The Test Matrix Toolbox for MATLAB (Version 3.0)

Nicholas J. Higham*

September 22, 1995

Abstract

We describe version 3.0 of the Test Matrix Toolbox for MATLAB 4.2. The toolbox contains a collection of test matrices, routines for visualizing matrices, routines for direct search optimization, and miscellaneous routines that provide useful additions to MATLAB's existing set of functions. There are 58 parametrized test matrices, which are mostly square, dense, nonrandom, and of arbitrary dimension. The test matrices include ones with known inverses or known eigenvalues; ill-conditioned or rank deficient matrices; and symmetric, positive definite, orthogonal, defective, involutary, and totally positive matrices. The visualization routines display surface plots of a matrix and its (pseudo-) inverse, the field of values, Gershgorin disks, and two- and three-dimensional views of pseudospectra. The direct search optimization routines implement the alternating directions method, the multidirectional search method and the Nelder–Mead simplex method. We explain the need for collections of test matrices and summarize the features of the collection in the toolbox. We give examples of the use of the toolbox and explain some of the interesting properties of the Frank matrix and magic square matrices. The leading comment lines from all the toolbox routines are listed.

Key words. test matrix, MATLAB, pseudospectrum, visualization, Frank matrix, magic square matrix, random matrix, direct search optimization.

AMS subject classifications. primary 65F05

1 Distribution

If you wish to distribute the toolbox please give exact copies of it, not selected routines.

2 Installation

The Test Matrix Toolbox is available by anonymous ftp from The MathWorks with URL

```
ftp://ftp.mathworks.com/pub/contrib/linalg/testmatrix
```

This document is `testmatrix.ps` in the same location. The MathWorks ftp server provides information on how to download a complete directory as one file.

The toolbox is also available from the URL

```
ftp://ftp.ma.man.ac.uk/pub/higham/testmatrix.tar.Z
```

This document is `narep276.ps.Z` in the same location. To install the toolbox from this location, download the tar file (in binary mode) into a `testmatrix` directory (`matlab/testmatrix` is recommended). Then uncompress the tar file and untar it:

```
uncompress testmatrix.tar.Z
tar xvf testmatrix
```

To try the toolbox from within MATLAB, change to the `testmatrix` directory and run the demonstration script by typing `tmtdemo`. For serious use it is best to put the `testmatrix` directory on the MATLAB path *before* the `matlab/toolbox` entries—this is because several toolbox routines have the same name as MATLAB routines and are intended to replace them (namely, `compan`, `cond`, `hadamard`, `hilb`, and `pascal`).

This document describes version 3.0 of the toolbox, dated September 19, 1995.

3 Release History

The first release of this toolbox (version 1.0, July 4 1989) was described in a technical report [19]. The collection was subsequently published as ACM Algorithm 694 [21]. Prior to the current version, version 3.0, the most recent release was version 2.0 (November 14 1993) [24]. Version 2.0 incorporated many additions and improvements over version 1.3 and took full advantage of the features of MATLAB 4.

The major changes in version 3.0 are as follows.

- New routines: `cgs` (classical Gram–Schmidt), `mgs` (modified Gram–Schmidt), `gj` (Gauss–Jordan elimination), `diagpiv` (diagonal pivoting factorization with partial pivoting for a symmetric matrix); `adsmax`, `mdsmax` and `nmsmax` for direct search optimization.
- Bug in `eigsens` corrected. Minor bugs in other routines corrected.

Version 3.0 of the toolbox was developed in conjunction with the book *Accuracy and Stability of Numerical Algorithms* [26]. The book contains a chapter *A Gallery of Test Matrices* which has sections

- The Hilbert and Cauchy Matrices
- Random Matrices
- "Randsvd" Matrices
- The Pascal Matrix
- Tridiagonal Toeplitz Matrices
- Companion Matrices
- Notes and References
- LAPACK
- Problems

Users of the toolbox should consult [26] for further information not contained in this document.

4 Quick Reference Tables

This section contains quick reference tables for the Test Matrix Toolbox. All the M-files in the toolbox are listed by category, with a short description. More detailed documentation is given in Section 10, or can be obtained on-line by typing `help M-file_name`.

Demonstration	
`tmtdemo`	Demonstration of Test Matrix Toolbox.

Test Matrices, A–K	
`augment`	Augmented system matrix.
`cauchy`	Cauchy matrix.
`chebspec`	Chebyshev spectral differentiation matrix.
`chebvand`	Vandermonde-like matrix for the Chebyshev polynomials.
`chow`	Chow matrix—a singular Toeplitz lower Hessenberg matrix.
`circul`	Circulant matrix.
`clement`	Clement matrix—tridiagonal with zero diagonal entries.
`compan`	Companion matrix.
`condex`	"Counterexamples" to matrix condition number estimators.
`cycol`	Matrix whose columns repeat cyclically.
`dingdong`	Dingdong matrix—a symmetric Hankel matrix.
`dorr`	Dorr matrix—diagonally dominant, ill conditioned, tridiagonal.
`dramadah`	A $(0,1)$ matrix whose inverse has large integer entries.
`fiedler`	Fiedler matrix—symmetric.
`forsythe`	Forsythe matrix—a perturbed Jordan block.
`frank`	Frank matrix—ill conditioned eigenvalues.
`gallery`	Famous, and not so famous, test matrices.
`gearm`	Gear matrix.
`gfpp`	Matrix giving maximal growth factor for Gaussian elimination with partial pivoting.
`grcar`	Grcar matrix—a Toeplitz matrix with sensitive eigenvalues.
`hadamard`	Hadamard matrix.
`hanowa`	A matrix whose eigenvalues lie on a vertical line in the complex plane.
`hilb`	Hilbert matrix.
`invhess`	Inverse of an upper Hessenberg matrix.
`invol`	An involutory matrix.
`ipjfact`	A Hankel matrix with factorial elements.
`jordbloc`	Jordan block.
`kahan`	Kahan matrix—upper trapezoidal.
`kms`	Kac–Murdock–Szegö Toeplitz matrix.
`krylov`	Krylov matrix.

Test Matrices, L–Z	
`lauchli`	Lauchli matrix—rectangular.
`lehmer`	Lehmer matrix—symmetric positive definite.
`lesp`	A tridiagonal matrix with real, sensitive eigenvalues.
`lotkin`	Lotkin matrix.
`makejcf`	A matrix with given Jordan canonical form.
`minij`	Symmetric positive definite matrix $\min(i,j)$.
`moler`	Moler matrix—symmetric positive definite.
`neumann`	Singular matrix from the discrete Neumann problem (sparse).
`ohess`	Random, orthogonal upper Hessenberg matrix.
`orthog`	Orthogonal and nearly orthogonal matrices.
`parter`	Parter matrix—a Toeplitz matrix with singular values near π.
`pascal`	Pascal matrix.
`pdtoep`	Symmetric positive definite Toeplitz matrix.
`pei`	Pei matrix.
`pentoep`	Pentadiagonal Toeplitz matrix (sparse).
`poisson`	Block tridiagonal matrix from Poisson's equation (sparse).
`prolate`	Prolate matrix—symmetric, ill-conditioned Toeplitz matrix.
`rando`	Random matrix with elements -1, 0 or 1.
`randsvd`	Random matrix with pre-assigned singular values.
`redheff`	A (0,1) matrix of Redheffer associated with the Riemann hypothesis.
`riemann`	A matrix associated with the Riemann hypothesis.
`rschur`	An upper quasi-triangular matrix.
`smoke`	Smoke matrix—complex, with a "smoke ring" pseudospectrum.
`tridiag`	Tridiagonal matrix (sparse).
`triw`	Upper triangular matrix discussed by Wilkinson and others.
`vand`	Vandermonde matrix.
`wathen`	Wathen matrix—a finite element matrix (sparse, random entries).
`wilk`	Various specific matrices devised/discussed by Wilkinson.

Visualization	
`fv`	Field of values (or numerical range).
`gersh`	Gershgorin disks.
`ps`	Dot plot of a pseudospectrum.
`pscont`	Contours and colour pictures of pseudospectra.
`see`	Pictures of a matrix and its (pseudo-) inverse.

Decompositions and Factorizations	
`cgs`	Classical Gram–Schmidt QR factorization.
`cholp`	Cholesky factorization with pivoting of a positive semidefinite matrix.
`cod`	Complete orthogonal decomposition.
`diagpiv`	Diagonal pivoting factorization with partial pivoting.
`ge`	Gaussian elimination without pivoting.
`gecp`	Gaussian elimination with complete pivoting.
`gj`	Gauss–Jordan elimination to solve $Ax = b$.
`mgs`	Modified Gram–Schmidt QR factorization.
`poldec`	Polar decomposition.
`signm`	Matrix sign decomposition.

Direct Search Optimization	
`adsmax`	Alternating directions direct search method.
`mdsmax`	Multidirectional search method for direct search optimization.
`mmsmax`	Nelder–Mead simplex method for direct search optimization.

Miscellaneous	
`bandred`	Band reduction by two-sided unitary transformations.
`chop`	Round matrix elements.
`comp`	Comparison matrices.
`cond`	Matrix condition number in 1, 2, Frobenius, or ∞-norm.
`cpltaxes`	Determine suitable `axis` for plot of complex vector.
`dual`	Dual vector with respect to Hölder p-norm.
`eigsens`	Eigenvalue condition numbers.
`house`	Householder matrix.
`matrix`	Test Matrix Toolbox information and matrix access by number.
`matsignt`	Matrix sign function of a triangular matrix.
`pnorm`	Estimate of matrix p-norm ($1 \leq p \leq \infty$).
`qmult`	Pre-multiply by random orthogonal matrix.
`rq`	Rayleigh quotient.
`seqa`	Additive sequence.
`seqcheb`	Sequence of points related to Chebyshev polynomials.
`seqm`	Multiplicative sequence.
`show`	Display signs of matrix elements.
`skewpart`	Skew-symmetric (skew-Hermitian) part.
`sparsify`	Randomly sets matrix elements to zero.
`sub`	Principal submatrix.
`symmpart`	Symmetric (Hermitian) part.
`trap2tri`	Unitary reduction of trapezoidal matrix to triangular form.

5 Test Matrices

Numerical experiments are an indispensable part of research in numerical analysis. We do them for several reasons:

- To gain insight and understanding into an algorithm that is only partially understood theoretically.
- To verify the correctness of a theoretical analysis and to see if the analysis completely explains the practical behaviour.
- To compare rival methods with regard to accuracy, speed, reliability, and so on.
- To tune parameters in algorithms and codes, and to test heuristics.

One of the difficulties in designing experiments is finding good test problems—ones that reveal extremes of behaviour, cover a wide range of difficulty, are representative of practical problems, and (ideally) have known solutions. In many areas of numerical analysis good test problems have been identified, and several collections of such problems have been published. For example, collections are available in the areas of nonlinear optimization [33], linear programming [13], [31], ordinary differential equations [10], and partial differential equations [34].

Probably the most prolific devisers of test problems have been workers in matrix computations. Indeed, in the 1950s and 1960s it was common for a whole paper to be devoted to a particular test matrix: typically its inverse or eigenvalues would be obtained in closed form. An early survey of test matrices was given by Rutishauser [36]; most of the matrices he discusses come from continued fractions or moment problems. Two well-known books present collections of test matrices. Gregory and Karney [15] deal exclusively with the topic, while Westlake [43] gives an appendix of test matrices. In the 24 years since these books appeared several interesting matrices have been discovered (and in fact both books omit some worthy test matrices that were known at the time).

