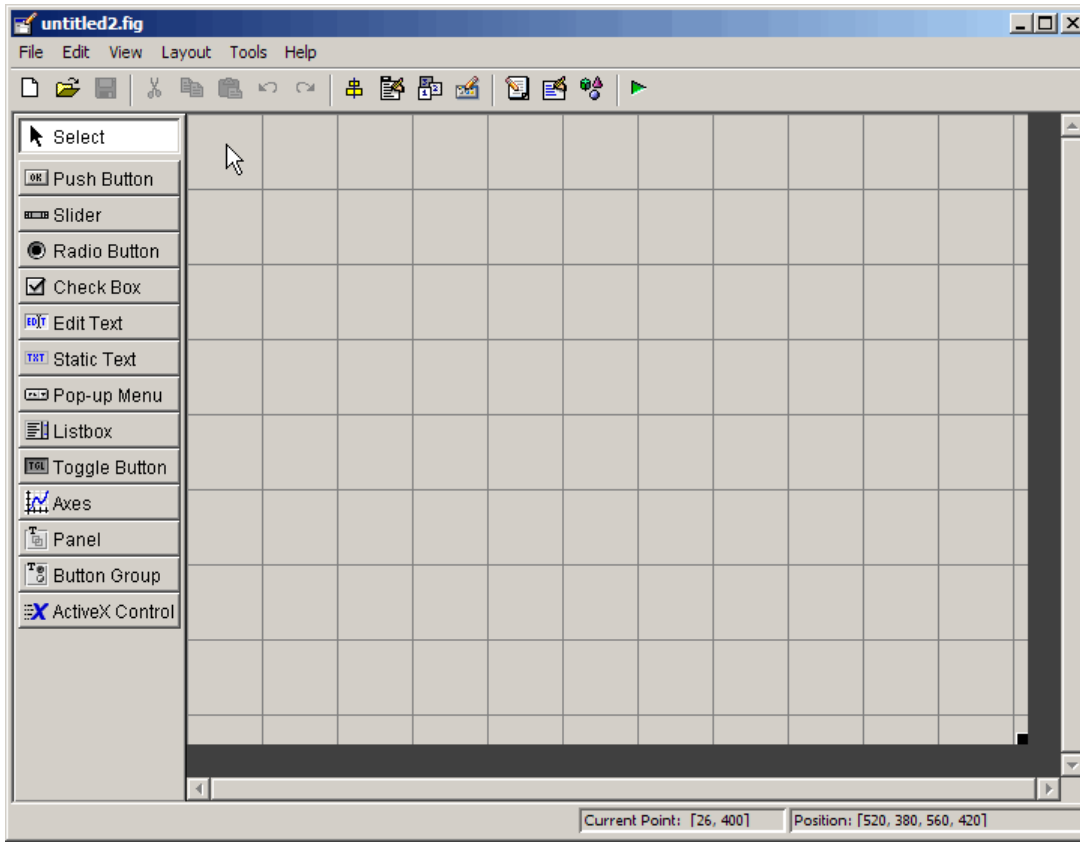
Template Descriptions

GUIDE provides four fully functional templates. They are described in the following sections:

Note To see how the template GUIs work, you can view their M-file code and look at their callbacks. You can also modify the callbacks for your own purposes. To view the M-file for any of these templates, open the template in the Layout Editor and click the **M-file Editor** button on the toolbar. For information about using callbacks, see Chapter 8, "Programming a GUIDE GUI".

Blank GUI

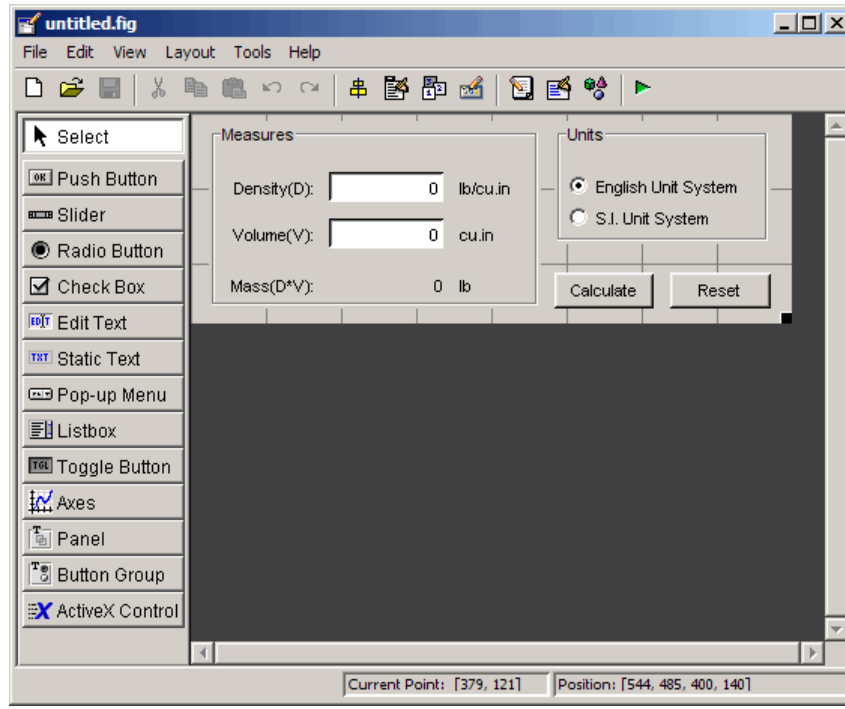
The blank GUI template displayed in the Layout Editor is shown in the following figure.



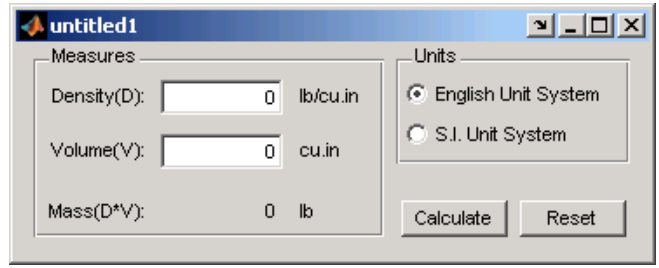
Select the blank GUI if the other templates are not suitable starting points for the GUI you are creating, or if you prefer to start with an empty GUI.

GUI with Uicontrols

The following figure shows the template for a GUI with user interface controls (uicontrols) displayed in the Layout Editor. User interface controls include push buttons, sliders, radio buttons, check boxes, editable and static text components, list boxes, and toggle buttons.



When you run the GUI by clicking the **Run** button, the GUI appears as shown in the following figure.

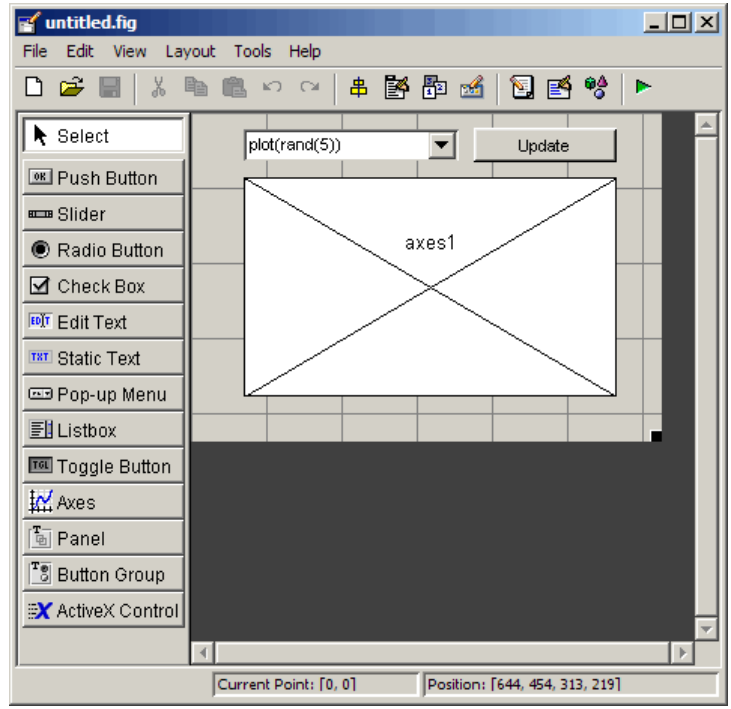


When a user enters values for the density and volume of an object, and clicks the **Calculate** button, the GUI calculates the mass of the object and displays the result next to **Mass(D*V)**.

To view the M-file code for these user interface controls, open the template in the Layout Editor and click the **M-file Editor** button on the toolbar.

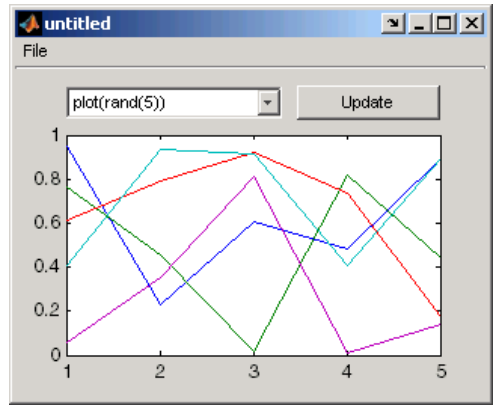
GUI with Axes and Menu

The template for a GUI with axes and menu is shown in the following figure.



untitled.fig
File Edit View Layout Tools Help
Select
Push Button
Slider
Radio Button
Check Box
Edit Text
Static Text
Pop-up Menu
Listbox
Toggle Button
Axes
Panel
Button Group
ActiveX Control
plot(rand(5))
Update
axes1
Current Point: [0, 0]
Position: [644, 454, 313, 219]

When you run the GUI by clicking the **Run** button on the toolbar, the GUI displays a plot of five lines, each of which is generated from random numbers using the MATLAB `rand(5)` command. The following figure shows an example.



You can select other plots in the pop-up menu. Clicking the **Update** button displays the currently selected plot on the axes.

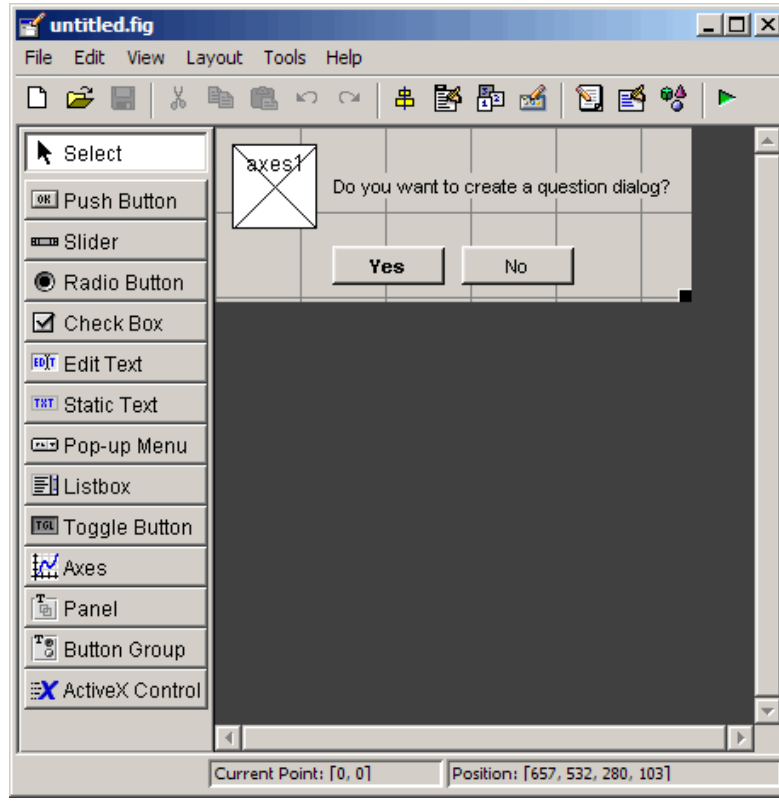
The GUI also has a **File** menu with three items:

- **Open** displays a dialog box from which you can open files on your computer.
- **Print** opens the Print dialog box. Clicking **OK** in the Print dialog box prints the figure.
- **Close** closes the GUI.

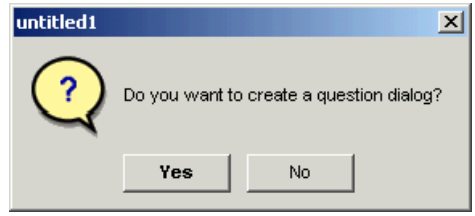
To view the M-file code for these menu choices, open the template in the Layout Editor and click the **M-file Editor** button on the toolbar.

Modal Question Dialog

The modal question dialog template displayed in the Layout Editor is shown in the following figure.



Running the GUI displays the dialog box shown in the following figure:



The GUI returns the text string `Yes` or `No`, depending on which button you click.

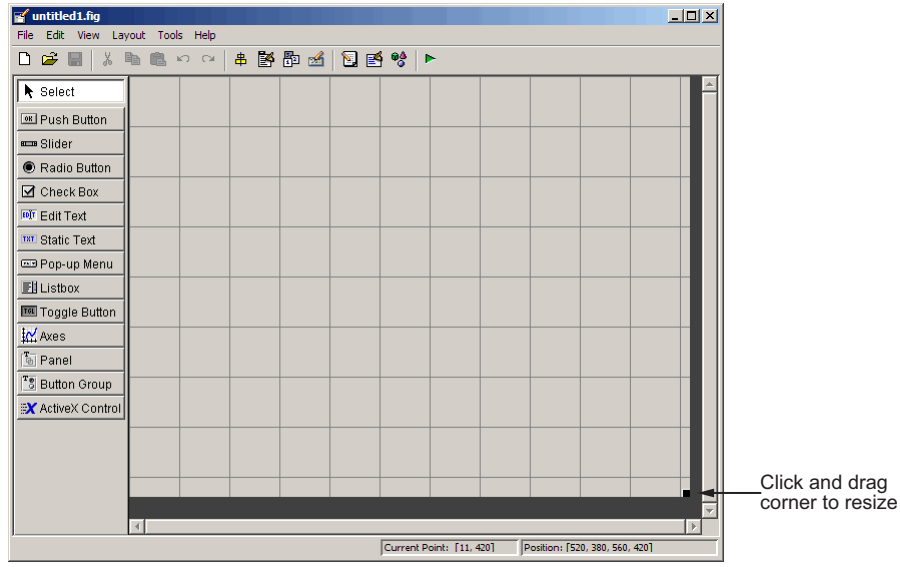
The GUI is *blocking*, which means that the current M-file stops executing until the GUI restores execution. The GUI is also *modal*, which means that the user cannot interact with other MATLAB windows until one of the buttons is clicked.

Select this template if you want your GUI to return a string or to be modal.

To view the M-file code for these capabilities, open the template in the Layout Editor and click the **M-file Editor** button  on the toolbar. See "Using a Modal Dialog to Confirm an Operation" on page 10-52 for an example of using this template with another GUI. Also see the figure `WindowStyle` property for more information.

Setting the GUI Size

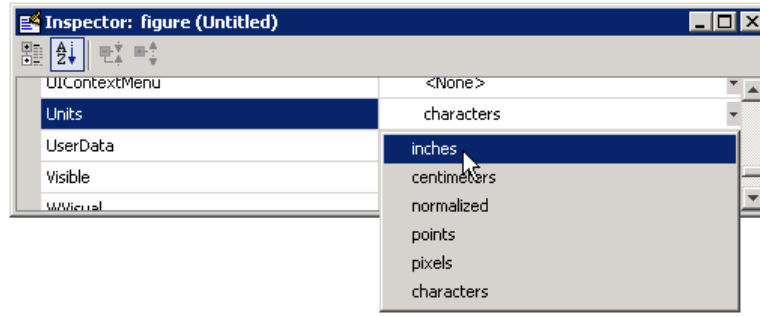
Set the size of the GUI by resizing the grid area in the Layout Editor. Click the lower-right corner and drag it until the GUI is the desired size. If necessary, make the window larger.



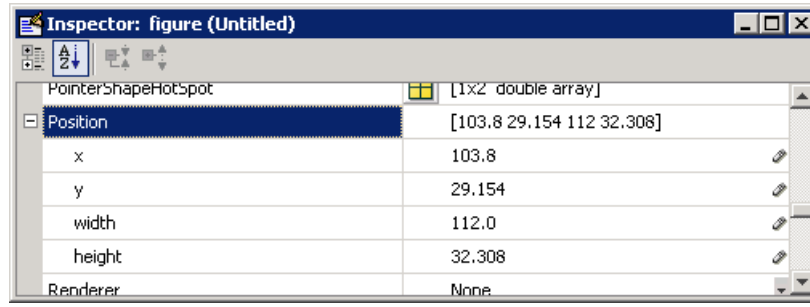
If you want to set the position or size of the GUI to an exact value, do the following:

1 Select **Property Inspector** from the **View** menu or click the **Property Inspector** button .

2 Scroll to the `Units` property and note whether the current setting is `characters` or `normalized`. Click the button next to `Units` and then change the setting to `inches` from the pop-up menu.



3 In the Property Inspector, click the **+** sign next to `Position`. The elements of the component's `Position` property are displayed.



4 Type the `x` and `y` coordinates of the point where you want the lower-left corner of the GUI to appear, and its width and height.

5 Reset the `Units` property to its previous setting, either `characters` or `normalized`.

Note Setting the `Units` property to `characters` (nonresizable GUIs) or `normalized` (resizable GUIs) gives the GUI a more consistent appearance across platforms. See "Cross-Platform Compatible Units" on page 6-103 for more information.

Adding Components to the GUI

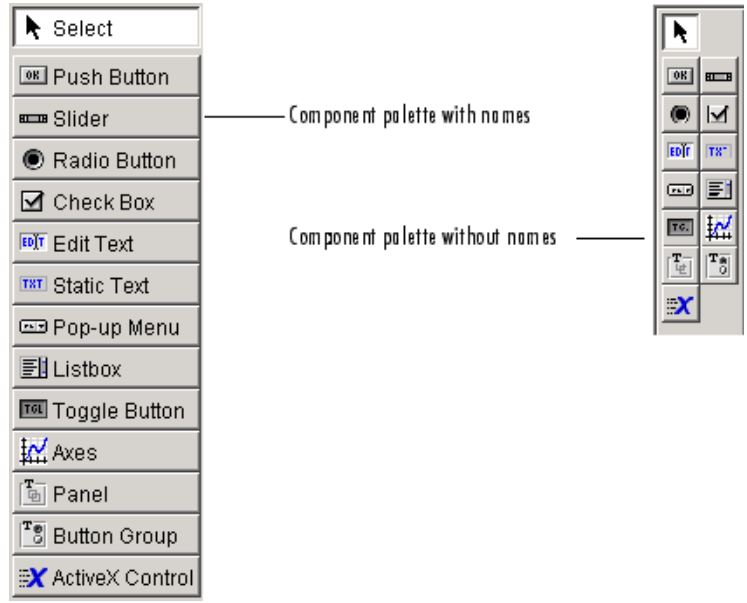
In this section...

Other topics that may be of interest:

- "Aligning Components" on page 6-62
- "Setting Tab Order" on page 6-67

Available Components

The component palette at the left side of the Layout Editor contains the components that you can add to your GUI. You can display it with or without names.



When you first open the Layout Editor, the component palette contains only icons. To display the names of the GUI components, select **Preferences** from the **File** menu, check the box next to **Show names in component palette**, and click **OK**.

See “Creating Menus” on page 6-70 for information about adding menus to a GUI.

Note This section provides information about using components to lay out a GUI. For information about programming these components see Chapter 8, “Programming a GUIDE GUI”.

Component	Icon	Description
Push Button		Push buttons generate an action when clicked. For example, an **OK** button might apply settings and close a dialog box. When you click a push button, it appears depressed; when you release the mouse button, the push button appears raised.
Toggle Button		Toggle buttons generate an action and indicate whether they are turned on or off. When you click a toggle button, it appears depressed, showing that it is on. When you release the mouse button, the toggle button remains depressed until you click it a second time. When you do so, the button returns to the raised state, showing that it is off. Use a button group to manage mutually exclusive toggle buttons.
Radio Button		Radio buttons are similar to check boxes, but radio buttons are typically mutually exclusive within a group of related radio buttons. That is, when you select one button the previously selected button is deselected. To activate a radio button, click the mouse button on the object. The display indicates the state of the button. Use a button group to manage mutually exclusive radio buttons.
Check Box		Check boxes can generate an action when checked and indicate their state as checked or not checked. Check boxes are useful when providing the user with a number of independent choices, for example, displaying a toolbar.
Edit Text		Edit text components are fields that enable users to enter or modify text strings. Use edit text when you want text as input. Users can enter numbers but you must convert them to their numeric equivalents.

Component	Icon	Description
Static Text		Static text controls display lines of text. Static text is typically used to label other controls, provide directions to the user, or indicate values associated with a slider. Users cannot change static text interactively.
Slider		Sliders accept numeric input within a specified range by enabling the user to move a sliding bar, which is called a slider or thumb. Users move the slider by clicking the slider and dragging it, by clicking in the trough, or by clicking an arrow. The location of the slider indicates the relative location within the specified range.
List Box		List boxes display a list of items and enable users to select one or more items.
Pop-Up Menu		Pop-up menus open to display a list of choices when users click the arrow.
Axes		Axes enable your GUI to display graphics such as graphs and images. Like all graphics objects, axes have properties that you can set to control many aspects of its behavior and appearance. See “Axes Properties” in the MATLAB Graphics documentation and commands such as the following for more information on axes objects: `plot`, `surf`, `line`, `bar`, `polar`, `pie`, `contour`, and `mesh`. See Functions — By Category in the MATLAB Function Reference documentation for a complete list.

Component	Icon	Description
Panel		Panels arrange GUI components into groups. By visually grouping related controls, panels can make the user interface easier to understand. A panel can have a title and various borders. Panel children can be user interface controls and axes as well as button groups and other panels. The position of each component within a panel is interpreted relative to the panel. If you move the panel, its children move with it and maintain their positions on the panel.
Button Group		Button groups are like panels but are used to manage exclusive selection behavior for radio buttons and toggle buttons.
ActiveX Component		ActiveX components enable you to display ActiveX controls in your GUI. They are available only on the Microsoft Windows platform. An ActiveX control can be the child only of a figure, i.e., of the GUI itself. It cannot be the child of a panel or button group. See “ActiveX Control” on page 8-33 in this document for an example. See “MATLAB COM Client Support” in the MATLAB External Interfaces documentation to learn more about ActiveX controls.

Adding Components to the GUIDE Layout Area

This topic tells you how to place components in the GUIDE layout area and give each component a unique identifier.

Note See “Creating Menus” on page 6-70 for information about adding menus to a GUI. See “Creating Toolbars” on page 6-84 for information about working with the toolbar.

---

1 Place components in the layout area according to your design.

- Drag a component from the palette and drop it in the layout area.
- Click a component in the palette and move the cursor over the layout area. The cursor changes to a cross. Click again to add the component in its default size, or click and drag to size the component as you add it.

The components listed in the following table need additional considerations.

If You Are Adding...	Then...
Panels or button groups	See "Adding a Component to a Panel or Button Group" on page 6-25.
ActiveX controls	See "Adding ActiveX Controls" on page 6-51.

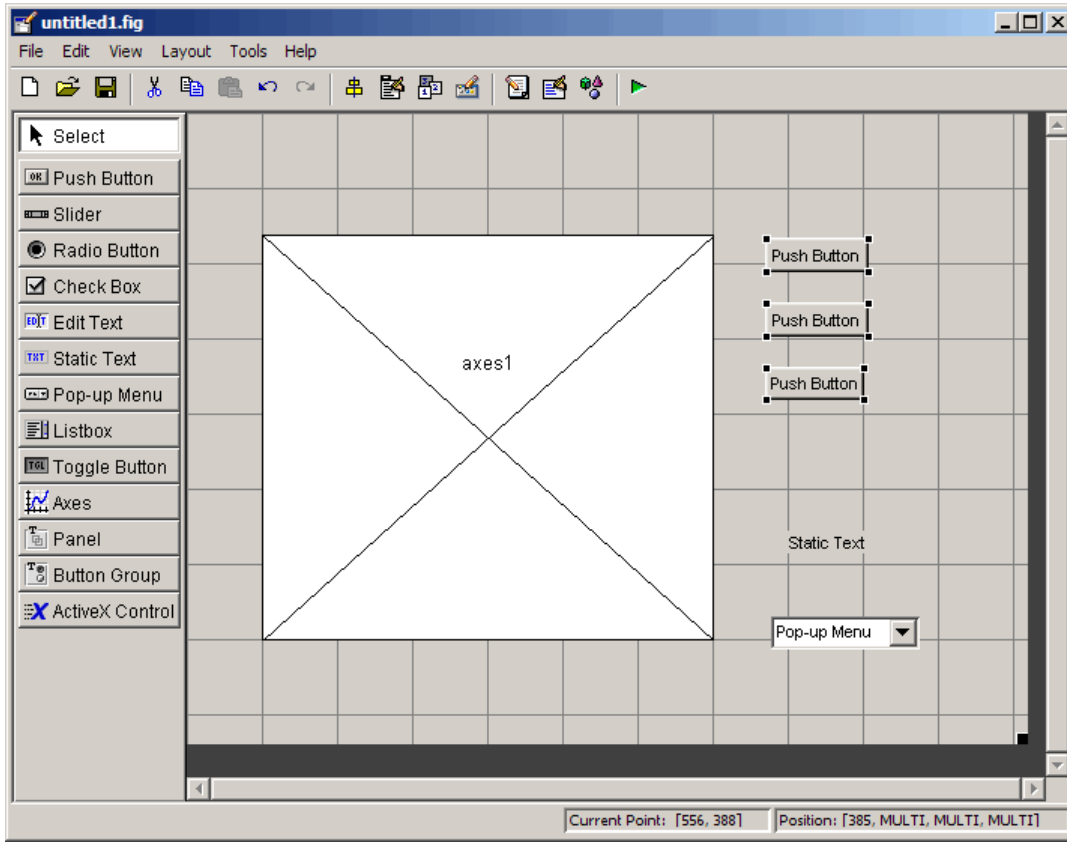
See "Grid and Rulers" on page 6-65 for information about using the grid.

2 Assign a unique identifier to each component. Do this by setting the value of the component `Tag` properties. See"Assigning an Identifier to Each Component" on page 6-27 for more information.

3 Specify the look and feel of each component by setting the appropriate properties. The following topics contain specific information.

- "Defining User Interface Controls" on page 6-27
- "Defining Panels and Button Groups" on page 6-43
- "Defining Axes" on page 6-48
- "Adding ActiveX Controls" on page 6-51

This is an example of a GUI in the Layout Editor. Components in the Layout Editor are not active. Chapter 7, “Saving and Running a GUIDE GUI” describes how to generate a functioning GUI.



Using Coordinates to Place Components

The status bar at the bottom of the GUIDE Layout Editor displays:

- **Current Point** — The current location of the mouse relative to the lower left corner of the grid area in the Layout Editor.
- **Position** — The `Position` property of the selected component, a 4-element vector: [distance from left, distance from bottom, width, height], where

distances are relative to the parent figure, panel, or button group. All values are given in pixels. Rulers also display pixels.

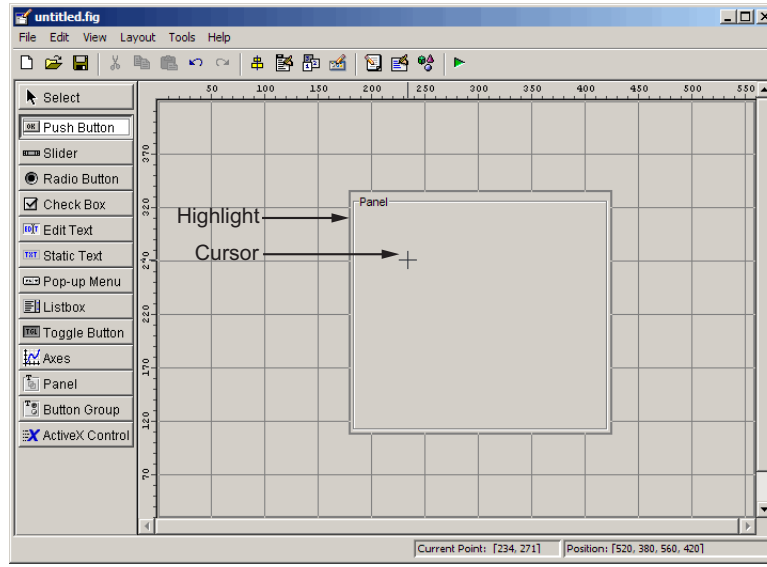
If you select a single component and move it, the first two elements of the position vector (distance from left, distance from bottom) are updated as you move the component. If you resize the component, the last two elements of the position vector (width, height) are updated as you change the size. The first two elements may also change if you resize the component such that the position of its lower left corner changes. If no components are selected, the position vector is that of the figure.

For more information, see "Using Coordinate Readouts" on page 6-57.

Adding a Component to a Panel or Button Group

To add a component to a panel or button group, select the component in the component palette then move the cursor over the desired panel or button group. The position of the cursor determines the component's parent.

GUIDE highlights the potential parent as shown in the following figure. The highlight indicates that if you drop the component or click the cursor, the component will be a child of the highlighted panel, button group, or figure.



Note If the component is not entirely contained in the panel or button group, it appears to be clipped in the Layout Editor. When you run the GUI, the entire component is displayed and straddles the panel or button group border. The component is nevertheless a child of the panel and behaves accordingly. You can use the Object Browser to determine the child objects of a panel or button group. “Viewing the Object Hierarchy” on page 6-100 tells you how.

Note Assign a unique identifier to each component in your panel or button group by setting the value of its `Tag` property. See “Assigning an Identifier to Each Component” on page 6-27 for more information.

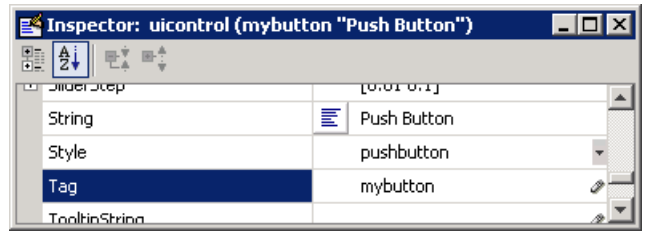
Assigning an Identifier to Each Component

Use the `Tag` property to assign each component a unique meaningful string identifier.

When you place a component in the layout area, GUIDE assigns a default value to the `Tag` property. Before saving the GUI, replace this value with a string that reflects the role of the component in the GUI.

The string value you assign `Tag` is used in the M-file code to identify the component and must be unique in the GUI. To set `Tag`:

1. Select **Property Inspector** from the **View** menu or click the **Property Inspector** button .
2. In the layout area, select the component for which you want to set `Tag`.
3. In the Property Inspector, select `Tag` and then replace the value with the string you want to use as the identifier. In the following figure, `Tag` is set to `mybutton`.



Defining User Interface Controls

User interface controls include push buttons, toggle buttons, sliders, radio buttons, edit text controls, static text controls, pop-up menus, check boxes, and list boxes.

To define user interface controls, you must set certain properties. To do this:

1. Use the Property Inspector to modify the appropriate properties. Open the Property Inspector by selecting **Property Inspector** from the **View** menu or by clicking the Property Inspector button .

2 In the layout area, select the component you are defining.

Subsequent topics describe commonly used properties of user interface controls and offer a simple example for each kind of control:

Note See "Available Components" on page 6-19 for descriptions of these components. See "Examples: Programming GUIDE GUI Components" on page 8-20 for basic examples of programming these components.

Commonly Used Properties

The most commonly used properties needed to describe a user interface control are shown in the following table. Instructions for a particular control may also list properties that are specific to that control.

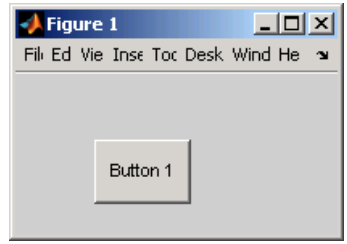
Property	Value	Description
`Enable`	`on`, `inactive`, `off`. Default is `on`.	Determines whether the control is available to the user

Property	Value	Description
`Max`	Scalar. Default is 1.	Maximum value. Interpretation depends on the type of component.
`Min`	Scalar. Default is 0.	Minimum value. Interpretation depends on the type of component.
`Position`	4-element vector: [distance from left, distance from bottom, width, height].	Size of the component and its location relative to its parent.
`String`	String. Can also be a cell array or character array of strings.	Component label. For list boxes and pop-up menus it is a list of the items.
`Units`	`characters`, `centimeters`, `inches`, `normalized`, `pixels`, `points`. Default is `characters`.	Units of measurement used to interpret the `Position` property vector
`Value`	Scalar or vector	Value of the component. Interpretation depends on the type of component.

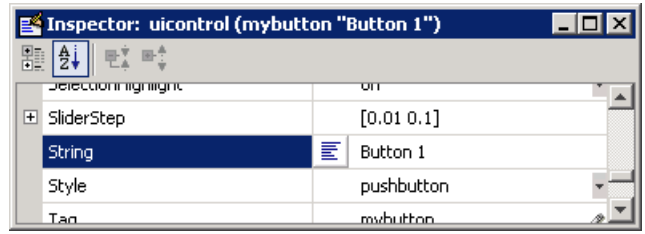
For a complete list of properties and for more information about the properties listed in the table, see Uicontrol Properties in the MATLAB documentation. Properties needed to control GUI behavior are discussed in Chapter 8, “Programming a GUIDE GUI”

Push Button

To create a push button with label **Button 1**, as shown in this figure:



- Specify the push button label by setting the `String` property to the desired label, in this case, `Button 1`.



To display the & character in a label, use two `&` characters in the string. The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

The push button accommodates only a single line of text. If you specify more than one line, only the first line is shown. If you create a push button that is too narrow to accommodate the specified `String`, MATLAB truncates the string with an ellipsis.

- If you want to set the position or size of the component to an exact value, then modify its `Position` property. See “Locating and Moving Components” on page 6-57 and “Resizing Components” on page 6-60 for details.
- To add an image to a push button, assign the button’s `CData` property an m-by-n-by-3 array of RGB values that defines a truecolor image. You must do this programmatically in the opening function of the GUI M-file. For

example, the array `img` defines a 16-by-64-by-3 truecolor image using random values between 0 and 1 (generated by `rand`).

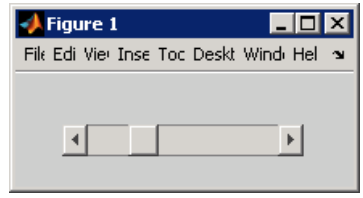
```
img = rand(16,64,3);
set(handles.pushbutton1,'CData',img);
```

where `pushbutton1` is the push button's `Tag` property.

Note Create your own icon with the icon editor described in "Icon Editor" on page 15-29. See `ind2rgb` for information on converting a matrix `X` and corresponding colormap, i.e., an `(X, MAP)` image, to RGB (truecolor) format.

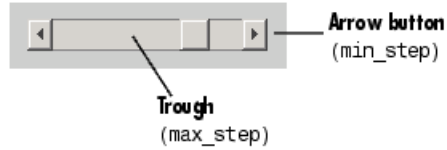
Slider

To create a slider as shown in this figure:



- Specify the range of the slider by setting its `Min` property to the minimum value of the slider and its `Max` property to the maximum value. The `Min` property must be less than `Max`.
- Specify the value indicated by the slider when it is created by setting the `Value` property to the appropriate number. This number must be less than or equal to `Max` and greater than or equal to `Min`. If you specify `Value` outside the specified range, the slider is not displayed.
- Control the amount the slider `Value` changes when a user clicks the arrow button to produce a minimum step or the slider trough to produce a

maximum step by setting the `SliderStep` property. Specify `SliderStep` as a two-element vector, `[min_step,max_step]`, where each value is in the range [0, 1] to indicate a percentage of the range.



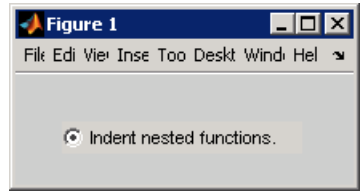
- If you want to set the position or size of the component to an exact value, then modify its `Position` property. See "Locating and Moving Components" on page 6-57 and "Resizing Components" on page 6-60 for details.

