# Function Reference

---

Data Processing (p. 1-3)	Represent, process, analyze, and manipulate data
Linear Model Identification (p. 1-5)	Estimate time response, frequency response, transfer function, input-output polynomial, and state-space models from time and frequency domain data
Nonlinear Black-Box Model Identification (p. 1-9)	Estimate nonlinear ARX and Hammerstein-Wiener models
ODE Parameter Estimation (p. 1-12)	Estimate parameters of linear and nonlinear ordinary differential or difference equations (grey-box models)
Recursive Techniques for Model Identification (p. 1-12)	Recursively estimate input-output linear models, such as AR, ARX, ARMAX, Box-Jenkins, and Output-Error models
Model Analysis (p. 1-13)	Validate and analyze models by comparing model output, computing parameter confidence intervals and prediction errors, and getting advice on estimated models

Simulation and Prediction (p. 1-16)	Simulate and predict linear and nonlinear model output, and estimate initial states
GUI (p. 1-17)	Start System Identification Toolbox™ GUI and customize preferences

## Data Processing

<code>advice</code>	Analysis and recommendations for data or estimated linear polynomial and state-space models
<code>covf</code>	Estimate covariance functions for time-domain <code>iddata</code> object
<code>delayest</code>	Estimate time delay (dead time) from data
<code>detrend</code>	Subtract trend from time-domain, frequency-domain, or time-series data signal
<code>diff</code>	Difference signals in <code>iddata</code> objects
<code>fcats</code>	Concatenate frequency-domain signals in <code>idfrd</code> and <code>iddata</code> objects
<code>feedback</code>	Identify possible feedback in <code>iddata</code> data
<code>fft</code>	Transform <code>iddata</code> object to frequency domain
<code>fselect</code>	Frequencies from <code>idfrd</code> object
<code>get</code>	Query properties of data and model objects
<code>getexp</code>	Specific experiments from multiple-experiment data set
<code>iddata</code>	Time- or frequency-domain data
<code>idfilt</code>	Filter data using user-defined passbands, general filters, or Butterworth filters
<code>idfrd</code>	Frequency-response data or model
<code>idinput</code>	Generate input signals
<code>idresamp</code>	Resample time-domain data by decimation or interpolation

<code>ifft</code>	Transform <code>iddata</code> objects from frequency to time domain
<code>isreal</code>	Determine whether model parameters or data values are real
<code>merge (iddata)</code>	Merge data sets into one <code>iddata</code> object
<code>misdata</code>	Reconstruct missing input and output data
<code>nkshift</code>	Shift data sequences
<code>pexcit</code>	Level of excitation of input signals
<code>plot</code>	Plot <code>iddata</code> or model objects
<code>realdata</code>	Determine whether <code>iddata</code> is based on real-valued signals
<code>resample</code>	Resample time-domain data by decimation or interpolation (requires Signal Processing Toolbox™ software)
<code>set</code>	Set properties of data and model objects
<code>size</code>	Dimensions of <code>iddata</code> , <code>idmodel</code> , <code>idn1model</code> , and <code>idfrd</code> objects
<code>timestamp</code>	Return date and time when object was created or last modified

## Linear Model Identification

ar	Estimate parameters of AR model for scalar time series returning idpoly object
armax	Estimate parameters of ARMAX or ARMA model returning idpoly object
arx	Estimate parameters of ARX or AR model using least squares returning idpoly or idarx object
arxdata	ARX parameters from multiple-output idarx or single-output idpoly objects with variance information
arxstruc	Compute and compare loss functions for single-output ARX models
balred	Reduce model order (requires Control System Toolbox™ product)
bj	Estimate parameters of Box-Jenkins model returning idpoly object
c2d	Transform linear model from continuous to discrete time
cra	Estimate impulse response using prewhitened-based correlation analysis
d2c	Transform linear model from discrete to continuous time
delayest	Estimate time delay (dead time) from data
etfe	Estimate empirical transfer functions and periodograms returning idfrd object

<code>feedback</code>	Identify possible feedback in <code>iddata</code> data
<code>frd</code>	Convert <code>idfrd</code> objects to Control System Toolbox frequency-response LTI model
<code>freqresp</code>	Frequency-response data from <code>idmodel</code> or <code>idfrd</code> object
<code>get</code>	Query properties of data and model objects
<code>idarx</code>	Multiple-output ARX polynomials, impulse response, or step response model
<code>idfrd</code>	Frequency-response data or model
<code>idgrey</code>	Linear ODE (grey-box model) with known and unknown parameters
<code>idmodel</code>	Superclass for linear models
<code>idpoly</code>	Linear polynomial input-output model
<code>idproc</code>	Linear, low-order, continuous-time transfer function
<code>idss</code>	State-space model
<code>impulse</code>	Plot impulse response with confidence interval
<code>init</code>	Set or randomize initial parameter values
<code>iv4</code>	Estimate ARX model using four-stage instrumental variable method returning <code>idpoly</code> or <code>idarx</code> object
<code>ivar</code>	Estimate AR model using instrumental variable method returning <code>idpoly</code> object

<code>ivstruc</code>	Loss functions for sets of ARX model structures
<code>ivx</code>	Estimate parameters of ARX model using instrumental variable method with arbitrary instruments returning <code>idpoly</code> or <code>idarx</code> object
LTI Commands	Apply Control System Toolbox commands to <code>idmodel</code> objects
<code>merge</code>	Merge estimated models
<code>n4sid</code>	Estimate state-space models using subspace method returning <code>idss</code> object
<code>nuderst</code>	Set step size for numerical differentiation
<code>oe</code>	Estimate parameters of output-error model returning <code>idpoly</code> object
<code>pem</code>	Estimate model parameters using iterative prediction-error minimization method
<code>pexcit</code>	Level of excitation of input signals
<code>polydata</code>	Polynomial model parameters from single-input and single-output <code>idpoly</code> object
<code>selstruc</code>	Select model order for single-output ARX models
<code>set</code>	Set properties of data and model objects
<code>setpname</code>	Set mnemonic parameter names for linear black-box model structures
<code>setstruc</code>	Set matrix structure for <code>idss</code> objects
<code>size</code>	Dimensions of <code>iddata</code> , <code>idmodel</code> , <code>idnlmodel</code> , and <code>idfrd</code> objects

<code>spa</code>	Estimate frequency response and spectrum using spectral analysis returning <code>idfrd</code> object
<code>spafdr</code>	Estimate frequency response and spectrum using spectral analysis with frequency-dependent resolution returning <code>idfrd</code> object
<code>ss</code>	Convert <code>idmodel</code> objects to Control System Toolbox LTI models
<code>ssdata</code>	State-space matrices from <code>idmodel</code> object
<code>step</code>	Plot step response with confidence interval
<code>struc</code>	Generate model structure matrices for single-input and single-output systems
<code>tf</code>	Convert <code>idmodel</code> objects to transfer-function Control System Toolbox LTI models
<code>tfdata</code>	Numerator and denominator of transfer function from <code>idmodel</code> object
<code>timestamp</code>	Return date and time when object was created or last modified
<code>zpk</code>	Convert <code>idmodel</code> objects to Control System Toolbox state-space LTI models
<code>zpkdata</code>	Zeros, poles, and gains of transfer function from <code>idmodel</code> object

## Nonlinear Black-Box Model Identification

<code>addreg</code>	Add custom regressors to <code>idnlarx</code> model
<code>customnet</code>	Class representing nonlinearity estimator with user-defined unit function for nonlinear ARX and Hammerstein-Wiener models
<code>customreg</code>	Class representing custom regressor for nonlinear ARX models
<code>data2state(idnlarx)</code>	Map past input/output data to current states of <code>idnlarx</code> model
<code>deadzone</code>	Class representing dead-zone nonlinearity estimator for Hammerstein-Wiener models
<code>evaluate</code>	Value of nonlinearity estimator at given input
<code>findop(idnlarx)</code>	Compute operating point for nonlinear ARX model
<code>findop(idnlhw)</code>	Compute operating point for Hammerstein-Wiener model
<code>get</code>	Query properties of data and model objects
<code>getDelayInfo</code>	Get input/output delay information for <code>idnlarx</code> model structure
<code>getreg</code>	Names of standard or custom regressors in nonlinear ARX model
<code>idnlarx</code>	Nonlinear black-box ARX model
<code>idnlhw</code>	Nonlinear black-box Hammerstein-Wiener model
<code>idnlmodel</code>	Superclass for nonlinear models
<code>init</code>	Set or randomize initial parameter values

<code>linapp</code>	Linear approximation of nonlinear ARX and Hammerstein-Wiener models for given input
<code>linear</code>	Specify to estimate nonlinear ARX model that is linear in (nonlinear) custom regressors
<code>linearize(idnlarx)</code>	Linearize nonlinear ARX model
<code>linearize(idnlhw)</code>	Linearize Hammerstein-Wiener model
<code>neuralnet</code>	Class representing neural network object created in Neural Network Toolbox™ product for estimating nonlinear ARX and Hammerstein-Wiener models
<code>nlarx</code>	Estimate nonlinear ARX models
<code>nlhw</code>	Estimate Hammerstein-Wiener models
<code>operspec(idnlarx)</code>	Construct operating point specification object for <code>idnlarx</code> model
<code>operspec(idnlhw)</code>	Construct operating point specification object for <code>idnlhw</code> model
<code>pem</code>	Estimate model parameters using iterative prediction-error minimization method
<code>poly1d</code>	Class representing single-variable polynomial nonlinear estimator for Hammerstein-Wiener models
<code>polyreg</code>	Generate custom regressors by computing powers and products of standard regressors

<code>pwnlinear</code>	Class representing piecewise-linear nonlinearity estimator for Hammerstein-Wiener models
<code>saturation</code>	Class representing saturation nonlinearity estimator for Hammerstein-Wiener models
<code>set</code>	Set properties of data and model objects
<code>sigmoidnet</code>	Class representing sigmoid network nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models
<code>treepartition</code>	Class representing binary-tree nonlinearity estimator for nonlinear ARX models
<code>unitgain</code>	Specify absence of nonlinearities for specific input or output channels in Hammerstein-Wiener models
<code>wavenet</code>	Class representing wavelet network nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models

## ODE Parameter Estimation

<code>get</code>	Query properties of data and model objects
<code>getinit</code>	Values of <code>idnlgrey</code> model initial states
<code>getpar</code>	Parameter values and properties of <code>idnlgrey</code> model parameters
<code>idgrey</code>	Linear ODE (grey-box model) with known and unknown parameters
<code>idnlgrey</code>	Nonlinear ODE (grey-box model) with unknown parameters
<code>idnlmodel</code>	Superclass for nonlinear models
<code>init</code>	Set or randomize initial parameter values
<code>pem</code>	Estimate model parameters using iterative prediction-error minimization method
<code>set</code>	Set properties of data and model objects
<code>setinit</code>	Set initial states of <code>idnlgrey</code> model object
<code>setpar</code>	Set initial parameter values of <code>idnlgrey</code> model object

## Recursive Techniques for Model Identification

<code>rarmax</code>	Estimate recursively parameters of ARMAX or ARMA models
<code>rarx</code>	Estimate parameters of ARX or AR models recursively

<code>rbj</code>	Estimate recursively parameters of Box-Jenkins models
<code>roe</code>	Estimate recursively output-error models (IIR-filters)
<code>rpem</code>	Estimate general input-output models using recursive prediction-error minimization method
<code>rp1r</code>	Estimate general input-output models using recursive pseudolinear regression method
<code>segment</code>	Segment data and estimate models for each segment

## Model Analysis

<code>advice</code>	Analysis and recommendations for data or estimated linear polynomial and state-space models
<code>aic</code>	Akaike Information Criterion for estimated model
<code>arxdata</code>	ARX parameters from multiple-output <code>idarx</code> or single-output <code>idpoly</code> objects with variance information
<code>balred</code>	Reduce model order (requires Control System Toolbox product)
<code>bode</code>	Plot Bode diagram of frequency response with confidence interval
<code>compare</code>	Compare model output and measured output
<code>ffplot</code>	Plot frequency response and spectra

<code>fpe</code>	Akaike Final Prediction Error for estimated model
<code>freqresp</code>	Frequency-response data from <code>idmodel</code> or <code>idfrd</code> object
<code>fselect</code>	Frequencies from <code>idfrd</code> object
<code>impulse</code>	Plot impulse response with confidence interval
<code>isreal</code>	Determine whether model parameters or data values are real
<code>ivstruc</code>	Loss functions for sets of ARX model structures
<code>noisecnv</code>	Transform <code>idmodel</code> object with noise channels to model with measured channels only
<code>nyquist</code>	Plot Nyquist curve of frequency response with confidence interval
<code>pe</code>	Prediction errors associated with model and data set
<code>plot</code>	Plot <code>iddata</code> or model objects
<code>polydata</code>	Polynomial model parameters from single-input and single-output <code>idpoly</code> object
<code>predict</code>	Predict output $k$ steps ahead
<code>predict(idnlarx)</code>	Predict output $k$ steps ahead for nonlinear ARX model
<code>predict(idnlgrey)</code>	Predict output $k$ steps ahead for nonlinear ODE model
<code>predict(idnlhw)</code>	Predict output $k$ steps ahead for Hammerstein-Wiener model
<code>present</code>	Display model information, including estimated uncertainty

<code>pzmap</code>	Plot zeros and poles with confidence interval
<code>resid</code>	Compute and test model residuals (prediction errors)
<code>selstruc</code>	Select model order for single-output ARX models
<code>sim</code>	Simulate linear models with confidence interval
<code>sim(idnlarx)</code>	Simulate nonlinear ARX model
<code>sim(idnlgrey)</code>	Simulate nonlinear ODE model
<code>sim(idnlhw)</code>	Simulate Hammerstein-Wiener model
<code>simsd</code>	Simulate models with uncertainty using Monte Carlo method
<code>ssdata</code>	State-space matrices from <code>idmodel</code> object
<code>step</code>	Plot step response with confidence interval
<code>tfdata</code>	Numerator and denominator of transfer function from <code>idmodel</code> object
<code>view</code>	Plot model characteristics using Control System Toolbox LTI Viewer GUI
<code>zpkdata</code>	Zeros, poles, and gains of transfer function from <code>idmodel</code> object

## Simulation and Prediction

<code>findstates(idmodel)</code>	Estimate initial states of linear model from data
<code>findstates(idnlarx)</code>	Estimate initial states of nonlinear ARX model from data
<code>findstates(idnlgrey)</code>	Estimate initial states of nonlinear grey-box model from data
<code>findstates(idnlhw)</code>	Estimate initial states of nonlinear Hammerstein-Wiener model from data
<code>idmdlsm</code>	Simulate <code>idmodel</code> objects using Simulink <sup>®</sup> software
<code>predict</code>	Predict output $k$ steps ahead
<code>predict(idnlarx)</code>	Predict output $k$ steps ahead for nonlinear ARX model
<code>predict(idnlgrey)</code>	Predict output $k$ steps ahead for nonlinear ODE model
<code>predict(idnlhw)</code>	Predict output $k$ steps ahead for Hammerstein-Wiener model
<code>sim</code>	Simulate linear models with confidence interval
<code>sim(idnlarx)</code>	Simulate nonlinear ARX model
<code>sim(idnlgrey)</code>	Simulate nonlinear ODE model
<code>sim(idnlhw)</code>	Simulate Hammerstein-Wiener model
<code>simsd</code>	Simulate models with uncertainty using Monte Carlo method

# Functions – Alphabetical List

---

# addreg

---

<b>Purpose</b>	Add custom regressors to idnlarx model
<b>Syntax</b>	<code>addreg(model,R)</code> <code>addreg(model,R,I)</code> <code>addreg(model,R1,I1,R2,I2,Rn,In)</code>
<b>Input</b>	<p><code>model</code> Name of the idnlarx model object.</p> <p><code>R</code> For single-output models, <code>R</code> can be an array of <code>customreg</code> objects. <code>R</code> can also be a cell array of strings, where each string is an expression in terms of input and output variables.</p> <p>For multiple-output models with <code>ny</code> outputs, <code>R</code> can be a 1-by-<code>ny</code> cell array containing names of <code>customreg</code> objects or strings of expressions.</p> <p><code>I</code> Scalar integer or vector of integers. Each integer specifies the index of a model output channel.</p>
<b>Description</b>	<p><code>addreg(model,R)</code> adds one or more custom regressors <code>R</code> to a nonlinear ARX model. For multiple-output systems, each element of the <code>R</code> cell array is added to the corresponding output channel of the model.</p> <p><code>addreg(model,R,I)</code> is used for multiple-output models and adds one or more custom regressors <code>R</code> to specific output channels.</p> <p><code>addreg(model,R1,I1,R2,I2,Rn,In)</code> is used for multiple-output models and specifies the regressor-channel pairs.</p>
<b>Examples</b>	<p>The following example shows how to add regressors to a nonlinear ARX model using a cell array of strings. <code>u1</code> and <code>y2</code> are input and output variables, respectively:</p> <pre>m1 = idnlarx([4 2 1], 'wavenet', 'nlnr', [1:3]); % Add regressors using cell array of strings</pre>

```
m2=addreg(m1,{'y1(t-2)^2';'u1(t)*y1(t-7)'})
```

Alternatively, you can use the `customreg` constructor to create regressors, and then add them to the model:

```
r1 = customreg(@(x)x^2, {'y1'}, 2)  
r2 = customreg(@(x,y)x*y, {'u1','y1'}, [0 7])  
m2=addreg(m1,[r1 r2]);
```

`getreg`

`nlarx`

`polyreg`

# advice

---

**Purpose** Analysis and recommendations for data or estimated linear polynomial and state-space models

**Syntax** `advice(model)`  
`advice(data)`

**Inputs**

`model`  
Name of the `idarx`, `idgrey`, `idpoly`, `idproc`, or `idss` model object. These model objects belong to the `idmodel` abstract class, representing linear polynomial and state-space models.

`data`  
Name of the `iddata` object.

**Description** `advice(model)` displays the following information about the estimated model in the MATLAB® Command Window:

- Does the model capture essential dynamics of the system and the disturbance characteristics?
- Is the model order higher than necessary?
- Is there potential output feedback in the validation data?
- Would a nonlinear ARX model perform better than a linear ARX model?

`advice(data)` displays the following information about the data in the MATLAB Command Window:

- What are the excitation levels of the signals and how does this affects the model orders? See also `pexcit`.
- Does it make sense to remove constant offsets and linear trends from the data? See also `detrend`.
- Is there an indication of output feedback in the data? See also `feedback`.

**See Also**

detrend  
feedback  
iddata  
pexcit

<b>Purpose</b>	Akaike Information Criterion for estimated model
<b>Syntax</b>	<pre>am = aic(model) am = aic(model1,model2,...)</pre>
<b>Arguments</b>	<p><code>model</code> Name of an <code>idarx</code>, <code>idgrey</code>, <code>idpoly</code>, <code>idproc</code>, <code>idss</code>, <code>idnlrx</code>, <code>idnlhw</code>, or <code>idnlgrey</code> model object.</p>
<b>Description</b>	<p><code>am = aic(model)</code> returns a scalar value of the Akaike's Information Criterion (AIC) for the estimated <code>model</code>.</p> <p><code>am = aic(model1,model2,...)</code> returns a row vector containing AIC values for the estimated models <code>model1,model2,...</code>.</p>
<b>Remarks</b>	Akaike's Information Criterion (AIC) provides a measure of model quality by simulating the situation where the model is tested on a different data set. After computing several different models, you can compare them using this criterion. According to Akaike's theory, the most accurate model has the smallest AIC.

---

**Note** If you use the same data set for both model estimation and validation, the fit always improves as you increase the model order and, therefore, the flexibility of the model structure.

---

Akaike's Information Criterion (AIC) is defined by the following equation:

$$AIC = \log V + \frac{2d}{N}$$

where  $V$  is the loss function,  $d$  is the number of estimated parameters, and  $N$  is the number of values in the estimation data set.

The loss function  $V$  is defined by the following equation:

$$V = \det \left( \frac{1}{N} \sum_1^N \varepsilon(t, \theta_N) (\varepsilon(t, \theta_N))^T \right)$$

where  $\theta_N$  represents the estimated parameters.

For  $d \ll N$ :

$$AIC = \log \left( V \left( 1 + \frac{2d}{N} \right) \right)$$

---

**Note**  $AIC$  is approximately equal to  $\log(FPE)$ .

---

$AIC$  is formally defined as the negative log-likelihood function  $\Lambda$ , evaluated at the estimated parameters, plus the number of estimated parameters. You can derive  $AIC$  from this definition, as follows:

If the disturbance source is Gaussian with the covariance matrix  $\Lambda$ , the logarithm of the likelihood function is

$$L(\theta, \Lambda) = -\frac{1}{2} \sum_1^N \varepsilon(t, \theta)^T \Lambda^{-1} \varepsilon(t, \theta) - \frac{N}{2} \log(\det \Lambda) + const$$

Maximizing this analytically with respect to  $\Lambda$ , and then maximizing the result with respect to  $\theta$ , gives

$$L(\theta, \Lambda) = const + \frac{Np}{2} + \frac{N}{2} \log(V)$$

where  $p$  is the number of outputs.

EstimationInfo

fpe

**Purpose** Algorithm properties affecting estimation process for linear models

**Syntax** `idprops idmodel algorithm`  
`Model.algorithm.PropertyName='PropertyValue'`

**Description** Algorithm is a property of the `idmodel` class that specifies the estimation algorithm. The `idmodel` subclasses are used to define various linear models, including `idarx`, `idss`, `idpoly`, `idproc`, and `idgrey`. These models inherit the `idmodel` Algorithm property.

---

**Note** For a description of nonlinear model Algorithm property, see the corresponding nonlinear model reference page.

---

Property names are not case sensitive. When you type a property name, you only need to enter enough characters to uniquely identify the property. The Algorithm fields can be accessed and modified as for any structure using dot syntax. For example, you can access the `SearchMethod` field by typing `Model.Algorithm.SearchMethod`.

---

**Note** You can use the `get` function or dot notation to fetch fields of Algorithm as if they were the properties of the model itself. Similarly you can use `set` or dot notation to set a particular field. This shortcut access is available for the fields of Algorithm only (not for deeper level struct fields such as `Search` or `Threshold` options). For example:

```
method = Model.SearchMethod;  
Model.MaxIter = 100;
```

is equivalent to

```
get(Model, 'SearchMethod')  
set(Model, 'maxiter', 100);
```

---

# Algorithm Properties

---

When you create a new model by refining an existing model `m`, the algorithm properties of `m` are inherited by the new model.

---

**Note** You can estimate a model with specific algorithm settings and define a structure variable to store the algorithm values. For example:

```
model = n4sid(data,order)
myalg = model.Algorithm;
myalg.Focus='Simulation';
m = pem(data,model,'alg',myalg)
```

You can also specify the algorithm properties (except advanced properties) as property-value pairs when creating the linear model (using `idpoly`, `idss`, etc.) or when estimating them (using `pem`, `n4sid`, `armax`, `oe` etc.).

---

## Algorithm Properties

- **Criterion:** Specifies criterion used during minimization. Criterion can have the following values:
  - **'Det':** Minimize  $\det(E^*E)$ , where  $E$  represents the prediction error. This is the optimal choice in a statistical sense and leads to the maximum likelihood estimates in case nothing is known about the variance of the noise. It uses the inverse of the estimated noise variance as the weighting function. This is the default criterion used for all models, except `idnlgrey` which uses **'Trace'** by default.
  - **'Trace':** Minimize the trace of the weighted prediction error matrix  $\text{trace}(E^*E*W)$ , where  $E$  is the matrix of prediction errors, with one column for each output, and  $W$  is a positive semi-definite symmetric matrix of size equal to the number of outputs. By default,  $W$  is an identity matrix of size equal to the number of model outputs (so the minimization criterion becomes  $\text{trace}(E^*E)$ ), or the traditional least-sum-of-squared-errors criterion. You can

specify the relative weighting of prediction errors for each output using the `Weighting` field of the `Algorithm` property.

---

**Note** The difference between the two criteria is meaningful in multiple-output cases only. In single-output models, the two criteria are equivalent. Both the `Det` and `Trace` criteria are derived from a general requirement of minimizing a weighted sum of squares of prediction errors. The `Det` criterion can be interpreted as estimating the covariance matrix of the noise source and using the inverse of that matrix as the weighting. When using the `Trace` criterion, you must specify the weighting using the `Weighting` property.

If you want to achieve better accuracy for a particular channel in multiple-input multiple-output models, you should use `Trace` with weighting that favors that channel. Otherwise it is natural to use the `Det` criterion. When using `Det`, you can check `cond(model.NoiseVariance)` after estimation. If the matrix is ill-conditioned, it may be more robust to use the `Trace` criterion. You can also use `compare` on validation data to check whether the relative error for different channels corresponds to your needs or expectations. Use the `Trace` criterion if you need to modify the relative errors, and check `model.NoiseVariance` to determine what weighting modifications to specify.

The search method of `lsqnonlin` supports the `Trace` criterion only.

---

- **Focus:** Defines how the errors  $e$  between the measured and the modeled outputs are weighed at specific frequencies during the minimization of the following loss function:

$$V = \sum_i \lambda_i e_i^2$$

# Algorithm Properties

---

Higher weighting at specific frequencies emphasizes the requirement for a good fit at these frequencies. Focus can have the following values:

- 'Prediction': (Default) Automatically calculates the weighting function as a product of the input spectrum and the inverse of the noise model. This minimizes the one-step-ahead prediction, which typically favors fitting small time intervals (higher frequency range). From a statistical-variance point of view, this is the optimal weighting function. However, this method neglects the approximation aspects (bias) of the fit. Might not result in a stable model. Use 'Stability' when you want to ensure a stable model.
- 'Simulation': Estimates the model using the frequency weighting of the transfer function that is given by the input spectrum. Typically, this method favors the frequency range where the input spectrum has the most power. In other words, the resulting model will produce good simulations for inputs that have the same spectra as used for estimation. For models that have no disturbance model, there is no difference between 'Simulation' and 'Prediction'. In this case,  $y = Gu + He$  with  $H=1$ , which is equivalent to  $A=C=D=1$  for idpoly models and  $K = 0$  for idss models.

For models that have a disturbance model,  $G$  is first estimated with  $H=1$ , and then  $H$  is estimated using a prediction-error method with a fixed estimated transfer function  $\hat{G}$ . This guarantees a stable transfer function  $G$ .

- 'Stability': This weighting is the same as for 'Prediction', but the model is forced to be stable. Use only when you know the system is stable. In some cases, forcing the model to be stable can result in a bad model.
- Enter a row vector or a matrix containing frequency values that define desired passbands. For example:

```
[w1,wh]  
[w1l,w1h;w2l,w2h;w3l,w3h;...]
```

where  $w_l$  and  $w_h$  represent upper and lower limits of a passband. For a matrix with several rows defining frequency passbands, the algorithm uses union of frequency ranges to define the estimation passband.

- Enter any SISO linear filter in any of the following ways:

A single-input-single-output (SISO) `idmodel` object.

An `ss`, `tf`, or `zpk` model from the Control System Toolbox product.

Using the format `{A,B,C,D}`, which specifies the state-space matrices of the filter.

Using the format `{numerator, denominator}`, which specifies the numerator and denominator of the filter transfer function

This calculates the weighting function as a product of the filter and the input spectrum to estimate the transfer function from input to output,  $G$ . To obtain a good model fit for a specific frequency range, you must choose the filter with a passband in this range. After estimating  $G$ , the algorithm computes the disturbance model using a prediction-error method and keeping the estimated transfer function fixed (similar to the 'Simulation' case). For a model that has no disturbance model, the estimation result is the same if you first prefilter the data using `idfilt`.

- For frequency-domain data only, enter a column vector of weights for 'Focus'. This vector must have the same size as length of the frequency vector of the data set, `Data.Frequency`. Each input and output response in the data is multiplied by the corresponding weight at that frequency.
- **Maxsize:** A positive integer, specified such that the input-output data is split into segments where each contains fewer than `MaxSize` elements. Setting `MaxSize` can improve computational performance. The default value of `MaxSize` is 'Auto', which uses the M-file `idmsize` to set the value. You can edit this file to optimize computational speed on a particular computer. `MaxSize` does not affect the numerical properties of the estimate except when you use `InitialState = 'backcast'` for frequency-domain data. In this

# Algorithm Properties

---

case, the frequency ranges where backcasting takes place might depend on `MaxSize` and affects estimates.

- **FixedParameter**: Vector of integers containing the indices of parameters that are not estimated and remain fixed at nominal or initial values. Parameter indices refer to their position in the list, stored in the property `'ParameterVector'`. You can also specify parameter names as values from the property `'PName'`. To specify fixed parameters using parameter names, enter `Fixedparameter` as a cell array of strings. For example, to fix parameters with names `'a'` and `'b'`, type `m.FixedParameter = {'a','b','c'}`. Strings can contain wildcards, such as `'*'` to specify the automatic completion of a string, or `'?'` to represent an arbitrary character. For example, to fix three parameters in a disturbance model that start with `'k'`, such as `'k1'`, `'k2'`, `'k3'`, use `FixedParameter = {'k*'}`. For structured state-space models, you can fix and free parameters by specifying structure matrices, such as `As` and `Bs` (see `idss`).

---

**Note** By default, the property `'PName'` is empty. Use `setpname` to assign default parameter names. For example, `m = setpname(m)`.

---

- **Weighting**: Positive semi-definite symmetric matrix `W` to use as weighting for minimization of the trace criterion `trace(E'*E*W)`. `Weighting` can be used to specify relative importance of outputs in multiple-input multiple-output models (or reliability of corresponding data) by specifying `W` as a diagonal matrix of non-negative values. `Weighting` is not useful in single-input single-output models. By default, `Weighting` is the identity matrix of size equal to the number of model outputs, assigning equal importance to each output during estimation.
- **Display**: Specifies what information displays in the MATLAB Command Window about the iterative search during estimation.
  - `'Off'`: Displays no information.
  - `'On'`: Displays the loss-function values for each iteration.

- 'Full': Displays the same information as 'On' and also include the current parameter values and the search direction (except when the Advanced SSPparameterization model property is set to 'Free' for idss models and the list of parameters can change between iterations).
- **LimitError**: Specifies when to adjust the weight of large errors from quadratic to linear. Default value is 0. Errors larger than **LimitError** times the estimated standard deviation have a linear weight in the criteria. The standard deviation is estimated robustly as the median of the absolute deviations from the median and divided by 0.7. (See the section about choosing a robust norm in [2].) **LimitError** = 0 disables the robustification and leads to a purely quadratic criterion. When estimating with frequency-domain data, **LimitError** is set to zero.

---

**Note** You can estimate the model with the default value of **LimitError** (zero) and plot the prediction errors using `pe(data.model)`. If the resulting plot shows occasional large values, repeat the estimation with `model.Algorithm.LimitError` set to a value between 1 and 2.

---

- **MaxIter**: Specifies the maximum number of iterations during loss-function minimization. The iterations stop when **MaxIter** is reached or another stopping criterion is satisfied, such as the **Tolerance**. The default value of **MaxIter** is 20. Setting **MaxIter** = 0 returns the result of the startup procedure. Use `EstimationInfo.Iterations` to get the actual number of iterations during an estimation.
- **Tolerance**: Specifies the minimum percentage difference (divided by 100) between the current value of the loss function and its expected improvement after the next iteration: When the percentage of expected improvement is less than **Tolerance**, the iterations are stopped. Default value is 0.01. The estimate of the expected

# Algorithm Properties

---

loss-function improvement at the next iteration is made based on the Gauss-Newton vector computed for the current parameter value.

- **SearchMethod**: The search method used for iterative parameter estimation. It can take one of the following values:
  - **'gn'**: The subspace Gauss-Newton direction. Singular values of the Jacobian matrix less than  $\text{GnPinvConst} \cdot \text{eps} \cdot \max(\text{size}(\mathbf{J})) \cdot \text{norm}(\mathbf{J})$  are discarded when computing the search direction, where  $\mathbf{J}$  is the Jacobian matrix. The Hessian matrix is approximated by  $\mathbf{J}^T \mathbf{J}$ . If there is no improvement along this direction, the gradient direction is also tried.
  - **'gna'**: An adaptive version of subspace Gauss-Newton approach, suggested by Wills and Ninness (IFAC World congress, Prague 2005). Eigenvalues less than  $\text{gamma} \cdot \max(\text{sv})$  of the Hessian are neglected, where  $\text{sv}$  are the singular values of the Hessian. The Gauss-Newton direction is computed in the remaining subspace.  $\text{gamma}$  has the initial value `InitGnaTol` (see below) and is increased by the factor `LmStep` each time the search fails to find a lower value of the criterion in less than 5 bisections. It is decreased by the factor  $2 \cdot \text{LmStep}$  each time a search is successful without any bisections.
  - **'lm'**: Uses the Levenberg-Marquardt method. This means that the next parameter value is  $-\text{pinv}(\mathbf{H} + \mathbf{d} \cdot \mathbf{I}) \cdot \text{grad}$  from the previous one, where  $\mathbf{H}$  is the Hessian,  $\mathbf{I}$  is the identity matrix, and  $\text{grad}$  is the gradient.  $\mathbf{d}$  is a number that is increased until a lower value of the criterion is found.
  - **'Auto'**: A choice among the above is made in the algorithm. This is the default choice.
  - **'lsqnonlin'**: Uses `lsqnonlin` optimizer from Optimization Toolbox software. You must have Optimization Toolbox installed to use this option. This search method can only handle the Trace criterion.

- **Advanced:** Structure that specifies advanced algorithm options and has the following fields:
  - **Search:** Uses the following fields to specify options for the iterative search:
    - 1 GnPinvConst:** Must be a positive real value. Specifies that singular values of the Jacobian that are smaller than  $\text{GnPinvConst} * \max(\text{size}(J) * \text{norm}(J) * \text{eps})$  are discarded when computing the search direction using the 'gn' method. Default value is  $1e4$ .
    - 2 InitGnaTol:** The initial value of gamma in the gna search algorithm. See SearchMethod for description of gna. Default is  $10^{-4}$ .
    - 3 LmStep:** The size of the Levenberg-Marquardt step. The next value of the search-direction length  $d$  in the Levenberg-Marquardt method is LmStep times the previous one. Default is 2.
    - 4 StepReduction:** For search directions other than the Levenberg-Marquardt direction, the step is reduced by the factor StepReduction after each iteration. Default is 2.
    - 5 MaxBisection:** The maximum number of bisections used by the line search along the search direction. Default is 25.
    - 6 LmStartValue:** The starting value of search-direction length  $d$  in the Levenberg-Marquardt method. Default is 0.001.
    - 7 RelImprovement:** The iterations are stopped if the relative improvement of the criterion is less than RelImprovement. Default is  $\text{RelImprovement} = 0$ . This property is different from Tolerance in that it uses the actual improvement of the loss function, as opposed to the expected improvement.
  - **Threshold:** Contains fields with thresholds for several tests:
  - 8 Sstability:** Specifies the location of the rightmost pole to test the stability of continuous-time models. A model is considered stable when its rightmost pole is to the left of Sstability. Default is 0.

# Algorithm Properties

---

- 9 **Zstability**: Specifies the maximum distance of all poles from the origin to test stability of discrete-time models. A model is considered stable if all poles are within the distance `Zstability` from the origin. Default is `1+sqrt(eps)`.
- **AutoInitialState**: Specifies when to automatically estimate the initial state. When `InitialState = 'Auto'`, the initial state is estimated when the ratio of the prediction-error norm with a zero initial state to the norm with an estimated initial state exceeds `AutoInitialState`. Default is `1.05`.

## Properties Relevant to Estimation of `n4sid`, State-Space (`idss`) Models

---

**Note** These properties apply to `n4sid`. Since `pem` commonly uses `n4sid` to initialize a model for iterative estimation, these properties affect the results of `pem` too.

---

- **N4Weight**: Calculates the weighting matrices used in the singular-value decomposition step of the algorithm and has three possible values:
  - `'Auto'`: (Default) Automatically chooses between `'MOESP'` and `'CVA'`.
  - `'MOESP'`: Uses the MOESP algorithm by Verhaegen.
  - `'CVA'`: Uses the canonical variable algorithm by Larimore.For more information about setting this property, see the `n4sid` reference page.
- **N4Horizon**: Determines the forward and backward prediction horizons used by the algorithm. Enter a row vector with three elements: `N4Horizon=[r sy su]`, where `r` is the maximum forward prediction horizon; that is, the algorithm uses up to `r` step-ahead predictors. `sy` is the number of past outputs, and `su` is the number of past inputs used for predictions. For an exact definition of these integers, see the section about subspace methods in [2], where they

are called  $r$ ,  $s1$ , and  $s2$ . These numbers can have a substantial influence on the quality of the resulting model and there are no simple rules for choosing them. Making 'N4Horizon' a k-by-3 matrix means that the algorithm tries each row of 'N4Horizon' and selects the value that gives the best (prediction) fit to the data. Choosing the best row is not available when you also specify to select the best model order. When you specify one column in 'N4Horizon', the interpretation is  $r=sy=su$ . The default choice is 'N4Horizon' = 'Auto', which uses an Akaike Information Criterion (AIC) for the selection of  $sy$  and  $su$ .

---

**Note** For algorithm properties of nonlinear models, see the reference pages for `idnlarx`, `idnlhw`, and `idnlgrey`.

<b>Purpose</b>	Estimate parameters of AR model for scalar time series returning <code>idpoly</code> object
<b>Syntax</b>	<code>m = ar(y,n)</code> <code>[m,refl] = ar(y,n,approach&gt;window)</code> <code>[m,refl] = ar(y,n,approach&gt;window, 'P1',V1,..., 'PN',VN)</code>
<b>Arguments</b>	<p><code>y</code>     <code>iddata</code> object that contains the time-series data (one output channel).</p> <p><code>n</code>     Scalar that specifies the order of the model you want to estimate (the number of <math>A</math> parameters in the AR model).</p> <p><code>approach</code>     Lets you choose the algorithm for computing the least squares AR model from the following options:</p> <ul style="list-style-type: none"><li>• <code>'burg'</code>: Burg's lattice-based method. Solves the lattice filter equations using the harmonic mean of forward and backward squared prediction errors.</li><li>• <code>'fb'</code>: (Default) Forward-backward approach. Minimizes the sum of a least-squares criterion for a forward model, and the analogous criterion for a time-reversed model.</li><li>• <code>'gl'</code>: Geometric lattice approach. Similar to Burg's method, but uses the geometric mean instead of the harmonic mean during minimization.</li><li>• <code>'ls'</code>: Least-squares approach. Minimizes the standard sum of squared forward-prediction errors.</li><li>• <code>'yw'</code>: Yule-Walker approach. Solves the Yule-Walker equations, formed from sample covariances.</li></ul> <p><code>window</code>     Lets you specify how to use information about the data outside the measured time interval (past and future values). The following windowing options are available:</p>

- 'now': (Default) No windowing. This value is the default except when the approach argument is 'yw'. Only measured data is used to form regression vectors. The summation in the criteria starts at the sample index equal to  $n+1$ .
- 'pow': Postwindowing. Missing end values are replaced with zeros and the summation is extended to time  $N+n$  ( $N$  is the number of observations).
- 'ppw': Pre- and postwindowing. Used in the Yule-Walker approach.
- 'prw': Prewindowing. Missing past values are replaced with zeros so that the summation in the criteria can start at time equal to zero.

'P1', V1, ..., 'PN', VN

Pairs of property names and property values can include any of the following.

Property Name	Property Value	Description
'Covariance'	<ul style="list-style-type: none"> <li>• 'None' Suppresses the calculation of the covariance matrix.</li> <li>• [] Empty.</li> <li>• Square matrix containing covariance values of size equal to the length of the parameter vector</li> </ul>	Specifies calculation of uncertainties in parameter estimates.

Property Name	Property Value	Description
'MaxSize'	Integer	See Algorithm Properties for the description.
'Ts'	Real positive number	Sets the sampling time and overrides the sampling time of y.

## Description

---

**Note** Use for scalar time series only. For multivariate data, use arx.

---

`m = ar(y,n)` returns an idpoly model `m`.

`[m,refl] = ar(y,n,approach>window)` returns an idpoly model `m` and the variable `refl`. For the two lattice-based approaches, 'burg' and 'gl', `refl` stores the reflection coefficients in the first row, and the corresponding loss function values in the second row. The first column of `refl` is the zeroth-order model, and the (2,1) element of `refl` is the norm of the time series itself.

`[m,refl] = ar(y,n,approach>window,'P1',V1,...,'PN',VN)` returns an idpoly model `m` and the variable `refl` using additional windowing criteria.

## Remarks

The AR model structure is given by the following equation:

$$A(q)y(t) = e(t)$$

AR model parameters are estimated using variants of the least-squares method. The following table summarizes the common names for methods with a specific combination of `approach` and `window` argument values.

Method	Approach and Windowing
Modified Covariance Method	(Default) Forward-backward approach and no windowing.
Correlation Method	Yule-Walker approach, which corresponds to least squares plus pre- and postwindowing.
Covariance Method	Least squares approach with no windowing. <code>arx</code> uses this routine.

## Examples

Given a sinusoidal signal with noise, compare the spectral estimates of Burg's method with those found from the forward-backward approach and no-windowing method on a Bode plot.

```
y = sin([1:300]') + 0.5*randn(300,1);
y = iddata(y);
mb = ar(y,4,'burg');
mfb = ar(y,4);
bode(mb,mfb)
```

step

**Purpose** Estimate parameters of ARMAX or ARMA model returning idpoly object

**Syntax**

```
m = armax(data,orders)
m = armax(data,orders,'P1',V1,...,'PN',VN)
m = armax(data,'na',na,'nb',nb,'nc',nc,'nk',nk)
```

**Arguments**

**data**  
iddata object that contains the input-output data.

**orders**  
Vector of integers, specified using the format

```
orders = [na nb nc nk]
```

For multiple-input systems, nb and nk are row vectors where the ith element corresponds to the order and delay associated with the ith input.

When data is a time series, which has no input and one output, then

```
orders = [na nc]
```

---

**Tip** When refining an estimated model  $m_i$ , set the model orders as follows:

```
orders = m_i
```

---

'na',na,'nb',nb,'nc',nc,'nk',nk

'na', 'nb', and 'nc' are orders of the ARMAX model. nk is the delay. na, nb, nc, and nk are the corresponding integer values.

'P1',V1,...,'PN',VN

Pairs of property names and property values can include any of the following `idmodel` properties:

'Focus', 'InitialState', 'Display', 'MaxIter', 'Tolerance', 'LimitError', and 'FixedParameter'.

See `Algorithm Properties`, `idpoly`, and `idmodel` for more information.

## Description

---

**Note** `armax` only supports time-domain data with single or multiple inputs and single output. For frequency-domain data, use `oe`. For the multiple-output case, use `ARX` or a state-space model (see `n4sid` and `pem`).

---

`m = armax(data,orders)` returns an `idpoly` model `m` with estimated parameters and covariances (parameter uncertainties). Estimates the parameters using the prediction-error method and specified orders.

`m = armax(data,orders,'P1',V1,...,'PN',VN)` returns an `idpoly` model `m`. Use additional property-value pairs to specify the estimation algorithm properties.

`m = armax(data,'na',na,'nb',nb,'nc',nc,'nk',nk)` returns an `idpoly` model `m` with orders and delays specified as parameter-value pairs.

## Remarks

The ARMAX model structure is

$$\begin{aligned} y(t) + a_1 y(t-1) + \dots + a_{n_a} y(t-n_a) = \\ b_1 u(t-n_k) + \dots + b_{n_b} u(t-n_k-n_b+1) + \\ c_1 e(t-1) + \dots + c_{n_c} e(t-n_c) + e(t) \end{aligned}$$

A more compact way to write the difference equation is

$$A(q)y(t) = B(q)u(t - n_k) + C(q)e(t)$$

where

- $y(t)$  — Output at time  $t$ .
- $n_a$  — Number of poles.
- $n_b$  — Number of zeroes plus 1.
- $n_c$  — Number of  $C$  coefficients.
- $n_k$  — Number of input samples that occur before the input affects the output, also called the *dead time* in the system. For discrete systems with no dead time, there is a minimum 1-sample delay because the output depends on the previous input and  $n_k = 1$ .
- $y(t-1)\dots y(t-n_a)$  — Previous outputs on which the current output depends.
- $u(t-n_k)\dots u(t-n_k-n_b+1)$  — Previous and delayed inputs on which the current output depends.
- $e(t-1)\dots e(t-n_c)$  — White-noise disturbance value.

The parameters  $n_a$ ,  $n_b$ , and  $n_c$  are the orders of the ARMAX model, and  $n_k$  is the delay.  $q$  is the delay operator. Specifically,

$$A(q) = 1 + a_1q^{-1} + \dots + a_{n_a}q^{-n_a}$$

$$B(q) = b_1 + b_2q^{-1} + \dots + b_{n_b}q^{-n_b+1}$$

$$C(q) = 1 + c_1q^{-1} + \dots + c_{n_c}q^{-n_c}$$

If data is a time series, which has no input channels and one output channel, then `armax` calculates an ARMA model for the time series

$$A(q)y(t) = e(t)$$

In this case

```
orders = [na nc]
```

## Algorithm

An iterative search algorithm with the properties `'SearchMethod'`, `'MaxIter'`, `'Tolerance'`, and `'Advanced'` minimizes a robustified quadratic prediction error criterion. The iterations are terminated either when `MaxIter` is reached, or when the expected improvement is less than `Tolerance`, or when a lower value of the criterion cannot be found. You can get information about the search criteria using `m.EstimationInfo`.

When you do not specify initial parameter values for the iterative search in `orders`, they are constructed in a special four-stage LS-IV algorithm.

The cutoff value for the robustification is based on the property `LimitError` and on the estimated standard deviation of the residuals from the initial parameter estimate. It is not recalculated during the minimization.

To ensure that only models corresponding to stable predictors are tested, the algorithm performs a stability test of the predictor. Generally, both  $C(q)$  and  $F(q)$  (if applicable) must have all zeros inside the unit circle.

Minimization information is displayed on the screen when the property `'Display'` is `'On'` or `'Full'`. With `'Display' = 'Full'`, both the current and the previous parameter estimates are displayed in column-vector form, listing parameters in alphabetical order. Also, the values of the criterion function are given and the Gauss-Newton vector and its norm are also displayed. With `'Display' = 'On'` only the criterion values are displayed.

**Purpose** Estimate parameters of ARX or AR model using least squares returning `idpoly` or `idarx` object

**Syntax**

```
m = arx(data,orders)
m = arx(data,orders, 'P1',V1,..., 'PN',VN)
m = arx(data, 'na',na, 'nb',nb, 'nc',nc, 'nk',nk)
```

**Arguments**

`data` An `iddata` object, an `frd` object, or an `idfrd` frequency-response-data object.

`orders` Vector of integers, specified using the format

```
orders = [na nb nk]
```

For multiple-input systems, `nb` and `nk` are row vectors where the *i*th element corresponds to the order and delay associated with the *i*th input.

When `data` is a time series, which has no input and one output, then

```
orders = [na]
```

---

**Note** When refining an estimated model `mi`, set the model orders as follows:

```
orders = mi
```

---

`'na',na, 'nb',nb, 'nc',nc, 'nk',nk`  
`'na', 'nb', and 'nc'` are orders of the ARMAX model. `nk` is the delay. `na, nb, nc, and nk` are the corresponding integer values.

'P1', V1, ..., 'PN', VN

Pairs of property names and property values can include any of the following `idmodel` properties:

'Focus', 'InitialState', 'Display', 'MaxIter', 'Tolerance', 'LimitError', and 'FixedParameter'.

See Algorithm Properties, `idpoly`, and `idmodel` for more information.

## Description

---

**Note** `arx` does not support multiple-output continuous-time models. Use state-space model structure instead. When the true noise term  $e(t-1)\dots e(t-n_c)$  in the ARX model structure is not white noise and `na` is nonzero, the model estimate is incorrect. In this case, use `armax`, `bj`, `iv4`, or `oe`.

---

`m = arx(data, orders)` returns a model `m` with estimated parameters and covariances (parameter uncertainties). For single-output data, the model is an `idpoly` object. For multiple-output data, the model is an `idarx` object. Uses the least-squares method and specified orders.

`m = arx(data, orders, 'P1', V1, ..., 'PN', VN)` returns a model `m`. Use additional property-value pairs to specify the estimation algorithm properties.

`m = arx(data, 'na', na, 'nb', nb, 'nc', nc, 'nk', nk)` returns a model `m` with orders and delays specified as parameter-value pairs.

## Remarks

`arx` estimates the parameters of the ARX model structure:

$$y(t) + a_1 y(t-1) + \dots + a_{n_a} y(t-n_a) = b_1 u(t-1) + \dots + b_{n_b} u(t-n_k - n_b + 1) + e(t)$$

The parameters `na` and `nb` are the orders of the ARX model, and `nk` is the delay.

- $y(t)$  — Output at time  $t$ .
- $n_a$  — Number of poles.
- $n_b$  — Number of zeroes plus 1.
- $n_k$  — Number of input samples that occur before the input affects the output, also called the *dead time* in the system. For discrete systems with no dead time, there is a minimum 1-sample delay because the output depends on the previous input and  $n_k = 1$ .
- $y(t-1)\dots y(t-n_a)$  — Previous outputs on which the current output depends.
- $u(t-n_k)\dots u(t-n_k-n_b+1)$  — Previous and delayed inputs on which the current output depends.
- $e(t-1)\dots e(t-n_c)$  — White-noise disturbance value.