The Test Matrix Toolbox contains an up-to-date, well documented and readily accessible collection of test matrices. The matrices are given in the form of self-documenting MATLAB M-files. For some of the matrices we give mathematical formulas for the matrix elements in comment lines; in other cases the formulas can be reconstructed from the MATLAB code. We do not give exhaustive descriptions of matrix properties, or proofs of these properties; instead, in the comment lines we list a few key properties and give references where further details can be found.

With a few exceptions each of the 58 matrices satisfies the following requirements:

- It is a square matrix with one or more variable parameters, one of which is the dimension. Thus it is actually a parametrized family of matrices of arbitrary dimension.
- It is dense.
- It has some property that makes it of interest as a test matrix.

The first criterion is enforced because it is often desirable to explore the behaviour of a numerical method as parameters such as the matrix dimension vary. The third criterion is somewhat subjective, and the matrices presented here represent the author's personal choice. Note that we have omitted plausible matrices that we thought not "sufficiently different" from others in the collection. Although all but two of our test matrices are usually real, those with an arbitrary parameter can be made complex by choosing a non-real value for the parameter.

As well as their obvious application to research in matrix computations we hope that the matrices presented here will be useful for constructing test problems in other areas, such as optimization (see, for example, [3]) and ordinary differential equations.

We mention some other collections of test matrices that complement ours. The Harwell-Boeing collection of sparse matrices, largely drawn from practical problems, is presented by Duff, Grimes and Lewis [8], [9]. Bai [2] is building a collection of test matrices for the large-scale nonsymmetric eigenvalue problem. Zielke [46] gives various parametrized rectangular matrices of fixed dimension with known generalized inverses. Demmel and McKenney [7] present a suite of Fortran 77 codes for generating random square and rectangular matrices with prescribed singular values, eigenvalues, band structure, and other properties. This suite is part of the testing code for LAPACK [1]. Our focus is primarily on non-random matrices but we include a class of random matrices `randsvd` that has some of the features of the Demmel and McKenney test set.

Where possible, we have chosen the names of the test matrices eponymously, since it is easier to remember, for example, "the Kahan matrix", than "Example 3.8". For portability reasons we restrict all M-file names in the toolbox to eight characters (since this is the limit in the MSDOS operating system, under which the Microsoft Windows version of MATLAB runs). We have written a routine `matrix` that accesses the matrices by number rather than by name; this makes it easy to run experiments on the whole collection of matrices (with parameters other than the matrix dimension set to their default values.)

The matrices described here can be modified in various ways while still retaining some or all of their interesting properties. Among the many ways of constructing new test matrices from old are:

- Similarity transformations $A \leftarrow X^{-1}AX$.
- Unitary transformations $A \leftarrow UAV$, where $U^*U = V^*V = I$.
- Kronecker products $A \leftarrow A \otimes B$ or $B \otimes A$ (for which MATLAB has a routine `kron`).
- Powers $A \leftarrow A^k$.

For a discussion of these techniques, and others, see [15, Chapter 2]. Techniques for obtaining a triangular, orthogonal, or symmetric positive definite matrix that is related to a given matrix include

- Bandwidth reduction using unitary transformations (see toolbox routine `bandred`).
- LU, Cholesky, QR and polar decompositions (see `lu`, `chol`, `qr` and, from the toolbox, `cholp`, `ge`, `gecp` and `poldec`.)

See [14] for details of these techniques.

Another way to generate a new matrix is to perturb an existing one. One approach is to add a random perturbation. Another is to round the matrix elements to a certain number of binary places; this can be done using the toolbox routine `chop`.

Our programming style is as follows. Each M-file `foo` begins with comment lines that are displayed when the user types `help foo`. The first comment line, the H1 line, is a self-contained statement of the purpose of the routine; the H1 lines are searched and displayed by MATLAB's `lookfor` command (e.g., `lookfor toeplitz`). Any further comments and references follow a blank line and so are not displayed by `help`. As far as possible, every routine sets default values for any arguments that are not specified. In particular, for most test matrix routines `testmat`, `A = testmat(n)` is a valid way to generate an $n \times n$ matrix. In general we have strived for

conciseness, modularity, speed, and minimal use of temporary storage in our MATLAB codes. Hence, where possible, we used matrix or vector constructs instead of `for` loops and have used calls to existing M-files.

Some of those matrices that are banded with a small bandwidth are given the sparse storage format, to allow large matrices to be generated. The `full` function can be used to convert to non-sparse storage (e.g., `A = full(tridiag(32))`). We check for errors in parameters in some, but not all, cases. A few of the test matrix routines do not properly handle the dimension $n = 1$ (for example, they halt with an error, or return an empty matrix). We decided not to add extra code for this case, since the routines are unlikely to be called with $n = 1$.

Tables 5.1 and 5.2 provide a summary of the properties of the test matrices. The column headings have the following meanings:

Inverse: the inverse of the matrix is known explicitly.

Ill-cond: the matrix is ill-conditioned for some values of the parameters.

Rank: the matrix is rank-deficient for some values of the parameters (we exclude "trivial" examples such as `vand`, which is singular if its vector argument contains repeated points). Note that there are some matrices that are mathematically rank-deficient but behave as ill-conditioned full rank matrices in the presence of rounding errors; these are listed only as rank-deficient (for example, `chebspec`).

Symm: the matrix is symmetric for some values of the parameters.

Pos Def: the matrix is symmetric positive definite for some values of the parameters.

Orth: the matrix is orthogonal, or a diagonal scaling of an orthogonal matrix, for some values of the parameters.

Eig: something is known about the eigensystem (or the singular values), ranging from bounds or qualitative knowledge of the eigenvalues to explicit formulas for some or all eigenvalues and eigenvectors.

We summarise further interesting properties possessed by some of the matrices. Recall that A is a *Hankel matrix* if the anti-diagonals are constant ($a_{ij} = r_{i+j}$), *idempotent* if $A^2 = A$, *normal* if $A^*A = AA^*$ (or, equivalently, A is unitarily diagonalizable), *nilpotent* if $A^k = 0$ for some k, *involutary* if $A^2 = I$, *totally positive (nonnegative)* if the determinant of every submatrix is positive (nonnegative), and a *Toeplitz matrix* if the diagonals are constant ($a_{ij} = r_{j-i}$). A totally positive matrix has distinct, real and positive eigenvalues and its ith eigenvector (corresponding to the ith largest eigenvalue) has exactly $i - 1$ sign changes [12, Theorem 13, p. 105]; this property is important in testing regularization algorithms [16], [17]. See [28] for further details of these matrix properties.

inverse of a tridiagonal matrix: `kms, lehmer, minij`

triangular: `dramadah, jordbloc, kahan, pascal, triw`

Finally, we note that several of the test matrices are related to those supplied with MATLAB. The functions `hadamard` and `pascal` were in the first release of the toolbox and were subsequently included by The MathWorks in the MATLAB distribution. The toolbox version of `hadamard` is the same as the one in MATLAB 4.2 except for the addition of an H1 line, whereas the toolbox version of `pascal` contains more informative comment lines than the MATLAB 4.2 version and produces a different `pascal(n,2)` matrix[3] (but one that is still a cube root of the identity). The toolbox routine `compan` is more versatile than the MATLAB 4.2 version. Similarly, the toolbox routine `vand` is more versatile than MATLAB 4.2's `vander`. The toolbox version of `hilb` is coded differently and contains more informative comments than the one in MATLAB 4.2. The toolbox routine `augment` is similar to MATLAB 4.2's `spaugment`, but produces a non-sparse matrix instead of a sparse one. The toolbox function `cond` supports the 1, 2, ∞ and Frobenius norms, whereas MATLAB 4.2's `cond` supports only the 2-norm.

6 Visualization

The toolbox contains five routines for visualizing matrices. The routines can give insight into the properties of a matrix that is not easy to obtain by looking at the numerical entries. They also provide an easy way to generate pretty pictures!

The routine `see` displays a figure with four subplots (strictly speaking four "axes", in MATLAB terminology) in the format

`mesh(A)`	`mesh(pinv(A))`
`semilogy(svd(A))`	`fv(A)`

An example for the `chebvand` matrix is given in Figure 6.1. MATLAB's `mesh` command plots a three-dimensional, coloured, wire-frame surface, by regarding the entries of a matrix as specifying heights above a plane. We use `axis('ij')`, so that the coordinate system for the plot matches the (i, j) matrix element numbering. `pinv(A)` is the Moore–Penrose pseudo-inverse A^+ of A, which is the usual inverse when A is square and nonsingular. `semilogy(svd(A))` plots the singular values of A (ordered in decreasing size) on a logarithmic scale; the singular values are denoted by circles, which are joined by a solid line to emphasise the shape of the distribution. From Figure 6.1 we can see that `chebvand(8)` has a 2-norm condition number of about 10^5 and that the largest elements of its inverse are in the lower triangle. For a sparse MATLAB matrix, `see` simply displays a `spy` plot, which shows the sparsity pattern of the matrix. The user could,

[1] `cauchy(x,y)` is totally positive if $0 < x_1 < \cdots < x_n$ and $0 < y_1 < \cdots < y_n$ [39, p. 295].

[2] `vand(p)` is totally positive if the p_i satisfy $0 < p_1 < \cdots < p_n$ [12, p. 99].

[3] The new `pascal(n,2)` is generated by a call to `rot90` and is "reverse upper triangular" instead of "reverse lower triangular" as in the MATLAB 4.2 version.

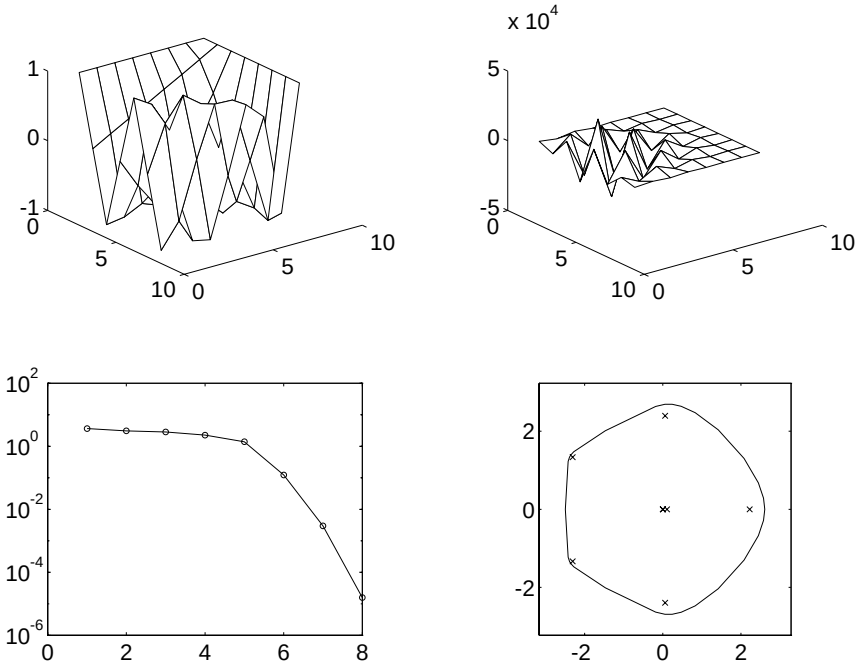

Figure 6.1: `see(chebvand(8))`.

of course, try `see(full(A))` for a sparse matrix, but for large dimensions the storage and time required would be prohibitive. Figure 6.2 displays the result of applying `see` to the Wathen matrix—a symmetric positive definite sparse matrix that comes from a finite element problem.