Note On Mac platforms, the height of a horizontal slider is constrained. If the height you set in the position vector exceeds this constraint, the displayed height of the slider is the maximum allowed. The height element of the position vector is not changed.

Note The slider component provides no text description or data entry capability. Use a "Static Text" on page 6-36 component to label the slider. Use an "Edit Text" on page 6-35 component to enable a user to provide a value for the slider.

Radio Button

To create a radio button with label **Indent nested functions**, as shown in this figure:



- Specify the radio button label by setting the `String` property to the desired label, in this case, `Indent nested functions`.

  To display the & character in a label, use two `&` characters in the string. The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

  The radio button accommodates only a single line of text. If you specify more than one line, only the first line is shown. If you create a radio button that is too narrow to accommodate the specified `String`, MATLAB truncates the string with an ellipsis.

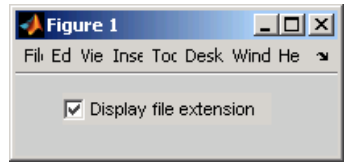
- Create the radio button with the button selected by setting its `Value` property to the value of its `Max` property (default is `1`). Set `Value` to `Min` (default is `0`) to leave the radio button unselected. Correspondingly, when the user selects the radio button, MATLAB sets `Value` to `Max`. MATLAB sets `Value` to `Min` when the user deselects it.
- If you want to set the position or size of the component to an exact value, then modify its `Position` property. See “Locating and Moving Components” on page 6-57 and “Resizing Components” on page 6-60 for details.
- To add an image to a radio button, assign the button’s `CData` property an m-by-n-by-3 array of RGB values that defines a truecolor image. You must do this programmatically in the opening function of the GUI M-file. For example, the array `img` defines a 16-by-24-by-3 truecolor image using random values between 0 and 1 (generated by `rand`).

```
img = rand(16,24,3);
set(handles.radiobutton1,'CData',img);
```

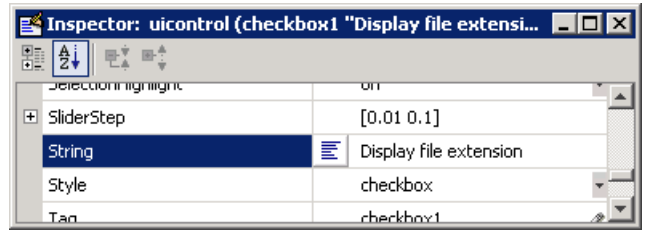
Note To manage exclusive selection of radio buttons and toggle buttons, put them in a button group. See “Button Group” on page 6-46 for more information.

Check Box

To create a check box with label **Display file extension** that is initially checked, as shown in this figure:



- Specify the check box label by setting the `String` property to the desired label, in this case, `Display file extension`.



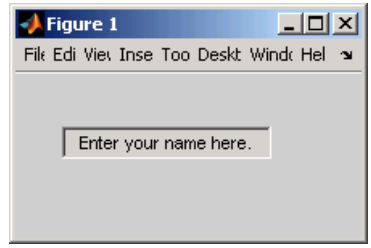
To display the & character in a label, use two & characters in the string. The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

The check box accommodates only a single line of text. If you specify a component width that is too small to accommodate the specified `String`, MATLAB truncates the string with an ellipsis.

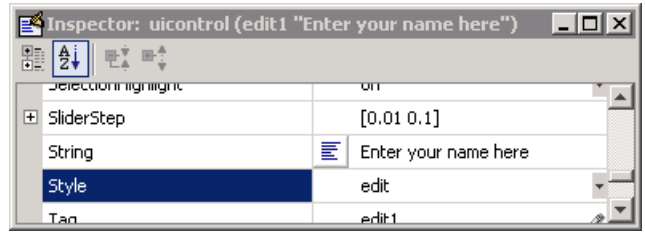
- Create the check box with the box checked by setting the `Value` property to the value of the `Max` property (default is `1`). Set `Value` to `Min` (default is `0`) to leave the box unchecked. Correspondingly, when the user clicks the check box, MATLAB sets `Value` to `Max` when the user checks the box and to `Min` when the user unchecks it.
- If you want to set the position or size of the component to an exact value, then modify its `Position` property. See "Locating and Moving Components" on page 6-57 and "Resizing Components" on page 6-60 for details.

Edit Text

To create an edit text component that displays the initial text **Enter your name here**, as shown in this figure:



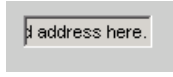
- Specify the text to be displayed when the edit text component is created by setting the `String` property to the desired string, in this case, `Enter your name here`.



To display the & character in a label, use two & characters in the string. The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

- To enable multiple-line input, specify the `Max` and `Min` properties so that their difference is greater than 1. For example, `Max = 2`, `Min = 0`. `Max` default is `1`, `Min` default is `0`. MATLAB wraps the string and adds a scroll bar if necessary.

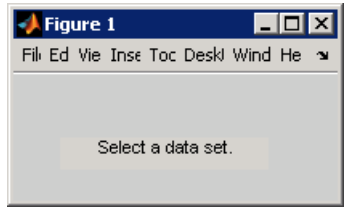
  If `Max-Min` is less than or equal to 1, the edit text component admits only a single line of input. If you specify a component width that is too small to accommodate the specified string, MATLAB displays only part of the string. The user can use the arrow keys to move the cursor over the entire string.



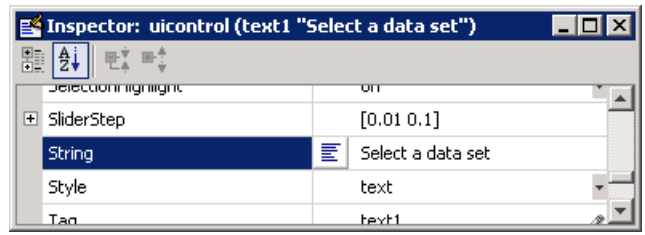
- If you want to set the position or size of the component to an exact value, then modify its `Position` property. See “Locating and Moving Components” on page 6-57 and “Resizing Components” on page 6-60 for details.

Static Text

To create a static text component with text **Select a data set**, as shown in this figure:

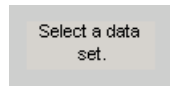


- Specify the text that appears in the component by setting the component `String` property to the desired text, in this case `Select a data set`.



To display the & character in a list item, use two & characters in the string. The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

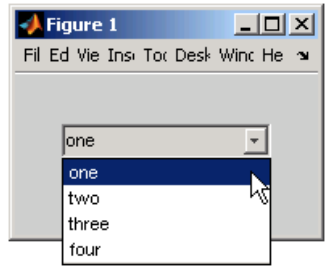
If your component is not wide enough to accommodate the specified `String`, MATLAB wraps the string.



- If you want to set the position or size of the component to an exact value, then modify its `Position` property. See “Locating and Moving Components” on page 6-57 and “Resizing Components” on page 6-60 for details.

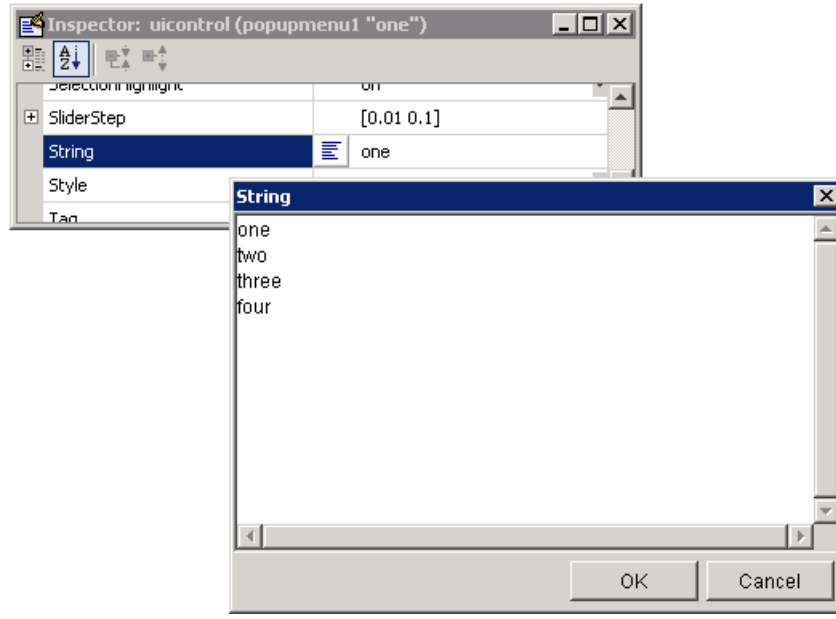
Pop-Up Menu

To create a pop-up menu (also known as a drop-down menu or combo box) with items **one**, **two**, **three**, and **four**, as shown in this figure:



- Specify the pop-up menu items to be displayed by setting the `String` property to the desired items. Click the

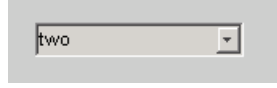
button to the right of the property name to open the Property Inspector editor.



To display the & character in a menu item, use two `&` characters in the string. The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

If the width of the component is too small to accommodate one or more of the specified strings, MATLAB truncates those strings with an ellipsis.

- To select an item when the component is created, set `Value` to a scalar that indicates the index of the selected list item, where `1` corresponds to the first item in the list. If you set `Value` to `2`, the menu looks like this when it is created:

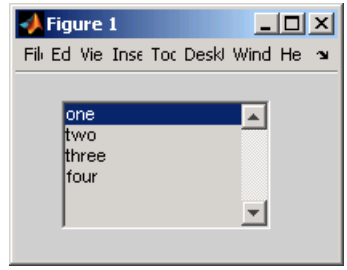


- If you want to set the position and size of the component to exact values, then modify its `Position` property. See “Locating and Moving Components” on page 6-57 and “Resizing Components” on page 6-60 for details. The height of a pop-up menu is determined by the font size. The height you set in the position vector is ignored.

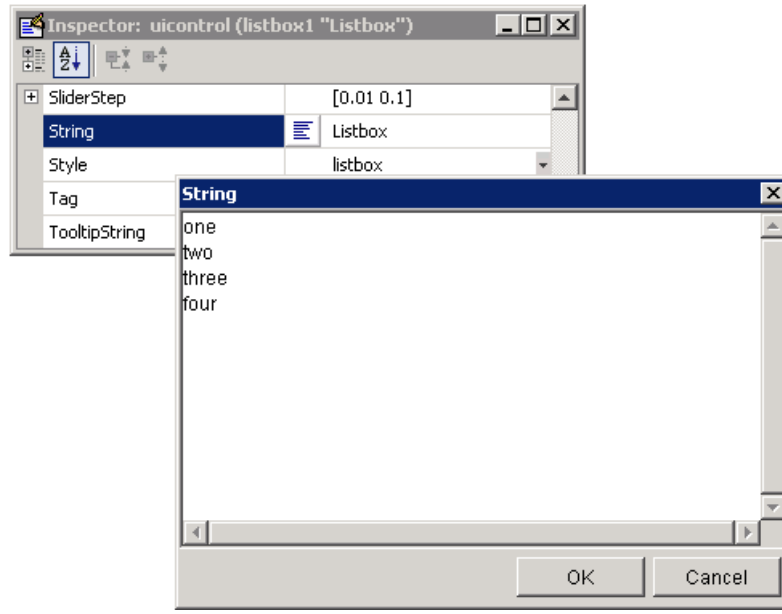
Note The pop-up menu does not provide for a label. Use a “Static Text” on page 6-36 component to label the pop-up menu.

List Box

To create a list box with items **one**, **two**, **three**, and **four**, as shown in this figure:



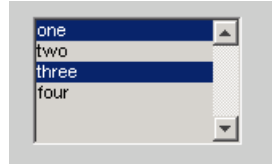
- Specify the list of items to be displayed by setting the `String` property to the desired list. Use the Property Inspector editor to enter the list. You can open the editor by clicking the  button to the right of the property name.



To display the & character in a label, use two `&` characters in the string. The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

If the width of the component is too small to accommodate one or more of the specified strings, MATLAB truncates those strings with an ellipsis.

- Specify selection by using the `Value` property together with the `Max` and `Min` properties.
  - To select a single item when the component is created, set `Value` to a scalar that indicates the index of the selected list item, where `1` corresponds to the first item in the list.
  - To select more than one item when the component is created, set `Value` to a vector of indices of the selected items. `Value = [1,3]` results in the following selection.



To enable selection of more than one item, you must specify the `Max` and `Min` properties so that their difference is greater than `1`. For example, `Max = 2`, `Min = 0`. `Max` default is `1`, `Min` default is `0`.

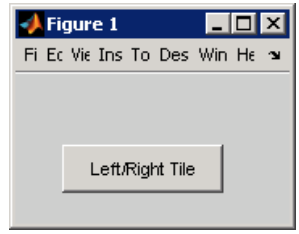
- If you want no initial selection, set the `Max` and `Min` properties to enable multiple selection, i.e., `Max - Min > 1`, and then set the `Value` property to an empty matrix `[]`.

- If the list box is not large enough to display all list entries, you can set the `ListBoxTop` property to the index of the item you want to appear at the top when the component is created.
- If you want to set the position or size of the component to an exact value, then modify its `Position` property. See "Locating and Moving Components" on page 6-57 and "Resizing Components" on page 6-60 for details.

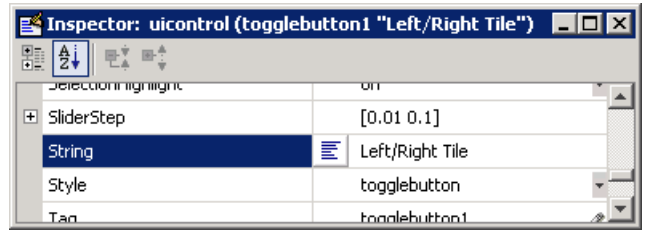
Note The list box does not provide for a label. Use a "Static Text" on page 6-36 component to label the list box.

Toggle Button

To create a toggle button with label **Left/Right Tile**, as shown in this figure:



- Specify the toggle button label by setting its `String` property to the desired label, in this case, `Left/Right Tile`.



To display the & character in a label, use two `&` characters in the string. The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

The toggle button accommodates only a single line of text. If you specify more than one line, only the first line is shown. If you create a toggle button that is too narrow to accommodate the specified `String`, MATLAB truncates the string with an ellipsis.

- Create the toggle button with the button selected (depressed) by setting its `Value` property to the value of its `Max` property (default is `1`). Set `Value` to `Min` (default is `0`) to leave the toggle button unselected (raised). Correspondingly, when the user selects the toggle button, MATLAB sets `Value` to `Max`. MATLAB sets `Value` to `Min` when the user deselects it. The following figure shows the toggle button in the depressed position.

- If you want to set the position or size of the component to an exact value, then modify its `Position` property. See “Locating and Moving Components” on page 6-57 and “Resizing Components” on page 6-60 for details.
- To add an image to a toggle button, assign the button’s `CData` property an m-by-n-by-3 array of RGB values that defines a truecolor image. You must do this programmatically in the opening function of the GUI M-file. For example, the array `img` defines a 16-by-64-by-3 truecolor image using random values between 0 and 1 (generated by `rand`).

```
img = rand(16,64,3);
set(handles.togglebutton1,'CData',img);
```

where `togglebutton1` is the toggle button's `Tag` property.

Note To manage exclusive selection of radio buttons and toggle buttons, put them in a button group. See "Button Group" on page 6-46 for more information.

Defining Panels and Button Groups

Panels and button groups are containers that arrange GUI components into groups. If you move the panel or button group, its children move with it and maintain their positions relative to the panel or button group.

To define panels and button groups, you must set certain properties. To do this:

1. Use the Property Inspector to modify the appropriate properties. Open the Property Inspector by selecting **Property Inspector** from the **View** menu or by clicking the Property Inspector button . 
2. In the layout area, select the component you are defining.

Note See "Available Components" on page 6-19 for descriptions of these components. See "Examples: Programming GUIDE GUI Components" on page 8-20 for basic examples of programming these components.

Subsequent topics describe commonly used properties of panels and button groups and offer a simple example for each component.

Commonly Used Properties

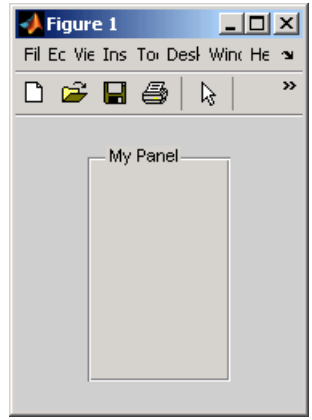
The most commonly used properties needed to describe a panel or button group are shown in the following table:

Property	Values	Description
Position	4-element vector: [distance from left, distance from bottom, width, height].	Size of the component and its location relative to its parent.
Title	String	Component label.
TitlePosition	`lefttop`, `centertop`, `righttop`, `leftbottom`, `centerbottom`, `rightbottom`. Default is `lefttop`.	Location of title string in relation to the panel or button group.
Units	`characters`, `centimeters`, `inches`, normalized, `pixels`, `points`. Default is `characters`.	Units of measurement used to interpret the `Position` property vector

For a complete list of properties and for more information about the properties listed in the table, see the Uipanel Properties and Uibuttongroup Properties in the MATLAB reference documentation. Properties needed to control GUI behavior are discussed in theChapter 8, "Programming a GUIDE GUI".

Panel

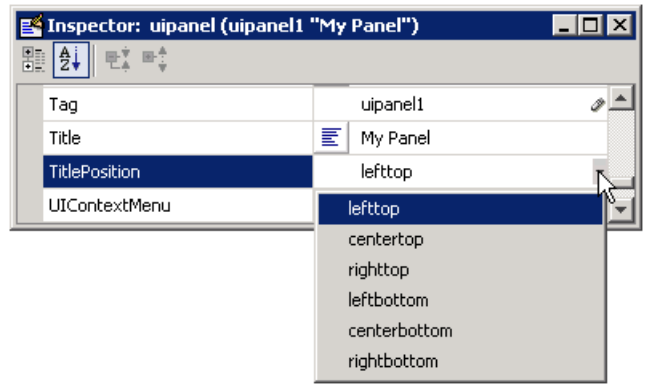
To create a panel with title **My Panel** as shown in the following figure:



- Specify the panel title by setting the `Title` property to the desired string, in this case `My Panel`.

  To display the & character in the title, use two & characters in the string. The words remove, default, and factory (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove**.

- Specify the location of the panel title by selecting one of the available `TitlePosition` property values from the pop-up menu, in this case `lefttop`. You can position the title at the left, middle, or right of the top or bottom of the panel.

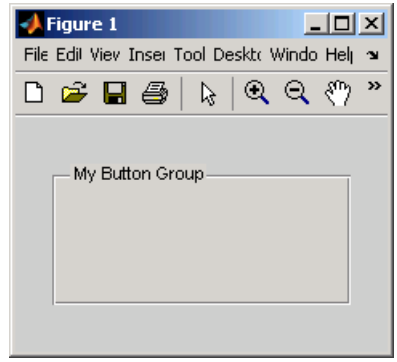


- If you want to set the position or size of the panel to an exact value, then modify its `Position` property. See "Locating and Moving Components" on page 6-57 and "Resizing Components" on page 6-60 for details.

Note For information about adding components to a panel, see "Adding a Component to a Panel or Button Group" on page 6-25.

Button Group

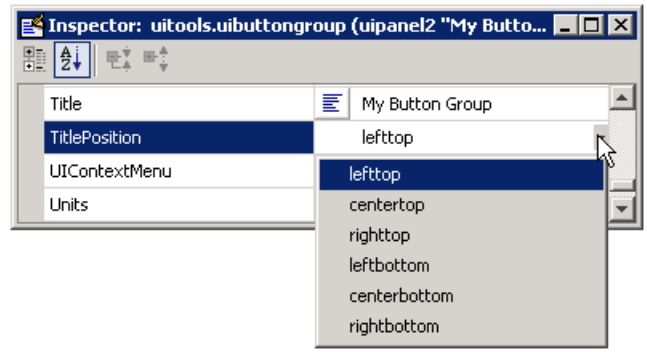
To create a button group with title **My Button Group** as shown in the following figure:



- Specify the button group title by setting the `Title` property to the desired string, in this case `My Button Group`.

  To display the & character in the title, use two & characters in the string. The words remove, default, and factory (case sensitive) are reserved. To use one of these as a label, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove**.

- Specify the location of the button group title by selecting one of the available `TitlePosition` property values from the pop-up menu, in this case `lefttop`. You can position the title at the left, middle, or right of the top or bottom of the button group.



- If you want to set the position or size of the button group to an exact value, then modify its `Position` property. See “Locating and Moving Components” on page 6-57 and “Resizing Components” on page 6-60 for details.

Note For information about adding components to a button group, see “Adding a Component to a Panel or Button Group” on page 6-25.

Defining Axes

Axes enable your GUI to display graphics such as graphs and images using commands such as: `plot`, `surf`, `line`, `bar`, `polar`, `pie`, `contour`, and `mesh`.

To define an axes, you must set certain properties. To do this:

1. Use the Property Inspector to modify the appropriate properties. Open the Property Inspector by selecting **Property Inspector** from the **View** menu or by clicking the Property Inspector button.
2. In the layout area, select the component you are defining.

Note See"Available Components" on page 6-19 for a description of this component.

Subsequent topics describe commonly used properties of axes and offer a simple example.

- "Commonly Used Properties" on page 6-48
- "Axes" on page 6-49

Commonly Used Properties

The most commonly used properties needed to describe an axes are shown in the following table:

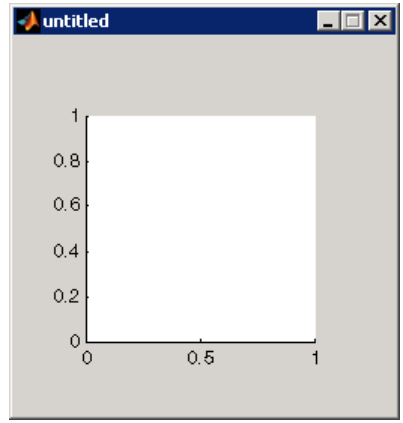
Property	Values	Description
Position	4-element vector: [distance from left, distance from bottom, width, height].	Size of the component and its location relative to its parent.
Units	`normalized`, `centimeters`, `characters`, `inches`, `pixels`, `points`. Default is `normalized`.	Units of measurement used to interpret position vector

For a complete list of properties and for more information about the properties listed in the table, see Axes Properties in the MATLAB documentation. Properties needed to control GUI behavior are discussed in Chapter 8, "Programming a GUIDE GUI".

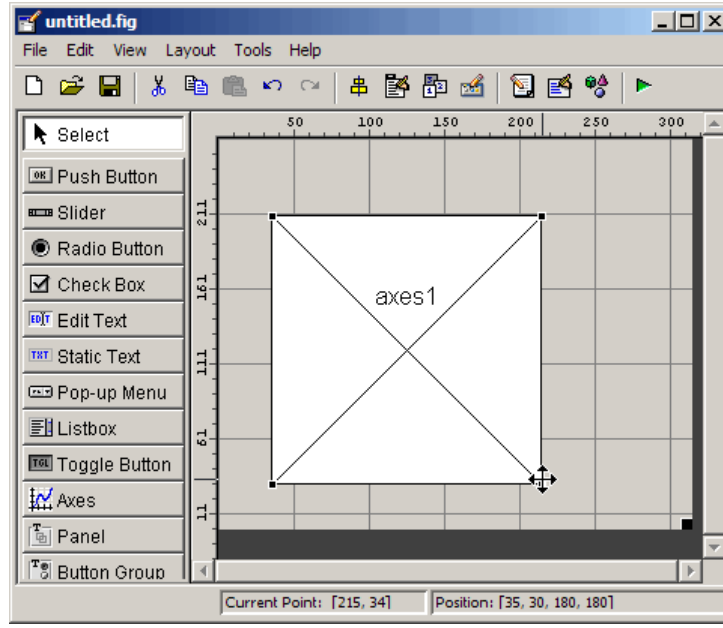
See commands such as the following for more information on axes objects: `plot`, `surf`, `line`, `bar`, `polar`, `pie`, `contour` and `mesh`. See Functions — By Category in the MATLAB Function Reference documentation for a complete list.

Axes

To create an axes as shown in the following figure:



- Allow for tick marks to be placed outside the box that appears in the Layout Editor. The axes above looks like this in the layout editor; placement allows space at the left and bottom of the axes for tick marks. Functions that draw in the axes update the tick marks appropriately.



- Use the `title`, `xlabel`, `ylabel`, `zlabel`, and `text` functions in the GUI M-file to label an axes component. For example,

  ```
  xlh = (axes_handle,'Years')
  ```

  labels the X-axis as `Years`. The handle of the X-axis label is `xlh`. See "Callback Syntax and Arguments" on page 8-12 for information about determining the axes handle.

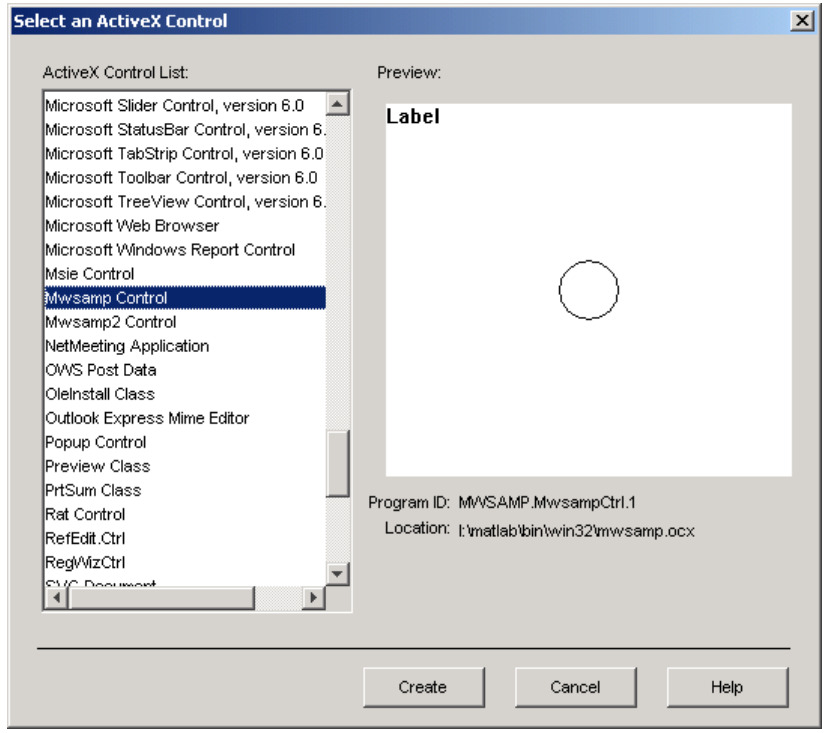
  The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these in component text, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

- If you want to set the position or size of the axes to an exact value, then modify its `Position` property. See "Locating and Moving Components" on page 6-57 and "Resizing Components" on page 6-60 for details.

Adding ActiveX Controls

When you drag an ActiveX component from the component palette into the layout area, GUIDE opens a dialog box, similar to the following, that lists the registered ActiveX controls on your system.

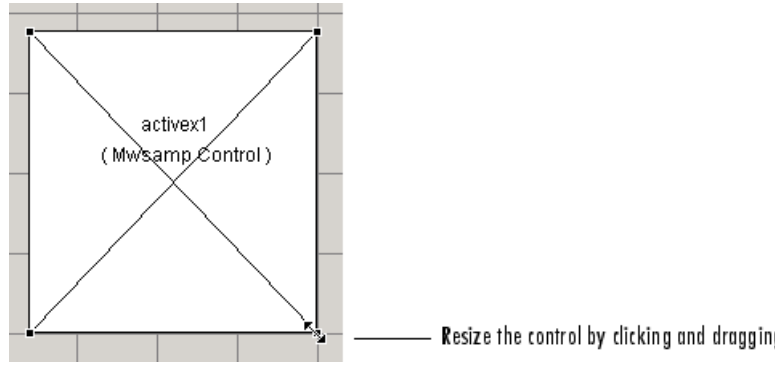
Note If MATLAB is not installed locally on your computer — for example, if you are running MATLAB over a network — you might not find the ActiveX control described in this example. To register the control, see "Registering Controls and Servers" in the MATLAB External Interfaces documentation.



1 Select the desired ActiveX control. The right panel shows a preview of the selected control.

2 Click **Create**. The control appears as a small box in the Layout Editor.

3 Resize the control to approximately the size of the square shown in the preview pane. You can do this by clicking and dragging a corner of the control, as shown in the following figure.



See “ActiveX Control” on page 8-33 for information about programming a sample ActiveX control and an example.

Working with Components in the Layout Area

This topic provides basic information about selecting, copying, pasting, and deleting components in the layout area.

Other topics that may be of interest are

Selecting Components

You can select components in the layout area in the following ways:

- Click a single component to select it.
- Press **Ctrl+A** to select all child objects of the figure. This does not select components that are child objects of panels or button groups.
- Click and drag the cursor to create a rectangle that encloses the components you want to select. If the rectangle encloses a panel or button group, only the panel or button group is selected, not its children. If the rectangle encloses part of a panel or button group, only the components within the rectangle that are child objects of the panel or button group are selected.
- Select multiple components using the **Shift** and **Ctrl** keys.

In some cases, a component may lie outside its parent's boundary. Such a component is not visible in the Layout Editor but can be selected by dragging a rectangle that encloses it or by selecting it in the Object Browser. Such a component is visible in the active GUI.

See "Viewing the Object Hierarchy" on page 6-100 for information about the Object Browser.

Note You can select multiple components only if they have the same parent. To determine the child objects of a figure, panel, or button group, use the Object Browser.

Copying, Cutting, and Clearing Components

Use standard menu and pop-up menu commands, toolbar icons, keyboard keys, and shortcut keys to copy, cut, and clear components.

Copying. Copying places a copy of the selected components on the clipboard. A copy of a panel or button group includes its children.

Cutting. Cutting places a copy of the selected components on the clipboard and deletes them from the layout area. If you cut a panel or button group, you also cut its children.

Clearing. Clearing deletes the selected components from the layout area. It does not place a copy of the components on the clipboard. If you clear a panel or button group, you also clear its children.

Pasting and Duplicating Components

Pasting. Use standard menu and pop-up menu commands, toolbar icons, and shortcut keys to paste components. GUIDE pastes the contents of the clipboard to the location of the last mouse click. It positions the upper-left corner of the contents at the mouse click.

Consecutive pastes place each copy to the lower right of the last one.

Duplicating. Select one or more components that you want to duplicate, then do one of the following:

- Copy and paste the selected components as described above.
- Select **Duplicate** from the **Edit** menu or the pop-up menu. **Duplicate** places the copy to the lower right of the original.
- Right-click and drag the component to the desired location. The position of the cursor when you drop the components determines the parent of all the selected components. Look for the highlight as described in “Adding a Component to a Panel or Button Group” on page 6-25.

Front-to-Back Positioning

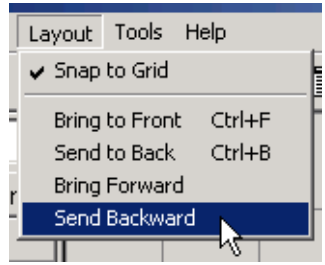
MATLAB figures maintain separate stacks that control the front-to-back positioning for different kinds of components:

- User interface controls such as buttons, sliders, and pop-up menus
- Panels, button groups, and axes
- ActiveX controls

You can control the front-to-back positioning of components that overlap only if those components are in the same stack. For overlapping components that are in different stacks:

- User interface controls always appear on top of panels, button groups, axes that they overlap. ActiveX controls appear on top of everything they overlap.
- Panels, button groups, and axes always appear on top of ActiveX controls.

The Layout Editor provides four operations that enable you to control front-to-back positioning. All are available from the **Layout** menu, which is shown in the following figure.



- **Bring to Front** — Move the selected object(s) in front of nonselected objects (available from the right-click context menu, the **Layout** menu, or the **Ctrl+F** shortcut).
- **Send to Back** — Move the selected object(s) behind nonselected objects (available from the right-click context menu, the **Layout** menu, or the **Ctrl+B** shortcut).
- **Bring Forward** — Move the selected object(s) forward by one level, i.e., in front of the object directly forward of it, but not in front of all objects that overlay it (available from the **Layout** menu).
- **Send Backward** — Move the selected object(s) back by one level, i.e., behind the object directly in back of it, but not behind all objects that are behind it (available from the **Layout** menu).

Note Changing front-to-back positioning of components also changes their tab order. See “Setting Tab Order” on page 6-67 for more information.

Locating and Moving Components

You can locate or move components in one of the following ways:

- "Using Coordinate Readouts" on page 6-57
- "Dragging Components" on page 6-58
- "Using Arrow Keys to Move Components" on page 6-58
- "Setting the Component's Position Property" on page 6-58

Another topic that may be of interest is

- "Aligning Components" on page 6-62

Using Coordinate Readouts

Coordinate readouts indicate where a component is placed and where the mouse pointer is located. Use these readouts to position and align components manually. The coordinate readout in the lower right corner of the Layout Editor shows the position of a selected component or components as `[xleft ybottom width height]`. These values are displayed in units of pixels, regardless of the coordinate units you select for components.

If you drag or resize the component, the readout updates accordingly. The readout to the left of the component position readout displays the current mouse position, also in pixels. The following readout example shows a selected component that has a position of `[35, 30, 180, 180]`, a 180-by-180 pixel object with a lower left corner at `x=35` and `y=30`, and locates the mouse position at `[200, 30]`.

When you select multiple objects, the **Position** readout displays numbers for `x`, `y`, `width` and `height` only if the objects have the same respective values; in all other cases it displays `'MULTI'`. For example, if you select two checkboxes, one with Position `[250, 140, 76, 20]` pixels and the other with position `[250, 190, 68, 20]` pixels, the **Position** readout indicates `[250, MULTI, MULTI, 20]`.

Dragging Components

Select one or more components that you want to move, then drag them to the desired position and drop them. You can move components from the figure into a panel or button group. You can move components from a panel or button group into the figure or into another panel or button group.

The position of the cursor when you drop the components also determines the parent of all the selected components. Look for the highlight as described in "Adding a Component to a Panel or Button Group" on page 6-25.

In some cases, one or more of the selected components may lie outside its parent's boundary. Such a component is not visible in the Layout Editor but can be selected by dragging a rectangle that encloses it or by selecting it in the Object Browser. Such a component is visible in the active GUI.

See "Viewing the Object Hierarchy" on page 6-100 for information about the Object Browser.

Note To select multiple components, they must have the same parent. That is, they must be contained in the same figure, panel, or button group.

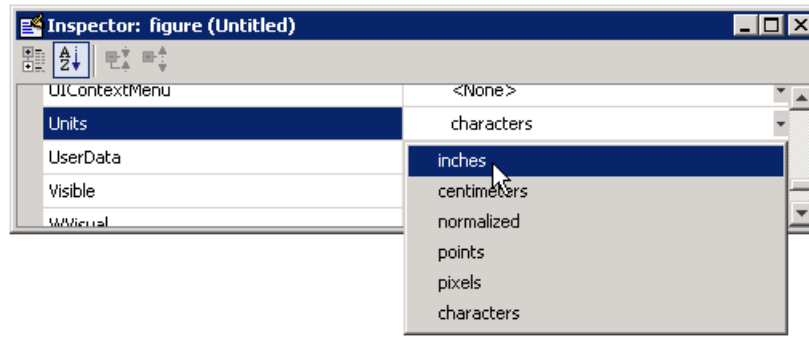
Using Arrow Keys to Move Components

Select one or more components that you want to move, then press and hold the arrow keys until the components have moved to the desired position. Note that the components remain children of the figure, panel, or button group from which you move them, even if they move outside its boundaries.