A more compact way to write the difference equation is

$$A(q)y(t) = B(q)u(t - n_k) + e(t)$$

$q$  is the delay operator. Specifically,

$$A(q) = 1 + a_1q^{-1} + \dots + a_{n_a}q^{-n_a}$$

$$B(q) = b_1 + b_2q^{-1} + \dots + b_{n_b}q^{-n_b+1}$$

### **Time Series Models**

For time-series data that contains no inputs, one output and orders =  $n_a$ , the model has AR structure of order  $n_a$ .

The AR model structure is

$$A(q)y(t) = e(t)$$

### Multiple Inputs and Single-Output Models

For multiple-input systems,  $nb$  and  $nk$  are row vectors where the  $i$ th element corresponds to the order and delay associated with the  $i$ th input.

$$y(t) + A_1y(t-1) + A_2y(t-2) + \dots + A_{na}y(t-na) = B_0u(t) + B_1u(t-1) + \dots + B_{nb}u(t-nb) + e(t)$$

### Multioutput Models

For models with multiple inputs and multiple outputs,  $na$ ,  $nb$ , and  $nk$  contain one row for each output signal.

In the multiple-output case, `arx` minimizes the trace of the prediction error covariance matrix, or the norm

$$\sum_{t=1}^N e^T(t)e(t)$$

To transform this to an arbitrary quadratic norm using a weighting matrix  $\Lambda$

$$\sum_{t=1}^N e^T(t)\Lambda^{-1}e(t)$$

use the syntax

```
m = arx(data,orders,'NoiseVariance', Lambda)
```

You can use `arx` to refine an existing model `m_initial` as an argument.

```
m = arx(data,m_initial)
```

The new model `m` uses the orders and the weighting matrix for the prediction errors from `m_initial`. You can further modify `m_initial`

by adding a list of property name and value pairs as arguments. This is especially useful when some parameters must be fixed using 'FixedParameter' property.

### Continuous-Time Models

For models with one output, continuous-time models can be estimated from continuous-time frequency-domain data. In this case, `na` is the number of estimated denominator coefficients and `nb` is number of estimated numerator coefficients.

---

**Note** For continuous-time models, omit the delay parameter `nk` because it has no meaning in this case. Because estimating continuous-time ARX models often produces bias, you might get better results by using the `oe` method.

---

For example, when `na = 4`, `nb = 2`, the model structure is:

$$G(s) = \frac{b_1s + b_2}{s^4 + a_1s^3 + a_2s^2 + a_3s + a_4}$$

---

**Tip** When using continuous-time data, limit the fit to a smaller frequency range using the 'Focus' `idmodel` property:

```
m = arx(datac,[na nb], 'focus', [0 wh])
```

---

### Estimating Initial Conditions

For time-domain data, the signals are shifted such that unmeasured signals are never required in the predictors. Therefore, there is no need to estimate initial conditions.

For frequency-domain data, it might be necessary to adjust the data by initial conditions that support circular convolution.

You can set the property 'InitialState' to one of the following values:

- 'zero' — No adjustment.
- 'estimate' — Perform adjustment to the data by initial conditions that support circular convolution.
- 'auto' — Automatically choose between 'zero' and 'estimate' based on the data.

See [Algorithm Properties](#) for more information on model properties.

## Algorithm

QR factorization solves the overdetermined set of linear equations that constitutes the least-squares estimation problem.

The regression matrix is formed so that only measured quantities are used (no fill-out with zeros). When the regression matrix is larger than `MaxSize`, data is segmented and QR factorization is performed iteratively on these data segments.

## Examples

This example generates input data based on a specified ARX model, and then uses this data to estimate an ARX model.

```
A = [1 -1.5 0.7]; B = [0 1 0.5];  
m0 = idpoly(A,B);  
u = iddata([],idinput(300,'rbs'));  
e = iddata([],randn(300,1));  
y = sim(m0, [u e]);  
z = [y,u];  
m = arx(z,[2 2 1]);
```

idpoly

iv4

ivar

ivx

pem

**Purpose** ARX parameters from multiple-output `idarx` or single-output `idpoly` objects with variance information

**Syntax**  
`[A,B] = arxdata(m)`  
`[A,B,dA,dB] = arxdata(m)`

**Arguments** `m`  
 Name of the `idarx` model object.

Also accepts `idpoly` models with an underlying ARX structure with orders `nc=nd=nf=0`.

**Description** `[A,B] = arxdata(m)` returns `A` and `B` as 3-D arrays.

Suppose  $n_y$  is the number of outputs (the dimension of the vector  $y(t)$ ) and  $n_u$  is the number of inputs.

`A` is an  $n_y$ -by- $n_y$ -by- $(n_a+1)$  array such that

$$\begin{aligned} A(:, :, k+1) &= A_k \\ A(:, :, 1) &= \text{eye}(n_y) \end{aligned}$$

where  $k=0, 1, \dots, n_a$ .

`B` is an  $n_y$ -by- $n_u$ -by- $(n_b+1)$  array with

$$B(:, :, k+1) = B_k$$

`A(0)` is always the identity matrix. The leading entries in `B` equal to zero, which means there are no delays in the model.

---

**Note** For a time series, `B = []`.

---

`[A,B,dA,dB] = arxdata(m)` returns `A` and `B` matrices, and `dA` and `dB` as the estimated standard deviations of `A` and `B`, respectively.

## Remarks

A and B are 2-D or 3-D arrays and are returned in the standard multivariable ARX format (see `idarx`), describing the model.

$$y(t) + A_1y(t-1) + A_2y(t-2) + \dots + A_{na}y(t-na) = B_0u(t) + B_1u(t-1) + \dots + B_{nb}u(t-nb) + e(t)$$

where  $A_k$  and  $B_k$  matrices have dimensions  $ny$ -by- $ny$  and  $ny$ -by- $nu$ , respectively.  $ny$  is the number of outputs (the dimension of the vector  $y(t)$ ) and  $nu$  is the number of inputs.

`idarx`  
`idpoly`

**Purpose** Compute and compare loss functions for single-output ARX models

**Syntax**  
`V = arxstruc(ze,zv,NN)`  
`V = arxstruc(ze,zv,NN,maxsize)`

**Arguments**

`ze`  
 Estimation data set can be `iddata` or `idfrd` object.

`zv`  
 Validation data set can be `iddata` or `idfrd` object.

`NN`  
 Matrix defines the number of different ARX-model structures. Each row of `NN` is of the form:

$$nn = [na \ nb \ nk]$$

`maxsize`  
 Specified maximum data size. See `Algorithm Properties` for an explanation.

**Description**

**Note** Use `arxstruc` for single-output systems only. `arxstruc` supports both single-input and multiple-input systems.

`V = arxstruc(ze,zv,NN)` returns `V`, which contains the loss functions in its first row. The remaining rows of `V` contain the transpose of `NN`, so that the orders and delays are given just below the corresponding loss functions. The last column of `V` contains the number of data points in `ze`.

`V = arxstruc(ze,zv,NN,maxsize)` uses the additional specification of the maximum data size.

with the same interpretation as described for `arx`. See `struc` for easy generation of typical `NN` matrices for single-input systems.

The output argument *V* is best analyzed using `selstruc`. The selection of a suitable model structure based on the information in *v* is normally done using `selstruc`.

## Remarks

Each of *ze* and *zv* is an `iddata` object containing output-input data. Frequency-domain data and `idfrd` objects are also supported. Models for each of the model structures defined by *NN* are estimated using the data set *ze*. The loss functions (normalized sum of squared prediction errors) are then computed for these models when applied to the validation data set *zv*. The data sets *ze* and *zv* need not be of equal size. They could, however, be the same sets, in which case the computation is faster.

## Examples

This example uses the simulation data from a second-order `idpoly` model with additive noise. The data is split into two parts, where one part is the estimation data and the other is the validation data. You select the best model is selected by comparing the output of models with orders ranging between 1 and 5 with the validating data. All models have an input-to-output delay of 1.

```
% Create an ARX model for generating data:
A = [1 -1.5 0.7]; B = [0 1 0.5];
m0 = idpoly(A,B);
% Generate a random input signal:
u = iddata([],idinput(400,'rbs'));
e = iddata([],0.1*randn(400,1));
% Simulate the output signal from the model m0:
y = sim(m0, [u e]);
z = [y,u]; % analysis data
NN = struc(1:5,1:5,1);
V = arxstruc(z(1:200),z(201:400),NN);
nn = selstruc(V,0);
m = arx(z,nn);
```

struc

# balred

---

**Purpose** Reduce model order (requires Control System Toolbox product)

**Syntax**  
`MRED = balred(M)`  
`MRED = balred(M,ORDER,'DisturbanceModel','None')`

**Description** This function reduces the order of any model `M` given as an `idmodel` object. The resulting reduced-order model, `MRED`, is an `idss` model.

The function requires routines from the Control System Toolbox product.

`ORDER`: The desired order (dimension of the state-space representation). If `ORDER = []`, which is the default, a plot shows how the diagonal elements of the observability and controllability Gramians of a balanced realization decay with the order of the representation. You are then prompted to select an order based on this plot. The idea is that such a small element has a negligible influence on the input-output behavior of the model. We recommend that you choose an order such that only large elements in these matrices are retained.

'DisturbanceModel': If the property `DisturbanceModel` is set to 'None', then an output-error model `MRED` is produced: that is, one with the Kalman gain  $K$  equal to zero. Otherwise (default), the disturbance model is also reduced.

The function recognizes whether `M` is a continuous- or discrete-time model and performs the reduction accordingly. The resulting model, `MRED`, is similar to `M` in this respect.

There are several options for how the reduction is performed: `AbsTol`, `RelTol`, `Offset`, `Elimination`.

**Algorithm** The function uses the `balred` algorithm in Control System Toolbox. The plot, in case `ORDER = []`, shows the vector `g` returned by `balreal`.

**Examples** Build a high-order multivariable ARX model, reduce its order to 3, and compare the frequency responses of the original and reduced models:

```
M = arx(data,[4*ones(3,3),4*ones(3,2),ones(3,2)]);
```

```
MRED = balred(M,3);  
bode(M,MRED)
```

Use the reduced-order model as an initial condition for a third-order state-space model.

```
M2 = pem(data,MRED);
```

**See Also**

`balreal`

**Purpose** Estimate parameters of Box-Jenkins model returning idpoly object

**Syntax**

```
m = bj(data,orders)
m = bj(data,'nb',nb,'nc',nc,'nd',nd,'nf',nf,'nk',nk)
m = bj(data,orders,'Property1',Value1,'Property2',Value2,...)
```

**Description** bj returns m as an idpoly object with the resulting parameter estimates, together with estimated covariances. The bj function estimates parameters of the Box-Jenkins model structure

$$y(t) = \frac{B(q)}{F(q)}u(t-nk) + \frac{C(q)}{D(q)}e(t)$$

using a prediction error method.

data is an iddata object containing the output-input data. Frequency-domain signals are not supported by bj. Use oe instead.

The model orders can be specified by setting the argument orders to

```
orders = [ nb nc nd nf nk]
```

The parameters nb, nc, nd, and nf are the orders of the Box-Jenkins model and nk is the delay. Specifically,

$$if: \quad F(q) = 1 + f_1q^{-1} + \dots + f_nfq^{-n}$$

$$nb: \quad B(q) = b_1 + b_2q^{-1} + \dots + b_nbq^{-nb+1}$$

$$nc: \quad C(q) = 1 + c_1q^{-1} + \dots + c_ncq^{-nc}$$

$$nd: \quad D(q) = 1 + d_1q^{-1} + \dots + d_ndq^{-nd}$$

The orders can also be defined as property name/property value pairs (...,'nb',nb,...). Alternatively, you can specify the vector as

```
orders = mi
```

where  $m_i$  is an initial Box-Jenkins model (idpoly model).

For multiple-input systems,  $nb$ ,  $nf$ , and  $nk$  are row vectors with as many entries as there are input channels. Entry number  $i$  then describes the orders and delays associated with the  $i$ th input.

The structure and the estimation algorithm are affected by any property name/property value pairs that are set in the input argument list. Useful properties are 'Focus', 'InitialState', 'Display', 'MaxIter', 'Tolerance', 'LimitError', and 'FixedParameter'.

See [Algorithm Properties](#) and the reference pages for `idmodel` and `idpoly` for details of these properties and their possible values.

`bj` does not support multiple-output models. Use a state-space model for this case (see `n4sid` and `pem`).

## Examples

Here is an example that generates data and stores the results of the startup procedure separately.

```
B = [0 1 0.5];
C = [1 -1 0.2];
D = [1 1.5 0.7];
F = [1 -1.5 0.7];
m0 = idpoly(1,B,C,D,F,0.1);
e = iddata([],randn(200,1));
u = iddata([],idinput(200));
y = sim(m0,[u e]);
z = [y u];
mi = bj(z,[2 2 2 2 1],'MaxIter',0)
m = bj(z,mi,'Maxi',10)
m.EstimationInfo
m = bj(z,m); % Continue if m.es.WhyStop shows that
             % maxiter is reached.
compare(z,m,mi)
```

## Algorithm

`bj` uses essentially the same algorithm as `armax` with modifications to the computation of prediction errors and gradients.

Algorithm Properties

EstimationInfo

idpoly

pem

**Purpose** Plot Bode diagram of frequency response with confidence interval

### Syntax

```
bode(m)
[mag,phase,w] = bode(m)
[mag,phase,w,sdmag,sdphase] = bode(m)
bode(m1,m2,m3,...,w)
bode(m1,'PlotStyle1',m2,'PlotStyle2',...)
bode(m1,m2,m3,..'sd',sd,'mode',mode,'ap',ap)
bode(m1,m2,m3,'sd',sd,'mode',mode,'ap',ap,'fill')
```

### Description

`bode` computes the magnitude and phase of the frequency response of `idmodel` and `idfrd` models. When invoked without left-hand arguments, `bode` produces a Bode plot on the screen.

`bode(m)` plots the Bode response of an arbitrary `idmodel` or `idfrd` model `m`. This model can be continuous or discrete, and SISO or MIMO. The `InputNames` and `OuputNames` properties of the models are used to plot the responses for different I/O channels in separate plots. Pressing the **Enter** key advances the plot from one input-output pair to the next one. Typing **Ctrl+C** aborts the plotting in an orderly fashion

If `m` contains information about both I/O channels and output noise spectra, only the I/O channels are shown. To show the output noise spectra, enter `m('n')` ('n' for 'noise') in the model list. Analogously, you can select specific I/O channels with normal subreferencing `m(ky,ku)`.

### Argument w

`bode(m,w)` explicitly specifies the frequency range or frequency points to be used for the plot or for computing the response.

To focus on a particular frequency interval `[wmin,wmax]`, set `w = {wmin,wmax}` (notice the curly braces). This plots the response for 100 frequency points logarithmically spaced from `wmin` to `wmax`. You can change this to `NP` points by using `w = {wmin,wmax,NP}`.

To use particular frequency points, set `w` to the vector of desired frequencies. Use `logspace` to generate logarithmically spaced frequency vectors. All frequencies should be specified in rad/s.

Note that the frequencies cannot be specified for `idfrd` objects. For those the plot and response are calculated for the internally stored frequencies. However, the plot is restricted to the range `{wmin,wmax}` if this is specified.

If no frequency range is specified, a default choice is made based on the dynamics of the model.

## **Property Name/Property Value Pairs 'sd'/sd, 'ap'/ap, and 'mode'/mode**

The pairs can appear in any order or be omitted.

- `sd`: If `sd` is specified as a number larger than zero, confidence intervals for the functions are added to the graph as dash-dotted curves (of the same color as the estimate curve). They indicate the confidence regions corresponding to `sd` standard deviations. If an argument `'fill'` is included in the argument list, the confidence region is marked as a filled band instead.
- `ap`: By default, amplitude and phase plots are shown simultaneously for each I/O channel present in `m`. For spectra, phase plots are omitted. To show amplitude plots only, use `ap = 'A'`. For phase plots only, use `ap = 'P'`. The default is `ap = 'B'` for both plots.
- `mode`: To obtain all input/output plots in the same diagram use `mode = 'same'`.

## **Several Models**

`bode(m1,m2,...,mN)` or `bode(m1,m2,...,mN,w)` plots the Bode response of several `idmodel` or `idfrd` models on a single figure. The models can be mixes of different sizes and continuous/discrete. The sorting of the plots is based on the `InputNames` and `OutputNames`. If the frequencies `w` are specified, these will apply to all non-`idfrd` models in the list. If you want different frequencies for different models, you should thus first convert them to `idfrd` objects using the `idfrd` command.

`bode(m1, 'PlotStyle1', ..., mN, 'PlotStyleN')` further specifies which color, line style, and/or marker should be used to plot each system, as in

```
bode(m1, 'r--', m2, 'gx')
```

## Arguments

The output argument `w` contains the frequencies for which the response is given, whether specified among the input arguments or not. The output arguments `mag` and `phase` are 3-D arrays with dimensions

```
(number of outputs)x(number of inputs)x(length of w)
```

For SISO systems, `mag(1,1,k)` and `phase(1,1,k)` give the magnitude and phase (in degrees) at the frequency  $\omega_k = w(k)$ . To obtain the result as a normal vector of responses, use `mag = mag(:)` and `phase = phase(:)`.

For MIMO systems, `mag(i,j,k)` is the magnitude of the frequency response at frequency `w(k)` from input `j` to output `i`, and similarly for `phase(i,j,k)`.

If `sdmag` and `sdphase` are specified, the standard deviations of the magnitude and phase are also computed. Then `sdmag` is an array of the same size as `mag`, containing the estimated standard deviations of the response, and analogously for `sdphase`.

# compare

---

## Purpose

Compare model output and measured output

## Syntax

```
compare(data,m);  
compare(data,m,k)  
compare(data,m,k,'Samples',sampnr,'InitialState',init,'OutputPlots',Yplots)  
compare(data,m1,m2,...,mN)  
compare(data,m1,'PlotStyle1',...,mN,'PlotStyleN')  
[yh,fit,x0] = compare(data,m1,'PlotStyle1',...,mN,'PlotStyleN',k)
```

## Description

`data` is the output-input data in the usual `iddata` object format. `data` can also be an `idfrd` object with frequency-response data.

`compare` computes the output `yh` that results when the model `m` is simulated with the input `u`. `m` can be any `idmodel` or `idnlmodel` model object. The result is plotted together with the corresponding measured output `y`. The percentage of the output variation that is explained by the model

$$\text{fit} = 100 \cdot (1 - \text{norm}(yh - y) / \text{norm}(y - \text{mean}(y)))$$

is also computed and displayed. For multiple-output systems, this is done separately for each output. For frequency-domain data (or in general for complex valued data) the `fit` is still calculated as above, but only the absolute values of `y` and `yh` are plotted.

When the argument `k` is specified, the  $k$  step-ahead prediction of `y` according to the model `m` are computed instead of the simulated output. In the calculation of  $y^h(t)$ , the model can use outputs up to time  $t-k$ :  $y(s), s = t-k, t-k-1, \dots$  (and inputs up to the current time  $t$ ). The default value of `k` is `inf`, which gives a pure simulation from the input only. Note that for frequency-domain data, only simulation (`k = inf`) is allowed, and for time-series data (no input) only prediction (`k` not `inf`) is possible.

### Property Name/Property Value Pairs

The optional property name/property value pairs 'Samples' /sampnr, 'InitialState' /init, and 'OutputPlots' /Yplots can be given in any order.

The argument Yplots can be a cell array of strings. Only the outputs with OutputName in this array are plotted, while all are used for the necessary computations. If Yplots is not specified, all outputs are plotted.

The argument sampnr indicates that only the sample numbers in this row vector are plotted and used for the calculation of the fit. The whole data record is used for the simulation/prediction.

The argument init determines how to handle initial conditions in the models:

- `init = 'e'` (for 'estimate') estimates the initial conditions for best fit.
- `init = 'm'` (for 'model') uses internally stored initial state of the model.
- `init = 'z'` (for 'zero') uses zero initial conditions.
- `init = x0`, where `x0` is a column vector of the same size as the state vector of the models, uses `x0` as the initial state.
- `init = 'e'` is the default.

### Several Models

When several models are specified, as in `compare(data,m1,m2,...,mN)`, the plots show responses and fits for all models. In that case `data` should contain all inputs and outputs that are required for the different models. However, some models might correspond to subselections of channels and might not need all channels in `data`. In that case the proper handling of signals is based on the `InputNames` and `OutputNames` of `data` and the models.

## compare

---

With `compare(data,m1,'PlotStyle1',...mN,'PlotStyle2')`, the color, line style, and/or marker can be specified for the curves associated with the different models. The markers are the same as for the regular `plot` command. For example,

```
compare(data,m1,'g_*',m2,'r:')
```

If `data` contains several experiments, separate plots are given for the different experiments. In this case `sampnr`, if specified, must be a cell array with as many entries as there are experiments.

### Arguments

When output arguments `[yh,fit,x0] = compare(data,m1,...,mN)` are specified, no plots are produced.

`yh` is a cell array of length equal to the number of models. Each cell contains the corresponding model output as an `iddata` object.

`fit` is, in the general case, a 3-D array with `fit(kexp,kmod,ky)` containing the fit (computed as above) for output `ky`, model `kmod`, and experiment `kexp`.

`x0` is a cell array, such that `x0{kmod}` is the estimated initial state for model number `kmod`. If `data` is multiexperiment, `X0{kmod}` is a matrix whose column number `kexp` is the initial state vector for experiment number `kexp`.

### Examples

Split the data record into two parts. Use the first one for estimating a model and the second one to check the model's ability to predict six steps ahead.

```
ze = z(1:250);
zv = z(251:500);
m= armax(ze,[2 3 1 0]);
compare(zv,m,6);
compare(zv,m,6,'Init','z') % No estimation of
                           % the initial state.
```

**See Also**

`findstates(idmodel)`

`pe`

`predict`

`sim`

**Purpose** Estimate covariance functions for time-domain iddata object

**Syntax**  
`R = covf(data,M)`  
`R = covf(data,M,maxsize)`

**Description** `data` is an iddata object and `M` is the maximum delay -1 for which the covariance function is estimated. The routine is intended for time-domain data only.

Let  $z$  contain the output and input channels

$$z(t) = \begin{bmatrix} y(t) \\ u(t) \end{bmatrix}$$

where  $y$  and  $u$  are the rows of `data.OutputData` and `data.InputData`, respectively, with a total of  $nz$  channels.

$R$  is returned as an  $nz^2$ -by- $M$  matrix with entries

$$R(i + (j - 1)nz, k + 1) = \frac{1}{N} \sum_{t=1}^N z_i(t)z_j(t+k) = \hat{R}_{ij}(k)$$

where  $z_j$  is the  $j$ th row of  $z$ , and missing values in the sum are replaced by zero.

The optional argument `maxsize` controls the memory size as explained under `Algorithm Properties`.

The easiest way to describe and unpack the result is to use

$$\text{reshape}(R(:,k+1),nz,nz) = E z(t)*z'(t+k)$$

Here  $'$  is complex conjugate transpose, which also explains how complex data is handled. The expectation symbol  $E$  corresponds to the sample means.

**Algorithm**

When `nz` is at most two, and when permitted by `maxsize`, a fast Fourier transform technique is applied. Otherwise, straightforward summing is used.

**See Also**

`iddata`

`spa`

**Purpose** Estimate impulse response using prewhitened-based correlation analysis

**Syntax**

```
cra(data);  
[ir,R,cl] = cra(data,M,na,plot);  
cra(R);
```

**Description** `data` is the output-input data given as an `iddata` object. The routine is intended for time-domain data only.

The routine only handles single-input-single-output data pairs. (For the multivariate case, apply `cra` to two signals at a time, or use `impulse`.) `cra` prewhitens the input sequence; that is, `cra` filters `u` through a filter chosen so that the result is as uncorrelated (white) as possible. The output `y` is subjected to the same filter, and then the covariance functions of the filtered `y` and `u` are computed and graphed. The cross correlation function between (prewhitened) input and output is also computed and graphed. Positive values of the lag variable then correspond to an influence from `u` to later values of `y`. In other words, significant correlation for negative lags is an indication of feedback from `y` to `u` in the data.

A properly scaled version of this correlation function is also an estimate of the system's impulse response `ir`. This is also graphed along with 99% confidence levels. The output argument `ir` is this impulse response estimate, so that its first entry corresponds to lag zero. (Negative lags are excluded in `ir`.) In the plot, the impulse response is scaled so that it corresponds to an impulse of height  $1/T$  and duration  $T$ , where  $T$  is the sampling interval of the data.

The output argument `R` contains the covariance/correlation information as follows:

- The first column of `R` contains the lag indices.
- The second column contains the covariance function of the (possibly filtered) output.

- The third column contains the covariance function of the (possibly prewhitened) input.
- The fourth column contains the correlation function. The plots can be redisplayed by `cra(R)`.

The output argument `c1` is the 99% confidence level for the impulse response estimate.

The optional argument `M` defines the number of lags for which the covariance/correlation functions are computed. These are from  $-M$  to  $M$ , so that the length of `R` is  $2M+1$ . The impulse response is computed from 0 to  $M$ . The default value of `M` is 20.

For the prewhitening, the input is fitted to an AR model of order `na`. The third argument of `cra` can change this order from its default value `na = 10`. With `na = 0` the covariance and correlation functions of the original data sequences are obtained.

`plot:` `plot = 0` gives no plots. `plot = 1` (the default) gives a plot of the estimated impulse response together with a 99% confidence region. `plot = 2` gives a plot of all the covariance functions.

An often better alternative to `cra` is the functions `impulse` and `step`, which use a high-order FIR model to estimate the impulse response.

## Examples

Compare a second-order ARX model's impulse response with the one obtained by correlation analysis.

```
ir = cra(z);
m = arx(z,[2 2 1]);
imp = [1;zeros(19,1)];
irth = sim(m,imp);
subplot(211)
plot([ir irth])
title('impulse responses')
subplot(212)
plot([cumsum(ir),cumsum(irth)])
title('step responses')
```

<b>Syntax</b>	<pre>C=customnet(H) C=customnet(H,Property1,Value1,...PropertyN,ValueN)</pre>
<b>Arguments</b>	<p>H</p> <p>User-defined function handle of the unit function of the custom net.</p> <p>H must point to a function of the form <code>[f,g,a] = function_name(x)</code>, where <code>f</code> is the value of the function, <code>g=df/dx</code>, and <code>a</code> indicates the unit function active range. <code>g</code> is significantly nonzero in the interval <code>[-a a]</code>.</p>
<b>Description</b>	<p>customnet is an object that stores a custom nonlinear estimator with a user-defined unit function.</p> <p>You can use the constructor to create the nonlinearity object, as follows:</p> <p><code>C=customnet(H)</code> creates a nonlinearity estimator object with a user-defined unit function using the function handle <code>H</code>.</p> <p><code>C=customnet(H,Property1,Value1,...PropertyN,ValueN)</code> creates a nonlinearity estimator using property-value pairs defined in “customnet Properties” on page 2-60.</p>
<b>Remarks</b>	<p>Use <code>customnet</code> to define a nonlinear function <math>y = F(x)</math>, where <math>y</math> is scalar and <math>x</math> is an <math>m</math>-dimensional row vector. The unit function is based on the following function expansion with a possible linear term <math>L</math>:</p> $F(x) = (x - r)PL + \alpha_1 f((x - r)Qb_1 + c_1) + \dots + \alpha_n f((x - r)Qb_n + c_n) + d$ <p>where <math>f</math> is a unit function that you define using the function handle <math>H</math>. <math>P</math> and <math>Q</math> are <math>m</math>-by-<math>p</math> and <math>m</math>-by-<math>q</math> projection matrices, respectively. The projection matrices <math>P</math> and <math>Q</math> are determined by principal component</p>

analysis of estimation data. Usually,  $p=m$ . If the components of  $x$  in the estimation data are linearly dependent, then  $p < m$ . The number of columns of  $Q$ ,  $q$ , corresponds to the number of components of  $x$  used in the unit function.

When used to estimate nonlinear ARX models,  $q$  is equal to the size of the `NonlinearRegressors` property of the `idnlarx` object. When used to estimate Hammerstein-Wiener models,  $m=q=1$  and  $Q$  is a scalar.

$r$  is a  $1$ -by- $m$  vector and represents the mean value of the regressor vector computed from estimation data.

$d$ ,  $a$ , and  $c$  are scalars.

$L$  is a  $p$ -by- $1$  vector.

$b$  represents  $q$ -by- $1$  vectors.

The function handle of the unit function of the custom net must have the form `[f,g,a] = function_name(x)`. This function must be vectorized, which means that for a vector or matrix  $x$ , the output arguments  $f$  and  $g$  must have the same size as  $x$  and be computed element-by-element.

### customnet Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
get(C)
% Get value of NumberOfUnits property
C.NumberOfUnits
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(C, 'LinearTerm', 'on')
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
NumberOfUnits	<p>Integer specifies the number of nonlinearity units in the expansion. Default=10.</p> <p>For example:</p> <pre>customnet(H, 'NumberOfUnits', 5)</pre>
LinearTerm	<p>Can have the following values:</p> <ul style="list-style-type: none"> <li>• 'on'—Estimates the vector <math>L</math> in the expansion.</li> <li>• 'off'—Fixes the vector <math>L</math> to zero.</li> </ul> <p>For example:</p> <pre>customnet(H, 'LinearTerm', 'on')</pre>
Parameters	<p>A structure containing the parameters in the nonlinear expansion, as follows:</p> <ul style="list-style-type: none"> <li>• RegressorMean: 1-by-m vector containing the means of <math>x</math> in estimation data, <math>r</math>.</li> <li>• NonLinearSubspace: m-by-q matrix containing <math>Q</math>.</li> <li>• LinearSubspace: m-by-p matrix containing <math>P</math>.</li> <li>• LinearCoef: p-by-1 vector <math>L</math>.</li> <li>• Dilation: q-by-1 matrix containing the values <math>b_k</math>.</li> <li>• Translation: 1-by-n vector containing the values <math>c_k</math>.</li> <li>• OutputCoef: n-by-1 vector containing the values <math>a_k</math>.</li> <li>• OutputOffset: scalar <math>d</math>.</li> </ul> <p>Typically, the values of this structure are set by estimating a model with a customnet nonlinearity.</p>
UnitFcn	Stores the function handle that points to the unit function.

## Examples

The following code, contained in `gaussunit.m`, defines a sample unit function.

```
[f, g, a] = GAUSSUNIT(x)
% x: unit function variable
% f: unit function value
% g: df/dx
% a: unit active range (g(x) is significantly
% nonzero in the interval [-a a])

% The unit function must be "vectorized": for
% a vector or matrix x, the output arguments f and g
% must have the same size as x,
% computed element-by-element.

% GAUSSUNIT customnet unit function example
[f, g, a] = gaussunit(x)
f = exp(-x.*x);
if nargout>1
    g = - 2*x.*f;
    a = 0.2;
end
```

You typically use custom networks in `nlarx` and `nlhw` model estimation commands. For example:

```
% Define handle to example unit function.
H = @gaussunit;
% Estimate nonlinear ARX model using
% Gauss unit function with 5 units.
m = nlarx(Data,Orders,customnet(H,'NumberOfUnits',5));
```

<b>Purpose</b>	Class representing custom regressor for nonlinear ARX models
<b>Syntax</b>	<p><code>C=customreg(Function,Arguments)</code>  <code>C=customreg(Function,Arguments,Delays,Vectorized)</code></p>
<b>Arguments</b>	<p><b>Function</b>          Function handle or string representing a function of input and output variables.</p> <p><b>Arguments</b>          Cell array of strings that represent the names of model inputs and outputs used in the function <code>Function</code>. Each input and output name must coincide with the strings in the <code>InputName</code> and <code>OutputName</code> properties of the corresponding <code>idnlarx</code> object. The size of <code>Arguments</code> must match the number of <code>Function</code> inputs.</p> <p><b>Delays</b>          Vector of positive integers representing the delays of <code>Arguments</code> variables. The size of <code>Delays</code> must match the size of <code>Arguments</code>. Default: 1 for each vector element.</p> <p><b>Vectorized</b>          Flag that indicates whether <code>Function</code> is in a format that supports vectorized computations when applied to vector arguments. Can have values 1 (true) and 0 (false). Default: 0.</p>
<b>Description</b>	<p><code>C=customreg(Function,Arguments)</code> creates an object that stores custom regressors for nonlinear ARX models. Custom regressor is defined using the function of input and output variables, <code>Function</code>.</p> <p><code>C=customreg(Function,Arguments,Delays,Vectorized)</code> create a custom regressor that includes the delays corresponding to inputs or outputs in <code>Arguments</code>.</p> <p>For multiple-output models with <code>p</code> outputs, the custom regressor is a <code>p</code>-by-1 cell array or an array of <code>customreg</code> object, where the <code>kyth</code> entry defines the custom regressor for output <code>ky</code>.</p>

## Remarks

Use the `customreg` object to define a custom regressor entering the nonlinearity estimator of the nonlinear ARX models (`idnlarx` object). The custom regressor function is usually a nonlinear function of inputs and outputs.

To list custom regressors of a multiple-output model, type the following command:

```
model.custom
```

To retrieve `r`th custom regressor for output `ky`, type the following command:

```
model.custom{ky}(r)
```

For more information about regressors, type `help regressors`.

For more information on creating custom regressors that are polynomial combinations of delayed inputs and outputs, type `help polyreg`.

Use the `Vectorized` property to specify whether to compute custom regressors using vectorized form. If you know that your regressor formulas can be vectorized, set `Vectorized` to 1 after creating the `customreg` object to achieve better performance. To better understand vectorization, consider that custom regressors are defined by a formula, such as  $z=@(x,y)x^2*y$ . `x` and `y` are vectors and each variable is evaluated over a time grid. Therefore, `z` must be evaluated for each  $(x_i, y_i)$  pair, and the results are concatenated to produce a `z` vector, as follows:

```
for k = 1:length(x)
    z(k) = x(k)^2*y(k)
end
```

The above expression is a nonvectorized computation and tends to be slow. Specifying a `Vectorized` computation uses MATLAB vectorization rules to evaluate the regressor expression using matrices instead of the FOR-loop and results in faster computation, as follows:

```
% "." indicates element-wise operation
```

```
z=(x.^2).*y
```

## customreg Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
get(C)
% Get value of Arguments property
C.Arguments
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(C, 'Vectorized', 0)
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
Function	<p>Function handle or string representing a function of standards regressors.</p> <p>For example:</p> <pre>cr = @(x,y) x*y</pre>
Arguments	<p>Cell array of strings that represent the names of model inputs and outputs used in the function <code>Function</code>. Each input and output name must coincide with the strings in the <code>InputName</code> and <code>OutputName</code> properties of the <code>idnlarx</code> object with the custom regressor. The size of <code>Arguments</code> must match the number of <code>Function</code> inputs.</p> <p>For example, <code>Arguments</code> correspond to <code>{'y1', 'u1'}</code> in the following syntax:</p> <pre>C = customreg(cr,{'y1', 'u1'},[2 3])</pre>

# customreg

Property Name	Description
Delays	<p>Vector of positive integers representing the delays of Arguments variables. The size of Delays must match the size of Arguments. Default: 1 for each vector element.</p> <p>For example, Delays correspond to [2 3] in the following syntax:</p> <pre>C = customreg(cr,{'y1','u1'},[2 3])</pre>
Vectorized	<p>Can have the following values:</p> <ul style="list-style-type: none"><li>• 1—Function is computed in vectorized form when called with vector arguments.</li><li>• 0—Function is not computed in vectorized form when called with vector arguments.</li></ul>

## Examples

Consider a system that has input  $u$  and output  $y$ . Suppose that the following transformations are useful for predicting future outputs, based on physical insight into the relationship between measured variables:

- $u(t-1)\sin(y(t-3))$
- $u(t-2)^3$

You can define custom regressors in two ways:

- Cell array of strings. For example:

```
C={'u(t-1)*sin(y(t-3))','u(t-2)^3'}
```

- Object array of customreg objects. For example:

```
cr1=@(x,y) x*sin(y)
cr2=@(x) x^3
C=[customreg(cr1,{'u' 'y'},[1 3]),...
  customreg(cr2,{'u'},2)]
```

After you define the custom regressors, estimate the nonlinear ARX model using the following syntax:

```
m = nlarx(Data,Orders,linear,'CustomRegressors',C)
```

In this case, `u` and `y` are `Data` channel names, and the nonlinearity estimator `linear` specifies that the prediction is a linear function of standard and custom regressors, where the custom regressor might be nonlinear. You can introduce additional nonlinearities using nonlinearity estimators. For a complete list of available nonlinearities, type `idprops idnlestimators`.

The following command is equivalent to the previous code snippet and incorporates custom regressor definitions directly in the estimator command:

```
m = nlarx(Data,Orders,'linear',...
          'CustomRegressors',...
          {'u1(t-1)*sin(y1(t-3))','u1(t-2)^3'});
```

## See Also

`customreg`  
`nlarx`

**Purpose** Transform linear model from continuous to discrete time

**Syntax**

```
md = c2d(mc,T)
md = c2d(mc,T,method)
[md,G] = c2d(mc,T,method)
```

**Description** `mc` is a continuous-time model such as any `idmodel` object (`idgrey`, `idproc`, `idpoly`, or `idss`). `md` is the model that is obtained when it is sampled with sampling interval `T`.

`method = 'zoh'` (default) makes the translation to discrete time under the assumption that the input is piecewise constant (zero-order hold).

`method = 'foh'` assumes the input to be piecewise linear between the sampling instants (first-order hold).

When you have the Control System Toolbox product installed, the following methods are also supported: `'tustin'`, `'prewarp'`, and `'matched'`. In these cases the covariance matrix is not transformed.

Note that the innovations variance  $\lambda$  of the continuous-time model is interpreted as the intensity of the spectral density of the noise spectrum. The noise variance in `md` is thus given as  $\lambda/T$ .

`idpoly` and `idss` models are returned in the same format. `idgrey` structures are preserved if their `CDMfile` property is equal to `'cd'`. Otherwise they are transformed to `idss` objects. `idproc` models are returned as `idgrey` objects.

For `idpoly` models, the covariance matrix is translated by the use of numerical derivatives. The step sizes used for the differentiation are given by the function `nuderst`. For `idss`, `idproc`, and `idgrey` models, the covariance matrix is not translated, but covariance information about the input-output properties is included in `md`. To inhibit the translation of covariance information (which may take some time), use `c2d(mc,T,'covariance','none')`.

The output argument `G` is a matrix that transforms the initial state `x0` of `mc` to the initial state of `md` as

$$X0d=G * [X0; u(0)],$$

where  $u(0)$  is the input at time 0. For `idproc` models, the state variables correspond to those of `idgrey(mc)`. For `idpoly` models, `G` is returned as the empty matrix.

## Examples

Define a continuous-time system and study the poles and zeros of the sampled counterpart.

```
mc = idpoly(1,1,1,1,[1 1 0], 'Ts', 0);  
md = c2d(mc, 0.5);  
pzmap(md)
```

`d2c`

# data2state(idnlarx)

---

**Purpose** Map past input/output data to current states of idnlarx model

**Syntax** `X = data2state(MODEL, IOSTRUCT)`  
`X = data2state(MODEL, DATA)`

**Description** `X = data2state(MODEL, IOSTRUCT)` maps the input and output samples in `IOSTRUCT` to the current states of `MODEL`, `X`. For a definition of the states of `idnlarx` models, see “Definition of `idnlarx` States” on page 2-185. The data in `IOSTRUCT` is interpreted as past samples of data, so that the returned state values must be interpreted as values at the time immediately after the time corresponding to the last (most recent) sample in the data.

`X = data2state(MODEL, DATA)` maps the input and output samples from `DATA` to the current states, `X`, of the model.

## Input

- `MODEL`: `idnlarx` model.
- `IOSTRUCT`: Structure with fields `Input` and `Output`. Samples in `IOSTRUCT` must be in the order of increasing time (the last row of values corresponds to the most recent time). Each field contains data samples corresponding to the past input and output of `MODEL` respectively.
  - `Input`: Matrix of `NU` columns, where `NU` is the number of inputs. The number of rows can be equal to either of the following:
    - Maximum input delay in `MODEL` (maximum across all input variables).
    - 1 to specify steady-state (constant) input values.
  - `Output`: Matrix of `NY` columns, where `NY` is the number of outputs. The number of rows can be equal to either of the following:
    - Maximum input delay in `MODEL` (maximum across all output variables).
    - 1 to specify steady-state (constant) output values.

- DATA: iddata object containing data samples. Samples in DATA must be in the order of increasing time (the last row of values corresponds to the most recent time). The number of samples in DATA must be greater than or equal to the maximum delay in the model across all input and output variables.

---

**Note** To determine maximum delay in each input and output channel of MODEL, use the `getDelayInfo` command. For more information, see the `getDelayInfo` reference page.

---

## Output

X is the state vector of MODEL corresponding to the time after the most recent sample in the input data (IOSTRUCT or DATA).

## Examples

In this example you determine the current state of an `idnlarx` model.

- 1 Load your data and create a data object.

```
load motorizedcamera;  
z = iddata(y,u,0.02,'Name','Motorized Camera', ...  
          'TimeUnit','s');
```

- 2 Estimate an `idnlarx` model from the data. The model has 6 inputs and 2 outputs.

```
mw1 = nlarx(z,[ones(2,2),ones(2,6),ones(2,6)],wavenet);
```

- 3 Compute the maximum delays across all output variables in `mw1`.

```
MaxDelays = getDelayInfo(mw1);
```

- 4 Represent the past input and output samples:

```
IOData = struct('Input', ...  
               rand(max(MaxDelays(3+1:end)),6), ...  
               'Output', ...
```

## data2state(idnlarx)

---

```
rand(max(MaxDelays(1:3)),2));
```

- 5 Compute the current states of mw1 based on the past data in IOSTRUCT.

```
X = data2state(mw1,IOData)
```

The previous command computes the state vector.

---

**Note** You can specify constant input levels with scalar values (10,20,30,40,50,60) for the input variables by setting IOSTRUCT.Input = [10, 20, 30, 40, 50, 60] instead of a matrix of values.

---

findstates(idnlarx)  
getDelayInfo
```

## Purpose

Class representing dead-zone nonlinearity estimator for Hammerstein-Wiener models

## Syntax

```
s=deadzone(ZeroInterval,I)
```

## Description

deadzone is an object that stores the dead-zone nonlinearity estimator for estimating Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`s=deadzone(ZeroInterval,I)` creates a dead-zone nonlinearity estimator object, initialized with the zero interval I.

Use `evaluate(d,x)` to compute the value of the function defined by the deadzone object d at x.

## Remarks

Use deadzone to define a nonlinear function  $y = F(x)$ , where  $F$  is a function of  $x$  and has the following characteristics:

$$\begin{array}{ll} a \leq x < b & F(x) = 0 \\ x < a & F(x) = x - a \\ x \geq b & F(x) = x - b \end{array}$$

$y$  and  $x$  are scalars.

## Properties

You can specify the property value as an argument in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List ZeroInterval property value
get(d)
d.ZeroInterval
```

You can also use the `set` function to set the value of particular properties. For example:

# deadzone

---

```
set(d, 'ZeroInterval', [-1.5 1.5])
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
ZeroInterval	<p>1-by-2 row vector that specifies the initial zero interval of the nonlinearity. Default=[NaN NaN].</p> <p>For example:</p> <pre>deadzone('ZeroInterval',[-1.5 1.5])</pre>

## Examples

Use `deadzone` to specify the dead-zone nonlinearity estimator in Hammerstein-Wiener models. For example:

```
m=nlhw(Data,Orders,deadzone([-1 1]),[]);
```

The dead-zone nonlinearity is initialized at the interval `[-1 1]`. The interval values are adjusted to the estimation data by `nlhw`.

## See Also

`nlhw`

**Purpose** Estimate time delay (dead time) from data

**Syntax**  
`nk = delayest(Data)`  
`nk = delayest(Data,na,nb,nkmin,nkmax,maxtest)`

**Description** Data is an iddata object containing the input-output data. It can also be an idfrd object defining frequency-response data. Only single-output data can be handled.

nk is returned as an integer or a row vector of integers, containing the estimated time delay in samples from the input(s) to the output in Data.

The estimate is based on a comparison of ARX models with different delays:

$$y(t) + a_1 y(t-1) + \dots + a_{na} y(t-na) = \dots \\ b_1 u(t-nk) + \dots + b_{nb} u(t-nb-nk+1)$$

The integer na is the order of the A polynomial (default 2). nb is a row vector of length equal to the number of inputs, containing the order(s) of the B polynomial(s) (default all 2).

nkmin and nkmax are row vectors of the same length as the number of inputs, containing the smallest and largest delays to be tested. Defaults are nkmin = 0 and nkmax = nkmin+20.

If nb, nkmax, and/or nkmin are entered as scalars in the multiple-input case, all inputs will be assigned the same values.

maxtest is the largest number of tests allowed (default 10,000).

# detrend

---

**Purpose** Subtract trend from time-domain, frequency-domain, or time-series data signal

**Syntax** `zd = detrend(z)`  
`zd = detrend(z,o,brkp)`

**Input** `z` Name of iddata object in the MATLAB workspace containing time-domain, frequency-domain, or time-series data.

---

**Note** For frequency-domain data, you can only remove a zeroth-order trend.

---

`o` Order of the trend, specified as one of the following values:

- 0: (Default) Specifies to subtract a mean value (zeroth-order trend) from each signal.
- 1: Specifies to subtract a linear trend (first-order trend) from each signal after performing a least-squares fit on the data.

`brkp` Data sample index that defines the discontinuities between successive linear trends, specified as one of the following types of values:

- Scalar: Specifies one discontinuity.
- Vector: Specifies several discontinuities, indicating to subtract multiple linear trends.

**Description** `zd = detrend(z)` subtracts the mean value (zeroth-order trend) from each signal in `z` and returns an iddata object `zd`. If `z` is frequency-domain data, the response at frequency 0 is zero.

`zd = detrend(z,o,brkp)` subtracts the mean value ( $o = 0$ ) or linear trend ( $o = 1$ ). You can subtract piecewise linear trends by specifying one or more breakpoints `brkp`, where a *breakpoint* is a data sample index (time value) that defines the discontinuities between successive linear trends. When `brkp` contains breakpoints that match the time vector, `detrend` subtracts a continuous piecewise linear trend.

---

**Note** `detrend` for `iddata` objects differs from `detrend` in the Signal Processing Toolbox product.

---

## Examples

### Example 1

In this example, you subtract several linear trends that connect at three breakpoints `[30 60 90]`, which correspond to the data sample indexes `data` where breakpoints occur.

```
data = detrend(data,1,[30 60 90]);
```

### Example 2

In this example, you subtract a mean value from the input signal and a V-shaped trend from the output signal, such that the V peak occurs at the breakpoint value of 119.

```
zd1 = z(:, :, []); zd2 = z(:, [], :);
zd1(:, 1, []) = detrend(z(:, 1, []), 1, 119);
zd2(:, [], 1) = detrend(z(:, [], 1));
zd = [zd1, zd2];
```

## See Also

“Subtracting Trends from Signals (Detrending)”

# diff

---

**Purpose**            Difference signals in iddata objects

**Syntax**            `zdi = diff(z)`  
                      `zdi = diff(z,n)`

**Description**        `z` is a time-domain iddata object. `diff(z)` and `diff(z,n)` apply this command to each of the input/output signals in `z`.

**Purpose**

Transform linear model from discrete to continuous time

**Syntax**

```
mc = d2c(md)
mc = d2c(md,method)
mc = d2c(md,'CovarianceMatrix',cov,'InputDelay',inpd)
```

**Description**

The discrete-time model `md`, given as any `idmodel` object, is converted to a continuous-time counterpart `mc`. The covariance matrix of the parameters in the model is also translated using the Gauss approximation formula and numerical derivatives of the transformation. The step sizes in the numerical derivatives are determined by the function `nuderst`. To inhibit the translation of the covariance matrix and save time, enter among the input arguments (`...,'CovarianceMatrix','None',...`) (any abbreviations will do).

`method` is one of the input intersample behaviors `'zoh'` (zero-order hold) or `'foh'` (first-order hold). If `method` is not specified, the `InterSample` behavior of the data from which `md` was estimated is used.

When you have Control System Toolbox installed, the following methods are also supported: `'tustin'`, `'prewarp'`, and `'matched'`. In these cases no translation of the covariance matrix takes place.

If the discrete-time model contains pure time delays, that is,  $nk > 1$ , then these are first removed before the transformation is made. These delays are appended as pure time delay (dead time) to the continuous-time model as the property `InputDelay`. To have the time delay approximated by a finite-dimensional continuous system, enter among the input arguments (`...,'InputDelay',0,...`).

If the noise variance is  $\lambda$  in `md`, and its sampling interval is  $T$ , then the continuous-time model has an indicated level of noise spectral density equal to  $T\lambda$ .

While `idpoly` and `idss` models are returned in the same format, `idvarx` models are returned as `idss` models `mc`. The reason is that the transformation does not preserve the special structure of `idvarx`. The `idgrey` structures are preserved if their `CDMfile` property is equal to `cd`. Otherwise they are transformed to `idss` objects.

---

**Note** The transformation from discrete to continuous time is not unique. `d2c` selects the continuous-time counterpart with the slowest time constants consistent with the discrete-time model. The lack of uniqueness also means that the transformation can be ill-conditioned or even singular. In particular, poles on the negative real axis, in the origin, or in the point 1, are likely to cause problems. Interpret the results with care.

---

## Examples

Transform an identified model to continuous time and compare the frequency responses of the two models.