The routine `fv` plots the field of values of a square matrix $A \in \mathbf{C}^{n\times n}$ (also called the numerical range), which is the set of all Rayleigh quotients,

$$\left\{ \frac{x^*Ax}{x^*x} : 0 \neq x \in \mathbf{C}^n \right\};$$

the eigenvalues of A are plotted as crosses. The field of values is a convex set that contains the eigenvalues. It is the convex hull of the eigenvalues when A is a normal matrix. If A is Hermitian, the field of values is just a segment of the real line. For non-Hermitian A the field of values is usually two-dimensional and its shape and size gives some feel for the behaviour of the matrix. Trefethen [41] notes that the field of values is the largest reasonable answer to the question "Where in $\mathbf{C}$ does a matrix A 'live'?" and the spectrum is the smallest reasonable answer.

Some examples of field of values plots are given in Figure 6.3. The `circul` matrix is normal, hence its field of values is the convex hull of the eigenvalues. For an example of how the field of values gives insight into the problem of finding a nearest normal matrix see [35]. An excellent reference for the theory of the field of values is [29, Chapter 1].

The routine `gersh` plots the Gershgorin disks for an $A \in \mathbf{C}^{n\times n}$, which are the n disks

$$D_i = \{ z \in \mathbf{C} : |z - a_{ii}| \leq \sum_{\substack{j=1 \\ j\neq i}}^{n} |a_{ij}| \}$$

in the complex plane. Gershgorin's theorem tells us that the eigenvalues of A lie in the union of the disks, and an extension of the theorem states that if k disks form a connected region that is isolated from the other disks, then there are precisely k eigenvalues in this region. Thus the size of the disks gives a feel for how nearly diagonal A is, and their locations give information

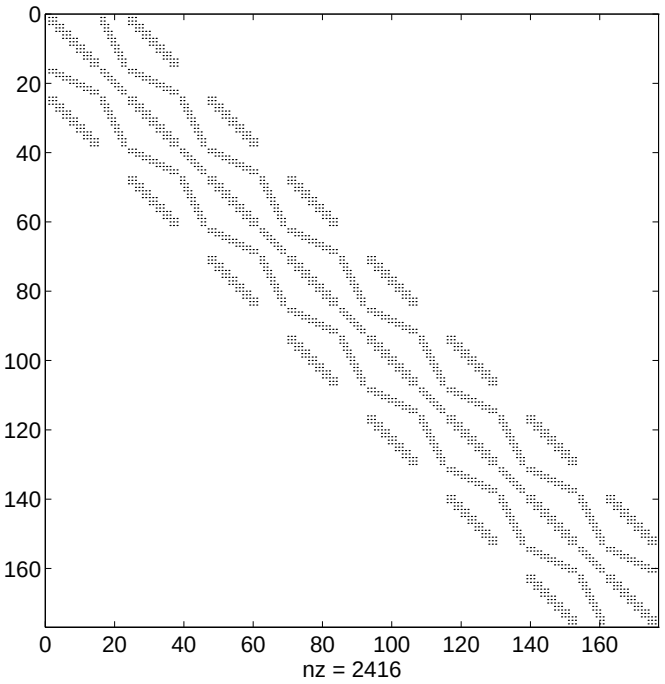

Figure 6.2: `see(wathen(7,7))`.

on where the eigenvalues lie in the complex plane. Four examples of Gershgorin disk plots are given in Figure 6.4; Gershgorin's theorem provides nontrivial information only for the third matrix, `ipjfact(8,1)`.

The last two routines, `ps` and `pscont`, are concerned with pseudospectra. The ϵ-pseudospectrum of a matrix $A \in \mathbf{C}^{n\times n}$ is defined, for a given $\epsilon > 0$, to be the set

$$\Lambda_\epsilon(A) = \{\, z : z \text{ is an eigenvalue of } A + E \text{ for some } E \text{ with } \|E\|_2 \le \epsilon \,\}.$$

In other words, it is the set of all complex numbers that are eigenvalues of $A + E$ for some perturbation E of 2-norm at most ϵ. For a normal matrix A the ϵ-pseudospectrum is the union of the balls of radius ϵ around the eigenvalues of A. For nonnormal matrices the ϵ-pseudospectrum can take a wide variety of shapes and sizes, depending on the matrix and how nonnormal it is. Pseudospectra play an important role in many numerical problems. For full details see the work of Trefethen—in particular, [40] and [41].

The routine `ps` plots an approximation to the ϵ-pseudospectrum $\Lambda_\epsilon(A)$, which it obtains by computing the eigenvalues of a given number of random perturbations of A. The eigenvalues are plotted as crosses and the pseudo-eigenvalues as dots. Arguments to `ps` control the number and type of perturbations. Figure 6.5 gives four examples of 10^{-3}-pseudospectra, all of which involve the pentadiagonal Toeplitz matrix `pentoep`.

Another characterization of $\Lambda_\epsilon(A)$, in terms of the resolvent $(zI - A)^{-1}$, is

$$\Lambda_\epsilon(A) = \{\, z : \|(zI - A)^{-1}\|_2 \ge \epsilon^{-1} \,\}.$$

An alternative way of viewing the pseudospectrum is to plot the function

$$f(z) = \|(zI - A)^{-1}\|_2^{-1} = \sigma_{\min}(zI - A)$$

over the complex plane, where $\sigma_{\min}$ denotes the smallest singular value [41]. The routine `pscont` plots $\log_{10} f(z)^{-1}$ and offers several ways to view the surface: by its contour lines alone, or as

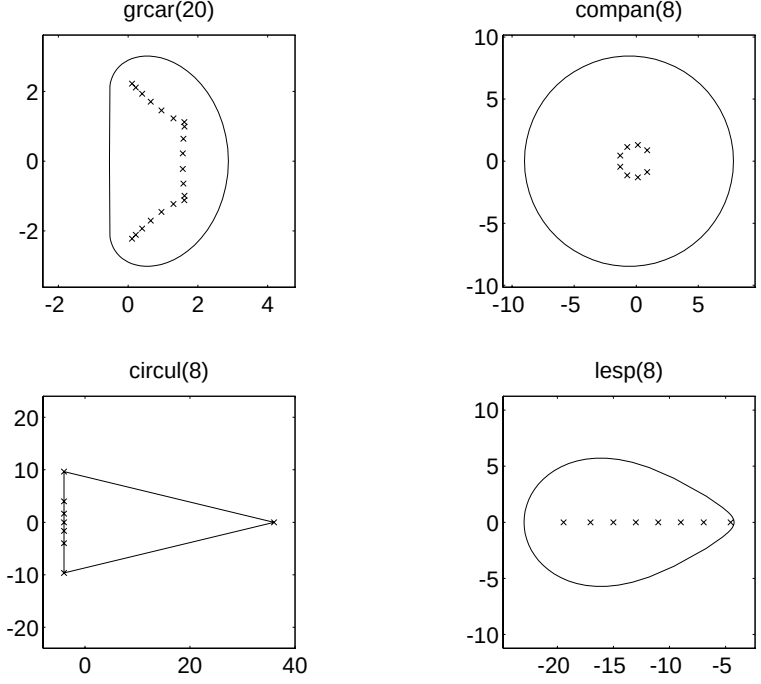

Figure 6.3: Fields of values (`fv`).

a coloured surface plot in two or three dimensions, with or without contour lines. (The two-dimensional plot is the view from directly above the surface.) Two different `pscont` views of the pseudospectra of the triangular matrix `triw(11)` are given in Figures 6.6 and 6.7. Since all the eigenvalues of this matrix are equal to 1, there is a single point where the resolvent is unbounded in norm—this is the "bottomless pit" in the pictures. The spike in Figure 6.7 should be infinitely deep; since `pscont` evaluates $f(z)$ on a finite grid, the spike has a finite depth dependent on the grid spacing. Also because of the grid spacing chosen, the contours are a little jagged. Various aspects of the plots can be changed from the MATLAB command line upon return from `pscont`; for example, the colour map (`colormap`), the shading (`shading`), and the viewing angle (`view`). For Figure 6.6 we set `shading interp` and `colormap copper`.

Both pseudospectrum routines are computationally intensive, so the defaults for the arguments are chosen to produce a result in a reasonable time (under 20 seconds on a SPARC-2 processor or equivalent); for plots that reveal reasonable detail it is usually necessary to override the defaults.

7 Direct Search Optimization

The toolbox contains three multivariate direct search maximization routines `mdsmax`, `adsmax` and `nmsmax`, together with a demonstration function `fdemo` on which to try them. The routines are competitors to `fmins`, which is supplied with MATLAB (but `fmins` minimizes rather than maximizes). `nmsmax` is actually a modified version of `fmins` with the same interface as `mdsmax` and `adsmax`.

`mdsmax`, `adsmax` and `nmsmax` are direct search methods (as is `fmins`), that is, they attempt to maximize a real function f of a vector argument x using function values only. `mdsmax` uses the multidirectional search method, `adsmax` uses the method of alternating directions, and `nmsmax` uses the Nelder–Mead simplex method. In general, `mdsmax` and `nmsmax` can be expected to perform better than `adsmax` since they use a more sophisticated method.

These routines were developed during the work described in [23].

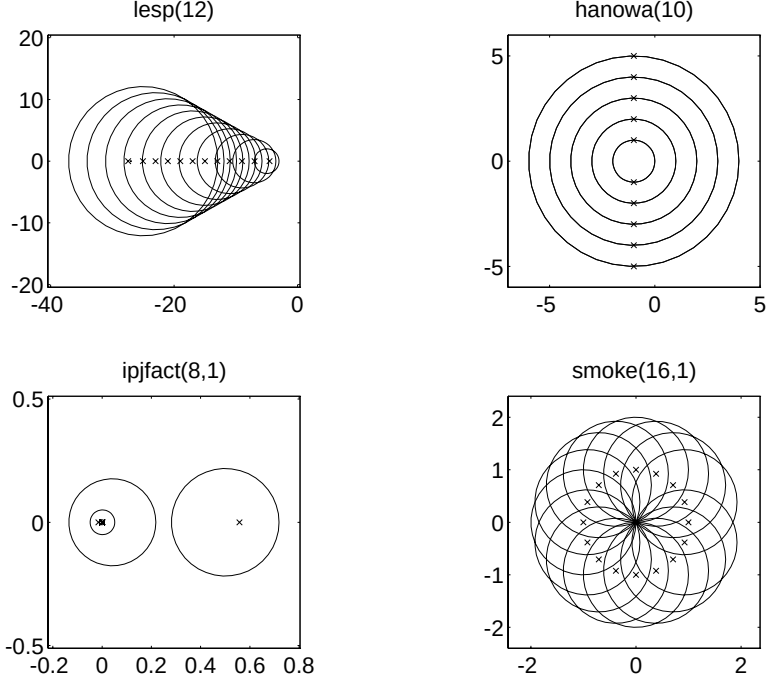

Figure 6.4: Gershgorin disks (`gersh`).