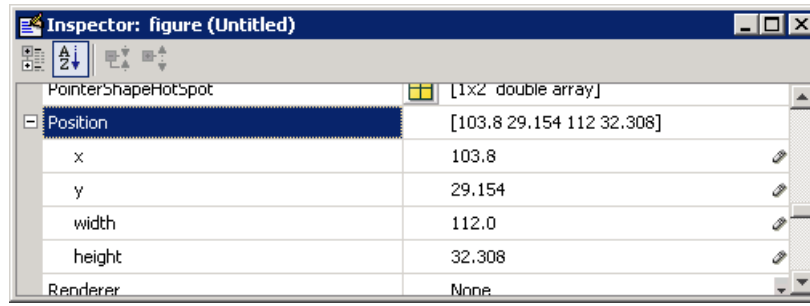
Setting the Component's Position Property

Select one or more components that you want to move. Then open the Property Inspector from the **View** menu or by clicking the Property Inspector button  .

1. In the Property Inspector, scroll to the `Units` property and note whether the current setting is `characters` or `normalized`. Click the button next to `Units` and then change the setting to `inches` from the pop-up menu.



2 Click the **+** sign next to `Position`. The Property Inspector displays the elements of the `Position` property.



3 If you have selected

- Only one component, type the `x` and `y` coordinates of the point where you want the lower-left corner of the component to appear.
- More than one component, type either the `x` or the `y` coordinate to align the components along that dimension.

4 Reset the `Units` property to its previous setting, either `characters` or `normalized`.

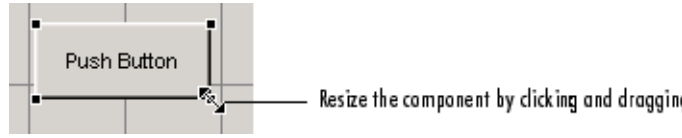
Note Setting the `Units` property to `characters` (nonresizable GUIs) or `normalized` (resizable GUIs) gives the GUI a more consistent appearance across platforms. See "Cross-Platform Compatible Units" on page 6-103 for more information.

Resizing Components

You can resize components in one of the following ways:

Dragging a Corner of the Component

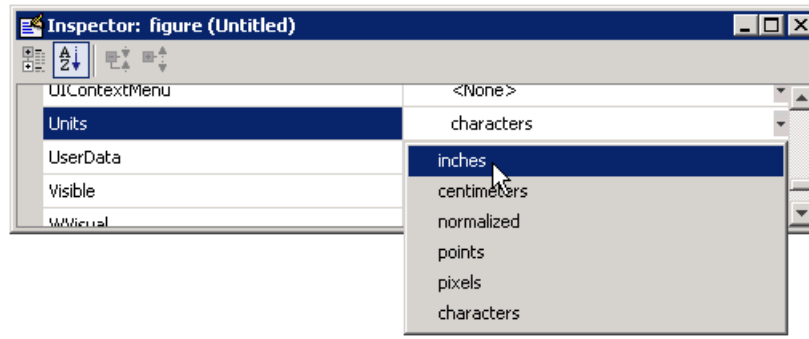
Select the component you want to resize. Click one of the corner handles and drag it until the component is the desired size.



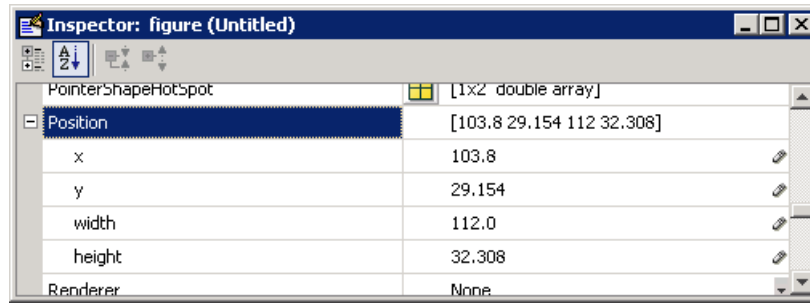
Setting the Component's Position Property

Select one or more components that you want to resize. Then open the Property Inspector from the **View** menu or by clicking the Property Inspector button .

1. In the Property Inspector, scroll to the `Units` property and note whether the current setting is `characters` or `normalized`. Click the button next to `Units` and then change the setting to `inches` from the pop-up menu.



2 Click the **+** sign next to `Position`. The Property Inspector displays the elements of the `Position` property.



3 Type the `width` and `height` you want the components to be.

4 Reset the `Units` property to its previous setting, either `characters` or `normalized`.

Note To select multiple components, they must have the same parent. That is, they must be contained in the same figure, panel, or button group. See "Selecting Components" on page 6-54 for more information. Setting the `Units` property to `characters` (nonresizable GUIs) or `normalized` (resizable GUIs) gives the GUI a more consistent appearance across platforms. See "Cross-Platform Compatible Units" on page 6-103 for more information.

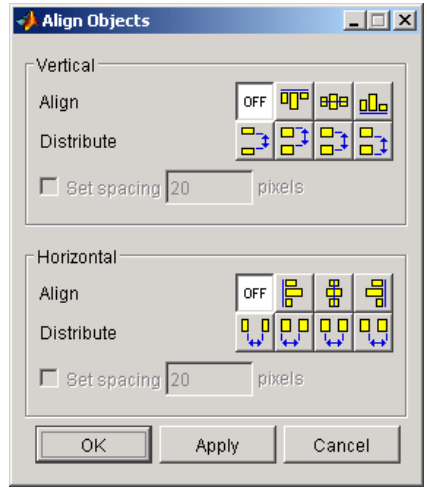
Aligning Components

In this section...

Alignment Tool

The Alignment Tool enables you to position objects with respect to each other and to adjust the spacing between selected objects. The specified alignment operations apply to all components that are selected when you press the **Apply** button.

Note To select multiple components, they must have the same parent. That is, they must be contained in the same figure, panel, or button group. See “Selecting Components” on page 6-54 for more information.



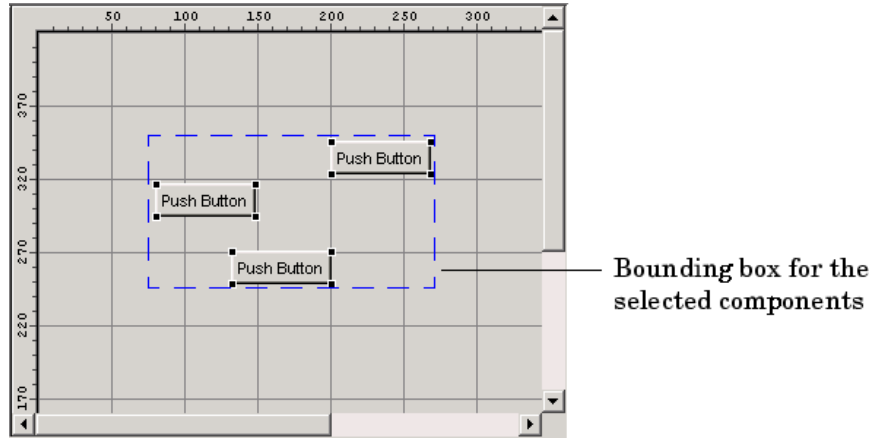
The alignment tool provides two types of alignment operations:

- **Align** — Align all selected components to a single reference line.
- **Distribute** — Space all selected components uniformly with respect to each other.

Both types of alignment can be applied in the vertical and horizontal directions. In many cases, it is better to apply alignments independently to the vertical and horizontal using two separate steps.

Align Options

There are both vertical and horizontal align options. Each option aligns selected components to a reference line, which is determined by the bounding box that encloses the selected objects. For example, the following picture of the layout area shows the bounding box (indicated by the dashed line) formed by three selected push buttons.



All of the align options (vertical top, center, bottom and horizontal left, center, right) place the selected components with respect to the corresponding edge (or center) of this bounding box.

Distribute Options

Distributing components adds equal space between all components in the selected group. The distribute options operate in two different modes:

- Equally space selected components within the bounding box (default)
- Space selected components to a specified value in pixels (check **Set spacing** and specify a pixel value)

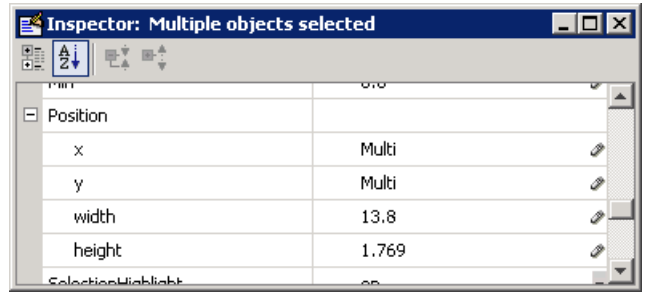
Both modes enable you to specify how the spacing is measured, as indicated by the button labels on the alignment tool. These options include spacing measured with respect to the following edges:

- Vertical — inner, top, center, and bottom
- Horizontal — inner, left, center, and right

Property Inspector

The Property Inspector enables you to align components by setting their `Position` properties. A component's `Position` property is a 4-element vector that specifies the location of the component on the GUI and its size: [distance from left, distance from bottom, width, height]. The values are given in the units specified by the `Units` property of the component.

1. Select the components you want to align. See "Selecting Components" on page 6-54 for information.
2. Select **Property Inspector** from the **View** menu or click the **Property Inspector** button  .
3. In the Property Inspector, scroll to the `Units` property and note its current setting, then change the setting to `inches`.
4. Scroll to the `Position` property. A `null` value means that the element differs in value for the different components. This figure shows the `Position` property for multiple components of the same size.

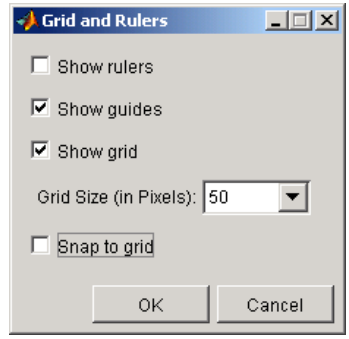


5 Change the value of `x` to align their left sides. Change the value of `y` to align their bottom edges. For example, setting `x` to 2.0 aligns the left sides of the components 2 inches from the left side of the GUI.

6 When the components are aligned, change the `Units` property back to its original setting.

Grid and Rulers

The layout area displays a grid and rulers to facilitate component layout. Grid lines are spaced at 50-pixel intervals by default and you can select from a number of other values ranging from 10 to 200 pixels. You can optionally enable *snap-to-grid*, which causes any object that is moved close to a grid line to jump to that line. Snap-to-grid works with or without a visible grid.



Use the Grid and Rulers dialog (select **Grid and Rulers** from the **Tools** menu) to:

- Control visibility of rulers, grid, and guide lines

- Set the grid spacing
- Enable or disable snap-to-grid

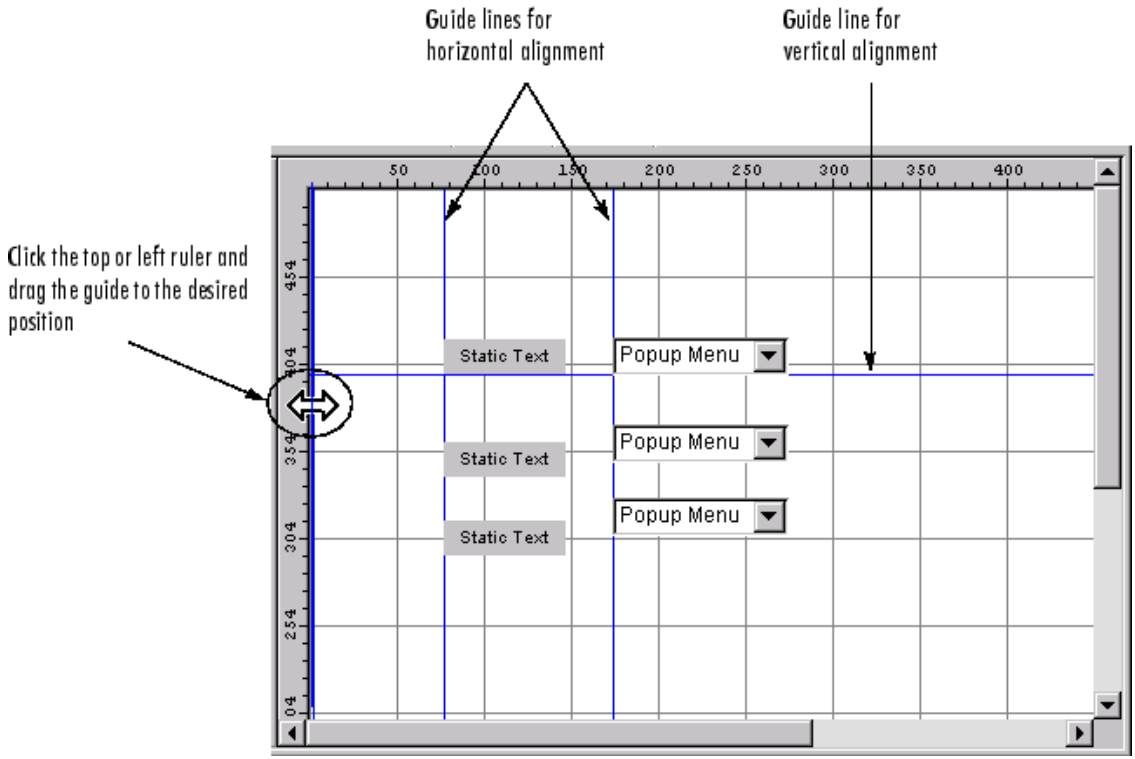
Guide Lines

The Layout Editor has both vertical and horizontal snap-to guide lines. Components snap to the line when you move them close to the line.

Guide lines are useful when you want to establish a reference for component alignment at an arbitrary location in the Layout Editor.

Creating Guide Lines

To create a guide line, click the top or left ruler and drag the line into the layout area.



Setting Tab Order

A GUI's tab order is the order in which components of the GUI acquire focus when a user presses the **Tab** key on the keyboard. Focus is generally denoted by a border or a dotted border.

You can set, independently, the tab order of components that have the same parent. The GUI figure and each panel and button group in it has its own tab order. For example, you can set the tab order of components that have the figure as a parent. You can also set the tab order of components that have a panel or button group as a parent.

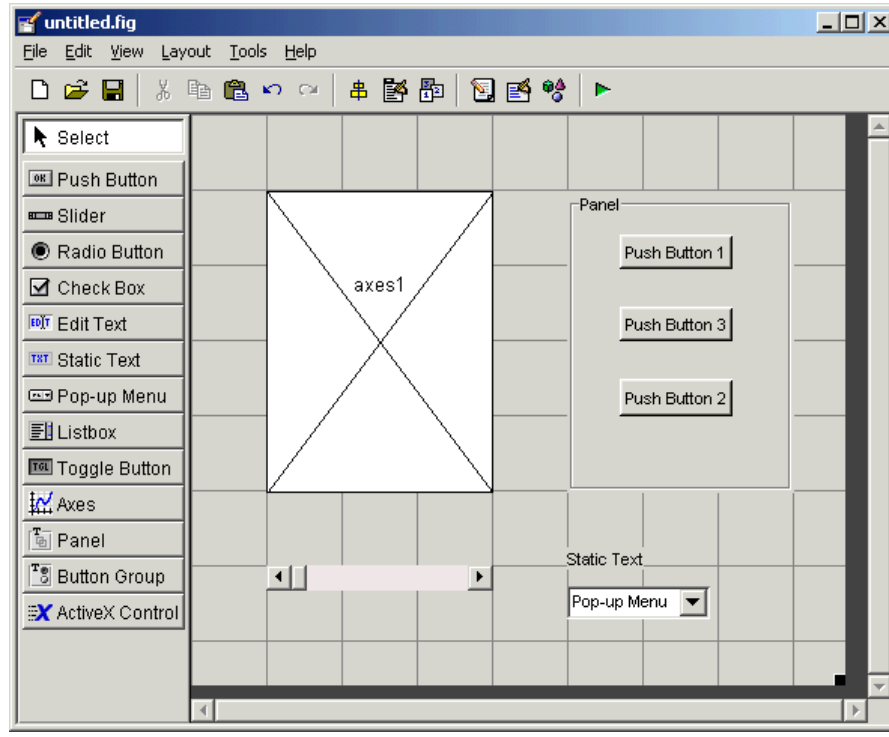
If, in tabbing through the components at the figure level, a user tabs to a panel or button group, then subsequent tabs sequence through the components of the panel or button group before returning to the level from which the panel or button group was reached.

Note Axes cannot be tabbed. From GUIDE, you cannot include ActiveX components in the tab order.

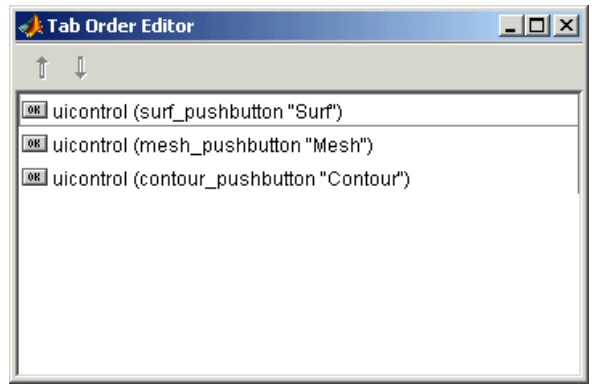
When you create a GUI, GUIDE sets the tab order at each level to be the order in which you add components to that level in the Layout Editor. This may not be the best order for the user.

Note Tab order also affects the stacking order of components. If components overlap, those that appear lower in the tabbing order, are drawn on top of those that appear higher in the order. See "Front-to-Back Positioning" on page 6-55 for more information.

The figure in the following GUI contains an axes component, a slider, a panel, static text, and a pop-up menu. Of these, only the slider, the panel, and the pop-up menu at the figure level can be tabbed. The panel contains three push buttons, which can all be tabbed.



To examine and change the tab order of the panel components, click the panel background to select it, then select **Tab Order Editor** in the **Tools** menu of the Layout Editor.



The Tab Order Editor displays the panel's components in their current tab order. To change the tab order, select a component and press the up or down arrow to move the component up or down in the list. If you set the tab order for the three components in the example to be

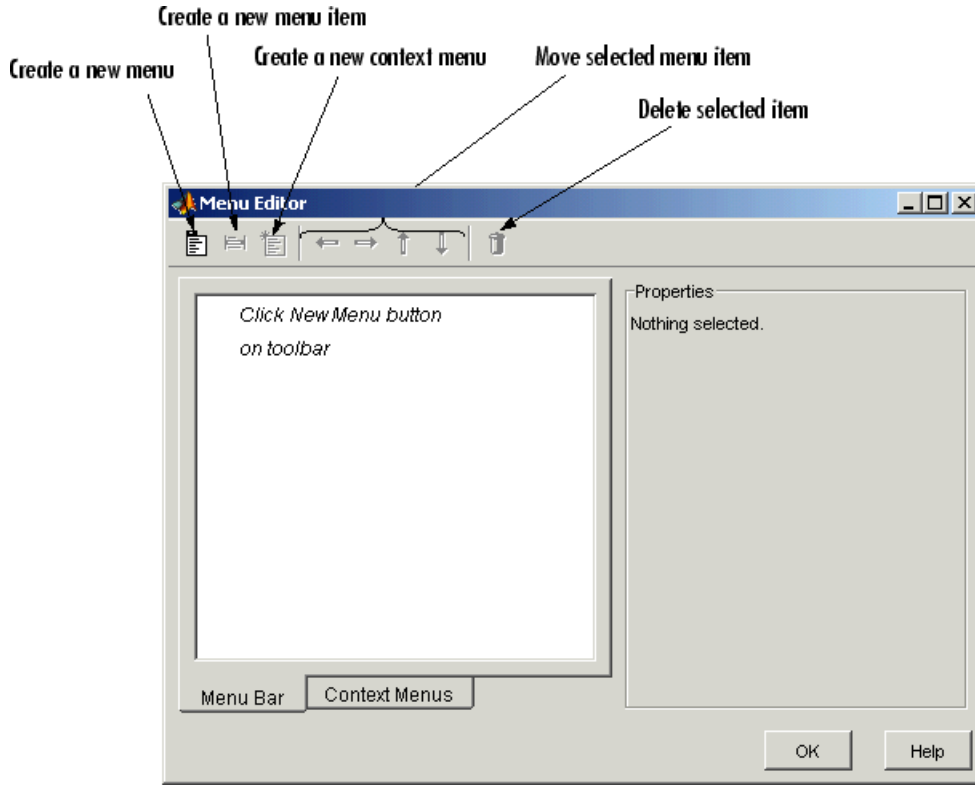
1. **Surf** push button
2. **Contour** push button
3. **Mesh** push button

the user first tabs to the **Surf** push button, then to the **Contour** push button, and then to the **Mesh** push button. Subsequent tabs sequence through the remaining components at the figure level.

Creating Menus

In this section...

You can create both types of menus using the Menu Editor. Access the Menu Editor from the **Tools** menu or click the **Menu Editor** button .



Note In general, programming conventions described for components in Chapter 8, "Programming a GUIDE GUI" also apply to menu items. See "Menu Item" on page 8-41 and "Updating a Menu Item Check" on page 8-42 for information about programming and basic examples.

Menus for the Menu Bar

When you create a drop-down menu, GUIDE adds its title to the GUI menu bar. You can then create menu items for that menu. Each menu item can have a cascading menu, also known as a submenu, and these items can have cascading menus, and so on.

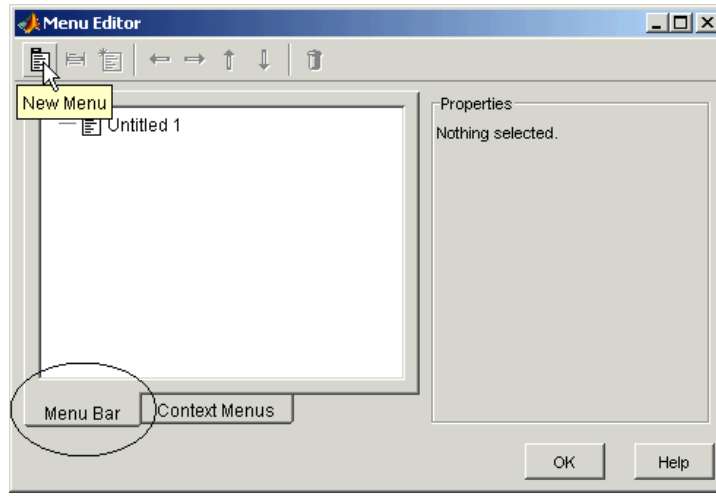
Adding Standard Menus to the Menu Bar

The figure `MenuBar` property controls whether your GUI displays the MATLAB standard menus on the menu bar. GUIDE initially sets the value of `MenuBar` to `none`. If you want your GUI to display the MATLAB standard menus, use the Property Inspector to set `MenuBar` to `figure`.

- If the value of `MenuBar` is `none`, GUIDE automatically adds a menu bar that displays only the menus you create.
- If the value of `MenuBar` is `figure`, the GUI displays the MATLAB standard menus and GUIDE adds the menus you create to this menu bar.

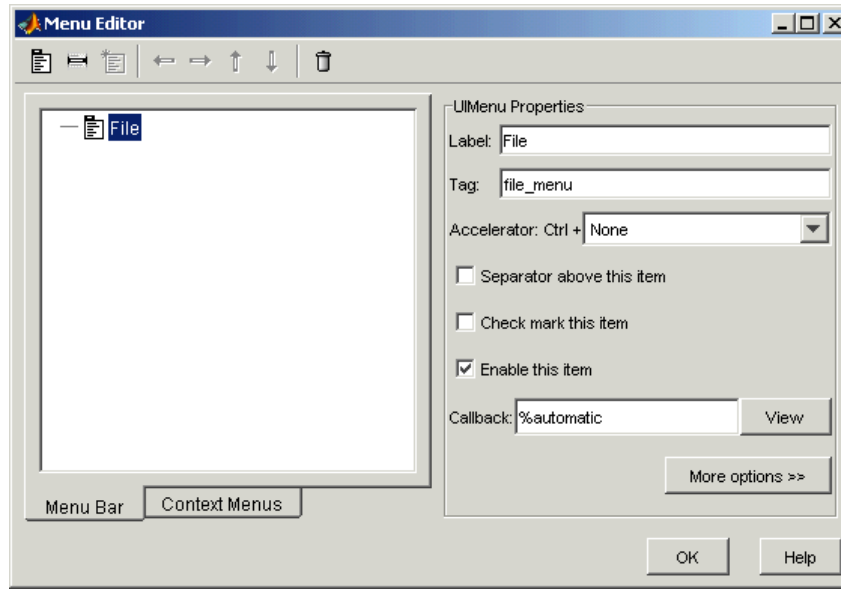
Creating a Menu

1 Start a new menu by clicking the New Menu button in the toolbar. A menu title, `Untitled 1`, appears in the left pane of the dialog box.



Note By default, GUIDE selects the **Menu Bar** tab when you open the Menu Editor.

2 Click the menu title to display a selection of menu properties in the right pane.



3 Fill in the **Label** and **Tag** fields for the menu. For example, set **Label** to `File` and set **Tag** to `file_menu`. Click outside the field for the change to take effect.

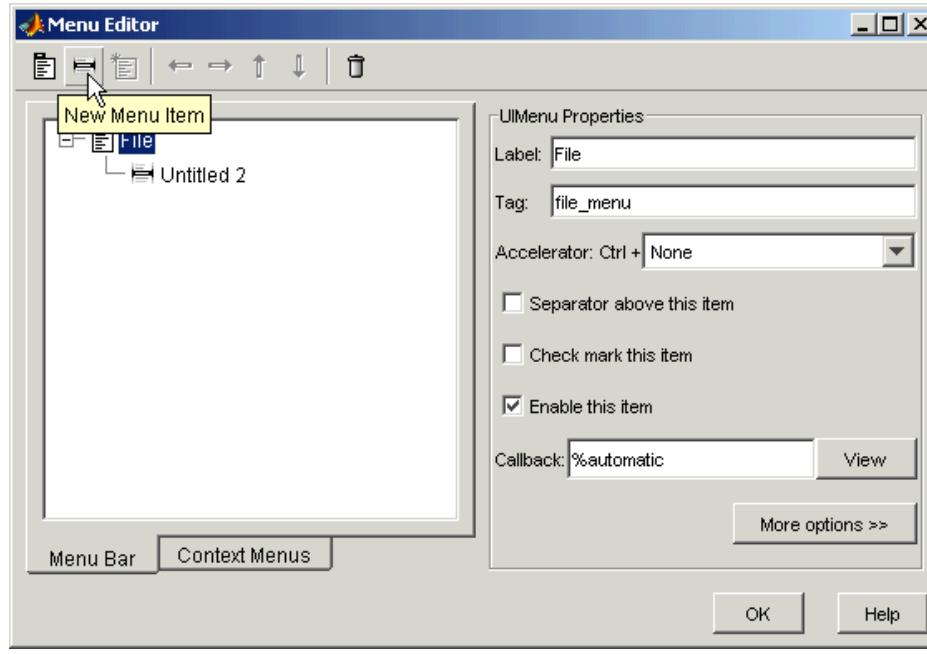
Label is a string that specifies the text label for the menu item. To display the & character in a label, use two & characters in the string. The words `remove`, `default`, and `factory` (case sensitive) are reserved. To use one of these as labels, prepend a backslash (`\`) to the string. For example, `\remove` yields **remove.**

Tag is a string that is an identifier for the menu object. It is used in the code to identify the menu item and must be unique in the GUI.

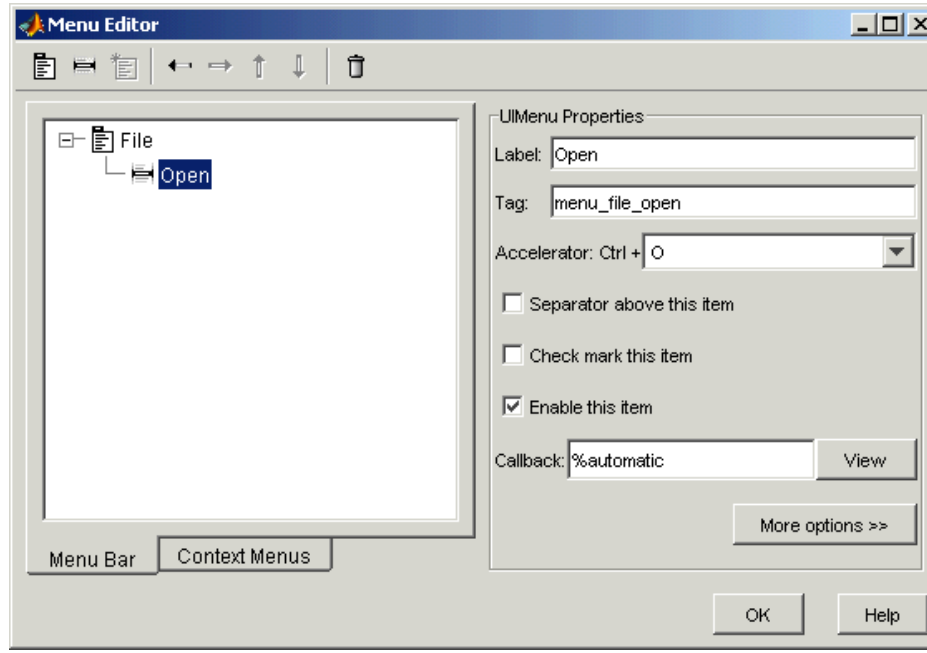
Adding Items to a Menu

Use the **New Menu Item** tool to create menu items that are displayed in the drop-down menu.

1. Add an **Open** menu item under `File`, by selecting `File` then clicking the **New Menu Item** button in the toolbar. A temporary numbered menu item label, `Untitled`, appears.



2 Fill in the **Label** and **Tag** fields for the new menu item. For example, set **Label** to `Open` and set **Tag** to `menu_file_open`. Click outside the field for the change to take effect.



You can also

- Choose an alphabetic keyboard accelerator for the menu item with the **Accelerator** pop-up menu. In combination with **Ctrl**, this is the keyboard equivalent for a menu item that does not have a child menu. Note that some accelerators may be used for other purposes on your system and that other actions may result.
- Display a separator above the menu item by checking **Separator above this item**.
- Display a check next to the menu item when the menu is first opened by checking **Check mark this item**. A check indicates the current state of the menu item. See the example in “Adding Items to the Context Menu” on page 6-80.

- Enable this item when the menu is first opened by checking **Enable this item**. This allows the user to select this item when the menu is first opened. If you uncheck this option, the menu item appears dimmed when the menu is first opened, and the user cannot select it.
- Specify a string for the routine, i.e., the **Callback**, that performs the action associated with the menu item. If you have not yet saved the GUI, the default value is `%automatic`. When you save the GUI, and if you have not changed this field, GUIDE automatically sets the value using a combination of the **Tag** field and the GUI filename. See "Menu Item" on page 8-41 for more information about specifying this field and for programming menu items.

  The **View** button displays the callback, if there is one, in an editor. If you have not yet saved the GUI, GUIDE prompts you to save it.
- Open the Property Inspector, where you can change all menu properties, by clicking the **More options** button. For detailed information about the properties, see Uimenu Properties in the MATLAB documentation.

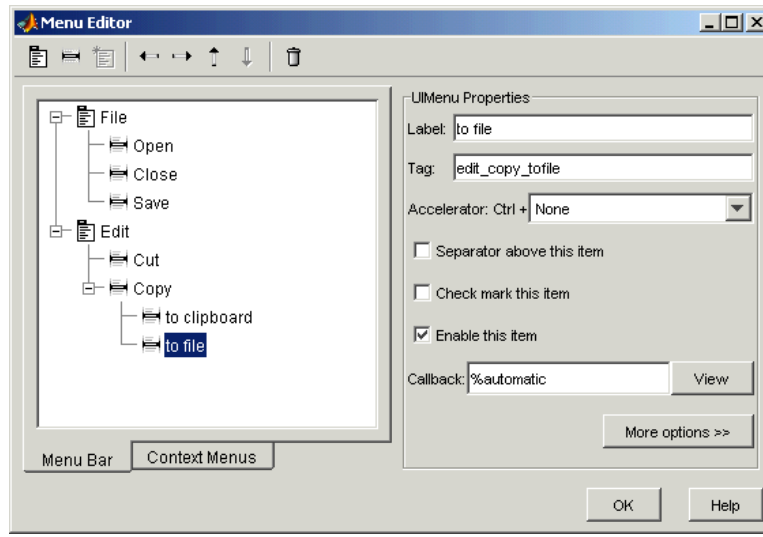
Note In general, programming conventions described for components in Chapter 8, "Programming a GUIDE GUI" also apply to menu items. See "Menu Item" on page 8-41 and "Updating a Menu Item Check" on page 8-42 for programming information and basic examples.

Additional Drop-Down Menus

To create additional drop-down menus, use the New Menu button in the same way you did to create the `File` menu. For example, the following figure also shows an `Edit` drop-down menu.

Cascading Menus

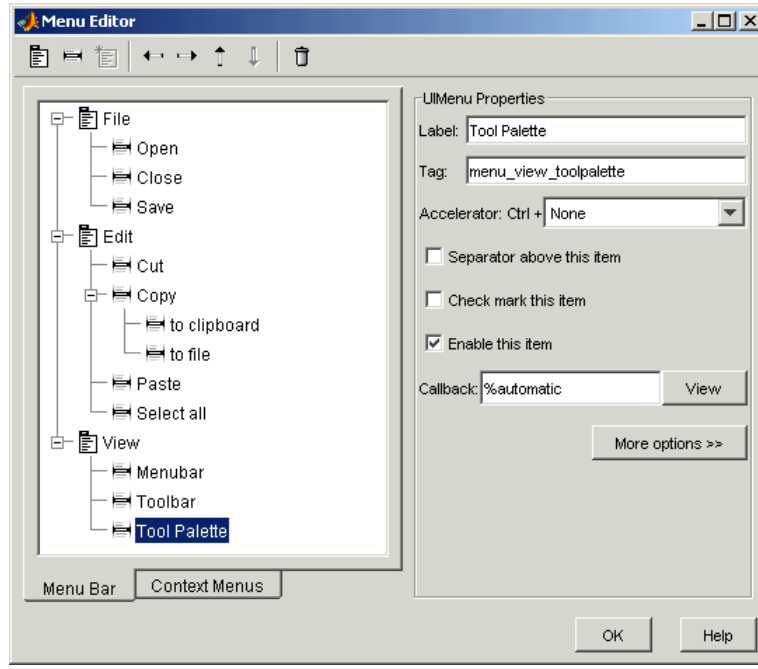
To create a cascading menu, select the menu item that will be the title for the cascading menu, then click the **New Menu Item** button. In the example below, `Copy` is a cascading menu.



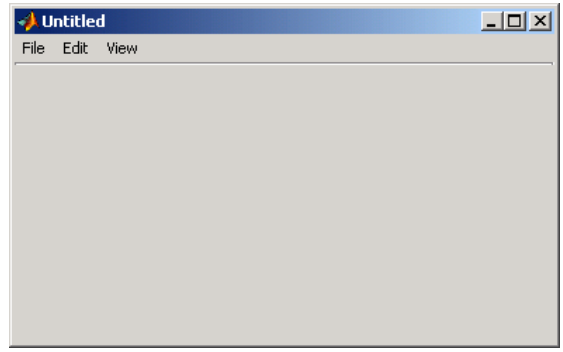
Note See “Menu Item” on page 8-41 for information about programming menu items.

Laying Out Three Menus

The following Menu Editor illustration shows three menus defined for the figure menu bar.



When you run the GUI, the menu titles appear in the menu bar.



Context Menus

A context menu is displayed when a user right-clicks the object for which the menu is defined. The Menu Editor enables you to define context menus and associate them with objects in the layout. The process has three steps:

1 “Creating the Parent Menu” on page 6-79

2 “Adding Items to the Context Menu” on page 6-80

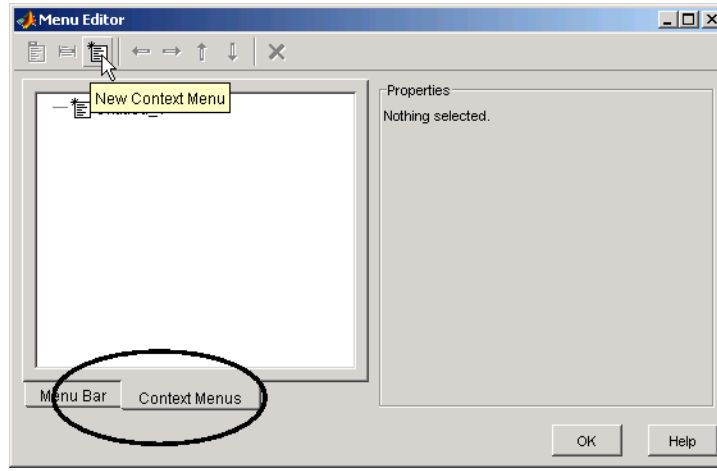
3 “Associating the Context Menu with an Object” on page 6-82

Note See “Menus for the Menu Bar” on page 6-71 for information about defining menus in general. See “Menu Item” on page 8-41 for information about defining callback subfunctions for your menus.