```
m = n4sid(data,3)
mc = d2c(m);
bode(m,mc,'sd',3)
```

Note that you can include the transformation to continuous time in the `n4sid` command by specifying the model to be continuous time.

```
mc = n4sid(data,3,'Ts',0)
```

## See Also

`c2d`  
`nuderst`

**Purpose** Information about linear model estimation results

**Syntax** `m.EstimationInfo`  
`m.es`  
`m.es.DataLength`, etc

**Description** `EstimationInfo` for linear models is a structure whose fields give information about the results of model estimation. Depending on whether it is an estimated parametric `idmodel` or an estimated frequency response `idfrd`, `EstimationInfo` contains different fields.

---

**Note** For a description of nonlinear model `EstimationInfo` property, see the corresponding nonlinear model reference page.

---

### **idmodel Case**

The model structure will contain the properties `ParameterVector`, `CovarianceMatrix`, and `NoiseVariance`, which are all calculated in the estimation process (see the reference page for `idmodel`). In addition, `EstimationInfo` contains the following fields:

- **Status:** Information whether the model has been estimated, or modified after being estimated.
- **Method:** Name of the estimation command that produced the model.
- **LossFcn:** Value of the identification criterion at the estimate. Normally equal to the determinant of the covariance matrix of the prediction errors, that is, the determinant of `NoiseVariance`. Note that the loss function for the minimization might be different due to `LimitError`. The value of the nonrobustified loss function is always stored in `LossFcn`.
- **FPE:** Akaike's Final Prediction Error, defined as  $\text{LossFcn} \cdot (1+d/N) / (1-d/N)$ , where  $d$  is the number of estimated parameters and  $N$  is the length of the data record.

# EstimationInfo

---

- **DataName**: Name of the data set from which the model was estimated. This is equal to the property name of the `iddata` object. If this was not defined, the name of the `iddata` variable is used.
- **DataLength**: Length of the data record.
- **DataTs**: Sampling interval of the data.
- **DataDomain**: 'Time' or 'Frequency', depending on the data domain.
- **DataInterSample**: Intersample behavior of the data from which the model was estimated. This equals the property `InterSample` of the `iddata` object. (See `iddata`.)
- **WhyStop**: For models that have been estimated by iterative search. The stopping rule that caused the iterations to terminate. Assumes values such as 'MaxIter reached', 'No improvement possible along the search vector', or 'Near (local) minimum'. The latter means that the expected improvement is less than `Tolerance` (see `Algorithm Properties`).
- **UpdateNorm**: Norm of the Gauss-Newton vector at the last iteration.
- **LastImprovement**: Relative improvement of the criterion value at the last iteration.
- **Iterations**: Number of iterations used in the search.
- **InitialState**: Option actually used when `Model.InitialState = 'auto'`.
- **N4Weight**: For `n4sid` estimates, or estimates that have been initialized by `n4sid`: the actual value of `N4Weight` used.
- **N4Horizon**: For `n4sid` estimates, or estimates that have been initialized by `n4sid`: the actual value of `N4Horizon` used. See `n4sid` and `Algorithm Properties`.

## **idfrd Case**

If the `idfrd` model is obtained from an estimated parametric model,

```
g = idfrd(Model)
```

`g.EstimationInfo` is the same as `Model.EstimationInfo` as described above.

For an `idfrd` model that has been estimated from `etfe`, `spa`, or `spafdr`, `EstimationInfo` contains the following fields:

- **Status:** Whether the model is estimated or directly constructed.
- **Method:** `etfe`, `spa`, or `spafdr`
- **WindowSize:** Resolution parameter (or vector) used for the estimation
- **DataName, DataLength, DataTs, DataDomain, DataInterSample:** Properties of the estimation data as above.

## See Also

Algorithm Properties

`idpoly`

`idss`

**Purpose** Estimate empirical transfer functions and periodograms returning idfrd object

**Syntax** `g = etfe(data)`  
`g = etfe(data,M,N)`

**Description** `etfe` estimates the transfer function `g` of the general linear model

$$y(t) = G(q)u(t) + v(t)$$

`data` contains the output-input data and is an `iddata` object (time or frequency domain).

`g` is given as an `idfrd` object with the estimate of  $G(e^{i\omega})$  at the frequencies

$$w = [1:N]/N*\pi/T$$

The default value of `N` is 128.

In case `data` contains a time series (no input channels), `g` is returned as the periodogram of `y`.

When `M` is specified other than the default value `M = []`, a smoothing operation is performed on the raw spectral estimates. The effect of `M` is then similar to the effect of `M` in `spa`. This can be a useful alternative to `spa` for narrowband spectra and systems, which require large values of `M`.

When `etfe` is applied to time series, the corresponding spectral estimate is normalized in the way that is defined in “Understanding Spectrum Normalization”. `etfe` normalization differs from the `spectrum` normalization in the Signal Processing Toolbox product.

If the (input) data is marked as periodic (`data.Period = integer`) and contains an even number of periods, the response is computed at the frequencies  $k*2*\pi/\text{period}$  for `k = 0` up to the Nyquist frequency.

## Examples

Compare an empirical transfer function estimate to a smoothed spectral estimate.

```
ge = etfe(z);  
gs = spa(z);  
bode(ge,gs)
```

Generate a periodic input, simulate a system with it, and compare the frequency response of the estimated model with the true system at the excited frequency points.

```
m = idpoly([1 -1.5 0.7],[0 1 0.5]);  
u = iddata([],idinput([50,1,10], 'sine'));  
u.Period = 50;  
y = sim(m,u);  
me = etfe([y u])  
bode(me, 'b*',m)
```

## Algorithm

The empirical transfer function estimate is computed as the ratio of the output Fourier transform to the input Fourier transform, using `fft`. The periodogram is computed as the normalized absolute square of the Fourier transform of the time series.

You obtain the smoothed versions ( $M$  less than the length of  $z$ ) by applying a Hamming window to the output fast Fourier transform (FFT) times the conjugate of the input FFT, and to the absolute square of the input FFT, respectively, and subsequently forming the ratio of the results. The length of this Hamming window is equal to the number of data points in  $z$  divided by  $M$ , plus one.

# fcats

---

**Purpose** Concatenate frequency-domain signals in `idfrd` and `iddata` objects

**Syntax** `Mc = fcats(M1,M2,...Mn)`

**Description** `M1`, `M2`, etc., are all `idfrd` objects or `iddata` frequency-domain objects.

`Mc` is the corresponding object obtained by concatenation of the responses at all the frequencies in `Mk`.

Note that for `iddata` objects, this is the same as vertical concatenation (`vertcat`).

$$Mc = [M1;M2;...;Mn].$$

`iddata`  
`idfrd`

---

<b>Purpose</b>	Identify possible feedback in iddata data
<b>Syntax</b>	<code>[fbck,fbck0,nudir] = feedback(Data)</code>
<b>Description</b>	<p>Data is an iddata set with <math>N_y</math> outputs and <math>N_u</math> inputs.</p> <p>fbck is an <math>N_y</math>-by-<math>N_u</math> matrix indicating the feedback. The <math>k_y, k_u</math> entry is a measure of feedback from output <math>k_y</math> to input <math>k_u</math>. The value is a probability <math>P</math> in percent. Its interpretation is that if the hypothesis that there is no feedback from output <math>k_y</math> to input <math>k_u</math> were tested at the level <math>P</math>, it would have been rejected. An intuitive but technically incorrect way of thinking about this is to see <math>P</math> as “the probability of feedback.” Often only values above 90% are taken as indications of feedback. When fbck is calculated, direct dependence at lag zero between <math>u(t)</math> and <math>y(t)</math> is not regarded as a feedback effect.</p> <p>fbck0: Same as fbck, but direct dependence at lag 0 between <math>u(t)</math> and <math>y(t)</math> is viewed as feedback effect.</p> <p>nudir: A vector containing those input numbers that appear to have a direct effect on some outputs, that is, no delay from input to output.</p>
<b>See Also</b>	<p>advice</p> <p>iddata</p> <p>idmodel</p>

# ffplot

---

**Purpose** Plot frequency response and spectra

**Syntax**

```
ffplot(m)
[mag,phase,w] = ffplot(m)
[mag,phase,w,sdmag,sdphase] = ffplot(m)
ffplot(m1,m2,m3,...,w)
ffplot(m1,'PlotStyle1',m2,'PlotStyle2',...)
ffplot(m1,m2,m3,..'sd',sd,'mode',mode,'ap',ap)
```

**Description** This function has exactly the same syntax as `bode`. The only difference is that it gives graphs with linear frequency scales and Hz as the frequency unit.

<b>Purpose</b>	Transform <code>iddata</code> object to frequency domain
<b>Syntax</b>	<pre>Datf = fft(Data) Datf = fft(Data,N) Datf = fft(Data,N,'complex')</pre>
<b>Description</b>	<p>If <code>Data</code> is a time-domain <code>iddata</code> object with real-valued signals and with constant sampling interval <code>Ts</code>, <code>Datf</code> is returned as a frequency-domain <code>iddata</code> object with the frequency values equally distributed from frequency 0 to the Nyquist frequency. Whether the Nyquist frequency actually is included or not depends on the signal length (even or odd). Note that the FFTs are normalized by dividing each transform by the square root of the signal length. That is in order to preserve the signal power and noise level.</p> <p>In the default case, the length of the transformation is determined by the signal length. A second argument <code>N</code> will force FFT transformations of length <code>N</code>, padding with zeros if the signals in <code>Data</code> are shorter and truncating otherwise. Thus the number of frequencies in the real signal case will be <math>N/2</math> or <math>(N+1)/2</math>. If <code>Data</code> contains several experiments, <code>N</code> can be a row vector of corresponding length.</p> <p>For real signals, the default is that <code>Datf</code> only contains nonnegative frequencies. For complex-valued signals, negative frequencies are also included. To enforce negative frequencies in the real case, add a last argument, <code>'Complex'</code>.</p>
<b>See Also</b>	<pre>iddata ifft</pre>

# findop(idnlarx)

---

**Purpose** Compute operating point for nonlinear ARX model

**Syntax**

```
[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)
[X,U] = findop(SYS,SPEC)
[X,U] = findop(SYS,'snapshot',T,UIN,X0)
[X,U,REPORT] = findop(...)
findop(SYS,...,PVPairs)
```

**Description** `[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)` computes operating-point state values, X, and input values, U, from steady-state specifications for an `idnlarx` model. For more information about the states of an `idnlarx` model, see “Definition of `idnlarx` States” on page 2-185.

`[X,U] = findop(SYS,SPEC)` computes the equilibrium operating point using the specifications in the object `SPEC`. Whereas the previous command only lets you specify the input and output level, `SPEC` provides additional specification for computing the steady-state operating point.

`[X,U] = findop(SYS,'snapshot',T,UIN,X0)` computes the operating point at a simulation snapshot of time T using the specified input and initial state values.

`[X,U,REPORT] = findop(...)` creates a structure, `REPORT`, containing information about the algorithm for computing an operating point.

`findop(SYS,...,PVPairs)` specifies property-value pairs for setting algorithm options.

## Input

- `SYS`: `idnlarx` (nonlinear ARX) model.
- `'steady'`: Computes operating point using steady-state input and output levels.
- `'snapshot'`: Computes operating point at simulating snapshot of model `SYS` at time T.
- `InputLevel`: Steady-state input level for computing operating point. Use NaN when the value is unknown.

- **OutputLevel**: Steady-state output level for computing the operating point. Use NaN when the value is unknown.
- **SPEC**: Operating point specifications object. Use `SPEC = OPERSPEC(SYS)` to construct the SPEC object for model SYS. Then, configure SPEC options, such as signal bounds, known values, and initial guesses. See `operspec(idnlarx)` for more information.
- **T**: Simulation snapshot time at which to compute the operating point.
- **UIN**: Input for simulating the model. UIN is a double matrix or an `iddata` object. The number of input channels in UIN must match the number of SYS inputs.
- **X0**: Initial states for model simulation.  
Default: Zero.
- **PVPairs**: Property-value pairs for customizing the model `Algorithm` property fields, such as `SearchMethod`, `MaxSize`, and `Tolerance`.

## Output

- **X**: Operating point state values.
- **U**: Operating point input value.
- **REPORT**: Structure containing the following fields:
  - **SearchMethod**: String indicating the value of the `SearchMethod` property of `MODEL.Algorithm`.
  - **WhyStop**: String describing why the estimation stopped.
  - **Iterations**: Number of estimation iterations.
  - **FinalCost**: Final value of the sum of squared errors that the algorithm minimizes.
  - **FirstOrderOptimality**: Measure of the gradient of the search direction at the final parameter values when the search algorithm terminates. It is equal to the  $\infty$ -norm of the gradient vector.
  - **SignalLevels**: Structure containing fields `Input` and `Output`, which are the input and output signal levels of the operating point.

# findop(idnlarx)

---

## Algorithm

findop computes the operating point from steady-state operating point specifications or at a simulation snapshot.

### Computing the Operating Point from Steady-State Specifications

You specify to compute the steady-state operating point by calling findop in either of the following ways:

```
[X,U] = findop(SYS, 'steady', InputLevel, OutputLevel)
[X,U] = findop(SYS, SPEC)
```

When you use the syntax `[X,U] = findop(SYS, 'steady', InputLevel, OutputLevel)`, the algorithm assumes the following operating-point specifications:

- All finite input values are fixed values. Any NaN values specify an unknown input signal with the initial guess of 0.
- All finite output values are initial guess values. Any NaN values specify an unknown output signal with the initial guess of 0.
- The minimum and maximum bounds have default values (-/+ Inf) for both Input and Output properties in the specification object.

Using the syntax `[X,U] = findop(SYS, SPEC)`, you can specify additional information, such as the minimum and maximum constraints on the input/output signals and whether certain inputs are known (fixed).

To compute the states, X, and the input, U, of the steady-state operating point, findop uses the algorithm specified in the SearchMethod property of MODEL.Algorithm to minimize the norm of the error  $e(t) = y(t) - f(x(t), u(t))$ , where  $f$  is the nonlinearity estimator,  $x(t)$  are the model states, and  $u(t)$  is the input.

The algorithm uses the following independent variables for minimization:

- Unknown (unspecified) inputs

- Output signals

Because the states of a nonlinear ARX (`idnlarx`) model are delayed samples of the input and output variables, the values of all the states are the constant values of the corresponding steady-state inputs and outputs. For more information about the definition of nonlinear ARX model states, see “Definition of `idnlarx` States” on page 2-185.

## Computing the Operating Point at a Simulation Snapshot

When you use the syntax `[X,U] = findop(SYS, 'snapshot', T, UIN, X0)`, the algorithm simulates the model output until the snapshot time, `T`. At the snapshot time, the algorithm passes the input and output samples to the `data2state` command to map these values to the current state vector.

---

**Note** For snapshot-based computations, `findop` does not perform numerical optimization.

---

## Examples

In this example, you compute the operating point of an `idnlarx` model for a steady-state input level of 1.

- 1 Estimate an `idnlarx` model from sample data `iddata2`.

```
load iddata2;  
M = nlarx(z2,[4 3 2], 'wavenet');
```

- 2 Compute the steady-state operating point for an input level of 1.

```
x0 = findop(M, 'steady', 1, NaN)
```

# findop(idnlarx)

---

## See Also

`data2state(idnlarx)`

## Purpose

Compute operating point for Hammerstein-Wiener model

## Syntax

```
[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)
[X,U] = findop(SYS,SPEC)
[X,U] = findop(SYS,'snapshot',T,UIN,X0)
[X,U,REPORT] = findop(...)
findop(SYS,...,PVPairs)
```

## Description

`[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)` computes operating-point state values, `X`, and input values, `U`, from steady-state specifications for an `idnlhw` model. For more information about the states of an `idnlhw` model, see “Definition of `idnlhw` States” on page 2-218.

`[X,U] = findop(SYS,SPEC)` computes the equilibrium operating point using the specifications in the object `SPEC`. Whereas the previous command only lets you specify the input and output level, `SPEC` provides additional specification for computing the steady-state operating point.

`[X,U] = findop(SYS,'snapshot',T,UIN,X0)` computes the operating point at a simulation snapshot of time `T` using the specified input and initial state values.

`[X,U,REPORT] = findop(...)` creates a structure, `REPORT`, containing information about the algorithm for computing an operating point.

`findop(SYS,...,PVPairs)` specifies property-value pairs for setting algorithm options.

## Input

- `SYS`: `idnlhw` (Hammerstein-Wiener) model.
- `'steady'`: Computes operating point using steady-state input and output levels.
- `'snapshot'`: Computes operating point at simulating snapshot of model `SYS` at time `T`.
- `InputLevel`: Steady-state input level for computing operating point. Use `NaN` when the value is unknown. Do not enter `OutputLevel` when `InputLevel` does not contain any `NaN` values.

# findop(idnlhw)

---

- **OutputLevel**: Steady-state output level for computing the operating point. Use NaN when the value is unknown.
- **SPEC**: Operating point specifications object. Use `SPEC = OPERSPEC(SYS)` to construct the SPEC object for model SYS. Then, configure SPEC options, such as signal bounds, known values, and initial guesses. See `operspec(idnlhw)` for more information.
- **T**: Simulation snapshot time at which to compute the operating point.
- **UIN**: Input for simulating the model. UIN is a double matrix or an `iddata` object. The number of input channels in UIN must match the number of SYS inputs.
- **X0**: Initial states for model simulation.  
Default: Zero.
- **PVPairs**: Property-value pairs for customizing the model `Algorithm` property fields, such as `SearchMethod`, `MaxSize`, and `Tolerance`.

## Output

- **X**: Operating point state values.
- **U**: Operating point input value.
- **REPORT**: Structure containing the following fields:
  - **SearchMethod**: String indicating the value of the `SearchMethod` property of `MODEL.Algorithm`.
  - **WhyStop**: String describing why the estimation stopped.
  - **Iterations**: Number of estimation iterations.
  - **FinalCost**: Final value of the sum of squared errors that the algorithm minimizes.
  - **FirstOrderOptimality**: Measure of the gradient of the search direction at the final parameter values when the search algorithm terminates. It is equal to the  $\infty$ -norm of the gradient vector.
  - **SignalLevels**: Structure containing fields `Input` and `Output`, which are the input and output signal levels of the operating point.

## Algorithm

findop computes the operating point from steady-state operating point specifications or at a simulation snapshot.

### Computing the Operating Point from Steady-State Specifications

You specify to compute the steady-state operating point by calling findop in either of the following ways:

```
[X,U] = findop(SYS, 'steady', InputLevel, OutputLevel)
[X,U] = findop(SYS, SPEC)
```

When you use the syntax `[X,U] = findop(SYS, 'steady', InputLevel, OutputLevel)`, the algorithm assumes the following operating-point specifications:

- All finite input values are fixed values. Any NaN values specify an unknown input signal with the initial guess of 0.
- All finite output values are initial guess values. Any NaN values specify an unknown output signal with the initial guess of 0.
- The minimum and maximum bounds have default values (-/+ Inf) for both Input and Output properties in the specification object.

Using the syntax `[X,U] = findop(SYS, SPEC)`, you can specify additional information, such as the minimum and maximum constraints on the input/output signals and whether certain inputs are known (fixed).

findop uses a different approach to compute the steady-state operating point depending on how much information you provide for this computation:

- When you specify values for all input levels (no NaN values). For a given input level,  $U$ , the equilibrium state values are  $X = \text{inv}(I-A)*B*f(U)$ , where  $[A,B,C,D] = \text{ssdata}(\text{model.LinearModel})$ , and  $f()$  is the input nonlinearity.

- When you specify known and unknown input levels. `findop` uses numerical optimization to minimize the norm of the error and compute the operating point. The total error is the union of contributions from  $e_1$  and  $e_2$ ,  $e(t) = (e_1(t)e_2(t))$ , such that:
  - $e_1$  applies for known outputs and the algorithm minimizes  $e_1 = y - g(L(x, f(u)))$ , where  $f$  is the input nonlinearity,  $L(x, u)$  is the linear model with states  $x$ , and  $g$  is the output nonlinearity.
  - $e_2$  applies for unknown outputs and the error is a measure of whether these outputs are within the specified minimum and maximum bounds. If a variable is within its specified bounds, the corresponding error is zero. Otherwise, the error is equal to the distance from the nearest bound. For example, if a free output variable has a value  $z$  and its minimum and maximum bounds are  $L$  and  $U$ , respectively, then the error is  $e_2 = \max[z - U, L - z, 0]$ .

The independent variables for the minimization problem are the unknown inputs. In the error definition  $e$ , both the input  $u$  and the states  $x$  are free variables. To get an error expression that contains only unknown inputs as free variables, the algorithm `findop` specifies the states as a function of inputs by imposing steady-state conditions:  $x = \text{inv}(I-A)*B*f(U)$ , where  $[A, B, C, D]$  are state-space parameters corresponding to the linear model  $L(x, u)$ . Thus, substituting  $x = \text{inv}(I-A)*B*f(U)$  into the error function results in an error expression that contains only unknown inputs as free variables computed by the optimization algorithm.

### Computing the Operating Point at a Simulation Snapshot

When you use the syntax `[X,U] = findop(SYS, 'snapshot', T, UIN, X0)`, the algorithm simulates the model output until the snapshot time,  $T$ . At the snapshot time, the algorithm computes the inputs for the linear model block of the Hammerstein-Wiener model (`LinearModel` property of the `idnlhw` object) by transforming the given inputs using the input nonlinearity:  $w = f(u)$ . `findop` uses the resulting  $w$  to compute  $x$  until the snapshot time using the following equation:  $x(t+1) = Ax(t) + Bw(t)$ , where  $[A, B, C, D] = \text{ssdata}(\text{model.LinearModel})$ .

---

**Note** For snapshot-based computations, `findop` does not perform numerical optimization.

---

## Examples

In this example, you compute the operating point of an `idnlhw` model for a steady-state input level of 1.

- 1 Estimate an `idnlhw` model from sample data `iddata2`.

```
load iddata2;
M = nlnhw(z2,[4 3 2], 'wavenet', 'pw1');
```

- 2 Compute the steady-state operating point for an input level of 1.

```
x0 = findop(M, 'steady', 1, NaN)
```

The resulting operating-point state values are, as follows:

```
x0 =
    4.309851305460448
   -4.468881971945637
    1.242120308173632
   -0.085288756364965
    0.613281249999998
```

```

# findstates(idmodel)

---

**Purpose** Estimate initial states of linear model from data

**Syntax**  
`X0 = findstates(MODEL,DATA)`  
`X0 = findstates(MODEL,DATA,INIT)`

**Description** `X0 = findstates(MODEL,DATA)` estimates the initial states of `MODEL` that provide the best fit to output signal in `DATA`.  
`X0 = findstates(MODEL,DATA,INIT)` specifies how the initial states should be estimated using the flag `INIT`.

**Input**

- `MODEL`: `idmodel` object. If `MODEL` is not in state-space form, initial states must be interpreted as state values corresponding to `idss(MODEL)`.
- `DATA`: `iddata` object with matching input/output dimensions.
- `INIT`: Flag indicating how the initial states should be estimated. This flag can have the following values:
  - `'e'`: (Default) Estimate initial state so that the norm of prediction error is minimized.
  - `'d'`: (Only available for discrete-time models) Same as `'e'`, but if `MODEL.InputDelay` is non-zero, these delays are first converted to explicit model delays, and the extra initial states (those corresponding to the delays) are also estimated and returned.

**Output**

- `X0`: Estimated initial state vector corresponding to time `DATA.TStart`. For multi-experiment data, `X0` is a matrix with as many columns as there are experiments.

**Examples** In this example you estimate an `idpoly` model and simulate it such that the response of the estimated model matches the estimation data's output signal as closely as possible.

**1** Load sample data.

```
load iddata1 % estimation data z1;
```

**2** Estimate a linear model from the data.

```
model = arx(z1, [2 2 1]); % idpoly model
```

**3** Estimate the value of the initial states to best fit the measured output `z1.y`.

```
x0est = findstates(model, z1);
```

**4** Simulate the model.

```
sim(model, z1.u, 'init', x0est)
```

# findstates(idnlarx)

---

**Purpose** Estimate initial states of nonlinear ARX model from data

**Syntax**

```
X0 = findstates(MODEL,DATA)
X0 = findstates(MODEL,DATA,X0INIT)
X0 = findstates(MODEL,DATA,X0INIT,PRED_OR_SIM)
X0 = findstates(MODEL,DATA,X0INIT,PRED_OR_SIM,PVPairs)
[X0, REPORT] = findstates(...)
```

**Description** `X0 = findstates(MODEL,DATA)` estimates the initial states of an `idnlarx` model that minimize the error between the output measurements in `DATA` and the predicted output of the model. The states of an `idnlarx` model are defined as the delayed samples of input and output variables. For more information about the definition of states for `idnlarx` models, see “Definition of `idnlarx` States” on page 2-185.

`X0 = findstates(MODEL,DATA,X0INIT)` specifies an initial guess for estimating the initial states.

`X0 = findstates(MODEL,DATA,X0INIT,PRED_OR_SIM)` allows switching between prediction-error (default) and simulation-error minimization.

`X0 = findstates(MODEL,DATA,X0INIT,PRED_OR_SIM,PVPairs)` lets you specify the algorithm properties that control the numerical optimization process as property-value pairs.

`[X0, REPORT] = findstates(...)` creates a report to summarize results of numerical optimization that is performed to search for the model states.

**Input**

- `MODEL`: `idnlarx` model.
- `DATA`: `iddata` object from which to estimate the initial states of `MODEL`.
- `X0INIT`: Initial guess for value of `X0`. Must be a vector of length equal to the number of the states of `MODEL` (`sum(getDelayInfo(MODEL))`).
- `PRED_OR_SIM`: Specifies minimization criteria using one of the following values:

- 'prediction': (Default) Estimation of initial states by minimizing the difference between the measured output data and 1-step-ahead predicted response of the model.
- 'simulation': Estimation of initial states by minimizing the difference between the measured output and the simulated response of the model. This estimation algorithm can be slower than 'prediction'.
- PVPairs: Property-value pairs that specify the algorithm properties that control numerical optimization process. By default, algorithm properties are read from the `Algorithm` property of `MODEL`. You can override `MODEL.Algorithm` properties using property-value pairs. For example you might set `SearchMethod`, `MaxSize`, `Tolerance`, and `Display`.

## Output

- `X0`: Estimated initial state vector corresponding to time `DATA.TStart`. For multi-experiment data, `X0` is a matrix with as many columns as there are experiments.
- `REPORT`: Structure containing the following fields:
  - 'EstimationCriterion': String containing the minimization method used.
  - 'SearchMethod': String indicating the value of the `SearchMethod` property of `MODEL.Algorithm`.
  - 'WhyStop': String describing why the estimation was stopped.
  - 'Iterations': Number of iterations carried out during estimation.
  - 'FinalCost': The final value of the sum of squared errors that the search method attempts to minimize
  - 'FirstOrderOptimality': Measure of the gradient of the search direction at the final value of the parameter set when the search algorithm terminates. It is equal to the  $\infty$ -norm of the gradient vector.

# findstates(idnlarx)

---

## Examples

### Estimating Initial States

In this example, you use sample data `z1` to create a nonlinear ARX model. You use `findstates` to compute the initial states of the model such that the difference between the predicted output of the model and the output data in `z2` is minimized.

- 1 Load the sample data and create two data objects `z1` and `z2`.

```
load twotankdata
% Create data objects z1 and z2.
z = iddata(y,u,0.2,'Name','Two tank system');
z1 = z(1:1000); z2 = z(1001:2000);
```

- 2 Estimate the `idnlarx` model.

```
% Estimate a nonlinear ARX model from data in z1.
mw1 = nlarx(z1,[5 1 3],wavenet('NumberOfUnits',8));
```

- 3 Estimate the initial states of the model.

```
% Find the initial states X0 of mw1 that minimize
% the error between the output data of z2 and the
% simulated output of mw1.
X0 = findstates(mw1,z2,[],'sim')
```

### Estimating Initial States for Multiple-Experiment Data

In this example, you estimate the initial states for each data set in a multiple-experiment data object.

- 1 Create a multi-experiment data set from `z1` and `z2`:

```
% Create a multi-experiment data set.
zm = merge(z1,z2);
```

- 2 Estimate the initial states for each experiment in the data set, such that the one-step-ahead prediction error is minimized for each data set.

```
% Estimate initial states for each data set in zm.  
X0 = findstates(mw1,zm)
```

findstates(idmodel)  
findstates(idnlhw)
```

# findstates(idnlgrey)

---

**Purpose** Estimate initial states of nonlinear grey-box model from data

**Syntax**

```
X0 = findstates(NLSYS,DATA);  
[X0,ESTINFO] = findstates(NLSYS,DATA);  
[X0,ESTINFO] = findstates(NLSYS,DATA,X0INIT);
```

**Description** `X0 = findstates(NLSYS,DATA);` estimates the initial states of an `idnlgrey` model from given data. For more information about the states of `idnlgrey` models, see “Definition of `idnlgrey` States” on page 2-206.

`[X0,ESTINFO] = findstates(NLSYS,DATA);` returns basic information about the estimation.

`[X0,ESTINFO] = findstates(NLSYS,DATA,X0INIT);` specifies an initial guess for `X0`.

## Input

- `NLSYS`: `idnlgrey` model whose output is to be predicted.
- `DATA`: Input/output data  $DATA = [Y \ U]$ , where `U` and `Y` are the following:
  - `U`: Input data that can be given either as an `iddata` object or as a matrix  $U = [U_1 \ U_2 \ \dots \ U_m]$ , where the  $k^{th}$  column vector is input  $U_k$
  - `Y`: Either an `iddata` object or a matrix of outputs (with as many columns as there are outputs).

---

**Note** For time-continuous `idnlgrey` models, `DATA` passed as a matrix will cause the data sample interval  $T_s$  to be assumed to be equal to 1.

---

- `X0INIT`: Initial state strategy to use:
  - `'zero'`: Use zero initial state and estimate all states (`NLSYS.InitialStates.Fixed` is thus ignored). Notice that all states are estimated, whereas they are fixed in `predict`.

- 'estimate': NLSYS.InitialStates determines the values of the states, but all initial states are estimated (NLSYS.InitialStates.Fixed is thus ignored).
- 'model': (Default) NLSYS.InitialStates determines the values of the initial states, which initial states to estimate, as well as their maximum and minimum values.
- vector/matrix: Column vector of appropriate length to be used as an initial guess for initial states. For multiple experiment DATA, X0INIT may be a matrix whose columns give different initial states for each experiment. With this option, all initial states are estimated (and not fixed as in predict) (NLSYS.InitialStates.Fixed is thus ignored).
- struct array: Nx-by-1 structure array with fields:
  - Name: Name of the state (a string).
  - Unit: Unit of the state (a string).
  - Value: Value of the states (a finite real 1-by-Ne vector, where Ne is the number of experiments).
  - Minimum: Minimum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same minimum value).
  - Maximum: Maximum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same maximum value).
  - Fixed: Boolean 1-by-Ne vector, or a scalar Boolean (applicable for all states) specifying whether the initial state is fixed or not.

## Output

- X0: Matrix containing the initial states. In the single experiment case it is a column vector of length Nx. For multi-experiment data, X0 is a matrix with as many columns as there are experiments.
- ESTINFO: Structure or Ne-by-1 structure array containing basic information about the estimation result (some of the fields normally stored in NLSYS.EstimationInfo). For multi-experiment data,

# findstates(idnlgrey)

---

ESTINFO is an Ne-by-1 structure array with elements providing initial state estimation information related to each experiment.

## Examples

### Estimating Individual Initial States Selectively

In this example you estimate the initial states of a model selectively, fixing the first state and allowing the second state of the model to be estimated. First you create a model from sample data and set the `Fixed` property of the model such that the second state is free and the first is fixed.

- 1 Specify the file describing the model structure, the model orders, and model parameters.

```
% Specify the file describing the model structure:
FileName = 'dcmotor_m';
% Specify the model orders [ny nu nx]
Order = [2 1 2];
% Specify the model parameters
% (see idnlgreydemo1 for more information)
Parameters = [0.24365; 0.24964];
```

- 2 Estimate the model parameters and set the model properties:

```
nlgr = idnlgrey(FileName, Order, Parameters);
set(nlgr, 'InputName', 'Voltage', 'OutputName', ...
    {'Angular position', 'Angular velocity'});
```

- 3 Free the second state while keeping the first one fixed.

```
setinit(nlgr, 'Fixed', {1 0});
```

- 4 Load the estimation data.

```
load(fullfile(matlabroot, 'toolbox', 'ident', ...
    'iddemos', 'data', 'dcmotordata'));
z = iddata(y,u,0.1, 'Name', 'DC-motor', ...
    'InputName', 'Voltage', 'OutputName', ...
    {'Angular position', 'Angular velocity'});
```

- 5 Estimate the free states of the model.

```
[X0,EstInfo] = findstates(nlgr,z)
```

## Estimating Initial States Starting from States Stored in Model

This example shows how you can estimate all of the initial states, starting from the initial state 0, then from the initial states stored in the model `nlgr`, and finally using a numerical initial states vector as the initial guess.

- 1 Estimate all the initial states starting from 0.

```
X0 = findstates(nlgr,z,'zero');
```

- 2 Estimate the free initial states specified by `nlgr`, starting from the initial state stored in `nlgr`.

```
X0 = findstates(nlgr, z, 'mod');
```

- 3 Estimate all the initial states, starting from an initial state vector that you specify.

```
nlgr.Algorithm.Display = 'full';
```

```
% Starting from an initial state vector [10;10]  
X0 = findstates(nlgr,z,[10;10])
```

## Advanced Use of findstates(idnlgrey)

The following example shows advanced use of `findstates`. Here you estimate states for multi-experiment data, such that the states of model `nlgr` are estimated separately for each experiment. After creating a 3-experiment data set `z3`, you estimate individual initial states separately.

- 1 Create a three-experiment data set.

## findstates(idnlgrey)

---

```
z3 = merge(z, z, z); % 3-experiment data
```

- 2 Fix some initial states and only estimate the free initial states starting of with the initial state in `nlgr`. This means that both elements of state vector 1 will be estimated, that no state of the second state vector will be estimated, and that only the first state of state vector 3 is estimated.

```
% prepare model for 3-experiment data  
nlgr = pem(z3, nlgr, 'Display', 'off');
```

- 3 Specify which initial states to fix, and set the `Display` property of `Algorithm` to `'full'`.

```
nlgr.InitialStates(1).Fixed = [true false true];  
nlgr.InitialStates(2).Fixed = [true false false];  
nlgr.Algorithm.Display = 'full';
```

- 4 Estimate the initial states and obtain information about the estimation.

```
[X0, EstInfo] = findstates(nlgr, z3);
```

# findstates(idnlhw)

---

## Output

- X0: Estimated initial state vector corresponding to time DATA.TStart. For multi-experiment data, X0 is a matrix with as many columns as there are experiments.
- REPORT: Structure containing the following fields:
  - 'EstimationCriterion': String containing the minimization method used.
  - 'SearchMethod': String indicating the value of the SearchMethod property of MODEL.Algorithm.
  - 'WhyStop': String describing why the estimation was stopped.
  - 'Iterations': Number of iterations carried out during estimation.
  - 'FinalCost': The final value of the sum of squared errors that the search method attempts to minimize
  - 'FirstOrderOptimality': Measure of the gradient of the search direction at the final value of the parameter set when the search algorithm terminates. It is equal to the  $\infty$ -norm of the gradient vector.

## Examples

In this example, you create an idnlrx model from sample data and estimate initial states using another data set. Next you jointly estimate the states for separate data sets contained in multi-experiment data.

- 1 Load the data and create iddata objects z1 and z2.

```
load twotankdata

z = iddata(y, u, 0.2, 'Name', 'Two tank system');
z1 = z(1:1000); z2 = z(1001:2000);
```

- 2 Estimate an idnlhw model from data.

```
m1=idnlhw(z1,[4 2 1], 'unitgain' , 'pwnlinear')
```

- 3 Estimate the initial states of m1 using data z2.

```
% Estimate initial states. View estimation trace and use  
% only 5 iterations in the search algorithm  
X0 = findstates(m1,z2,[],'MaxIter',5,'Display','on')
```

- 4** Estimate states using multiple-experiment data. There are separate sets of initial states for each experiment. The states of all data experiments are jointly estimated, and X0 is returned as a matrix with as many columns as there are data experiments.

```
zm = merge(z1,z2);  
X0 = findstates(m1, zm)
```

# frd

---

**Purpose** Convert idfrd objects to Control System Toolbox frequency-response LTI model

**Syntax** `sys = frd(mod)`

**Description** `mod` is an idfrd object. `sys` is returned as an frd object. The fields `Frequency`, `ResponseData`, `Units`, `Ts`, `InputDelay`, `InputName`, `OutputName` and `Notes` in `mod` are transferred to `sys`. The remaining fields (`SpectrumData`, `CovarianceData` and `NoiseCovariance`) are ignored. The command, therefore, cannot be applied to a time-series idfrd model object.

**See Also** `ss`  
`tf`  
`zpk`

<b>Purpose</b>	Frequency-response data from <code>idmodel</code> or <code>idfrd</code> object
<b>Alternative</b>	<code>idfrd</code> computes the same information as <code>freqresp</code> and stores it in the <code>idfrd</code> model object.
<b>Syntax</b>	<code>H = freqresp(m)</code> <code>[H,w,covH] = freqresp(m,w)</code>
<b>Description</b>	<p><code>H = freqresp(m)</code> returns the frequency response <code>H</code> of the model <code>m</code> at default frequencies determined from the dynamics of the model. For <code>idmodel</code> models, computes the frequency response of the model. For <code>idfrd</code> models, extracts the frequency data from the model object. If <code>m</code> contains nonzero delays (stored as <code>m.InputDelay</code>), these delays are absorbed into the returned frequency response.</p> <p><code>[H,w,covH] = freqresp(m,w)</code> returns the frequency response <code>H</code> of the model <code>m</code> at frequencies <code>w</code>. For <code>idfrd</code> models with input channels, the frequency response is <code>H = m.ResponseData</code> and the covariance of the response is <code>covH = m.CovarianceData</code>. For time-series <code>idfrd</code> models (power spectra), the frequency response is <code>H = m.SpectrumData</code> and the covariance of the response is <code>covH = m.NoiseCovariance</code>.</p>

---

**Tip** For a SISO model, use `H(:)` to obtain a vector of the frequency response. If models containing input channels, you can get the spectrum information of the noise (output disturbance) signal using `freqresp(m('n'))`.

---

### Inputs

`m`  
Name of the `idmodel` or `idfrd` model object.

**w**  
Frequencies for computing the frequency response, specified as a vector of real values in rad/s.

---

**Note** If you do not specify **w**, **freqresp** returns the frequency response at default frequencies determined from the dynamics of the model.

---

## Outputs

**H**  
Frequency response data of the model.

If **m** has **ny** outputs and **nu** inputs, and **w** contains **Nw** frequencies, the output **H** is an **ny-by-nu-by-Nw** array such that  $H(:, :, k)$  is a complex-valued response at frequency  $w(k)$ .

**w**  
Frequencies of the response, returned as a vector of real values in rad/s.

**covH**  
For a model with input channels, covariance of the response of a model that is a 5-D array. **covH(ky, ku, k, :, :)** is the 2-by-2 covariance matrix of the response from the input **ku** to the output **ky** at frequency  $w(k)$ . The (1,1) element is the variance of the real part, the (2,2) element is the variance of the imaginary part, and the (1,2) and (2,1) elements are the covariance between the real and imaginary parts.

---

**Tip** **squeeze(covH(ky, ku, k, :, :))** returns the covariance matrix of the corresponding response.

---

For a time-series model (no input channels),  $H$  is an  $n_y$ -by- $n_y$ -by- $N_w$  array of the power spectrum of the outputs. Thus,  $H(:, :, k)$  is the spectrum matrix at frequency  $w(k)$ . The element  $H(k_1, k_2, k)$  is the cross spectrum between outputs  $k_1$  and  $k_2$  at frequency  $w(k)$ . When  $k_1 = k_2$ , this is the real-valued power spectrum of output  $k_1$ .

$\text{covH}$  is then the covariance of the estimated spectrum  $H$  such that  $\text{covH}(k_1, k_1, k)$  is the variance of the power spectrum estimate of output  $k_1$  at frequency  $w(k)$ . No information about the variance of the cross spectra is given; that is,  $\text{covH}(k_1, k_2, k) = 0$  for  $k_1$  not equal to  $k_2$ .

**Purpose** Akaike Final Prediction Error for estimated model

**Syntax** `fp = fpe(Model1,Model2,Model3,...)`

**Description** Model is the name of an `idarx`, `idgrey`, `idpoly`, `idproc`, `idss`, `idnlarx`, `idnlhw`, or `idnlgrey` model object.

`fp` is returned as a row vector containing the values of the Akaike Final Prediction Error (FPE) for the different models.

**Definition** Akaike's Final Prediction Error (FPE) criterion provides a measure of model quality by simulating the situation where the model is tested on a different data set. After computing several different models, you can compare them using this criterion. According to Akaike's theory, the most accurate model has the smallest FPE.

---

**Note** If you use the same data set for both model estimation and validation, the fit always improves as you increase the model order and, therefore, the flexibility of the model structure.

---

Akaike's Final Prediction Error (FPE) is defined by the following equation:

$$FPE = V \left( \frac{1 + d/N}{1 - d/N} \right)$$

where  $V$  is the loss function,  $d$  is the number of estimated parameters, and  $N$  is the number of values in the estimation data set.

The toolbox assumes that the final prediction error is asymptotic for  $d \ll N$  and uses the following approximation to compute FPE:

$$FPE = V \left( 1 + 2d/N \right)$$

The loss function  $V$  is defined by the following equation:

$$V = \det \left( \frac{1}{N} \sum_1^N \varepsilon(t, \theta_N) (\varepsilon(t, \theta_N))^T \right)$$

where  $\theta_N$  represents the estimated parameters.

# fselect

---

**Purpose**                      Frequencies from idfrd object

**Syntax**                      `idfm = fselect(idf,index)`  
`idfm = fselect(idf,Fmin,Fmax)`

**Description**                `idf` is any `idfrd` object. `index` is a row vector of frequency indices, so that `idfm` is the `idfrd` object that contains the response at frequencies `idf.Frequency(Index)`.

If `Fmin` and `Fmax` are specified, `idfm` contains responses at frequencies between `Fmin` and `Fmax`.

Note that the operation is the same as `dat(index)` for an `iddata` object.

**Examples**                    Select every fifth frequency:

```
idfm = fselect(idf,5:5:100)
```

Select the response in the third quadrant:

```
ph = angle(squeeze(idf.response));  
idfm = fselect(idf,find(ph>-pi & ph <-pi/2))
```

**Purpose** Get input/output delay information for idnlarx model structure

**Syntax**  
DELAYS = getDelayInfo(MODEL)  
DELAYS = getDelayInfo(MODEL,TYPE)

**Description** DELAYS = getDelayInfo(MODEL) obtains the maximum delay in each input and output variable of an idnlarx model.

DELAYS = getDelayInfo(MODEL,TYPE) lets you choose between obtaining maximum delays across all input and output variables or maximum delays for each output variable individually. When delays are obtained for each output variable individually a matrix is returned, where each row is a vector containing  $n_y+n_u$  maximum delays for each output variable, and:

- $n_y$  is the number of outputs of MODEL.
- $n_u$  is the number of inputs of MODEL.

Delay information is useful for determining the number of states in the model. For nonlinear ARX models, the states are related to the set of delayed input and output variables that define the model structure (regressors). For example, if an input or output variable  $p$  has a maximum delay of  $D$  samples, then it contributes  $D$  elements to the state vector:

$$p(t-1), p(t-2), \dots, p(t-D)$$

The number of states of a nonlinear ARX model equals the sum of the maximum delays of each input and output variable. For more information about the definition of states for idnlarx models, see “Definition of idnlarx States” on page 2-185

**Input** getDelayInfo accepts the following arguments:

- MODEL: idnlarx model.

# getDelayInfo

---

- TYPE: (Optional) Specifies whether to obtain channel delays 'channelwise' or 'all' as follows:
  - 'all': Default value. DELAYS contains the maximum delays across each output (vector of  $n_y+n_u$  entries, where  $[n_y, n_u] = \text{size}(\text{MODEL})$ ).
  - 'channelwise': DELAYS contains delay values separated for each output ( $n_y$ -by- $(n_y+n_u)$  matrix).

## Output

- DELAYS: Contains delay information in a vector of length  $n_y+n_u$  arranged with output channels preceding the input channels, i.e.,  $[y_1, y_2, \dots, u_1, u_2, \dots]$ .

## Examples

In the following example you create a 2-output, 3-input nonlinear ARX model, then verify the number of delays using `getDelayInfo`.

**1** Create an `idnlarx` model.

```
M = idnlarx([2 0 2 2 1 1 0 0; 1 0 1 5 0 1 1 0],...  
            'linear');
```

**2** Compute the maximum delays for each output variable individually.