Note: These routines, like `fmins`, are not competitive with more sophisticated methods such as (quasi-)Newton methods when applied to smooth problems. They are at their best when applied to non-smooth problems such as the one in the example below.

The routines are fully documented in their leading comment lines, but it is appropriate to add here a few comments about the format of the output and the use of the `savit` argument.

`mdsmax` produces output to the screen (this can be suppressed by setting the input argument `stopit(5) = 0`). The output is illustrated by

```
Iter. 10,  inner =  2,  size = -4,  nf = 401,  f = 4.7183e+001  (51.0%)
```

The means that on the tenth iteration, two inner iterations were required, and at the end of the iteration the simplex edges were 2^{-4} times the length of those of the initial simplex. Further, `nf` is the total number of function evaluations so far, `f` is the current highest function value, and the percentage increase in function value over the tenth iteration is 51%.

The output produced by `adsmax` is similar to that of `mdsmax` and is illustrated by the following extract from the start of the second outer iteration:

```
Iter  2  (nf = 146)
Comp. =  1,  steps = 12,  f = 1.5607e+000  (0.4%)
```

`Comp` denotes the component of x being varied on the current stage and steps is the number of steps in the crude line search for this stage.

The output from `nmsmax` is also similar to that from `mdsmax`, but only iterations on which an increase in the function value is achieved are reported.

In all three routines, if a non-empty fourth input argument string `savit` is present then at the end of each iteration the following "snapshot" is written to the file specified by `savit`: the largest function value found so far, `fmax`, the point at which it is achieved, `x`, and the total number of function evaluations, `nf`. This option enables the user to abort an optimization, load and examine `x`, `fmax` and nf using MATLAB's `load` command, and then possibly restart the optimization at `x`.

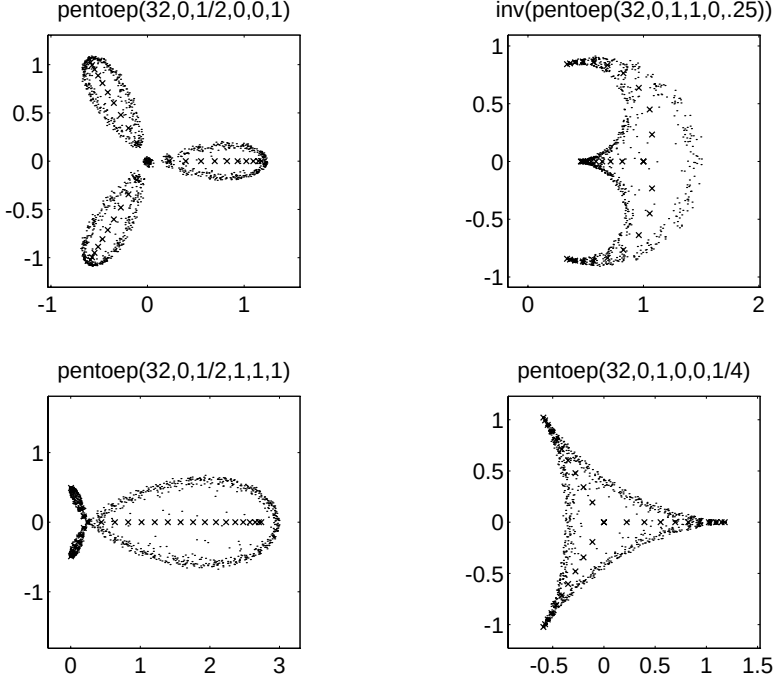

Figure 6.5: Pseudospectra (`ps`).

One further point worth mentioning is that `mdsmax`, `adsmax` and `nmsmax` always call the function `f` to be maximized with an argument of the same dimensions (or shape) as the starting value `x0`. Similarly, the output argument `x` and the variable `x` in `savit` saves have the same shape as `x0`. This feature is very convenient when `f` is a function of a matrix, as in the example below.

To facilitate a quick test of the routines the toolbox includes a function `fdemo`, which takes a square matrix argument `A` and evaluates the ratio of `rcond(A)` to the exact 1-norm condition number of the matrix `A`. (`rcond` is MATLAB's built-in condition estimator.) Making `fdemo` large corresponds to finding a matrix where `rcond` returns a poor condition number estimate.

Here is an extract from output produced by MATLAB 4.2b on a 486DX PC; similar output should be obtained on other machines (a machine that uses IEEE arithmetic will probably produce identical results). In this example MDSMAX rapidly achieves a function value of over 100, but ADSMAX and NMSMAX make only slow progress and terminate when the default convergence tests are satisfied.

```
>> A = hilb(5);  % Starting matrix.
>> B = mdsmax('fdemo', A);

f(x0) = 1.3596e+000

For more on the use of direct search in "automatic error analyis" see [23] or [26, Ch. 24].

8 Miscellaneous Routines

In addition to the test matrices and visualization routines, the Test Matrix Toolbox provides several routines that can be used to manipulate matrices or compute matrix functions or decompositions.

The decomposition functions offered are as follows.

• `cgs` and `mgs` apply the classical and modified Gram–Schmidt methods, respectively, to a matrix $A \in \mathbf{C}^{m\times n}$ of full rank n, to produce the factorization $A = QR$, where $Q \in \mathbf{C}^{m\times n}$ has orthonormal columns and $R \in \mathbf{C}^{n\times n}$ is upper triangular. The methods are identical in exact arithmetic but produce different results in the presence of rounding errors [26].

• `cholp` computes the Cholesky factorization with pivoting $\Pi^T A \Pi = R^* R$ of a Hermitian positive semi-definite matrix $A \in \mathbf{C}^{n\times n}$. Here, R is upper triangular with nonnegative diagonal elements and Π is a permutation matrix chosen to permute the largest diagonal element to the pivot position at each stage of the reduction (see [14, Section 4.2.9]). For the usual Cholesky factorization, as computed by `chol`, Π is the identity. Whereas `chol` can break down when presented with a Hermitian positive semi-definite matrix that is singular, `cholp` will always succeed.

• `cod` computes the complete orthogonal decomposition of a rank r matrix $A \in \mathbf{C}^{m\times n}$,

$$A = U \begin{bmatrix} R & 0 \\ 0 & 0 \end{bmatrix} V,$$

where $R \in \mathbf{C}^{r\times r}$ is upper triangular and $U \in \mathbf{C}^{m\times m}$ and $V \in \mathbf{C}^{n\times n}$ are unitary. The criterion used to define the numerical rank is a simple one based on the diagonal elements of the upper triangular matrix from the QR factorization with column pivoting. The complete orthogonal decomposition is an important tool in rank-deficient least squares problems [14, Sec. 5.5.2], [37].

• `diagpiv` implements the diagonal pivoting factorization with partial pivoting of a symmetric matrix A. It produces the factorization $PAP^T = LDL^T$, where P is a permutation, L is unit lower triangular, and D is block diagonal with 1×1 and 2×2 diagonal blocks. The Bunch–Kaufman partial pivoting strategy is used [4].

• `ge` implements Gaussian elimination without pivoting. This routine is similar to `lu`, except that no row interchanges are done. Thus the routine computes, if possible, the LU factorization

$A = LU$ of $A \in \mathbf{C}^{n\times n}$. The routine is of pedagogical interest, but also of practical interest because there are certain classes of $Ax = b$ problem where a more accurate solution is obtained from LU factorization when there are no row or column interchanges [20], [26].

• `gecp` implements Gaussian elimination with complete pivoting. Thus it computes the factorization $PAQ = LU$ of $A \in \mathbf{C}^{n\times n}$, where P and Q are permutation matrices and L and U are lower and upper triangular, respectively. At the kth stage of the reduction of A to triangular form, row and column interchanges are used to bring the element of largest absolute value in the active submatrix to the pivot position (k,k) [14, Sec. 3.4.8].

• `gj` implements Gauss–Jordan elimination for solving a nonsingular linear system $Ax = b$.

• `poldec` computes the polar decomposition $A = UH \in \mathbf{C}^{m\times n}$, where $H \in \mathbf{C}^{n\times n}$ is Hermitian positive semi-definite and $U \in \mathbf{C}^{m\times n}$ has orthonormal columns or rows, according as $m \geq n$ or $m \leq n$. The polar decomposition is a generalization of the polar representation $z = re^{i\theta}$ for complex numbers. The factor U has the property that when $m \geq n$ it is the nearest matrix with orthonormal columns to A for both the 2-norm and the Frobenius norm:

$$\|A - U\| = \min\{\, \|A - Q\| : Q^*Q = I,\ Q \in \mathbf{C}^{m\times n} \,\}.$$

For more details see [18] or [28].

• `signm` computes the matrix sign decomposition $A = SN \in \mathbf{C}^{n\times n}$, where $S = \mathrm{sign}(A)$ is the matrix sign function [25]. If A has the Jordan canonical form

$$A = XJX^{-1} = X \begin{bmatrix} J_1 & 0 \\ 0 & J_2 \end{bmatrix} X^{-1},$$

where the eigenvalues of J_1 lie in the open left half-plane and those of J_2 lie in the open right half-plane, then

$$\mathrm{sign}(A) = X \begin{bmatrix} -I & 0 \\ 0 & I \end{bmatrix} X^{-1}.$$

(The sign function is not defined if A has any pure imaginary eigenvalues). The matrix sign function has several applications and is the subject of much recent research; see [25] for details and further references. Since $\mathrm{sign}(A)^2 = I$, `signm` provides one way to generate involutary matrices.

The toolbox contains further miscellaneous routines, including the following ones.

`bandred`: bandwidth reduction by unitary transformation (called by `randsvd`).

`comp`: forms comparison matrices.

`cond`: generalizes the `cond` function supplied with MATLAB 4.0 to work with the 1, ∞ and Frobenius norms (for square matrices) as well as the 2-norm.

`qmult`: Premultiplies a matrix by a random real orthogonal matrix from the Haar distribution (called by `randsvd`).

`seqa`, `seqm`: form additive or multiplicative sequences.

`sparsify`: randomly sets elements of a matrix to zero.

`pnorm`: estimates the p-norm of a matrix for $1 \leq p \leq \infty$ (MATLAB's `norm` works only for $p = 1, 2, \infty$, `'fro'`).

`eigsens`: evaluates the Wilkinson condition numbers for the eigenvalues of a matrix.

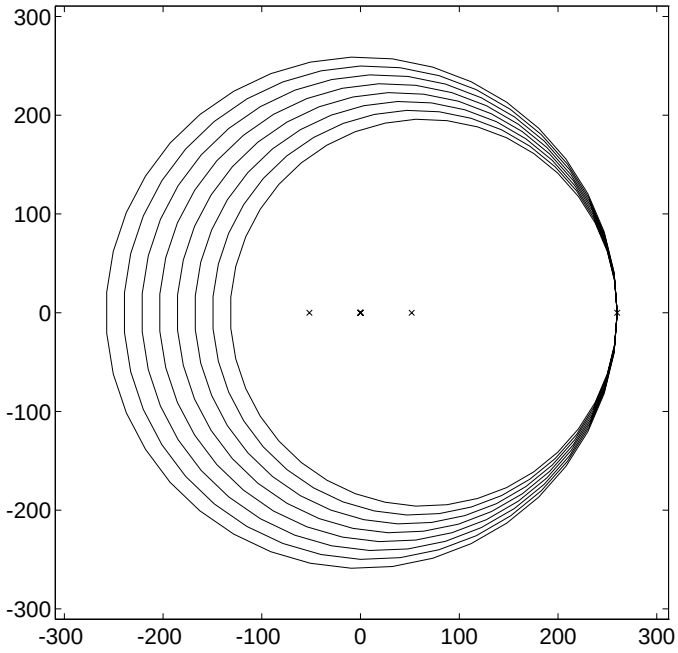

Figure 9.1: Gershgorin disks for `magic(8)`.

9 Examples

In this section we give examples of the use of the toolbox and explain some of the interesting properties of magic squares and the Frank matrix.

9.1 Magic Squares

In the winter 1993 MathWorks Newsletter, Moler described some of the fascinating properties of magic squares, as embodied in MATLAB's `magic` function [32]. Some further properties can be illustrated with the aid of the toolbox. Recall that a magic square is an $n \times n$ matrix containing the integers from 1 to n^2 whose row and column sums are all the same. Let μ_n denote the magic sum of `magic(n)` (thus, $\mu_n = n(n^2+1)/2$).

Moler pointed out that the largest singular value of `A = magic(n)` (namely `max(svd(A))`) is μ_n, but left the proof as an exercise. The largest singular value of A is its 2-norm, so the problem is to prove that $\|A\|_2 = \mu_n$. This leads naturally to the question of what is the p-norm of a magic square, for any p between 1 and ∞. The Hölder p-norm of an $m \times n$ matrix A is defined by

$$\|A\|_p = \max_{x \neq 0} \frac{\|Ax\|_p}{\|x\|_p}, \tag{9.1}$$

where $p \geq 1$ and $\|x\|_p = (\sum_{i=1}^{n} |x_i|^p)^{1/p}$. We can investigate the p-norm of a magic square using the toolbox function `pnorm`, which computes an *estimate* of $\|A\|_p$ using a generalization of the power method.