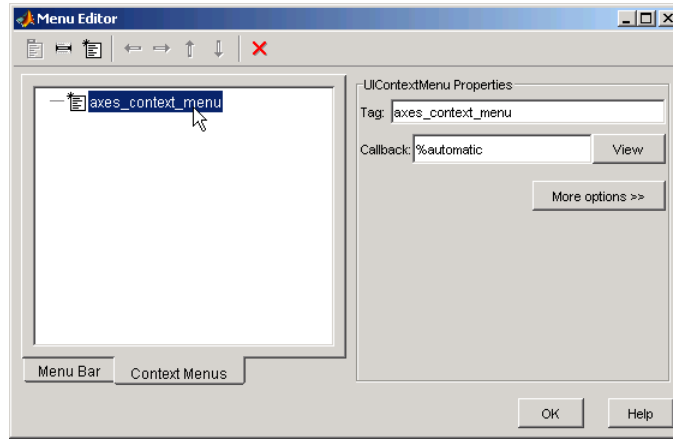
Creating the Parent Menu

All items in a context menu are children of a menu that is not displayed on the figure menu bar. To define the parent menu:

1 Select the Menu Editor’s **Context Menus** tab and select the New Context Menu button from the toolbar.



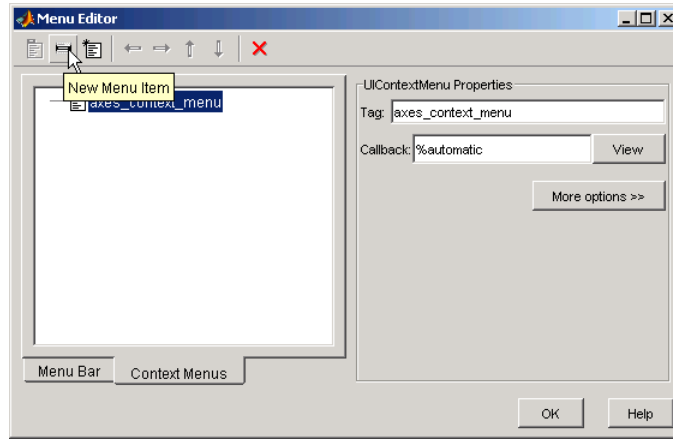
2 Select the menu and specify the **Tag** field to identify the context menu (`axes_context_menu` in this example).



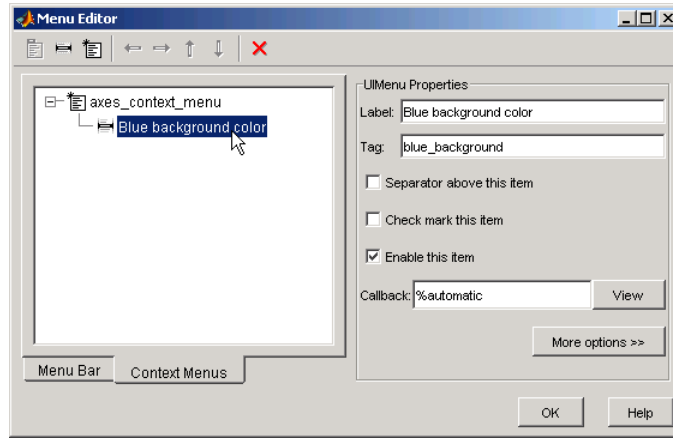
Adding Items to the Context Menu

Use the New Menu Item button to create menu items that are displayed in the context menu.

1 Add a **Blue background color** menu item to the menu by selecting `axes_context_menu` and clicking the **New Menu Item** tool. A temporary numbered menu item label, `Untitled`, appears.



2 Fill in the **Label** and **Tag** fields for the new menu item. For example, set **Label** to `Blue background color` and set **Tag** to `blue_background`. Click outside the field for the change to take effect.



You can also

- Display a separator above the menu item by checking **Separator above this item**.
- Display a check next to the menu item when the menu is first opened by checking **Check mark this item**. A check indicates the current state of

the menu item. See the example in "Adding Items to the Context Menu" on page 6-80. See "Updating a Menu Item Check" on page 8-42 for a code example.

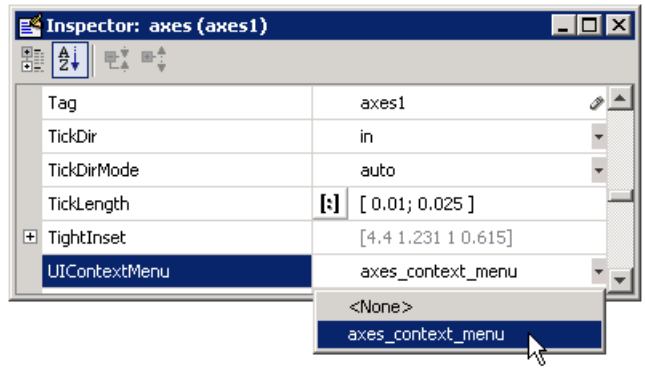
- Enable this item when the menu is first opened by checking **Enable this item**. This allows the user to select this item when the menu is first opened. If you uncheck this option, the menu item appears dimmed when the menu is first opened, and the user cannot select it.
- Specify a string for the routine, i.e., the **Callback**, that performs the action associated with the menu item. If you have not yet saved the GUI, the default value is `%automatic`. When you save the GUI, and if you have not changed this field, GUIDE automatically sets the value using a combination of the **Tag** field and the GUI filename. See "Menu Item" on page 8-41 for more information about specifying this field and for programming menu items.

  The **View** button displays the callback, if there is one, in an editor. If you have not yet saved the GUI, GUIDE prompts you to save it.
- Open the Property Inspector, where you can change all menu properties, by clicking the **More options** button. For detailed information about these properties, see Uicontextmenu Properties in the MATLAB documentation.

Associating the Context Menu with an Object

1. In the Layout Editor, select the object for which you are defining the context menu.
2. Use the Property Inspector to set this object's `UIContextMenu` property to the name of the desired context menu.

The following figure shows the `UIContextMenu` property for the `axes` object with `Tag` property `axes1`.



In the GUI M-file, complete the callback subfunction for each item in the context menu. Each callback executes when a user selects the associated context menu item. See “Menu Item” on page 8-41 for information on defining the syntax.

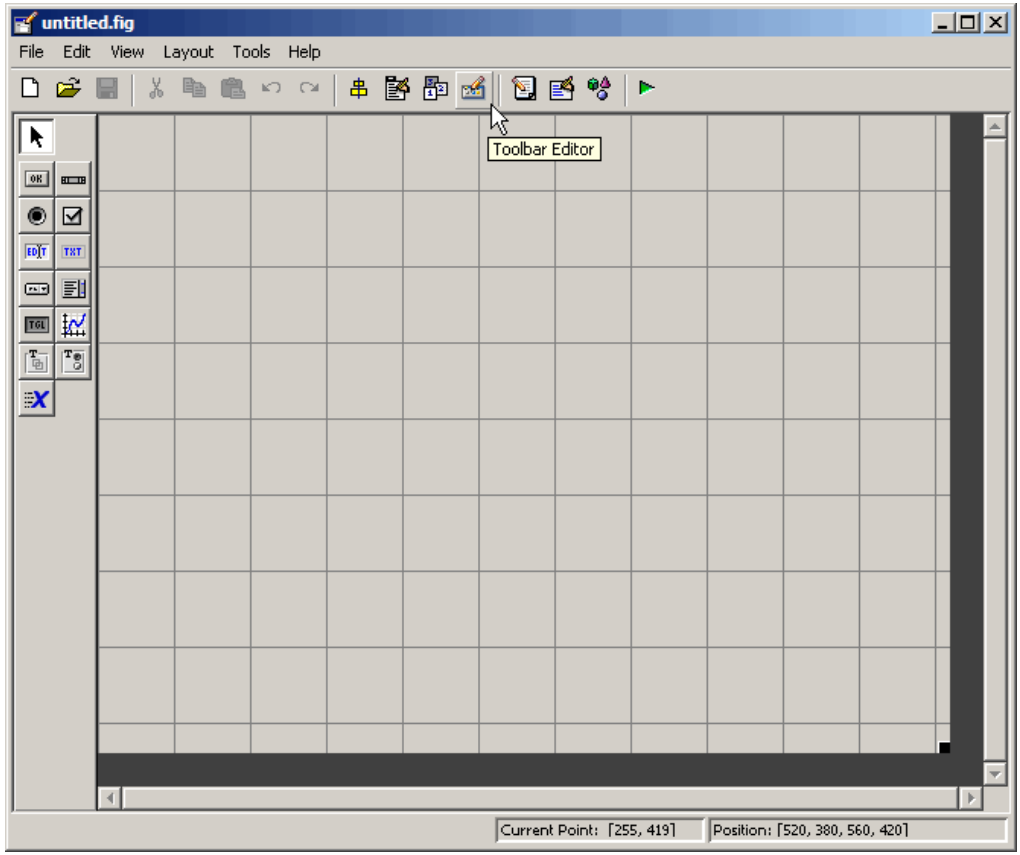
Note In general, programming conventions described for components in Chapter 8, “Programming a GUIDE GUI” also apply to menu items. See “Menu Item” on page 8-41 and “Updating a Menu Item Check” on page 8-42 for programming information and basic examples.

Creating Toolbars

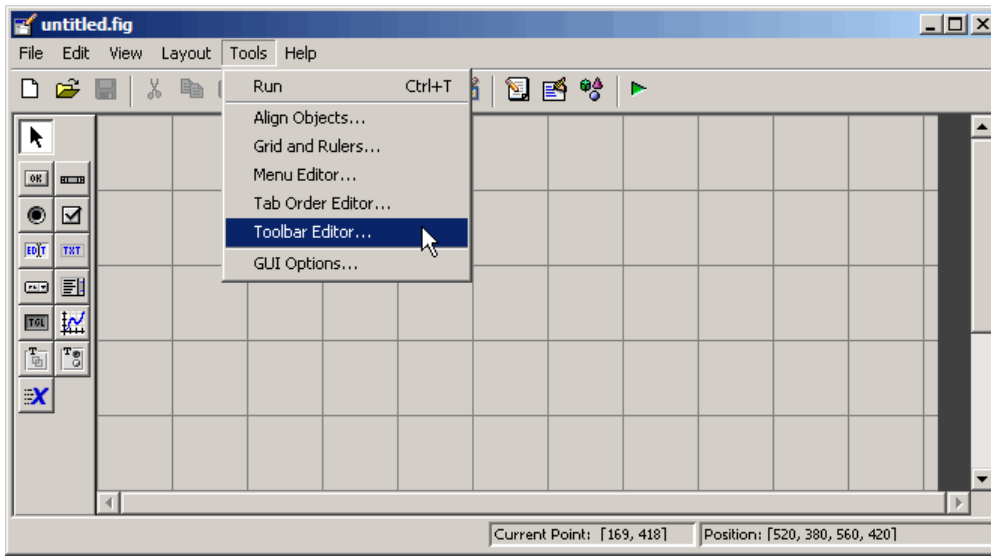
In this section...

Creating Toolbars with GUIDE

You can add a toolbar to a GUI you create in GUIDE with the Toolbar Editor, which you open from the GUIDE Layout Editor toolbar.



You can also open the Toolbar Editor from the Tools menu.



The Toolbar Editor gives you interactive access to all the features of the `uitoolbar`, `uipushtool`, and `uitoggletool` functions. It only operates in the context of GUIDE; you cannot use it to modify any of the built-in MATLAB toolbars. However, you can use the Toolbar Editor to add, modify, and delete a toolbar from any GUI in GUIDE.

Currently, you can add one toolbar to your GUI in GUIDE. However, your GUI can also include the standard MATLAB figure toolbar. If you need to, you can create a toolbar that looks like a normal figure toolbar, but customize its callbacks to make tools (such as pan, zoom, and open) behave in specific ways.

Note You do not need to use the Toolbar Editor if you simply want your GUI to have a standard figure toolbar. You can do this by setting the figure's `Toolbar` property to `'figure'`, as follows:

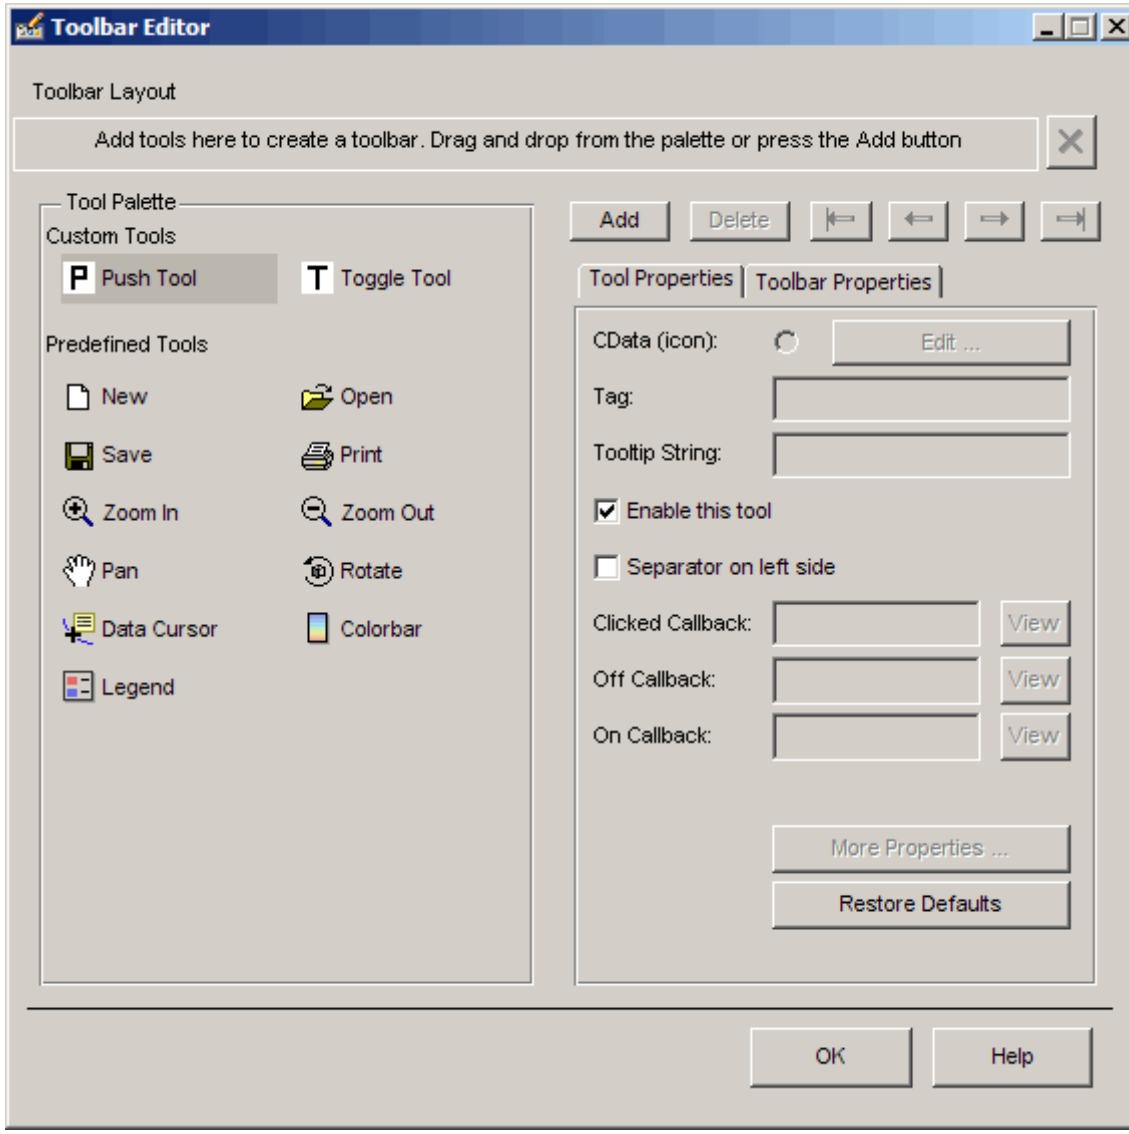
1. Open the GUI in GUIDE.
2. From the **View** menu, open **Property Inspector**.
3. Set the `Toolbar` property to `figure` using the drop-down menu.
4. Save the figure

If you later want to remove the figure toolbar, set the `Toolbar` property to `auto` and resave the GUI. This will not remove or hide your custom toolbar should the GUI have one. See "Creating Toolbars Programmatically" on page 6-98 for more information about creating a toolbar with M-code.

Using the Toolbar Editor

The Toolbar Editor contains three main parts:

- The **Toolbar Layout** preview area on the top
- The **Tool Palette** on the left
- Two tabbed property panes on the right



To add a tool, drag an icon from the **Tool Palette** into the **Toolbar Layout** (which initially contains the text prompt shown above), and edit the tool's properties in the **Tool Properties** pane.

When you first create a GUI, no toolbar exists on it. When you open the Toolbar Editor and place the first tool, a toolbar is created and a preview of the tool you just added appears in the top part of the window. If you later open a GUI that has a toolbar, the Toolbar Editor shows the existing toolbar, although the Layout Editor does not.

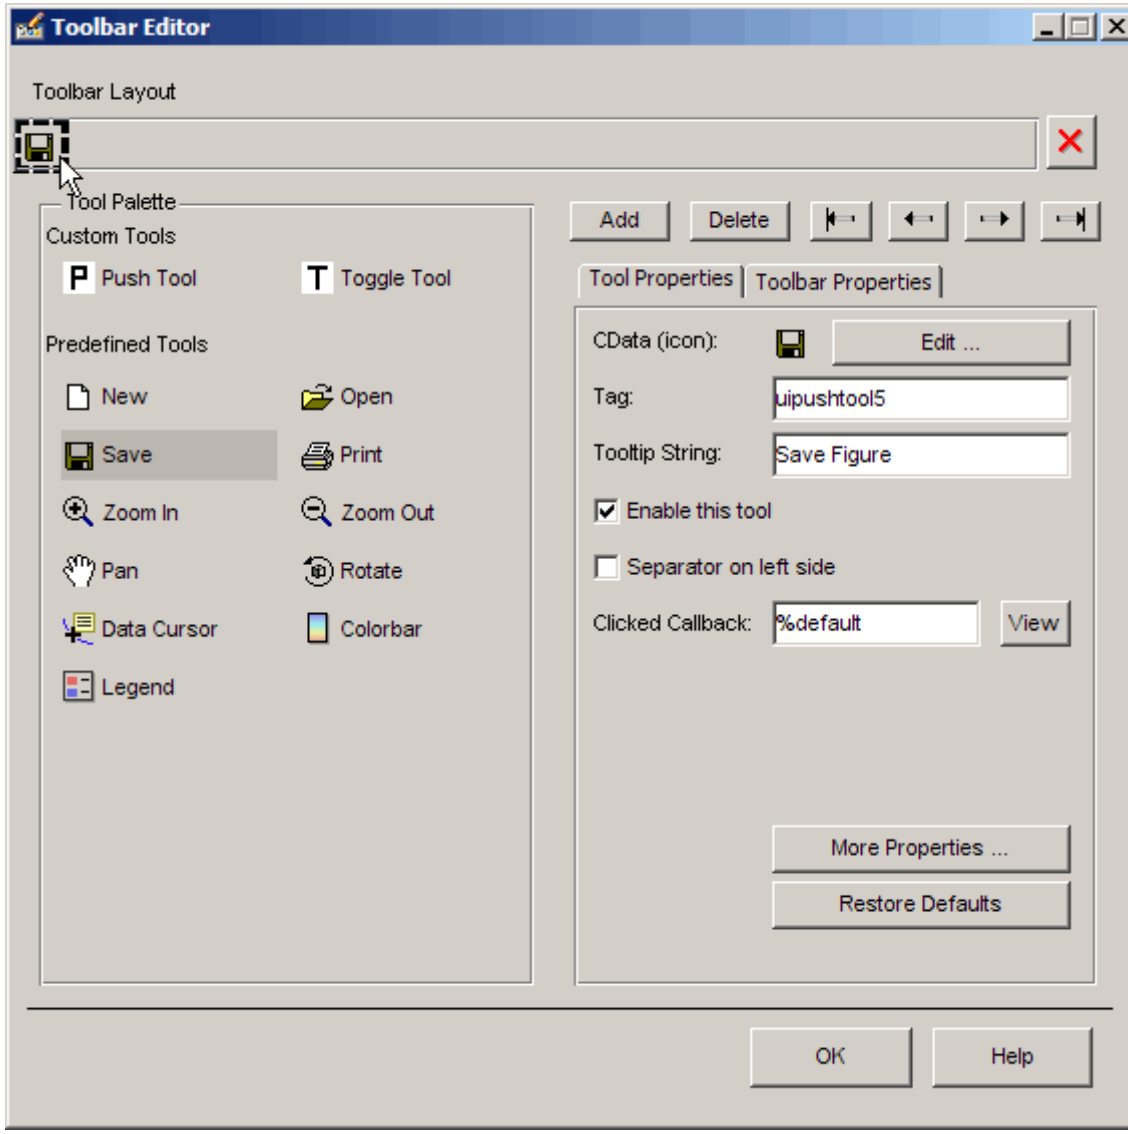
Adding Tools

You can add a tool to a toolbar in three ways:

- Drag and drop tools from the **Tool Palette**.
- Select a tool in the palette and click the **Add** button.
- Double-click a tool in the palette.

Dragging allows you to place a tool in any order on the toolbar. The other two methods place the tool to the right of the right-most tool on the **Toolbar Layout**. The new tool is selected (indicated by a dashed box around it) and its properties are shown in the **Tool Properties** pane. You can select only one tool at a time. You can cycle through the **Tool Palette** using the tab key or arrow keys on your computer keyboard. You must have placed at least one tool on the toolbar.

After you place tools from the **Tool Palette** into the **Toolbar Layout** area, the Toolbar Editor shows the properties of the currently selected tool, as the following illustration shows.



Predefined and Custom Tools

The Toolbar Editor provides two types of tools:

- Predefined tools, having standard icons and behaviors
- Custom tools, having generic icons and no behaviors

Predefined Tools. The set of icons on the bottom of the **Tool Palette** represent standard MATLAB figure tools. Their behavior is built in. Predefined tools that require an axes (such as pan and zoom) do not exhibit any behavior in GUIs lacking axes. The callback(s) defining the behavior of the predefined tool are shown as `%default`, which calls the same function that the tool calls in standard figure toolbars and menus (to open files, save figures, change modes, etc.). You can change `%default` to some other callback to customize the tool; GUIDE warns you that you will modify the behavior of the tool when you change a callback field or click the **View** button next to it, and asks if you want to proceed or not.

Custom Tools. The two icons at the top of the Tool Palette create pushtools and toggletools. These have no built-in behavior except for managing their appearance when clicked on and off. Consequently, you need to provide your own callback(s) when you add one to your toolbar. In order for custom tools to respond to clicks, you need to edit their callbacks to create the behaviors you desire. Do this by clicking the **View** button next to the callback in the **Tool Properties** pane, and then editing the callback in the Editor window.

Adding and Removing Separators

Separators are vertical bars that set off tools, enabling you to group them visually. You can add or remove a separator in any of three ways:

- Right-click on a tool's preview and select **Show Separator**, which toggles its separator on and off.
- Check or clear the checkbox **Separator** to the left in the tool's property pane.
- Change the `Separator` property of the tool from the Property Inspector

After adding a separator, that separator appears in the **Toolbar Layout** to the left of the tool. The separator is not a distinct object or icon; it is a property of the tool.

Moving Tools

You can reorder tools on the toolbar in two ways:

- Drag a tool to a new position.
- Select a tool in the toolbar and click one of the arrow buttons below the right side of the toolbar.

If a tool has a separator to its left, the separator moves with the tool.

Removing Tools

You can remove tools from the toolbar in three ways:

- Select a tool and press the **Delete** key.
- Select a tool and click the **Delete** button on the GUI.
- Right-click a tool and select **Delete** from the context menu.

You cannot undo any of these actions.

Editing a Tool's Properties

You edit the appearance and behavior of the currently selected tool using the **Tool Properties** pane, which includes controls for setting the most commonly used tool properties:

- CData — The tool's icon
- Tag — The internal name for the tool
- Enable — Whether users can click the tool
- Separator — A bar to the left of the icon for setting off and grouping tools
- Clicked Callback — The function called when users click the tool
- Off Callback (uitoggletool only) — The function called when the tool is put in the *off* state
- On Callback (uitoggletool only) — The function called when the tool is put in the *on* state

See “Callbacks: An Overview” on page 8-2 for details on programming the tool callbacks. You can also access these and other properties of the selected tool with the Property Inspector. To open the Property Inspector, clicki the **More Properties** button on the **Tool Properties** pane.

Editing Tool Icons

To edit a selected toolbar icon, click the **Edit** button in the **Tool Properties** pane, next to **CData (icon)** or right-click the **Toolbar Layout** and select **Edit Icon** from the context menu. The Icon Editor opens with the tool's `CData` loaded into it. For information about editing icons, see “Using the Icon Editor” on page 6-95.

Editing Toolbar Properties

If you click an empty part of the toolbar or click the **Toolbar Properties** tab, you can edit two of its properties:

- `Tag` — The internal name for the toolbar
- `Visible` — Whether the toolbar is displayed in your GUI

The `Tag` property is initially set to `uitoolbar1`. The `Visible` property is set to `on`. When on, the `Visible` property causes the toolbar to be displayed on the GUI regardless of the setting of the figure's `Toolbar` property. If you want to toggle a custom toolbar as you can built-in ones (from the **View** menu), you can create a menu item, a checkbox, or other control to control its Visible property.

To access nearly all the properties for the toolbar in the Property Inspector, click **More Properties**.

Testing Your Toolbar

To try out your toolbar, click the **Run** button in the Layout Editor. MATLAB asks if you want to save changes to its `.fig` file first.

Removing a Toolbar

You can remove a toolbar completely—destroying it—from the Toolbar Editor, leaving your GUI without a toolbar (other than the figure toolbar, which is not visible by default). The are two ways to remove a toolbar:

- Click the **Remove** button  on the right end of the toolbar.
- Right-click a blank area on the toolbar and select **Remove Toolbar** from the context menu.

If you remove all the individual tools in the ways shown in “Removing Tools” on page 6-92 without removing the toolbar itself, your GUI will contain an empty toolbar.

Closing the Toolbar Editor

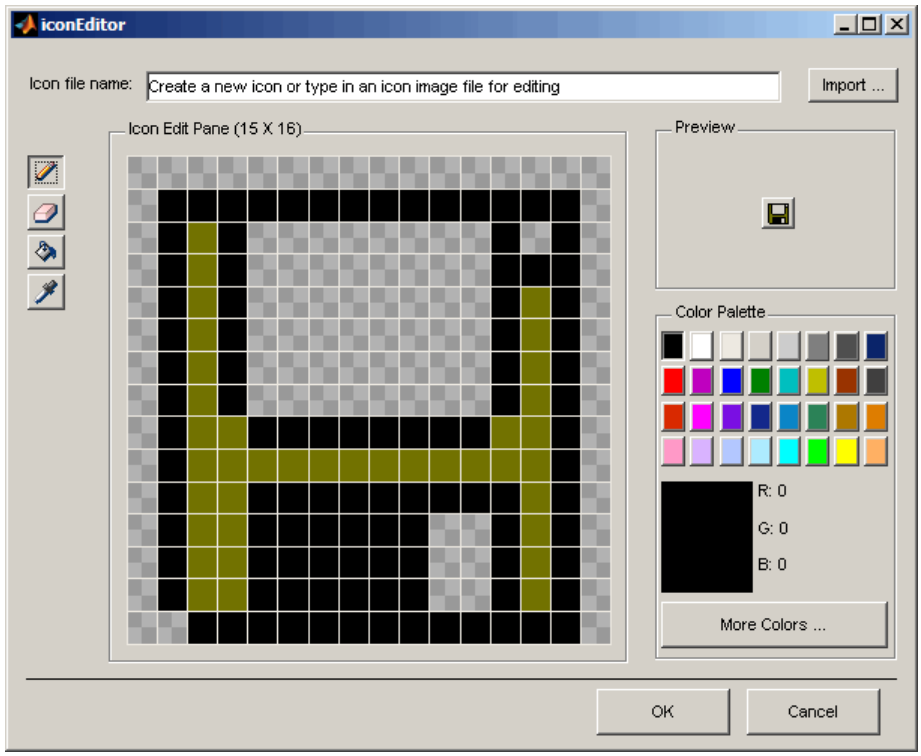
You can close the Toolbar Editor window in two ways:

- Press the **OK** button.
- Click the Close box in the title bar.

When you close the Toolbar Editor, the current state of your toolbar is saved with the GUI you are editing. You do not see the toolbar in the Layout Editor; you need to run the GUI to see or use it.

Editing Tool Icons

GUIDE includes its own Icon Editor, a GUI for creating and modifying icons such as icons on toolbars. You can access this editor only from the Toolbar Editor. This figure shows the Icon Editor loaded with a standard **Save** icon.



Note There are examples that show how to create your own icon editor. See the example in "Icon Editor" on page 15-29 and the discussion of sharing data among multiple GUIs in the portion of the GUI Building documentation.

Using the Icon Editor

The Icon Editor GUI includes the following components:

- **Icon file name** — The icon image file to be loaded for editing
- **Import** button — Opens a file dialog to select an existing icon file for editing
- Drawing tools — A group of four tools on the left side for editing icons

  - Pencil tool — Color icon pixels by clicking or dragging
  - Eraser tool — Erase pixels to be transparent by clicking or dragging
  - Paint bucket tool — Flood regions of same-color pixels with the current color
  - Pick color tool — Click a pixel or color palette swatch to define the current color
- **Icon Edit** pane — A n-by-m grid where you color an icon
- **Preview** pane — A button with a preview of current state of the icon
- **Color Palette** — Swatches of color that the pencil and paint tools can use
- **More Colors** button — Opens the Colors dialog box for choosing and defining colors
- **OK** button — Dismisses the GUI and returns the icon in its current state
- **Cancel** button — Closes the GUI without returning the icon

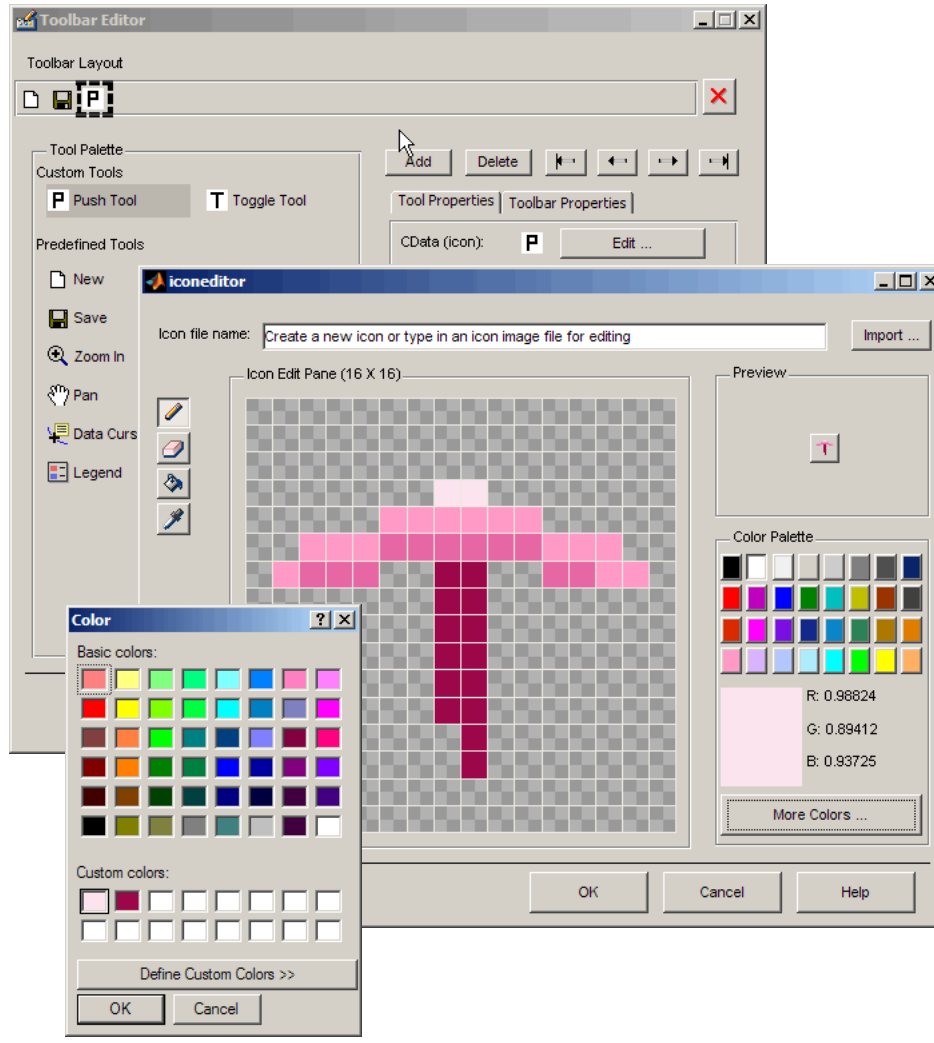
To work with the Icon Editor,

1. Open the Icon Editor for a selected tool's icon.
2. Using the Pencil tool, color the squares in the grid:
   - Click a color cell in the palette.
   - That color appears in the **Color Palette** preview swatch.
   - Click in specific squares of the grid to transfer the selected color to those squares.
   - Hold down the left mouse button and drag the mouse over the grid to transfer the selected color to the squares that you touch.
   - Change a color by writing over it with another color.
3. Using the Eraser tool, erase the color in some squares
   - Click the Eraser button on the palette.
   - Click in specific squares to erase those squares.

- Click and drag the mouse to erase the squares that you touch.
- Click a another drawing tool to disable the Eraser.

4 Click **OK** to close the GUI and return the icon you created or click **Cancel** to close the GUI without modifying the selected tool's icon.

The three GUIs are shown operating together below, before saving a uipushtool icon:



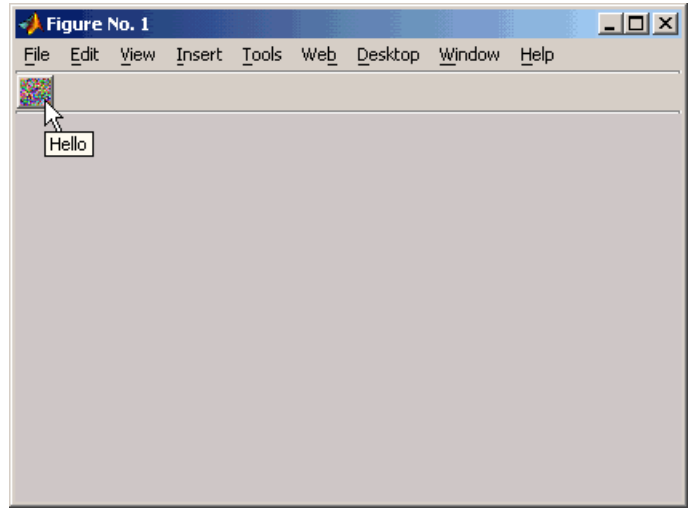
Creating Toolbars Programmatically

As described previously, GUIDE provides tools to enable you to add a toolbar to a GUI and add tools to it. You can also add a toolbar and tools programmatically by adding code to the opening function.

See “Initialization Callbacks” on page 8-16 for information about the opening function, and see the `uitoolbar`, `uipushtool`, and `uitoggletool` reference pages for information and examples.