```
Del = getDelayInfo(M, 'channelwise')
```

```
Del =
```

```
     2     0     2     1     0  
     1     0     1     5     0
```

The matrix `Del` contains the maximum delays for the first and second output of the model `M`. You can interpret the contents of matrix `Del` as follows:

- In the dynamics for the output 1 ( $y_1$ ) of model `M`, the maximum delays for each input/output channel are as follows:  $y_1$ : 2,  $y_2$ : 0,  $u_1$ : 2,  $u_2$ : 1,  $u_3$ : 0.

- Similarly, in the dynamics for the output 2 ( $y_2$ ) of the model, the maximum delays in channels  $y_1, y_2, u_1, u_2, u_3$  are 1, 0, 1, 5, and 0 respectively.

You can find the maximum delays for all the input and output variables in the order ( $y_1, y_2, u_1, u_2, u_3$ ) by executing the command

```
Del=getDelayInfo(M, 'all')
```

which returns

```
Del =
      2      0      2      5      0
```

---

**Note** The maximum delay across all output equations can be obtained by executing `MaxDel = max(Del, [], 1)`. Since input  $u_2$  has 5 delays (the 4th entry in `Del`, there are 5 terms corresponding to  $u_5$  in the state vector ( $u_5(t-1), \dots, u_5(t-5)$ ). Applying this definition to all I/O channels, the complete state vector for model `M` becomes:

$$X(t) = [y_1(t-1), y_1(t-2), u_1(t-1), u_1(t-2), u_2(t-1), u_2(t-2), u_2(t-3), u_2(t-4), u_2(t-5)]$$

---

## See Also

`data2state(idnlarx)`  
`getreg`  
`idnlarx`

# getexp

---

**Purpose** Specific experiments from multiple-experiment data set

**Syntax** `d1 = getexp(data,ExperimentNumber)`  
`d1 = getexp(data,ExperimentName)`

**Description** `data` is an `iddata` object that contains several experiments. `d1` is another `iddata` object containing the indicated experiment(s). The reference can either be by `ExperimentNumber`, as in `d1 = getexp(data,3)` or `d1 = getexp(data,[4 2])`; or by `ExperimentName`, as in `d1 = getexp(data,'Period1')` or `d1 = getexp(data,{'Day1','Day3'})`.

See `merge (iddata)` and `iddata` for how to create multiple-experiment data objects.

You can also retrieve the experiments using a fourth subscript, as in `d1 = data(:,:,,ExperimentNumber)`. Type `help iddata/subsref` for details on this.

---

<b>Purpose</b>	Values of idnlgrey model initial states
<b>Syntax</b>	<code>getinit(model)</code> <code>getinit(model,prop)</code>
<b>Arguments</b>	<code>model</code> Name of the idnlgrey model object.  <code>Property</code> Name of the InitialStates model property field, such as 'Name', 'Unit', 'Value', 'Minimum', 'Maximum', and 'Fixed'.  Default: 'Value'.
<b>Description</b>	<code>getinit(model)</code> gets the initial-state values in the 'Value' field of the InitialStates model property.  <code>getinit(model,prop)</code> gets the initial-state values of the prop field of the InitialStates model property. prop can be 'Name', 'Unit', 'Value', 'Minimum', 'Maximum', and 'Fixed'.  The returned values are an Nx-by-1 cell array of values, where Nx is the number of states.
<b>See Also</b>	<code>getpar</code> <code>idnlgrey</code> <code>setinit</code> <code>setpar</code>

# getpar

---

**Purpose** Parameter values and properties of idnlgrey model parameters

**Syntax** `getpar(model)`  
`getpar(model,prop)`

**Arguments** `model`  
Name of the idnlgrey model object.

`Property`  
Name of the Parameters model property field, such as 'Name', 'Unit', 'Value', 'Minimum', 'Maximum', or 'Fixed'.  
  
Default: 'Value'.

**Description** `getpar(model)` gets the model parameter values in the 'Value' field of the Parameters model property.

`getpar(model,prop)` gets the model parameter values in the `prop` field of the Parameters model property. `prop` can be 'Name', 'Unit', 'Value', 'Minimum', and 'Maximum'.

The returned values are an  $N_p$ -by-1 cell array of values, where  $N_p$  is the number of parameters.

**See Also** `getinit`  
`idnlgrey`  
`setinit`  
`setpar`

<b>Purpose</b>	Names of standard or custom regressors in nonlinear ARX model
<b>Syntax</b>	<pre>getreg(model) getreg(model,subset) R = getreg(model,subset)</pre>
<b>Arguments</b>	<p><code>model</code> Name of the <code>idnlarx</code> model object.</p> <p><code>subset</code> Has one of the following values: 'all', 'input', 'output', 'standard', 'custom', 'linear', and 'nonlinear'.</p>
<b>Description</b>	<p><code>getreg(model)</code> returns the regressor expressions for all of the regressors in the nonlinear ARX model.</p> <p><code>getreg(model,subset)</code> returns the regressor expressions for a specified subset of the regressors, as follows:</p> <ul style="list-style-type: none"><li>• 'all' — All regressors.</li><li>• 'input' — Input regressors only.</li><li>• 'output' — Output regressors only.</li><li>• 'standard' — Standard regressors only.</li><li>• 'custom' — Custom regressors only.</li><li>• 'linear' — Regressors that are not used in the nonlinear block.</li><li>• 'nonlinear' — Regressors used in the nonlinear block.</li></ul>

---

**Note** You can use 'nl' as an abbreviation for 'nonlinear'.

---

`R = getreg(model,subset)` returns a cell array of strings of the regressors for a specified subset of the regressors. For multiple-output models, returns a cell array of cell arrays.

# getreg

---

## See Also

`addreg`

`customreg`

`nlrx`

`polyreg`

**Purpose**

Multiple-output ARX polynomials, impulse response, or step response model

**Syntax**

`m = idarx(A,B,Ts)`  
`m = idarx(A,B,Ts,'Property1',Value1,...,'PropertyN',ValueN)`

**Description**

idarx creates an object containing parameters that describe the general multiple-input, multiple-output model structure of ARX type.

$$y(t) + A_1y(t-1) + A_2y(t-2) + \dots + A_{na}y(t-na) =$$

$$B_0u(t) + B_1u(t-1) + \dots + B_{nb}u(t-nb) + e(t)$$

Here  $A_k$  and  $B_k$  are matrices of dimensions  $ny$ -by- $ny$  and  $ny$ -by- $nu$ , respectively. ( $ny$  is the number of outputs, that is, the dimension of the vector  $y(t)$ , and  $nu$  is the number of inputs.)

The arguments A and B are 3-D arrays that contain the A matrices and the B matrices of the model in the following way.

A is an  $ny$ -by- $ny$ -by- $(na+1)$  array such that:

$$A(:, :, k+1) = A_k$$

$$A(:, :, 1) = \text{eye}(ny)$$

Similarly B is an  $ny$ -by- $nu$ -by- $(nb+1)$  array with:

$$B(:, :, k+1) = B_k$$

Note that A always starts with the identity matrix, and that delays in the model are defined by setting the corresponding leading entries in B to zero. For a multivariate time series, take  $B = []$ .

The optional property `NoiseVariance` sets the covariance matrix of the driving noise source  $e(t)$  in the model above. The default value is the identity matrix.

The argument `Ts` is the sampling interval. Note that continuous-time models ( $Ts = 0$ ) are not supported.

The use of `idarx` is twofold. You can use it to create models that are simulated (using `sim`) or analyzed (using `bode`, `pzmap`, etc.). You can also use it to define initial value models that are further adjusted to data (using `arx`). The free parameters in the structure are consistent with the structure of `A` and `B`; that is, leading zeros in the rows of `B` are regarded as fixed delays, and trailing zeros in `A` and `B` are regarded as a definition of lower-order polynomials. These zeros are fixed, while all other parameters are free.

For a model with one output, ARX models can be described both as `idarx` and `idpoly` models. The internal representation is different, however.

## **idarx** **Properties**

- `A`, `B`: The `A` and `B` polynomials as 3-D arrays, described above.
- `dA`, `dB`: The standard deviations of `A` and `B`. Same format as `A` and `B`. Cannot be set.
- `na`, `nb`, `nk`: The orders and delays of the model. `na` is an `ny-by-ny` matrix whose  $i$ - $j$  entry is the order of the polynomial corresponding to the  $i$ - $j$  entry of `A`. Similarly `nb` is an `ny-by-nu` matrix with the orders of `B`. `nk` is also an `ny-by-nu` matrix, whose  $i$ - $j$  entry is the delay from input  $j$  to output  $i$ , that is, the number of leading zeros in the  $i$ - $j$  entry of `B`.
- `InitialState`: This describes how the initial state (initial values in filtering, etc.) should be handled. For time-domain applications, this is typically handled by starting the filtering when all data are available. For frequency-domain data, you must estimate initial states. The possible values of `InitialState` are `'zero'`, `'estimate'`, and `'auto'` (which makes a data-dependent choice between zero and estimate).

In addition to these properties, `idarx` objects also have all the properties of the `idmodel` object. See `idmodel`, `Algorithm Properties`, and `EstimationInfo`.

Note that you can set and retrieve all properties either with the `set` and `get` commands or by subscripts. Autofill applies to all properties and values, and they are case insensitive.

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`. See also `idprops idarx`.

## idarx Definition of States

The states of an `idarx` model are defined as those corresponding to the model obtained by converting them to the state-space format using the `idss` command. For example, if you have an `idarx` model defined by `m1 = idarx(A,B,1)`, then the initial states of this model correspond to those of `m2 = idss(m1)`. The concept of states is useful for functions such as `sim`, `predict`, `compare` and `findstates`.

## Examples

Simulate a second-order ARX model with one input and two outputs, and then estimate a model using the simulated data.

```
A = zeros(2,2,3);
B = zeros(2,1,3)
A(:,:,1) =eye(2);
A(:,:,2) = [-1.5 0.1;-0.2 1.5];
A(:,:,3) = [0.7 -0.3;0.1 0.7];
B(:,:,2) = [1;-1];
B(:,:,3) = [0.5;1.2];
m0 = idarx(A,B,1);
u = iddata([],idinput(300));
e = iddata([],randn(300,2));
y = sim(m0,[u e]);
m = arx([y u],[[2 2;2 2],[2;2],[1;1]]);
```

## See Also

Algorithm Properties

`arx`

`arxdata`

`EstimationInfo`

idmodel

idpoly

**Purpose**

Time- or frequency-domain data

**Syntax**

```
data = iddata(y,[],Ts)
data = iddata(y,u,Ts)
data = iddata(y,u,Ts,'Frequency',W)
data = iddata(y,u,Ts,'P1',V1,...,'PN',VN)
data = iddata(idfrd_object)
```

**Arguments**

y

Name of MATLAB variable that represents the output signal from a system. Sets the `OutputData` `iddata` property. For a single-output system, this is a column vector. For a multiple-output system with  $N_y$  output channels and  $N_T$  time samples, this is an  $N_T$ -by- $N_y$  matrix.

---

**Note** Output data must be in the same domain as input data.

---

u

Name of MATLAB variable that represents the input signal to a system. Sets the `InputData` `iddata` property. For a single-input system, this is a column vector. For a multiple-output system with  $N_u$  output channels and  $N_T$  time samples, this is an  $N_T$ -by- $N_u$  matrix.

---

**Note** Input data must be in the same domain as output data.

---

Ts

Time interval between successive data samples in seconds. Default value is 1. For continuous-time data in the frequency domain, set `Ts` to 0.

'P1',V1,...,'PN',VN

Pairs of `iddata` property names and property values.

`idfrd_object`  
Name of `idfrd` data object.

## Description

`data = iddata(y,[],Ts)` creates an `iddata` object for time-series data, containing a time-domain output signal `y` and an empty input signal `[],` respectively. `Ts` specifies the sampling interval of the experimental data.

`data = iddata(y,u,Ts)` creates an `iddata` object containing a time-domain output signal `y` and input signal `u,` respectively. `Ts` specifies the sampling interval of the experimental data.

`data = iddata(y,u,Ts,'Frequency',W)` creates an `iddata` object containing a frequency-domain output signal `y` and input signal `u,` respectively. `Ts` specifies the sampling interval of the experimental data. `W` specifies the `iddata` property `'frequency'` as a vector of frequencies.

`data = iddata(y,u,Ts,'P1',V1,...,'PN',VN)` creates an `iddata` object containing a time-domain or frequency-domain output signal `y` and input signal `u,` respectively. `Ts` specifies the sampling interval of the experimental data. `'P1',V1,...,'PN',VN` are property-value pairs, as described in “`iddata` Properties” on page 2-138.

`data = iddata(idfrd_object)` transforms an `idfrd` object to a frequency-domain `iddata` object.

## iddata Properties

The following table describes `iddata` object properties and their values. These properties are specified as property-value arguments `'P1',V1,...,'PN',VN` in the `iddata` constructor, or you can set them using the `set` command or dot notation. In the list below, `N` denotes the number of data samples in the input and output signals, `ny` is the number of output channels, `nu` is the number of input channels, and `Ne` is the number of experiments.

---

**Tip** Property names are not case sensitive. You do not need to type the entire property name. However, the portion you enter must be enough to uniquely identify the property.

---

<b>Property Name</b>	<b>Description</b>	<b>Value</b>
Domain	Specifies whether the data is in the time domain or frequency domain.	<ul style="list-style-type: none"> <li>'Frequency' — Frequency-domain data.</li> <li>'Time' (Default) — Time-domain data.</li> </ul>
ExperimentName	Name of each data set contained in the <code>iddata</code> object.	For $N_e$ experiments, a 1-by- $N_e$ cell array of strings. Each cell contains the name of the corresponding experiment. Default names are {'Exp1', 'Exp2', ...}.
Frequency	(Frequency-domain data only) Frequency values for defining the Fourier Transforms of the signals.	For a single experiment, this is an $N$ -by-1 vector. For $N_e$ experiments, a 1-by- $N_e$ cell array and each cell contains the frequencies of the corresponding experiment.
InputData	Name of MATLAB variable that stores the input signal to a system.	For $nu$ input channels and $N$ data samples, this is an $N$ -by- $nu$ matrix.
InputName	Specifies the names of individual input channels.	Cell array of length $nu$ -by-1 contains the name string of each input channel. Default names are {'u1', 'u2', ...}.
InputUnit	Specifies the units of each input channel.	Cell array of length $nu$ -by-1. Each cell contains a string that specifies the units of each input channel.

Property Name	Description	Value
InterSample	Specifies the behavior of the input signals between samples for transformations between discrete-time and continuous-time.	<p>For a single experiment:</p> <ul style="list-style-type: none"> <li>• zoh— (Default) Zero-order hold maintains a piecewise-constant input signal between samples.</li> <li>• foh— First-order hold maintains a piecewise-linear input signal between samples.</li> <li>• b1— Band-limited behavior specifies that the continuous-time input signal has zero power above the Nyquist frequency.</li> </ul> <p>For <math>N_e</math> experiments, InterSample is an <math>n_u</math>-by-<math>N_e</math> cell array. Each cell contains one of these values corresponding to each experiment.</p>
Name	Name of the data set.	Text string.
Notes	Comments about the data set.	Text string.
OutputData	Name of MATLAB variable that stores the output signal from a system.	For $n_y$ output channels and $N$ samples, this is an $N$ -by- $n_y$ matrix.

Property Name	Description	Value
OutputName	For a multiple-output system, specifies the names of individual output channels.	Cell array of length ny-by-1 contains the name string of each output channel. Default names are {'y1'; 'y2'; ...}.
OutputUnit	Specifies the units of each output channel.	For ny output channels, a cell array of length ny-by-1. Each cell contains a string that specifies the units of the corresponding output channel.
Period	Period of the input signal.	(Default) For a nonperiodic signal, set to inf. For a multiple-input signal, this is an nu-by-1 vector and the kth entry contains the period of the kth input. For Ne experiments, this is a 1-by-Ne cell array and each cell contains a scalar or vector of periods for the corresponding experiment.
SamplingInstants	(Time-domain data only) The time values in the time vector calculated from the properties Tstart and Ts.	For a single experiment, this is an N-by-1 vector. For Ne experiments, this is a 1-by-Ne cell array and each cell contains the sampling instants of the corresponding experiment.
TimeUnit	(Time-domain data only) Time unit.	A string that specifies the time unit for the time vector.

Property Name	Description	Value
Ts	<p>Time interval between successive data samples in seconds. Must be specified for both time- and frequency-domain data. For frequency-domain, it is used to compute Fourier transforms of the signals as discrete-time Fourier transforms (DTFT) with the indicated sampling interval.</p> <hr/> <p><b>Note</b> Your data must be uniformly sampled.</p> <hr/>	<p>Default value is 1. For continuous-time data in the frequency domain, set to 0; the inputs and outputs are interpreted as continuous-time Fourier transforms of the signals. Note that Ts is essential also for frequency-domain data, for proper interpretation of how the Fourier transforms were computed: They are interpreted as discrete-time Fourier transforms (DTFT) with the indicated sampling interval.. For multiple-experiment data, Ts is a 1-by-Ne cell array and each cell contains the sampling interval of the corresponding experiment.</p>
Tstart	<p>(Time-domain data only) Specifies the start time of the time vector.</p>	<p>For a single experiment, this is a scalar. For Ne experiments, Tstart is a 1-by-Ne cell array and each cell contains the starting time of the corresponding experiment.</p>

Property Name	Description	Value
Units	(Frequency-domain data only) Frequency unit.	Specified as rad/s or Hz. For multiexperiment data with <i>Ne</i> experiments, <i>Units</i> is a 1-by- <i>Ne</i> cell array and each cell contains the frequency unit for each experiment.
UserData	Additional comments.	Text string.

# ident

---

**Purpose** Open System Identification Tool GUI

**Syntax** `ident`  
`ident(session,path)`

**Description** `ident` by itself opens the main interface window, or brings it forward if it is already open.

`session` is the name of a previous session with the graphical user interface, and typically has extension `.sid`. The `path` argument is the complete path for the location of this file. If the session file is on the `MATLABPATH`, `path` can be omitted.

When the session is specified, the interface will open with this session active. Typing `ident(session,path)` in the MATLAB Command Window, when the interface is active, will load and open the session in question.

For more information about the graphical user interface, see “Using the System Identification Tool GUI”.

**Examples**

```
ident('iddata1.sid')
ident('mydata.sid','\matlab\data\cdplayer\')
```

**See Also** `midprefs`

**Purpose** Filter data using user-defined passbands, general filters, or Butterworth filters

**Syntax**

```
Zf = idfilt(Z,filter)
Zf = idfilt(Z,filter,causality)
Zf = idfilt(Z,filter,'FilterOrder',NF)
```

**Description** Z is the data, defined as an iddata object. Zf contains the filtered data as an iddata object. The filter can be defined in three ways:

- As an explicit system that defines the filter,

```
filter = idm or filter = {num,den} or filter = {A,B,C,D}
```

idm can be any SISO idmodel or LTI model object. Alternatively the filter can be defined as a cell array {A,B,C,D} of SISO state-space matrices or as a cell array {num,den} of numerator/denominator filter coefficients.

- As a vector or matrix that defines one or several passbands,

```
filter=[ [wp1l,wp1h]; [ wp2l,wp2h]; ... ; [wpl,wpnh] ]
```

The matrix is n-by-2, where each row defines a passband in rad/s. A filter is constructed that gives the union of these passbands. For time-domain data, it is computed as cascaded Butterworth filters or order NF. The default value of NF is 5.

For example, to define a stopband between ws1 and ws2, use

```
filter = [0 ws1; ws2,Nyqf]
```

where Nyqf is the Nyquist frequency.

- For frequency-domain data, only the frequency response of the filter can be specified:

```
filter = Wf
```

Here  $W_f$  is a vector of possibly complex values that define the filter's frequency response, so that the inputs and outputs at frequency  $Z$ .Frequency ( $k_f$ ) are multiplied by  $W_f(k_f)$ .  $W_f$  is a column vector of length = number of frequencies in  $Z$ . If the data object has several experiments,  $W_f$  is a cell array of length = # of experiments in  $Z$ .

For time-domain data, the filtering is carried out in the time domain as causal filtering as default. This corresponds to a last argument `causality = 'causal'`. With `causality = 'noncausal'`, a noncausal, zero-phase filter is used for the filtering (corresponding to `filtfilt` in the Signal Processing Toolbox product).

For frequency-domain data, the signals are multiplied by the frequency response of the filter. With the filters defined as passband, this gives ideal, zero-phase filtering ("brickwall filters"). Frequencies that have been assigned zero weight by the filter (outside the passband, or via the frequency response) are removed from the `iddata` object  $Z_f$ .

It is common practice in identification to select a frequency band where the fit between model and data is concentrated. Often this corresponds to bandpass filtering with a passband over the interesting breakpoints in a Bode diagram. For identification where a disturbance model is also estimated, it is better to achieve the desired estimation result by using the property 'Focus' (see Algorithm Properties) than just to prefilter the data. The proper values for 'Focus' are the same as the argument `filter` in `idfilt`.

## Algorithm

The Butterworth filter is the same as `butter` in the Signal Processing Toolbox product. Also, the zero-phase filter is equivalent to `filtfilt` in that toolbox.

Algorithm Properties  
`iddata`

**Purpose**

Frequency-response data or model

**Syntax**

```
h = idfrd(Response,Freq,Ts)
h = idfrd(Response,Freq,Ts,...
    'CovarianceData',Covariance,'SpectrumData',Spec,...
    'NoiseCovariance',Speccov)
h = idfrd(Response,Freq,Ts,...
    'P1',V1,'PN',VN)
h = idfrd(mod)
h = idfrd(mod,Freqs)
```

**Description**

`h = idfrd(Response,Freq,Ts)` constructs an `idfrd` object that stores the frequency response `Response` of a linear system at frequency values `Freq`. `Ts` is the sampling time interval. For a continuous-time system, set `Ts=0`.

`h = idfrd(Response,Freq,Ts,...`  
`'CovarianceData',Covariance,'SpectrumData',Spec,...`  
`'NoiseCovariance',Speccov)` also stores the uncertainty of the response `Covariance`, the spectrum of the additive disturbance (noise) `Spec`, and the uncertainty of the noise `Speccov`.

`h = idfrd(Response,Freq,Ts,...`  
`'P1',V1,'PN',VN)` constructs an `idfrd` object that stores a frequency-response model with properties specified by the `idfrd` model property-value pairs.

`h = idfrd(mod)` converts a System Identification Toolbox or Control System Toolbox linear model to frequency-response data at default frequencies, including the output noise spectra and their covariance. If the linear model has an input-to-output delay, this delay is converted to a phase lag.

`h = idfrd(mod,Freqs)` converts a System Identification Toolbox or Control System Toolbox linear model to frequency-response data at frequencies `Freqs`.

For a model

$$y(t) = G(q)u(t) + H(q)e(t)$$

stores the transfer function estimate  $G$

$$G(e^{i\omega})$$

as well as the spectrum of the additive noise ( $\Phi_v$ ) at the output

$$\Phi_v(\omega) = \lambda T |H(e^{i\omega T})|^2$$

where  $\lambda$  is the estimated variance of  $e(t)$ , and  $T$  is the sampling interval.

## Creating idfrd from Given Responses

`Response` is a 3-D array of dimension `ny-by-nu-by-Nf`, with `ny` being the number of outputs, `nu` the number of inputs, and `Nf` the number of frequencies (that is, the length of `Freqs`). `Response(ky,ku,kf)` is thus the complex-valued frequency response from input `ku` to output `ky` at frequency  $\omega = \text{Freqs}(kf)$ . When defining the response of a SISO system, `Response` can be given as a vector.

`Freqs` is a column vector of length `Nf` containing the frequencies of the response.

`Ts` is the sampling interval. `T = 0` means a continuous-time model.

`Covariance` is a 5-D array containing the covariance of the frequency response. It has dimension `ny-by-nu-by-Nf-by-2-by-2`. The structure is such that `Covariance(ky,ku,kf, :, :)` is the 2-by-2 covariance matrix of the response `Response(ky,ku,kf)`. The 1-1 element is the variance of the real part, the 2-2 element is the variance of the imaginary part, and the 1-2 and 2-1 elements are the covariance between the real and imaginary parts. `squeeze(Covariance(ky,ku,kf, :, :))` thus gives the covariance matrix of the corresponding response.

The information about spectrum is optional. The format is as follows:

`spec` is a 3-D array of dimension `ny-by-ny-by-Nf`, such that `spec(ky1,ky2,kf)` is the cross spectrum between the noise at output `ky1` and the noise at output `ky2`, at frequency `Freqs(kf)`. When `ky1 =`

ky2 the (power) spectrum of the noise at output ky1 is thus obtained. For a single-output model, `spec` can be given as a vector.

`speccov` is a 3-D array of dimension `ny-by-ny-by-Nf`, such that `speccov(ky1, ky1, kf)` is the variance of the corresponding power spectrum. Normally, no information is included about the covariance of the nondiagonal spectrum elements.

If only `SpectrumData` is to be packaged in the `idfrd` object, set `Response = []`.

### Creating idfrd from a Given Model

`idfrd` can also be computed from a given model `mod` (defined as any `idmodel` object).

If the frequencies `Freqs` are not specified, a default choice is made based on the dynamics of the model `mod`.

If `mod` has `InputDelay` different from zero, these are appended as phase lags, and `h` will then have an `InputDelay` of 0.

The estimated covariances are computed using the Gauss approximation formula from the uncertainty information in `mod`. For models with complicated parameter dependencies, numerical differentiation is applied. The step sizes for the numerical derivatives are determined by `nuderst`.

Frequency responses for submodels can be obtained by the standard subreferencing, `h = idfrd(m(2,3))`. See `idmodel`. In particular, `h = idfrf(m('measured'))` gives an `h` that just contains the `ResponseData` (`G`) and no spectra. Also `h = idfrd(m('noise'))` gives an `h` that just contains `SpectrumData`.

The `idfrd` models can be graphed with `bode`, `ffplot`, and `nyquist`, which all accept mixtures of `idmodel` and `idfrd` models as arguments. Note that `spa`, `spafdr`, and `etfe` return their estimation results as `idfrd` objects.

## idfrd Properties

- **ResponseData:** 3-D array of the complex-valued frequency response as described above. For SISO systems use `Response(1,1,:)` to obtain a vector of the response data.
- **Frequency:** Column vector containing the frequencies at which the responses are defined.
- **CovarianceData:** 5-D array of the covariance matrices of the response data as described above.
- **SpectrumData:** 3-D array containing power spectra and cross spectra of the output disturbances (noise) of the system.
- **NoiseCovariance:** 3-D array containing the variances of the power spectra, as explained above.
- **Units:** Unit of the frequency vector. Can assume the values 'rad/s' and 'Hz'.
- **Ts:** Scalar denoting the sampling interval of the model whose frequency response is stored. 'Ts' = 0 means a continuous-time model.
- **Name:** An optional name for the object.
- **InputName:** String or cell array containing the names of the input channels. It has as many entries as there are input channels.
- **OutputName:** Correspondingly for the output channels.
- **InputUnit:** Units in which the input channels are measured. It has the same format as 'InputName'.
- **OutputUnit:** Correspondingly for the output channels.
- **InputDelay:** Row vector of length equal to the number of input channels. Contains the delays from the input channels. These should thus be appended as phase lags when the response is calculated. This is done automatically by `freqresp`, `bode`, `ffplot`, and `nyquist`. Note that if the `idfrd` is calculated from an `idmodel`, possible input delays in that model are converted to phase lags, and the `InputDelay` of the `idfrd` model is set to zero.

- **Notes:** An arbitrary field to store extra information and notes about the object.
- **UserData:** An arbitrary field for any possible use.
- **EstimationInfo:** Structure that contains information about the estimation process that is behind the frequency data. It contains the following fields (see also the reference page for `EstimationInfo`).
  - **Status:** Gives the status of the model, for example, 'Not estimated'.
  - **Method:** The identification routine that created the model.
  - **WindowSize:** If the model was estimated by `spa`, `spafdr`, or `etfe`, the size of window (input argument `M`, the resolution parameter) that was used. This is scalar or a vector.
  - **DataName:** Name of the data set from which the model was estimated.
  - **DataLength:** Length of this data set.

Note that you can set or retrieve all properties either with the `set` and `get` commands or by subscripts. Autofill applies to all properties and values, and these are case insensitive:

```
h.ts = 0
loglog(h.fre,squeeze(h.spe(2,2,:)))
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`. See also `idprops idfrd`.

**Subreferencing** The different channels of the `idfrd` are retrieved by subreferencing.

```
h(outputs,inputs)
```

`h(2,3)` thus contains the response data from input channel 3 to output channel 2, and, if applicable, the output spectrum data for output channel 2. The channels can also be referred to by their names, as in `h('power',{'voltage','speed'})`.

```
h('m')
```

contains the information for measured inputs only, that is, just `ResponseData`, while

```
h('n')
```

(`'n'` for `'noise'`) just contains `SpectrumData`.

## Horizontal Concatenation

Adding input channels,

```
h = [h1,h2,...,hN]
```

creates an `idfrd` model `h`, with `ResponseData` containing all the input channels in `h1, ..., hN`. The output channels of `hk` must be the same, as well as the frequency vectors. `SpectrumData` is ignored.

## Vertical Concatenation

Adding output channels,

```
h = [h1;h2;... ;hN]
```

creates an `idfrd` model `h` with `ResponseData` containing all the output channels in `h1, h2, ..., hN`. The input channels of `hk` must all be the same, as well as the frequency vectors. `SpectrumData` is also appended for the new outputs. The cross spectrum between output channels is then set to zero.

## Converting to iddata

You can convert an `idfrd` object to a frequency-domain `iddata` object by

```
Data = iddata(Idfrdmodel)
```

See `iddata`.

## Examples

Compare the results from spectral analysis and an ARMAX model.

```
m = armax(z,[2 2 2 1]);  
g = spa(z)  
g = spafdr(z,[],{0,10})
```

```
bode(g,m)
```

Compute separate idfrd models, one containing the frequency function and the other the noise spectrum.

```
g = idfrd(m('m'))  
phi = idfrd(m('n'))
```

## Purpose

Linear ODE (grey-box model) with known and unknown parameters

## Syntax

```
m = idgrey(MfileName,ParameterVector,CDmfile)
m = idgrey(MfileName,ParameterVector,CDmfile,FileArgument,Ts,...
'Property1',Value1,...,'PropertyN',ValueN)
```

## Description

The function `idgrey` is used to create arbitrarily parameterized state-space models as `idgrey` objects.

`MfileName` is the name of an M-file that defines how the state-space matrices depend on the parameters to be estimated. The format of this M-file is given by

```
[A,B,C,D,K,X0] = mymfile(pars,Tsm,Auxarg)
```

and is further discussed below.

`ParameterVector` is a column vector of the nominal/initial parameters. Its length must be equal to the number of free parameters in the model (that is, the argument `pars` in the example below).

The argument `CDmfile` describes how the user-written M-file handles continuous and discrete-time models. It takes the following values:

- `CDmfile = 'cd'`: The M-file returns the continuous-time state-space matrices when called with the argument `Tsm = 0`. When called with a value `Tsm > 0`, the M-file returns the discrete-time state-space matrices, obtained by sampling the continuous-time system with sampling interval `Tsm`. The M-file must consequently in this case include the sampling procedure.
- `CDmfile = 'c'`: The M-file always returns the continuous-time state-space matrices, no matter the value of `Tsm`. In this case the toolbox's estimation routines will provide the sampling when you are fitting the model to discrete-time data.
- `CDmfile = 'd'`: The M-file always returns discrete-time state-space matrices that may or may not depend on `Tsm`.

The argument `FileArgument` corresponds to the auxiliary argument `Auxarg` in the user-written M-file. It can be used to handle several variants of the model structure, without having to edit the M-file. If it is not used, enter `FileArgument = []`. (Default.)

$T_s$  denotes the sampling interval of the model. Its default value is  $T_s = 0$ , that is, a continuous-time model.

The `idgrey` object is a child of `idmodel`. Therefore any `idmodel` properties can be set as property name/property value pairs in the `idgrey` command. They can also be set by the command `set`, or by `subassignment`, as in

```
m.InputName = {'speed', 'voltage'}
m.FileArgument = 0.23
```

There are also two properties, `DisturbanceModel` and `InitialState`, that can be used to affect the parameterizations of  $K$  and  $X0$ , thus overriding the outputs from the M-file.

## idgrey Properties

- `MfileName`: Name of the user-written M-file.
- `CDmfile`: How this file handles continuous and discrete-time models depending on its second argument,  $T$ .
  - `CDmfile = 'cd'` means that the M-file returns the continuous-time state-space model matrices when the argument  $T = 0$ , and the discrete-time model, obtained by sampling with sampling interval  $T$ , when  $T > 0$ .
  - `CDmfile = 'c'` means that the M-file always returns continuous-time model matrices, no matter the value of  $T$ .
  - `CDmfile = 'd'` means that the M-file always returns discrete-time model matrices that may or may not depend on the value of  $T$ .
- `FileArgument`: Possible extra input arguments to the user-written M-file.
- `DisturbanceModel`: Affects the parameterization of the  $K$  matrix. It can assume the following values:

- 'Model': This is the default. It means that the K matrix obtained from the user-written M-file is used.
- 'Estimate': The K matrix is treated as unknown and all its elements are estimated as free parameters.
- 'Fixed': The K matrix is fixed to a given value.
- 'None': The K matrix is fixed to zero, thus producing an output-error model.

Note that in the three last cases the output K from the user-written M-file is ignored. The estimated/fixed value is stored internally and does not change when the model is sampled, resampled, or converted to continuous time. Note also that this estimated value is tailored only to the sampling interval of the data.

- InitialState: Affects the parameterization of the X0 vector. It can assume the following values:
  - 'Model': This is the default. It means that the X0 vector is obtained from the user-written M-file.
  - 'Estimate': The X0 matrix is treated as unknown and all its elements are estimated as free parameters.
  - 'Fixed': The X0 vector is fixed to a given value.
  - 'Backcast': The X0 vector is estimated using a backcast operation analogous to the idss case.
  - 'Auto': Makes a data-dependent choice among 'Estimate', 'Backcast', and 'Model'.
- A, B, C, D, K, and X0: The state-space matrices. For idgrey models, only 'K' and 'X0' can be set; the others can only be retrieved. The set 'K' and 'X0' are relevant only when DisturbanceModel/InitialState are Estimate or Fixed.
- dA, dB, dC, dD, dK, and dX0: The estimated standard deviations of the state-space matrices. These cannot be set, only retrieved.

In addition, any `idgrey` object also has all the properties of `idmodel`. See [Algorithm Properties](#) and the reference page for `idmodel`.

Note that you can set or retrieve all properties using either the `set` and `get` commands or subscripts. Autofill applies to all properties and values, and they are case insensitive.

```
m.fi = 10;
set(m, 'search', 'gn')
p = roots(m.a)
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`.

## M-File Details

The model structure corresponds to the general linear state-space structure

$$\dot{\tilde{x}}(t) = A(\theta)x(t) + B(\theta)u(t) + K(\theta)e(t)$$

$$x(0) = x_0(\theta)$$

$$y(t) = C(\theta)x(t) + D(\theta)u(t) + e(t)$$

Here  $\dot{\tilde{x}}(t)$  is the time derivative  $\dot{x}(t)$  for a continuous-time model and  $x(t + Ts)$  for a discrete-time model.

The matrices in this time-discrete model can be parameterized in an arbitrary way by the vector  $\theta$ . Write the format for the M-file as follows:

```
[A,B,C,D,K,x0] = mymfile(pars,T,Auxarg)
```

Here the vector `pars` contains the parameters  $\theta$ , and the output arguments `A`, `B`, `C`, `D`, `K`, and `x0` are the matrices in the model description that correspond to this value of the parameters and this value of the sampling interval `T`.

`T` is the sampling interval, and `Auxarg` is any variable of auxiliary quantities with which you want to work. (In that way you can change certain constants and other aspects in the model structure without

having to edit the M-file.) Note that the two arguments `T` and `Auxarg` must be included in the function head of the M-file, even if they are not used within the M-file.

A comment about `CDmfile`: If a continuous-time model is sought, it is easiest to let the M-file deliver just the continuous-time model, that is, have `CDmfile = 'c'` and rely upon the toolbox's routines for the proper sampling. Similarly, if the underlying parameterization is indeed discrete time, it is natural to deliver the discrete-time model matrices and let `CDmfile = 'd'`. If the underlying parameterization is continuous, but you prefer for some reason to do your own sampling inside the M-file in accordance with the value of `T`, then let your M-file deliver the continuous-time model when called with `T = 0`, that is, the alternative `CMmfile = 'cd'`. This avoids sampling and then transforming back (using `d2c`) to find the continuous-time model.

## idgrey Definition of States

The states of an `idgrey` model are defined explicitly by the user in the M-file or MEX-file (as specified in `MfileName` property) storing the model structure. The concept of states is useful for functions such as `sim`, `predict`, `compare` and `findstates`.

## Examples

In this example, you use the M-file `mynoise` given in “Example – Estimating a Discrete-Time Grey-Box Model with Parameterized Disturbance” to obtain a physical parameterization of the Kalman gain. You estimate the unknown parameters of this model using the estimation data `z`.

```
mn = idgrey('mynoise',[0.1,-2,1,3,0.2]','d',1)
m = pem(z,mn)
```

**Purpose**

Generate input signals

**Syntax**

```
u = idinput(N)
u = idinput(N,type,band,levels)
[u,freqs] = idinput(N,'sine',band,levels,sinedata)
```

**Description**

`idinput` generates input signals of different kinds, which are typically used for identification purposes. `u` is returned as a matrix or column vector.

For further use in the toolbox, we recommend that you create an `iddata` object from `u`, indicating sampling time, input names, periodicity, and so on:

```
u = iddata([],u);
```

`N` determines the number of generated input data. If `N` is a scalar, `u` is a column vector with this number of rows.

`N = [N nu]` gives an input with `nu` input channels each of length `N`.

`N = [P nu M]` gives a periodic input with `nu` channels, each of length `M*P` and periodic with period `P`.

Default is `nu = 1` and `M = 1`.

`type` defines the type of input signal to be generated. This argument takes one of the following values:

- `type = 'rgs'`: Gives a random, Gaussian signal.
- `type = 'rbs'`: Gives a random, binary signal. This is the default.
- `type = 'prbs'`: Gives a pseudorandom, binary signal.
- `type = 'sine'`: Gives a signal that is a sum of sinusoids.

The frequency contents of the signal is determined by the argument `band`. For the choices `type = 'rs'`, `'rbs'`, and `'sine'`, this argument is a row vector with two entries

```
band = [wlow, whigh]
```

that determine the lower and upper bound of the passband. The frequencies `wlow` and `whigh` are expressed in fractions of the Nyquist frequency. A white noise character input is thus obtained for `band = [0 1]`, which is also the default value.

For the choice `type = 'prbs'`,

```
band = [0, B]
```

where `B` is such that the signal is constant over intervals of length  $1/B$  (the clock period). In this case the default is `band = [0 1]`.

The argument `levels` defines the input level. It is a row vector

```
levels = [minu, maxu]
```

such that the signal `u` will always be between the values `minu` and `maxu` for the choices `type = 'rbs'`, `'prbs'`, and `'sine'`. For `type = 'rgs'`, the signal level is such that `minu` is the mean value of the signal, minus one standard deviation, while `maxu` is the mean value plus one standard deviation. Gaussian white noise with zero mean and variance one is thus obtained for `levels = [-1, 1]`, which is also the default value.

## Some PRBS Aspects

If more than one period is demanded (that is,  $M > 1$ ), the length of the data sequence and the period of the PRBS signal are adjusted so that an integer number of maximum length PRBS periods is always obtained. If  $M = 1$ , the period of the PRBS signal is chosen so that it is longer than  $P = N$ . In the multiple-input case, the signals are maximally shifted. This means  $P/nu$  is an upper bound for the model orders that can be estimated with such a signal.

## Some Sine Aspects

In the `'sine'` case, the sinusoids are chosen from the frequency grid

```
freq = 2*pi*[1:Grid_Skip:fix(P/2)]/P
```

intersected with  $\pi * [\text{band}(1) \text{ band}(2)]$ . For `Grid_Skip`, see below. For multiple-input signals, the different inputs use different frequencies from this grid. An integer number of full periods is always delivered. The selected frequencies are obtained as the second output argument, `freqs`, where row `ku` of `freqs` contains the frequencies of input number `ku`. The resulting signal is affected by a fifth input argument, `sinedata`

```
sinedata = [No_of_Sinusoids, No_of_Trials, Grid_Skip]
```

meaning that `No_of_Sinusoids` is equally spread over the indicated band. `No_of_Trials` (different, random, relative phases) are tried until the lowest amplitude signal is found.

```
Default: sinedata = [10,10,1];
```

`Grid_Skip` can be useful for controlling odd and even frequency multiples, for example, to detect nonlinearities of various kinds.

## Algorithm

Very simple algorithms are used. The frequency contents are achieved for 'rgs' by an eighth-order Butterworth, noncausal filter, using `idfilt`. This is quite reliable. The same filter is used for the 'rbs' case, before making the signal binary. This means that the frequency contents are not guaranteed to be precise in this case.

For the 'sine' case, the frequencies are selected to be equally spread over the chosen grid, and each sinusoid is given a random phase. A number of trials are made, and the phases that give the smallest signal amplitude are selected. The amplitude is then scaled so as to satisfy the specifications of `levels`.

## References

See Söderström and Stoica (1989), Chapter C5.3. For a general discussion of input signals, see Ljung (1999), Section 13.3.

## Examples

Create an input consisting of five sinusoids spread over the whole frequency interval. Compare the spectrum of this signal with that of its square. The frequency splitting (the square having spectral support at other frequencies) reveals the nonlinearity involved:

# idinput

---

```
u = idinput([100 1 20], 'sine', [], [], [5 10 1]);
u = iddata([], u, 1, 'per', 100);
u2 = u.u.^2;
u2 = iddata([], u2, 1, 'per', 100);
ffplot(etfe(u), 'r*', etfe(u2), '+')
```

**Purpose** Simulate `idmodel` objects using Simulink software

**Syntax** `idmdlsim`

**Description** Typing `idmdlsim` launches the Idmodel Simulink block. By clicking the block you can specify the `idmodel` to simulate, whether to include initial state values, and whether to add noise to the simulation in accordance with the model's own noise description.

**See Also**

- `compare`
- `pe`
- `predict`
- `sim`
- `simsd`

# idmodel

---

**Purpose** Superclass for linear models

**Description** `idmodel` is an object that you do not deal with directly. It contains all the common properties of the model objects `idarx`, `idgrey`, `idpoly`, `idproc`, and `idss`, which are returned by the different estimation routines.

## Basic Use

If you just estimate models from data, the model objects should be transparent. All parametric estimation routines return `idmodel` results.

```
m = arx(Data,[2 2 1])
```

The model `m` contains all relevant information. Just typing `m` will give a brief account of the model. `present(m)` also gives information about the uncertainties of the estimated parameters. `get(m)` gives a complete list of model properties.

Most of the interesting properties can be directly accessed by subreferencing:

```
m.a  
m.da
```

See the property list obtained by `get(m)`, as well as the property lists of `idgrey`, `idarx`, `idpoly`, and `idss` in Chapter 2, “Functions – Alphabetical List” for more details on this. See also `idprops`.

The characteristics of the model `m` can be directly examined and displayed by commands like `impulse`, `step`, `bode`, `nyquist`, and `pzmap`. The quality of the model is assessed by commands like `compare` and `resid`. When you have Control System Toolbox software installed, you can use `view(m)` to access various display functions.

To extract state-space matrices, transfer function polynomials, etc., use the commands `arxdata`, `polydata`, `tfdata`, `ssdata`, and `zpkdata`.

To compute the frequency response of the model, use the commands `idfrd` and `freqresp`.

## Creating and Modifying Model Objects

If you want to define a model to use, for example, for simulating data, you need to use the model creator functions:

- `idarx`, for multivariable ARX models
- `idgrey`, for user-defined grey-box state-space models
- `idpoly`, for single-output polynomial models
- `idproc`, for simple, continuous-time process models
- `idss`, for state-space models

If you want to estimate a state-space model with a specific internal parameterization, you need to create an `idss` model or an `idgrey` model. See the reference pages for these functions.

## Dealing with Input and Output Channels

For multivariable models, you construct submodels containing a subset of inputs and outputs by simple subreferencing. The outputs and input channels can be referenced according to

```
m(outputs,inputs)
```

Use a colon (:) to denote all channels and an empty matrix ([]) to denote no channels. The channels can be referenced by number or by name. For several names, you must use a cell array, such as

```
m3 = m('position',{'power','speed'})
```

or

```
m3 = m(3,[1 4])
```

Thus `m3` is the model obtained from `m` by looking at the transfer functions from input numbers 1 and 4 (with input names 'power' and 'speed') to output number 3 (with name `position`).

For a single-output model  $m$ ,

$$m4 = m(\text{inputs})$$

selects the corresponding input channels, and for a single-input model,

$$m5 = m(\text{outputs})$$

selects the indicated output channels.

Subreferencing is quite useful, for example, when a plot of just some channels is desired.

## Noise Channels

The estimated models have two kinds of input channels: the measured inputs  $u$  and the noise inputs  $e$ . For a general linear model  $m$ , we have

$$y(t) = G(q)u(t) + H(q)e(t)$$

where  $u$  is the  $nu$ -dimensional vector of measured input channels and  $e$  is the  $ny$ -dimensional vector of noise channels. The covariance matrix of  $e$  is given by the property 'NoiseVariance'. Occasionally this matrix  $\Lambda$  is written in factored form,

$$\Lambda = LL^T$$

This means that  $e$  can be written as

$$e = Lv$$

where  $v$  is white noise with identity covariance matrix (independent noise sources with unit variances).

If  $m$  is a time series ( $nu = 0$ ),  $G$  is empty and the model is given by

$$y(t) = H(q)e(t)$$

For the model  $m$ , the restriction to the transfer function matrix  $G$  is obtained by

```
m1 = m('measured') or just m1 = m('m')
```

Then  $e$  is set to 0 and  $H$  is removed.

Analogously,

```
m2 = m('noise') or just m2 = m('n')
```

creates a time-series model  $m2$  from  $m$  by ignoring the measured input. That is,  $m2$  describes the signal  $He$ .

For a system with measured inputs, `bode`, `step`, and other transformation and display functions deal with the transfer function matrix  $G$ . To obtain or graph the properties of the disturbance model  $H$ , it is therefore important to make the transformations  $m('n')$ . For example,

```
bode(m('n'))
```

plots the additive noise spectra according to the model  $m$ , while

```
bode(m)
```

just plots the frequency responses of  $G$ .

To study the noise contributions in more detail, it is useful to convert the noise channels to measured channels, using the command `noisecnv`.

```
m3 = noisecnv(m)
```

This creates a model  $m3$  with all input channels, both measured  $u$  and noise sources  $e$ , treated as measured signals. That is,  $m3$  is a model from  $u$  and  $e$  to  $y$ , describing the transfer functions  $G$  and  $H$ . The information about the variance of the innovations  $e$  is lost. For example, studying the step response from the noise channels does not take into consideration how large the noise contributions actually are.

To include that information,  $e$  should first be normalized,  $e = Lv$ , so that  $v$  becomes white noise with an identity covariance matrix.

```
m4 = noisecnv(m, 'Norm')
```

This creates a model *m4* where *u* and *v* are treated as measured signals.

$$y(t) = G(q)u(t) + H(q)Lv(t) = \begin{bmatrix} G & HL \end{bmatrix} \begin{bmatrix} u \\ v \end{bmatrix}$$

For example, the step responses from *v* to *y* will now reflect the typical size of the disturbance influence because of the scaling by *L*. In both cases, the previous noise sources that have become regular inputs will automatically get input names that are related to the corresponding output. The unnormalized noise sources *e* have names like 'e@ynam1' (noise *e* at output channel ynam1), while the normalized sources *v* are called 'v@ynam1'.

## Retrieving Transfer Functions

The functions that retrieve transfer function properties, `ssdata`, `tfdata`, and `zpkdata`, behave, as follows, for a model with measured inputs. (fcn is `ssdata`, `tfdata`, or `zpkdata`.)

`fcn(m)` returns the properties of *G* (*ny* outputs and *nu* inputs).

`fcn(m('n'))` returns the properties of the transfer function *H* (*ny* outputs and *ny* inputs).

`fcn(noisecnv(m, 'Norm'))` returns the properties of the transfer function  $[G \ HL]$  (*ny* outputs and *ny+nu* inputs). Analogously,

```
m1 = m('n');  
fcn(noisecnv(m1, 'Norm'))
```

returns the properties of the transfer function *HL* (*ny* outputs and *ny* inputs).

If *m* is a time-series model, `fcn(m)` returns the properties of *H*, while

```
fcn(noisecnv(m, 'Norm'))
```

returns the properties of *HL*.

Note that the estimated covariance matrix `NoiseVariance` itself is uncertain. This means that the uncertainty information about  $H$  is different from that of  $HL$ .

## idmodel Properties

In the list below, `ny` is the number of output channels, and `nu` is the number of input channels:

- `Name`: An optional name for the data set. An arbitrary string.
- `OutputName`, `InputName`: Cell arrays of length `ny-by-1` and `nu-by-1` containing the names of the output and input channels. For estimated models, these are inherited from the data. If not specified, they are given default names `{'y1', 'y2', ...}` and `{'u1', 'u2', ...}`.
- `OutputUnit`, `InputUnit`: Cell arrays of length `ny-by-1` and `nu-by-1` containing the units of the output and input channels. Inherited from data for estimated models.
- `TimeUnit`: Unit for the sampling interval.
- `Ts`: Sampling interval. A nonnegative scalar. `Ts = 0` denotes a continuous-time model. Note that changing just `Ts` will not recompute the model parameters. Use `c2d` and `d2c` for recomputing the model to other sampling intervals.
- `ParameterVector`: Vector of adjustable parameters in the model structure. Initial/nominal values or estimated values, depending on the status of the model. A column vector.
- `PName`: The names of the parameters. A cell array of the length of the parameter vector. If not specified, it will contain empty strings. See also `setpname`.
- `CovarianceMatrix`: Estimated covariance matrix of the parameter vector. For a nonestimated model this is the empty matrix. For state-space models in the 'Free' parameterization the covariance matrix is also the empty matrix, since the individual matrix elements are not identifiable then. Instead, in this case, the covariance information is hidden (in the hidden property 'Utility') and retrieved by the relevant functions when necessary. Setting

CovarianceMatrix to 'None' inhibits calculation of covariance and uncertainty information. This can save substantial time for certain models.

- **NoiseVariance:** Covariance matrix of the noise source  $e$ . An  $n_y$ -by- $n_y$  matrix.
- **InputDelay:** Vector of size  $n_u$ -by-1, containing the input delay from each input channel. For a continuous-time model ( $T_s = 0$ ) the delay is measured in `TimeUnit`, while for discrete-time models ( $T_s > 0$ ) the delay is measured as the number of samples. Note the difference between `InputDelay` and `nk` (which is a property of `idarx`, `idss`, and `idpoly`). '`Nk`' is a model structure property that tells the model structure to include such an input delay. In that case, the corresponding state-space matrices and polynomials will explicitly contain `Nk` input delays. The property `InputDelay`, on the other hand, is an indication that in addition to the model as defined, the inputs should be shifted by the given amount. `InputDelay` is used by `sim` and the estimation routines to shift the input data. When computing frequency responses, the `InputDelay` is also respected. Note that `InputDelay` can be both positive and negative.
- **Algorithm:** See the reference page for `Algorithm Properties`.
- **EstimationInfo:** See the reference page for `EstimationInfo`.
- **Notes:** An arbitrary field to store extra information and notes about the object.
- **UserData:** An arbitrary field for any possible use.

---

**Note** All properties can be set or retrieved either by these commands or by subscripts. `Autofill` applies to all properties and values, and is case insensitive.

---

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`.

**Subreferencing** The outputs and input channels can be referenced according to

```
m(outputs,inputs)
```

Use a colon (:) to denote all channels and an empty matrix ([]) to denote no channels. The channels can be referenced by number or by name. For several names, you must use a cell array.

```
m2 = m('y3',{ 'u1' , 'u4' })
m3 = m(3,[1 4])
```

For a single output model m,

```
m4 = m(inputs)
```

selects the corresponding input channels, and for a single input model,

```
m5 = m(outputs)
```

selects the indicated output channels.

The string 'measured' (or any abbreviation like 'm') means the measured input channels.