```
for p = [1 1.5 2 exp(1) pi 10 inf]
    fprintf(' %9.4f    %9.4f\n', p, pnorm(magic(10),p))
end
    1.0000     505.0000
    1.5000     504.9968
    2.0000     504.9968
```

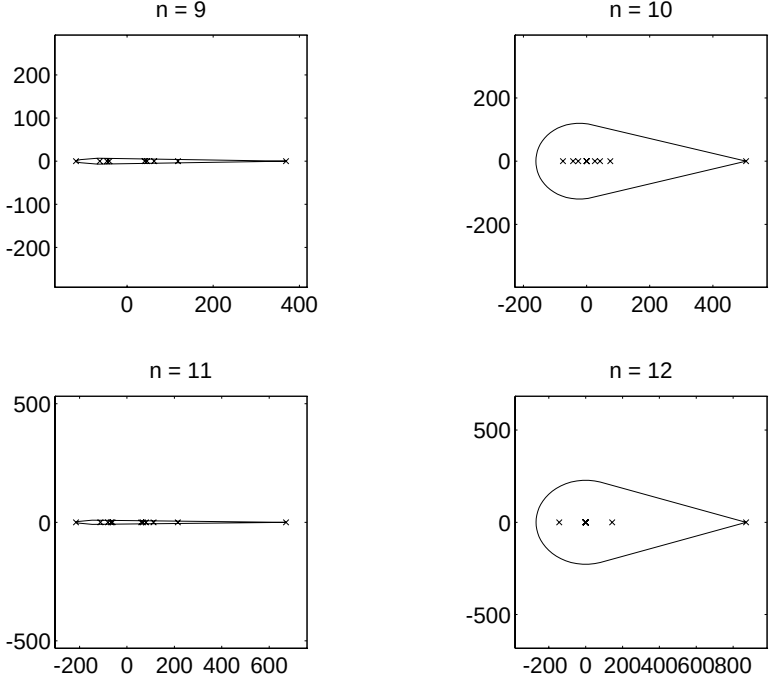

Figure 9.2: Field of values for `magic(n)`.

```
    2.7183      504.9971

   10.0000      504.9988
       Inf      505.0000
```

All the p-norms in this example are very close to $\mu_{10} = 505$. Since the default convergence tolerance for `pnorm` is 10^{-4}, the exact p-norms could all be 505, as far as we can tell from the estimates. In fact, $\|A\|_p \equiv \mu_n$ for all $1 \leq p \leq \infty$. The proof relies on the convexity of the p-norm, which yields the inequality (see, [22], for example)

$$\|A\|_p \leq \|A\|_1^{1/p} \|A\|_\infty^{1-1/p}.$$

(This inequality is well-known for $p = 2$.) For a magic square, $\|A\|_1 = \|A\|_\infty = \mu_n$, so the inequality gives $\|A\|_p \leq \mu_n$. But by taking x in (9.1) to be the vector of all ones, we see that $\|A\|_p \geq \mu_n$, and so it follows that $\|A\|_p = \mu_n$. This result is actually a special case of an apparently little-known 1962 result of Stoer and Witzgall, which says that the norm of a doubly stochastic matrix is 1 for any norm subordinate to a permutation-invariant absolute vector norm [38].

To estimate the eigenvalues of `magic(n)` we can apply Gershgorin's theorem. Unfortunately, the results are not very informative because the Gershgorin disks are all approximately the same, as is clear from the structure of the matrix; see Figure 9.1.

In his article, Moler pointed out that the function `magic` uses different algorithms for odd n, even n divisible by 4, and even n not divisible by 4. He gave four `mesh` plots to illustrate the difference. Another approach is to look at the fields of values—see Figure 9.2. The plot for $n = 10$ reflects the fact that `magic(n)` has rank $n/2 + 2$ when n is even and not divisible by 4—there are only 6 eigenvalues away from the origin (`magic(10)` is diagonalizable). For n divisible by 4 the rank is only 3.

9.2 The Frank Matrix

A famous test matrix for eigensolvers is the $n \times n$ upper Hessenberg matrix F_n introduced by Frank in 1958 [11], illustrated for $n = 8$ by

```
F = frank(8)

F =

     8     7     6     5     4     3     2     1
     7     7     6     5     4     3     2     1
     0     6     6     5     4     3     2     1
     0     0     5     5     4     3     2     1
     0     0     0     4     4     3     2     1
     0     0     0     0     3     3     2     1
     0     0     0     0     0     2     2     1
     0     0     0     0     0     0     1     1
```

In evaluating three eigenvalue algorithms Frank found that this matrix "gives our selected procedures difficulties", and that "accuracy was lost in the smaller roots". The difficulties encountered by Frank's codes were shown by Wilkinson [44, Section 8], [45, pp. 92–93] to be caused by the inherent sensitivity of the eigenvalues to perturbations in the matrix.

The Frank matrix is interesting to analyze using MATLAB. The toolbox function `eigsens` evaluates the Wilkinson eigenvalue condition numbers, which are the reciprocals of the cosines of the angles between the left and right eigenvectors:

```
F = frank(10);
[V, D, s] = eigsens(F); d = diag(D); [x, k] = sort(d);
[d(k) s(k)]  % Eigenvalue followed by its condition number.
ans =

  3.9100e-002  1.4082e+005
  6.7743e-002  2.5897e+005
  1.2426e-001  1.4103e+005
  2.5692e-001  2.4028e+004
  6.1859e-001  1.1837e+003
  1.6166e+000  3.1920e+001
  3.8922e+000  2.2871e+000
  8.0476e+000  1.8287e+000
  1.4762e+001  3.0303e+000
  2.5575e+001  2.3393e+000
```

The output shows that the condition numbers grow, almost monotonically, as the eigenvalues decrease in size—in other words, the smallest eigenvalues are the most sensitive to perturbations in the matrix. The varying eigenvalue sensitivities can also be seen from pseudospectral plots. Figure 9.3 shows the 0.1-pseudospectrum, which shows that perturbations to F_{10} of 2-norm at most 0.1 have the greatest effect on the smallest eigenvalues. Another view is provided by Figure 9.4, for which we set `colormap hot`.

Further insight into the eigenvalues of F_n can be obtained by looking at its characteristic polynomial:

```
poly(F)
```

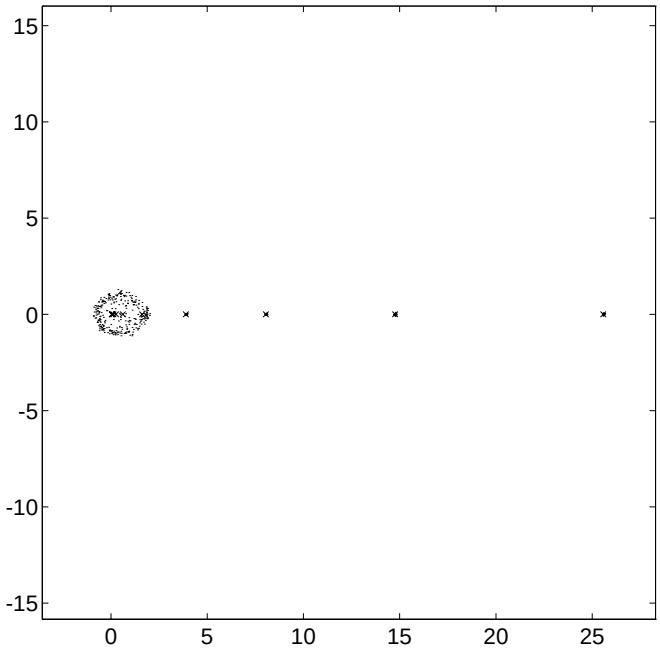

Figure 9.3: `ps(frank(10), 50, 1e-1, 0, 1)`.

```
ans =

  1.0e+004 *

  Columns 1 through 7

    0.0001   -0.0055    0.1035   -0.8310    2.9505   -4.5297    2.9505

  Columns 8 through 11

   -0.8310    0.1035   -0.0055    0.0001
```

The coefficients seem to be palindromic! As a check we use the function `charpoly` from MATLAB 4's Maple Symbolic Toolbox [5] to compute the characteristic polynomial exactly:

```
charpoly(F)

ans =

1-55*x+1035*x^2-8310*x^3+29505*x^4-45297*x^5+29505*x^6-8310*x^7+1035*x^8-55*x^9+x^10
```

Any matrix whose characteristic polynomial π_n has a palindromic coefficient vector has eigenvalues occurring in reciprocal pairs, since $\pi_n(\lambda) = \lambda^n \pi_n(1/\lambda)$. In particular, it has determinant 1, and 1 is an eigenvalue when n is odd. We can check the determinant property numerically:

```
F = frank(20); [det(F) det(F')]

ans =
```

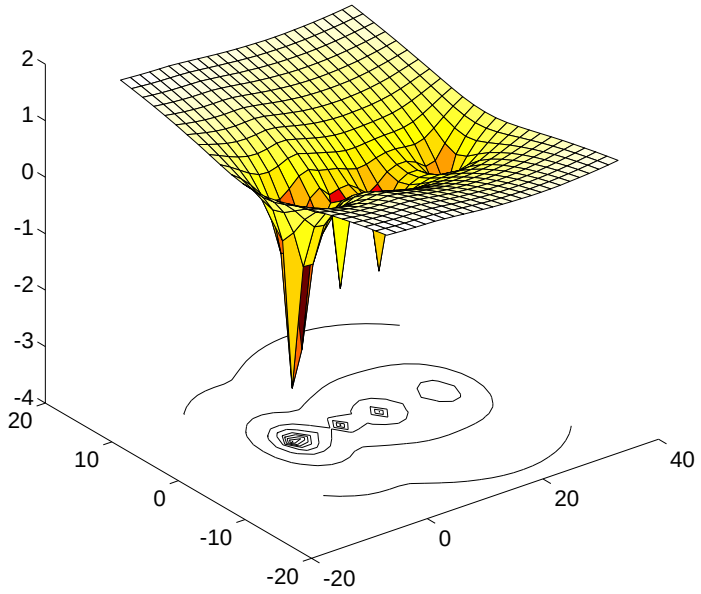

Figure 9.4: `pscont(frank(10), 2, 25, [-7 33 -20 20])`.