This example creates a toolbar (`uitoolbar`) and places a toggle tool (`uitoggletool`) on it. Add the following code to the GUI's opening function to produce the toolbar shown:

```
ht = uitoolbar(hObject)
a = rand(16,16,3);
htt = uitoggletool(ht,'CData',a,'TooltipString','Hello')
```

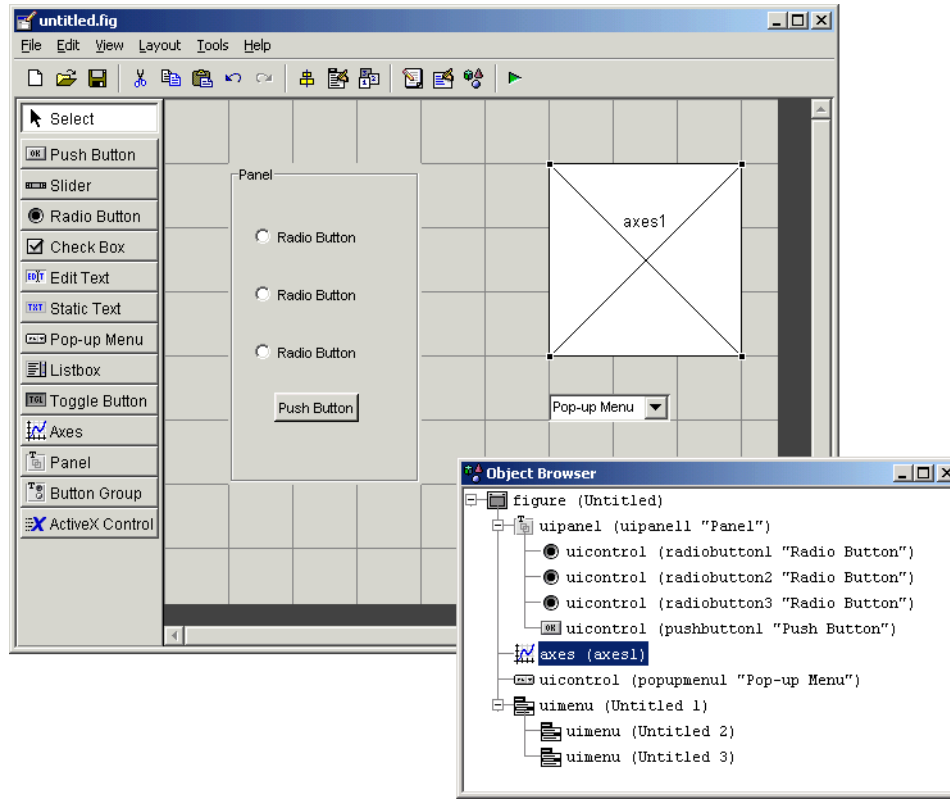


In the opening function, `hObject` is an input argument that holds the figure handle. The `CData` property enables you to display a truecolor image on the toggle tool.

Viewing the Object Hierarchy

The Object Browser displays a hierarchical list of the objects in the figure, including both components and menus. As you lay out your GUI, check the object hierarchy periodically, especially if your GUI contains menus, panes, or button groups.

The following illustration shows a figure object and its child objects. It also shows the child objects of the pane and a menu that was created.



To determine a component's place in the hierarchy, select it in the Layout Editor. It is automatically selected in the Object Browser. Similarly, if you select an object in the Object Browser, it is automatically selected in the Layout Editor.

Designing for Cross-Platform Compatibility

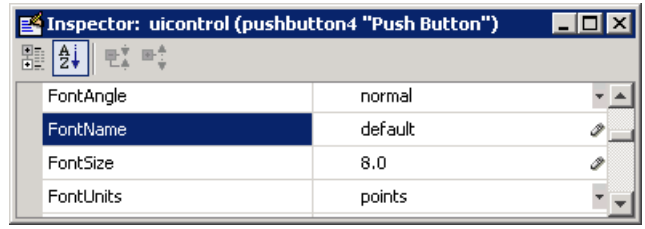
In this section...

Default System Font

By default, user interface controls (uicontrols) use the default font for the platform on which they are running. For example, when displaying your GUI on PCs, uicontrols use MS San Serif. When your GUI runs on a different platform, it uses that computer’s default font. This provides a consistent look with respect to your GUI and other application GUIs.

If you have set the `FontName` property to a named font and want to return to the default value, you can set the property to the string `default`. This ensures that MATLAB uses the system default at run-time.

You can use the Property Inspector to set this property:



Or you can use the `set` command to set the property in the GUI M-file. For example, if there is a push button in your GUI and its handle is stored in the `pushbutton1` field of the `handles` structure, then the statement

```
set(handles.pushbutton1,'FontName','default')
```

sets the `FontName` property to use the system default.

Specifying a Fixed-Width Font

If you want to use a fixed-width font for a user interface control, set its `FontName` property to the string `fixedwidth`. This special identifier ensures that your GUI uses the standard fixed-width font for the target platform.

You can find the name of the fixed-width font that is used on a given platform by querying the root `FixedWidthFontName` property.

```
get(0,'FixedWidthFontName')
```

Using a Specific Font Name

You can specify an actual font name (such as Times or Courier) for the `FontName` property. However, doing so may cause your GUI to not look as you intended when run on a different computer. If the target computer does not have the specified font, it will substitute another font that may not look good in your GUI or may not be the standard font used for GUIs on that system. Also, different versions of the same named font may have different size requirements for a given set of characters.

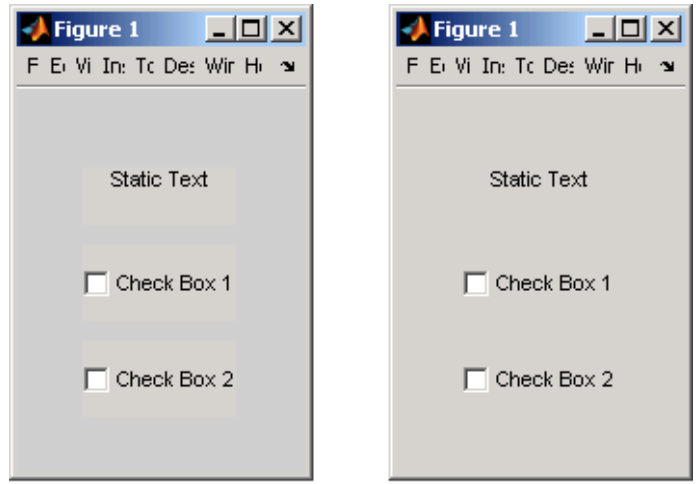
Standard Background Color

The default component background color is the standard system background color on which the GUI is running. This color varies on different computer systems, e.g., the standard shade of gray on the PC differs from that on UNIX, and may not match the default GUI background color.

If you use the default component background color, you can use that same color as the background color for your GUI. This provides a consistent look with respect to your GUI and other application GUIs. To do this in GUIDE, check **Options > Use system color scheme for background** on the Layout Editor **Tools** menu.

Note This option is available only if you first select the **Generate FIG-file and M-File** option.

The following figures illustrate the results with and without system color matching.



Without system color matching

With system color matching

Cross-Platform Compatible Units

Cross-platform compatible GUIs should look correct on computers having different screen sizes and resolutions. Since the size of a pixel can vary on different computer displays, using the default figure `Units` of `pixels` does not produce a GUI that looks the same on all platforms.

For this reason, GUIDE defaults the `Units` property for the figure to `characters`.

System-Dependent Units

Character units are defined by characters from the default system font. The width of a character unit equals the width of the letter `x` in the system font. The height of a character unit is the distance between the baselines of two lines of text. Note that character units are not square.

Units and Resize Behavior

If you set your GUI's resize behavior from the GUI Options dialog box, GUIDE automatically sets the units for the GUI's components in a way that maintains the intended look and feel across platforms. To specify the resize behavior option, select **GUI Options** from the **Tools** menu, then specify **Resize behavior** by selecting **Non-resizable**, **Proportional**, or **Other (Use ResizeFcn)**.

If you choose **Non-resizable**, GUIDE defaults the component units to `characters`. If you choose **Proportional**, it defaults the component units to `normalized`. In either case, these settings enable your GUI to automatically adjust the size and relative spacing of components as the GUI displays on different computers.

If you choose **Other (Use ResizeFcn)**, GUIDE defaults the component units to `characters`. However, you must provide a `ResizeFcn` callback to customize the GUI's resize behavior.

Note GUIDE does not automatically adjust component units if you modify the figure's `Resize` property programmatically or in the Property Inspector.

At times, it may be convenient to use a more familiar unit of measure, e.g., inches or centimeters, when you are laying out the GUI. However, to preserve the look of your GUI on different computers, remember to change the figure `Units` property back to `characters`, and the components' `Units` properties to `characters` (nonresizable GUIs) or `normalized` (resizable GUIs) before you save the GUI.

7

Saving and Running a GUIDE GUI

Naming a GUI and Its Files

In this section...

The GUI Files

By default, GUIDE stores a GUI in two files which are generated the first time you save or run the GUI:

- A FIG-file, with extension `.fig`, that contains a complete description of the GUI layout and the GUI components, such as push buttons, axes, panels, menus, and so on. The FIG-file is a binary file and you cannot modify it except by changing the layout in GUIDE. Note that a FIG-file is a kind of MAT-file. See "MAT-Files Preferences" in the MATLAB Desktop Tools and Development Environment documentation for more information.
- An M-file, with extension `.m`, that contains the code that controls the GUI, including the callbacks for its components.

These two files usually reside in the same directory. They correspond to the tasks of laying out and programming the GUI. When you lay out the GUI in the Layout Editor, your work is stored in the FIG-file. When you program the GUI, your work is stored in the corresponding M-file.

Note that if your GUI includes ActiveX components, GUIDE also generates a file for each ActiveX component. See "ActiveX Control" on page 8-33 for more information.

For more information about these files, see "GUI Files: An Overview" on page 8-5.

File and GUI Names

The M-file and the FIG-file that define your GUI must have the same name. This name is also the name of your GUI.

For example, if your files are named `mygui.fig` and `mygui.m`, then the name of the GUI is `mygui`, and you can run the GUI by typing `mygui` at the command line. This assumes that the M-file and FIG-file are in the same directory and that the directory is in your path.

Names are assigned when you save the GUI the first time. See "Ways to Save a GUI" on page 7-4 for information about saving GUIs.

Renaming GUIs and GUI Files

To rename a GUI, rename the GUI FIG-file using **Save As** from the Layout Editor **File** menu. When you do this, GUIDE renames both the FIG-file and the GUI M-file, updates any callback properties that contain the old name to use the new name, and updates all instances of the file name in the body of the M-file.

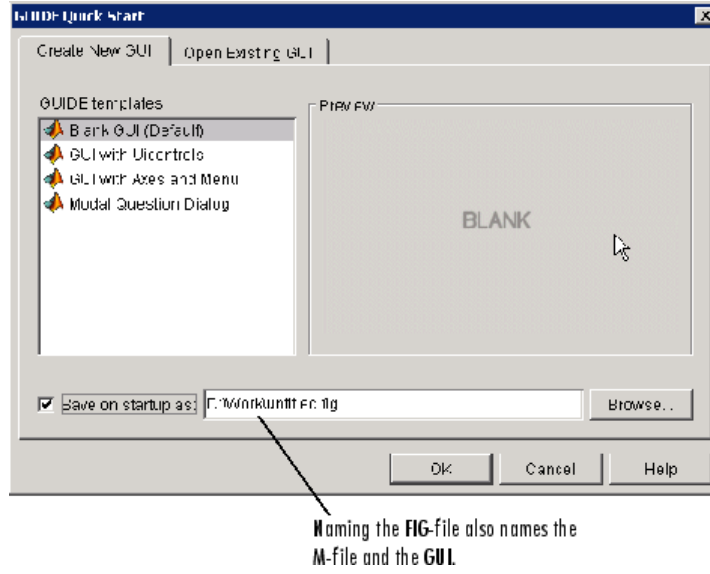
Saving a GUI

In this section...

Ways to Save a GUI

You can save a GUI in GUIDE in any of these ways:

- From the GUIDE Quick Start dialog box. Before you select a template, GUIDE lets you select a name for your GUI. When you click **OK**, GUIDE saves the GUI M-file and FIG-file using the name you specify.



- The first time you save the files by
  - Clicking the Save icon on the Layout Editor toolbar
  - Selecting the **Save** or **Save as** options on the **File** menu

In either case, GUIDE prompts you for a name before saving the GUI.

- The first time you run the GUI by
  - Clicking the Run icon on the Layout Editor toolbar
  - Selecting **Run** from the **Tools** menu

  In each case, GUIDE prompts you for a name and saves the GUI files before activating the GUI.

In all cases, GUIDE creates a template M-file and opens it in your default editor. See “Naming of Callback Functions” on page 8-13 for more information about the template M-file.

Note In most cases you should save your GUI to your current directory or to your path. GUIDE-generated GUIs cannot run correctly from a private directory. GUI FIG-files that are created or modified with MATLAB 7.0 or a later MATLAB version, are not automatically compatible with Version 6.5 and earlier versions. To make a FIG-file, which is a kind of MAT-file, backward compatible, you must check **General > MAT-Files > Ensure backward compatibility (-v6)** in the MATLAB **Preferences** dialog box before saving the file. Button groups and panels are introduced in MATLAB 7.0, and you should not use them in GUIs that you expect to run in earlier MATLAB versions.

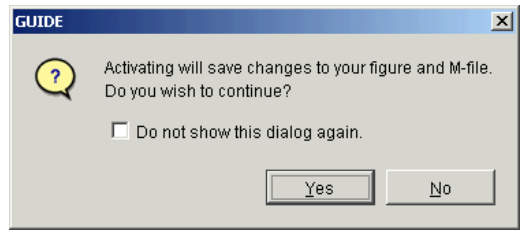
Saving a New GUI

Follow these steps if you are saving a GUI for the first time, or if you are using **Save as** from the **File** menu.

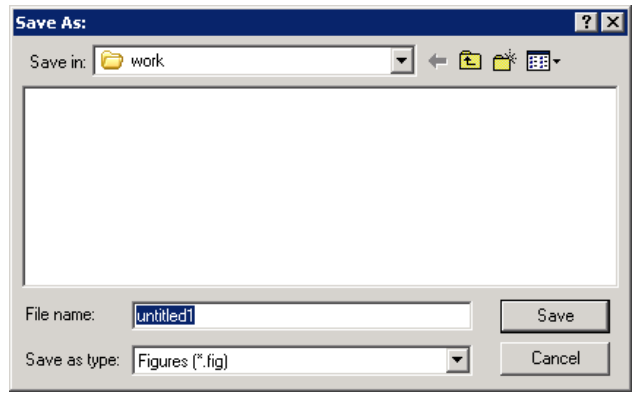
Note If you select **Save as** from the **File** menu or click the **Save** button on the toolbar, GUIDE saves the GUI without activating it. However, if you select **Run** from the **Tools** menu or click the **Run** icon on the toolbar, GUIDE saves the GUI before activating it.

---

1 If you have made changes to the GUI and elect to activate the GUI by selecting **Run** from the **Tools** menu or by clicking the **Run** icon on the toolbar, GUIDE displays the following dialog box. Click **Yes** to continue.



2 If you clicked **Yes** in the previous step, if you are saving the GUI without activating it, or if you are using **Save as** from the File menu, GUIDE opens a **Save As** dialog box and prompts you for a FIG-file name.

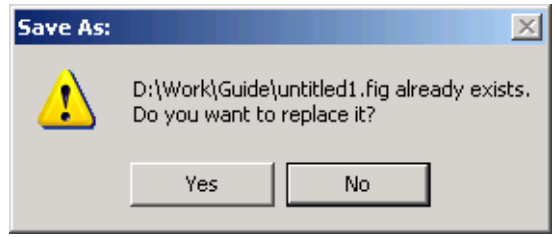


3 Change the directory if you choose, and then enter the name you want to use for the FIG-file. Be sure to choose a writable directory. GUIDE saves both the FIG-file and the M-file using this name.

Note In most cases you should save your GUI to your current directory or to your path. GUIDE-generated GUIs cannot run correctly from a private directory.

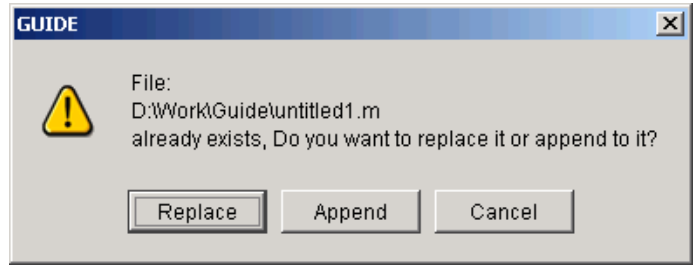
---

4 If you choose an existing filename, GUIDE displays a dialog box that asks you if you want to replace the existing FIG-file. Click **Yes** to continue.

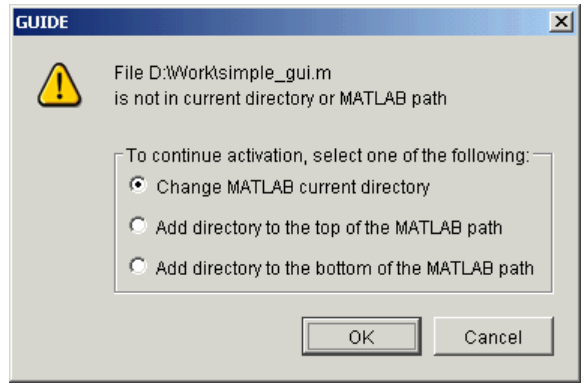


5 If you chose **Yes** in the previous step, GUIDE displays a dialog that asks if you want to replace the existing M-file or append to it. The most common choice is **Replace**.

If you choose **Append**, GUIDE adds callbacks to the existing M-file for components in the current layout that are not present in the existing M-file. Before you append the new components, ensure that their `Tag` properties do not duplicate `Tag` values that appear in callback function names in the existing M-file. See “Assigning an Identifier to Each Component” on page 6-27 for information about specifying the `Tag` property. See “Naming of Callback Functions” on page 8-13 for more information about callback function names.



6 If you chose to activate the GUI by selecting **Run** from the **Tools** menu or by clicking the **Run** button on the toolbar, and if the directory in which you save the GUI is not on the MATLAB path, GUIDE opens a dialog box, giving you the option of changing the current working directory to the directory containing the GUI files, or adding that directory to the top or bottom of the MATLAB path.



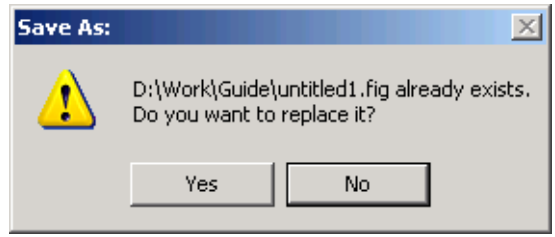
7 After you save the files, GUIDE opens the GUI M-file in your default editor. If you elected to run the GUI, it also activates the GUI.

Saving an Existing GUI

Follow these steps if you are saving an existing GUI to its current location. See "Saving a New GUI" on page 7-5 if you are using **Save as** from the **File** menu.

If you have made changes to a GUI and choose to save and activate the GUI by selecting **Run** from the **Tools** menu or by clicking the Run button on the toolbar, GUIDE saves the GUI and then activates it. It does not automatically open the M-file, even if you added new components.

If you select **Save** from the **File** menu or click the Save button on the toolbar, GUIDE saves the GUI without activating it.



Running a GUI

In this section...

Executing the M-file

Generally, you run your GUI by executing the M-file that GUIDE generates. This M-file contains the commands to load the GUI and provides a framework for the component callbacks. See "GUI Files: An Overview" on page 8-5 for more information about the M-file.

When you execute the M-file, a fully functional copy of the GUI displays on the screen. You can run a GUI:

Note You can display a copy of the GUI figure using the `openfig`, `open`, or `hgload` function. These commands load FIG-files into the MATLAB workspace. The displayed GUI is active, and you can manipulate the components. But nothing happens. This is because no corresponding M-file has been executed.

From the GUIDE Layout Editor

Run your GUI from the GUIDE Layout Editor by:

- Clicking the ▶ button on the Layout Editor toolbar
- Selecting **Run** from the **Tools** menu

In either case, if the GUI has changed or has never been saved, GUIDE saves the GUI files before activating it and opens the GUI M-file in your default editor. See "Saving a GUI" on page 7-4 for information about this process. See "GUI Files: An Overview" on page 8-5 for more information about GUI M-files.

From the Command Line

Run your GUI from its M-file by executing the GUI M-file. For example, if your GUI M-file is `mygui.m`, type

```
mygui
```

at the command line. The files must reside on your path or in your current directory.

If a GUI accepts arguments when it is run, they are passed to the GUI's opening function. See "Opening Function" on page 8-16 for more information.

Note Consider whether you want to allow more than one copy of the GUI to be active at the same time. If you want only one GUI to be active, select **Options > GUI Allows Only One Instance to Run (Singleton)** from the Layout Editor **View** menu. See "GUI Options" on page 5-9 for more information.

From an M-file

Run your GUI from an M-file by executing the GUI M-file. For example, if your GUI M-file is `mygui.m`, include the following statement in your M-file script.

```
mygui
```

The M-file must reside on the MATLAB path or in the current MATLAB directory where the GUI is run.

If a GUI accepts arguments when it is run, they are passed to the GUI's opening function. See "Opening Function" on page 8-16 for more information.

Note Consider whether you want to allow more than one copy of the GUI to be active at the same time. If you want only one GUI to be active, select **Options** from the Layout Editor **View** menu, then select **GUI Allows Only One Instance to Run (Singleton)**. See "GUI Options" on page 5-9 for more information.

8

Programming a GUIDE GUI

Callbacks: An Overview

In this section...

Programming of GUIs Created Using GUIDE

After you have laid out your GUI, you need to program its behavior. The code you write controls how the GUI responds to events such as button clicks, slider movement, menu item selection, or the creation and deletion of components. This programming takes the form of a set of functions, called callbacks, for each component and for the GUI figure itself.

What Is a Callback?

A callback is a function that you write and associate with a specific GUI component or with the GUI figure. It controls GUI or component behavior by performing some action in response to an event for its component. This kind of programming is often called event-driven programming.

When an event occurs for a component, MATLAB invokes the component's callback that is triggered by that event. As an example, suppose a GUI has a button that triggers the plotting of some data. When the user clicks the button, MATLAB calls the callback you associated with clicking that button, and the callback, which you have programmed, then gets the data and plots it.

A component can be any control device such as a push button, list box, or slider. For purposes of programming, it can also be a menu or a container such as a panel or button group. See "Available Components" on page 6-19 for a list and descriptions of components.

Kinds of Callbacks

The GUI figure and each type of component has specific kinds of callbacks with which it can be associated. The callbacks that are available for each component are defined as properties of that component. For example, a push

button has five callback properties: `ButtonDownFcn`, `Callback`, `CreateFcn`, `DeleteFcn`, and `KeyPressFcn`. A panel has four callback properties: `ButtonDownFcn`, `CreateFcn`, `DeleteFcn`, and `ResizeFcn`. You can, but are not required to, create a callback function for each of these properties. The GUI itself, which is a figure, also has certain kinds of callbacks with which it can be associated.

Each kind of callback has a triggering mechanism or event that causes it to be called. The following table lists the callback properties that GUIDE makes available, their triggering events, and the components to which they apply.

Callback Property	Triggering Event	Components
`ButtonDownFcn`	Executes when the user presses a mouse button while the pointer is on or within five pixels of a component or figure. If the component is a user interface control, its `Enable` property must be `on`.	Axes, figure, button group, panel, user interface controls
`Callback`	Component action. Executes, for example, when a user clicks a push button or selects a menu item.	Context menu, menu, user interface controls
`CloseRequestFcn`	Executes before the figure closes.	Figure
`CreateFcn`	Component creation. It can be use to initialize the component when it is created. It executes after the component or figure is created, but before it is displayed.	Axes, figure, button group, context menu, menu, panel, user interface controls
`DeleteFcn`	Component deletion. It can be used to perform cleanup operations just before the component or figure is destroyed.	Axes, figure, button group, context menu, menu, panel, user interface controls
`KeyPressFcn`	Executes when the user presses a keyboard key and the callback's component or figure has focus.	Figure, user interface controls
`KeyReleaseFcn`	Executes when the user releases a keyboard key and the figure has focus.	Figure

Callback Property	Triggering Event	Components
`ResizeFcn`	Executes when a user resizes a panel, button group, or figure whose figure `Resize` property is set to `On`.	Button group, figure, panel
`SelectionChangeFcn`	Executes when a user selects a different radio button or toggle button in a button group component.	Button group
`WindowButtonDownFcn`	Executes when you press a mouse button while the pointer is in the figure window.	Figure
`WindowButtonMotionFcn`	Executes when you move the pointer within the figure window.	Figure
`WindowButtonUpFcn`	Executes when you release a mouse button.	Figure
`WindowScrollWheelFcn`	Executes when the mouse wheel is scrolled while the figure has focus.	Figure

Note User interface controls include push buttons, sliders, radio buttons, check boxes, editable text boxes, static text boxes, list boxes, and toggle buttons. They are sometimes referred to as uicontrols.

Check the properties reference page for your component, e.g., `UicontrolProperties`, to get specific information for a given callback property.

GUI Files: An Overview

In this section...

M-Files and FIG-Files

By default, the first time you save or run a GUI, GUIDE stores the GUI in two files:

- A FIG-file, with extension `.fig`, that contains a complete description of the GUI layout and the GUI components, such as push buttons, axes, panels, menus, and so on. The FIG-file is a binary file and you cannot modify it except by changing the layout in GUIDE. Note that a FIG-file is a kind of MAT-file. See "MAT-Files Preferences" for more information.
- An M-file, with extension `.m`, that initially contains initialization code and templates for some callbacks that are needed to control GUI behavior. You must add the callbacks you write for your GUI components to this file.

  When you save your GUI the first time, GUIDE automatically opens the M-file in your default editor.

The FIG-file and the M-file, usually reside in the same directory. They correspond to the tasks of laying out and programming the GUI. When you lay out the GUI in the Layout Editor, your work is stored in the FIG-file. When you program the GUI, your work is stored in the corresponding M-file.

If your GUI includes ActiveX components, GUIDE also generates a file for each ActiveX component. See "ActiveX Control" on page 8-33 for more information.

For more information about naming and saving a GUI, see Chapter 7, "Saving and Running a GUIDE GUI". If you want to change the name of your GUI and its files, see "Renaming GUIs and GUI Files" on page 7-3.

GUI M-File Structure

The GUI M-file that GUIDE generates is a function file. The name of the main function is the same as the name of the M-file. For example, if the name of the M-file is `mygui.m`, then the name of the main function is `mygui`. Each callback in the file is a subfunction of the main function.

When GUIDE generates an M-file, it automatically includes templates for the most commonly used callbacks for each component. The M-file also contains initialization code, as well as an opening function callback and an output function callback. You must add code to the component callbacks for your GUI to work as you want. You may also want to add code to the opening function callback and the output function callback. The major sections of the GUI M-file are ordered as shown in the following table.

Section	Description
Comments	Displayed at the command line in response to the `help` command. Edit these as necessary for your GUI.
Initialization	GUIDE initialization tasks. *Do not edit this code.*
Opening function	Performs your initialization tasks before the user has access to the GUI.
Output function	Returns outputs to the MATLAB command line after the opening function returns control and before control returns to the command line.
Component and figure callbacks	Control the behavior of the GUI figure and of individual components. MATLAB calls a callback in response to a particular event for a component or for the figure itself.
Utility/helper functions	Perform miscellaneous functions not directly associated with an event for the figure or a component.

Adding Callback Templates to an Existing GUI M-File

When you save the GUI, GUIDE automatically adds templates for some callbacks to the M-file. However, you may want to add other callbacks to the M-file.

Within GUIDE, you can add a callback subfunction template to the GUI M-file in one of two ways. With the component selected for which you want to add the callback:

- Click the right mouse button to display the Layout Editor context menu. Select the desired callback from the **View callbacks** submenu. GUIDE adds the callback template to the GUI M-file and opens the M-file for editing at the callback it just added.
- In the **View** menu, select the desired callback from the **View callbacks** submenu. GUIDE adds the callback template to the GUI M-file and opens the M-file for editing at the callback you just added.

Note In either case, if you select a callback that already exists in the GUI M-file, GUIDE adds no callback, but opens the M-file for editing at the callback you select.

For more information, see “Associating Callbacks with Components” on page 8-8.

Associating Callbacks with Components

In this section...

GUI Components

A GUI can have many components and GUIDE provides a way of specifying which callback should run in response to a particular event for a particular component. The callback that runs when the user clicks a **Yes** button is not the one that runs for the **No** button. Similarly, each menu item usually performs a different function.

GUIDE uses each component's callback properties to associate specific callbacks with that component.

Note "Kinds of Callbacks" on page 8-2 provides a list of callback properties and the components to which each applies.

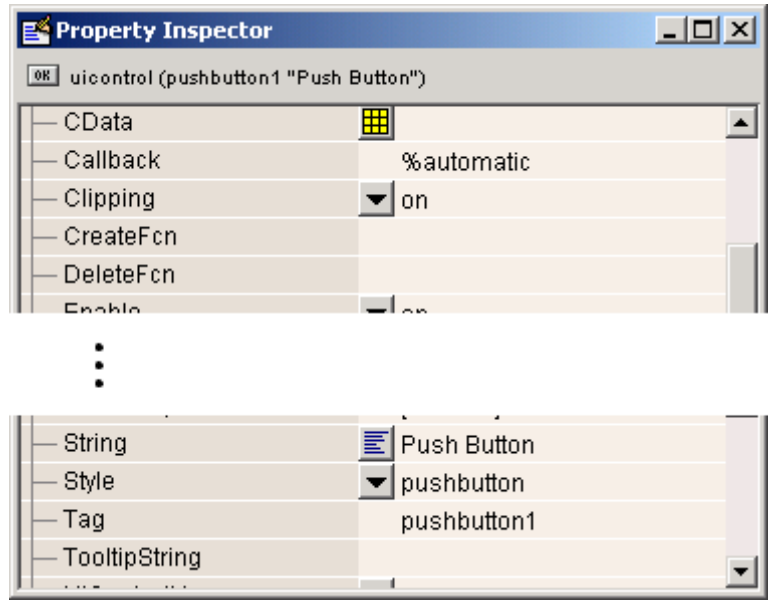
Setting Callback Properties Automatically

GUIDE initially sets the value of the most commonly used callback properties for each component to `%automatic`. For example, a push button has five callback properties, `ButtonDownFcn`, `Callback`, `CreateFcn`, `DeleteFcn`, and `KeyPressFcn`. GUIDE sets only the `Callback` property, the most commonly used callback, to `%automatic`. You can use the Property Inspector to set the other callback properties to `%automatic`.

When you next save the GUI, GUIDE replaces `%automatic` with a MATLAB expression that is the GUI calling sequence for the callback. Within the calling sequence, it constructs the callback name, i.e., the subfunction name, from the component's `Tag` property and the name of the callback property.

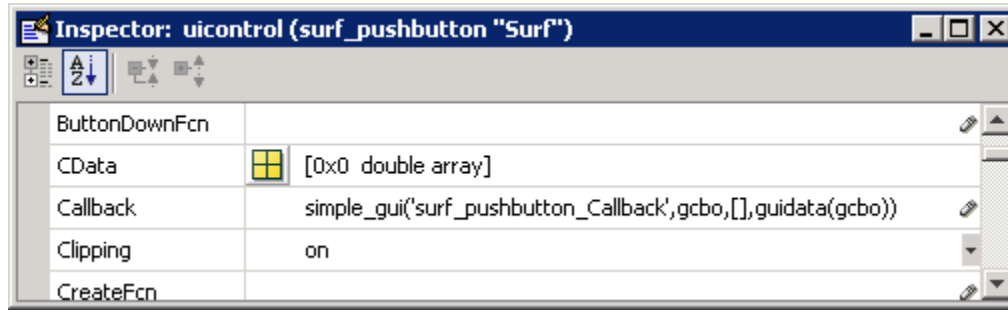
The following figure shows an example of a push button's `Callback` and `Tag` properties in the GUIDE Property Inspector before the GUI is saved.

Note If you change the string `%automatic` before saving the GUI, GUIDE does not automatically add a callback for that component or menu item.



When you save the GUI, GUIDE constructs the name of the callback by appending an underscore (_) and the name of the callback property to the value of the component's `Tag` property. For example, the MATLAB expression for the `Callback` property for a push button in the GUI `simple_gui` with `Tag` property `pushbutton1` is

```
simple_gui(pushbutton1_Callback,gcbo,[],guidata(gcbo))
```



`simple_gui` is the name of the GUI M-file as well as the name of the main function for that GUI. The remaining arguments generate input arguments for `pushbutton1_Callback`. Specifically,

- `gcbo` is a command that returns the handle of the callback object (i.e., `pushbutton1`).
- `[]` is a place holder for the currently unused `eventdata` argument.
- `guidata(gcbo)` returns the `handles` structure for this GUI.

See “Input Arguments” on page 8-14 for information about the callback input arguments.

When you save the GUI, GUIDE also opens the GUI M-file in your editor. The M-file then contains a template for the `Callback` callback for the component whose `Tag` is `pushbutton1`. If you activate the GUI, clicking the push button triggers the execution of the `Callback` callback for the component.

For information about changing the callback name after GUIDE assigns it, see “Changing Callback Names Assigned by GUIDE” on page 8-13. For information about adding callback templates to the GUI M-file, see “Adding Callback Templates to an Existing GUI M-File” on page 8-6.

The next topic, “Callback Syntax and Arguments” on page 8-12, provides more information about the callback template.

Deleting Callbacks from a GUI M-File

There are times when you want to delete a callback from a GUI M-file. The callback may have been automatically generated or you may have added it yourself. Some common reasons for wanting to delete a callback are:

- You have deleted the component for which the callback was generated.
- You want the component to use other code and you have already edited the appropriate callback property in the Property Inspector to point to the other code.

To delete a callback, whether it is automatically generated or whether you added it explicitly, you must first ensure that the callback is not used. Only then should you delete the callback.

To ensure that the callback is not used elsewhere in the GUI:

- Search for occurrences of the name of the callback in the GUI M-file.
- Open the GUI in GUIDE and use the Property Inspector to check for the name of the callback you want to delete in the callback properties of all the components.

In either case, if you find a reference to the callback, you must either remove the reference or retain the callback. Once you have assured yourself that the code is not used by the GUI, manually delete the entire callback subfunction from the M-file.

Callback Syntax and Arguments

In this section...

Callback Templates

GUIDE defines conventions for callback syntax and arguments and implements these conventions in the callback templates it adds to the M-file. Each template is similar to this one for the `Callback` subfunction for a push button.

```
% --- Executes on button press in pushbutton1.
function pushbutton1_Callback(hObject, eventdata, handles)
% hObject    handle to pushbutton1 (see GCBO)
% eventdata  reserved - to be defined in a future version of MATLAB
% handles    structure with handles and user data (see GUIDATA)

...
```

The first comment line describes the event that triggers execution of the callback. This is followed by the function definition line. The remaining comments describe the input arguments.

Insert your code after the last comment.

Note You can avoid automatic generation of the callback comment lines for new callbacks. In the Preferences dialog box, select **GUIDE** and uncheck **Add comments for newly generated callback functions**.

Naming of Callback Functions

The previous callback example shows the following function definition:

```
function pushbutton1_Callback(hObject,eventdata,handles)
```

When GUIDE generates the template, it creates the callback name by appending an underscore (_) and the name of the callback property to the component's `Tag` property. In the example above, `pushbutton1` is the `Tag` property for the push button, and `Callback` is one of the push button's callback properties. The `Tag` property uniquely identifies a component within the GUI.

The first time you save the GUI after adding a component, GUIDE adds callbacks for that component to the M-file and generates the callback names using the current value of the `Tag` property. If you want to change the default `Tag` value, you should do it before you save the GUI.

See "Associating Callbacks with Components" on page 8-8 for more information.

Changing Callback Names Assigned by GUIDE

You can change callback names assigned by GUIDE in either of the following ways:

Note If possible, change callback names for a component immediately after you add the component to the layout and before you save the GUI.