```
m4 = m(3,'m')
m('m') is the same as m(:, 'm')
```

Similarly, the string 'noise' (or any abbreviation) refers to the noise input channels. See “Noise Channels” on page 2-166 for more details.

## Horizontal Concatenation

Adding input channels,

```
m = [m1,m2,...,mN]
```

creates an idmodel object m, consisting of all the input channels in m1, ... mN. The output channels of mk must be the same.

# idmodel

---

## Vertical Concatenation

Adding output channels,

```
m = [m1;m2;... ;mN]
```

creates an `idmodel` object `m` consisting of all the output channels in `m1`, `m2`, ..`mN`. The input channels of `mk` must all be the same.

You can specify the model properties directly in the <code>nlarx</code> syntax.</p> <p>For information about the nonlinear ARX model structure, see “Definition of the Nonlinear ARX Model”.</p> <p>The information in these reference pages summarizes the <code>idnlarx</code> model constructor and properties. It discusses the following topics:</p> <ul style="list-style-type: none"><li>• “<code>idnlarx</code> Constructor” on page 2-173</li><li>• “<code>idnlarx</code> Properties” on page 2-175</li><li>• “<code>idnlarx</code> Algorithm Properties” on page 2-178</li><li>• “<code>idnlarx</code> Advanced Algorithm Properties” on page 2-182</li><li>• “<code>idnlarx</code> EstimationInfo Properties” on page 2-184</li></ul>
<b>idnlarx Constructor</b>	<p>Typically, you use the <code>nlarx</code> estimator command to specify the model properties and estimate the nonlinear ARX model. However, you can also use the <code>idnlarx</code> constructor to create the nonlinear ARX model object in advance, and then estimate the parameters of this object using <code>pem</code>.</p> <p><code>m=idnlarx([na nb nk])</code> creates an <code>idnlarx</code> object with the specified number of output terms <code>na</code>, input terms <code>nb</code>, and input delays <code>nk</code>. It uses <code>wavenet</code> as the nonlinearity estimator.</p> <p><code>m=idnlarx([na nb nk],Nonlinearity)</code> creates an <code>idnlarx</code> object with the specified nonlinearity estimator.</p>

`m=idnlarx([na nb nk],Nonlinearity,P1,V1,...,PN,VN)` creates an `idnlarx` object and specifies `idnlarx` property-value pairs. For more information about `idnlarx` properties, see “`idnlarx` Properties” on page 2-175.

The constructor arguments have the following specifications:

`[na nb nk]`

`na` is the number of output terms, `nb` is the number of input terms, and `nk` is the input delays from each input to output.

For `ny` outputs and `nu` inputs, `[na nb nk]` has as many rows as there are outputs. In this case, `na` is an `ny`-by-`ny` matrix whose *i*-*j*th entry gives the number of delayed *j*th outputs used to compute the *i*th output. `nb` and `nk` are `ny`-by-`nu` matrices.

These orders specify the regressors and the predicted output is a nonlinear function of these regressors:

$$F(y(t-1),\dots,y(t-na),u(t-nk),\dots,u(t-nk-nb+1))$$

**Nonlinearity**

Specifies the nonlinearity estimator object (formula for *F* above) as one of the following: `wavenet` (default), `sigmoidnet`, `treepartition`, `customnet`, `neuralnet`, and `linear`. The nonlinearity estimator objects have properties that you can set in the constructor, as follows:

```
m=idnlarx([2 3 1],sigmoidnet('Num',15))
```

For `ny` outputs, `Nonlinearity` is an `ny`-by-1 array, such as `[sigmoidnet;wavenet]`. However, if you specify a scalar object, this nonlinearity object applies to all outputs.

To use default nonlinearity properties, you may also specify the nonlinearity object name as a string. For example:

```
m=idnlarx([3 2 1],'sigmoidnet')
```

```

% Abbreviated.
m=idnlarx([3 2 1], 'sig')

% The estimator 'linear' or [] denotes the
% absence of nonlinearity
m=idnlarx([2 2 1], []) % m contains no nonlinearity

```

For more information about nonlinearity properties, see the corresponding reference pages.

## idnlarx Properties

You can include property-value pairs in the model estimator or constructor to specify the model structure and estimation algorithm properties.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```

% Get the model time unit
get(m, 'TimeUnit')
% Get value of Nonlinearity property
m.Nonlinearity

```

The following table summarizes `idnlarx` model properties. The general `idnlmodel` properties also apply to this nonlinear model object (see the corresponding reference pages).

Property Name	Description
Algorithm	A structure that specifies the estimation algorithm options, as described in “idnlarx Algorithm Properties” on page 2-178.

Property Name	Description
CustomRegressors	<p>Custom expression in terms of standard regressors. Assignable values:</p> <ul style="list-style-type: none"> <li>• Cell array of strings. For example: <code>{'y1(t-3)^3', 'y2(t-1)*u1(t-3)', 'sin(u3(t-2))'}</code>.</li> <li>• Object array of <code>customreg</code> objects. These objects can be created using commands such as <code>customreg</code> and <code>polyreg</code>. For more information about this object, see the corresponding reference pages.</li> </ul>
EstimationInfo	<p>A read-only structure that stores estimation settings and results, as described in “idnlarx EstimationInfo Properties” on page 2-184.</p>
Focus	<p>Specifies 'Prediction' or 'Simulation'.</p> <p>Assignable values:</p> <ul style="list-style-type: none"> <li>• 'Prediction' — The estimation algorithm minimizes <math>\ y - \hat{y}\ </math>, where <math>\hat{y}</math> is the 1-step ahead predicted output.</li> <li>• 'Simulation' — The estimation algorithm minimizes the output error fit. That is, when computing <math>\hat{y}</math>, <math>y</math> in the regressors in <math>F</math> are replaced by values simulated from the input only.</li> </ul> <hr/> <p><b>Note</b> You cannot use 'Simulation' when the model <code>treepartition</code> or <code>neuralnet</code> as a nonlinearity estimator.</p>

Property Name	Description
NonlinearRegressors	<p data-bbox="557 319 1326 444">Specifies which standard or custom regressors enter the nonlinear block. For multiple-output models, use cell array of <math>n_y</math> elements (<math>n_y</math> = number of model outputs). For each output, assignable values are:</p> <ul data-bbox="557 479 1326 942" style="list-style-type: none"><li data-bbox="557 479 1205 506">• 'all' — All regressors enter the nonlinear block.</li><li data-bbox="557 527 1012 555">• 'input' — Input regressors only.</li><li data-bbox="557 576 1044 604">• 'output' — Output regressors only.</li><li data-bbox="557 624 1101 652">• 'standard' — Standard regressors only.</li><li data-bbox="557 673 1050 701">• 'custom' — Custom regressors only.</li><li data-bbox="557 722 1326 777">• 'search' — Specifies that the estimation algorithm perform an exhaustive search of the best regressor combination.</li><li data-bbox="557 798 1190 826">• '[]' — No regressors enter the nonlinear block.</li><li data-bbox="557 847 1299 942">• A vector of indices: Specifies the indices of the regressors that should be used in the nonlinear estimator. To determine the order of regressors, use the <code>getreg</code> function.</li></ul>

Property Name	Description
Nonlinearity	<p>Nonlinearity estimator object. Assignable values include <code>wavenet</code> (default), <code>sigmoidnet</code>, <code>treepartition</code>, <code>customnet</code>, <code>neuralnet</code>, and <code>linear</code>. If the model contains only one regressor, you can also use <code>saturation</code>, <code>deadzone</code>, <code>pwnlinear</code> or <code>poly1d</code> as a nonlinearity estimator.</p> <p>For <math>n_y</math> outputs, <code>Nonlinearity</code> is an <math>n_y</math>-by-1 array, such as <code>[sigmoidnet;wavenet]</code> for a two-output model. However, if you specify a scalar object, this nonlinearity object applies to all outputs.</p>
<p><code>na</code> <code>nb</code> <code>nk</code></p>	<p>Model orders and input delays, where <code>na</code> is the number of output terms, <code>nb</code> is the number of input terms, and <code>nk</code> is the delay from input to output in terms of the number of samples.</p> <p>For <math>n_y</math> outputs and <math>n_u</math> inputs, <code>na</code> is an <math>n_y</math>-by-<math>n_y</math> matrix whose <math>i</math>-<math>j</math>th entry gives the number of delayed <math>j</math>th outputs used to compute the <math>i</math>th output. <code>nb</code> and <code>nk</code> are <math>n_y</math>-by-<math>n_u</math> matrices.</p>

## idnlarx Algorithm Properties

The following table summarizes the fields of the Algorithm `idnlarx` model properties. `Algorithm` is a structure that specifies the estimation-algorithm options.

Property Name	Description
Advanced	A structure that specifies additional estimation algorithm options, as described in “ <code>idnlarx</code> Advanced Algorithm Properties” on page 2-182.

Property Name	Description
Criterion	<p>Specifies criterion used during minimization. Criterion can have the following values:</p> <ul style="list-style-type: none"> <li>• 'Det': Minimize <math>\det(E^*E)</math>, where E represents the prediction error. This is the optimal choice in a statistical sense and leads to the maximum likelihood estimates in case nothing is known about the variance of the noise. It uses the inverse of the estimated noise variance as the weighting function. This is the default criterion used for all models, except <code>idnlgrey</code> which uses 'Trace' by default.</li> <li>• 'Trace': Minimize the trace of the weighted prediction error matrix <math>\text{trace}(E^*E*W)</math>, where E is the matrix of prediction errors, with one column for each output, and W is a positive semi-definite symmetric matrix of size equal to the number of outputs. By default, W is an identity matrix of size equal to the number of model outputs (so the minimization criterion becomes <math>\text{trace}(E^*E)</math>, or the traditional least-squares criterion). You can specify the relative weighting of prediction errors for each output using the <code>Weighting</code> field of the <code>Algorithm</code> property. If the model contains <code>neuralnet</code> or <code>treepartition</code> as one of its nonlinearity estimators, weighting is not applied since the estimations are performed independently for each output.</li> </ul>
IterWavenet	<p>(For <code>wavenet</code> nonlinear estimator only)  Toggles performing iterative or noniterative estimation.  Default: 'auto'.  Assignable values:</p> <ul style="list-style-type: none"> <li>• 'auto' — First estimation is noniterative and subsequent estimation are iterative.</li> <li>• 'On' — Perform iterative estimation only.</li> <li>• 'Off' — Perform noniterative estimation only.</li> </ul>

Property Name	Description
LimitError	<p>Robustification criterion that limits the influence of large residuals, specified as a positive real value. Residual values that are larger than 'LimitError' times the estimated residual standard deviation have a linear cost instead of the usual quadratic cost.</p> <p>Default: 0 (no robustification).</p>
MaxIter	<p>Maximum number of iterations for the estimation algorithm, specified as a positive integer.</p> <p>Default: 20.</p>
MaxSize	<p>The number of elements (size) of the largest matrix to be formed by the algorithm. Computational loops are used for larger matrices. Use this value for memory/speed trade-off. MaxSize can be any positive integer.</p> <p>Default: 250000.</p> <hr/> <p><b>Note</b> The original data matrix of <math>u</math> and <math>y</math> must be smaller than MaxSize.</p> <hr/>
SearchMethod	<p>Method used by the iterative search algorithm.</p> <p>Assignable values:</p> <ul style="list-style-type: none"> <li>• 'Auto' — Automatically chooses from the following methods.</li> <li>• 'gn' — Subspace Gauss-Newton method.</li> <li>• 'gna' — Adaptive Gauss-Newton method.</li> <li>• 'grad' — A gradient method.</li> <li>• 'lm' — Levenberg-Marquardt method.</li> <li>• 'lsqnonlin' — Nonlinear least-squares method (requires the Optimization Toolbox™ product). This method only handles the 'Trace' criterion.</li> </ul>

Property Name	Description
Tolerance	Specifies to terminate the iterative search when the expected improvement of the parameter values is less than <b>Tolerance</b> , specified as a positive real value in %. Default: 0.01.
Display	Toggles displaying or hiding estimation progress information in the MATLAB Command Window. Default: 'Off'. Assignable values: <ul data-bbox="560 618 1089 697" style="list-style-type: none"><li>• 'Off' — Hide estimation information.</li><li>• 'On' — Display estimation information.</li></ul>
Weighting	Positive semi-definite matrix <b>W</b> used for weighted trace minimization. When <b>Criterion</b> = 'Trace', $\text{trace}(E'E*W)$ is minimized. <b>Weighting</b> can be used to specify relative importance of outputs in multiple-input multiple-output models (or reliability of corresponding data) when <b>W</b> is a diagonal matrix of nonnegative values. <b>Weighting</b> is not useful in single-output models. By default, <b>Weighting</b> is an identity matrix of size equal to the number of outputs.

---

**Note** The `Criterion` property setting is meaningful in multiple-output cases only. In single-output models, the two criteria are equivalent. Both the `Det` and `Trace` criteria are derived from a general requirement of minimizing a weighted sum of least squares of prediction errors. The `Det` criterion can be interpreted as estimating the covariance matrix of the noise source and using the inverse of that matrix as the weighting. You should specify the weighting when using the `Trace` criterion.

If you want to achieve better accuracy for a particular channel in multiple-input multiple-output models, you should use `Trace` with weighting that favors that channel. Otherwise it is natural to use `Det`. When using `Det` you can check `cond(model.NoiseVariance)` after estimation. If the matrix is ill-conditioned, it may be more robust to use the `Trace` criterion. You can also use `compare` on validation data to check whether the relative error for different channels corresponds to your needs or expectations. Use the `Trace` criterion if you need to modify the relative errors, and check `model.NoiseVariance` to determine what weighting modifications to specify.

The search method of `lsqnonlin` supports the `Trace` criterion only.

---

## idnlarx Advanced Algorithm Properties

The following table summarizes the fields of the `Algorithm.Advanced` model properties. The fields in the `Algorithm.Advanced` structure specify additional estimation-algorithm options.

Property Name	Description
<code>GnPinvConst</code>	When the search direction is computed, the algorithm discards the singular values of the Jacobian that are smaller than $\text{GnPinvConst} \times \max(\text{size}(J)) \times \text{norm}(J) \times \text{eps}$ . Singular values that are closer to 0 are included when <code>GnPinvConst</code> is decreased. Default: <code>1e4</code> . Assign a positive, real value.

Property Name	Description
LMStartValue	(For Levenberg-Marquardt search algorithm) The starting level of <i>regularization</i> when using the Levenberg-Marquardt search method ( <code>Algorithm.SearchMethod='lm'</code> ). Default: 0.001. Assign a positive real value.
LMStep	(For Levenberg-Marquardt search algorithm) Try this next level of <i>regularization</i> to get a lower value of the criterion function. The level of regularization is LMStep times the previous level. At the start of a new iteration, the level of regularization is computed as 1/LMStep times the value from the previous iteration. Default: 10. Assign a real value >1.
MaxBisections	Maximum number of bisections performed by the line search algorithm along the search direction (number of rotations of search vector for 'lm'). Used by 'gn', 'lm', 'gna' and 'grad' search methods ( <code>Algorithm.SearchMethod</code> property) Default: 10. Assign a positive integer value.
MaxFunEvals	The iterations are stopped if the number of calls to the model file exceeds this value. Default: Inf. Assign a positive integer value.
MinParChange	The smallest parameter update allowed per iteration. Default: 1e-16. Assign a positive, real value.

Property Name	Description
RelImprovement	<p>The iterations are stopped if the relative improvement of the criterion function is less than RelImprovement. Default: 0. Assign a positive real value.</p> <hr/> <p><b>Note</b> Does not apply to Algorithm.SearchMethod='lsqnonlin'</p>
StepReduction	<p>(For line search algorithm) The suggested parameter update is reduced by the factor 'StepReduction' after each try until either 'MaxBisections' tries are completed or a lower value of the criterion function is obtained. Default: 2. Assign a positive, real value &gt;1.</p> <hr/> <p><b>Note</b> Does not apply to Algorithm.SearchMethod='lsqnonlin'</p>

## idnlarx EstimationInfo Properties

The following table summarizes the fields of the EstimationInfo model properties. The read-only fields of the EstimationInfo structure store estimation settings and results.

Property Name	Description
Status	Shows whether the model parameters were estimated.
Method	Shows the estimation method.
LossFcn	Value of the loss function, equal to $\det(E' * E / N)$ , where E is the residual error matrix (one column for each output) and N is the total number of samples.

Property Name	Description
FPE	Value of Akaike's Final Prediction Error (see <code>fpe</code> ).
DataName	Name of the data from which the model is estimated.
DataLength	Length of the estimation data.
DataTs	Sampling interval of the estimation data.
DataDomain	'Time' means time domain data. 'Frequency' is not supported.
DataInterSample	Intersample behavior of the input estimation data used for interpolation: <ul style="list-style-type: none"> <li>'zoh' means zero-order-hold, or piecewise constant.</li> <li>'foh' means first-order-hold, or piecewise linear.</li> </ul>
EstimationTime	Duration of the estimation.
InitRandState	The value of <code>randn('state')</code> at the last randomization of the initial parameter vector.
Iterations	Number of iterations performed by the estimation algorithm.
UpdateNorm	Norm of the Gauss-Newton in the last iteration. Empty when 'lsqnonlin' is the search method.
LastImprovement	Criterion improvement in the last iteration, shown in %. Empty when 'lsqnonlin' is the search method.
Warning	Any warnings encountered during parameter estimation.
WhyStop	Reason for terminating parameter estimation iterations.

## Definition of idnlarx States

The states of an `idnlarx` object are defined by the set of delayed input and output variables that define the structure of the model. The concept of states is useful for functions such as `sim`, `predict`, `compare`, `findstates`, `data2state`, `findop`, and `linearize`. A nonlinear ARX model consists of two essential elements — regressors and nonlinearities. The regressors represent the dynamic element of the model while the nonlinearities are static. The regressors include

delayed samples of input and output variables (standard regressors) and user-defined transformations of delayed input and output variables (custom regressors). To determine the states of an `idnlarx` model, you must determine the maximum delay in each input and output variable used by the regressors. If a variable  $p$  has a maximum delay of  $D$  samples, then it contributes  $D$  elements to the state vector:  $p(t-1)$ ,  $p(t-2)$ , ...,  $p(t-D)$ .

For example, if you have a single-input, single-output `idnlarx` model defined as:

```
m = idnlarx([2 3 0], 'wavenet', ...  
            'CustomRegressors', ...  
            {'y1(t-10)*u1(t-1)'});
```

You can use the function to show that `m` has the following 6 regressors:

```
>> getreg(m)  
Regressors:  
    y1(t-1)  
    y1(t-2)  
    u1(t)  
    u1(t-1)  
    u1(t-2)  
    y1(t-10)*u1(t-1)
```

From the list of regressors, it can be seen that the maximum delay in output variable `y1` is 10 samples, while the maximum delay in input `u1` is 2 samples. Therefore there are 12 states in this model composed of 10 delayed sampled of output `y1` and 2 delayed samples of input `u1`:

$$\mathbf{X}(t) = [y1(t-1), y2(t-2), \dots, y1(t-10), u1(t-1), u1(t-2)]$$

---

**Note** The states vector contains the output variables first, followed by the input variables.

---

As another example, consider the 2-output, 3-input model:

```
m = idnlarx([2 0 2 2 1 1 0 0; 1 0 1 5 0 1 1 0], ...
            [wavenet; linear])
```

You can use `getreg` to find that the model has following regressors:

```
>> getreg(m)
Regressors:
For output 1:
  y1(t-1)
  y1(t-2)
  u1(t-1)
  u1(t-2)
  u2(t)
  u2(t-1)
  u3(t)
For output 2:
  y1(t-1)
  u1(t-1)
  u2(t-1)
  u2(t-2)
  u2(t-3)
  u2(t-4)
  u2(t-5)
```

The maximum delay in output variable  $y_1$  is 2 samples, which occurs in regressor set for output 1. Variable  $y_2$  does not appear in the regressor set since the maximum delay in  $y_2$  is zero. The maximum delays in the three input variables are 2, 5 and 0 respectively. Summarizing this information as before, the state vector is:

$$X(t) = [y_1(t-1), y_1(t-2), u_1(t-1), u_1(t-2), u_2(t-1), u_2(t-2), u_2(t-3), u_2(t-4), u_2(t-5)]$$

You can see that the variables  $y_2$  and  $u_3$  do not contribute to the state vector, because the maximum delay in these variables is zero. The above

analysis of determining states from an inspection of regressors can be automated using the `getDelayInfo` command. This function returns the maximum delays in all I/O variables across all model outputs. For the multiple-input multiple-output model `m`, `getDelayInfo` returns:

```
maxDel = getDelayInfo(m)
maxDel =
     2     0     2     5     0
```

`maxDel` contains the maximum delays for all the input and output variables in the order (`y1`, `y2`, `u1`, `u2`, `u3`). The total number of model states is `sum(maxDel) = 9`.

---

**Note** The set of states for an `idnlarx` model is not minimal.

---

## See Also

`getreg`  
`nlrx`  
`pem`

**Purpose**

Nonlinear ODE (grey-box model) with unknown parameters

**Syntax**

```
m = idnlgrey('filename',Order,Parameters)
m = idnlgrey('filename',Order,Parameters,InitialStates)
m = idnlgrey('filename',Order,Parameters,InitialStates,Ts)
m = idnlgrey('filename',Order,Parameters,InitialStates,
Ts,P1,V1,...,PN,VN)
```

**Description**

idnlgrey is an object that represents the nonlinear grey-box model.

For information about the nonlinear grey-box models, see “Estimating Nonlinear Grey-Box Models”.

The information in these reference pages summarizes the idnlgrey model constructor and properties. It discusses the following topics:

- “idnlgrey Constructor” on page 2-189
- “idnlgrey Properties” on page 2-190
- “idnlgrey Advanced Algorithm Properties” on page 2-197
- “idnlgrey Simulation Options” on page 2-199
- “idnlgrey Gradient Options” on page 2-203
- “idnlgrey EstimationInfo Properties” on page 2-204

**idnlgrey  
Constructor**

Use the following syntax to define the idnlgrey model object:

```
m = idnlgrey('filename',Order,Parameters)
m = idnlgrey('filename',Order,Parameters,InitialStates)
m = idnlgrey('filename',Order,Parameters,InitialStates,Ts)
m =
idnlgrey('filename',Order,Parameters,InitialStates,Ts,P1,V1,...,PN,VN)
```

The idnlgrey arguments are defined as follows:

- *'filename'* — Name of the M-file or MEX-file storing the model structure (ODE file).
- *Order* — Vector with three entries [*Ny Nu Nx*], specifying the number of model outputs *Ny*, the number of inputs *Nu*, and the number of states *Nx*.
- *Parameters* — Parameters, specified as struct arrays, cell arrays, or double arrays.
- *InitialStates* — Specified in a same way as parameters. Must be fourth input to the `idnlgrey` constructor.
- The command

```
m = idnlgrey('filename',Order,Parameters,...  
            InitialStates,Ts,P1,V1,...,PN,VN)
```

specifies `idnlgrey` property-value pairs. See information on properties of `idnlgrey` objects below.

Estimate the parameters of this object using `pem`.

## idnlgrey Properties

You can include property-value pairs in the model estimator or constructor to specify the model structure and estimation algorithm properties.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% Get the model time unit  
get(m,'TimeUnit')  
m.TimeUnit
```

The following table summarizes `idnlgrey` model properties. The general `idnlgrey` properties also apply to this nonlinear model object (see the corresponding reference pages).

Property Name	Description
Algorithm	A structure that specifies the estimation algorithm options, as described in “idnlgrey Algorithm Properties” on page 2-194.
CovarianceMatrix	Covariance matrix of the estimated Parameters. Assignable values: <ul style="list-style-type: none"> <li>• 'None' to omit computing uncertainties and save time during parameter estimation.</li> <li>• 'Estimate' to estimation covariance. Symmetric and positive <math>N_p</math>-by-<math>N_p</math> matrix (or []) where <math>N_p</math> is the number of free model parameters.</li> </ul>
EstimationInfo	A read-only structure that stores estimation settings and results, as described in “idnlgrey EstimationInfo Properties” on page 2-204.
FileArgument	Contains auxiliary variables passed to the ODE file (M-file or MEX-file) specified in FileName. These variables may be used as extra inputs for specifying the state and/or output equations. FileArgument should be specified as a cell array. Default: {}.
FileName	File name string (without extension) or a function handle for computing the states and the outputs. If 'FileName' is a string, then it must point to an M-file or MEX-file. For more information about the file variables, see “Specifying the Nonlinear Grey-Box Model Structure”.

Property Name	Description
InitialStates	<p>An Nx-by-1 structure array with fields as follows. Here, Nx is the number of states of the model.</p> <ul style="list-style-type: none"> <li>• <b>Name:</b> Name of the state (a string). Default value is 'x#i', where #i is an integer in [1, Nx].</li> <li>• <b>Unit:</b> Unit of the state (a string). Default value is ''.</li> <li>• <b>Value:</b> Initial value of the initial state(s). Assignable values are: <ul style="list-style-type: none"> <li>▪ A finite real scalar</li> <li>▪ A finite real 1-by-Ne vector, where Ne is the number of experiments in the data set to be used for estimation</li> </ul> </li> <li>• <b>Minimum:</b> Minimum value of the initial state(s). Must be a real scalar/1-by-Ne vector of the same size as Value and such that Minimum &lt;= Value for all components. Default value: -Inf(size(Value)).</li> <li>• <b>Maximum:</b> Maximum value of the initial state(s). Must be a real scalar/1-by-Ne vector of the same size as Value and such that Value &lt;= Maximum for all components. Default value: Inf(size(Value)).</li> <li>• <b>Fixed:</b> Specifies which component(s) of the initial state(s) are fixed to their known values. Must be a Boolean scalar/1-by-Ne vector of the same size as Value. Default value: true(size(Value)) (that is, do not estimate the initial states).</li> </ul> <p>For an idnlgrey model M, the ith initial state is accessed through M.InitialStates(i) and its subfields as M.InitialStates(i).FIELDNAME.</p>

Property Name	Description
Order	<p>Structure with following fields:</p> <ul style="list-style-type: none"> <li>• <code>ny</code> — Number of outputs of the model structure.</li> <li>• <code>nu</code> — Number of inputs of the model structure.</li> <li>• <code>nx</code> — Number of states of the model structure.</li> </ul> <p>For time series, <code>nu</code> is 0. For static model structures, <code>nx</code> is 0.</p>
Parameters	<p><code>Np</code>-by-1 structure array with information about the model parameters containing the following fields:</p> <ul style="list-style-type: none"> <li>• <b>Name:</b> Name of the parameter (a string). Default value is '<code>p#i</code>', where <code>#i</code> is an integer in <code>[1, Np]</code>.</li> <li>• <b>Unit:</b> Unit of the parameter (a string). Default value is ''.</li> <li>• <b>Value:</b> Initial value of the parameter(s). Assignable values are: <ul style="list-style-type: none"> <li>▪ A finite real scalar</li> <li>▪ A finite real column vector</li> <li>▪ A 2-dimensional real matrix</li> </ul> </li> <li>• <b>Minimum:</b> Minimum value of the parameter(s). Must be a real scalar/column vector/matrix of the same size as <code>Value</code> and such that <code>Minimum &lt;= Value</code> for all components. Default value: <code>-Inf(size(Value))</code>.</li> <li>• <b>Maximum:</b> Maximum value of the parameter(s). Must be a real scalar/column vector/matrix of the same size as <code>Value</code> and such that <code>Value &lt;= Maximum</code> for all components. Default value: <code>Inf(size(Value))</code>.</li> <li>• <b>Fixed:</b> Specifies which component(s) of the parameter(s) are fixed to their known values. Must be a Boolean scalar/column vector/matrix of the same size as <code>Value</code>. Default value: <code>false(size(Value))</code>, (estimate all parameter components).</li> </ul> <p>For an <code>idnlgrey</code> model <code>M</code>, the <code>i</code>th parameter is accessed through <code>M.Parameters(i)</code> and its subfields as <code>M.Parameters(i).FIELDNAME</code>.</p>

## idnlgrey Algorithm Properties

The following table summarizes the fields of the Algorithm `idnlgrey` model properties. `Algorithm` is a structure that specifies the estimation-algorithm options.

Property Name	Description
Advanced	A structure that specifies additional estimation algorithm options, as described in “idnlgrey Advanced Algorithm Properties” on page 2-197.
Criterion	<p>Specifies criterion used during minimization. <code>Criterion</code> can have the following values:</p> <ul style="list-style-type: none"> <li>• <code>'Det'</code>: Minimize <math>\det(E' * E)</math> where <math>E</math> represents the prediction error. This is the optimal choice in a statistical sense and leads to the maximum likelihood estimates in case nothing is known about the variance of the noise. It uses the inverse of the estimated noise variance as the weighting function. This is the default criterion used for all models, except <code>idnlgrey</code> which uses <code>'Trace'</code> by default.</li> <li>• <code>'Trace'</code>: Minimize the trace of the weighted prediction error matrix <math>\text{trace}(E' * E * W)</math>, where <math>E</math> is the matrix of prediction errors, with one column for each output, and <math>W</math> is a positive semi-definite symmetric matrix of size equal to the number of outputs. By default, <math>W</math> is an identity matrix of size equal to the number of model outputs (so the minimization criterion becomes <math>\text{trace}(E' * E)</math>, or the traditional least-sum-of-squared-errors criterion. You can specify the relative weighting of prediction errors for each output using the <code>Weighting</code> field of the <code>Algorithm</code> property.</li> </ul>
LimitError	<p>Robustification criterion that limits the influence of large residuals, specified as a positive real value. Residual values that are larger than <code>'LimitError'</code> times the estimated residual standard deviation have a linear cost instead of the usual quadratic cost.</p> <p>Default: 0 (no robustification).</p>

Property Name	Description
MaxIter	Maximum number of iterations for the estimation algorithm, specified as a positive integer. Default: 20.
SearchMethod	Method used by the iterative search algorithm. Assignable values: <ul style="list-style-type: none"> <li>• 'Auto' — Automatically chooses from the following methods.</li> <li>• 'gn' — Gauss-Newton method.</li> <li>• 'gna' — Adaptive Gauss-Newton method.</li> <li>• 'grad' — A gradient method.</li> <li>• 'lm' — Levenberg-Marquardt method.</li> <li>• 'lsqnonlin' — Nonlinear least-squares method (requires the Optimization Toolbox product). This method handles only the 'Trace' criterion.</li> </ul>
Tolerance	Specifies to terminate the iterative search when the expected improvement of the parameter values is less than Tolerance, specified as a positive real value in %. Default: 0.01.
GradientOptions	A structure that specifies the options related to calculation of gradient of the cost, “idnlgrey Gradient Options” on page 2-203.
SimulationOptions	A structure that specifies the simulation method and related options, as described in “idnlgrey Simulation Options” on page 2-199.

Property Name	Description
Display	<p>Toggles displaying or hiding estimation progress information in the MATLAB Command Window.</p> <p>Default: 'Off'.</p> <p>Assignable values:</p> <ul style="list-style-type: none"><li>• 'Off' — Hide estimation information.</li><li>• 'On' — Display estimation information.</li></ul>
Weighting	<p>Positive semi-definite matrix <math>W</math> used for weighted trace minimization. When <code>Criterion = 'Trace'</code>, <math>\text{trace}(E'E*W)</math> is minimized. <code>Weighting</code> can be used to specify relative importance of outputs in multiple-input multiple-output models (or reliability of corresponding data) when <math>W</math> is a diagonal matrix of nonnegative values. <code>Weighting</code> is not useful in single-output models. By default, <code>Weighting</code> is an identity matrix of size equal to the number of outputs.</p>

---

**Note** The `Criterion` property setting is meaningful in multiple-output cases only. In single-output models, the two criteria are equivalent. Both the `Det` and `Trace` criteria are derived from a general requirement of minimizing a weighted sum of least squares of prediction errors. The `Det` criterion can be interpreted as estimating the covariance matrix of the noise source and using the inverse of that matrix as the weighting. You should specify the weighting when using the `Trace` criterion.

If you want to achieve better accuracy for a particular channel in multiple-input multiple-output models, you should use `Trace` with weighting that favors that channel. Otherwise it is natural to use `Det`. When using `Det` you can check `cond(model.NoiseVariance)` after estimation. If the matrix is ill-conditioned, it may be more robust to use the `Trace` criterion. You can also use `compare` on validation data to check whether the relative error for different channels corresponds to your needs or expectations. Use the `Trace` criterion if you need to modify the relative errors, and check `model.NoiseVariance` to determine what weighting modifications to specify.

The search method of `lsqnonlin` supports the `Trace` criterion only.

---

## **idnlgrey Advanced Algorithm Properties**

The following table summarizes the fields of the `Algorithm.Advanced` model properties. The fields in the `Algorithm.Advanced` structure specify additional estimation-algorithm options.

Property Name	Description
GnPinvConst	When the search direction is computed, the algorithm discards the singular values of the Jacobian that are smaller than $\text{GnPinvConst} * \max(\text{size}(\mathbf{J})) * \text{norm}(\mathbf{J}) * \text{eps}$ . Singular values that are closer to 0 are included when GnPinvConst is decreased. Default: 1e4. Assign a positive, real value.
LMStartValue	(For Levenberg-Marquardt search algorithm) The starting level of <i>regularization</i> when using the Levenberg-Marquardt search method (Algorithm.SearchMethod='lm'). Default: 0.001. Assign a positive real value.
LMStep	(For Levenberg-Marquardt search algorithm) Try this next level of <i>regularization</i> to get a lower value of the criterion function. The level of regularization is LMStep times the previous level. At the start of a new iteration, the level of regularization is computed as 1/LMStep times the value from the previous iteration. Default: 10. Assign a real value >1.
MaxBisections	Maximum number of bisections performed by the line search algorithm along the search direction (number of rotations of search vector for 'lm'). Used by 'gn', 'lm', 'gna' and 'grad' search methods (Algorithm.SearchMethod property) Default: 25. Assign a positive integer value.
MaxFunEvals	The iterations are stopped if the number of calls to the model file exceeds this value. Default: Inf. Assign a positive integer value.

Property Name	Description
MinParChange	The smallest parameter update allowed per iteration. Default: 1e-16. Assign a positive, real value.
RelImprovement	The iterations are stopped if the relative improvement of the criterion function is less than RelImprovement. Default: 0. Assign a positive real value.  <b>Note</b> Does not apply to Algorithm.SearchMethod='lsqnonlin'
StepReduction	(For line search algorithm) The suggested parameter update is reduced by the factor 'StepReduction' after each try until either 'MaxBisections' tries are completed or a lower value of the criterion function is obtained. Default: 2. Assign a positive, real value >1.  <b>Note</b> Does not apply to Algorithm.SearchMethod='lsqnonlin'

## idnlgrey Simulation Options

The following table summarizes the fields of Algorithm.SimulationOptions model properties.

Property Name	Description
AbsTol	<p>Absolute error tolerance. This scalar applies to all components of the state vector. AbsTol applies only to the variable step solvers.</p> <p>Default: 1e-6.</p> <p>Assignable value: A positive real value.</p>
FixedStep	<p>(For fixed-step time-continuous solvers) Step size used by the solver.</p> <p>Default: 'Auto'.</p> <p>Assignable values:</p> <ul style="list-style-type: none"> <li>• 'Auto' — Automatically chooses the initial step.</li> <li>• A real value such that <math>0 &lt; \text{FixedStep} \leq 1</math>.</li> </ul>
InitialStep	<p>(For variable-step time-continuous solvers) Specifies the initial step at which the ODE solver starts.</p> <p>Default: 'Auto'.</p> <p>Assignable values:</p> <ul style="list-style-type: none"> <li>• 'Auto' — Automatically chooses the initial step.</li> <li>• A positive real value such that <math>\text{MinStep} \leq \text{InitialStep} \leq \text{MaxStep}</math>.</li> </ul>
MaxOrder	<p>(For ode15s) Specifies the order of the Numerical Differentiation Formulas (NDF).</p> <p>Default: 5.</p> <p>Assignable values: 1, 2, 3, 4 or 5.</p>
MaxStep	<p>(For variable-step time-continuous solvers) Specifies the largest time step of the ODE solver.</p> <p>Default: 'Auto' — 1/15 of the simulation interval.</p> <p>Assignable values:</p> <ul style="list-style-type: none"> <li>• 'Auto' — Automatically chooses the time step.</li> <li>• A positive real value <math>&gt; \text{MinStep}</math>.</li> </ul>

Property Name	Description
MinStep	<p>(For variable-step time-continuous solvers) Specifies the smallest time step of the ODE solver. Default: 'Auto'. Assignable values:</p> <ul style="list-style-type: none"><li>• 'Auto' — Automatically chooses the time step.</li><li>• A positive real value &lt; MaxStep.</li></ul>

Property Name	Description
RelTol	<p>(For variable-step time-continuous solvers) Relative error tolerance that applies to all components of the state vector. The estimated error in each integration step satisfies <math> e(i)  \leq \max(\text{RelTol} \cdot \text{abs}(x(i)), \text{AbsTol}(i))</math>.            Default: <math>1e-3</math> (0.1% accuracy).            Assignable value: A positive real value.</p>
Solver	<p>ODE (Ordinary Differential/Difference Equation) solver for solving state space equations.</p> <p>A. Variable-step solvers for time-continuous idnlgrey models:</p> <ul style="list-style-type: none"> <li>• 'ode45' — Runge-Kutta (4,5) solver for nonstiff problems.</li> <li>• 'ode23' — Runge-Kutta (2,3) solver for nonstiff problems.</li> <li>• 'ode113' — Adams-Bashforth-Moulton solver for nonstiff problems.</li> <li>• 'ode15s' — Numerical Differential Formula solver for stiff problems.</li> <li>• 'ode23s' — Modified Rosenbrock solver for stiff problems.</li> <li>• 'ode23t' — Trapezoidal solver for moderately stiff problems.</li> <li>• 'ode23tb' — Implicit Runge-Kutta solver for stiff problems.</li> </ul> <p>B. Fixed-step solvers for time-continuous idnlgrey models:</p> <ul style="list-style-type: none"> <li>• 'ode5' — Dormand-Prince solver.</li> <li>• 'ode4' — Fourth-order Runge-Kutta solver.</li> <li>• 'ode3' — Bogacki-Shampine solver.</li> <li>• 'ode2' — Heun or improved Euler solver.</li> <li>• 'ode1' — Euler solver.</li> </ul> <p>C. Fixed-step solvers for time-discrete idnlgrey models:            'FixedStepDiscrete'</p> <p>D. General: 'Auto' — Automatically chooses one of the previous solvers (default).</p>

**idnlgrey  
Gradient  
Options**

The following table summarizes the fields of the `Algorithm.GradientOptions` model properties. `Algorithm` is a structure that specifies the estimation-algorithm options.

Property Name	Description
<code>DiffMaxChange</code>	Largest allowed parameter perturbation when computing numerical derivatives. Default: <code>Inf</code> . Assignable value: A positive real value <code>&gt;'DiffMinChange'</code> .
<code>DiffMinChange</code>	Smallest allowed parameter perturbation when computing numerical derivatives. Default: <code>0.01*sqrt(eps)</code> . Assignable value: A positive real value <code>&lt;'DiffMaxChange'</code> .

Property Name	Description
DiffScheme	Method for computing numerical derivatives with respect to the components of the parameters and/or the initial state(s) to form the Jacobian. Default: 'Auto' Assignable values: <ul style="list-style-type: none"><li>• 'Auto' - Automatically chooses from the following methods.</li><li>• 'Central approximation'</li><li>• 'Forward approximation'</li><li>• 'Backward approximation'</li></ul>
GradientType	Method used when computing derivatives (Jacobian) of the parameters or the initial states to be estimated. Default: 'Auto'. Assignable values: <ul style="list-style-type: none"><li>• 'Auto' — Automatically chooses from the following methods.</li><li>• 'Basic' — Individually computes all numerical derivatives required to form each column of the Jacobian.</li><li>• 'Refined' — Simultaneously computes all numerical derivatives required to form each column of the Jacobian.</li></ul>

## idnlgrey EstimationInfo Properties

The following table summarizes the fields of the EstimationInfo model properties. The read-only fields of the EstimationInfo structure store estimation settings and results.

Property Name	Description
Status	Shows whether the model parameters were estimated.

Property Name	Description
Method	Names of the solver and the optimizer used during estimation.
LossFcn	Value of the loss function, equal to $\det(E' * E / N)$ , where E is the residual error matrix (one column for each output) and N is the total number of samples. Provides a quantitative description of the model quality.
FPE	Value of Akaike's Final Prediction Error (see <code>fpe</code> ).
DataName	Name of the data from which the model is estimated.
DataLength	Length of the estimation data.
DataTs	Sampling interval of the estimation data.
DataDomain	'Time' means time domain data. 'Frequency' is not supported.
DataInterSample	Intersample behavior of the input estimation data used for interpolation: <ul style="list-style-type: none"> <li>'zoh' means zero-order-hold, or piecewise constant.</li> <li>'foh' means first-order-hold, or piecewise linear.</li> </ul>
EstimationTime	Duration of the estimation.
InitialGuess	Structure with the fields <code>InitialStates</code> and <code>Parameters</code> , specifying the values of these quantities before the last estimation.
Iterations	Number of iterations performed by the estimation algorithm.
LastImprovement	Criterion improvement in the last iteration, shown in %. Empty when <code>SearchMethod='lsqnonlin'</code> is the search method.
UpdateNorm	Norm of the search vector (Gauss-Newton vector) at the last iteration. Empty when <code>'lsqnonlin'</code> is the search method.
Warning	Any warnings encountered during parameter estimation.
WhyStop	Reason for terminating parameter estimation iterations.

## **Definition of idnlgrey States**

The states of an `idnlgrey` model are defined explicitly by the user in the M-file or MEX-file (as specified in the `FileName` property of the model) storing the model structure . The concept of states is useful for functions such as `sim`, `predict`, `compare`, and `findstates`.

---

**Note** The initial values of the states are configured by the `InitialStates` property of the `idnlgrey` model.

<b>Purpose</b>	Nonlinear black-box Hammerstein-Wiener model
<b>Syntax</b>	<pre>m=idnlhw([nb nf nk]) m=idnlhw([nb nf nk],InputNL,OutputNL) m=idnlhw([nb nf nk],InputNL,OutputNL,P1,V1,...,PN,VN)</pre>
<b>Description</b>	<p><code>idnlhw</code> is an object that stores Hammerstein-Wiener model properties, including model parameters.</p> <p>Typically, you use the <code>nlhw</code> command to both specify the Hammerstein-Wiener model properties and estimate the model. You can specify the model properties directly in the <code>nlhw</code> syntax.</p> <p>For information about the Hammerstein-Wiener model structure, see “Definition of the Hammerstein-Wiener Model”.</p> <p>The information in these reference pages summarizes the <code>idnlhw</code> model constructor and properties. It discusses the following topics:</p> <ul style="list-style-type: none"><li>• “<code>idnlhw</code> Constructor” on page 2-209</li><li>• “<code>idnlhw</code> Properties” on page 2-210</li><li>• “<code>idnlhw</code> Algorithm Properties” on page 2-212</li><li>• “<code>idnlhw</code> Advanced Algorithm Properties” on page 2-215</li><li>• “<code>idnlhw</code> EstimationInfo Properties” on page 2-217</li></ul> <p>Hammerstein-Wiener models describe dynamic systems using one or two static nonlinear blocks in series with a linear block. Only the linear block contains dynamic elements.</p> <p>The linear block is a discrete-time transfer function and the nonlinear blocks are implemented using nonlinearity estimators, such as saturation, wavenet, and deadzone.</p> <p>The input signal passes through the first nonlinear block, a linear block, and a second nonlinear block to produce the output signal, as shown in the following figure.</p>

The following general equation describes the Hammerstein-Wiener structure:

$$w(t) = f(u(t))$$

$$x(t) = \frac{B_{j,i}(q)}{F_{j,i}(q)} w(t)$$

$$y(t) = h(x(t))$$

which contains the following variables:

- $u(t)$  and  $y(t)$  are the inputs and outputs for the system, respectively.
- $f$  and  $h$  are nonlinear functions that correspond to the input and output nonlinearities, respectively.

For multiple inputs and multiple outputs,  $f$  and  $h$  are defined independently for each input and output channel.

- $w(t)$  and  $x(t)$  are internal variables that define the input and output of the linear block, respectively.

$w(t)$  has the same dimension as  $u(t)$ .  $x(t)$  has the same dimension as  $y(t)$ .

- $B(q)$  and  $F(q)$  in the linear dynamic block are linear functions, which are similar to the polynomial in an Output-Error model, as described in “What Are Black-Box Polynomial Models?”.

For  $n_y$  outputs and  $n_u$  inputs, the linear block is a transfer function matrix containing entries in the following form:

$$\frac{B_{j,i}(q)}{F_{j,i}(q)}$$

where  $j = 1, 2, \dots, n_y$  and  $i = 1, 2, \dots, n_u$ .

If only the input nonlinearity is present, the model is called a Hammerstein model. If only the output nonlinearity is present, the model is called a Wiener model.

## idnlhw Constructor

Typically, you use the `n1hw` estimator command to specify the model properties and estimate the Hammerstein-Wiener model. However, you can also use the `idnlhw` constructor to create the Hammerstein-Wiener model object in advance, and then estimate the parameters of this object using `pem`.

`m=idnlhw([nb nf nk])` creates an `idnlhw` object with the specified orders `nb`, `nf`, and input delays `nk`. It uses `pwnlinear` as the default input and output nonlinearity estimators.

`m=idnlhw([nb nf nk],InputNL,OutputNL)` creates an `idnlhw` object with the specified input and output nonlinearity estimator.

`m=idnlhw([nb nf nk],InputNL,OutputNL,P1,V1,...,PN,VN)` creates an `idnlhw` object and specifies `idnlhw` property-value pairs. For more information about `idnlhw` properties, see “`idnlx` Properties” on page 2-175.

The constructor arguments have the following specifications:

`[nb nf nk]`

Model orders and input delays, where `nb` is the number of zeros plus 1, `nf` is the number of poles, and `nk` is the delay from input to output in terms of the number of samples.

For `nu` inputs and `ny` outputs, `nb`, `nf` and, `nk` are `ny`-by-`nu` matrices whose *i*-*j*th entry specifies the orders and delay of the transfer function from the *j*th input to the *i*th output.

`InputNL` and `OutputNL`

Specify the input and output nonlinearity estimator objects as one of the following: `pwnlinear` (default), `deadzone`, `wavenet`, `saturation`, `customnet`, `sigmoidnet`, `poly1d`, and `unitgain`. The nonlinearity estimator objects have properties that you can set in the constructor, as follows:

```
m=idnlhw([2 2 1],sigmoidnet('num',5),deadzone([-1,2]))
```

To use default nonlinearity properties, specify the nonlinearity object name as a string. For example:

```
m=idnlhw([2 2 1], 'sigmoidnet', 'deadzone')  
m=idnlhw([2 2 1], 'sig', 'dead') % Abbreviated
```

The estimator `unitgain` (can also be entered as `[]`) denotes the absence of nonlinearity. Thus, `m=idnlhw([2 2 1], 'saturation', [])` gives a Hammerstein model (no output nonlinearities). For more information about nonlinearity properties, see the corresponding reference pages.

## idnlhw Properties

You can include property-value pairs in the model estimator or constructor to specify the model structure and estimation algorithm properties.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% Get the model B parameters  
get(m, 'b')  
% Get value of InputNonlinearity property  
m.InputNonlinearity
```

The following table summarizes `idnlhw` model properties. The general `idnlmodel` properties also apply to this nonlinear model object (see the corresponding reference pages).

Property Name	Description
Algorithm	A structure that specifies the estimation algorithm options, as described in “ <code>idnlhw</code> Algorithm Properties” on page 2-212.

Property Name	Description
b	<i>B</i> polynomial as a cell array of $N_y$ -by- $N_u$ elements, where $N_y$ is the number of outputs and $N_u$ is the number of inputs. An element $b\{i, j\}$ is a row vector representing the numerator polynomial for the $j$ :th input to $i$ th output transfer function. It contains as many leading zeros as there are input delays.
f	<i>F</i> polynomial as a cell array of $N_y$ -by- $N_u$ elements, where $N_y$ is the number of outputs and $N_u$ is the number of inputs. An element $f\{i, j\}$ is a row vector representing the denominator polynomial for the $j$ :th input to $i$ th output transfer function.
LinearModel	(Read only) The linear model is an Output-Error (OE) model. For single output, represented as an <code>idpoly</code> object. For multiple output, represented as an <code>idss</code> object.
EstimationInfo	A read-only structure that stores estimation settings and results, as described in “idnlhw EstimationInfo Properties” on page 2-217.
InputNonlinearity	<p>Nonlinearity estimator object. Assignable values include <code>pwnlinear</code> (default), <code>deadzone</code>, <code>wavenet</code>, <code>saturation</code>, <code>customnet</code>, <code>sigmoidnet</code>, <code>poly1d</code>, and <code>unitgain</code>. For more information, see the corresponding reference pages.</p> <p>For <math>n_y</math> outputs, <code>Nonlinearity</code> is an <math>n_y</math>-by-1 array, such as <code>[sigmoidnet;wavenet]</code>. However, if you specify a scalar object, this nonlinearity object applies to all outputs.</p>
OutputNonlinearity	Same as <code>InputNonlinearity</code> .
nb nf nk	<p>Model orders and input delays, where <math>n_b</math> is the number of zeros plus 1, <math>n_f</math> is the number of poles, and <math>n_k</math> is the delay from input to output in terms of the number of samples.</p> <p>For <math>n_u</math> inputs and <math>n_y</math> outputs, <math>n_b</math>, <math>n_f</math> and, <math>n_k</math> are <math>n_y</math>-by-<math>n_u</math> matrices whose <math>i</math>-<math>j</math>th entry specifies the orders and delay of the transfer function from the <math>j</math>th input to the <math>i</math>th output.</p>

## idnlhw Algorithm Properties

The following table summarizes the fields of the Algorithm `idnlhw` model properties. Algorithm is a structure that specifies the estimation-algorithm options.