```
     1   -14

F = frank(25); [det(F) det(F')]

ans =

            1   -48886168
```

Since $\det(A) = \det(A^T)$ for any matrix A, the output is mathematically incorrect. The reason is that rounding errors influence MATLAB's evaluation of $\det(F_n^T)$ much more than its evaluation of $\det(F_n)$; an illuminating discussion of this phenomenon is given by Frank [11] and Wilkinson [44, Section 8], [45, pp. 92–93]. The extreme sensitivity of $\det(F_n)$ to perturbations in F_n is easy to see: if we change the $(1,n)$ element from 1 to $1+\epsilon$, then $\det(F_n)$ changes from 1 to $1 + (-1)^n(n-1)!\epsilon$.

The inverse of F_n is lower Hessenberg. This can be seen using the following representation of F_n noted by Rutishauser [36, Sec. 9]:

$$F_n = PC_nP,$$

where P is the identity with the order of its columns reversed (`I = eye(n); P = I(:, n:-1:1)` in MATLAB notation) and

$$C_n = \begin{bmatrix} 1 & & & & \\ -1 & 1 & & & \\ & -1 & 1 & & \\ & & \ddots & \ddots & \\ & & & -1 & 1 \end{bmatrix}^{-1} \begin{bmatrix} 1 & 1 & & & \\ & 1 & 2 & & \\ & & 1 & \ddots & \\ & & & \ddots & n-1 \\ & & & & 1 \end{bmatrix}.$$

(By manipulating the identity $\det(F_n - \lambda I) = \det(C_n - \lambda I)$ the reciprocal pair property of the eigenvalues can be proved; cf. [42].) As an illustration, here is the exact inverse as returned

by the Maple Symbolic Toolbox (the MATLAB function `inv` produces nonzero, but tiny, upper triangular elements because of rounding errors):

```
inverse(frank(8))

ans =

[    1,    -1,    0,    0,   0,  0,  0,  0]
[   -7,     8,   -1,    0,   0,  0,  0,  0]
[   42,   -48,    7,   -1,   0,  0,  0,  0]
[ -210,   240,  -35,    6,  -1,  0,  0,  0]
[  840,  -960,  140,  -24,   5, -1,  0,  0]
[-2520,  2880, -420,   72, -15,  4, -1,  0]
[ 5040, -5760,  840, -144,  30, -8,  3, -1]
[-5040,  5760, -840,  144, -30,  8, -3,  2]
```

In his 1958 paper, Frank commented

> "At the moment, the largest matrices resolved on the [Univac] 1103A are two 20-order matrices, one real symmetric and one complex. In both cases computing time was approximately one hour, and 6–8 places of accuracy were obtained."

The complete eigensystem of a complex 20×20 matrix A is found in under a second by the MATLAB command `eig(A)` on the workstation used for the examples reported here! This improvement over Frank's timing is attributable not only to hardware advances but also to an algorithmic breakthrough: `eig` uses the QR algorithm, which was not available to Frank.

9.3 Numerical Linear Algebra

The Test Matrix Toolbox M-files embody some well-known and other not so well-known results from numerical linear algebra.

The function `gfpp` generates $n \times n$ matrices that produce the maximum growth of 2^{n-1} for Gaussian elimination with partial pivoting; these include Wilkinson's classic example [45, p. 212]

```
gfpp(7)

ans =

     1     0     0     0     0     0     1
    -1     1     0     0     0     0     1
    -1    -1     1     0     0     0     1
    -1    -1    -1     1     0     0     1
    -1    -1    -1    -1     1     0     1
    -1    -1    -1    -1    -1     1     1
    -1    -1    -1    -1    -1    -1     1
```

as well as all members of the "2^{n-1} class" described by Higham and Higham [27]. The following extract uses the toolbox routine `gecp` to evaluate the growth factor for complete pivoting on the Wilkinson matrix.

```
n = 20; A = gfpp(n);
[L, U] = lu(A);    % Partial pivoting.
[max(max(abs(U))) / max(max(abs(A)))  2^(n-1)] % Approximation to growth factor.

ans =

      524288      524288

% Complete pivoting using toolbox routine GECP.
[L, U, P, Q, rho] = gecp(A); rho

rho =

     2
```

As the output shows, complete pivoting is perfectly stable for these matrices. However, several of the matrices produced by `orthog` yield relatively large growth for complete pivoting: growth of order $n/2$ for real data, or n for a particular complex matrix [27].

```
n = 50;
for k = [-2 -1 1 2 3]
    A = orthog(n, k);
    [L, U, P, Q, rho] = gecp(A);
    fprintf(' %g\n', rho)
end
 25.3116
 24.7028
 25.6214
 25.3296
 50

A = hadamard(64);
[L, U, P, Q, rho] = gecp(A); rho

rho =

    64
```

It is easy to show that complete pivoting suffers growth of at least n for an $n \times n$ Hadamard matrix. However, Hadamard matrices do not exist for all n.

The MATLAB function `rcond` computes an upper bound for $\kappa_1(A)^{-1} = (\|A\|_1\|A^{-1}\|_1)^{-1}$ using the LINPACK condition estimation algorithm. Although this algorithm is very reliable in general, parametrized matrices are known for which it can perform arbitrarily badly [6]. Here are two examples, from the toolbox routine `condex`. The underestimation ratio is approximately the same in both examples, but the second is probably the more serious because `rcond` does not detect any ill-conditioning whatsoever.

```
A = condex(4, 1, 1e8);  format short e
% True         estimate     true/estimate
[cond(A,1)  1/rcond(A)  cond(A,1)*rcond(A)]

ans =
```

```
  8.0000e+016   5.6000e+008   1.4286e+008

A = condex(3, 2, 1e8);
[cond(A,1)   1/rcond(A)   cond(A,1)*rcond(A)]

ans =

  6.0000e+008   7.5000e+000   8.0000e+007
```

The QR decomposition with column pivoting of $A \in \mathbf{C}^{m\times n}$ $(m \geq n)$ is a decomposition $A\Pi = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$ where Π is a permutation matrix chosen according to a certain pivoting strategy, Q is orthogonal, and R is upper triangular [14, Section 5.4.1]. This decomposition is often used to estimate the rank of A; in particular, $|r_{nn}|$ provides an upper bound for the smallest singular value $\sigma_{\min}(A)$ of A that is usually at most a factor of 10 too big. Kahan [30] designed a matrix for which $|r_{nn}|$ can be approximately 2^{n-1} times bigger than $\sigma_{\min}(A)$, and which thus shows the fallibility of the QR decomposition with column pivoting for revealing rank. The toolbox function `kahan` generates Kahan's matrix:

```
n = 25;
A = kahan(n, 0.6);
[Q, R, Pi] = qr(A);
norm(Pi-eye(n),1), R(n,n)/min(svd(A))

ans =

     0

ans =

  1.0638e+006
```

Kahan's matrix $A(\theta)$ is upper triangular and is designed so that Π is the identity in the QR decomposition with column pivoting. In practice, rounding errors can cause Π to differ from the identity for the Kahan matrix, thus nullifying the example (the test on $\Pi - I$ in the above example confirms that Π is indeed the identity here). The toolbox routine adds a small perturbation to the diagonal elements of $A(\theta)$ so that $\Pi = I$ for a range of choices of n and θ. If we set the perturbation in the above example to zero, this is what happens:

```
A = kahan(n, 0.6, 0);  % Third parameter is the diagonal perturbation.
[Q, R, Pi] = qr(A);
norm(Pi-eye(n),1), R(n,n)/min(svd(A))

ans =

     2

ans =

    1.1953
```

The toolbox contains two matrices, one a Toeplitz matrix and the other a Hankel matrix, whose eigenvalues or singular values are related to π:

```
A = parter(10); format long
e = svd(A); [e  e-pi]

ans =

   3.14159265358968  -0.00000000000011

   0.65048453501485  -0.92031179178005
```

Finally, here is an example of the use of the function `matrix` to access the test matrices sequentially, by number. The following piece of code steps through all the square matrices of arbitrary dimension, setting A to each 10×10 matrix in turn (any matrix parameters are at their default values). It evaluates the 2-norm condition number and the ratio $\mu(A) = \max_i |\lambda_i(A)| / \min_i |\lambda_i(A)|$ of the largest to smallest eigenvalue in absolute value.

```
c = []; e = [];
j = 1;
for i=1:matrix(0)
    A = full(matrix(i, 10));
    if norm(skewpart(A),1)  % If not Hermitian...
       c1 = cond(A);
       eg = eig(A);
       e1 = max(abs(eg)) / min(abs(eg));
       % Filter out extremely ill-conditioned matrices.
```

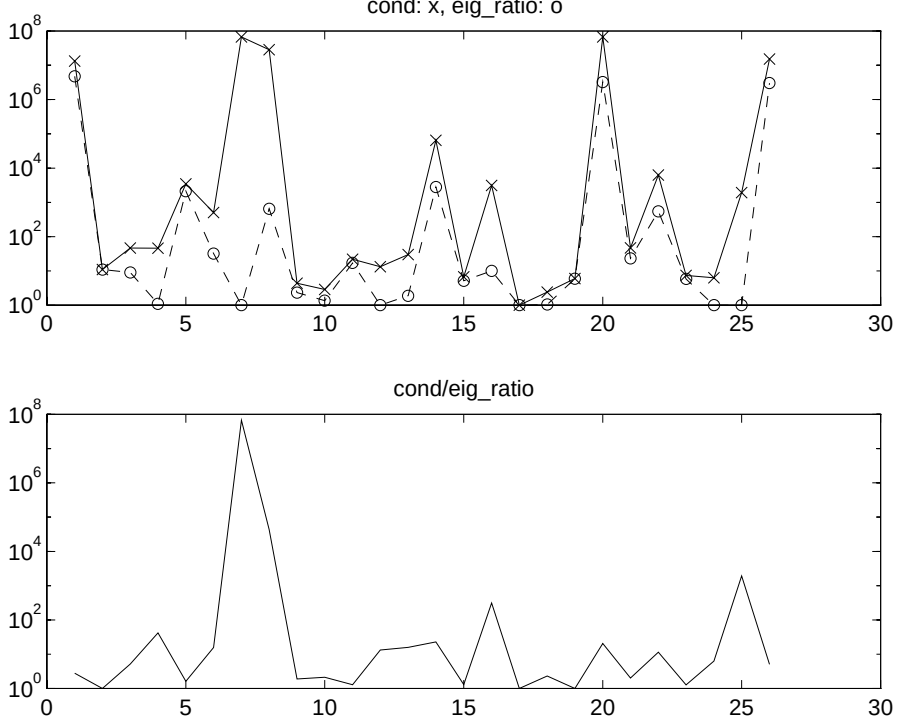

Figure 9.5: Comparison of condition number with extremal eigenvalue ratio.