Changing the Tag Property

You can change `Tag` properties to give a component's callbacks more meaningful names, e.g., you might change the `Tag` property from `pushbutton1` to `closebutton`. If possible, change the `Tag` property before saving the GUI, then GUIDE automatically uses the new value when it names the callbacks. However, if you change the `Tag` property after saving the GUI,

GUIDE updates the following items according to the new `Tag`, provided that all components have distinct tags:

- The component's callback functions in the M-file
- The value of the component's callback properties, which you can view in the Property Inspector
- References in the M-file to the field of the `handles` structure that contains the component's handle. See "handles Structure" on page 8-15 for more information about the `handles` structure.

Changing the Callback Property

To rename a particular callback subfunction without changing the `Tag` property,

- Replace the name string in the callback property with the new name. For example, if the value of the callback property for a push button in `mygui` is

  ```
  mygui('pushbutton1_Callback',gcbo,[],guidata(gcbo))
  ```

  the string `pushbutton1_Callback` is the name of the callback function. Change the name to the desired name, for example, `closebutton_Callback`.
- As necessary, update instances of the callback function name in the M-file.

Input Arguments

All callbacks in the GUI M-file have the following input arguments:

- `hObject` — Handle of the object, e.g., the GUI component, for which the callback was triggered. For a button group `SelectionChangeFcn` callback, `hObject` is the handle of the selected radio button or toggle button.
- `eventdata` — Reserved for later use.
- `handles` — Structure that contains the handles of all the objects in the figure. It may also contain application-defined data. See "handles Structure" on page 8-15 for information about this structure.

handles Structure

GUIDE creates a `handles` structure that contains the handles of all the objects in the figure. For a GUI that contains an edit text, a panel, a pop-up menu, and a push button, the `handles` structure originally looks similar to this. GUIDE uses each component's `Tag` property to name the structure element for its handle.

```
handles =
        figure1: 160.0011
          edit1: 9.0020
         uipanel1: 8.0017
      popupmenu1: 7.0018
     pushbutton1: 161.0011
          output: 160.0011
```

GUIDE creates and maintains the `handles` structure as GUI data. It is passed as an input argument to all callbacks and enables a GUI's callbacks to share property values and application data.

For information about GUI data, see "Mechanisms for Managing Data" on page 9-2 and the `guidata` reference page.

For information about adding fields to the `handles` structure and instructions for correctly saving the structure, see Chapter 13, "Managing Application-Defined Data".

Initialization Callbacks

In this section...

Opening Function

The opening function is the first callback in every GUI M-file. It is executed just before the GUI is made visible to the user, but after all the components have been created, i.e., after the components' `CreateFcn` callbacks, if any, have been run.

You can use the opening function to perform your initialization tasks before the user has access to the GUI. For example, you can use it to create data or to read data from an external source. GUI command-line arguments are passed to the opening function.

Function Naming and Template

GUIDE names the opening function by appending `_OpeningFcn` to the name of the M-file. This is an example of an opening function template as it might appear in the `mygui` M-file.

```
% --- Executes just before mygui is made visible.
function mygui_OpeningFcn(hObject, eventdata, handles, varargin)
% This function has no output args, see OutputFcn.
% hObject    handle to figure
% eventdata  reserved - to be defined in a future version of MATLAB
% handles    structure with handles and user data (see GUIDATA)
% varargin   command line arguments to mygui (see VARARGIN)

% Choose default command line output for mygui
handles.output = hObject;
```

```
% Update handles structure
guidata(hObject, handles);

% UIWAIT makes mygui wait for user response (see UIRESUME)
% uiwait(handles.mygui);
```

Input Arguments

The opening function has four input arguments `hObject`, `eventdata`, `handles`, and `varargin`. The first three are the same as described in “Input Arguments” on page 8-14. the last argument, `varargin`, enables you to pass arguments from the command line to the opening function. The opening function can make such arguments available to the callbacks by adding them to the `handles` structure.

For more information about `varargin`, see the `varargin` reference page and“Passing Variable Numbers of Arguments” in the MATLAB Programming documentation.

All command-line arguments are passed to the opening function via `varargin`. If you open the GUI with a property name/property value pair as arguments, the GUI opens with the property set to the specified value. For example, `my_gui('Position', [71.8 44.9 74.8 19.7])` opens the GUI at the specified position, since `Position` is a valid figure property.

If the input argument is not a valid figure property, you must add code to the opening function to make use of the argument. For an example, look at the opening function for the **Modal Question Dialog** GUI template, available from the GUIDE Quick Start dialog box. The added code enables you to open the modal dialog with the syntax

```
mygui('String','Do you want to exit?')
```

which displays the text `'Do you want to exit?'` on the GUI. In this case, it is necessary to add code to the opening function because `'String'` is not a valid figure property.

Initial Template Code

Initially, the input function template contains these lines of code:

- `handles.output = hObject` adds a new element, `output`, to the `handles` structure and assigns it the value of the input argument `hObject`, which is the handle of the figure, i.e., the handle of the GUI. This handle is used later by the output function. For more information about the output function, see "Output Function" on page 8-18.
- `guidata(hObject,handles)` saves the `handles` structure. You must use `guidata` to save any changes that you make to the `handles` structure. It is not sufficient just to set the value of a `handles` field. See "handles Structure" on page 8-15 and "GUI Data" on page 9-2 for more information.
- `uiwait(handles.mygui)`, initially commented out, blocks GUI execution until `uiresume` is called or the GUI is deleted. Note that `uiwait` allows the user access to other MATLAB windows. Remove the comment symbol for this statement if you want the GUI to be blocking when it opens.

Output Function

The output function returns, to the command line, outputs that are generated during its execution. It is executed when the opening function returns control and before control returns to the command line. This means that you must generate the outputs in the opening function, or call `uiwait` in the opening function to pause its execution while other callbacks generate outputs.

Function Naming and Template

GUIDE names the output function by appending `_OutputFcn` to the name of the M-file. This is an example of an output function template as it might appear in the `mygui` M-file.

```
% --- Outputs from this function are returned to the command line.
function varargout = mygui_OutputFcn(hObject, eventdata,...
                     handles)
% varargout  cell array for returning output args (see VARARGOUT);
% hObject    handle to figure
% eventdata  reserved - to be defined in a future version of MATLAB
% handles    structure with handles and user data (see GUIDATA)
```

```
% Get default command line output from handles structure
varargout{1} = handles.output;
```

Input Arguments

The output function has three input arguments: `hObject`, `eventdata`, and `handles`. They are the same as described in "Input Arguments" on page 8-14.

Output Arguments

The output function has one output argument, `varargout`, which it returns to the command line. By default, the output function assigns `handles.output` to `varargout`. So the default output is the handle to the GUI, which was assigned to `handles.output` in the opening function.

You can change the output by

- Changing the value of `handles.output`. It can be any valid MATLAB value including a structure or cell array.
- Adding output arguments to `varargout`.

  `varargout` is a cell array. It can contain any number of output arguments. By default, GUIDE creates just one output argument, `handles.output`. To create an additional output argument, create a new field in the `handles` structure and add it to `varargout` using a command similar to

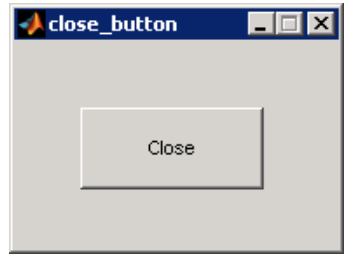
  ```
  varargout{2} = handles.second_output;
  ```

Examples: Programming GUIDE GUI Components

In this section...

Push Button

This example contains only a push button. Clicking the button, closes the GUI.



This is the push button’s `Callback` callback. It displays the string `Goodbye` at the command line and then closes the GUI.

```
function pushbutton1_Callback(hObject, eventdata, handles)
```

```
display Goodbye
close(handles.figure1);
```

Adding an Image to a Push Button or Toggle Button

To add an image to a push button or toggle button, assign the button's `CData` property an m-by-n-by-3 array of RGB values that defines "RGB (Truecolor) Images". For example, the array `a` defines 16-by-64 truecolor image using random values between 0 and 1 (generated by `rand`).

```
a(:,:,1) = rand(16,64);
a(:,:,2) = rand(16,64);
a(:,:,3) = rand(16,64);
set(hObject,'CData',a)
```

To add the image when the button is created, add the code to the button's `CreateFcn` callback. You may want to delete the value of the button's `String` property, which would usually be used as a label.

See `ind2rgb` for information on converting a matrix `X` and corresponding colormap, i.e., an `(X, MAP)` image, to RGB (truecolor) format.

Toggle Button

The callback for a toggle button needs to query the toggle button to determine what state it is in. MATLAB sets the `Value` property equal to the `Max` property when the toggle button is pressed (`Max` is 1 by default) and equal to the `Min` property when the toggle button is not pressed (`Min` is 0 by default).

The following code illustrates how to program the callback in the GUI M-file.

```
function togglebutton1_Callback(hObject, eventdata, handles)
button_state = get(hObject,'Value');
if button_state == get(hObject,'Max')
 % Toggle button is pressed-take approperiate action
```

```
   ...
elseif button_state == get(hObject,'Min')
 % Toggle button is not pressed-take appropriate action
    ...
end
```

You can also change the state of a toggle button programmatically by setting the toggle button `Value` property to the value of the `Max` or `Min` property. For example,

```
set(handles.togglebutton1,'Value','Max')
```

puts the toggle button with `Tag` property `togglebutton1` in the pressed state.

Note You can use a button group to manage exclusive selection behavior for toggle buttons. See "Button Group" on page 8-28 for more information.

Radio Button

You can determine the current state of a radio button from within its callback by querying the state of its `Value` property, as illustrated in the following example:

```
if (get(hObject,'Value') == get(hObject,'Max'))
 % Radio button is selected-take approriate action
else
 % Radio button is not selected-take approriate action
end
```

You can also change the state of a radio button programmatically by setting the radio button `Value` property to the value of the `Max` or `Min` property. For example,

```
set(handles.radiobutton1,'Value','Max')
```

puts the radio button with `Tag` property `radiobutton1` in the selected state.

Note You can use a button group to manage exclusive selection behavior for radio buttons. See “Button Group” on page 8-28 for more information.

Check Box

You can determine the current state of a check box from within its callback by querying the state of its `Value` property, as illustrated in the following example:

```
function checkbox1_Callback(hObject, eventdata, handles)
if (get(hObject,'Value') == get(hObject,'Max'))
 % Checkbox is checked-take approriate action
else
 % Checkbox is not checked-take approriate action
end
```

You can also change the state of a check box by programmatically by setting the check box `Value` property to the value of the `Max` or `Min` property. For example,

```
set(handles.checkbox1,'Value','Max')
```

puts the check box with `Tag` property `checkbox1` in the checked state.

Edit Text

To obtain the string a user types in an edit box, get the `String` property in the `Callback` callback.

```
function edittext1_Callback(hObject, eventdata, handles)
user_string = get(hObject,'String');
% Proceed with callback
```

If the edit text `Max` and `Min` properties are set such that `Max - Min > 1`, the user can enter multiple lines. For example, setting `Max` to `2`, with the default value of `0` for `Min`, enables users to enter multiple lines.

Retrieving Numeric Data from an Edit Text Component

MATLAB returns the value of the edit text `String` property as a character string. If you want users to enter numeric values, you must convert the characters to numbers. You can do this using the `str2double` command, which converts strings to doubles. If the user enters nonnumeric characters, `str2double` returns `NaN`.

You can use the following code in the edit text callback. It gets the value of the `String` property and converts it to a double. It then checks whether the converted value is `NaN` (`isnan`), indicating the user entered a nonnumeric character and displays an error dialog (`errordlg`).

```
function edittext1_Callback(hObject, eventdata, handles)
user_entry = str2double(get(hObject,'string'));
if isnan(user_entry)
 errordlg('You must enter a numeric value','Bad Input','modal')
 return
end
% Proceed with callback...
```

Triggering Callback Execution

If the contents of the edit text component have been changed, clicking inside the GUI but outside the edit text causes the edit text callback to execute. The user can also press **Enter** for an edit text that allows only a single line of text, or **Ctrl+Enter** for an edit text that allows multiple lines.

Available Keyboard Accelerators

GUI users can use the following keyboard accelerators to modify the content of an edit text. These accelerators are not modifiable.

- **Ctrl+X** — Cut
- **Ctrl+C** — Copy
- **Ctrl+V** — Paste
- **Ctrl+H** — Delete last character
- **Ctrl+A** — Select all

Slider

You can determine the current value of a slider from within its callback by querying its `Value` property, as illustrated in the following example:

```
function slider1_Callback(hObject, eventdata, handles)
slider_value = get(hObject,'Value');
% Proceed with callback...
```

The `Max` and `Min` properties specify the slider's maximum and minimum values. The slider's range is `Max - Min`.

List Box

When the list box `Callback` callback is triggered, the list box `Value` property contains the index of the selected item, where `1` corresponds to the first item in the list. The `String` property contains the list as a cell array of strings.

This example retrieves the selected string. It assumes `listbox1` is the value of the `Tag` property. Note that it is necessary to convert the value returned from the `String` property from a cell array to a string.

```
function listbox1_Callback(hObject, eventdata, handles)
index_selected = get(hObject,'Value');
list = get(hObject,'String');
item_selected = list{index_selected}; % Convert from cell array
                                      % to string
```

You can also select a list item programmatically by setting the list box `Value` property to the index of the desired item. For example,

```
set(handles.listbox1,'Value',2)
```

selects the second item in the list box with `Tag` property `listbox1`.

Triggering Callback Execution

MATLAB executes the list box's `Callback` callback after the mouse button is released or after certain key press events:

- The arrow keys change the `Value` property, trigger callback execution, and set the figure `SelectionType` property to `normal`.

- The **Enter** key and space bar do not change the `Value` property but trigger callback execution and set the figure `SelectionType` property to `open`.

If the user double-clicks, the callback executes after each click. MATLAB sets the figure `SelectionType` property to `normal` on the first click and to `open` on the second click. The callback can query the figure `SelectionType` property to determine if it was a single or double click.

List Box Examples

See the following examples for more information on using list boxes:

- "List Box Directory Reader" on page 10-9 — Shows how to creates a GUI that displays the contents of directories in a list box and enables users to open a variety of file types by double-clicking the filename.
- "Accessing Workspace Variables from a List Box" on page 10-16 — Shows how to access variables in the MATLAB base workspace from a list box GUI.

Pop-Up Menu

When the pop-up menu `Callback` callback is triggered, the pop-up menu `Value` property contains the index of the selected item, where `1` corresponds to the first item on the menu. The `String` property contains the menu items as a cell array of strings.

Note A pop-up menu is sometimes referred to as a drop-down menu or combo box.

Using Only the Index of the Selected Menu Item

This example retrieves only the index of the item selected. It uses a switch statement to take action based on the value. If the contents of the pop-up menu are fixed, then you can use this approach. Else, you can use the index to retrieve the actual string for the selected item.

```
function popupmenu1_Callback(hObject, eventdata, handles)
val = get(hObject,'Value');
switch val
case 1
```

```
% User selected the first item
case 2
% User selected the second item
% Proceed with callback...
```

You can also select a menu item programmatically by setting the pop-up menu `Value` property to the index of the desired item. For example,

```
set(handles.popupmenu1,'Value',2)
```

selects the second item in the pop-up menu with `Tag` property `popupmenu1`.

Using the Index to Determine the Selected String

This example retrieves the actual string selected in the pop-up menu. It uses the pop-up menu `Value` property to index into the list of strings. This approach may be useful if your program dynamically loads the contents of the pop-up menu based on user action and you need to obtain the selected string. Note that it is necessary to convert the value returned by the `String` property from a cell array to a string.

```
function popupmenu1_Callback(hObject, eventdata, handles)
val = get(hObject,'Value');
string_list = get(hObject,'String');
selected_string = string_list{val}; % Convert from cell array
                                    % to string
% Proceed with callback...
```

Panel

Panels group GUI components and can make a GUI easier to understand by visually grouping related controls. A panel can contain panels and button groups as well as axes and user interface controls such as push buttons, sliders, pop-up menus, etc. The position of each component within a panel is interpreted relative to the lower-left corner of the panel.

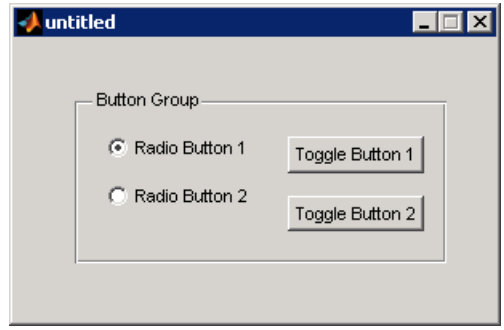
Generally, if the GUI is resized, the panel and its components are also resized. However, you can control the size and position of the panel and its components. You can do this by setting the GUI **Resize behavior** to **Other (Use ResizeFcn)** and providing a `ResizeFcn` callback for the panel.

Note To set **Resize behavior** for the figure to **Other (Use ResizeFcn)**, select **GUI Options** from the Layout Editor **Tools** menu. See "Cross-Platform Compatible Units" on page 6-103 for information about the effect of units on resize behavior.

Button Group

Button groups are like panels except that they manage exclusive selection behavior for radio buttons and toggle buttons. If a button group contains a set of radio buttons, toggle buttons, or both, the button group allows only one of them to be selected. When a user clicks a button, that button is selected and all others are deselected.

The following figure shows a button group with two radio buttons and two toggle buttons. **Radio Button 1** is selected.



If a user clicks the other radio button or one of the toggle buttons, it becomes selected and **Radio Button 1** is deselected. The following figure shows the result of clicking **Toggle Button 2**.

The button group's `SelectionChangeFcn` callback is called whenever a selection is made. Its `hObject` input argument contains the handle of the selected radio button or toggle button.

If you have a button group that contains a set of radio buttons and toggle buttons and you want:

- An immediate action to occur when a radio button or toggle button is selected, you must include the code to control the radio and toggle buttons in the button group's `SelectionChangeFcn` callback function, not in the individual toggle button `Callback` functions. "Color Palette" on page 15-17 provides a practical example of a `SelectionChangeFcn` callback.
- Another component such as a push button to base its action on the selection, then that component's `Callback` callback can get the handle of the selected radio button or toggle button from the button group's `SelectedObject` property.

This example of a `SelectionChangeFcn` callback uses the `Tag` property of the selected object to choose the appropriate code to execute. For GUIDE GUIs, unlike other callbacks, the `hObject` argument of the `SelectionChangeFcn` callback contains the handle of the selected radio button or toggle button.

```
function uibuttongroup1_SelectionChangeFcn(hObject,...
    eventdata,handles)
```

```
switch get(hObject,'Tag')   % Get Tag of selected object
    case 'radiobutton1'
        % Code for when radiobutton1 is selected.
    case 'radiobutton2'
        % Code for when radiobutton2 is selected.
    case 'togglebutton1'
        % Code for when togglebutton1 is selected.
    case 'togglebutton2'
        % Code for when togglebutton2 is selected.
    % Continue with more cases as necessary.
    otherwise
        % Code for when there is no match.
end
```

See the `uibuttongroup` reference page for another example.

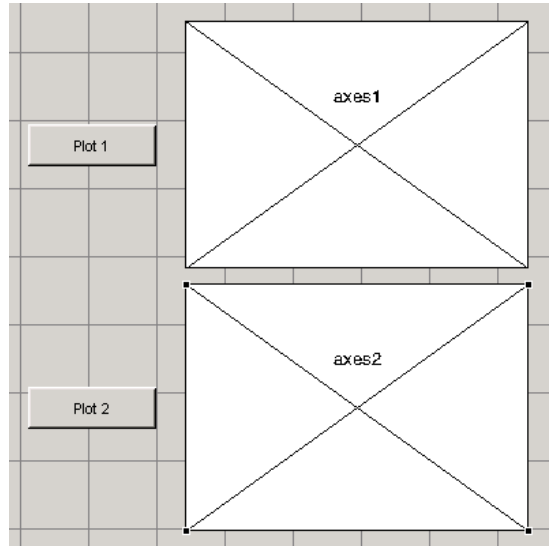
Axes

Axes components enable your GUI to display graphics, such as graphs and images. This topic briefly tells you how to plot to axes components in your GUI.

Plotting to an Axes

In most cases, you create a plot in an axes from a callback that belongs to some other component in the GUI. For example, pressing a button might trigger the plotting of a graph to an axes. In this case, the button's `Callback` callback contains the code that generates the plot.

The following example contains two axes and two buttons. Clicking one button generates a plot in one axes and clicking the other button generates a plot in the other axes. The following figure shows these components as they might appear in the Layout Editor.



1. Add this code to the **Plot 1** push button's `Callback` callback. The `surf` function produces a 3-D shaded surface plot. The `peaks` function returns a square matrix obtained by translating and scaling Gaussian distributions.

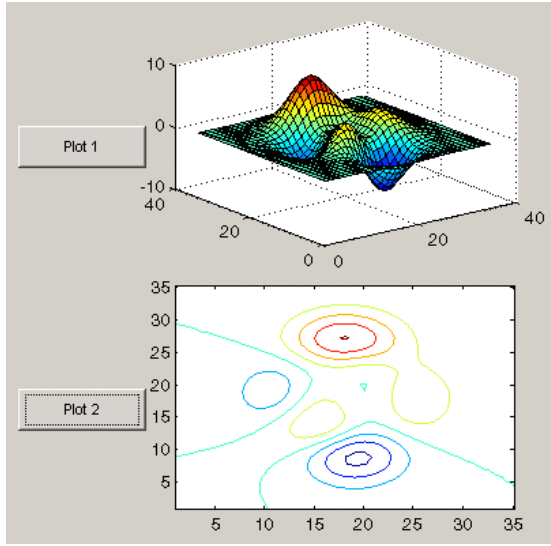
   ```
   surf(handles.axes1,peaks(35));
   ```

2. Add this code to the **Plot 2** push button's `Callback` callback. The `contour` function displays the contour plot of a matrix, in this case the output of `peaks`.

   ```
   contour(handles.axes2,peaks(35));
   ```

3. Run the GUI by selecting **Run** from the **Tools** menu.

4 Click the **Plot 1** button to display the surf plot in the first axes. Click the **Plot 2** button to display the contour plot in the second axes.



See “GUI with Multiple Axes” on page 10-2 for a more complex example that uses two axes.

Note For information about properties that you can set to control many aspects of axes behavior and appearance, see “Axes Properties” in the MATLAB Graphics documentation. For information about plotting in general, see “Plots and Plotting Tools” in the MATLAB Graphics documentation.

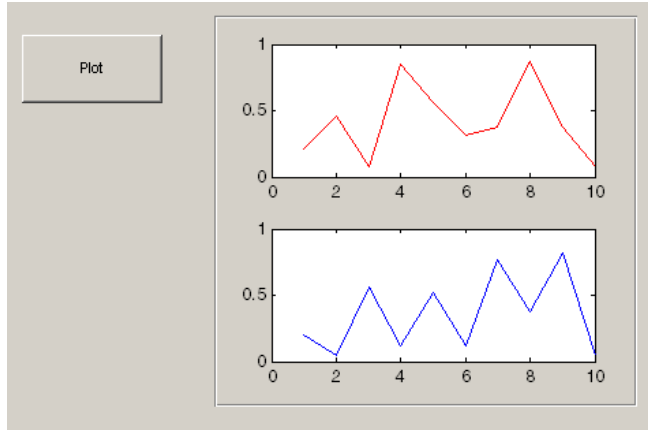
If your GUI contains axes, you should make sure that the **Command-line accessibility** option in the GUI Options dialog box is set to **Callback** (the default). From the Layout Editor select **Tools > GUI Options > Command Line Accessibility: Callback**. See “Command-Line Accessibility” on page 5-10 for more information about how this option works.

Creating Subplots

Use the `subplot` function to create axes in a tiled pattern. If your GUIDE-generated GUI contains components other than the subplots, the subplots must be contained in a panel.

As an example, the following code uses the `subplot` function to create an axes with two subplots in the panel with `Tag` property `uipanel1`. This code is part of the **Plot** push button `Callback` callback. Each time you press the **Plot** button, the code draws a line in each subplot. `a1` and `a2` are the handles of the subplots.

```
a1=subplot(2,1,1,'Parent',handles.uipanel1);
plot(a1,rand(1,10),'r');
a2=subplot(2,1,2,'Parent',handles.uipanel1);
plot(a2,rand(1,10),'b');
```



For more information about subplots, see the `subplot` reference page. For information about adding panels to your GUI, see “Adding Components to the GUIDE Layout Area” on page 6-22.

ActiveX Control

This example programs a sample ActiveX control **Mwsamp Control**. It first enables a user to change the radius of a circle by clicking on the circle. It then programs a slider on the GUI to do the same thing.

This topic also discusses:

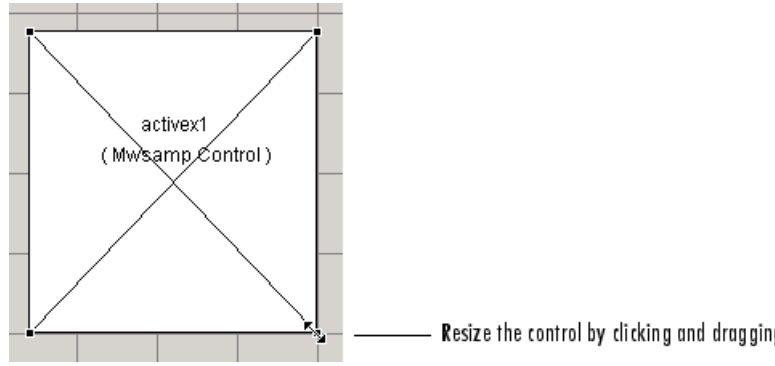
Note See "MATLAB COM Client Support" in the MATLAB External Interfaces documentation to learn more about ActiveX controls.

Programming an ActiveX Control

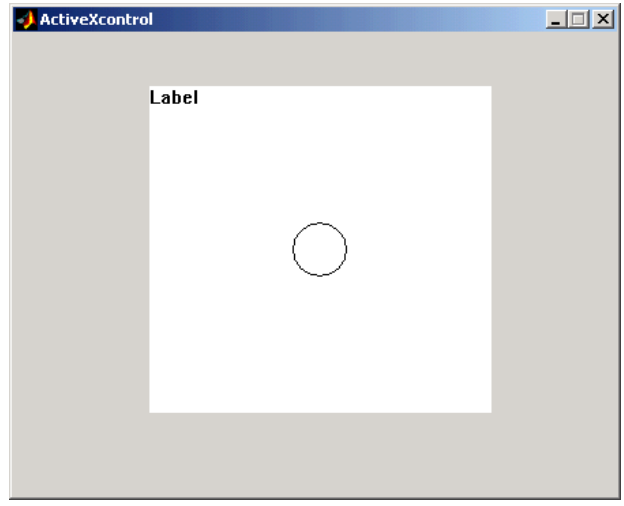
The sample ActiveX control **Mwsamp Control** contains a circle in the middle of a square. This example programs the control to change the circle radius when the user clicks the circle, and to update the label to display the new radius.

1 Add the sample ActiveX control **Mwsamp** to your GUI and resize it to approximately the size of the square shown in the preview pane. The following figure shows the ActiveX control as it appears in the Layout Editor.

If you need help adding the component, see “Adding Components to the GUIDE Layout Area” on page 6-22.

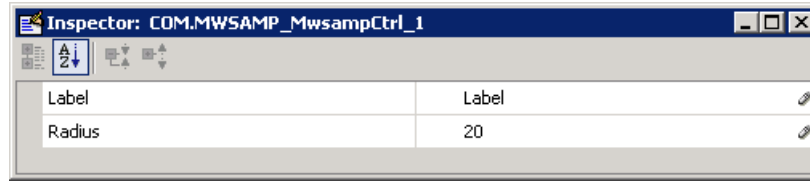


2 Activate the GUI by clicking the button on the toolbar and save the GUI when prompted. GUIDE displays the GUI shown in the following figure and opens the GUI M-file.



3 View the ActiveX Properties with the Property Inspector. Select the control in the Layout Editor, and then select **Property Inspector** from the **View** menu or by clicking the **Property Inspector** button on the toolbar.

The following figure shows properties of the `mwsamp` ActiveX control as they appear in the Property Inspector. The properties on your system may differ.



This ActiveX control `mwsamp` has two properties:

- `Label`, which contains the text that appears at the top of the control
- `Radius`, the default radius of the circle, which is 20

4 Add the following code to the `mswamp` control's `Click` callback. This code programs the ActiveX control to change the circle radius when the user clicks the circle, and updates the label to display the new radius.

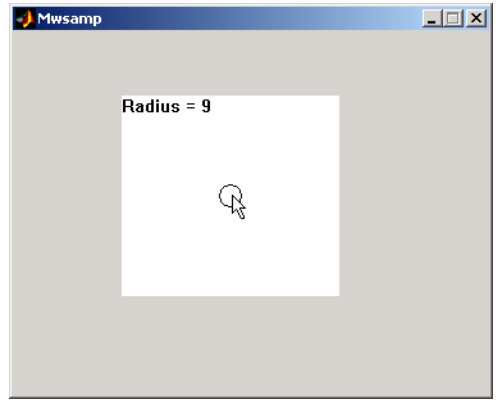
```
hObject.radius = .9*hObject.radius;
hObject.label = ['Radius = ' num2str(hObject.radius)];
refresh(handles.figure1);
```

To locate the `Click` callback in the GUI M-file, select **View Callbacks** from the **View** menu and then select **Click**.

5 Add the following commands to the opening function. This code initializes the label when you first open the GUI.

```
handles.activex1.label = ...
['Radius = ' num2str(handles.activex1.radius)];
```

Save the M-file. Now, when you open the GUI and click the ActiveX control, the radius of the circle is reduced by 10 percent and the new value of the radius is displayed. The following figure shows the GUI after clicking the circle six times.



If you click the GUI enough times, the circle disappears.

Programming a User Interface Control to Update an ActiveX Control

This topic continues the previous example by adding a slider to the GUI and programming the slider to change the circle radius. This example must also update the slider if the user clicks the circle.

1 Add a slider to your layout and then add the following code to the `slider1 Callback` callback:

```
handles.activex1.radius = ...
    get(hObject,'Value')*handles.default_radius;
handles.activex1.label = ...
    ['Radius = ' num2str(handles.activex1.radius)];
refresh(handles.figure1);
```

The first command

- Gets the `Value` of the slider, which in this example is a number between 0 and 1, the default values of the slider's `Min` and `Max` properties.

- Sets `handles.activex1.radius` equal to the `Value` times the default radius.

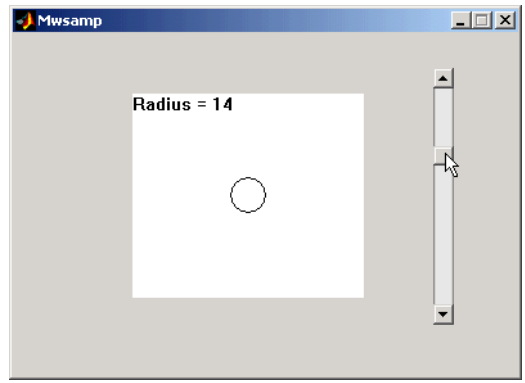
2. In the opening function, add the default radius to the `handles` structure. The `activex1_Click` callback uses the default radius to update the slider value if the user clicks the circle.

```
handles.default_radius = handles.activex1.radius;
```

3. In the `activex1_Click` callback, reset the slider's `Value` each time the user clicks the circle in the ActiveX control. The following command causes the slider to change position corresponding to the new value of the radius.

```
set(handles.slider1,'Value',...
    hObject.radius/handles.default_radius);
```

When you open the GUI and move the slider by clicking and dragging, the radius changes to a new value between 0 and the default radius of 20, as shown in the following figure.



Viewing the Methods for an ActiveX Control

To view the available methods for an ActiveX control, you first need to obtain the handle to the control. One way to do this is the following:

1. In the GUI M-file, add the command `keyboard` on a separate line of the `activex1_Click` callback. The command `keyboard` puts MATLAB in

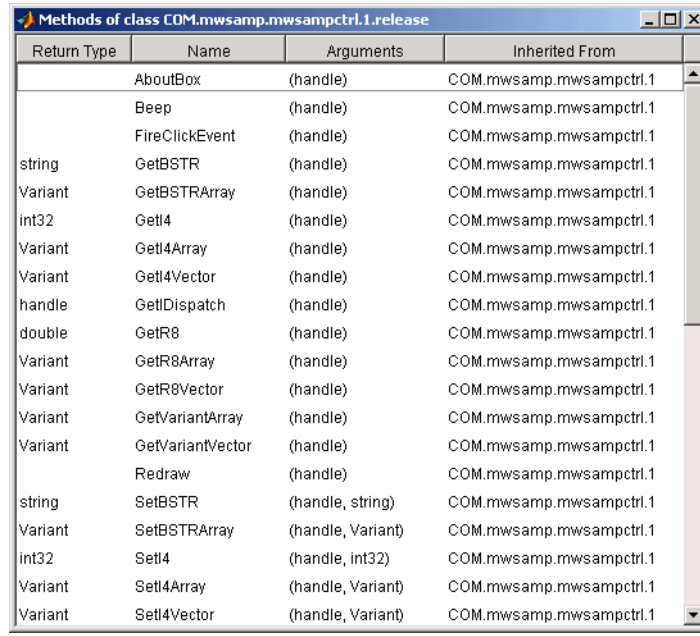
debug mode and pauses at the `activex1_Click` callback when you click the ActiveX control.

2 Run the GUI and click the ActiveX control. The handle to the control is now set to `hObject`.

3 To view the methods for the control, enter

```
methodsview(hObject)
```

This displays the available methods in a new window, as shown in the following figure.



Alternatively, you can enter

```
methods(hObject)
```

which displays the available methods in the MATLAB Command Window.

For more information about methods for ActiveX controls, see "Invoking Methods" in the External Interfaces documentation. See the reference pages for `methodsview` and `methods` for more information about these functions.

Saving a GUI That Contains an ActiveX Control

When you save a GUI that contains ActiveX controls, GUIDE creates a file in the current directory for each such control. The filename consists of the name of the GUI followed by an underscore (_) and `activex`*`n`*, where `n` is a sequence number. For example, if the GUI is named `mygui`, then the filename would be `mygui_activex1`. The filename does not have an extension.

Compiling a GUI That Contains an ActiveX Control

If you use the MATLAB Compiler `mcc` command to compile a GUI that contains an ActiveX control, you must use the `-a` flag to add the ActiveX file, which GUIDE saves in the current directory, to the CTF archive. Your command should be similar to

```
mcc -m mygui -a mygui_activex1
```

where `mygui_activex1` is the name of the ActiveX file. See the "MATLAB Compiler" documentation for more information. If you have more than one such file, use a separate `-a` flag for each file. You must have installed the MATLAB Compiler to compile a GUI.

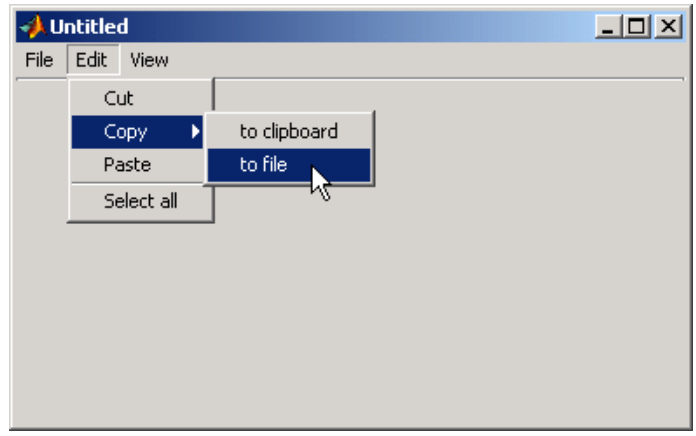
Menu Item

The Menu Editor generates an empty callback subfunction for every menu item, including menu titles.

Programming a Menu Title

Because clicking a menu title automatically displays the menu below it, you may not need to program callbacks at the title level. However, the callback associated with a menu title can be a good place to enable or disable menu items below it.