Property Name	Description
Advanced	A structure that specifies additional estimation algorithm options, as described in “idnlhw Advanced Algorithm Properties” on page 2-215.
Criterion	<p>Specifies criterion used during minimization. Criterion can have the following values:</p> <ul style="list-style-type: none"><li>• 'Det': Minimize <math>\det(E' * E)</math>, where E represents the prediction error. This is the optimal choice in a statistical sense and leads to the maximum likelihood estimates in case nothing is known about the variance of the noise. It uses the inverse of the estimated noise variance as the weighting function. This is the default criterion used for all models, except <code>idnlgrey</code> which uses 'Trace' by default.</li><li>• 'Trace': Minimize the trace of the weighted prediction error matrix <math>\text{trace}(E' * E * W)</math>, where E is the matrix of prediction errors, with one column for each output, and W is a positive semi-definite symmetric matrix of size equal to the number of outputs. By default, W is an identity matrix of size equal to the number of model outputs (so the minimization criterion becomes <math>\text{trace}(E' * E)</math>, or the traditional least-squares criterion. You can specify the relative weighting of prediction errors for each output using the <code>Weighting</code> field of the Algorithm property.</li></ul>

Property Name	Description
IterWavenet	<p>(For wavenet nonlinear estimator only)  Toggles performing iterative or noniterative estimation.  Default: 'auto'.  Assignable values:</p> <ul style="list-style-type: none"> <li>• 'auto' — First estimation is noniterative and subsequent estimations are iterative.</li> <li>• 'On' — Perform iterative estimation only.</li> <li>• 'Off' — Perform noniterative estimation only.</li> </ul>
LimitError	<p>Robustification criterion that limits the influence of large residuals, specified as a positive real value. Residual values that are larger than 'LimitError' times the estimated residual standard deviation have a linear cost instead of the usual quadratic cost.  Default: 0 (no robustification).</p>
MaxIter	<p>Maximum number of iterations for the estimation algorithm, specified as a positive integer.  Default: 20.</p>
MaxSize	<p>The number of elements (size) of the largest matrix to be formed by the algorithm. Computational loops are used for larger matrices. Use this value for memory/speed trade-off. MaxSize can be any positive integer. Default: 250000.</p> <hr/> <p><b>Note</b> The original data matrix of <math>u</math> and <math>y</math> must be smaller than MaxSize.</p> <hr/>

Property Name	Description
SearchMethod	<p>Method used by the iterative search algorithm. Assignable values:</p> <ul style="list-style-type: none"> <li>• 'Auto' — Automatically chooses from the following methods.</li> <li>• 'gn' — Gauss-Newton method.</li> <li>• 'gna' — Adaptive Gauss-Newton method.</li> <li>• 'grad' — A gradient method.</li> <li>• 'lm' — Levenberg-Marquardt method.</li> <li>• 'lsqnonlin' — Nonlinear least-squares method (requires the Optimization Toolbox product). This method handles only the 'Trace' criterion.</li> </ul>
Tolerance	<p>Specifies to terminate the iterative search when the expected improvement of the parameter values is less than <b>Tolerance</b>, specified as a positive real value in %. Default: 0.01.</p>
Display	<p>Toggles displaying or hiding estimation progress information in the MATLAB Command Window. Default: 'Off'. Assignable values:</p> <ul style="list-style-type: none"> <li>• 'Off' — Hide estimation information.</li> <li>• 'On' — Display estimation information.</li> </ul>
Weighting	<p>Positive semi-definite matrix <b>W</b> used for weighted trace minimization. When <b>Criterion</b> = 'Trace', <math>\text{trace}(E'E*W)</math> is minimized. <b>Weighting</b> can be used to specify relative importance of outputs in multiple-input multiple-output models (or reliability of corresponding data) when <b>W</b> is a diagonal matrix of nonnegative values. <b>Weighting</b> is not useful in single-output models. By default, <b>Weighting</b> is an identity matrix of size equal to the number of outputs.</p>

---

**Note** The Criterion property setting is meaningful in multiple-output cases only. In single-output models, the two criteria are equivalent. Both the Det and Trace criteria are derived from a general requirement of minimizing a weighted sum of least squares of prediction errors. The Det criterion can be interpreted as estimating the covariance matrix of the noise source and using the inverse of that matrix as the weighting. You should specify the weighting when using the Trace criterion.

If you want to achieve better accuracy for a particular channel in multiple-input multiple-output models, you should use Trace with weighting that favors that channel. Otherwise it is natural to use Det. When using Det you can check `cond(model.NoiseVariance)` after estimation. If the matrix is ill-conditioned, it may be more robust to use the Trace criterion. You can also use `compare` on validation data to check whether the relative error for different channels corresponds to your needs or expectations. Use the Trace criterion if you need to modify the relative errors, and check `model.NoiseVariance` to determine what weighting modifications to specify.

The search method of `lsqnonlin` supports the Trace criterion only.

---

## idnlhw Advanced Algorithm Properties

The following table summarizes the fields of the `Algorithm.Advanced` model properties. The fields in the `Algorithm.Advanced` structure specify additional estimation-algorithm options.

Property Name	Description
GnPinvConst	When the search direction is computed, the algorithm discards the singular values of the Jacobian that are smaller than $\text{GnPinvConst} * \max(\text{size}(J)) * \text{norm}(J) * \text{eps}$ . Singular values that are closer to 0 are included when GnPinvConst is decreased. Default: $1e4$ . Assign a positive, real value.

Property Name	Description
LMStartValue	(For Levenberg-Marquardt search algorithm) The starting level of <i>regularization</i> when using the Levenberg-Marquardt search method ( <code>Algorithm.SearchMethod='lm'</code> ). Default: 0.001. Assign a positive real value.
LMStep	(For Levenberg-Marquardt search algorithm) Try this next level of <i>regularization</i> to get a lower value of the criterion function. The level of regularization is LMStep times the previous level. At the start of a new iteration, the level of regularization is computed as 1/LMStep times the value from the previous iteration. Default: 10. Assign a real value >1.
MaxBisections	Maximum number of bisections performed by the line search algorithm along the search direction (number of rotations of search vector for 'lm'). Used by 'gn', 'lm', 'gna' and 'grad' search methods ( <code>Algorithm.SearchMethod</code> property). Default: 10. Assign a positive integer value.
MaxFunEvals	The iterations are stopped if the number of calls to the model file exceeds this value. Default: Inf. Assign a positive integer value.
MinParChange	The smallest parameter update allowed per iteration. Default: 1e-16. Assign a positive, real value.

Property Name	Description
RelImprovement	<p>The iterations are stopped if the relative improvement of the criterion function is less than RelImprovement. Default: 0. Assign a positive real value.</p> <hr/> <p><b>Note</b> This does not apply when Algorithm.SearchMethod='lsqnonlin'.</p>
StepReduction	<p>(For line search algorithm) The suggested parameter update is reduced by the factor 'StepReduction' after each try until either 'MaxBisections' tries are completed or a lower value of the criterion function is obtained. Default: 2. Assign a positive, real value &gt;1.</p> <hr/> <p><b>Note</b> This does not apply when Algorithm.SearchMethod='lsqnonlin'.</p>

## idnlhw EstimationInfo Properties

The following table summarizes the fields of the EstimationInfo model properties. The read-only fields of the EstimationInfo structure store estimation settings and results.

Property Name	Description
Status	Shows whether the model parameters were estimated.
Method	Shows the estimation method.
LossFcn	Value of the loss function, equal to $\det(E' * E / N)$ , where E is the residual error matrix (one column for each output) and N is the total number of samples.

Property Name	Description
FPE	Value of Akaike's Final Prediction Error (see <code>fpe</code> ).
DataName	Name of the data from which the model is estimated.
DataLength	Length of the estimation data.
DataTs	Sampling interval of the estimation data.
DataDomain	'Time' means time domain data. 'Frequency' is not supported.
DataInterSample	Intersample behavior of the input estimation data used for interpolation: <ul style="list-style-type: none"> <li>'zoh' means zero-order-hold, or piecewise constant.</li> <li>'foh' means first-order-hold, or piecewise linear.</li> </ul>
WhyStop	Reason for terminating parameter estimation iterations.
UpdateNorm	Norm of the search vector (gn-vector) in the last iteration. Empty when 'lsqnonlin' is the search method.
LastImprovement	Criterion improvement in the last iteration, shown in %. Empty when 'lsqnonlin' is the search method.
Iterations	Number of iterations performed by the estimation algorithm.
Warning	Any warnings encountered during parameter estimation.
InitRandState	The value of <code>randn('state')</code> at the last randomization of the initial parameter vector.
EstimationTime	Duration of the estimation.

## Definition of idnlhw States

The Hammerstein-Weiner model structure consists of static nonlinearities around linear model as shown in the following figure.

The dynamic element of the model consists of the linear model alone. The states of the `idnlhw` model are the states of this linear component of the model. If this linear model is not a state-space structure (such as with single-input single-output cases), the states are defined as those of model `Mss` where `Mss = idss(Model.LinearModel)` and `Model` is the `idnlhw` object. The concept of states is useful for functions such as `sim`, `predict`, `compare`, `findstates`, `data2state`, `findop`, and `linearize`.

**See Also**`pem``predict(idnlhw)`

# idnlmodel

---

**Purpose** Superclass for nonlinear models

**Description** You do not use the `idnlmodel` class directly. Instead, `idnlmodel` defines the common properties and methods inherited by its subclasses, `idnlarx`, `idnlgrey`, and `idnlhw`.

**idnlmodel Properties** The following table lists the properties shared by the `idnlarx`, `idnlgrey`, and `idnlhw`, defined in terms of  $N_y$  outputs and  $N_u$  inputs.

Property Name	Description
InputName	Specifies the names of individual input channels. Default: {'u1'; 'u2'; ...; 'uNu'}.  Assignable values: <ul style="list-style-type: none"><li>• For single-output models, a string. For example, 'torque'.</li><li>• For multiple-output models, an <math>n_u</math>-by-1 cell array. For example: {'thrust'; 'aileron deflection'}</li></ul>
InputUnit	Specifies the units of each input channel. Default: ''.  Assignable values: <ul style="list-style-type: none"><li>• For single-output models, a string. For example, 'm/s'.</li><li>• For multiple-output models, an <math>n_u</math>-by-1 cell array.</li></ul>
Name	Name of the model, specified as a string.
NoiseVariance	Noise variance (covariance matrix) of the model innovations $e$ . Assignable value is an $n_y$ -by- $n_y$ matrix. Typically set automatically by the estimation algorithm.

Property Name	Description
OutputName	<p>Specifies the names of individual output channels. Default: {'y1'; 'y2'; ...; 'yNy'}.</p> <p>Assignable values:</p> <ul style="list-style-type: none"> <li>• For single-output models, a string. For example, 'torque'.</li> <li>• For multiple-output models, an ny-by-1 cell array. For example: { 'thrust'; 'aileron deflection' }</li> </ul>
OutputUnit	<p>Specifies the units of each output channel. Default: ''.</p> <p>Assignable values:</p> <ul style="list-style-type: none"> <li>• For single-output models, a string. For example, 'm/s'.</li> <li>• For multiple-output models, an ny-by-1 cell array.</li> </ul>
TimeUnit	<p>Unit of the sampling interval and time vector, specified as a string. Default: ''.</p>
TimeVariable	<p>Independent variable for the inputs, outputs, and—when available—internal states, specified as a string. Default: 't' (time).</p>
Ts	<p>Sampling interval with the unit specified by TimeUnit. Default: 1.</p> <p>Assignable values:</p> <ul style="list-style-type: none"> <li>• For discrete-time models, positive scalar value of the sampling interval.</li> <li>• For continuous-time models, 0.</li> </ul>

## See Also

`idnlarx`

`idnlgrey`

`idnlhw`

**Purpose**

Linear polynomial input-output model

**Syntax**

```
m = idpoly(A,B)
m = idpoly(A,B,C,D,F,NoiseVariance,Ts)
m = idpoly(A,B,C,D,F,NoiseVariance,Ts,'Property1',Value1,...
          'PropertyN',ValueN)
m = idpoly(mi)
```

**Description**

idpoly creates a model object containing parameters that describe the general multiple-input single-output model structure.

$$A(q)y(t) = \frac{B_1(q)}{F_1(q)}u_1(t-nk_1) + \dots + \frac{B_{nu}(q)}{F_{nu}(q)}u_{nu}(t-nk_{nu}) + \frac{C(q)}{D(q)}e(t)$$

A, B, C, D, and F specify the polynomial coefficients.

For single-input systems, these are all row vectors.

$$A = [1 \ a_1 \ a_2 \ \dots \ a_{na}]$$

consequently describes

$$A(q) = 1 + a_1q^{-1} + \dots + a_{na}q^{-na}$$

A, C, D, and F all start with 1, while B contains leading zeros to indicate the delays. See “What Are Black-Box Polynomial Models?”.

For multiple-input systems, B and F are matrices with one row for each input.

For time series, B and F are entered as empty matrices.

$$B = []; \quad F = [];$$

NoiseVariance is the variance of the white noise sequence  $e(t)$ , while Ts is the sampling interval.

Trailing arguments C, D, F, NoiseVariance, and Ts can be omitted, in which case they are taken as 1. (If B = [], then F is taken as [].) The property name/property value pairs can start directly after B.

Ts = 0 means that the model is a continuous-time one. Then the interpretation of the arguments is that

$$A = [1 \ 2 \ 3 \ 4]$$

corresponds to the polynomial  $s^3 + 2s^2 + 3s + 4$  in the Laplace variable  $s$ , and so on. For continuous-time systems, NoiseVariance indicates the level of the spectral density of the innovations. A sampled version of the model has the innovations variance NoiseVariance/Ts, where Ts is the sampling interval. The continuous-time model must have a white noise component in its disturbance description. See “Understanding Spectrum Normalization”.

For discrete-time models (Ts > 0), note the following: idpoly strips any trailing zeros from the polynomials when determining the orders. It also strips leading zeros from the B polynomial to determine the delays. Keep this in mind when you use idpoly and polydata to modify earlier estimates to serve as initial conditions for estimating new structures.

idpoly can also take any single-output idmodel or LTI object mi as an input argument. If an LTI system has an input group with name 'Noise', these inputs are interpreted as white noise with unit variance, and the noise model of the idpoly model is computed accordingly.

## Properties

- na, nb, nc, nd, nf, nk: The orders and delays of the polynomials. Integers or row vectors of integers.
- a, b, c, d, f: The polynomials, described by row vectors and matrices as detailed above.
- da, db, dc, dd, df: The estimated standard deviation of the polynomials. Cannot be set.
- 'InitialState': How to deal with the initial conditions that are required to compute the prediction of the output. Possible values are:

- 'Estimate': The necessary initial states are estimated from data as extra parameters.
- 'Backcast': The necessary initial states are estimated by a backcasting (backward filtering) process, described in Knudsen (1994).
- 'Zero': All initial states are taken as zero.
- 'Auto': An automatic choice among the above is made, guided by the data.

In addition, any `idpoly` object also has all the properties of `idmodel`. See `idmodel` properties and `Algorithm Properties`.

Note that you can set or retrieve all properties either with the `set` and `get` commands or by subscripts. Autofill applies to all properties and values, and these are case insensitive.

```
m.a=[1 -1.5 0.7];
set(m,'ini','b')
p = roots(m.a)
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`.

## Examples

To create a system of ARMAX, type

```
A = [1 -1.5 0.7];
B = [0 1 0.5];
C = [1 -1 0.2];
m0 = idpoly(A,B,C);
```

This gives a system with one delay ( $nk = 1$ ).

Create the continuous-time model

$$y(t) = \frac{1}{s(s+1)}u_1(t) + \frac{s+3}{s^2+2s+4}u_2(t) + e(t)$$

Sample it with  $T = 0.1$  and then simulate it without noise.

```
B=[0 1;1 3];  
F=[1 1 0;1 2 4]  
m = idpoly(1,B,1,1,F,1,0)  
md = c2d(m,0.1)  
y = sim(md,[u1 u2])
```

Note that the continuous-time model is automatically sampled to the sampling interval of the data, when simulated, so the above is also achieved by

```
u = iddata([], [u1 u2], 0.1)  
y = sim(m,u)
```

## idpoly Definition of States

The states of an `idpoly` model are defined as those corresponding to the model obtained by converting them to the state-space format using the `idss` command. For example, if you have an `idpoly` model defined by `m1 = idpoly([1 2 1],[2 2])`, then the initial states of this model correspond to those of `m2 = idss(m1)`. The concept of states is useful for functions such as `sim`, `predict`, `compare` and `findstates`.

`idss`

`sim`

"Extracting Parameter Values  
from Linear Models"

**Purpose**

Linear, low-order, continuous-time transfer function

**Syntax**

```
m = idproc(Type)
m = idproc(Type, 'Property1', Value1, ..., 'PropertyN', ValueN)
m = pem(Data, Type) % to directly estimate an idproc model
```

**Description**

The function `idproc` is used to create typical simple, continuous-time process models as `idproc` objects. The model has one output, but can have several inputs.

The character of the model is defined by the argument `Type`. This is an acronym made up of the following symbols:

- P: All 'Type' acronyms start with this letter.
- 0, 1, 2, or 3: This integer denotes the number of time constants (poles) to be modeled. Possible integrations (poles in the origin) are not included in this number.
- I: The letter I is included to mark that an integration is enforced (self-regulation process).
- D: The letter D is used to mark that the model contains a time delay (dead time).
- Z: The letter Z is used to mark an extra numerator term: a zero.
- U: The letter U is included to mark that underdamped modes (complex-valued poles) are permitted. If U is not included, all poles are restricted to be real.

This means, for example, that `Type = 'P1D'` corresponds to the model with transfer function

$$G(s) = \frac{K_p}{1 + sT_{p1}} e^{-T_d s}$$

while `Type = 'POI'` is

$$G(s) = \frac{K_p}{s}$$

and Type = 'P3UZ' is

$$G(s) = K_p \frac{1 + T_z s}{(1 + 2\zeta T_w s + (T_w s)^2)(1 + T_{p3} s)}$$

For multiple-input systems, Type is a cell array where each cell describes the character of the model from the corresponding input, like Type = {'P1D' 'P0I'} for the two-input model

$$Y(s) = \frac{K_p(1)}{1 + sT_{p1}(1)} e^{-T_d s} U_1(s) + \frac{K_p(2)}{s} U_2(s) \quad (2-1)$$

The parameters of the model are

- Kp: The static gain
- Tp1, Tp2, Tp3: The real-time constants (corresponding to poles in 1/Tp1, etc.)
- Tw and Zeta: The “resonance time constant” and the damping factor corresponding to a denominator factor  $(1 + 2\zeta T_w s + (T_w s)^2)$ . If underdamped modes are allowed, Tw and Zeta replace Tp1 and Tp2. A third real pole, Tp3, could still be included.
- Td: The time delay
- Tz: The numerator zero

These properties contain fields that give the values of the parameters, upper and lower bounds, and information whether they are locked to zero, have a fixed value, or are to be estimated. For multiple-input models, the number of entries in these fields equals the number of inputs. This is described in more detail below.

The idproc object is a child of idmodel. Therefore any idmodel properties can be set as property name/property value pairs in the

idproc command. They can also be set by the command `set`, or by `subassignment`, as in

```
m.InputName = {'speed', 'voltage'}
m.kp = 12
```

In the multiple-input case, models for specific inputs can be obtained by regular subreferencing.

```
m(ku)
```

There are also two properties, `DisturbanceModel` and `InitialState`, that can be used to expand the model. See below.

## idproc Properties

- **Type:** A string or a cell array of strings with as many elements as there are inputs. The string is an acronym made up of the characters P, Z, I, U, D and an integer between 0 and 3. The string must start with P, followed by the integer, while possible other characters can follow in any order. The integer is the number of poles (not counting a possible integration), Z means the inclusion of a numerator zero, D means inclusion of a time delay, while U marks that the modes can be underdamped (a pair of complex conjugated poles). I means that an integration in the model is enforced.
- **Kp, Tp1, Tp2, Tp3, Tw, Zeta, Tz, Td:** These are the parameters as explained above. Each of these is a structure with the following fields:
  - **value:** Numerical value of the parameter.
  - **max:** Maximum allowed value of the parameter when it is estimated.
  - **min:** Minimum allowed value of the parameter when it is estimated. For multiple-input models, these are row vectors.
  - **status:** Assumes one of 'Estimate', 'Fixed', or 'Zero'.  
 'Zero' means that the parameter is locked to zero and not included in the model. Assigning, for example, `Type = 'P1'` means that the status of `Tp2`, `Tp3`, `Tw`, and `Zeta` will be 'Zero'.

The value 'Fixed' means that the parameter is fixed to its value, and will not be estimated.

The value 'Estimate' means that the parameter value should be estimated.

For multiple-input modes, `status` is a cell array with one element for each input, while `value`, `max`, and `min` are row vectors.

- `DisturbanceModel`: Allows an additive disturbance model as in

$$y(t) = G(s)u(t) + \frac{C(s)}{D(s)}e(t) \quad (2-2)$$

where  $G(s)$  is a process model and  $e(t)$  is white noise, and  $C/D$  is a first- or second-order transfer function.

`DisturbanceModel` can assume the following values:

- 'None': This is the default. No disturbance model is included (that is,  $C=D=I$ ).
- 'arma1': The disturbance model is a first-order ARMA model (that is,  $C$  and  $D$  are first-order polynomials).
- 'arma2' or 'Estimate': The disturbance model is a second-order ARMA model (that is,  $C$  and  $D$  are second-order polynomials).

When a disturbance model has been estimated, the property `DisturbanceModel` is returned as a cell array, with the first entry being the status as just defined, and the second entry being the actual model, delivered as a continuous-time `idpoly` object.

- `InitialState`: Affects the parameterization of the initial values of the states of the model. It assumes the same values as for other models:
  - 'Zero': The initial states are fixed to zero.
  - 'Estimate': The initial states are treated as parameters to be estimated.

- 'Backcast': The initial state vector is adjusted, during the parameter estimation step, to a suitable value, but it is not stored.
- 'Auto': Makes a data-dependent choice among the values above.
- InputLevel: The offset level of the input signal(s). This is of particular importance for those input channels that contain an integration. InputLevel will then define the level from which the integration takes place, and that cannot be handled by estimating initial states. InputLevel has the same structure as the model parameters Kp, etc., and thus contains the following fields:
  - value: Numerical value of the parameter. For multiple-input models, this is a row vector.
  - max: Maximum allowed value of the parameter when it is estimated.
  - min: Minimum allowed value of the parameter when it is estimated. For multiple-input models, these are row vectors.
  - status: Assumes one of 'Estimate', 'Fixed', or 'Zero' with the same interpretations.

In addition, any idproc object also has all the properties of idmodel. See Algorithm Properties, EstimationInfo, and idmodel.

Note that all properties can be set or retrieved using either the set and get commands or subscripts. Autofill applies to all properties and values, and these are case insensitive. Also 'u' and 'y' are short for 'Input' and 'Output', respectively. You can also set all properties at estimation time as property name/property value pairs in the call to pem. An extended syntax allows direct setting of the fields of the parameter values, so that assigning a numerical value is automatically attributed to the value field, while a string is attributed to the status field.

```
m.kp = 10 % Alternative for m.Kp.value = 10
m.Tp1 = 'estimate' % Alternative for
                % m.Tp1.status = {'estimate'}
% Initializing the parameter Kp at the value 10
m = pem(Data, 'P1D', 'kp', 10)
```

```
% Fixing the parameter Kp to the value 10
m = pem(Data,'P1D','kp',10,'kp','fix')
% constraining Kp to lie between 3 and 4
m = pem(Data,'P2U','kp',{'max',4},'kp',{'min',3})
% For two inputs, estimate the offset level
% of the first input
m = pem(Data',{'P2I','P1D'},'ulevel',{'est','zer'})
% estimate a noise model
m = pem(Data,'P2U','dist','est')
% Use a fixed noisemodel,
% given by the continuous-time idpoly model noimod
m = pem(Data,'P2U','dist',{'fix',noimod})
% (minimum Kp for the second input)
m.kp.min(2) = 12
% fixing the gain for the second input.
m.kp.status{2} = 'fix'
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`.

## idproc Definition of States

The states of an `idproc` model are defined as those corresponding to the model obtained by converting them to the state-space format using the `idss` command. For example, if you have an `idproc` model defined by `m1 = idproc('P1D');`, then the initial states of this model correspond to those of `m2 = idss(m1)`. The concept of states is useful for functions such as `sim`, `predict`, `compare` and `findstates`.

## Examples

In this example, you estimate a process model with two real poles and dead time, including an ARMA1 model to capture disturbance dynamics:

```
m = pem(Data,'P2D','dist','arma1')
```

---

<b>Purpose</b>	Resample time-domain data by decimation or interpolation
<b>Syntax</b>	<pre>datar = idresamp(data,R) datar = idresamp(data,R,order,tol) [datar,res_fact] = idresamp(data,R,order,tol)</pre>
<b>Description</b>	<p><code>datar = idresamp(data,R)</code> resamples data on a new sample interval <code>R</code> and stores the resampled data as <code>datar</code>.</p> <p><code>datar = idresamp(data,R,order,tol)</code> filters the data by applying a filter of specified <code>order</code> before interpolation and decimation. Replaces <code>R</code> by a rational approximation that is accurate to a tolerance <code>tol</code>.</p> <p><code>[datar,res_fact] = idresamp(data,R,order,tol)</code> returns <code>res_fact</code>, which corresponds to the value of <code>R</code> approximated by a rational expression.</p>
<b>Input</b>	<p><code>data</code> Name of time-domain <code>iddata</code> object or a matrix of data. Can be input-output or time-series data.</p> <p>Data must be sampled at equal time intervals.</p> <p><code>R</code> Resampling factor, such that <math>R &gt; 1</math> results in decimation and <math>R &lt; 1</math> results in interpolation.</p> <p>Any positive number you specify is replaced by the rational approximation, <math>Q/P</math>.</p> <p><code>order</code> Order of the filters applied before interpolation and decimation.</p> <p>Default: 8</p> <p><code>tol</code> Tolerance of the rational approximation for the resampling factor <code>R</code>.</p>

# idresamp

---

Smaller tolerance might result in larger  $P$  and  $Q$  values, which produces more accurate answers at the expense of slower computation.

Default: 0.1

## Output

`datar`

Name of the resampled data variable. `datar` class matches the data class, as specified.

`res_fact`

Rational approximation for the specified resampling factor  $R$  and tolerance `tol`.

Any positive number you specify is replaced by the rational approximation,  $Q/P$ , where the data is interpolated by a factor  $P$  and then decimated by a factor  $Q$ .

`resample`

**Purpose**

State-space model

**Syntax**

```
m = idss(A,B,C,D)
m = idss(A,B,C,D,K,x0,Ts, 'Property1',Value1,...
    'PropertyN',ValueN)
mss = idss(m1)
```

**Description**

The function `idss` is used to construct state-space model structures with various parameterizations. It is a complement to `idgrey` and deals with parameterizations that do not require the user to write a special M-file. Instead it covers parameterizations that are either 'Free', that is, all parameters in the A, B, and C matrices can be adjusted freely, or 'Canonical', meaning that the matrices are parameterized as canonical forms. The parameterization can also be 'Structured', which means that certain elements in the state-space matrices are free to be adjusted, while others are fixed. This is explained below.

`Ts` is the sampling interval. `Ts = 0` means a continuous-time model. The default is `Ts = 1`.

The `idss` object `m` describes state-space models in innovations form of the following kind:

$$\dot{\tilde{x}}(t) = A(\theta)x(t) + B(\theta)u(t) + K(\theta)e(t)$$

$$x(0) = x_0(\theta)$$

$$y(t) = C(\theta)x(t) + D(\theta)u(t) + e(t)$$

Here  $\dot{\tilde{x}}(t)$  is the time derivative  $\dot{x}(t)$  for a continuous-time model and  $x(t + Ts)$  for a discrete-time model.

The model `m` will contain information both about the nominal/initial values of the A, B, C, D, K, and X0 matrices and about how these matrices are parameterized by the parameter vector `g` (to be estimated).

The nominal model is defined by `idss(A,B,C,D,K,X0)`. If K and X0 are omitted, they are taken as zero matrices of appropriate dimensions.

Defining an `idss` object from a given model,

```
mss = idss(m1)
```

constructs an `idss` model from any `idmodel` or LTI system `m1`.

If `m1` is an LTI system (`ss`, `tf`, or `zpk`) that has no `InputGroup` called `'Noise'`, the corresponding state-space matrices  $A$ ,  $B$ ,  $C$ ,  $D$  are used to define the `idss` object. The Kalman gain  $K$  is then set to zero.

If the LTI system has an `InputGroup` called `'Noise'`, these inputs are interpreted as white noise with a covariance matrix equal to the identity matrix. The corresponding Kalman gain and noise variance are then computed and entered into the `idss` model together with  $A$ ,  $B$ ,  $C$ , and  $D$ .

## Parameterizations

There are several different ways to define the parameterization of the state-space matrices. The parameterization determines which parameters can be adjusted to data by the parameter estimation routine `pem`.

- Free black-box parameterizations: This is the default situation and corresponds to letting all parameters in  $A$ ,  $B$ , and  $C$  be freely adjustable. You do this by setting the property `'SSParameterization' = 'Free'`. The parameterizations of  $D$ ,  $K$ , and  $X0$  are then determined by the following properties:
  - `'nk'`: A row vector of the same length as the number of inputs. The  $k$ th element is the delay from input channel number  $k$ . Thus  $nk = [0, \dots, 0]$  means that there is no delay from any of the inputs, and that consequently all elements of the  $D$  matrix should be estimated.  $nk = [1, \dots, 1]$  means that there is a delay of 1 from each input, so that the  $D$  matrix is fixed to be zero.
  - `'DisturbanceModel'`: This property affects the parameterization of  $K$  and can assume the following values:
    - `'Estimate'`: All elements of the  $K$  matrix are to be estimated.
    - `'None'`: All elements of  $K$  are fixed to zero.

- 'Fixed': All elements of  $K$  are fixed to their nominal/initial values.
- 'InitialState': Affects the parameterization of  $X0$  and can assume the following values:
  - 'Auto': An automatic choice of the following is made, depending on data (default).
  - 'Estimate': All elements of  $X0$  are to be estimated.
  - 'Zero': All elements of  $X0$  are fixed to zero.
  - 'Fixed': All elements of  $X0$  are fixed to their nominal/initial values.
  - 'Backcast': The vector  $X0$  is adjusted, during the parameter estimation step, to a suitable value, but it is not stored as an estimation result.
- Canonical black-box parameterizations: You do this by setting the property 'SSParameterization' = 'Canonical'. The matrices  $A$ ,  $B$ , and  $C$  are then parameterized as an observer canonical form, which means that  $n_y$  (number of output channels) rows of  $A$  are fully parameterized while the others contain 0's and 1's in a certain pattern. The  $C$  matrix is built up of 0's and 1's while the  $B$  matrix is fully parameterized. See Equation (A.16) in Ljung (1999) for details. The exact form of the parameterization is affected by the property 'CanonicalIndices'. The default value 'Auto' is a good choice. The parameterization of the  $D$ ,  $K$ , and  $X0$  matrices in this case is determined by the properties 'nk', 'DisturbanceModel', and 'InitialState'.
- Arbitrarily structured parameterizations: The general case, where arbitrary elements of the state-space matrices are fixed and others can be freely adjusted, corresponds to the case 'SSParameterization' = 'Structured'. The parameterization is determined by the idss properties  $As$ ,  $Bs$ ,  $Cs$ ,  $Ds$ ,  $Ks$ , and  $X0s$ . These are the *structure matrices* that are “shadows” of the state-space matrices, so that an element in these matrices that is equal to NaN indicates a freely adjustable parameter, while a numerical value

in these matrices indicates that the corresponding system matrix element is fixed (nonadjustable) to this value.

## idss Properties

- **SSParameterization** has the following possible values:
  - 'Free': Means that all parameters in  $A$ ,  $B$ , and  $C$  are freely adjustable, and the parameterizations of  $D$ ,  $K$ , and  $X0$  depend on the properties 'nk', 'DisturbanceModel', and 'InitialState'.
  - 'Canonical': Means that  $A$  and  $C$  are parameterized as an observer canonical form. The details of this parameterization depend on the property 'CanonicalIndices'. The  $B$  matrix is always fully parameterized, and the parameterizations of  $D$ ,  $K$ , and  $X0$  depend on the properties 'nk', 'DisturbanceModel', and 'InitialState'.
  - 'Structured': Means that the parameterization is determined by the properties (the structure matrices) 'As', 'Bs', 'Cs', 'Ds', 'Ks', and 'X0s'. A NaN in any position in these matrices denotes a freely adjustable parameter, and a numeric value denotes a fixed and nonadjustable parameter.
- **nk**: A row vector with as many entries as the number of input channels. The entry number  $k$  denotes the time delay from input number  $k$  to  $y(t)$ . This property is relevant only for 'Free' and 'Canonical' parameterizations. If any delay is larger than 1, the structure of the  $A$ ,  $B$ , and  $C$  matrices will accommodate this delay, at the price of a higher-order model.
- **DisturbanceModel** has the following possible values:
  - 'Estimate': Means that the  $K$  matrix is fully parameterized.
  - 'None': Means that the  $K$  matrix is fixed to zero. This gives a so-called output-error model, since the model output depends on past inputs only.
  - 'Fixed': Means that the  $K$  matrix is fixed to the current nominal values.
- **InitialState** has the following possible values:

- 'Estimate': Means that  $X0$  is fully parameterized.
  - 'Zero': Means that  $X0$  is fixed to zero.
  - 'Fixed': Means that  $X0$  is fixed to the current nominal value.
  - 'Backcast': The value of  $X0$  is estimated by the identification routines as the best fit to data, but it is not stored.
  - 'Auto': Gives an automatic and data-dependent choice among 'Estimate', 'Zero', and 'Backcast'.
- A, B, C, D, K, and X0: The state-space matrices that can be set and retrieved at any time. These contain both fixed values and estimated/nominal values.
  - dA, dB, dC, dD, dK, and dX0: The estimated standard deviations of the state-space matrices. These cannot be set, only retrieved. Note that these are not defined for an idss model with 'Free' SSPparameterization. You can then convert the parameterization to 'Canonical' and study the uncertainties of the matrix elements in that form.
  - As, Bs, Cs, Ds, Ks, and X0s: These are the structure matrices that have the same sizes as A, B, C, etc., and show the freely adjustable parameters as NaNs in the corresponding position. These properties are used to define the model structure for 'SSPparameterization' = 'Structured'. They are always defined, however, and can be studied also for the other parameterizations.
  - CanonicalIndices: Determines the details of the canonical parameterization. It is a row vector of integers with as many entries as there are outputs. They sum up to the system order. This is the so-called pseudocanonical multiindex with an exact definition, for example, on page 132 in Ljung (1999). A good default choice is 'Auto'. This property is relevant only for the canonical parameterization case. Note however, that for 'Free' parameterizations, the estimation algorithms also store a canonically parameterized model to handle the model uncertainty.

In addition to these properties, `idss` objects also have all the properties of the `idmodel` object. See `idmodel` properties, `Algorithm Properties`, and `EstimationInfo`.

Note that all properties can be set and retrieved either by the `set` and `get` commands or by subscripts. Autofill applies to all properties and values, and these are case insensitive.

```
m.ss='can'  
set(m,'ini','z')  
p = eig(m.a)
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`.

## Examples

Define a continuous-time model structure corresponding to

$$\dot{x} = \begin{bmatrix} \theta_1 & 0 \\ 0 & \theta_2 \end{bmatrix} x + \begin{bmatrix} \theta_3 \\ \theta_4 \end{bmatrix} u$$

$$y = \begin{bmatrix} 1 & 1 \end{bmatrix} x + e$$

with initial values

$$\theta = \begin{bmatrix} -0.2 \\ -0.3 \\ 2 \\ 4 \end{bmatrix}$$

and estimate the free parameters.

```
A = [-0.2, 0; 0, -0.3]; B = [2;4]; C=[1, 1]; D = 0  
m0 = idss(A,B,C,D);  
m0.As = [NaN,0;0,NaN];  
m0.Bs = [NaN;NaN];  
m0.Cs = [1,1];
```

```
m0.Ts = 0;  
m = pem(z,m0);
```

Estimate a model in free parameterization. Convert it to continuous time, then convert it to canonical form and continue to fit this model to data.

```
m1 = n4sid(data,3);  
m1 = d2c(m1);  
m1.ss = 'can';  
m = pem(data,m1);
```

All of this can be done at once by

```
m = pem(data,3,'ss','can','ts',0)
```

# ifft

---

**Purpose** Transform `iddata` objects from frequency to time domain

**Syntax** `dat = ifft(Datf)`

**Description** `ifft` transforms a frequency-domain `iddata` object to the time domain. It requires the frequencies on `Datf` to be equally spaced from frequency 0 to the Nyquist frequency. This means that if there are  $N$  frequencies in `Datf` and the time sampling interval is  $T_s$ , then

`Datf.Frequency = [0:df:F]`, where  $F$  is  $\pi/T_s$  if  $N$  is odd and  $F = \pi/T_s \cdot (1 - 1/N)$  if  $N$  is even.

**See Also** `iddata`  
`fft`

**Purpose**

Plot impulse response with confidence interval

**Syntax**

```
impulse(m)
impulse(data)
impulse(m, 'sd', sd, Time)
impulse(m, 'sd', sd, Time, 'fill')
impulse(data, 'sd', sd, 'pw', na, Time)
impulse(m1, m2, ..., dat1, ..., mN, Time, 'sd', sd)
impulse(m1, 'PlotStyle1', m2, 'PlotStyle2', ..., dat1, 'PlotStylek', ...,
mN, 'PlotStyleN', Time, 'sd', sd)
[y, t, ysd] = impulse(m)
mod = impulse(data)
```

**Description**

impulse can be applied both to idmodels and to iddata sets, as well as to any mixture.

For a discrete-time idmodel *m*, the impulse response *y* and, when required, its estimated standard deviation *ysd*, are computed using `sim`. When called with output arguments, *y*, *ysd*, and the time vector *t* are returned. When `impulse` is called without output arguments, a plot of the impulse response is shown. If *sd* is given a value larger than zero, a confidence region around zero is drawn. It corresponds to the confidence of *sd* standard deviations. In the plots, the impulse is inversely scaled with the sampling interval so that it has the same energy regardless of the sampling interval.

Adding an argument `'fill'` among the input arguments gives an uncertainty region marked by a filled area rather than by dash-dotted lines.

**Setting the Time Interval**

You can specify the start time *T1* and the end time *T2* using `Time= [T1 T2]`. If *T1* is not given, it is set to  $-T2/4$ . The negative time lags (the impulse is always assumed to occur at time 0) show possible feedback effects in the data when the impulse is estimated directly from data. If `Time` is not specified, a default value is used.

## Estimating the Impulse Response from Data

For an `iddata` object, `impulse(data)` estimates a high-order, noncausal FIR model after first having prefiltered the data so that the input is “as white as possible.” The impulse response of this FIR model and, when asked for, its confidence region, are then plotted. Note that it is not always possible to deliver the demanded time interval when the response is estimated. A warning is then issued. When called with an output argument, `impulse`, in the `iddata` case, returns this FIR model, stored as an `idarx` model. The order of the prewhitening filter can be specified by the property name/property value pair `'pw'/na`. The default value is `na = 10`.

## Several Models/Data Sets

Any number and any mixture of models and data sets can be used as input arguments. The responses are plotted with each input/output channel (as defined by the model and data set `InputName` and `OutputName` properties) as a separate plot. Colors, line styles, and marks can be defined by `PlotStyle` values. These are the same as for the regular `plot` command, as in

```
impulse(m1, 'b-*', m2, 'y--', m3, 'g')
```

## Noise Channels

The noise input channels in `m` are treated as follows:

Consider a model `m` with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$y = Gu + He$$
$$\text{cov}(e) = \Lambda = LL'$$

where  $L$  is a lower triangular matrix. Note that `m.NoiseVariance =  $\Lambda$` . The model can also be described with unit variance, using a normalized noise source  $v$ :

$$y = Gu + HLv$$

$$\text{cov}(v) = I$$

- `impulse(m)` plots the impulse response of the transfer function  $G$ .
- `impulse(m('n'))` plots the impulse response of the transfer function  $H$  ( $n_y$  inputs and  $n_y$  outputs). The input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- If `m` is a time series, that is  $nu = 0$ , `impulse(m)`, plots the impulse response of the transfer function  $H$ .
- `impulse(noiseconv(m))` plots the impulse response of the transfer function  $[G H]$  ( $nu+n_y$  inputs and  $n_y$  outputs). The noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- `impulse(noiseconv(m,'norm'))` plots the impulse response of the transfer function  $[G HL]$  ( $nu+n_y$  inputs and  $n_y$  outputs). The noise input channels have names `v@yname`, where `yname` is the name of the corresponding output.

## Arguments

If `impulse` is called with a single `idmodel` `m`, the output argument `y` is a 3-D array of dimension  $N_t$ -by- $n_y$ -by- $n_u$ . Here  $N_t$  is the length of the time vector `t`,  $n_y$  is the number of output channels, and  $n_u$  is the number of input channels. Thus `y(:,ky,ku)` is the response in output `ky` to an impulse in the `kuth` input channel.

`ysd` has the same dimensions as `y` and contains the standard deviations of `y`.

If `impulse` is called with an output argument and a single data set in the input arguments, the output is returned as an `idarx` model `mod` containing the high-order FIR model and its uncertainty. By calling `impulse` with `mod`, the responses can be displayed and returned without your having to redo the estimation.

## Examples

Suppose that you have a two-input and three-output data set. To estimate and plot the impulse response for all I/O pairs, including

# impulse

---

the confidence region corresponding to 3 standard deviations, use the following command:

```
impulse(data,'sd',3) % Response from input 3 to output 2
```

To take a closer look at the subsystems, do the following:

```
mod = impulse(data)
impulse(mod(2,3),'sd',3)
```

cra  
step

---

<b>Purpose</b>	Set or randomize initial parameter values
<b>Syntax</b>	<pre>m = init(m0) m = init(m0,R,pars,sp)</pre>
<b>Description</b>	<p>This function randomizes initial parameter estimates for model structures <code>m0</code> for any <code>idmodel</code>, <code>idnlarx</code>, and <code>idnlhw</code> model object. It does not support <code>idnlgrey</code> models. <code>m</code> is the same model structure as <code>m0</code>, but with a different nominal parameter vector. This vector is used as the initial estimate by <code>pem</code>.</p> <p>The parameters are randomized around <code>pars</code> with variances given by the row vector <code>R</code>. Parameter number <math>k</math> is randomized as <math>\text{pars}(k) + e \cdot \sqrt{R(k)}</math>, where <math>e</math> is a normal random variable with zero mean and a variance of 1. The default value of <code>R</code> is all ones, and the default value of <code>pars</code> is the nominal parameter vector in <code>m0</code>.</p> <p>Only models that give stable predictors are accepted. If <code>sp = 'b'</code>, only models that are both stable and have stable predictors are accepted. <code>sp = 's'</code> requires stability only of the model, and <code>sp = 'p'</code> requires stability only of the predictor. <code>sp = 'p'</code> is the default.</p> <p>Sufficiently free parameterizations can be stabilized by direct means without any random search. To just stabilize such an initial model, set <code>R = 0</code>. With <code>R &gt; 0</code>, randomization is also done.</p> <p>For model structures where a random search is necessary to find a stable model/predictor, a maximum of 100 trials is made by <code>init</code>. It can be difficult to find a stable predictor for high-order systems by trial and error.</p>

# isreal

---

**Purpose** Determine whether model parameters or data values are real

**Syntax** `isreal(Data)`  
`isreal(Model)`

**Description** Data is an `iddata` set and Model is any `idmodel`. The `isreal` function returns 1 if all parameters of the model are real and if all signals of the data set are real.

**See Also** `realdata`

**Purpose** Estimate AR model using instrumental variable method returning idpoly object

**Syntax** `m = ivar(y,na)`  
`m = ivar(y,na,nc,maxsize)`

**Description** The parameters of an AR model structure

$$A(q)y(t) = v(t)$$

are estimated using the instrumental variable method.  $y$  is the signal to be modeled, entered as an iddata object (outputs only).  $na$  is the order of the  $A$  polynomial (the number of  $A$  parameters). The resulting estimate is returned as an idpoly model  $m$ . The routine is for scalar time-domain signals only.

In the above model,  $v(t)$  is an arbitrary process, assumed to be a moving average process of order  $nc$ , possibly time varying. (Default is  $nc = na$ .) Instruments are chosen as appropriately filtered outputs, delayed  $nc$  steps.

The optional argument `maxsize` is explained under Algorithm Properties.

**Examples** Compare spectra for sinusoids in noise, estimated by the IV method and by the forward-backward least squares method.

```
y = iddata(sin([1:500]'*1.2) + sin([1:500]'*1.5) + ...
           0.2*randn(500,1),[]);
miv = ivar(y,4);
mls = ar(y,4);
bode(miv,mls)
```

**References** Stoica, P., et al., *Optimal Instrumental variable estimates of the AR-parameters of an ARMA process*, IEEE Trans. Autom. Control, Vol. AC-30, 1985, pp. 1066-1074.

etfe

idpoly

pem

spa

step

**Purpose**

Loss functions for sets of ARX model structures

**Syntax**

```
v = ivstruc(ze,zv,NN)
v = ivstruc(ze,zv,NN,p,maxsize)
```

**Description**

NN is a matrix that defines a number of different structures of the ARX type. Each row of NN is of the form

$$nn = [na \ nb \ nk]$$

with the same interpretation as described for `arx`. See `struc` for easy generation of typical NN matrices for single-input systems.

`ze` and `zv` are `iddata` objects containing output-input data. Only time-domain data is supported. Models for each model structure defined in NN are estimated using the instrumental variable (IV) method on data set `ze`. The estimated models are simulated using the inputs from data set `zv`. The normalized quadratic fit between the simulated output and the measured output in `zv` is formed and returned in `v`. The rows below the first row in `v` are the transpose of NN, and the last row contains the logarithms of the condition numbers of the IV matrix

$$\sum \zeta(t) \Phi^T(t)$$

A large condition number indicates that the structure is of unnecessarily high order (see Ljung, L. *System Identification: Theory for the User*, Upper Saddle River, NJ, Prentice-Hal PTR, 1999, p. 498).

The information in `v` is best analyzed using `selstruc`.

If `p` is equal to zero, the computation of condition numbers is suppressed. For the use of `maxsize`, see [Algorithm Properties](#).

The routine is for single-output systems only.

---

**Note** The IV method used does not guarantee that the models obtained are stable. The output-error fit calculated in `v` can then be misleading.

---

# ivstruc

---

## Examples

Compare the effect of different orders and delays, using the same data set for both the estimation and validation.