```
        if c1 <= 1e10, c(j) = c1; e(j) = e1; j = j + 1; end
    end
end
```

As is well known, $\kappa_2(A)$ can be arbitrarily larger than $\mu(A)$. The plots in Figure 9.5, produced from the vectors `c` and `e` from the above code, confirm that $\kappa_2(A)/\mu(A)$ can be large.

%           Vandermonde-like systems, SIAM J. Matrix Anal. Appl., 11 (1990),
%           pp. 23-41.
```

```
function [R, P, I] = cholp(A, pivot)
%CHOLP  Cholesky factorization with pivoting of a pos. semidefinite matrix.
%       [R, P] = CHOLP(A) returns R and a permutation matrix P such that
%       R'*R = P'*A*P.  Only the upper triangular part of A is used.
%       [R, P, I] = CHOLP(A) returns in addition the index I of the last
%       positive diagonal element of R.  The first I rows of R contain
%       the Cholesky factor of A.
```

```
%       [R, I] = CHOLP(A, 0) forces P = EYE(SIZE(A)), and therefore produces
%       the same output as R = CHOL(A) when A is positive definite (to
%       within roundoff).

%       This routine is based on the LINPACK routine CCHDC.  It works
%       for both real and complex matrices.

%          companion form systems, Math. Control Signals Systems, 1 (1988),
%          pp. 239-256. (Gives explicit formulas for the singular values of
%          COMPAN(P).)
```

```
function y = cond(A, p)
%COND   Matrix condition number in 1, 2, Frobenius, or infinity norm.
%       For p = 1, 2, 'fro', inf,  COND(A,p) = NORM(A,p) * NORM(INV(A),p).
%       If p is omitted then p = 2 is used.
%       A may be a rectangular matrix if p = 2; in this case COND(A)
%       is the ratio of the largest singular value of A to the smallest
%       (and hence is infinite if A is rank deficient).
```

```
function A = condex(n, k, theta)
%CONDEX   'Counterexamples' to matrix condition number estimators.
%         CONDEX(N, K, THETA) is a 'counterexample' matrix to a condition
%         estimator.  It has order N and scalar parameter THETA (default 100).
%         If N is not equal to the 'natural' size of the matrix then
%         the matrix is padded out with an identity matrix to order N.
%         The matrix, its natural size, and the estimator to which it applies
%         are specified by K (default K = 4) as follows:
%             K = 1:   4-by-4,     LINPACK (RCOND)
%             K = 2:   3-by-3,     LINPACK (RCOND)
%             K = 3:   arbitrary,  LINPACK (RCOND) (independent of THETA)
%             K = 4:   N >= 4,     SONEST (Higham 1988)
%         (Note that in practice the K = 4 matrix is not usually a
%          counterexample because of the rounding errors in forming it.)
```

```

```
function [c, d, e] = dorr(n, theta)
%DORR  Dorr matrix - diagonally dominant, ill conditioned, tridiagonal.
%      [C, D, E] = DORR(N, THETA) returns the vectors defining a row diagonally
%      dominant, tridiagonal M-matrix that is ill conditioned for small
%      values of the parameter THETA >= 0.
%      If only one output parameter is supplied then
%      C = FULL(TRIDIAG(C,D,E)), i.e., the matrix iself is returned.
%      The columns of INV(C) vary greatly in norm.  THETA defaults to 0.01.
%      The amount of diagonal dominance is given by (ignoring rounding errors):
%            COMP(C)*ONES(N,1) = THETA*(N+1)^2 * [1 0 0 ... 0 1]'.

%      Reference:
%      F.W. Dorr, An example of ill-conditioning in the numerical
%      solution of singular perturbation problems, Math. Comp., 25 (1971),
%      pp. 271-283.
```

```
function A = dramadah(n, k)
%DRAMADAH  A (0,1) matrix whose inverse has large integer entries.
%          An anti-Hadamard matrix A is a matrix with elements 0 or 1 for
%          which MU(A) := NORM(INV(A),'FRO') is maximal.
%          A = DRAMADAH(N, K) is an N-by-N (0,1) matrix for which MU(A) is
%          relatively large, although not necessarily maximal.
%          Available types (the default is K = 1):
%          K = 1: A is Toeplitz, with ABS(DET(A)) = 1, and MU(A) > c(1.75)^N,
%                 where c is a constant.
%          K = 2: A is upper triangular and Toeplitz.
%          The inverses of both types have integer entries.
%
%          Another interesting (0,1) matrix:
%          K = 3: A has maximal determinant among (0,1) lower Hessenberg
%          matrices: det(A) = the n'th Fibonacci number.  A is Toeplitz.
%          The eigenvalues have an interesting distribution in the complex
%          plane.

```
function A = forsythe(n, alpha, lambda)
%FORSYTHE  Forsythe matrix - a perturbed Jordan block.
%          FORSYTHE(N, ALPHA, LAMBDA) is the N-by-N matrix equal to
%          JORDBLOC(N, LAMBDA) except it has an ALPHA in the (N,1) position.
%          It has the characteristic polynomial
%                  DET(A-t*EYE) = (LAMBDA-t)^N - (-1)^N ALPHA.
%          ALPHA defaults to SQRT(EPS) and LAMBDA to 0.
```

```
function F = frank(n, k)
%FRANK   Frank matrix---ill conditioned eigenvalues.
%        F = FRANK(N, K) is the Frank matrix of order N.  It is upper
%        Hessenberg with determinant 1.  K = 0 is the default; if K = 1 the
%        elements are reflected about the anti-diagonal (1,N)--(N,1).
%        F has all positive eigenvalues and they occur in reciprocal pairs
%        (so that 1 is an eigenvalue if N is odd).
%        The eigenvalues of F may be obtained in terms of the zeros of the
%        Hermite polynomials.
%        The FLOOR(N/2) smallest eigenvalues of F are ill conditioned,
%        the more so for bigger N.

%        DET(FRANK(N)') comes out far from 1 for large N---see Frank (1958)
%        and Wilkinson (1960) for discussions.
%
%        This version incorporates improvements suggested by W. Kahan.

```
function [f, e] = fv(B, nk, thmax, noplot)
%FV     Field of values (or numerical range).
%       FV(A, NK, THMAX) evaluates and plots the field of values of the
%       NK largest leading principal submatrices of A, using THMAX
%       equally spaced angles in the complex plane.
%       The defaults are NK = 1 and THMAX = 16.
%       (For a 'publication quality' picture, set THMAX higher, say 32.)
%       The eigenvalues of A are displayed as 'x'.
%       Alternative usage: [F, E] = FV(A, NK, THMAX, 1) suppresses the
%       plot and returns the field of values plot data in F, with A's
%       eigenvalues in E.   Note that NORM(F,INF) approximates the
%       numerical radius,
%                 max {abs(z): z is in the field of values of A}.

%       Theory:
%       Field of values FV(A) = set of all Rayleigh quotients. FV(A) is a
%       convex set containing the eigenvalues of A.  When A is normal FV(A) is
%       the convex hull of the eigenvalues of A (but not vice versa).
%               z = x'Ax/(x'x),  z' = x'A'x/(x'x)
%               => REAL(z) = x'Hx/(x'x),   H = (A+A')/2
%       so      MIN(EIG(H)) <= REAL(z) <= MAX(EIG(H))
%       with equality for x = corresponding eigenvectors of H.  For these x,
%       RQ(A,x) is on the boundary of FV(A).
%

%        M. Lotkin, A set of test matrices, MTAC, 9 (1955), pp. 153-161.
```

```
function A = makejcf(n, e, m, X)
%MAKEJCF   A matrix with given Jordan canonical form.
%          MAKEJCF(N, E, M) is a matrix having the Jordan canonical form
%          whose i'th Jordan block is of dimension M(i) with eigenvalue E(i),
%          and where N = SUM(M).
%          Defaults: E = 1:N, M = ONES(SIZE(E)) with M(1) so that SUM(M) = N.
%          The matrix is constructed by applying a random similarity
%          transformation to the Jordan form.
%          Alternatively, the matrix used in the similarity transformation
%          can be specified as a fifth parameter.
```

```
%          In particular, MAKEJCF(N, E, M, EYE(N)) returns the Jordan form
%          itself.
%          NB: The JCF is very sensitive to rounding errors.
```

```
function A = matrix(k, n)
%MATRIX    Test Matrix Toolbox information and matrix access by number.
%          MATRIX(K, N) is the N-by-N instance of the matrix number K in
%          the Test Matrix Toolbox (including some of the matrices provided
%          with MATLAB), with all other parameters set to their default.
%          N.B. Only those matrices which take an arbitrary dimension N
%               are included (thus GALLERY is omitted, for example).
%          MATRIX(K) is a string containing the name of the K'th matrix.
%          MATRIX(0) is the number of matrices, i.e. the upper limit for K.
%          Thus to set A to each N-by-N test matrix in turn use a loop like
%                for k=1:matrix(0)
%                    A = matrix(k, N);
%                    Aname = matrix(k);   % The name of the matrix
%                end
%          MATRIX(-1) returns the version number and date of the toolbox.
%          MATRIX with no arguments lists the names of the M-files in the
%          collection.

%          References:

%             MATLAB, ACM Trans. Math. Soft., 17 (1991), pp. 289-305.
%
%          Matrices omitted are: gallery, hadamard, hanowa, lauchli,
%          neumann, wathen, wilk.
%          Matrices provided with MATLAB that are included here: invhilb,
%          magic.
```

```
function S = matsignt(T)
%MATSIGNT    Matrix sign function of a triangular matrix.
%            S = MATSIGN(T) computes the matrix sign function S of the
%            upper triangular matrix T using a recurrence.

%            Adapted from FUNM.  Called by SIGNM.
```

```
function [x, fmax, nf] = mdsmax(fun, x, stopit, savit)
%MDSMAX  Multidirectional search method for direct search optimization.
%        [x, fmax, nf] = MDSMAX(fun, x0, STOPIT, SAVIT) attempts to
%        maximize the function specified by the string fun, using the
%        starting vector x0.  The method of multidirectional search is used.
%        Output arguments:
%               x    = vector yielding largest function value found,
```

```
%               fmax = function value at x,
%               nf   = number of function evaluations.
%       The iteration is terminated when either
%               - the relative size of the simplex is <= STOPIT(1)
%                 (default 1e-3),
%               - STOPIT(2) function evaluations have been performed
%                 (default inf, i.e., no limit), or
%               - a function value equals or exceeds STOPIT(3)
%                 (default inf, i.e., no test on function values).
%       The form of the initial simplex is determined by STOPIT(4):
%          STOPIT(4) = 0: regular simplex (sides of equal length, the default)
%          STOPIT(4) = 1: right-angled simplex.
%       Progress of the iteration is not shown if STOPIT(5) = 0 (default 1).
%       If a non-empty fourth parameter string SAVIT is present, then
%       'SAVE SAVIT x fmax nf' is executed after each inner iteration.
%       NB: x0 can be a matrix.  In the output argument, in SAVIT saves,
%           and in function calls, x has the same shape as x0.

function [est, x, k] = pnorm(A, p, tol, noprint)
%PNORM   Estimate of matrix p-norm (1 <= p <= inf).
%        [EST, x, k] = PNORM(A, p, TOL) estimates the Holder p-norm of a
%        matrix A, using the p-norm power method with a specially
%        chosen starting vector.
%        TOL is a relative convergence tolerance (default 1E-4).
%        Returned are the norm estimate EST (which is a lower bound for the
%        exact p-norm), the corresponding approximate maximizing vector x,
%        and the number of power method iterations k.
%        A nonzero fourth argument causes trace output to the screen.
%        If A is a vector, this routine simply returns NORM(A, p).
%
%        See also NORM, NORMEST.