Consider the example illustrated in the following picture.



When a user selects the **to file** option under the **Edit** menu's **Copy** option, only the **to file** callback is required to perform the action.

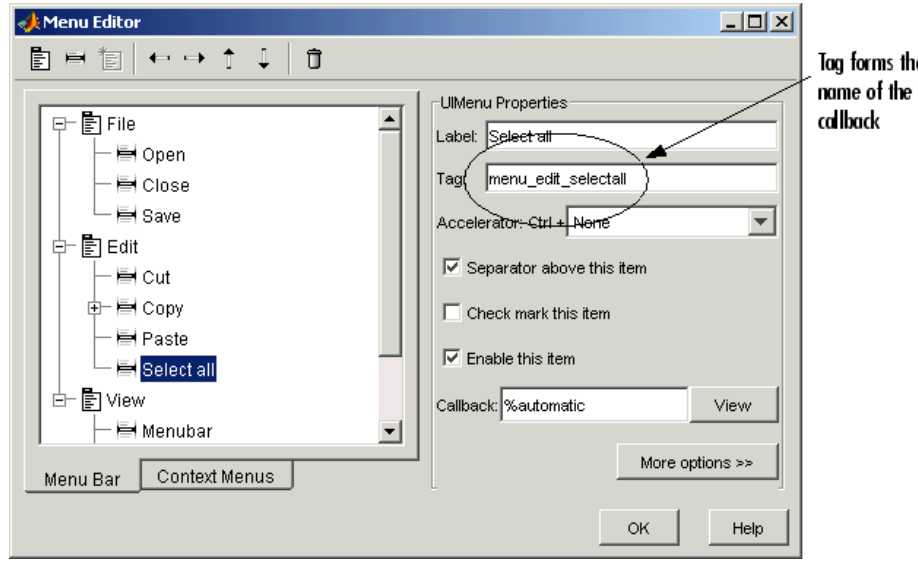
Suppose, however, that only certain objects can be copied to a file. You can use the **Copy** item `Callback` callback to enable or disable the **to file** item, depending on the type of object selected.

Opening a Dialog Box from a Menu Callback

The `Callback` callback for the **to file** menu item could contain code such as the following to display the standard dialog box for saving files.

```
[file,path] = uiputfile('animinit.m','Save file name');
```

`'Save file name'` is the dialog box title. In the dialog box, the filename field is set to `animinit.m`, and the filter set to M-files (`*.m`). For more information, see the `uiputfile` reference page.



Updating a Menu Item Check

A check is useful to indicate the current state of some menu items. If you selected **Check mark this item** in the Menu Editor, the item initially appears checked. Each time the user selects the menu item, the callback for that item must turn the check on or off. The following example shows you how to do this by changing the value of the menu item's `Checked` property.

```
if strcmp(get(hObject, 'Checked'),'on')
    set(hbject,'Checked','off');
else
    set(hObject,'Checked','on');
end
```

`hObject` is the handle of the component, for which the callback was triggered. The `strcmp` function compares two strings and returns logical `1` (true) if the two are identical and logical `0` (false) otherwise.

Use of checks when the GUI is first displayed should be consistent with the display. For example, if your GUI has an axes that is visible when a user first opens it and the GUI has a **Show axes** menu item, be sure to set the menu item's `Checked` property `on` when you create it so that a check appears next to the **Show axes** menu item initially.

Note From the Menu Editor, you can view a menu item's `Callback` callback in your editor by selecting the menu item and clicking the **View** button.

Managing and Sharing Application Data in GUIDE

Mechanisms for Managing Data (p. 9-2)	Describes various mechanisms for managing application-defined data. Explains how GUIDE uses several of these mechanisms.
Sharing Data Among a GUI's Callbacks (p. 9-8)	Shows how each mechanism for managing data can be used to share data among a GUI's callbacks.
Making Multiple GUIs Work Together (p. 9-15)	Ways and means to communicate application-defined data between multiple GUIs

Mechanisms for Managing Data

In this section...

Overview

Most GUIs generate or use data that is specific to the application. This topic describes the three mechanisms for managing application-defined data in the GUI environment. These mechanisms provide a way for applications to save and retrieve data stored with the GUI.

The GUI data and application data mechanisms are similar but GUI data can be simpler to use. GUIDE specifically uses GUI data to manage the `handles` structure, but you can use either the GUI data `handles` structure or application data to manage application-defined data. The `UserData` property can also hold application-defined data.

GUI Data

GUI data is managed using the `guidata` function. This function can store a single variable as GUI data. It is also used to retrieve the value of that variable.

About GUI Data

GUI data is always associated with the GUI figure. It is available to all callbacks of all components of the GUI. If you specify a component handle

when you save or retrieve GUI data, MATLAB automatically associates the data with the component's parent figure.

GUI data can contain only one variable at any time. Writing GUI data overwrites the existing GUI data. For this reason, GUI data is usually defined to be a structure to which you can add fields as you need them.

GUI data provides application developers with a convenient interface to a figure's application data:

- You do not need to create and maintain a hard-coded name for the data throughout your source code.
- You can access the data from within a callback routine using the component's handle, without having to find the figure handle. For GUIDE users, the object handle is automatically passed to each callback as `hObject`.

GUI Data in GUIDE

GUIDE uses `guidata` to create and maintain the `handles` structure. The `handles` structure contains the handles of all components in the GUI. GUIDE automatically passes the `handles` structure to every callback as an input argument.

In a GUI created using GUIDE, you cannot use `guidata` to manage any variable other than the `handles` structure. If you do, you may overwrite the `handles` structure and your GUI will not work. If you want to use GUI data to share application-defined data among callbacks, you must save the data in fields that you add to the `handles` structure.

The GUIDE templates use the `handles` structure to store application-defined data. See "Selecting a GUI Template" on page 6-7 for information about the templates.

Note For more information, see "handles Structure" on page 8-15.

Adding Fields to the handles Structure

To add a field to the `handles` structure, which is passed as an argument to every callback in GUIDE.

1. Assign a value to the new field. This adds the field to the structure. For example

   ```
   handles.number_errors = 0;
   ```

   adds the field `number_errors` to the structure `handles` and sets it to `0`.

2. Use the following command to save the data.

   ```
   guidata(hObject,handles)
   ```

   where `hObject` is the handle of the component for which the callback was triggered. It is passed automatically to every callback.

Changing GUI Data in an M-File Generated by GUIDE

In a GUIDE-generated M-file, GUI data is always represented by the `handles` structure. This example updates the `handles` structure and then saves it.

1. Assume that the `handles` structure contains an application-defined field `handles.when` whose value is `'now'`.

2. In a GUI callback, make the desired change to the `handles` structure. This step changes the value of `handles.when` to `'later'`, but does not save the `handles` structure.

   ```
   handles.when = 'later';
   ```

3. Save the changed version of the `handles` structure with the command

   ```
   guidata(hObject,handles)
   ```

   where `hObject`, which is passed automatically to every callback, is the handle of the component for which the callback was triggered. If you do not save the `handles` structure with `guidata`, the change you made to it in the previous step is lost.

Application Data

Application data provides a way for applications to save and retrieve data associated with a specified object. For a GUI, this is usually the GUI figure but can also be any component. The data is stored as name/value pairs. Application data enables you to create what are essentially user-defined properties for an object.

The following table summarizes the functions that provide access to application data. For more detailed information, see the individual function reference pages.

Functions for Managing Application Data

Function	Purpose
`setappdata`	Specify named application data for an object. The object does not have to be a figure. You can specify more than one named application data for an object. However, each name must be unique for that object and can be associated with only one value, usually a structure.
`getappdata`	Retrieve named application data. To retrieve named application data, you must know the name associated with the application data and the handle of the object with which it is associated.
`isappdata`	True if the named application data exists.
`rmappdata`	Remove the named application data.

Creating Application Data in GUIDE

Use the `setappdata` function to create application data. This example generates a 35-by-35 matrix of normally distributed random numbers in the opening function and creates application data `mydata` to manage it.

```
function mygui_OpeningFcn(hObject, eventdata, handles, varargin)
matrices.rand_35 = randn(35);
setappdata(hObject,'mydata',matrices);
```

Because this code appears in the opening function, `hObject` is the handle of the GUI figure, and the code associates `mydata` with the figure.

Adding Fields to an Application Data Structure in GUIDE

Application data is usually defined as a structure to enable you to add fields as necessary. In this example, a push button adds a field to the application data structure `mydata` created in the previous topic.

1. Use `getappdata` to retrieve the structure.

   From the example in the previous topic, the name of the application data structure is `mydata`. It is associated with the figure whose `Tag` is `figure1`. Since the `handles` structure is passed to every callback, the code can specify the figure's handle as `handles.figure1`.

   ```
   function mygui_pushbutton1(hObject, eventdata, handles)
   matrices = getappdata(handles.figure1,'mydata');
   ```

2. Create a new field and assign it a value. For example

   ```
   matrices.randn_50 = randn(50);
   ```

   adds the field `randn_50` to the `matrices` structure and sets it to a 50-by-50 matrix of normally distributed random numbers.

3. Use `setappdata` to save the data. This example uses `setappdata` to save the `matrices` structure as the application data structure `mydata`.

   ```
   setappdata(handles.figure1,'mydata',matrices);
   ```

UserData Property

All GUI components, including menus, and the figure have a `UserData` property. You can assign any valid MATLAB value to the `UserData` property. To retrieve the data, a callback must know the handle of the component with which the data is associated.

1. In this example, an edit text component stores the user-entered string in its `UserData` property.

   ```
   function mygui_edittext1(hObject, eventdata, handles)
   mystring = get(hObject,'String');
   set(hObject,'UserData',mystring);
   ```

2 A push button retrieves the string from the edit text component `UserData` property. The callback uses the `handles` structure and the edit text `Tag` property, `edittext1`, to specify the edit text handle.

```
function mygui_pushbutton1(hObject, eventdata, handles)
string = get(handles.edittext1,'UserData');
```

Sharing Data Among a GUI's Callbacks

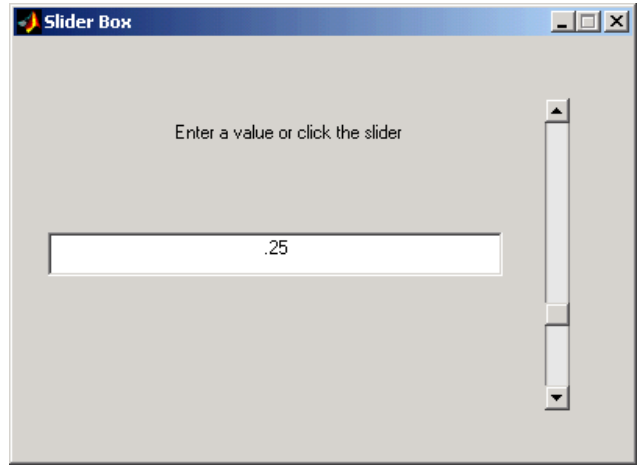
In this section...

GUI Data

GUI data, which you manage with the `guidata` function, is accessible to all callbacks of the GUI. A callback for one component can set a value in GUI data, which can then be read by a callback for another component. See "GUI Data" on page 9-2 for more information about GUI data.

GUI Data Example: Passing Data Between Components

This example uses a GUI that contains a slider and an edit text component as shown in the following figure. A static text component instructs the user to enter a value in the edit text or click the slider. The example uses GUI data to initialize and maintain an error counter.



The GUI behavior is as follows:

- When a user moves the slider, the edit text component displays the slider's current value.
- When a user types a value into the edit text component, the slider updates to this value.
- If a user enters a value in the edit text that is out of range for the slider — that is, a value that is not between 0 and 1 — the application returns a message in the edit text component indicating how many times the user has entered an erroneous value.

The commands given in the following steps initialize the error counter and implement the interchange between the slider and the edit text component.

1 Define the error counter in the opening function. The GUI records the number of times a user enters an erroneous value in the edit text component and stores this number in a field of the `handles` structure.

Start by defining this field, called `number_errors`, in the opening function as follows:

```
handles.number_errors = 0;
```

Type the preceding statement before the following line, which GUIDE automatically inserts into the opening function.

```
guidata(hObject,handles); % Save the updated handles structure.
```

The `guidata` command saves the modified `handles` structure so that it can be retrieved in the GUI's callbacks.

2 Set the value of the edit text component `String` property from the slider `Callback` callback. The following command in the slider `Callback` updates the value displayed in the edit text component when a user moves the slider and releases the mouse button.

```
set(handles.edittext1,'String',...
   num2str(get(handles.slider1,'Value')));
```

The code combines three commands:

- The `get` command obtains the current value of the slider.

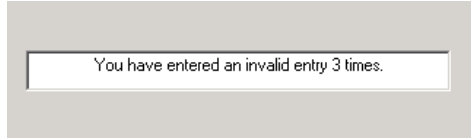
- The `num2str` command converts the value to a string.
- The `set` command sets the `String` property of the edit text to the updated value.

3. Set the slider value from the edit text component's `Callback` callback. The edit text `Callback` sets the slider's value to the number the user types in, after checking to see if it is a single numeric value between 0 and 1. If the value is out of range, then the error count is incremented and the edit text displays a message telling the user how many times they have entered an invalid number. Because this code appears in the edit text `Callback`, `hObject` is the handle of the edit text component.

```
val = str2double(get(hobject,'String'));
% Determine whether val is a number between 0 and 1.
if isnumeric(val) && length(val)==1 && ...
   val >= get(handles.slider1,'Min') && ...
   val <= get(handles.slider1,'Max')
   set(handles.slider1,'Value',val);
else
% Increment the error count, and display it.
   handles.number_errors = handles.number_errors+1;
   guidata(hObject,handles); % Store the changes.
   set(hobject,'String',...
   ['You have entered an invalid entry ',...
num2str(handles.number_errors),' times.']);
end
```

If the user types a number between 0 and 1 in the edit text component and then presses **Enter** or clicks outside the edit text, the `Callback` sets `handles.slider1` to the new value and the slider moves to the corresponding position.

If the entry is invalid — for example, `2.5` — the GUI increments the value of `handles.number_errors` and displays a message like the following in the edit text component:



Application Data

Application data can be associated with any object — a component, menu, or the figure itself. To access application data, a callback must know the name of the data and the handle of the component with which it is associated. Use the functions `setappdata`, `getappdata`, `isappdata`, and `rmappdata` to manage application data.

See "Application Data" on page 9-5 for more information about application data.

Application Data Example: Passing Data Between Components

The previous topic, "GUI Data Example: Passing Data Between Components" on page 9-8, uses GUI data to initialize and maintain an error counter. This example shows you how to do the same thing using application data. Refer to the previous topic for details of the example.

1. Define the error counter in the opening function. Add the following code to the opening function. This code first creates a structure `slider_data`, then assigns it to the named application data `slider`. Because this code appears in the opening function, using `hObject` associates the application data with the figure.

   ```
   slider_data.number_errors = 0;
   setappdata(hObject,'slider',slider_data);
   ```

2. Set the value of the edit text `String` property from the slider `Callback` callback. Before you can do this, you must convert the slider `Value` property to a string. Add this statement to the callback.

   ```
   set(handles.edittext1,'String',num2str(get(hObject,'Value')));
   ```

   Because this statement appears in the slider Callback, `hObject` is the handle of the slider.

3 Set the slider value from the edit text component's `Callback` callback. Add this code to the callback. It assumes the figure's `Tag` property is `figure1`.

To update the number of errors, the code must first retrieve the named application data `slider`, then increment the count. It then saves the application data and displays the new error count.

```
val = str2double(get(hObject,'String'));
% Determine whether val is a number between 0 and 1.
if isnumeric(val) && length(val)==1 && ...
   val >= get(handles.slider1,'Min') && ...
   val <= get(handles.slider1,'Max')
   set(handles.slider1,'Value',val);
else
% Retrieve and increment the error count.
   slider_data = getappdata(handles.figure1,'slider');
   slider_data.number_errors = slider_data.number_errors+1;
% Save the changes.
   setappdata(handles.figure1,'slider',slider_data);
% Display new total.
   set(hObject,'String',...
   ['You have entered an invalid entry ',...
num2str(slider_data.number_errors),' times.']);
end
```

UserData Property

Every GUI component, and the figure itself, has a `UserData` property that you can use to store application-defined data. To access `UserData`, a callback must know the handle of the component with which the property is associated.

Use the `get` function to retrieve `UserData`, and the `set` function to set it.

UserData Property Example: Passing Data Between Components

A previous topic, "GUI Data Example: Passing Data Between Components" on page 9-8, uses GUI data to initialize and maintain an error counter. This example shows you how to do the same thing using the edit text component's `UserData` property to store the error count. Refer to the GUI data example for example details.

1 Initialize the edit text component `UserData` property in the opening function by adding the following code to the opening function. This code initializes the data in a structure to allow for other data that may be needed.

```
data.number_errors = 0;
set(handles.edittext1,'UserData',data.number_errors)
```

Note Alternatively, you could add a `CreateFcn` callback for the edit text, and initialize the error counter there.

---

2 Set the edit text value from the slider `Callback` callback. Add this statement to the callback.

```
set(handles.edittext1,'String',...
   num2str(get(hObject,'Value')));
```

where `hObject` is the handle of the slider.

3 Set the slider value from the edit text `Callback` callback. To do this, add the following code to the callback.

To update the number or errors, the code must first retrieve the value of the edit text `UserData` property, then increment the count. It then saves the updated error count in the `UserData` property and displays the new count.

```
val = str2double(get(hObject,'String'));
% Determine whether val is a number between 0 and 1.
if isnumeric(val) && length(val)==1 && ...
   val >= get(handles.slider1,'Min') && ...
   val <= get(handles.slider1,'Max')
   set(handles.slider1,'Value',val);
else
% Retrieve and increment the error count.
   data = get(hObject,'UserData');
   data.number_errors = data.number_errors+1;
% Save the changes.
   set(hObject,'UserData',data);
% Display new total.
   set(hObject,'String',...
```

```
   ['You have entered an invalid entry ',...
num2str(number_errors),' times.']);
end
```

Because this code appears in the edit text `Callback`, `hObject` is the handle of the edit text component.

Making Multiple GUIs Work Together

In this section...

Overview of Data Sharing Techniques

Although most GUIs created in GUIDE use single figures, you can make several GUIDE-generated GUIs work together if your application requires more than a single figure. For example, your GUI may need to use several dialogs to display and obtain some of the parameters used by the GUI, or your GUI may include several individual tools that work together, either at the same time or in succession. This section describes the different techniques you can use to share data among multiple GUIDE GUIs to make them operate together. It also provides examples that show you how to use these techniques to make a set of GUIs cooperate with one another.

GUIs can share data in many ways. In a given application, more than one technique can be—and often is—used. Without resorting to communicating via files or workspace variables, you can use any of the approaches described in this table.

Data Sharing Method	How it Works	Use for
Property/Value pairs	Send data into a newly invoked or existing GUI by passing it along as input arguments.	Communicating data to new GUIs

Data Sharing Method	How it Works	Use for
Output	Return data from the invoked GUI.	Communicating data back to the invoking GUI, such as passing back the handles structure of the invoked GUI
Function Handles	Pass function handles as data through one of the three following methods.	Exposing functionality of the GUI within a GUI or between GUIs
userdata	Store data in a figure or component; communicate to other GUIs via handle references.	Communicating data within a GUI or between GUIs
getappdata/setappdata	Store data as a property in a figure or component; communicate to other GUIs via handle references	Communicating data within a GUI or across GUIs
guidata	Store data in the handles structure of a GUI; communicate to other GUIs via handle references.	Communicating data within a GUI or across GUIs; a convenient way to manage application data

The techniques described in “Sharing Data Among a GUI’s Callbacks” on page 9-8 that enable you to share data within a GUI—userdata, application data, and guidata—can also share data between several GUIs as long as the handles to objects in the first GUI are made available to other GUIs. The rest of this section provides two examples that illustrate these techniques. The first example describes how a simple GUI can open and receive data from a modal dialog. The second, more extensive, example illustrates how the three components of an icon editor are made to interact.

Note The examples that follow omit portions of code in order to more clearly convey data sharing techniques. The omissions are noted by ellipses like these:

.
.
.

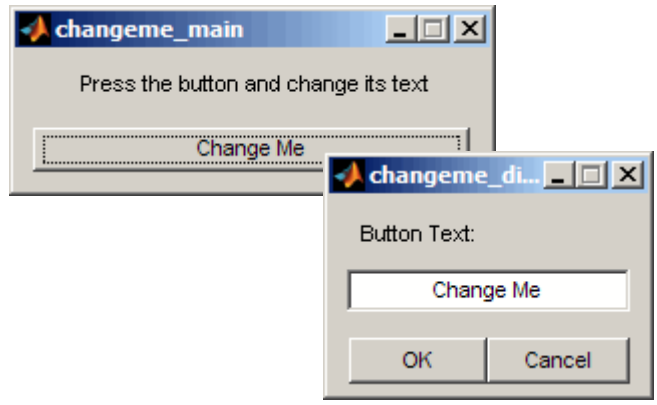
Complete M-files and FIG-files that you can run, view, and modify are provided for the examples.

Example — A GUIDE GUI with a Modal Dialog for User Input

This simple example demonstrates how data is passed to a modal dialog invoked from a GUIDE GUI. The dialog displays text data in an edit field in the dialog. Any changes to it that the user makes are passed back to the main GUI. That data can be used by the main GUI in various ways. In this example, the data updates the appearance of one of the components of the main GUI. The example illustrates how to do many common tasks involved in making multiple GUIs work together, for example, how to position a second GUI relative to the main GUI.

The main GUI contains one pushbutton and a static text field giving instructions. Clicking the button opens a modal dialog box. In it, the button's current string displays in an editable text field, and the user can change it. If the user clicks OK, the value of the text field is returned to the main GUI,

which sets the string property of its button to be that value. The main GUI and its modal dialog box are shown in the following figure.



Note The following links execute MATLAB commands and work only within the MATLAB Help browser. If you are reading this on the Web or in the PDF, go to the corresponding section in the MATLAB Help Browser to use the links.

- Click here to display the `changeme` GUIs in the Layout Editor.
- Click here to display the `changeme` GUI M-files in the editor.

Opening the Text Change Dialog

Clicking the **Change Me** button causes the Text Change dialog to be invoked. When invoking the dialog, arguments include a property/value pair with name `'changeme_main'` (the main GUI's name) and value set to the handle to the main figure. This data enables the dialog to access the main GUI's data; if it is missing, the dialog displays an error that describes proper usage and exits.

```
function buttonChangeMe_Callback(hObject, ...
         eventdata, handles)
changeme_dialog('changeme_main', handles.figure);
```

Managing the Text Change Dialog

The Text Change dialog should be modal. In the Property Inspector for the Text Change dialog's figure, set the `'WindowStyle'` property to `'Modal'`. This ensures that the user can interact with no other figures while it is active.

To ensure proper behavior, use `uiwait` in the `OpeningFcn` of the dialog. Invoking `uiwait` puts off calling the output function until `uiresume` is called. This also keeps the invocation call of the GUI from returning until that time:

```
function changeme_dialog_OpeningFcn(hObject, ...
         eventdata, handles, varargin)
.
.
.
uiwait(hObject);
.
.
.
```

Every callback in which the GUI needs to close should call `uiresume`. In this example, it can happen in the `CloseRequestFcn` for the figure, the **Cancel** button, and the **OK** button:

```
function buttonCancel_Callback(hObject, ...
         eventdata, handles)
uiresume(handles.figure);

function figure_CloseRequestFcn(hObject, ...
         eventdata, handles)
uiresume(hObject);

function buttonOK_Callback(hObject, e...
         ventdata, handles)
.
.
.
uiresume(handles.figure);
```

In the `OutputFcn`, make sure to delete the figure, so that it closes:

```
function varargout = changeme_dialog_Dialog_OutputFcn(hObject, ...
```

```
         eventdata, handles)
varargout{1} = [];
delete(hObject);
```

Protecting the Text Change Dialog

If the Text Change dialog is not invoked from the main GUI, it displays an error and exits. The `OpeningFcn` for the dialog scans the input arguments for the `changeme_main` property. If it isn't found or has a value that is not valid, the modal dialog displays a message and then destroys itself. To be able to exit immediately, do not call `uiwait` until after validating the input. If `uiwait` is not called, the dialog immediately calls its `OutputFcn` and returns. As described earlier, the `OutputFcn` closes the figure.

```
function changeme_dialog_OpeningFcn(hObject, ...
         eventdata, handles, varargin)

% Check to see the changeme_main gui is passed in
dontOpen = false;
mainGuiInput = find(strcmp(varargin, 'changeme_main'));
if (isempty(mainGuiInput))
  || (length(varargin) <= mainGuiInput)
  || (~ishandle(varargin{mainGuiInput+1}))
    dontOpen = true;
else
.
.
.
end
.
.
.
if dontOpen
   disp('------------------------------------------------------');
   disp('Improper input arguments. Pass a property value pair')
   disp('whose name is "changeme_main" and value is the handle')
   disp('to the changeme_main figure.');
   disp('eg:');
   disp('   x = changeme_main()');
   disp('   changeme_dialog('changeme_main', x)');
```

```
   disp('--------------------------------------------------');
else
   uiwait(hObject);
end
```

Positioning the Text Change Dialog

The Text Change dialog (`changeme_dialog`) should position itself close to the invoking figure. To avoid distracting the user, the dialog box appears next to the main GUI. If the main figure is moved somewhere and the dialog is invoked, it opens in a different location from where it would have otherwise. Using the passed-in handle to the main figure, get the main figure's position and do some calculations to offset the dialog box to the right and down:

```
function changeme_dialog_OpeningFcn(hObject, ...
         eventdata, handles, varargin)
.
.
.
mainGuiInput = find(strcmp(varargin, 'changeme_main'));
.
.
.
handles.changeMeMain = varargin{mainGuiInput+1};
.
.
.
    % Position to be relative to parent:
    parentPosition = getpixelposition(handles.changeMeMain);
    currentPosition = get(hObject, 'Position');
    % Sets the position to be directly centered on the main figure
    newX = parentPosition(1) + (parentPosition(3)/2 ...
         - currentPosition(3)/2);
    newY = parentPosition(2) + (parentPosition(4)/2 ...
         - currentPosition(4)/2);
    newW = currentPosition(3);
    newH = currentPosition(4);

    set(hObject, 'Position', [newX, newY, newW, newH]);
.
```

```
.
.
```

Initializing the Text Change Dialog's Text

Initialize the Text Change dialog's text to the **Change Me** button's current text. From the main GUI's handle that was passed to the modal dialog, get the main GUI's handles structure. From that, get the **Change Me** button and get its `String` property. Then set the `String` property to the edit box's value in the dialog's `OpeningFcn`:

```
function changeme_dialog_OpeningFcn(hObject, ...
         eventdata, handles, varargin)

mainGuiInput = find(strcmp(varargin, 'changeme_main'));
.
.
.
% Remember the handle, and adjust our position
handles.changeMeMain = varargin{mainGuiInput+1};

% Set the initial text
mainHandles = guidata(handles.changeMeMain);
set(handles.editChangeMe, 'String',
    get(mainHandles.buttonChangeMe, 'String'));
.
.
.
```

Canceling the Text Change Dialog

If **Cancel** is clicked or the window is closed, do not modify the main GUI. There is really nothing to do, other than to call `uiresume` to close the modal dialog:

```
function buttonCancel_Callback(hObject, ...
         eventdata, handles)
uiresume(handles.figure);

function figure_CloseRequestFcn(hObject, ...
         eventdata, handles)
```

```
uiresume(hObject);
```

Applying the Text Change

If **OK** is clicked, set the main GUI's **Change Me** button label to the value of the textbox. This is where the main GUI gets modified. The modal dialog's `OpeningFcn` saved the reference to the main GUI in the handles structure. Now use that reference to get the main GUI's handles, and from that get the button's handle and modify its text:

```
function buttonOK_Callback(hObject, ...
         eventdata, handles)
text = get(handles.editChangeMe, 'String');
main = handles.changeMeMain;
mainHandles = guidata(main);
changeMeButton = mainHandles.buttonChangeMe;
set(changeMeButton, 'String', text);
uiresume(handles.figure);
```

Example — Individual GUIDE GUIs that Work Together as an Application

The following example demonstrates creating an icon editor application in GUIDE. The editor consists of three GUIs:

- The drawing area (Icon Editor)
- The tool selection toolbar (Tool Palette)
- The color picker (Color Palette)

These GUIs share data and expose functionality to one another using several different techniques.

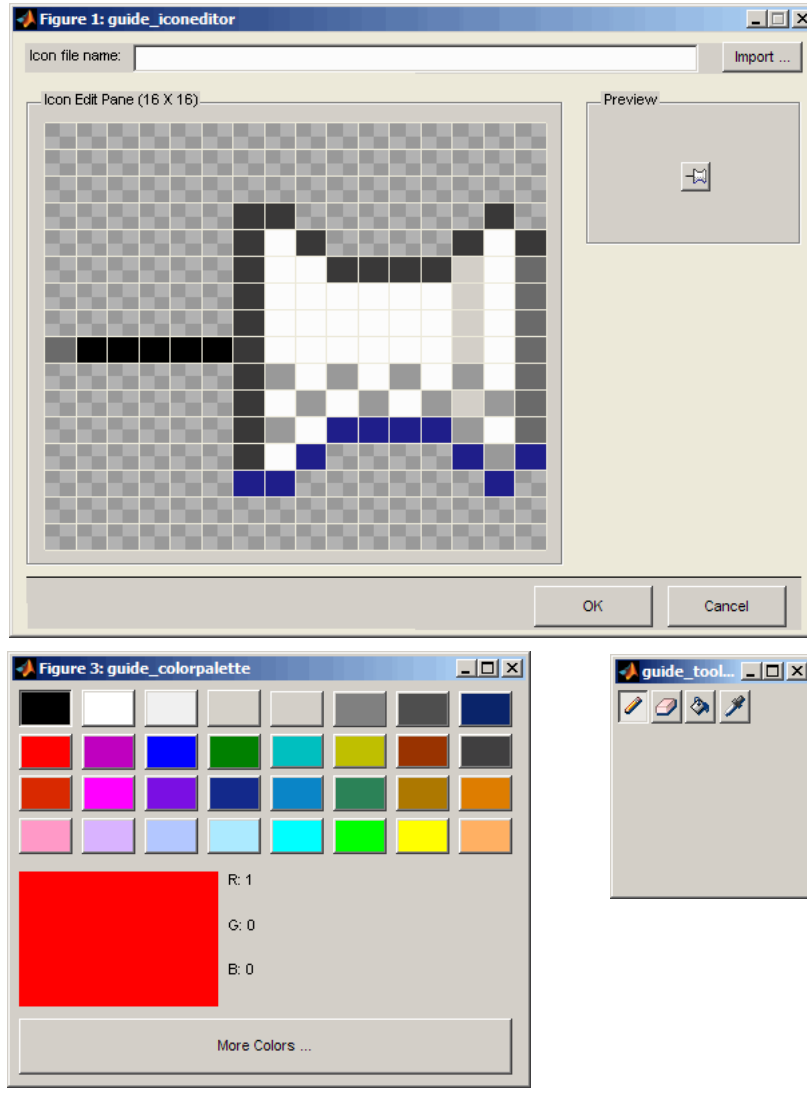


Figure 1: guide_iconeditor
Icon file name:
Import ...
Icon Edit Pane (16 X 16)
Preview
OK
Cancel
Figure 3: guide_colorpalette
R: 1
G: 0
B: 0
More Colors ...
guide_tool...

Note The following links execute MATLAB commands and are designed to work within the MATLAB Help browser. If you are reading this on the Web or in the PDF, go to the corresponding section in the MATLAB Help Browser to use the links.

- Click here to display the icon editor GUIs in the Layout Editor.
- Click here to display the icon editor GUI M-files in the MATLAB editor.

Requirements for the GUIs

The Icon Editor application needs to behave as follows:

- When starting Icon Editor, create the Tool Palette and Color Palette.
- Set the initial color on the Color Palette when Icon Editor starts.
- Give the Icon Editor access to the Color Palette's current color.
- When clicking in the editing area, apply the currently selected tool from the Tool Palette.
- When the mouse pointer is over the edit area, display the current tool's cursor
- Close all windows only when the Icon Editor completes.

Click any item above to jump to that section.

M-file Implementations

This application uses three M-files and FIG-files that were fully implemented in GUIDE. You can modify and enhance them in the GUIDE environment should you choose to do so. The FIG-files are:

- `guide_iconeditor.fig` — Main GUI, for drawing and modifying icon files
- `guide_colorpalette.fig` — Palette for selecting a current color
- `guide_toolpalette.fig` — Palette for selecting one of four editing tools

The associated M-files contain the following functions and signatures:

- guide_iconeditor.m

```
guide_iconeditor(varargin)
guide_iconeditor_OpeningFcn(hObject, eventdata, handles, varargin)
guide_iconeditor_OutputFcn(hObject, eventdata, handles)
editFilename_CreateFcn(hObject, eventdata, handles)
buttonImport_Callback(hObject, eventdata, handles)
buttonOK_Callback(hObject, eventdata, handles
buttonCancel_Callback(hObject, eventdata, handles)
editFilename_ButtonDownFcn(hObject, eventdata, handles)
editFilename_Callback(hObject, eventdata, handles)
figure_CloseRequestFcn(hObject, eventdata, handles)
figure_WindowButtonDownFcn(hObject, eventdata, handles)
figure_WindowButtonUpFcn(hObject, eventdata, handles)
figure_WindowButtonMotionFcn(hObject, eventdata, handles)
getToolPalette(handles)
getColorPalette(handles)
setColor(hObject, color)
getColor(hObject)
updateCursor(hObject, overicon)
applyCurrentTool(handles)
localUpdateIconPlot(handles)
localGetIconCDataWithNaNs(handles)
```

- guide_colorpalette.m

```
guide_colorpalette(varargin)
guide_colorpalette_OpeningFcn(hObject, eventdata, handles, varargin)
guide_colorpalette_OutputFcn(hObject, eventdata, handles)
buttonMoreColors_Callback(hObject, eventdata, handles)
colorCellCallback(hObject, eventdata, handles)
figure_CloseRequestFcn(hObject, eventdata, handles)
localUpdateColor(handles)
setSelectedColor(hObject, color)
```

- guide_toolPalatte.m

```
guide_toolpalette(varargin)
guide_toolpalette_OpeningFcn(hObject, eventdata, handles, varargin)
guide_toolpalette_OutputFcn(hObject, eventdata, handles)
toolPencil_CreateFcn(hObject, eventdata, handles)
```

```
toolEraser_CreateFcn(hObject, eventdata, handles)
toolBucket_CreateFcn(hObject, eventdata, handles)
toolPicker_CreateFcn(hObject, eventdata, handles)
toolPalette_SelectionChangeFcn(hObject, eventdata, handles)
figure_CloseRequestFcn(hObject, eventdata, handles)
getIconEditor(handles)
pencilToolCallback(handles, toolstruct, cdata, point)
eraserToolCallback(handles, toolstruct, cdata, point)
bucketToolCallback(handles, toolstruct, cdata, point)
fillWithColor(cdata, rows, cols, color, row, col, seedcolor)
colorpickerToolCallback(handles, toolstruct, cdata, point)
```

1. When Icon Editor launches, create the Tool Palette and Color Palette

Starting the Icon Editor GUI should launch the Tool Palette and Color Palette. These GUIs are its children. The parent and children communicate using the following techniques:

- Property/Value pairs — Send data into a newly-invoked or existing GUI by passing it as input arguments.
- Guidata — Store data in the handles structure of a GUI; this can communicate data within one GUI or across several of them.
- Output — Returned data from the invoked GUI; this is used to communicate data, such as the handles structure of the invoked GUI, back to the invoking GUI.