```
v = ivstruc(z,z, struc(1:3,1:2,2:4));  
nn = selstruc(v)  
m = iv4(z,nn);
```

## Algorithm

A maximum-order ARX model is computed using the least squares method. Instruments are generated by filtering the input(s) through this model. The models are subsequently obtained by operating on submatrices in the corresponding large IV matrix.

<b>Purpose</b>	Estimate parameters of ARX model using instrumental variable method with arbitrary instruments returning <code>idpoly</code> or <code>idarx</code> object
<b>Syntax</b>	<code>m = ivx(data,orders,x)</code> <code>m = ivx(data,orders,x,maxsize)</code>
<b>Description</b>	<p><code>ivx</code> is a routine analogous to the <code>iv4</code> routine, except that you can use arbitrary instruments. These are contained in the matrix <code>x</code>. Make this the same size as the output, <code>data.y</code>. In particular, if <code>data</code> contains several experiments, <code>x</code> must be a cell array with one matrix/vector for each experiment. The instruments used are then analogous to the regression vector itself, except that <code>y</code> is replaced by <code>x</code>.</p> <p>Note that <code>ivx</code> does not return any estimated covariance matrix for <code>m</code>, since that requires additional information. <code>m</code> is returned as an <code>idpoly</code> object for single-output systems and as an <code>idarx</code> object for multiple-output systems.</p> <p>Use <code>iv4</code> as the basic IV routine for ARX model structures. The main interest in <code>ivx</code> lies in its use for nonstandard situations, for example, when there is feedback present in the data, or when other instruments need to be tried out. Note that there is also an IV version that automatically generates instruments from certain filters you define (type <code>help iv</code>).</p>

<b>Purpose</b>	Estimate ARX model using four-stage instrumental variable method returning <code>idpoly</code> or <code>idarx</code> object
<b>Syntax</b>	<pre>m = iv4(data,orders) m = iv4(data,'na',na,'nb',nb,'nk',nk) m= iv4(data,orders,'Property1',Value1,...,'PropertyN',ValueN)</pre>
<b>Description</b>	This function is an alternative to <code>arx</code> and the use of the arguments is entirely analogous to the <code>arx</code> function. The main difference is that the procedure is not sensitive to the color of the noise term $e(t)$ in the model equation.
<b>Examples</b>	<p>Here is an example of a two-input, one-output system with different delays on the inputs <math>u_1</math> and <math>u_2</math>.</p> <pre>z = iddata(y, [u1 u2]); nb = [2 2]; nk = [0 2]; m= iv4(z,[2 nb nk]);</pre>
<b>Algorithm</b>	<p>The first stage uses the <code>arx</code> function. The resulting model generates the instruments for a second-stage IV estimate. The residuals obtained from this model are modeled as a high-order AR model. At the fourth stage, the input-output data is filtered through this AR model and then subjected to the IV function with the same instrument filters as in the second stage.</p> <p>For the multiple-output case, optimal instruments are obtained only if the noise sources at the different outputs have the same color. The estimates obtained with the routine are reasonably accurate, however, even in other cases.</p>

<b>Purpose</b>	Specify to estimate nonlinear ARX model that is linear in (nonlinear) custom regressors
<b>Syntax</b>	<pre>lin=linear lin=linear('Parameters',Par)</pre>
<b>Description</b>	<p><code>linear</code> is an object that specifies that the nonlinear ARX model is linear in custom (nonlinear) regressors. You define custom regressors using <code>customreg</code>.</p> <p><code>lin=linear</code> instantiates the <code>linear</code> object.</p> <p><code>lin=linear('Parameters',Par)</code> instantiates the <code>linear</code> object and specifies optional values in the <code>Par</code> structure. For more information about this structure, see “linear Properties” on page 2-259.</p>
<b>Remarks</b>	<p><code>linear</code> is a linear (affine) function <math>y = F(x)</math>, defined as follows:</p> $F(x) = xL + d$ <p><math>y</math> is scalar, and <math>x</math> is a 1-by-<math>m</math> vector.</p> <p>Use <code>evaluate(lin,x)</code> to compute the value of the function defined by the <code>linear</code> object <code>lin</code> at <math>x</math>.</p>
<b>linear Properties</b>	<p>You can include property-value pairs in the constructor to specify the object.</p> <p>After creating the object, you can use <code>get</code> or dot notation to access the object property values. For example:</p> <pre>% List Parameters values get(lin) % Get value of Parameters property lin.Parameters</pre>

# linear

---

Property Name	Description
Parameters	Structure containing the following fields: <ul style="list-style-type: none"><li>• <code>LinearCoef</code>: <math>m</math>-by-1 vector <math>L</math>.</li><li>• <code>OutputOffset</code>: Scalar <math>d</math>.</li></ul>

## Examples

To specify that the nonlinear ARX model is linear in custom regressors, first specify one or more `customreg` objects. Then, include the `linear` object in the `nlarx` estimator command.

For example, to estimate a nonlinear ARX model linear in the custom regressors, use the following syntax:

```
m=nlarx(Data,Orders,linear,'custom',{ 'y(t-1)*u(t-2) '});
```

---

**Note** In this example, the custom regressor is a nonlinear function of input and output variables.

---

## See Also

`customreg`  
`nlarx`

**Purpose** Linearize nonlinear ARX model

**Syntax** `SYS = linearize(NLSYS,U0,X0)`

**Description** `SYS = linearize(NLSYS,U0,X0)` linearizes a nonlinear ARX model about the specified operating point `U0` and `X0`. The linearization is based on tangent linearization. For more information about the definition of states for `idnlarx` models, see “Definition of `idnlarx` States” on page 2-185.

**Input**

- `NLSYS`: `idnlarx` model.
- `U0`: Matrix containing the constant input values for the model.
- `X0`: Model state values. The states of a nonlinear ARX model are defined by the time-delayed samples of input and output variables. For more information about the states of nonlinear ARX models, see the `getDelayInfo` reference page.

---

**Note** To estimate `U0` and `X0` from operating point specifications, use the `findop(idnlarx)` command.

---

**Output**

- `SYS` is an `idss` model.

When the Control System Toolbox product is installed, `SYS` is an LTI object.

**Algorithm** The following equations govern the dynamics of an `idnlarx` model:

$$X(t+1) = AX(t) + B\tilde{u}(t)$$

$$y(t) = f(X, u)$$

where  $X(t)$  is a state vector,  $u(t)$  is the input, and  $y(t)$  is the output.  $A$  and  $B$  are constant matrices.  $\tilde{u}(t)$  is  $[y(t), u(t)]^T$ .

The output at the operating point is given by

# linearize(idnlarx)

---

$$y^* = f(X^*, u^*)$$

where  $X^*$  and  $u^*$  are the state vector and input at the operating point.

The linear approximation of the model response is as follows:

$$\Delta X(t+1) = (A + B_1 f_X) \Delta X(t) + (B_1 f_u + B_2) \Delta u(t)$$

$$\Delta y(t) = f_X \Delta X(t) + f_u \Delta u(t)$$

where

- $\Delta X(t) = X(t) - X^*(t)$
- $\Delta u(t) = u(t) - u^*(t)$
- $\Delta y(t) = y(t) - y^*(t)$
- $B\tilde{U} = [B_1, B_2] \begin{bmatrix} Y \\ U \end{bmatrix} = B_1 Y + B_2 U$
- $f_X = \left. \frac{\partial}{\partial X} f(X, U) \right|_{X^*, U^*}$
- $f_U = \left. \frac{\partial}{\partial U} f(X, U) \right|_{X^*, U^*}$

---

**Note** For linear approximations over larger input ranges, use `linapp`. For more information, see the `linapp` reference page.

---

## Example

In this example, you linearize a nonlinear ARX model around an operating point corresponding to a simulation snapshot at a specific time. Create an `idnlarx` model estimated using sample data.

**1** Load sample data:

```
load iddata2
```

**2** Estimate idnlarx model from sample data:

```
nlsys = nlarx(z2,[4 3 10],'tree','custom',...  
{'sin(y1(t-2)*u1(t))+y1(t-2)*u1(t)+u1(t).*u1(t-13)',...  
'y1(t-5)*y1(t-5)*y1(t-1)'},'nlr',[1:5, 7 9]);
```

**3** Plot the response of the model for a step input:

```
step(nlsys, 20)
```

The model step response is a steady-state value of 0.8383 at  $T = 20$  seconds.

**4** Compute the operating point corresponding to  $T = 20$ .

```
stepinput = iddata([], [zeros(10,1); ones(200,1)], ...  
                    nlsys.Ts);  
% Compute operating point.  
[x,u] = findop(nlsys,'snapshot',20,stepinput);
```

## linearize(idnlarx)

---

- 5 Linearize the model about the operating point corresponding to the model snapshot at  $T=20$ .

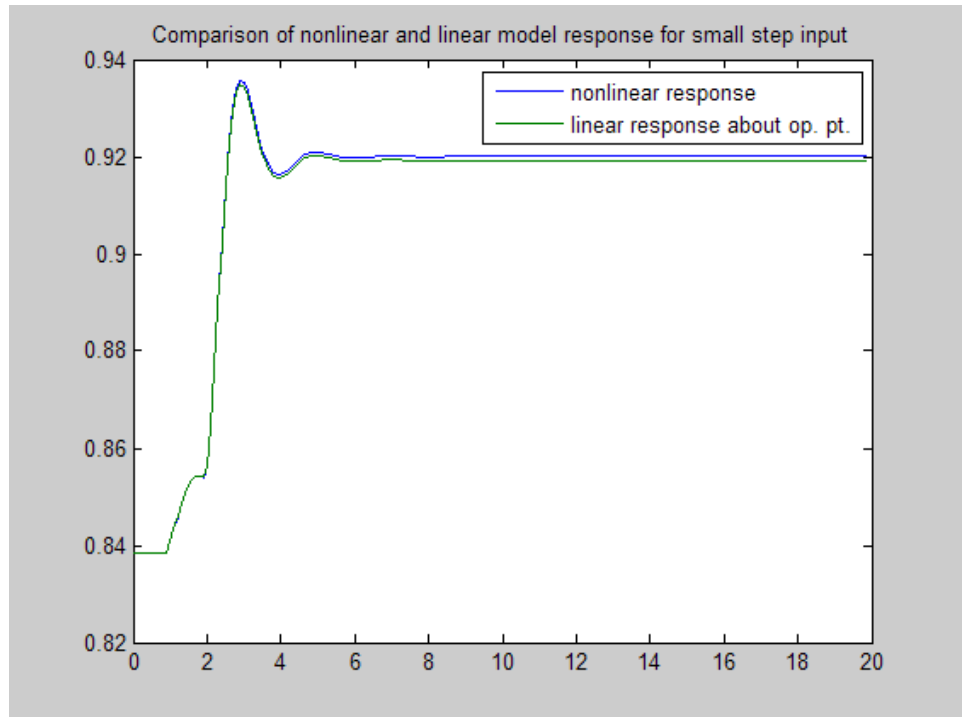

```
sys = linearize(nlsys,u,x)
```

- 6 To validate the linear model, apply a small perturbation `delta_u` to the steady-state input of the nonlinear model `nlsys`. If the linear approximation is accurate, the following should match:
- The response of the nonlinear model `y_nl` to an input that is the sum of the equilibrium level and the perturbation `delta_u`.
  - The sum of the response of the linear model to a perturbation input `delta_u` and the output equilibrium level.

the response of the linear model to a perturbation input that is added to the equilibrium level.

```
% Generate a 200-sample step signal with amplitude 0.1
% This is the perturbation signal.
delta_u = [zeros(10,1); 0.1*ones(190,1)];
%
% For a nonlinear system with a steady-state input of 1
% and a steady-state output of 0.8383,
% compute the steady-state response
% y_nl to the perturbed input u_nl. Use equilibrium state
% values x as initial conditions (see Step 4).
u_nl = 1 + delta_u;
y_nl = sim(nlsys,u_nl,x);
%
% Compute the response of the linear model to a perturbation input
% and add it to the output equilibrium level:
y_lin = 0.8383 + lsim(sys,delta_u);
%
% Compare the response of nonlinear and linear models:
time = [0:0.1:19.9]';
```

```
plot(time,y_nl,time,y_lin)
legend('Nonlinear response',...
      'Linear response about op. pt.')
title(['Comparison of nonlinear and linear model response'...
      ' for small step input'])
```

The linearized model response tracks the nonlinear model output.

# linearize(idnlhw)

---

**Purpose** Linearize Hammerstein-Wiener model

**Syntax**  
`SYS = linearize(NLSYS,U0)`  
`SYS = linearize(NLSYS,U0,X0)`

**Description** `SYS = linearize(NLSYS,U0)` linearizes a Hammerstein-Wiener model around the equilibrium operating point. When using this syntax, equilibrium state values for the linearization are calculated automatically using `U0`.

`SYS = linearize(NLSYS,U0,X0)` linearizes the `idnlhw` model `NLSYS` around the operating point specified by the input `U0` and state values `X0`. In this usage, `X0` need not contain equilibrium state values. For more information about the definition of states for `idnlhw` models, see “Definition of `idnlhw` States” on page 2-218.

The output is a linear model that is the best linear approximation for inputs that vary in a small neighborhood of a constant input  $u(t) = U$ . The linearization is based on tangent linearization.

**Input**

- `NLSYS`: `idnlhw` model.
- `U0`: Matrix containing the constant input values for the model.
- `X0`: Operating point state values for the model.

---

**Note** To estimate `U0` and `X0` from operating point specifications, use the `findop(idnlhw)` command.

---

**Output**

- `SYS` is an `idss` model.

When the Control System Toolbox product is installed, `SYS` is an LTI object.

**Algorithm** The `idnlhw` model structure represents a nonlinear system using a linear system connected in series with one or two static nonlinear

systems. For example, you can use a static nonlinearity to simulate saturation or dead-zone behavior. The following figure shows the nonlinear system as a linear system that is modified by static input and output nonlinearities, where function  $f$  represents the input nonlinearity,  $g$  represents the output nonlinearity, and  $[A,B,C,D]$  represents a state-space parameterization of the linear model.

The following equations govern the dynamics of an idnlhw model:

$$v(t) = f(u(t))$$

$$X(t+1) = AX(t) + Bv(t)$$

$$w(t) = CX(t) + Dv(t)$$

$$y(t) = g(w(t))$$

where

- $u$  is the input signal
- $v$  and  $w$  are intermediate signals (outputs of the input nonlinearity and linear model respectively)
- $y$  is the model output

The linear approximation of the Hammerstein-Weiner model around an operating point  $(X^*, u^*)$  is as follows:

$$\Delta X(t+1) = A\Delta X(t) + Bf_u\Delta u(t)$$

$$\Delta y(t) \approx g_w C\Delta X(t) + g_w Df_u\Delta u(t)$$

where

- $\Delta X(t) = X(t) - X^*(t)$
- $\Delta u(t) = u(t) - u^*(t)$

# linearize(idnlhw)

---

- $\Delta y(t) = y(t) - y^*(t)$

- $f_u = \left. \frac{\partial}{\partial u} f(u) \right|_{u=u^*}$

- $g_w = \left. \frac{\partial}{\partial w} g(w) \right|_{w=w^*}$

where  $y^*$  is the output of the model corresponding to input  $u^*$  and state vector  $X^*$ ,  $v^* = f(u^*)$ , and  $w^*$  is the response of the linear model for input  $v^*$  and state  $X^*$ .

---

**Note** For linear approximations over larger input ranges, use `linapp`. For more information, see the `linapp` reference page.

---

## Examples

In this example you linearize a Hammerstein-Wiener model with two inputs at an equilibrium point, and compare the linearized model response to the original model response.

**1** Load the sample data to create `iddata` object `z`.

```
load iddata2
load iddata3
z2.Ts = z3.Ts;
z = [z2(1:300),z3]; % Estimation data
```

**2** Estimate an `idnlhw` model using a combination of `pwlinear`, `poly1d`, `sigmoidnet` and `customnet` nonlinearities.

```
orders = [2 2 3 4 1 5; 2 5 1 2 5 2];
nlsys = nlhw(z,orders,[pwlinear;poly1d],...
            [sigmoidnet;customnet(@gaussunit)]);
```

**3** Linearize the model at an equilibrium operating point corresponding to input levels of 10 and 5 respectively. To do this you first compute

the operating point using `findop`, then linearize the model around the computed input and state values.

```
[x,u_s,report] = findop(nlsys,'steady',[10,5]);  
sys = linearize(nlsys,u_s,x);  
% sys is a state-space model
```

**4** To validate the linear model, apply a small perturbation `delta_u` to the steady-state input of the nonlinear model `nlsys`. If the linear approximation is accurate, the following should match:

- The response of the nonlinear model `y_nl` to an input that is the sum of the equilibrium level and the perturbation `delta_u`.
- The sum of the response of the linear model to a perturbation input `delta_u` and the output equilibrium level.

```
% Generate a 300-sample step signal with amplitude 0.1  
% This is the perturbation input signal.  
delta_u = [zeros(20,2); 0.1*ones(280,2)];  
%  
% Compute the response of the linear model delta_y_lin  
% to the perturbed input signal delta_u:  
delta_y_lin = lsim(sys,delta_u);  
%  
% For the nonlinear system with a steady-state input u_s,  
% compute the steady-state output y_s from the  
% SignalLevels field of the findop report (see Step 3):  
y_s = report.SignalLevels.Output;  
%  
% Compute the perturbed input to the nonlinear system  
% as the sum of the steady-state input u_s and  
% the perturbation signal delta_u:  
u_nl = bsxfun(@plus,delta_u,u_s);  
  
% Compute the steady-state response of the  
% nonlinear system y_nl to the perturbed input u_nl.  
% Use equilibrium state values x as initial conditions.
```

# linearize(idnlhw)

```
y_nl = sim(nlsys,u_nl,x);  
%  
% Compare the response of nonlinear and linear models:  
time = (0:299)';  
subplot(211)  
plot(time,y_nl(:,1),time,delta_y_lin(:,1)+y_s(1),'.')  
legend('Nonlinear response',...  
       'Linear response about op. pt.')  
title('Comparison of signal values for output 1')  
  
subplot(212)  
plot(time,y_nl(:,2),time,delta_y_lin(:,2)+y_s(2),'.')  
legend('Nonlinear response',...  
       'Linear response about op. pt.')  
title('Comparison of signal values for output 2')
```

`findop(idnlhw)`

# LTI Commands

---

<b>Purpose</b>	Apply Control System Toolbox commands to <code>idmodel</code> objects
<b>Syntax</b>	<code>append</code> , <code>augstate</code> , <code>balreal</code> , <code>canon</code> , <code>d2d</code> , <code>feedback</code> , <code>inv</code> , <code>minreal</code> , <code>modred</code> , <code>norm</code> , <code>parallel</code> , <code>series</code> , <code>ss2ss</code>
<b>Description</b>	When you have the Control System Toolbox product installed, you can apply the listed LTI commands to <code>idmodel</code> objects, including <code>idarx</code> , <code>idgrey</code> , <code>idpoly</code> , and <code>idss</code> models. You can also use the overloaded operations <code>+</code> , <code>-</code> , and <code>*</code> . The same operations are performed and the result is delivered as an <code>idmodel</code> . The original covariance information is lost most of the time, however.
<b>Examples</b>	<p>You have two more or less identical processes connected in series. Estimate a model for one of them, and use that to form an initial estimate for a model of the connected process.</p> <pre>% data concerns one of the processes m = pem(data) % data2 is from the entire connected process m2 = pem(data2,m*m)</pre>

**Purpose** Merge data sets into one iddata object

**Syntax** `dat = merge(dat1,dat2,...,datN)`

**Description** `dat` collects the data sets in `dat1`, ..., `datN` into one iddata object, with several *experiments*. The number of experiments in `dat` will be the sum of the number of experiments in `datk`. For the merging to be allowed, a number of conditions must be satisfied:

- All of `datk` must have the same number of input channels, and the `InputNames` must be the same.
- All of `datk` must have the same number of output channels, and the `OutputNames` must be the same. If some input or output channel is lacking in one experiment, it can be replaced by a vector of NaNs to conform with these rules.
- If the `ExperimentNames` of `datk` have been specified as something other than the default 'Exp1', 'Exp2', etc., they must all be unique. If default names overlap, they are modified so that `dat` will have a list of unique `ExperimentNames`.

The sampling intervals, the number of observations, and the input properties (`Period`, `InterSample`) might be different in the different experiments.

You can retrieve the individual experiments by using the command `getexp`. You can also retrieve them by subreferencing with a fourth index.

```
dat1 = dat(:,:,,ExperimentNumber)
```

or

```
dat1 = dat(:,:,,ExperimentName)
```

Storing multiple experiments as one iddata object can be very useful for handling experimental data that has been collected on different

## merge (iddata)

---

occasions, or when a data set has been split up to remove “bad” portions of the data. All the toolbox routines accept multiple-experiment data.

### Examples

Bad portions of data have been detected around sample 500 and between samples 720 to 730. Cut out these bad portions and form a multiple-experiment data set that can be used to estimate models without the bad data destroying the estimate.

```
dat = merge(dat(1:498), dat(502:719), dat(731:1000))
m = pem(dat)
```

Use the first two parts to estimate the model and the third one for validation.

```
m = pem(getexp(dat, [1,2]));
compare(getexp(dat,3), m)
```

See also `iddemo #9`.

### See Also

`iddata`  
`getexp`

**Purpose** Merge estimated models

**Syntax** `m = merge(m1,m2,...,mN)`  
`[m,tv] = merge(m1,m2)`

**Description** The models  $m_1, m_2, \dots, m_N$  must all be of the same structure, just differing in parameter values and covariance matrices. Then  $m$  is the merged model, where the parameter vector is a statistically weighted mean (using the covariance matrices to determine the weights) of the parameters of  $m_k$ .

When two models are merged,

```
[m, tv] = merge(m1,m2)
```

returns a test variable  $tv$ . It is  $\chi^2$  distributed with  $n$  degrees of freedom, if the parameters of  $m_1$  and  $m_2$  have the same means. Here  $n$  is the length of the parameter vector. A large value of  $tv$  thus indicates that it might be questionable to merge the models.

For `idfrd` models, `merge` is a statistical average of two responses in the individual models, weighted using inverse variances. You can only merge two `idfrd` models with responses at the same frequencies and nonzero covariances.

Merging models is an alternative to merging data sets and estimating a model for the merged data.

```
m1 = arx(z1,[2 3 4]);  
m2 = arx(z2,[2 3 4]);  
ma = merge(m1,m2);
```

and

```
mb = arx(merge(z1,z2),[2 3 4]);
```

result in models  $ma$  and  $mb$  that are related and should be close. The difference is that merging the data sets assumes that the signal-to-noise

## merge

---

ratios are about the same in the two experiments. Merging the models allows one model to be much more uncertain, for example, due to more disturbances in that experiment. If the conditions are about the same, we recommend that you merge data rather than models, since this is more efficient and typically involves better conditioned calculations.

---

<b>Purpose</b>	Set directory for storing <code>idprefs.mat</code> containing GUI startup information
<b>Syntax</b>	<code>midprefs</code> <code>midprefs(path)</code>
<b>Description</b>	<p>The graphical user interface <code>ident</code> allows a large number of variables for customized choices. These include the window layout, the default choices of plot options, and names and directories of the four most recent sessions with <code>ident</code>. This information is stored in the file <code>idprefs.mat</code>, which should be placed on the user's <code>MATLABPATH</code>. The default, automatic location for this file is in the same directory as the user's <code>startup.m</code> file.</p> <p><code>midprefs</code> is used to select or change the directory where you store <code>idprefs.mat</code>. Either type <code>midprefs</code> and follow the instructions, or give the directory name as the argument. Include all directory delimiters, as in the PC case</p> <pre>midprefs('c:\matlab\toolbox\local\')</pre> <p>or in the UNIX<sup>®</sup> case</p> <pre>midprefs('/home/ljung/matlab/')</pre>
<b>See Also</b>	<code>ident</code>

# misdata

---

## Purpose

Reconstruct missing input and output data

## Syntax

```
Datae = misdata(Data)
Datae = misdata(Data,Model)
Datae = misdata(Data,Maxiter,Tol)
```

## Description

Data is time-domain input-output data in the `iddata` object format. Missing data samples (both in inputs and in outputs) are entered as NaNs.

Datae is an `iddata` object where the missing data has been replaced by reasonable estimates.

Model is any `idmodel` (`idarx`, `idgrey`, `idpoly`, `idss`) used for the reconstruction of missing data.

If no suitable model is known, it is estimated in an iterative fashion using default order state-space models.

Maxiter is the maximum number of iterations carried out (the default is 10). The iterations are terminated when the difference between two consecutive data estimates differs by less than Tol%. The default value of Tol is 1.

## Algorithm

For a given model, the missing data is estimated as parameters so as to minimize the output prediction errors obtained from the reconstructed data. See Section 14.2 in Ljung (1999). Treating missing outputs as parameters is not the best approach from a statistical point of view, but is a good approximation in many cases.

When no model is given, the algorithm alternates between estimating missing data and estimating models, based on the current reconstruction.

<b>Purpose</b>	Class representing neural network object created in Neural Network Toolbox product for estimating nonlinear ARX and Hammerstein-Wiener models
<b>Syntax</b>	<code>n=neuralnet(Network)</code>
<b>Description</b>	<p><code>neuralnet</code> is an object that stores the neural network nonlinearity estimator for estimating nonlinear ARX and Hammerstein-Wiener models.</p> <p>You can use the constructor to create the nonlinearity object, as follows:</p> <p><code>n=neuralnet(Network)</code> creates a neural network nonlinearity estimator based on the network object you created using the Neural Network Toolbox product.</p> <p>The neural network must meet the following requirements:</p> <ul style="list-style-type: none"><li>• Neural network must be created using the Neural Network Toolbox <code>newff</code> or <code>newcf</code> command (feedforward networks used for function approximation).</li><li>• Neural network must represent a static mapping between the inputs and the output. It should not contain I/O delays or feedback.</li><li>• Neural network must have one output. If you want to use neural networks for multiple-output nonlinear ARX model, you must assign a separate <code>neuralnet</code> estimator for each output—that is, each estimator must represent a single-output network object.</li></ul> <p>Use <code>evaluate(n,x)</code> to compute the value of the function defined by the <code>neuralnet</code> object <code>n</code> at <code>x</code>.</p>
<b>Remarks</b>	<p>Use <code>neuralnet</code> to define a nonlinear function <math>y = F(x)</math>, where <math>F</math> is a multilayer feedforward neural network, as defined in the Neural Network Toolbox documentation.</p> <p><code>y</code> is a scalar and <code>x</code> is an <code>m</code>-dimensional row vector.</p>

When you have installed the Neural Network Toolbox product, you can create a multilayer feedforward neural network using `newff`:

```
ff = newff(P,T,[nL_1,nL_2,...,nL_r],{tf_1,tf_2,...,tf_r})
```

where  $P$  is an  $m$ -by- $N$  matrix containing inputs  $x$ , and  $T$  is a  $1$ -by- $N$  matrix containing output (target) values for one of the model outputs. You can also use `newcf`

There are  $r+1$  layers and  $nL_k$  neurons in the  $k$ th layer, except for the last layer. The last layer has one neuron assigned automatically, such that  $nL_{(r+1)}=1$ . The transfer function (or unit function) in the  $k$ th layer is  $tf_k$ .

If  $m$  is unknown at the time of creation of the network, use  $P = \text{zeros}(0,N)$  with arbitrary  $N>0$ . After this initialization,  $m$  is adjusted to the estimation data by `nlarx` or `nlhw`. Similarly, you can set  $T$  to any vector (number of rows=1).

## neuralnet Properties

You include the property as an argument in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List Network property value  
get(n)  
n.Network
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(d, 'Network', net_obj)
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
Network	Neural network object. You must use the Neural Network Toolbox <code>newff</code> or <code>newcf</code> command to create such an object.

The `newff` and `newcf` commands automatically create a network object configured for use with the System Identification Toolbox software. When you manually configure the network object (`net`), specify its properties as follows:

- `net.numInputs=1`

The single input can be a vector.

- `net.numLayers`

Must be a positive integer (`nL`).

- `net.inputConnect=[1;zeros(nL-1,1)]`

The first layer must be connected to the input.

- `net.outputConnect=[zeros(1,nL-1) 1]`

The last layer must be connected to the output.

- `net.layerConnect`

Must be an `nL-by-nL` logical matrix that satisfies the following conditions:

- Each layer, except the last one, must have its output connected to another layer `all(any(net.layerConnect(:,1:end-1),1),2) == true`
- Each layer, except the first one, must have its input connected to another layer `all(any(net.layerConnect(2:end,:),2),1) == true`

Typical value is `diag(true(1,nL-1),-1)` and represents a series connection from the first layer to the last layer.

- `net.trainFcn`

Must be set to the MATLAB training function name (M-file, MEX-file, built-in, or P-file).

`all(any(net.layerConnect(2:end,:),2),1) == true`

- `net.inputs{1}.size`

Must be set zero (undetermined) or a positive integer equal to the number of regressors.

- `net.initFcn='initlay'`

Indicates the use of layer initialization functions.

- `net.gradientFcn='calcjx'`

- `net.performFcn`

Must be set to the MATLAB performance function name (M-file, MEX-file, built-in, or P-file).

```
any(exist(net.performFcn)==[2 3 5 6]) == true
```

Typical value is 'mse'.

- `net.trainParam`

Must be a structure with fields:

```
epochs
goal
max_fail
mem_reduc
min_grad
mu
mu_dec
mu_inc
mu_max
show
showCommandLine
showWindow
time
```

- `net.layers(k).initFcn` for `k=1:nL`

Must be set to the MATLAB initialization function name (M-file, MEX-file, built-in, or P-file).

```
any(exist(net.layers{k}.initFcn)==[2 3 5 6]) == true
```

Typical value is 'initnw'.

- `net.biasConnect=logical(net.biasConnect)`

Must be a logical value.

---

**Note** The layer numbers, namely the values of `k` in `net.layers{k}`, are labels referring to the different layers. The layers are not necessarily connected in the natural order indicated by `k`. It means that, in principle, `net.layers{1}` is not necessarily the input layer, and `net.layers{end}` is not necessarily the output layer. However, topologically, there is no loss of generality to assume that `net.layers{1}` is the input layer and `net.layers{end}` is the output layer. The previous requirements make these assumptions to simplify how you can validate your network object.

---

## Examples

Use `neuralnet` to specify the neural network nonlinearity estimator in nonlinear ARX and Hammerstein-Wiener models. For example:

```
% Create network object using Neural Network Toolbox
net_obj=newff(zeros(0,10),rand(1,10),[6 8 2],...
             {'logsig','logsig','purelin'})
% Estimate nonlinear ARX model using
% net_obj as the neural network
m=nlarx(z1,[2,6,10],neuralnet(net_obj));
```

## See Also

`nlarx`  
`nlhw`

# nkshift

---

**Purpose** Shift data sequences

**Syntax** `Datas = nkshift(Data,nk)`

**Description** Data contains input-output data in the `iddata` format.  
`nk` is a row vector with the same length as the number of input channels in `Data`.

`Datas` is an `iddata` object where the input channels in `Data` have been shifted according to `nk`. A positive value of `nk(ku)` means that input channel number `ku` is delayed `nk(ku)` samples.

`nkshift` supports both frequency- and time-domain data. For frequency-domain data it multiplies with  $e^{in k\omega T}$  to obtain the same effect as shifting in the time domain. For continuous-time frequency-domain data ( $T_s = 0$ ), `nk` should be interpreted as the shift in seconds.

`nkshift` lives in symbiosis with the `InputDelay` property of `idmodel`:

```
m1 = pem(dat,4,'InputDelay',nk)
```

is related to

```
m2 = pem(nkshift(dat,nk),4);
```

such that `m1` and `m2` are the same models, but `m1` stores the delay information and uses this information when computing the frequency response, for example. When using `m2`, the delay value must be accounted for separately when computing time and frequency responses.

Note the difference from the `idss` and `idpoly` property `nk`.

```
m3 = pem(dat,4,'nk',nk)
```

gives a model that itself explicitly contains a delay of `nk` samples. In contrast, `m1` contains a total delay of `m1.nk + m1.InputDelay = 4`.

**See Also**

Algorithm Properties

idss

## Purpose

Estimate nonlinear ARX models

## Syntax

```
m=nlarx(data,[na nb nk])  
m=nlarx(data,[na nb nk],Nonlinearity)  
m=nlarx(data,[na nb nk],P1,V1,...,PN,VN)
```

## Input

data

Time-domain iddata model object.

[na nb nk]

na is the number of output terms, nb is the number of input terms, and nk is the input delays from each input to output.

For ny outputs and nu inputs, [na nb nk] has as many rows as there are outputs. In this case, na is an ny-by-ny matrix whose *i*-*j*th entry gives the number of delayed *j*th outputs used to compute the *i*th output. nb and nk are ny-by-nu matrices.

These orders specify the regressors and the predicted output is the following function of these regressors:

$$F(y(t-1), \dots, y(t-na), u(t-nk), \dots, u(t-nk-nb+1))$$

Nonlinearity

Specifies the nonlinearity estimator object as one of the following: wavenet (default), sigmoidnet, treepartition, customnet, neuralnet, and linear.

For ny outputs, Nonlinearity is an ny-by-1 array, such as [sigmoidnet;wavenet]. However, if you specify a scalar object, this nonlinearity object applies to all outputs.

For more information about nonlinearity properties, see the corresponding reference pages.

## Description

`m=nlarx(data,[na nb nk])` constructs and estimates a nonlinear ARX model with orders `[na nb nk]` and wavenet nonlinearity. `data` is the estimation data set.

`m=nlarx(data,[na nb nk],Nonlinearity)` constructs and estimates a nonlinear ARX model with orders `[na nb nk]` and `Nonlinearity`. `data` is the estimation data set.

`m=nlarx(data,[na nb nk],P1,V1,...,PN,VN)` constructs and estimates the model with additional property-value pairs. For more information about model `idnlarx` model properties, see the corresponding reference pages.

## Examples

The following commands construct and estimate a nonlinear ARX model:

```
load iddata1
m1=nlarx(z1,[4 2 1], 'wave', 'nlr', [1:3])
```

To perturb the parameters slightly and avoid being trapped in local minima, use the `init` command:

```
m2=init(m1)
```

Estimate the model with perturbed initial parameter values, use the following command:

```
m2=nlarx(z1,m2)
```

## See Also

```
addreg
customreg
getreg
idnlarx
init
polyreg
```

## Purpose

Estimate Hammerstein-Wiener models

## Syntax

```
m=nlhw(data,[nb nf nk])
m=nlhw(data,[nb nf nk],Nonlinearity)
m=nlhw(data,[nb nf nk],P1,V1,...,PN,VN)
m=nlhw(data,[nb nf nk],InputNL,OutputNL,...
    'InitialState',init)
```

## Arguments

`data`

Time-domain `iddata` model object.

`[nb nf nk]`

Model orders and input delays, where `nb` is the number of zeros plus 1, `nf` is the number of poles, and `nk` is the delay from input to output in terms of the number of samples.

For `nu` inputs and `ny` outputs, `nb`, `nf` and, `nk` are `ny`-by-`nu` matrices whose *i*-*j*th entry specifies the orders and delay of the transfer function from the *j*th input to the *i*th output.

`InputNL` and `OutputNL`

Specify the input and output nonlinearity estimator objects as one of the following: `pwlinear` (default), `poly1d`, `deadzone`, `wavenet`, `saturation`, `customnet`, `sigmoidnet`, and `unitgain`. The nonlinearity estimator objects have properties that you can set in the constructor, as follows:

```
m=nlhw(data,[2 2 1],sigmoidnet('num',5),deadzone([-1,2]))
```

To use default nonlinearity properties, specify the nonlinearity object name as a string. For example:

```
m=nlhw(data,[2 2 1],'sigmoidnet','deadzone')
m=nlhw(data,[2 2 1],'sig','dead') % Abbreviated
```

The estimator `unitgain` (can also be entered as `[]`) means no nonlinearity. Thus, `m=nlhw(data,[2 2 1],'saturation', '[]')`.

For more information about nonlinearity properties, see the corresponding reference pages.

#### InitialState

The value of the initial state. `InitialState` can have the following values:

- `z`: Zero (Default).
- `e`: Estimate initial state.

## Description

`m=nlhw(data,[nb nf nk])` constructs and estimates a Hammerstein-Wiener model with orders `[na nf nk]` and the `pwnlinear` nonlinearity. `data` is the estimation data set.

`m=nlhw(data,[nb nf nk],Nonlinearity)` constructs and estimates a Hammerstein-Wiener model with orders `[na nf nk]` and `Nonlinearity`. `data` is the estimation data set.

`m=nlhw(data,[nb nf nk],P1,V1,...,PN,VN)` constructs and estimates the model with additional property-value pairs. For more information about model `idnlhw` model properties, see the corresponding reference pages.

`m=nlhw(data,[nb nf nk],InputNL,OutputNL,...  
'InitialState',init)` lets you choose the initial state.

## Examples

The following commands construct and estimate a Hammerstein-Wiener model:

```
load iddata1
m1=nlhw(z1,[4 2 1],'sigmoidnet','deadzone')
```

## See Also

`idnlhw`  
`init`  
`pem`

**Purpose** Transform idmodel object with noise channels to model with measured channels only

**Syntax**

```
mod1 = noisecnv(mod)
mod2 = noisecnv(mod, 'norm')
```

**Description** mod is any idmodel, idarx, idgrey, idpoly, or idss.

The noise input channels in mod are converted as follows: Consider a model with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$y = Gu + He$$
$$\text{cov}(e) = \Lambda = LL'$$

where  $L$  is a lower triangular matrix. Note that `mod.NoiseVariance =  $\Lambda$` . The model can also be described with unit variance, using a normalized noise source  $v$ :

$$y = Gu + HLv$$
$$\text{cov}(v) = I$$

- `mod1 = noisecnv(mod)` converts the model to a representation of the system  $[G H]$  with  $nu+ny$  inputs and  $ny$  outputs. All inputs are treated as measured, and `mod1` does not have any noise model. The former noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- `mod2 = noisecnv(mod, 'norm')` converts the model to a representation of the system  $[G HL]$  with  $nu+ny$  inputs and  $ny$  outputs. All inputs are treated as measured, and `mod2` does not have any noise model. The former noise input channels have names `v@yname`, where `yname` is the name of the corresponding output. Note that the noise variance matrix factor  $L$  typically is uncertain (has a nonzero covariance). This is taken into account in the uncertainty description of `mod2`.

- If `mod` is a time series, that is,  $nu = 0$ , `mod1` is a model that describes the transfer function  $H$  with measured input channels. Analogously, `mod2` describes the transfer function  $HL$ .

Note the difference with subreferencing:

- `mod('m')` gives a description of  $G$  only.
- `mod('n')` gives a description of the noise model characteristics as a time-series model, that is, it describes  $H$  and also the covariance of  $e$ . In contrast, `noisecnv(m('n'))` describes just the transfer function  $H$ . To obtain a description of the normalized transfer function  $HL$ , use `noisecnv(m('n'), 'norm')`.

Converting the noise channels to measured inputs is useful to study the properties of the individual transfer functions from noise to output. It is also useful for transforming `idmodel` objects to representations that do not handle disturbance descriptions explicitly.

# nuderst

---

**Purpose** Set step size for numerical differentiation

**Syntax** `nds = nuderst(pars)`

**Description** The function `pem` uses numerical differentiation with respect to the model parameters when applied to state-space structures. The same is true for many functions that transform model uncertainties to other representations.

The step size used in these numerical derivatives is determined by the M-file `nuderst`. The output argument `nds` is a row vector whose *k*th entry gives the increment to be used when differentiating with respect to the *k*th element of the parameter vector `pars`.

The default version of `nuderst` uses a very simple method. The step size is the maximum of  $10^{-4}$  times the absolute value of the current parameter and  $10^{-7}$ . You can adjust this to the actual value of the corresponding parameter by editing `nuderst`. Note that the nominal value, for example 0, of a parameter might not reflect its normal size.

**Purpose** Plot Nyquist curve of frequency response with confidence interval

**Syntax**

```
nyquist(m)
[fr,w] = nyquist(m)
[fr,w,covfr] = nyquist(m)
nyquist(m1,m2,m3,...,w)
nyquist(m1,'PlotStyle1',m2,'PlotStyle2',...)
nyquist(m1,m2,m3,..'sd*5',sd,'mode',mode)
```

**Description** `nyquist` computes the complex-valued frequency response of `idmodel` and `idfrd` models. When invoked without left-hand arguments, `nyquist` produces a Nyquist plot on the screen, that is, a graph of the frequency response's imaginary part against its real part.

The argument `m` is an arbitrary `idmodel` or `idfrd` model. This model can be continuous or discrete, and SISO or MIMO. The `InputNames` and `OutputNames` of the models are used to plot the responses for different I/O channels in separate plots. Pressing the **Enter** key advances the plot from one input-output pair to the next one. You can select specific I/O channels with normal subreferencing: `m(ky,ku)`. With `mode = 'same'`, all plots are given in the same diagram.

`nyquist(m,w)` explicitly specifies the frequency range or frequency points to be used for the plot. To focus on a particular frequency interval `[wmin,wmax]`, set `w = {wmin,wmax}`. To use particular frequency points, set `w` to the vector of desired frequencies. Use `logspace` to generate logarithmically spaced frequency vectors. All frequencies should be specified in rad/s.

`nyquist(m1,m2,...,mN)` or `nyquist(m1,m2,...,mN,w)` plots the Bode responses of several `idmodels` or `idfrd` models on a single figure. The models can be mixes of different sizes, and continuous or discrete. The sorting of the plots is based on the `InputNames` and `OutputNames`.

`nyquist(m1,'PlotStyle1',...,mN,'PlotStyleN')` further specifies which color, line style, and/or marker should be used to plot each system, as in

```
nyquist(m1,'r--',m2,'gx')
```

When `sd` is specified as a number larger than zero, confidence regions are also plotted. These are ellipses in the complex plane and correspond to the region where the true response at the frequency in question is to be found with a confidence corresponding to `sd` standard deviations (of the Gaussian distribution).

If the argument indicating standard deviations is given as in `'sd+5'`, a confidence region is plotted for every 5:th frequency, marking the center point by `'+'`. The default is `'sd+10'`.

Note that the frequencies cannot be specified for `idfrd` objects. For those, the plot and response are calculated for the internally stored frequencies. If the frequencies `w` are specified when several models are treated, they will apply to all non-`idfrd` models in the list. If you want different frequencies for different models, you should first convert them to `idfrd` objects using the `idfrd` command.

For time-series models (no input channels), the Nyquist plot is not defined.

## Input

When `nyquist` is called with a single system and output arguments,

```
fr = nyquist(m,w) or [fr,w,covfr] = nyquist(m)
```

no plot is drawn on the screen. If `m` has `ny` outputs and `nu` inputs, and `w` contains `Nw` frequencies, then `fr` is an `ny-by-nu-by-Nw` array such that `fr(ky,ku,k)` gives the complex-valued frequency response from input `ku` to output `ky` at the frequency `w(k)`. For a SISO model, use `fr(:)` to obtain a vector of the frequency response. The uncertainty information `covfr` is a 5-D array where `covfr(ky,ku,k, :, :)` is the 2-by-2 covariance matrix of the response from input `ku` to output `ky` at frequency `w(k)`. The 1,1 element is the variance of the real part, the 2,2 element is the variance of the imaginary part, and the 1,2 and 2,1 elements are the covariance between the real and imaginary parts.

`squeeze(covfr(ky,ku,k, :, :))` gives the covariance matrix of the corresponding response.

If  $m$  is a time series (no input),  $fr$  is returned as the (power) spectrum of the outputs, an  $ny$ -by- $ny$ -by- $Nw$  array. Hence  $fr(:, :, k)$  is the spectrum matrix at frequency  $w(k)$ . The element  $fr(k1, k2, k)$  is the cross spectrum between outputs  $k1$  and  $k2$  at frequency  $w(k)$ . When  $k1 = k2$ , this is the real-valued power spectrum of output  $k1$ . The  $covfr$  is then the covariance of the spectrum  $fr$ , so that  $covfr(k1, k1, k)$  is the variance of the power spectrum of output  $k1$  at frequency  $w(k)$ . No information about the variance of the cross spectra is normally given. (That is,  $covfr(k1, k2, k) = 0$  for  $k1$  not equal to  $k2$ .)

If the model  $m$  is not a time series, use  $fr = nyquist(m('n'))$  to obtain the spectrum information of the noise (output disturbance) signals.

## Examples

```
g = spa(data)
m = n4sid(data,3)
nyquist(g,m,'sd',3)
```

## See Also

```
bode
etfe
ffplot

idfrd
spa
spafdr
```

**Purpose** Estimate state-space models using subspace method returning idss object

**Syntax** `m = n4sid(data)`  
`m = n4sid(data,order,'Property1',Value1,...,'PropertyN',ValueN)`

**Description** `n4sid` estimates models in state-space form and returns them as an idss object `m`. `n4sid` handles an arbitrary number of inputs and outputs, including the time-series case (no input). The state-space model is in the innovations form

$$\begin{aligned}x(t+Ts) &= Ax(t) + Bu(t) + Ke(t) \\ y(t) &= Cx(t) + Du(t) + e(t)\end{aligned}$$

If `data` is continuous-time (frequency-domain) data, a corresponding continuous-time state-space model is estimated.

`data`: An iddata object containing the output-input data. Both time-domain and frequency-domain signals are supported. `data` can also be a frd or idfrd frequency-response data object.

`order`: The desired order of the state-space model. If `order` is entered as a row vector (as in `order = [1:10]`), preliminary calculations for all the indicated orders are carried out. A plot is then given that shows the relative importance of the dimension of the state vector. More precisely, the singular values of the Hankel matrices of the impulse response for different orders are graphed. You are prompted to select the order, based on this plot. The idea is to choose an order such that the singular values for higher orders are comparatively small. If `order = 'best'`, a model of “best” (default choice) order is computed among the orders 1:10. This is the default choice of `order`.

### Estimating the D Matrix

Whether the  $D$  matrix is estimated or not is governed by the property `nk`, which is further described below. The default is that  $D$  is not estimated. By setting the  $k$ th entry of `nk` to 0, the  $k$ th column of  $D$  (corresponding to the  $k$ th input) is estimated. To estimate a full  $D$  matrix thus, let `nk = zeros(1,nu)` as in

```
m = n4sid(data,order,'nk',[0 .. 0])
```

This holds for both discrete- and continuous-time models.

## Properties

The list of property name/property value pairs can contain any `idss` and algorithm properties. See `idss` and Algorithm Properties.

`idss` properties that are of particular interest for `n4sid` are

- `nk`: For time-domain data, this gives delays from the inputs to the outputs, a row vector with the same number of entries as the number of input channels. Default is `nk = [1 1... 1]`. Note that delays of 0 or 1 show up as zeros or estimated parameters in the D matrix. Delays larger than 1 mean that a special structure of the A, B, and C matrices is used to accommodate the delays. This also means that the actual order of the state-space model will be larger than `order`. For continuous-time models estimated from continuous-time (frequency-domain) data, the elements of `nk` are restricted to the values 1 and 0.
- `CovarianceMatrix` (can be abbreviated to `'co'`): Setting `CovarianceMatrix` to `'None'` blocks all calculations of uncertainty measures. These can take the major part of the computation time. Note that, for a `'Free'` parameterization, the individual matrix elements cannot be associated with any variance. (These parameters are not identifiable.) Instead, the resulting model `m` stores a hidden state-space model in canonical form that contains covariance information. This is used when the uncertainty of various input-output properties is calculated. It can also be retrieved by `m.ss = 'can'`. The actual covariance properties of `n4sid` estimates are not known today. Instead the Cramer-Rao bound is computed and stored as an indication of the uncertainty.
- `DisturbanceModel`: Setting `DisturbanceModel` to `'None'` will deliver a model with `K = 0`. This has no direct effect on the dynamics model other than that the default choice of `N4Horizon` will not involve past outputs.

- **InitialState:** The initial state is always estimated for better accuracy. However, it is returned with `m` only if `InitialState = 'Estimate'`.

Algorithm properties that are of special interest are

- **Focus:** Assumes the values 'Prediction' (default), 'Simulation', 'Stability', passbands, or any SISO linear filter (given as an LTI or `idmodel` object, or as filter coefficients. See `Algorithm Properties`.) Setting 'Focus' to 'Simulation' chooses weights that should give a better simulation performance for the model. In particular, a stable model is guaranteed. Selecting a linear filter focuses the fit to the frequency ranges that are emphasized by this filter.
- **N4Weight:** This property determines some weighting matrices used in the singular-value decomposition that is a central step in the algorithm. Two choices are offered: 'MOESP', corresponding to the MOESP algorithm by Verhaegen, and 'CVA', which is the canonical variable algorithm by Larimore. The default value is 'N4Weight' = 'Auto', which gives an automatic choice between the two options. `m.EstimationInfo.N4Weight` tells you what the actual choice turned out to be.
- **N4Horizon:** Determines the prediction horizons forward and backward used by the algorithm. This is a row vector with three elements: `N4Horizon = [r sy su]`, where `r` is the maximum forward prediction horizon. That is, the algorithm uses up to `r` step-ahead predictors. `sy` is the number of past outputs, and `su` is the number of past inputs that are used for the predictions. See pages 209 and 210 in Ljung (1999) for the exact meaning of this. These numbers can have a substantial influence on the quality of the resulting model, and there are no simple rules for choosing them. Making 'N4Horizon' a `k`-by-3 matrix means that each row of 'N4Horizon' is tried, and the value that gives the best (prediction) fit to data is selected. (This option cannot be combined with selection of model order.) If the property 'Display' is 'On', information about the results is given in the MATLAB Command Window.

If you specify only one column in 'N4Horizon', the interpretation is  $r=sy=su$ . The default choice is 'N4Horizon' = 'Auto', which uses an Akaike Information Criterion (AIC) for the selection of  $sy$  and  $su$ . If 'DisturbanceModel' = 'None',  $sy$  is set to 0. Typing `m.EstimationInfor.N4Horizon` will tell you what the final choices of horizons were.

## Algorithm

The algorithm is described in Section 10.6 in Ljung (1999).

## Examples

Build a fifth-order model from data with three inputs and two outputs. Try several choices of auxiliary orders. Look at the frequency response of the model.

```
z = iddata([y1 y2],[ u1 u2 u3]);
m = n4sid(z,5,'n4h',[7:15]','Display','on');
bode(m,'sd',3)
```

Estimate a continuous-time model, in a canonical form parameterization, focusing on the simulation behavior. Determine the order yourself after seeing the plot of singular values.

```
m = n4sid(z,[1:10],'foc','sim','ssp','can','ts',0)
bode(m)
```

Algorithm Properties

idss

pem

**Purpose**

Estimate parameters of output-error model returning idpoly object

**Syntax**

```
m = oe(data,orders)
m = oe(data,'nb',nb,'nf',nf,'nk',nk)
m = oe(data,orders,'Property1',Value1,'Property2',Value2,...)
```

**Description**

oe returns `m` as an idpoly object with the resulting parameter estimates, together with estimated covariances. The parameters of the output-error model structure

$$y(t) = \frac{B(q)}{F(q)}u(t-nk) + e(t)$$

are estimated using a prediction error method.

`data` is an iddata object containing the output-input data. Both time- and frequency-domain data are supported. Moreover, `data` can be an `frd` or `idfrd` frequency-response data object.

The structure information can either be given explicitly as

```
(..., 'nb',nb,'nf',nf,'nk',nk,...)
```

or in the argument `orders`, given as

```
orders = [nb nf nk]
```

The parameters `nb` and `nf` are the orders of the output-error model and `nk` is the delay. Specifically,

$$nb: \quad B(q) = b_1 + b_2q^{-1} + \dots + b_{nb}q^{-nb+1}$$

$$nf: \quad F(q) = 1 + f_1q^{-1} + \dots + f_{nf}q^{-nf}$$

Alternatively, you can specify the vector as

```
orders = mi
```

where `mi` is an initial guess at the output-error model given in `idpoly` format. See “What Are Black-Box Polynomial Models?” in the User’s Guide.

For multiple-input systems, `nb`, `nf`, and `nk` are row vectors with as many entries as there are input channels. Entry number `i` then describes the orders and delays associated with the `i`th input.

### Continuous-Time Models

If `data` is continuous-time (frequency-domain) data, `oe` estimates a continuous-time model with transfer function

$$G(s) = \frac{B(s)}{F(s)} = \frac{b_{nb}s^{(nb-1)} + b_{nb-1}s^{(nb-2)} + \dots + b_1}{s^{nf} + f_{nf}s^{(nf-1)} + \dots + f_1}$$

The orders of the numerator and denominator are thus determined by `nb` and `nf` just as in the discrete-time case. However, the delay `nk` has no meaning and should be omitted. For multiple-input systems, `nb` and `nf` are row vectors with obvious interpretation.

### Properties

The structure and the estimation algorithm are affected by any property name/property value pairs that are set in the input argument list. Useful properties are 'Focus', 'InitialState', 'InputDelay', 'SearchMethod', 'MaxIter', 'Tolerance', 'LimitError', 'FixedParameter', and 'Display'.

See Algorithm Properties, `idpoly`, and `idmodel` for details of these properties and their possible values.

`oe` does not support multiple-output models. Use a state-space model for this case (see `n4sid` and `pem`).

## Algorithm

`oe` uses essentially the same algorithm as `armax`, with modifications to the computation of prediction errors and gradients.

## Examples

Suppose fast sampled data ( $T_s = 0.001$ ) is available from a plant with a bandwidth of about 500 rad/s. The data is treated as continuous-time frequency-domain data, and a model of the type

$$G(s) = \frac{b}{s^3 + f_1 s^2 + f_2 s + f_3}$$

is estimated.