%        Note: The estimate is exact for p = 1, but is not always exact for
%        p = 2 or p = inf.  Code could be added to treat p = 2 and p = inf
%        separately.

%          187:269--278, 1993.
```

```
function y = ps(A, m, tol, rl, marksize)
%PS     Dot plot of a pseudospectrum.
%       PS(A, M, TOL, RL) plots an approximation to a pseudospectrum
%       of the square matrix A, using M random perturbations of size TOL.
%       M defaults to a SIZE(A)-dependent value and TOL to 1E-3.
%       RL defines the type of perturbation:
%         RL =  0 (default): absolute complex perturbations of 2-norm TOL.
%         RL =  1:           absolute real perturbations of 2-norm TOL.
%         RL = -1:           componentwise real perturbations of size TOL.
%       The eigenvalues of A are plotted as crosses 'x'.
%       PS(A, M, TOL, RL, MARKSIZE) uses the specified marker size instead
%       of a size that depends on the figure size, the matrix order, and M.
```

```
%       If MARKSIZE < 0, the plot is suppressed and the plot data is returned
%       as an output argument.
%       PS(A, 0) plots just the eigenvalues of A.

%       For a given TOL, the pseudospectrum of A is the set of
%       pseudo-eigenvalues of A, that is, the set
%       { e : e is an eigenvalue of A+E, for some E with NORM(E) <= TOL }.
%
%       Reference:
%       L.N. Trefethen, Pseudospectra of matrices, in D.F. Griffiths and
%            G.A. Watson, eds, Numerical Analysis 1991, Proceedings of the 14th
%            Dundee Conference, vol. 260, Pitman Research Notes in Mathematics,

```

```
function [x, y, z, m] = pscont(A, k, npts, ax, levels)
%PSCONT   Contours and colour pictures of pseudospectra.
%         PSCONT(A, K, NPTS, AX, LEVELS) plots LOG10(1/NORM(R(z))),
%         where R(z) = INV(z*I-A) is the resolvent of the square matrix A,
%         over an NPTS-by-NPTS grid.
%         NPTS defaults to a SIZE(A)-dependent value.
%         The limits are AX(1) and AX(2) on the x-axis and
%                        AX(3) and AX(4) on the y-axis.
%         If AX is omitted, suitable limits are guessed based on the
%         eigenvalues of A.
%         The eigenvalues of A are plotted as crosses 'x'.
%         K determines the type of plot:
%             K = 0 (default) PCOLOR and CONTOUR
%             K = 1           PCOLOR only
%             K = 2           SURFC (SURF and CONTOUR)
%             K = 3           SURF only
%             K = 4           CONTOUR only
%         The contours levels are specified by the vector LEVELS, which
%         defaults to -10:-1 (recall we are plotting log10 of the data).
%         Thus, by default, the contour lines trace out the boundaries of
%         the epsilon pseudospectra for epsilon = 1e-10, ..., 1e-1.
%         [X, Y, Z, NPTS] = PSCONT(A, ...) returns the plot data X, Y, Z
%         and the value of NPTS used.
%
%         After calling this function you may want to change the
%         color map (e.g., type COLORMAP HOT - see HELP COLOR) and the
%         shading (e.g., type SHADING INTERP - see HELP INTERP).
%         For an explanation of the term 'pseudospectra' see PS.M.
%         When A is real and the grid is symmetric about the x-axis, this
%         routine exploits symmetry to halve the computational work.

%         Colour pseduospectral pictures of this type are referred to as
%         'spectral portraits' by Godunov, Kostin, and colleagues.

```

```
function A = rando(n, k)
%RANDO   Random matrix with elements -1, 0 or 1.
%        A = RANDO(N, K) is a random N-by-N matrix with elements from
%        one of the following discrete distributions (default K = 1):
%          K = 1:  A(i,j) =  0 or 1    with equal probability,
%          K = 2:  A(i,j) = -1 or 1    with equal probability,
%          K = 3:  A(i,j) = -1, 0 or 1 with equal probability.
%        N may be a 2-vector, in which case the matrix is N(1)-by-N(2).
```

```
function A = randsvd(n, kappa, mode, kl, ku)
%RANDSVD  Random matrix with pre-assigned singular values.
%      RANDSVD(N, KAPPA, MODE, KL, KU) is a (banded) random matrix of order N
%      with COND(A) = KAPPA and singular values from the distribution MODE.
%      N may be a 2-vector, in which case the matrix is N(1)-by-N(2).
%      Available types:
%             MODE = 1:   one large singular value,
%             MODE = 2:   one small singular value,
%             MODE = 3:   geometrically distributed singular values,
%             MODE = 4:   arithmetically distributed singular values,
%             MODE = 5:   random singular values with unif. dist. logarithm.
%      If omitted, MODE defaults to 3, and KAPPA defaults to SQRT(1/EPS).
%      If MODE < 0 then the effect is as for ABS(MODE) except that in the
%      original matrix of singular values the order of the diagonal entries
%      is reversed: small to large instead of large to small.
%      KL and KU are the lower and upper bandwidths respectively; if they
%      are omitted a full matrix is produced.
%      If only KL is present, KU defaults to KL.
%      Special case: if KAPPA < 0 then a random full symmetric positive
```

```
%                   definite matrix is produced with COND(A) = -KAPPA and
%                   eigenvalues distributed according to MODE.
%                   KL and KU, if present, are ignored.

%SUB     Principal submatrix.
%        SUB(A,i,j) is A(i:j,i:j).
%        SUB(A,i)  is the leading principal submatrix of order i,
%        A(1:i,1:i), if i>0, and the trailing principal submatrix
%        of order ABS(i) if i<0.
```

```
function S = symmpart(A)
%SYMMPART  Symmetric (Hermitian) part.
%          SYMMPART(A) is the symmetric (Hermitian) part of A, (A + A')/2.
%          It is the nearest symmetric (Hermitian) matrix to A in both the
%          2- and the Frobenius norms.
```

```
function [Q, T] = trap2tri(L)
%TRAP2TRI  Unitary reduction of trapezoidal matrix to triangular form.
%          [Q, T] = TRAP2TRI(L), where L is an m-by-n lower trapezoidal
%          matrix with m >= n, produces a unitary Q such that QL = [T; 0],
%          where T is n-by-n and lower triangular.
%          Q is a product of Householder transformations.

%          Called by RANDSVD.
%

%          G.H. Golub and C.F. Van Loan, Matrix Computations, second edition,
%          Johns Hopkins University Press, Baltimore, Maryland, 1989.
%          P5.2.5, p. 220.
```

```
function T = tridiag(n, x, y, z)
%TRIDIAG  Tridiagonal matrix (sparse).
%         TRIDIAG(X, Y, Z) is the tridiagonal matrix with subdiagonal X,
%         diagonal Y, and superdiagonal Z.
%         X and Z must be vectors of dimension one less than Y.
%         Alternatively TRIDIAG(N, C, D, E), where C, D, and E are all
%         scalars, yields the Toeplitz tridiagonal matrix of order N
%         with subdiagonal elements C, diagonal elements D, and superdiagonal
%         elements E.   This matrix has eigenvalues (Todd 1977)
%                  D + 2*SQRT(C*E)*COS(k*PI/(N+1)), k=1:N.
%         TRIDIAG(N) is the same as TRIDIAG(N,-1,2,-1), which is
%         a symmetric positive definite M-matrix (the negative of the
%         second difference matrix).

```

```
function t = triw(n, alpha, k)
%TRIW   Upper triangular matrix discussed by Wilkinson and others.
%       TRIW(N, ALPHA, K) is the upper triangular matrix with ones on
%       the diagonal and ALPHAs on the first K >= 0 superdiagonals.
%       N may be a 2-vector, in which case the matrix is N(1)-by-N(2) and
%       upper trapezoidal.
%       Defaults: ALPHA = -1,
%                 K = N - 1     (full upper triangle).
%       TRIW(N) is a matrix discussed by Kahan, Golub and Wilkinson.
%
%       Ostrowski (1954) shows that
%         COND(TRIW(N,2)) = COT(PI/(4*N))^2,
%       and for large ABS(ALPHA),
%         COND(TRIW(N,ALPHA)) is approximately ABS(ALPHA)^N*SIN(PI/(4*N-2)).
%
%       Adding -2^(2-N) to the (N,1) element makes TRIW(N) singular,
%       as does adding -2^(1-N) to all elements in the first column.

```

```
function V = vand(m, p)
%VAND   Vandermonde matrix.
%       V = VAND(P), where P is a vector, produces the (primal)
%       Vandermonde matrix based on the points P, i.e. V(i,j) = P(j)^(i-1).
%       VAND(M,P) is a rectangular version of VAND(P) with M rows.
%       Special case: If P is a scalar then P equally spaced points on [0,1]
%                     are used.

%       confluent Vandermonde-like systems, SIAM J. Matrix Anal. Appl.,
%       11 (1990), pp. 23-41.
```

```
function A = wathen(nx, ny, k)
%WATHEN  Wathen matrix - a finite element matrix (sparse, random entries).
%        A = WATHEN(NX,NY) is a sparse random N-by-N finite element matrix
%        where N = 3*NX*NY + 2*NX + 2*NY + 1.
%        A is precisely the 'consistent mass matrix' for a regular NX-by-NY
%        grid of 8-node (serendipity) elements in 2 space dimensions.
%        A is symmetric positive definite for any (positive) values of
%        the 'density', RHO(NX,NY), which is chosen randomly in this routine.
%        In particular, if D = DIAG(DIAG(A)), then
%             0.25 <= EIG(INV(D)*A) <= 4.5
%        for any positive integers NX and NY and any densities RHO(NX,NY).
%        This diagonally scaled matrix is returned by WATHEN(NX,NY,1).

%        mass matrix, IMA J. Numer. Anal., 7 (1987), pp. 449-457.
```

```
function [A, b] = wilk(n)
%WILK   Various specific matrices devised/discussed by Wilkinson.
%       [A, b] = WILK(N) is the matrix or system of order N.
%       N = 3: upper triangular system Ux=b illustrating inaccurate solution.
%       N = 4: lower triangular system Lx=b, ill-conditioned.
%       N = 5: HILB(6)(1:5,2:6)*1.8144.  Symmetric positive definite.
%       N = 21: W21+, tridiagonal.   Eigenvalue problem.

Acknowledgements

In preparing the earlier test matrix collections I benefited from the helpful suggestions of people too numerous to mention. While working on version 2.0 of the toolbox I received valuable advice from Cleve Moler and Nick Trefethen, and Per Christian Hansen offered helpful comments on a draft version of the manual accompanying version 2.0.