The Icon Editor is passed into the Tool Palette and Color Palette as a Property/Value (p/v) pair in order to let the Tool Palette make calls back into Icon Editor. The output value from calling both of the palettes is the handle to their GUI figures. These figure handles are saved into the handles structure of Icon Editor:

```
% in Icon Editor
function guide_Icon Editor_OpeningFcn(hObject, ...
         eventdata, handles, varargin)
.
```

```
.
.
handles.colorPalette = guide_colorpalette('iconEditor', hObject);
handles.toolPalette = guide_toolpalette('iconEditor', hObject);
.
.
.
% Update handles structure
guidata(hObject, handles);
```

The Color Palette needs to remember the Icon Editor for later:

```
% in colorPalette
function guide_colorpalette_OpeningFcn(hObject, ...
         eventdata, handles, varargin)
handles.output = hObject;
.
.
.
handles.iconEditor = [];

iconEditorInput = find(strcmp(varargin, 'iconEditor'));
if ~isempty(iconEditorInput)
   handles.iconEditor = varargin{iconEditorInput+1};
end
.
.
.
% Update handles structure
guidata(hObject, handles);
```

The Tool Palette also needs to remember the Icon Editor:

```
% in toolPalette
function guide_toolpalette_OpeningFcn(hObject, ...
         eventdata, handles, varargin)
handles.output = hObject;
.
.
.
handles.iconEditor = [];
```

```
iconEditorInput = find(strcmp(varargin, 'iconEditor'));
if ~isempty(iconEditorInput)
   handles.iconEditor = varargin{iconEditorInput+1};
end
.
.
.
% Update handles structure
guidata(hObject, handles);
```

2. Set the initial color on the Color Palette when the Icon Editor starts

After all three GUIs have been created, set the initial color. When the Color Palette is invoked from the Icon Editor, the Color Palette needs to tell the Icon Editor how to set the initial color and provides the functionality via a function handle, which it stores in its handles structure. Color Palette outputs the handle to its figure, from which its handles structure can be retrieved:

```
% in colorPalette
function guide_colorpalette_OpeningFcn(hObject, ...
         eventdata, handles, varargin)
handles.output = hObject;
.
.
.
% Set the initial palette color to black
handles.mSelectedColor = [0 0 0];

% Publish the function setSelectedColor
handles.setColor = @setSelectedColor;
.
.
.
% Update handles structure
guidata(hObject, handles);

% in colorPalette
```

```
function setSelectedColor(hObject, color)
handles = guidata(hObject);
.
.
.
handles.mSelectedColor =color;
.
.
.
guidata(hObject, handles);
```

Call the publicized function from the Icon Editor, setting the initial color to `'red'`:

```
% in Icon Editor
function guide_iconeditor_OpeningFcn(hObject, ...
         eventdata, handles, varargin)
.
.
.
handles.colorPalette = guide_colorpalette('iconEditor', hObject);
.
.
.
colorPalette = handles.colorPalette;
colorPaletteHandles = guidata(colorPalette);
colorPaletteHandles.setColor(colorPalette, [1 0 0]);
.
.
.
% Update handles structure
guidata(hObject, handles);
```

3. Give the Icon Editor access to the Color Palette's current color

The Color Palette initializes the current color data:

```
%in colorPalette
function guide_colorpalette_OpeningFcn(hObject, ...
         eventdata, handles, varargin)
handles.output = hObject;
```

```
.
.
.
handles.mSelectedColor = [0 0 0];
.
.
.
% Update handles structure
guidata(hObject, handles);
```

The Icon Editor retrieves the inital color from the Color Palette's guidata via its handles structure:

```
% in Icon Editor
function color = getColor(hObject)
handles = guidata(hObject);
colorPalette = handles.colorPalette;
colorPaletteHandles = guidata(colorPalette);
color = colorPaletteHandles.mSelectedColor;
```

4. When clicking in the editing area, apply the currently selected tool from the Tool Palette

This example demonstrates how the `UserData` property of components in your GUIDE GUI can be used to share data. Every tool in the Tool Palette can modify the icon being edited, altering `CData` whatever tool is selected when the mouse is clicked in the icon editing area. The `UserData` property of each tool is used to record the function called when a tool is selected and applied to the icon editing area. Different tools do different things to the icon data. The following code shows how the *pencil tool* works.

In the `CreateFcn` for the pencil button, add the user data that points to the function for the pencil tool:

```
% in toolPalette
function toolPencil_CreateFcn(hObject, eventdata, handles)
set(hObject,'UserData', struct('Callback', @pencilToolCallback));
```

The currently selected tool is tracked by the Tool Palette in a field in its handles structure called `mCurrentTool`, which you can get from other GUIs

once you have the handles structure of the Tool Palette. The currently selected tool is set by calling `guidata` after you click a button in the Tool Palette:

```
% in toolPalette
function toolPalette_SelectionChangeFcn(hObject, ...
        eventdata, handles)
handles.mCurrentTool = hObject;
guidata(hObject, handles);
```

When you select the pencil tool and click in the icon editing area, the function of the pencil tool is eventually called by the Icon Editor:

```
% in iconEditor
function iconEditor_WindowButtonDownFcn(hObject,...
         eventdata, handles)
toolPalette = handles.toolPalette;
toolPaletteHandles = guidata(toolPalette);
 .
 .
 .
userData = get(toolPaletteHandles.mCurrentTool, 'UserData');
handles.mIconCData = userData.Callback(toolPaletteHandles, ...
        toolPaletteHandles.mCurrentTool, handles.mIconCData, ...);
```

If you are curious about what the pencil tool does, here is the code that shows how the pixel value in the icon editing area under the mouse click (the Tool icon's `CData`) is changed to the color currently selected in the Color Palette:

```
% in toolPalette
function cdata = pencilToolCallback(handles, toolstruct, cdata,...)
iconEditor = handles.iconEditor;
iconEditorHandles = guidata(iconEditor);
x = ...
y = ...
% update color of the selected block
color = iconEditorHandles.getColor(iconEditor);
cdata(y, x,:) = color;
```

5. When mouse pointer is in the edit area, display the current tool's cursor

Icon Editor must set the cursor with every mouse motion. If the mouse is not in the editing area, the pointer is the default arrow. Otherwise, it displays the currently selected tool's pointer icon. Identify the selected tool through the Tool Palette's handles:

```
% in Icon Editor
function iconEditor_WindowButtonMotionFcn(hObject, ...
        eventdata, handles)
.
.
.
rows = size(handles.mIconCData,1);
cols = size(handles.mIconCData,2);
pt = get(handles.icon,'currentpoint');
overicon = (pt(1,1)>=0 && pt(1,1)<=rows) && ...
           (pt(1,2)>=0 && pt(1,2)<=cols);
.
.
.
if ~overicon
    set(hObject,'pointer','arrow');
else
    toolPalette = handles.toolPalette;
    toolPaletteHandles = guidata(toolPalette);
    tool = toolPaletteHandles.mCurrentTool;
    cdata = round(mean(get(tool, 'cdata'),3))+1;
    if ~isempty(cdata)
        set(hObject,'pointer','custom','PointerShapeCData', ...
        cdata(1:16, 1:16),'PointerShapeHotSpot',[16 1]);
    end
end
.
.
.
```

6. Close all windows only when the Icon Editor completes

When launching Icon Editor, Color Palette and Tool Palette were also invoked and remembered within the handles structure of Icon Editor. However, Icon Editor also invokes uiwait to defer output until the GUI is finished, which complicates the shutdown sequence. Furthermore, neither the Color Palette nor Tool Palette is permitted to close independently of Icon Editor shutdown. The only ways out are the **OK** button, the **Cancel** button, or closing the Icon Editor's window directly. Closing the Color Palette and Tool Palette windows (by clicking their `X` box) has to be blocked.

Finally, upon closing, set the output of Icon Editor to be the `cdata` of the icon. The opening function for Icon Editor, with `uiwait`, contains this code:

```
% in Icon Editor
function guide_iconeditor_OpeningFcn(hObject, eventdata, ...
        handles, varargin)

.
.
.
handles.colorPalette = guide_colorpalette();
handles.toolPalette = guide_toolpalette('iconEditor', hObject);
.
.
.
% Update handles structure
guidata(hObject, handles);
uiwait(hObject);
```

Because Icon Editor calls `uiwait` to begin with, `uiresume` must be called on each exit path:

```
% in Icon Editor
function buttonOK_Callback(hObject, eventdata, handles)
uiresume(handles.figure);

function buttonCancel_Callback(hObject, eventdata, handles)
% Make sure the return data will be empty if we cancelled
handles.mIconCData =[];
guidata(handles.figure, handles);
```

```
uiresume(handles.figure);

function Icon Editor_CloseRequestFcn(hObject, eventdata, handles)
uiresume(hObject);
```

To ensure that the Color Palette is not closed any other way, override its `closerequestfcn` to do nothing:

```
% in colorPalette
function figure_CloseRequestFcn(hObject, eventdata, handles)
% Don't close this figure. It must be deleted from Icon Editor
```

Do the same for Tool Palette:

```
% in toolPalette
function figure_CloseRequestFcn(hObject, eventdata, handles)
% Don't close this figure. It must be deleted from Icon Editor
```

Finally, in the output function, destroy all three GUIs:

```
% in Icon Editor
function varargout = guide_iconeditor_OutputFcn(hObject, ...
        eventdata, handles)
% Return the cdata of the icon. If cancelled, this will be empty
varargout{1} = handles.mIconCData;
delete(handles.toolPalette);
delete(handles.colorPalette);
delete(hObject);
```

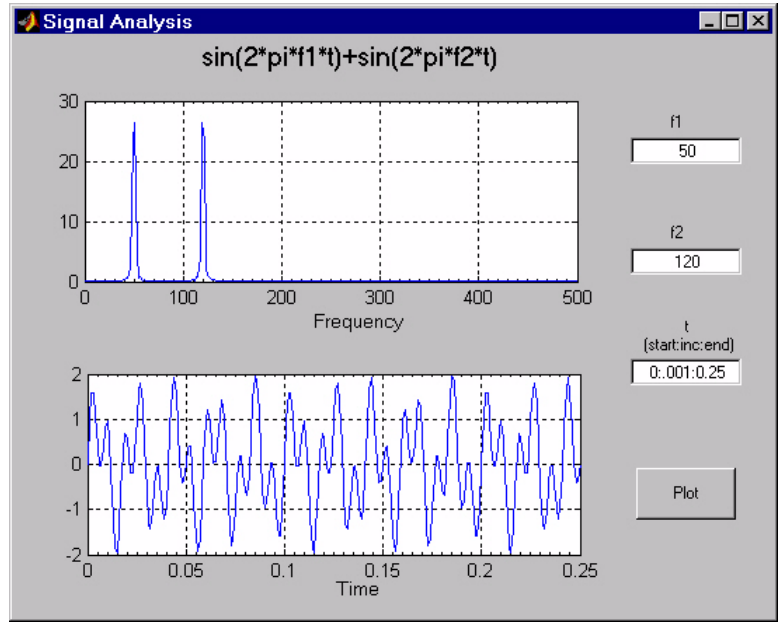
Examples of GUIDE GUIs

GUI with Multiple Axes

In this section...

Multiple Axes Example Outcome

This example creates a GUI that contains two axes for plotting data. For simplicity, this example obtains data by evaluating an expression using parameters entered by the user.



Techniques Used in the Example

GUI-building techniques illustrated in this example include

- Controlling which axes is the target for plotting commands.
- Using edit text controls to read numeric input and MATLAB expressions.

View Completed Layout and Its GUI M-File

If you are reading this in the MATLAB Help browser, you can click the following links to display the GUIDE Layout Editor and the MATLAB Editor with a completed version of this example. This enables you to see the values of all component properties and to understand how the components are assembled to create the GUI. You can also see a complete listing of the code that is discussed in the following sections.

Note The following links execute MATLAB commands and are designed to work within the MATLAB Help browser. If you are reading this online or in PDF, you should go to the corresponding section in the MATLAB Help Browser to use the links.

- Click here to display this GUI in the Layout Editor.
- Click here to display the GUI M-file in the MATLAB Editor.

Design of the GUI

This GUI requires three input values:

- Frequency one (`f1`)
- Frequency two (`f2`)
- A time vector (`t`)

When the user clicks the **Plot** button, the GUI puts these values into a MATLAB expression that is the sum of two sine function:

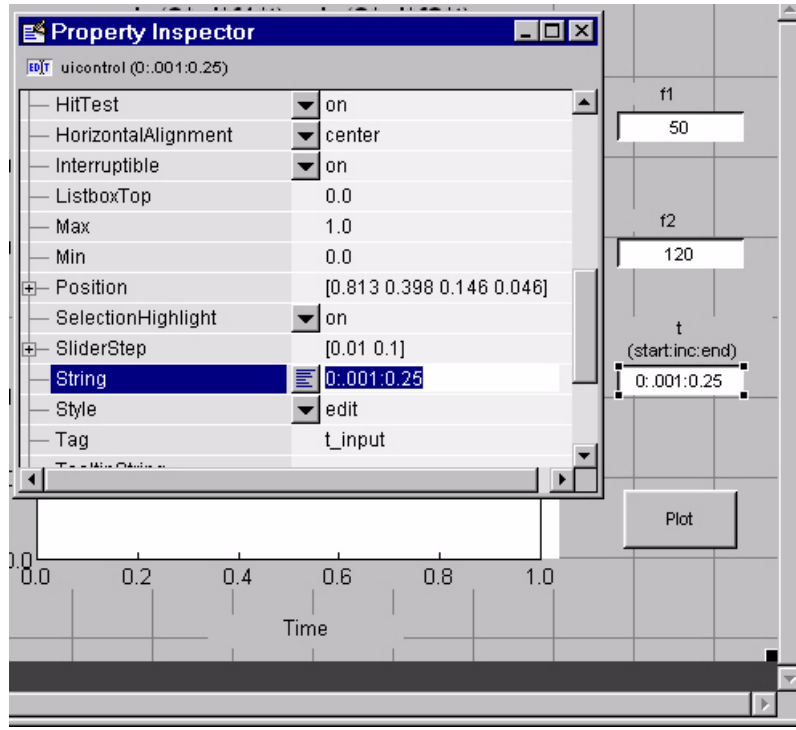
```
x = sin(2*pi*f1*t) + sin(2*pi*f2*t)
```

The GUI then calculates the FFT of `x` and creates two plots — one frequency domain and one time domain.

Specifying Default Values for the Inputs

The GUI uses default values for the three inputs. This enables users to click on the **Plot** button and see a result as soon as the GUI is run. It also helps to indicate what values the user might enter.

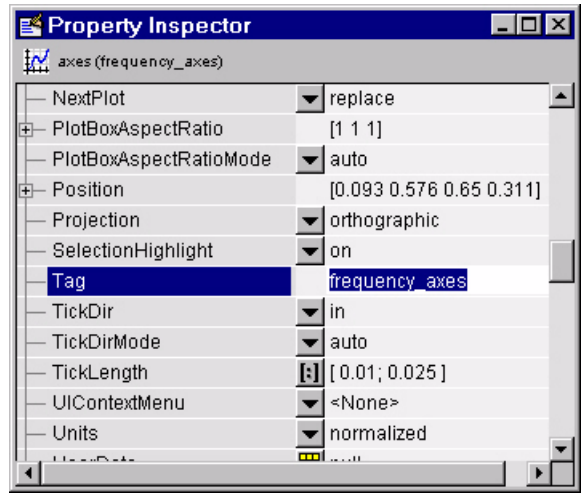
To create the default values, set the `String` property of the edit text. The following figure shows the value set for the time vector.



Identifying the Axes

Since there are two axes in this GUI, you must be able to specify which one you want to target when you issue the plotting commands. To do this, use the `handles` structure, which contains the handles of all components in the GUI.

The field name in the `handles` structure that contains the handle of any given component is derived from the component's `Tag` property. To make code more readable (and to make it easier to remember) this example sets the `Tag` property to descriptive names.



For example, the `Tag` of the axes used to display the FFT is set to `frequency_axes`. Therefore, within a callback, you access its handle with

```
handles.frequency_axes
```

Likewise, the `Tag` of the time axes is set to `time_axes`.

See "handles Structure" on page 8-15 for more information on the `handles` structure. See "Plot Push Button Callback" on page 10-6 for the details of how to use the handle to specify the target axes.

GUI Option Settings

There are two GUI option settings that are particularly important for this GUI:

- Resize behavior: **Proportional**
- Command-line accessibility: **Callback**

Proportional Resize Behavior. Selecting **Proportional** as the resize behavior enables users to change the GUI to better view the plots. The components change size in proportion to the GUI figure size. This generally produces good results except when extremes of dimensions are used.

Callback Accessibility of Object Handles. When GUIs include axes, handles should be visible from within callbacks. This enables you to use plotting commands like you would on the command line. Note that **Callback** is the default setting for command-line accessibility.

See "GUI Options" on page 5-9 for more information.

Plot Push Button Callback

This GUI uses only the **Plot** button callback; the edit text callbacks are not needed and have been deleted from the GUI M-file. When a user clicks the **Plot** button, the callback performs three basic tasks — it gets user input from the edit text components, calculates data, and creates the two plots.

Getting User Input

The three edit text boxes provide a way for the user to enter values for the two frequencies and the time vector. The first task for the callback is to read these values. This involves:

- Reading the current values in the three edit text boxes using the `handles` structure to access the edit text handles.
- Converting the two frequency values (`f1` and `f2`) from string to doubles using `str2double`.
- Evaluating the time string using `eval` to produce a vector `t`, which the callback used to evaluate the mathematical expression.

The following code shows how the callback obtains the input.

```
% Get user input from GUI
f1 = str2double(get(handles.f1_input,'String'));
f2 = str2double(get(handles.f2_input,'String'));
t = eval(get(handles.t_input,'String'));
```

Calculating Data

Once the input data has been converted to numeric form and assigned to local variables, the next step is to calculate the data needed for the plots. See the `fft` function for an explanation of how this is done.

Targeting Specific Axes

The final task for the callback is to actually generate the plots. This involves

- Making the appropriate axes current using the `axes` command and the handle of the axes. For example,

  ```
  axes(handles.frequency_axes)
  ```

- Issuing the `plot` command.
- Setting any properties that are automatically reset by the `plot` command.

The last step is necessary because many plotting commands (including `plot`) clear the axes before creating the graph. This means you cannot use the Property Inspector to set the `XMinorTick` and grid properties that are used in this example, since they are reset when the callback executes `plot`.

When looking at the following code listing, note how the `handles` structure is used to access the handle of the axes when needed.

Plot Button Code Listing

```
function plot_button_Callback(hObject, eventdata, handles)
% hObject    handle to plot_button (see GCBO)
% eventdata  reserved - to be defined in a future version of MATLAB
% handles    structure with handles and user data (see GUIDATA)

% Get user input from GUI
f1 = str2double(get(handles.f1_input,'String'));
f2 = str2double(get(handles.f2_input,'String'));
t = eval(get(handles.t_input,'String'));

% Calculate data
x = sin(2*pi*f1*t) + sin(2*pi*f2*t);
```

```
y = fft(x,512);
m = y.*conj(y)/512;
f = 1000*(0:256)/512;

% Create frequency plot
axes(handles.frequency_axes) % Select the proper axes
plot(f,m(1:257))
set(handles.frequency_axes,'XMinorTick','on')
grid on

% Create time plot
axes(handles.time_axes) % Select the proper axes
plot(t,x)
set(handles.time_axes,'XMinorTick','on')
grid on
```

List Box Directory Reader

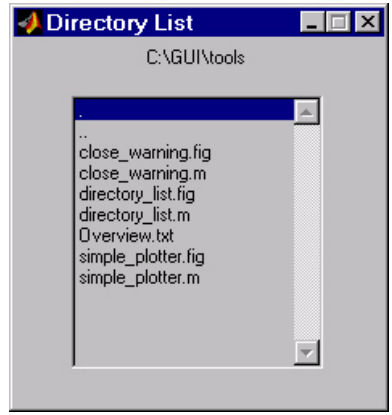
In this section...

List Box Example Outcome

This example uses a list box to display the files in a directory. When the user double clicks on a list item, one of the following happens:

- If the item is a file, the GUI opens the file appropriately for the file type.
- If the item is a directory, the GUI reads the contents of that directory into the list box.
- If the item is a single dot (**.**), the GUI updates the display of the current directory.
- If the item is two dots (**..**), the GUI changes to the directory up one level and populates the list box with the contents of that directory.

The following figure illustrates the GUI.



View Layout and GUI M-File

If you are reading this in the MATLAB Help browser, you can click the following links to display the GUIDE Layout Editor and the MATLAB Editor with a completed version of this example. This enables you to see the values of all component properties and to understand how the components are assembled to create the GUI. You can also see a complete listing of the code that is discussed in the following sections.

Note The following links execute MATLAB commands and are designed to work within the MATLAB Help browser. If you are reading this online or in PDF, you should go to the corresponding section in the MATLAB Help Browser to use the links.

- Click here to display this GUI in the Layout Editor.
- Click here to display the GUI M-file in the editor.

Implementing the GUI

The following sections describe the implementation:

- “Specifying the Directory to List” on page 10-11 — shows how to pass a directory path as input argument when the GUI is run.

- "Loading the List Box" on page 10-12 — describes the subfunction that loads the contents of the directory into the list box. This subfunction also saves information about the contents of a directory in the `handles` structure.
- "The List Box Callback" on page 10-13 — explains how the list box is programmed to respond to user double clicks on items in the list box.

Specifying the Directory to List

You can specify the directory to list when the GUI is first opened by passing the string `'create'` and a string containing the full path to the directory as arguments. The syntax for doing this is `list_box('create','dir_path')`. If you do not specify a directory (i.e., if you call the GUI M-file with no input arguments), the GUI then uses the MATLAB current directory.

The default behavior of the GUI M-file that GUIDE generates is to run the GUI when there are no input arguments or to call a subfunction when the first input argument is a character string. This example changes this behavior so that you can call the M-file with

- No input arguments — run the GUI using the MATLAB current directory.
- First input argument is `'dir'` and second input argument is a string that specifies a valid path to a directory — run the GUI, displaying the specified directory.
- First input argument is not a directory, but is a character string and there is more than one argument — execute the subfunction identified by the argument (execute callback).

The following code listing show the setup section of the GUI M-file, which does one the following:

- Sets the list box directory to the current directory, if no directory is specified.
- Changes the current directory, if a directory is specified.

```
function lbox2_OpeningFcn(hObject, eventdata, handles, varargin)
% This function has no output args, see OutputFcn.
% hObject    handle to figure
% eventdata  reserved - to be defined in a future version of MATLAB
% handles    structure with handles and user data (see GUIDATA)
% varargin   command line arguments to untitled (see VARARGIN)
```

```
% Choose default command line output for lbox2
handles.output = hObject;

% Update handles structure
guidata(hObject, handles);

if nargin == 3,
    initial_dir = pwd;
elseif nargin > 4
    if strcmpi(varargin{1},'dir')
        if exist(varargin{2},'dir')
            initial_dir = varargin{2};
        else
            errordlg({'Input argument must be a valid',...
                      'directory'},'Input Argument Error!')
            return
        end
    else
        errordlg('Unrecognized input argument',...
                 'Input Argument Error!');
        return;
    end
end
% Populate the listbox
load_listbox(initial_dir,handles)
```

Loading the List Box

This example creates a subfunction to load items into the list box. This subfunction accepts the path to a directory and the `handles` structure as input arguments. It performs these steps:

- Change to the specified directory so the GUI can navigate up and down the tree as required.
- Use the `dir` command to get a list of files in the specified directory and to determine which name is a directory and which is a file. `dir` returns a structure (`dir_struct`) with two fields, `name` and `isdir`, which contain this information.

- Sort the file and directory names (`sortrows`) and save the sorted names and other information in the `handles` structure so this information can be passed to other functions.

  The `name` structure field is passed to `sortrows` as a cell array, which is transposed to get one file name per row. The `isdir` field and the sorted index values, `sorted_index`, are saved as vectors in the `handles` structure.

- Call `guidata` to save the `handles` structure.
- Set the list box `String` property to display the file and directory names and set the `Value` property to `1`. This is necessary to ensure `Value` never exceeds the number of items in `String`, since MATLAB updates the `Value` property only when a selection occurs and not when the contents of `String` changes.
- Displays the current directory in the text box by setting its `String` property to the output of the `pwd` command.

The `load_listbox` function is called by the opening function of the GUI M-file as well as by the list box callback.

```
function load_listbox(dir_path, handles)
cd (dir_path)
dir_struct = dir(dir_path);
[sorted_names,sorted_index] = sortrows({dir_struct.name}');
handles.file_names = sorted_names;
handles.is_dir = [dir_struct.isdir];
handles.sorted_index = sorted_index;
guidata(handles.figure1,handles)
set(handles.listbox1,'String',handles.file_names,...
 'Value',1)
set(handles.text1,'String',pwd)
```

The List Box Callback

The list box callback handles only one case: a double-click on an item. Double clicking is the standard way to open a file from a list box. If the selected item is a file, it is passed to the `open` command; if it is a directory, the GUI changes to that directory and lists its contents.

Defining How to Open File Types

The callback makes use of the fact that the `open` command can handle a number of different file types. However, the callback treats FIG-files differently. Instead of opening the FIG-file, it passes it to the `guide` command for editing.

Determining Which Item the User Selected

Since a single click on an item also invokes the list box callback, it is necessary to query the figure `SelectionType` property to determine when the user has performed a double click. A double-click on an item sets the `SelectionType` property to `open`.

All the items in the list box are referenced by an index from `1` to `n`, where `1` refers to the first item and `n` is the index of the nth item. MATLAB saves this index in the list box `Value` property.

The callback uses this index to get the name of the selected item from the list of items contained in the `String` property.

Determining if the Selected Item is a File or Directory

The `load_listbox` function uses the `dir` command to obtain a list of values that indicate whether an item is a file or directory. These values (1 for directory, 0 for file) are saved in the `handles` structure. The list box callback queries these values to determine if current selection is a file or directory and takes the following action:

- If the selection is a directory — change to the directory (`cd`) and call `load_listbox` again to populate the list box with the contents of the new directory.
- If the selection is a file — get the file extension (`fileparts`) to determine if it is a FIG-file, which is opened with `guide`. All other file types are passed to `open`.

The `open` statement is called within a `try/catch` block to capture errors in an error dialog (`errordlg`), instead of returning to the command line.

```
get(handles.figure1,'SelectionType');
% If double click
```

```
if strcmp(get(handles.figure1,'SelectionType'),'open')
    index_selected = get(handles.listbox1,'Value');
    file_list = get(handles.listbox1,'String');
    % Item selected in list box
    filename = file_list{index_selected};
    % If directory
    if  handles.is_dir(handles.sorted_index(index_selected))
        cd (filename)
        % Load list box with new directory.
        load_listbox(pwd,handles)
    else
        [path,name,ext,ver] = fileparts(filename);
        switch ext
            case '.fig'
                % Open FIG-file with guide command.
                guide (filename)
            otherwise
                try
                    % Use open for other file types.
                    open(filename)
                catch
                    errordlg(lasterr,'File Type Error','modal')
                end
        end
    end
end
```

Opening Unknown File Types

You can extend the file types that the `open` command recognizes to include any file having a three-character extension. You do this by creating an M-file with the name `openxyz`, where `xyz` is the extension. Note that the list box callback does not take this approach for FIG-files since `openfig.m` is required by the GUI M-file. See `open` for more information.

Accessing Workspace Variables from a List Box

In this section...

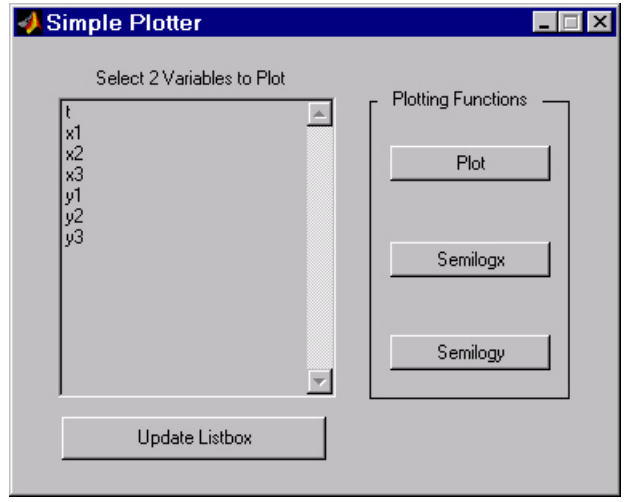
Workspace Variable Example Outcome

This GUI uses a list box to display workspace variables, which the user can then plot.

Techniques Used in This Example

- Populate the list box with the variable names that exist in the base workspace.
- Display the list box with no items initially selected.
- Enable multiple item selection in the list box.
- Update the list items when the user press a button.
- Evaluate the plotting commands in the base workspace.

The following figure illustrates the layout.



Note that the list box callback is not used in this program because the plotting actions are initiated by push buttons. In this situation you must do one of the following:

- Leave the empty list box callback in the GUI M-file.
- Delete the string assigned to the list box `Callback` property.

View Completed Layout and Its GUI M-File

If you are reading this in the MATLAB Help browser, you can click the following links to display the GUIDE Layout Editor and the MATLAB Editor with a completed version of this example. This enables you to see the values of all component properties and to understand how the components are assembled to create the GUI. You can also see a complete listing of the code that is discussed in the following sections.

Note The following links execute MATLAB commands and are designed to work within the MATLAB Help browser. If you are reading this online or in PDF, you should go to the corresponding section in the MATLAB Help Browser to use the links.

- Click here to display this GUI in the Layout Editor.
- Click here to display the GUI M-file in the editor.

Reading Workspace Variables

When the GUI initializes, it needs to query the workspace variables and set the list box `String` property to display these variable names. Adding the following subfunction to the GUI M-file accomplishes this using `evalin` to execute the `who` command in the base workspace. The `who` command returns a cell array of strings, which are used to populate the list box.

```
function update_listbox(handles)
vars = evalin('base','who');
set(handles.listbox1,'String',vars)
```

The function's input argument is the handles structure generated by the GUI M-file. This structure contains the handle of the list box, as well as the handles all other components in the GUI.

The callback for the **Update Listbox** push button also calls `update_listbox`.

Reading the Selections from the List Box

This GUI requires the user to select two variables from the workspace and then choose one of three plot commands to create the graph: `plot`, `semilogx`, or `semilogy`.

Enabling Multiple Selection

To enable multiple selection in a list box, you must set the `Min` and `Max` properties so that `Max - Min > 1`. This requires you to change the default `Min` and `Max` values of `0` and `1` to meet these conditions. Use the Property Inspector to set these properties on the list box.

How Users Select Multiple Items

List box multiple selection follows the standard for most systems:

- **Ctrl**+click left mouse button — noncontiguous multi-item selection
- **Shift**+click left mouse button — contiguous multi-item selection

Users must use one of these techniques to select the two variables required to create the plot.

Returning Variable Names for the Plotting Functions

The `get_var_names` subroutine returns the two variable names that are selected when the user clicks on one of the three plotting buttons. The function

- Gets the list of all items in the list box from the `String` property.
- Gets the indices of the selected items from the `Value` property.
- Returns two string variables, if there are two items selected. Otherwise `get_var_names` displays an error dialog explaining that the user must select two variables.

Here is the code for `get_var_names`:

```
function [var1,var2] = get_var_names(handles)
list_entries = get(handles.listbox1,'String');
index_selected = get(handles.listbox1,'Value');
if length(index_selected) ~= 2
 errordlg('You must select two variables',...
   'Incorrect Selection','modal')
else
 var1 = list_entries{index_selected(1)};
 var2 = list_entries{index_selected(2)};
end
```

Callbacks for the Plotting Buttons

The callbacks for the plotting buttons call `get_var_names` to get the names of the variables to plot and then call `evalin` to execute the plot commands in the base workspace.

For example, here is the callback for the `plot` function:

```
function plot_button_Callback(hObject, eventdata, handles)
[x,y] = get_var_names(handles);
evalin('base',['plot(' x ',' y ')'])
```

The command to evaluate is created by concatenating the strings and variables that result in the command:

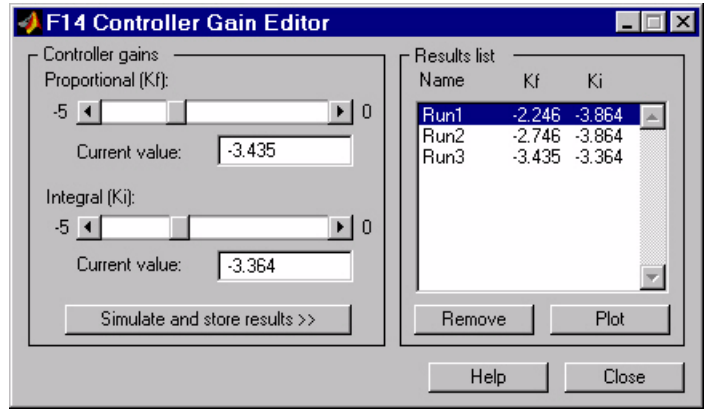
```
plot(x,y)
```

A GUI to Set Simulink Model Parameters

In this section...

Set Simulink Model Parameters Example Outcome

This example illustrates how to create a GUI that sets the parameters of a Simulink® model. In addition, the GUI can run the simulation and plot the results. The following picture shows the GUI after running three simulations with different values for controller gains.



Techniques Used in This Example

This example illustrates a number of GUI building techniques:

- Opening and setting parameters on a Simulink model from a GUI.
- Implementing sliders that operate in conjunction with text boxes, which display the current value as well as accepting user input.
- Enabling and disabling controls, depending on the state of the GUI.
- Managing a variety of shared data using the `handles` structure.
- Directing graphics output to figures with hidden handles.
- Adding a help button that displays `.html` files in the MATLAB Help browser.

View Completed Layout and Its GUI M-File

If you are reading this in the MATLAB Help browser, you can click the following links to display the GUIDE Layout Editor and the MATLAB Editor with a completed version of this example. This enables you to see the values of all component properties and to understand how the components are assembled to create the GUI. You can also see a complete listing of the code that is discussed in the following sections.

Note The following links execute MATLAB commands and are designed to work within the MATLAB Help browser. If you are reading this online or in PDF, you should go to the corresponding section in the MATLAB Help Browser to use the links.

- Click here to display this GUI in the Layout Editor.
- Click here to display the GUI M-file in the editor.

How to Use the GUI (Text of GUI Help)

You can use the F14 Controller Gain Editor to analyze how changing the gains used in the Proportional-Integral Controller affect the aircraft's angle of attack and the amount of G force the pilot feels.

Note that the Simulink diagram `f14.mdl` must be open to run this GUI. If you close the F14 Simulink model, the GUI reopens it whenever it requires the model to execute.

Changing the Controller Gains

You can change gains in two blocks:

- The Proportional gain (Kf) in the Gain block
- The Integral gain (Ki) in the Transfer Function block

You can change either of the gains in one of the two ways:

- Move the slider associated with that gain.
- Type a new value into the **Current value** edit field associated with that gain.

The block's values are updated as soon as you enter the new value in the GUI.

Running the Simulation

Once you have set the gain values, you can run the simulation by clicking the **Simulate and store results** button. The simulation time and output vectors are stored in the **Results list**.

Plotting the Results

You can generate a plot of one or more simulation results by selecting the row of results (`Run1`, `Run2`, etc.) in the **Results list** that you want to plot and clicking the **Plot** button. If you select multiple rows, the graph contains a plot of each result.

The graph is displayed in a figure, which is cleared each time you click the **Plot** button. The figure's handle is hidden so that only the GUI can display graphs in this window.

Removing Results

To remove a result from the **Results list**, select the row or rows you want to remove and click the **Remove** button.

Running the GUI

The GUI is nonblocking and nonmodal since it is designed to be used as an analysis tool.

GUI Options Settings

This GUI uses the following GUI option settings:

- Resize behavior: **Non-resizable**
- Command-line accessibility: **Off**
- M-file options selected:
  - Generate callback function prototypes
  - GUI allows only one instance to run

Opening the Simulink Block Diagrams

This example is designed to work with the F14 Simulink model. Since the GUI sets parameters and runs the simulation, the F14 model must be open when the GUI is displayed. When the GUI M-file runs the GUI, it executes the `model_open` subfunction. The purpose of the subfunction is to

- Determine if the model is open (`find_system`).
- Open the block diagram for the model and the subsystem where the parameters are being set, if not open already (`open_system`).
- Change the size of the controller Gain block so it can display the gain value (`set_param`).
- Bring the GUI forward so it is displayed on top of the Simulink diagrams (`figure`).