```
z = iddata(y,u,0.001);  
zf = fft(z);  
zf.ts = 0;  
m = oe(zf,[1 3], 'foc',[0 500])
```

# operspec(idnlarx)

---

**Purpose** Construct operating point specification object for `idnlarx` model

**Syntax** `SPEC = operspec(NLSYS)`

**Description** `SPEC = operspec(NLSYS)` creates an operating point specification object for the `idnlarx` model `NLSYS`. The object encapsulates constraints on input and output signal values. These specifications are used to determine an operating point of the `idnlarx` model using `findop(idnlarx)`.

**Input**

- `NLSYS`: `idnlarx` model.

**Output**

- `SPEC`: Operating point specification object. `SPEC` contains the following properties:
  - `Input`: Structure with fields:
    - `Value`: Initial guess for the values of the input signals. Specify a vector of length equal to number of model inputs. Default value: Vector of zeros.
    - `Min`: Minimum value constraint on values of input signals for the model. Default: `-Inf` for all channels.
    - `Max`: Maximum value constraint on values of input signals for the model. Default: `Inf` for all channels.
    - `Known`: Specifies when `Value` is known (fixed) or is an initial guess. Use a logical vector to denote which signals are known (logical 1, or `true`) and which have to be estimated using `findop` (logical 0, or `false`). Default value: `true`.
  - `Output`: Structure with fields:
    - `Value`: Initial guess for the values of the output signals. Default value: Vector of zeros.
    - `Min`: Minimum value constraint on values of output signals for the model. Default value: `-Inf`.

- **Max:** Maximum value constraint on values of output signals for the model. Default value: `-Inf`.

### **See Also**

`findop(idnlarx)`

# operspec(idnlhw)

---

**Purpose** Construct operating point specification object for `idnlhw` model

**Syntax** `SPEC = operspec(NLSYS)`

**Description** `SPEC = operspec(NLSYS)` creates an operating point specification object for the `idnlhw` model `NLSYS`. The object encapsulates constraints on input and output signal values. These specifications are used to determine an operating point of the `idnlhw` model using `findop(idnlhw)`.

**Input**

- `NLSYS`: `idnlhw` model.

**Output**

- `SPEC`: Operating point specification object. `SPEC` contains the following fields:
  - `Value`: Initial guess for the values of the input signals. Specify a vector of length equal to number of model inputs. Default value: Vector of zeros.
  - `Min`: Minimum value constraint on values of input signals for the model. Default: `-Inf` for all channels.
  - `Max`: Maximum value constraint on values of input signals for the model. Default: `Inf` for all channels.
  - `Known`: Specifies when `Value` is known (fixed) or is an initial guess. Use a logical vector to denote which signals are known (logical 1, or `true`) and which have to be estimated using `findop` (logical 0, or `false`). Default value: `true`.

---

**Note**

- 1** If the input is completely known ('Known' field is set to true for all input channels), then the initial state values are determined using input values only. In this case, `findop(idnlhw)` ignores the output signal specifications.
  - 2** If the input values are not completely known, `findop(idnlhw)` uses the output signal specifications to achieve the following objectives:
    - Match target values of known output signals (output channels with `Known = true`).
    - Keep the free output signals (output channels with `Known = false`) within the specified min/max bounds.
- 

**See Also**`findop(idnlhw)`

**Purpose** Prediction errors associated with model and data set

**Syntax**  
`e = pe(m,data)`  
`[e,x0] = pe(m,data,init)`

**Description** `data` is the output-input data set, given as an `iddata` object, and `m` is any `idmodel` or `idn1model` object. Both time-domain and frequency-domain data are supported, and `data` can also be an `idfrd` object.

`e` is returned as an `iddata` object, so that `e.OutputData` contains the prediction errors that result when model `m` is applied to the data.

$$e(t) = H^{-1}(q)[y(t) - G(q)u(t)]$$

The argument `init` determines how to deal with the initial conditions:

- `init = 'e(stimate)'` means that the initial state is chosen so that the norm of prediction error is minimized. This initial state is returned as `x0`.
- `init = 'd(elayexpand)'`: Same as 'estimate', but for a model with nonzero `InputDelay`, the delays are first converted to explicit model delays (using `inpd2nk`) so that they are contained in `x0`.
- `init = 'z(ero)'` sets the initial state to zero.
- `init = 'm(odel)'` uses the model's internally stored initial state.
- `init = x0i`, where `x0i` is a column vector of appropriate dimension, uses that value as initial state. For multiexperiment data, `x0i` may be a matrix whose columns give different initial states for each experiment. For a continuous-time model `m`, `x0` is the initial state for this model. Any modifications of the initial state that sampling might require are automatically handled. If `m` has a non-zero `InputDelay`, and you need to access the values of the inputs during this delay, you must first apply `inpd2nk(m)`. If `m` is continuous in time, it must first be sampled before `inpd2nk` can be applied.

If `init` is not specified for linear models, its value is determined, as follows:

- If `m.InitialState` is 'Estimate', 'Backcast', and 'Auto', `init` = 'Estimate'.
- If `m.InitialState` is 'Zero', `init` = 'zero'.
- If `m.InitialState` is 'Model' or 'Fixed', `init` = 'model'. For `idss`, `idproc`, and `idgrey` models, `init` corresponds to the `m.x0` values. For other linear models, `init` = 'zero'.

If `init` is not specified for `idnlgrey` models, `init` = 'Model' is the default. The values and their estimation behavior are inherited from `m.InitialStates`.

If `init` is not specified for `idnlrx` models, `init` = 'Estimate' is the default. This corresponds to the first few samples of predicted outputs exactly matching the first few output samples in the data set.

If `init` is not specified for `idnlhw` models, `init` = 'Estimate' is the default. This computes initial states by minimizing the prediction errors over the available data range.

The output argument `x0` is the value of the initial state used. If data contains several experiments, `x0` is a matrix containing the initial states from each experiment.

```

## How to Use

If you are using the System Identification Tool GUI, you can specify PEM for low-order continuous-time process models, linear state-space, and polynomial models. If you are working in the MATLAB Command Window, you can use the `pem` command to both construct and estimate these linear models and to also estimate linear and nonlinear grey-box models.

Alternatively, you can use PEM to try to refine initial parameter estimates for all linear and nonlinear parametric models. For more information about refining initial model estimates, see “Refining Nonlinear Black-Box Models”.

## Description

`pem` is the basic estimation command in the toolbox and covers a variety of situations.

`data` is always an `iddata` object that contains the input/output data. Both time-domain and frequency-domain signals are supported. `data` can also be an `frd` or `idfrd` frequency-response data object. Estimation of noise models (K in state-space models and A, C, and D in polynomial models) is not supported for frequency-domain data.

### With Initial Model

`mi` is any `idmodel` or `idnlmodel` object. It could be a result of another estimation routine, or constructed and modified by the constructors (`idarx`, `idpoly`, `idss`, `idgrey`, `idproc`) and `set`. The properties of `mi`

can also be changed by any property name/property value pairs in pem as indicated in the syntax.

m is then returned as the best fitting model in the model structure defined by mi. The iterative search is initialized at the parameters of the initial/nominal model mi. m will be of the same class as mi.

### Black-Box State-Space Models

With  $m = \text{pem}(\text{data}, n)$ , where  $n$  is a positive integer, or  $m = \text{pem}(\text{data}, 'nx', n)$ , a state-space model of order  $n$  is estimated.

$$\begin{aligned}x(t + Ts) &= Ax(t) + Bu(t) + Ke(t) \\y(t) &= Cx(t) + Du(t) + e(t)\end{aligned}$$

If data is continuous-time (frequency-domain) data, a corresponding continuous-time state space model is estimated.

The default is that it is estimated in a 'Free' parameterization that can be further modified by the properties 'nk', 'DisturbanceModel', and 'InitialState' (see the corresponding reference pages for idss and n4sid). The model is initialized by n4sid and then further adjusted by optimizing the prediction error fit.

You can choose among several different orders by

$$m = \text{pem}(\text{data}, 'nx', [n1, n2, \dots, nN])$$

and you are then prompted for the “best” order. By

$$m = \text{pem}(\text{data}, 'best')$$

an automatic choice of order among 1:10 is made.

$$m = \text{pem}(\text{data})$$

is short for  $m = \text{pem}(\text{data}, 'best')$ . To work with other delays, use, for example,  $m = \text{pem}(\text{data}, 'best', 'nk', [0, \dots, 0])$ .

In this case m is returned as an idss model.

### Estimating the D, K, and X0 Matrices

Whether the  $D$  matrix is estimated or not is governed by the property  $nk$ , which is further described below. The default is that  $D$  is not estimated. By setting the  $k$ th entry of  $nk$  to 0, the  $k$ th column of  $D$  (corresponding to the  $k$ th input) is estimated. To estimate a full  $D$  matrix, let  $nk = \text{zeros}(1, nu)$ , as in

```
m = pem(data,order,'nk',[0 .. 0])
```

This holds for both discrete- and continuous-time models.

For frequency-domain data,  $K$  is always fixed to 0. For time-domain data,  $K$  is estimated by default. To fix  $K$  to 0 in this case, use

```
m = pem(data,order,'DisturbanceModel','none')
```

Similarly,  $X0$  is estimated if 'InitialState' is set to 'Estimate', and fixed to 0 if 'InitialState' is set to 'Zero'.

### Black-Box Multiple-Input-Single-Output Models

The function pem also handles the general multiple-input-single-output structure

$$A(q)y(t) = \frac{B_1(q)}{F_1(q)}u_1(t-nk_1) + \dots + \frac{B_{nu}(q)}{F_{nu}(q)}u_{nu}(t-nk_{nu}) + \frac{C(q)}{D(q)}e(t)$$

The orders of this general model are given either as

```
orders = [na nb nc nd nf nk]
```

or with (... 'na', na, 'nb', nb, ...) as shown in the syntax. Here na, nb, nc, nd, and nf are the orders of the model, and nk is the delay(s). For multiple-input systems, nb, nf, and nk are row vectors giving the orders and delays of each input. (See "What Are Black-Box Polynomial Models?" in the User's Guide for a definition of the orders.) When the orders are specified with separate entries, those not given are taken as zero.

For frequency-domain data, only estimation of **B** and **F** is supported. It is simpler to use `oe` in that case.

In this case, `m` is returned as an `idpoly` object.

### Continuous-Time Process Models

Entering for the initial model an acronym for a process model, as in

```
m = pem(data, 'P2UI')
```

will estimate a continuous-time process model of the indicated type. See the reference page for `idproc` for details of possible model types and associated property name/property value pairs.

In this case, `m` is returned as an `idproc` model.

## Properties

In all cases the algorithm is affected by the properties (see [Algorithm Properties](#) for details):

- `Focus` can be set to `'Prediction'` (default), `'Simulation'`, or a passband range.
- `MaxIter` and `Tolerance` govern the stopping criteria for the iterative search.
- `LimitError` deals with how the criterion can be made less sensitive to outliers and bad data.
- `MaxSize` determines the largest matrix ever formed by the algorithm. The algorithm goes into `for` loops to avoid larger matrices, which can be more efficient than using virtual memory.
- `Display`, with possible values `'Off'`, `'On'`, and `'Full'`, governs the information sent to the MATLAB Command Window.

For black-box state-space models, `'N4Weight'` and `'N4Horizon'` will also affect the result, since these models are initialized with an `n4sid` estimate. See the reference page for `n4sid`.

Typical `idmodel` properties are (see `idmodel` properties for more details):

- `Ts` is the sampling interval. Set `'Ts' = 0` to obtain a continuous-time state-space model. For discrete-time models, `'Ts'` is automatically set to the sampling interval of the data. Note that, in the black-box case, it is usually better to first estimate a discrete-time model, and then convert that to continuous time using `d2c`.
- `nk` is the time delays from the inputs (not applicable to structured state-space models). Time delays specified by `'nk'` will be included in the model.
- `DisturbanceModel` determines the parameterization of `K` for free and canonical state-space parameterizations, as well as for `idgrey` models. It also determines whether a noise model should be included for `idproc` models.
- `InitialState`: The initial state can have a substantial influence on the estimation result for systems with slow responses. It is most pronounced for output-error models (`K = 0` for state-space and `na = nc = nd = 0` for input/output models). The default value `'Auto'` estimates the influence of the initial state and sets the value to `'Estimate'`, `'Backcast'`, or `'Zero'` based on this effect. Possible values of `'InitialState'` are `'Auto'`, `'Estimate'`, `'Backcast'`, `'Zero'`, and `'Fixed'`.

## Examples

Here is an example of a system with three inputs and two outputs. A canonical form state-space model of order 5 is sought.

```
z = iddata([y1 y2],[ u1 u2 u3]);  
m = pem(z,5,'ss','can')
```

Building an ARMAX model for the response to output 2,

```
ma = pem(z(:,2,:), 'na', 2, 'nb', [2 3 1], 'nc', 2, 'nk', [1 2 0])
```

Comparing the models (`compare` automatically matches the channels using the channel names),

compare(z,m,ma)

## Algorithm

pem uses essentially the same algorithm as armax, with modifications to the computation of prediction errors and gradients.

PEM uses optimization to minimize the *cost function*, defined as follows for scalar outputs:

$$V_N(G,H) = \sum_{t=1}^N e^2(t)$$

where  $e(t)$  is the difference between the measured output and the predicted output of the model. For a linear model, this error is defined by the following equation:

$$e(t) = H^{-1}(q)[y(t) - G(q)u(t)]$$

$e(t)$  is a vector and the cost function  $V_N(G,H)$  is a scalar value. The subscript  $N$  indicates that the cost function is a function of the number of data samples and becomes more accurate for larger values of  $N$ . For multiple-output models, the previous equation is more complex.

For black-box models, PEM estimates an initial model and then varies the parameter values along a specific direction to decrease the cost function. As with any nonlinear optimization algorithm, there is a chance that the model might find a local minimum that is not accurate for a specific system.

# pexcit

---

**Purpose** Level of excitation of input signals

**Syntax** `Ped = pexcit(Data)`  
`[Ped.Maxnr] = pexcit(Data,Maxnr,Threshold)`

**Description** Data is an `iddata` object with time- or frequency-domain signals.

Ped is the degree or order of excitation of the inputs in Data. A row vector of integers with as many components as there are inputs in Data. The intuitive interpretation of the degree of excitation in an input is the order of a model that the input is capable of estimating in an unambiguous way.

Maxnr is the maximum order tested. Default is  $\min(N/3, 50)$ , where N is the number of input data.

Threshold is the threshold level used to measure which singular values are significant. Default is  $1e-9$ .

**References** Section 13.2 in Ljung (1999).

**Purpose** Polynomial model parameters from single-input and single-output idpoly object

**Syntax** [A,B,C,D,F] = polydata(m)  
[A,B,C,D,F,dA,dB,dC,dD,dF] = polydata(m)

**Description** This is essentially the inverse of the idpoly constructor. It returns the polynomials of the general model

$$A(q)y(t) = \frac{B_1(q)}{F_1(q)}u_1(t-nk_1) + \dots + \frac{B_{nu}(q)}{F_{nu}(q)}u_{nu}(t-nk_{nu}) + \frac{C(q)}{D(q)}e(t)$$

as contained in the model m.

dA, dB, etc. are the standard deviations of A, B, etc.

m can be any single-output idmodel, that is, not just idpoly.

For multiple-output models you can use [A,B,C,D,F] = polydata(m(ky,:)) to obtain the polynomials for the kyth output.

<b>Purpose</b>	Generate custom regressors by computing powers and products of standard regressors
<b>Syntax</b>	<pre>polyreg(model, 'MaxPower', n) polyreg(model, 'MaxPower', n, 'CrossTerm', 'on') polyreg(model, 'MaxPower', n, 'CrossTerm', 'off')</pre>
<b>Input</b>	<p><code>model</code> Name of the <code>idnlarx</code> model object.</p> <p><code>MaxPower</code>—<code>n</code> Property-value pair specifies the maximum power of the multivariable polynomial in terms of standard regressors of the model.  Default: 2.</p> <p><code>CrossTerms</code>—'on' or 'off' Property-value pair specifies whether to include or exclude cross-terms of the polynomial, or products of standard regressors.  Default: 'off'.</p>
<b>Description</b>	<p><code>polyreg</code> is a method of the <code>idnlarx</code> model object.</p> <p><code>polyreg(model, 'MaxPower', n)</code> adds one or more custom regressors to nonlinear ARX model <code>model</code>. Custom regressors are powers of custom regressors up to the maximum power <code>n</code>, but excluding terms of power 1.</p> <p><code>polyreg(model, 'MaxPower', n, 'CrossTerm', 'on')</code> one or more custom regressors to nonlinear ARX model <code>model</code> and includes cross-terms of the polynomial (products of standards regressors).</p> <p><code>polyreg(model, 'MaxPower', n, 'CrossTerm', 'off')</code> one or more custom regressors to nonlinear ARX model <code>model</code> and excludes cross-terms of the polynomial (products of standards regressors).</p>

## Examples

### Example 1

Consider a model  $M$  that has three standard regressors:  $a$ ,  $b$  and  $c$ . The following command creates sixteen custom regressors corresponding to all second and third order polynomials:

```
R = polyreg(M, 'MaxPower', 3, 'CrossTerm', 'on')
```

These custom regressors include  $a^2$ ,  $b^2$ ,  $c^2$ ,  $a*b$ ,  $a*c$ ,  $b*c$ ,  $a^2*b$ ,  $a^2*c$ ,  $a*b^2$ ,  $a*b*c$ ,  $a*c^2$ ,  $b^2*c$ ,  $b*c^2$ ,  $a^3$ ,  $b^3$ , and  $c^3$ .

### Example 2

```
% Construct a nonlinear ARX model that is  
% linear in the regressors.  
M=idnlarx([2 2 1], 'linear')  
% Define custom regressors with default settings,  
% which include second-order polynomials of standard  
% regressors and no cross-terms.  
P=polyreg(M)  
% Estimate model using custom regressors  
% in the nonlinear block.  
M=pem(Data, M, 'customreg', P)
```

**Purpose** Class representing single-variable polynomial nonlinear estimator for Hammerstein-Wiener models

**Syntax**

```
t=poly1d('Degree',n)
t=poly1d('Coefficients',C)
t=poly1d(n)
```

**Description** poly1d is an object that stores the single-variable polynomial nonlinear estimator for Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

t=poly1d('Degree',n) creates a polynomial nonlinearity estimator object of nth degree.

t=poly1d('Coefficients',C) creates a polynomial nonlinearity estimator object with coefficients C.

t=poly1d(n) a polynomial nonlinearity estimator object of nth degree.

Use evaluate(p,x) to compute the value of the function defined by the poly1d object p at x.

**Remarks** Use poly1d to define a nonlinear function  $y = F(x)$ , where  $F$  is a single-variable polynomial function of  $x$ :

$$F(x) = c(1)x^n + c(2)x^{(n-1)} + \dots + c(n)x + c(n+1)$$

**poly1d Properties** After creating the object, you can use get or dot notation to access the object property values. For example:

```
% List all property values
get(p)
% Get value of Coefficients property
p.Coefficients
```

# poly1d

---

Property Name	Description
Degree	Positive integer specifies the degree of the polynomial Default=1. For example: <pre>poly1d('Degree',3)</pre>
Coefficients	1-by-(n+1) matrix containing the polynomial coefficients.

## Examples

Use `poly1s` to specify the single-variable polynomial nonlinearity estimator in Hammerstein-Wiener models. For example:

```
m=n1hw(Data,Orders,poly1d('deg',3),[]);
```

where 'deg' is an abbreviation for the property 'Degree'.

## See Also

`n1hw`

**Purpose**

Predict output  $k$  steps ahead

**Syntax**

```
yp = predict(m,data)
[yp,x0p,mpred] = predict(m,data,k,'InitialState',init)
```

**Description**

`data` is the output-input data as an `iddata` object, and `m` is any `idmodel` or `idnlmodel` object. `predict` is meaningful only for time-domain data.

The argument `k` indicates that the  $k$  step-ahead prediction of  $y$  according to the model `m` is computed. In the calculation of  $yp(t)$ , the model can use outputs up to time

$$t-k:y(s),s = t-k:t-k-1,\dots$$

and inputs up to the current time  $t$ . The default value of `k` is 1.

The output `yp` is an `iddata` object containing the predicted values as `OutputData`.

`x0p` is the used (estimated) initial state vector. For multiexperiment data, `x0p` is a matrix, whose columns contain the initial states for each experiment.

The output argument `mpred` contains the  $k$  step-ahead predictor. This is given as a cell array, whose  $k$ th entry is an `idpoly` model for the predictor of output number  $k$ . Note that these predictor models have as input both input and output signals in the data set. The channel names indicate how the predictor model and the data fit together.

`init` determines how to deal with the initial state:

- `init = 'e(stimate)'`: The initial state is set to a value that minimizes the norm of the prediction error associated with the model and the data.
- `init = 'd(elayexpand)'`: Same as 'estimate', but for a model with nonzero `InputDelay`, the delays are first converted to explicit model delays (using `inpd2nk`) so that they are contained in `x0p`.
- `init = 'z(ero)'` sets the initial state to zero.

- `init = 'm(odel)'` uses the model's internally stored initial state.
- `init = x0`, where `x0` is a column vector of appropriate dimension, uses that value as initial state. For multiexperiment data, `x0` can be a matrix whose columns give different initial states for each experiment. For a continuous-time model `m`, `x0` is the initial state for this model. Any modifications of the initial state that sampling might require are automatically handled. If `m` has a non-zero `InputDelay`, and you need to access the values of the inputs during this delay, you must first apply `inpd2nk(m)`. When `m` is a continuous-time model, it must first be sampled before `inpd2nk` can be applied.

If `init` is not specified for linear models, its value is determined, as follows:

- If `m.InitialState` is 'Estimate', 'Backcast', and 'Auto', `init = 'Estimate'`.
- If `m.InitialState` is 'Zero', `init = 'zero'`.
- If `m.InitialState` is 'Model' or 'Fixed', `init = 'model'`. For `idss`, `idproc`, and `idgrey` models, `init` corresponds to the `m.x0` values. For other linear models, `init = 'zero'`.

If `init` is not specified for `idnlgrey` models, `init = 'Model'` is the default. The values and their estimation behavior are inherited from `m.InitialStates`.

If `init` is not specified for `idnlarx` models, `init = 'Estimate'` is the default. This corresponds to the first few samples of predicted outputs exactly matching the first few output samples in the data set.

If `init` is not specified for `idnlhw` models, `init = 'Estimate'` is the default. This computes initial states by minimizing the prediction errors over the available data range.

An important use of `predict` is to evaluate a model's properties in the mid-frequency range. Simulation with `sim` (which conceptually corresponds to `k = inf`) can lead to levels that drift apart, since the low-frequency behavior is emphasized. One step-ahead prediction is

not a powerful test of the model's properties, since the high-frequency behavior is stressed. The trivial predictor  $\hat{y}(t) = y(t-1)$  can give good predictions in case the sampling of the data is fast.

Another important use of `predict` is to evaluate time-series models. The natural way of studying a time-series model's ability to reproduce observations is to compare its  $k$  step-ahead predictions with actual data.

Note that for output-error models, there is no difference between the  $k$  step-ahead predictions and the simulated output, since, by definition, output-error models only use past inputs to predict future outputs.

## Algorithm

The model is evaluated in state-space form, and the state equations are simulated  $k$  steps ahead with initial value  $x(t-k) = \hat{x}(t-k)$ , where  $\hat{x}(t-k)$  is the Kalman filter state estimate.

## Examples

Simulate a time series, estimate a model based on the first half of the data, and evaluate the four step-ahead predictions on the second half.

```
m0 = idpoly([1 -0.99],[],[1 -1 0.2]);  
e = iddata([],randn(400,1));  
y = sim(m0,e);  
m = armax(y(1:200),[1 2]);  
yp = predict(m,y,4);  
plot(y(201:400),yp(201:400))
```

Note that the last two commands are also achieved by

```
compare(y,m,4,201:400);
```

# predict(idnlarx)

---

## Purpose

Predict output  $k$  steps ahead for nonlinear ARX model

## Syntax

```
YP = predict(MODEL,DATA,K)
YP = predict(SYS,DATA,K,INIT)
YP = predict(MODEL,DATA,K,'InitialState',INIT)
```

## Description

YP = predict(MODEL,DATA,K) predicts the  $k$ -step ahead output with an idnlarx model.

YP = predict(SYS,DATA,K,INIT) or YP = predict(MODEL,DATA,K,'InitialState',INIT) specifies the initialization.

## Input

- MODEL: idnlarx model object.
- DATA: iddata object.
- K: Prediction horizon. Old outputs up to time  $t-K$  are used to predict the output at time  $t$ . All relevant inputs are used. Default value:  $K = 1$ ).
- INIT: initialization specification. INIT can be the following:
  - 'e': Assume the initial states of the model are such that the first  $N$  values of the predicted output match the first  $N$  samples of the measured output exactly, where  $N$  is the maximum channel delay in the model ( $N = \max(\text{getDelayInfo}(\text{model}))$ ). The initial states are not computed explicitly, but are assumed to exist. The prediction starts at the  $(N+1)^{\text{th}}$  sample, while a perfect match is assumed for the first  $N$  samples. If you want prediction of response values starting from the first data sample, you must estimate and provide the initial state vector explicitly as described in the following option for  $\text{INIT} = X0$ .
  - Real column vector  $X0$ , for the state vector corresponding to an appropriate number of output and input data samples prior to the simulation start time. To build an initial state vector from a given set of input-output data or to generate equilibrium states, use `data2state(idnlarx)`, `findstates(idnlarx)` or

`findop(idnlarx)`. For multi-experiment data, `X0` may be a matrix whose columns give different initial states for different experiments.

- `'z'`: (Default) Zero initial state, equivalent to a zero vector of appropriate size.
- `iddata` object containing output and input data samples prior to the simulation start time. If it contains more data samples than necessary, only the last samples are taken into account. This syntax is equivalent to `sim(MODEL, U, 'InitialState', data2state(MODEL, INIT))` where `data2state(idnlarx)` transforms the `iddata` object `INIT` to a state vector.

## Output

`YP`: Predicted output as an `iddata` object. If `DATA` contains multiple experiments, so will `YP`.

---

**Note** If `predict` is called without an output argument, MATLAB software displays the predicted output(s) in a plot window.

---

# predict(idnlgrey)

---

**Purpose** Predict output  $k$  steps ahead for nonlinear ODE model

**Syntax**

```
YP = predict(NLSYS,DATA);  
[YP,X0,XFINAL] = predict(NLSYS,DATA);  
[YP,X0,XFINAL] = predict(NLSYS,DATA,K);  
[YP,X0,XFINAL] = predict(NLSYS,DATA,K,X0INIT);
```

**Description**

`YP = predict(NLSYS,DATA);` predicts the  $k$ -step ahead output with an `idnlgrey` model.

`[YP,X0,XFINAL] = predict(NLSYS,DATA);` returns the initial states used in the prediction as well as the final states computed, in addition to the predicted output.

`[YP,X0,XFINAL] = predict(NLSYS,DATA,K);` specifies the prediction horizon to use during prediction.

`[YP,X0,XFINAL] = predict(NLSYS,DATA,K,X0INIT);` specifies the initialization for the  $k$ -step ahead prediction.

**Input**

- `NLSYS`: `idnlgrey` model for which output is to be predicted.
- `DATA`: Input-output data `[Y U]`. `U` is the input data that can be given either as an `iddata` object or as a matrix `U = [U1 U2 ... Um]`, where the  $k$ :th column vector is input  $U_k$ . Similarly, `Y` is either an `iddata` object or a matrix of outputs (with as many columns as there are outputs). For time-continuous `idnlgrey` objects, `DATA` passed as a matrix will lead to that the data sample interval, `Ts`, is set to one.
- `K`: Prediction horizon. `K` and can be set to an integer between 1 and `inf` (pure simulation). As `idnlgrey` assumes an output error model structure, where prediction and simulation coincide, `K` has no meaning.
- `X0INIT`: Initial state to use. It can take the following values:
  - `'zero'` : Zero initial state  $x(0)$  with all states fixed (`nlsys.InitialStates.Fixed` is thus ignored).

- 'fixed': (or NLSYS.InitialState) Determines the values of the model initial states, but all states are fixed (NLSYS.InitialStates.Fixed is ignored).
- 'estimate': NLSYS.InitialState determines the value of the initial states and all initial states are estimated (NLSYS.InitialStates.Fixed is ignored).
- (Default) 'model': NLSYS.InitialState determines the value of the initial states, which initial states to estimate, and minimum and maximum state values.
- vector/matrix: Column vector of initial states. For multiple-experiment DATA,  $x(0)$  can be a matrix where each column contains initial states for the corresponding experiment. All initial states are fixed (nlsys.InitialStates.Fixed is ignored).
- struct array : An Nx-by-1 structure array with fields:
  - Name: Name of the state (a string).
  - Unit: Unit of the state (a string).
  - Value: Value of the states (a finite real 1-by-Ne vector, where Ne is the number of experiments.)
  - Minimum: Minimum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same minimum value).
  - Maximum: Maximum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same maximum value).
  - (Default) Fixed: Uses initial state values from NLSYS.InitialState.Value. Ignores NLSYS.InitialState.Fixed.

The initial state can also be specified using the property-value pair InitialState or X0, followed by the value X0INIT. For example:  
predict(NLSYS,DATA,K, 'InitialState', X0INIT).

# predict(idnlgrey)

---

## Output

- **YP**: Predicted output. If **DATA** is an **iddata** object, then **YP** will also be an **iddata** object. Otherwise, **YP** will be a matrix where the **k**:th output is found in the **k**:th column of **YP**. If **DATA** is a multiple experiment **iddata** object, then **YP** will be as well.
- **X0**: Initial states. In the single experiment case it is a column vector of length **Nx**. For multi-experiment data, **X0** is an **Nx**-by-**Ne** matrix with the **i**th column specifying the initial state of experiment **i**.
- **XFINAL**: Final states computed. In the single experiment case it is a column vector of length **Nx**. For multi-experiment data, **XFINAL** is an **Nx**-by-**Ne** matrix with the **i**th column specifying the initial state of experiment **i**.

---

**Note** If **predict** is called without an output argument, **MATLAB** software displays the predicted output(s) in a plot window.

`findop(idnlhw)`  
`findstates(idnlhw)`  
`sim(idnlhw)`

**Purpose** Display model information, including estimated uncertainty

**Syntax** `present(m)`

**Description** The `present` function displays the model `m`, together with the estimated standard deviations of the parameters, loss function, and Akaike's Final Prediction Error (FPE) Criterion (which essentially equals the AIC). It also displays information about how `m` was created.

`m` is any `idmodel` or `idnlmodel` object.

`present` thus gives more detailed information about the model than the standard `display` function.

<b>Purpose</b>	Class representing piecewise-linear nonlinear estimator for Hammerstein-Wiener models
<b>Syntax</b>	<pre>t=pwlinear('NumberOfUnits',N) t=pwlinear('BreakPoints',BP) t=pwlinear(Property1,Value1,...PropertyN,ValueN)</pre>
<b>Description</b>	<p><code>pwlinear</code> is an object that stores the piecewise-linear nonlinear estimator for estimating Hammerstein-Wiener models.</p> <p>You can use the constructor to create the nonlinearity object, as follows:</p> <p><code>t=pwlinear('NumberOfUnits',N)</code> creates a piecewise-linear nonlinearity estimator object with <math>N</math> breakpoints.</p> <p><code>t=pwlinear('BreakPoints',BP)</code> creates a piecewise-linear nonlinearity estimator object with breakpoints at values <math>BP</math>.</p> <p><code>t=pwlinear(Property1,Value1,...PropertyN,ValueN)</code> creates a piecewise-linear nonlinearity estimator object specified by properties in “<code>pwlinear Properties</code>” on page 2-335.</p> <p>Use <code>evaluate(p,x)</code> to compute the value of the function defined by the <code>pwlinear</code> object <code>p</code> at <math>x</math>.</p>
<b>Remarks</b>	<p>Use <code>pwlinear</code> to define a nonlinear function <math>y = F(x)</math>, where <math>F</math> is a piecewise-linear (affine) function of <math>x</math> and there are <math>n</math> breakpoints <math>(x_k, y_k)</math>, <math>k=1, \dots, n</math>. <math>y_k = F(x_k)</math>. <math>F</math> is linearly interpolated between the breakpoints.</p> <p><math>y</math> and <math>x</math> are scalars.</p> <p><math>F</math> is also linear to the left and right of the extreme breakpoints. The slope of these extension is a function of <math>x_i</math> and <math>y_i</math> breakpoints. The breakpoints are ordered by ascending <math>x</math>-values, which is important when you set a specific breakpoint to a different value.</p> <p>There are minor deviations from the breakpoint values you set and the values actually stored in the object because the toolbox represent breakpoints differently internally.</p>

**pwlinear Properties**

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
get(p)
% Get value of NumberOfUnits property
p.NumberOfUnits
```

Property Name	Description
NumberOfUnits	Integer specifies the number of breakpoints. Default=10.  For example:  <code>pwlinear('NumberOfUnits',5)</code>
BreakPoints	2-by-n matrix containing the breakpoint x and y value, specified using the following format:  <code>[x_1,x_2,...,x_n;y_1,y_2,...,y_n]</code>  If set to a 1-by-n vector, the values are interpreted as x-values and the corresponding y-values are set to zero.

**Examples**

Use `pwlinear` to specify the piecewise nonlinearity estimator in Hammerstein-Wiener models. For example:

```
m=n1hw(Data,Orders,pwlinear('Br',[-1:0.1:1]),[]);
```

The piecewise nonlinearity is initialized at the specified breakpoints. The breakpoint values are adjusted to the estimation data by `n1hw`.

**See Also**

`n1hw`

**Purpose** Plot zeros and poles with confidence interval

**Syntax**

```
pzmap(m)
pzmap(m, 'sd', sd)
pzmap(m1, m2, m3, ...)
pzmap(m1, 'PlotStyle1', m2, 'PlotStyle2', ..., 'sd', sd)
pzmap(m1, m2, m3, ..., 'sd', sd, 'mode', mode, 'axis', axis)
```

**Description** `m` is any `idmodel` object: `idarx`, `idgrey`, `idss`, `idproc`, or `idpoly`.  
The zeros and poles of `m` are graphed, with `o` denoting zeros and `x` denoting poles. Poles and zeros at infinity are ignored. For discrete-time models, zeros and poles at the origin are also ignored.

The Property/Value pairs `'sd'/sd`, `'mode'/mode` and `'axis'/axis` can appear in any order. They are explained below.

If `sd` has a value larger than zero, confidence regions around the poles and zeros are also graphed. The regions corresponding to `sd` standard deviations are marked. The default value is `sd = 0`. Note that the confidence regions might sometimes stretch outside the plot, but they are always symmetric around the indicated zero or pole.

If the poles and zeros are associated with a discrete-time model, a unit circle is also drawn. For continuous-time models, the real and imaginary axes are drawn.

When `mi` contains information about several different input/output channels, you have the following options:

`mode = 'sub'` splits the screen into several plots, one for each input/output channel. These are based on the `InputName` and `OutputName` properties associated with the different models.

`mode = 'same'` gives all plots in the same diagram. Pressing the **Enter** key advances the plots.

`mode = 'sep'` erases the previous plot before the next channel pair is treated.

The default value is `mode = 'sub'`.

`axis = [x1 x2 y1 y2]` fixes the axis scaling accordingly. `axis = s` is the same as

$$\text{axis} = [-s \ s \ -s \ s]$$

You can select the colors associated with the different models by using the argument `PlotStyle`. Use `PlotStyle = 'b', 'g', etc.` Markers and line styles are not used.

The noise input channels in `m` are treated as follows: Consider a model `m` with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$\begin{aligned} y &= Gu + He \\ \text{cov}(e) &= \Lambda = LL' \end{aligned}$$

where  $L$  is a lower triangular matrix. Note that `m.NoiseVariance =  $\Lambda$` . The model can also be described with a unit variance, using a normalized noise source  $v$ .

$$\begin{aligned} y &= Gu + HLv \\ \text{cov}(v) &= I \end{aligned}$$

Then,

- `pzmap(m)` plots the zeros and poles of the transfer function  $G$ .
- `pzmap(m('n'))` plots the zeros and poles of the transfer function  $H$  ( $ny$  inputs and  $ny$  outputs). The input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- If `m` is a time series, that is  $nu = 0$ , `pzmap(m)` plots the zeros and poles of the transfer function  $H$ .
- `pzmap(noiseconv(m))` plots the zeros and poles of the transfer function  $[G \ H]$  ( $nu+ny$  inputs and  $ny$  outputs). The noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.

- `pzmap(noiseconv(m, 'norm'))` plots the zeros and poles of the transfer function  $[G \ HL]$  ( $nu+ny$  inputs and  $ny$  outputs). The noise input channels have names `v@yname`, where `yname` is the name of the corresponding output.

## Examples

```
mbj = bj(data,[2 2 1 1 1]);  
mar = armax(data,[2 2 2 1]);  
pzmap(mbj,mar,'sd',3)
```

shows all zeros and poles of two models along with the confidence regions corresponding to three standard deviations.

## See Also

`idmodel`  
`zpkdata`

**Purpose** Estimate recursively parameters of ARMAX or ARMA models

**Syntax** `thm = rarmax(z,nn,adm,adg)`  
`[thm,yhat,P,phi,psi] = rarmax(z,nn,adm,adg,th0,P0,phi0,psi0)`

**Description** The parameters of the ARMAX model structure

$$A(q)y(t) = B(q)u(t-nk) + C(q)e(t)$$

are estimated using a recursive prediction error method.

The input-output data is contained in `z`, which is either an `iddata` object or a matrix `z = [y u]` where `y` and `u` are column vectors. `nn` is given as

$$nn = [na \ nb \ nc \ nk]$$

where `na`, `nb`, and `nc` are the orders of the ARMAX model, and `nk` is the delay. Specifically,

$$na: \quad A(q) = 1 + a_1q^{-1} + \dots + a_{na}q^{-na}$$

$$nb: \quad B(q) = b_1 + b_2q^{-1} + \dots + b_{nb}q^{-nb+1}$$

$$nc: \quad C(q) = 1 + c_1q^{-1} + \dots + c_{nc}q^{-nc}$$

See “What Are Black-Box Polynomial Models?” for more information.

If `z` represents a time series `y` and `nn = [na nc]`, `rarmax` estimates the parameters of an ARMA model for `y`.

$$A(q)y(t) = C(q)e(t)$$

Only single-input, single-output models are handled by `rarmax`. Use `rpem` for the multiple-input case.

The estimated parameters are returned in the matrix `thm`. The `k`th row of `thm` contains the parameters associated with time `k`; that is, they are based on the data in the rows up to and including row `k` in `z`. Each row of `thm` contains the estimated parameters in the following order:

```
thm(k,:) = [a1,a2,...,ana,b1,...,bnb,c1,...,cnc]
```

yhat is the predicted value of the output, according to the current model; that is, row  $k$  of yhat contains the predicted value of  $y(k)$  based on all past data.

The actual algorithm is selected with the two arguments adm and adg. These are described under rarx.

The input argument th0 contains the initial value of the parameters, a row vector consistent with the rows of thm. The default value of th0 is all zeros.

The arguments P0 and P are the initial and final values, respectively, of the scaled covariance matrix of the parameters. See rarx. The default value of P0 is  $10^4$  times the unit matrix. The arguments phi0, psi0, phi, and psi contain initial and final values of the data vector and the gradient vector, respectively. The sizes of these depend on the chosen model orders. The normal choice of phi0 and psi0 is to use the outputs from a previous call to rarmax with the same model orders. (This call could be a dummy call with default input arguments.) The default values of phi0 and psi0 are all zeros.

Note that the function requires that the delay nk be larger than 0. If you want  $n_k = 0$ , shift the input sequence appropriately and use  $n_k = 1$ .

## Algorithm

The general recursive prediction error algorithm (11.44), (11.47) through (11.49) of Ljung (1999) is implemented. See “Algorithms for Recursive Estimation” for more information.

## Examples

Compute and plot, as functions of time, the four parameters in a second-order ARMA model of a time series given in the vector y. The forgetting factor algorithm with a forgetting factor of 0.98 is applied.

```
thm = rarmax(y,[2 2], 'ff', 0.98);  
plot(thm)
```

**Purpose**

Estimate parameters of ARX or AR models recursively

**Syntax**

```
thm = rarx(z,nn,adm,adg)
[thm,yhat,P,phi] = rarx(z,nn,adm,adg,th0,P0,phi0)
```

**Description**

`thm = rarx(z,nn,adm,adg)` estimates the parameters `thm` of single-output ARX model from input-output data `z` and model orders `nn` using the algorithm specified by `adm` and `adg`. If `z` is a time series `y` and `nn = na`, `rarx` estimates the parameters of a single-output AR model.

`[thm,yhat,P,phi] = rarx(z,nn,adm,adg,th0,P0,phi0)` estimates the parameters `thm`, the predicted output `yhat`, final values of the scaled covariance matrix of the parameters `P`, and final values of the data vector `phi` of single-output ARX model from input-output data `z` and model orders `nn` using the algorithm specified by `adm` and `adg`. If `z` is a time series `y` and `nn = na`, `rarx` estimates the parameters of a single-output AR model.

**Definitions**

The ARX model structure is defined, as follows:

$$A(q)y(t) = B(q)u(t-nk) + e(t)$$

$$na: \quad A(q) = 1 + a_1q^{-1} + \dots + a_{na}q^{-na}$$

$$nb: \quad B(q) = b_1 + b_2q^{-1} + \dots + b_{nb}q^{-nb+1}$$

Models with several inputs are defined, as follows:

$$A(q)y(t) = B_1(q)u_1(t-nk_1) + \dots + B_{nu}(q)u_{nu}(t-nk_{nu}) + e(t)$$

**Inputs**

`z`

Name of the matrix `iddata` object that represents the input-output data or a matrix `z = [y u]`, where `y` and `u` are column vectors.

For multiple-input models, the `u` matrix contains each input as a column vector:

$$u = [u_1 \dots u_n]$$

**nn**

For input-output models, specifies the structure of the ARX model as:

$$nn = [na \ nb \ nk]$$

where  $na$  and  $nb$  are the orders of the ARX model, and  $nk$  is the delay.

For multiple-input models,  $nb$  and  $nk$  are row vectors that define orders and delays for each input.

For time-series models,  $nn = na$ , where  $na$  is the order of the AR model.

---

**Note** The delay  $nk$  must be larger than 0. If you want  $nk = 0$ , shift the input sequence appropriately and use  $nk = 1$  (see `nkshift`).

---

**adm and adg**

$adm = 'ff'$  and  $adg = lam$  specify the *forgetting factor* algorithm with the forgetting factor  $\lambda = lam$ . This algorithm is also known as recursive least squares (RLS). In this case, the matrix  $P$  has the following interpretation:  $R_y/2 * P$  is approximately equal to the covariance matrix of the estimated parameters.  $R_y$  is the variance of the innovations (the true prediction errors  $e(t)$ ).

$adm = 'ug'$  and  $adg = gam$  specify the *unnormalized gradient* algorithm with gain  $gamma = gam$ . This algorithm is also known as the normalized least mean squares (LMS).

`adm = 'ng'` and `adg = gam` specify the *normalized gradient* or normalized least mean squares (NLMS) algorithm. In these cases, `P` is not applicable.

`adm = 'kf'` and `adg = R1` specify the *Kalman filter based* algorithm with  $R_2=1$  and  $R_1 = R1$ . If the variance of the innovations  $e(t)$  is not unity but  $R_2$ ; then  $R_2^* P$  is the covariance matrix of the parameter estimates, while  $R_1 = R1 / R_2$  is the covariance matrix of the parameter changes.

`th0`

Initial value of the parameters in a row vector, consistent with the rows of `thm`.

Default: All zeros.

`P0`

Initial values of the scaled covariance matrix of the parameters.

Default:  $10^4$  times the identity matrix.

`phi0`

The argument `phi0` contains the initial values of the data vector:

$$\varphi(t) = [y(t-1), \dots, y(t-na), u(t-1), \dots, u(t-nb-nk+1)]$$

If  $z = [y(1), u(1); \dots ; y(N), u(N)]$ , `phi0` =  $\varphi(1)$  and `phi` =  $\varphi(N)$ . For online use of `rarx`, use `phi0`, `th0`, and `P0` as the previous outputs `phi`, `thm` (last row), and `P`.

Default: All zeros.

## Outputs

`thm`

Estimated parameters of the model. The  $k$ th row of `thm` contains the parameters associated with time  $k$ ; that is, the estimate parameters are based on the data in rows up to and including row  $k$  in `z`. Each row of `thm` contains the estimated parameters in the following order:

$$\text{thm}(k, :) = [a_1, a_2, \dots, a_n, b_1, \dots, b_n]$$

For a multiple-input model, the  $b$  are grouped by input. For example, the  $b$  parameters associated with the first input are listed first, and the  $b$  parameters associated with the second input are listed next.

yhat

Predicted value of the output, according to the current model; that is, row  $k$  of yhat contains the predicted value of  $y(k)$  based on all past data.

P

Final values of the scaled covariance matrix of the parameters.

phi

phi contains the final values of the data vector:

$$\varphi(t) = [y(t-1), \dots, y(t-na), u(t-1), \dots, u(t-nb-nk+1)]$$

## Examples

Adaptive noise canceling: The signal  $y$  contains a component that originates from a known signal  $r$ . Remove this component by recursively estimating the system that relates  $r$  to  $y$  using a sixth-order FIR model and the NLMS algorithm.

```
z = [y r];
[thm,noise] = rarx(z,[0 6 1], 'ng', 0.1);
% noise is the adaptive estimate of the noise
% component of y
plot(y-noise)
```

If this is an online application, you can plot the best estimate of the signal  $y - \text{noise}$  at the same time as the data  $y$  and  $u$  become available, use the following code:

```
phi = zeros(6,1);
P=1000*eye(6);
th = zeros(1,6);
```

```
axis([0 100 -2 2]);
plot(0,0,'*'), hold on
% Use a while loop
while ~abort
[y,r,abort] = readAD(time);
[th,ns,P,phi] = rarx([y r], 'ff',0.98,th,P,phi);
plot(time,y-ns,'*')
time = time + Dt
end
```

This example uses a forgetting factor algorithm with a forgetting factor of 0.98. `readAD` is an M-file that reads the value of an A/D converter at the indicated time instant.

“Algorithms for Recursive Estimation”

**Purpose** Estimate recursively parameters of Box-Jenkins models

**Syntax**  
`thm = rbj(z, nn, adm, adg)`  
`[thm, yhat, P, phi, psi] = rbj(z, nn, adm, adg, th0, P0, phi0, psi0)`

**Description** The parameters of the Box-Jenkins model structure

$$y(t) = \frac{B(q)}{F(q)}u(t - nk) + \frac{C(q)}{D(q)}e(t)$$

are estimated using a recursive prediction error method.

The input-output data is contained in `z`, which is either an `iddata` object or a matrix `z = [y u]` where `y` and `u` are column vectors. `nn` is given as

$$nn = [nb \ nc \ nd \ nf \ nk]$$

where `nb`, `nc`, `nd`, and `nf` are the orders of the Box-Jenkins model, and `nk` is the delay. Specifically,

$$nb: \quad B(q) = b_1 + b_2q^{-1} + \dots + b_{nb}q^{-nb+1}$$

$$nc: \quad C(q) = 1 + c_1q^{-1} + \dots + c_{nc}q^{-nc}$$

$$nd: \quad D(q) = 1 + d_1q^{-1} + \dots + d_{nd}q^{-nd}$$

$$nf: \quad F(q) = 1 + f_1q^{-1} + \dots + f_{nf}q^{-nf}$$

See “What Are Black-Box Polynomial Models?” for more information.

Only single-input, single-output models are handled by `rbj`. Use `rpem` for the multiple-input case.

The estimated parameters are returned in the matrix `thm`. The `k`th row of `thm` contains the parameters associated with time `k`; that is, they are based on the data in the rows up to and including row `k` in `z`. Each row of `thm` contains the estimated parameters in the following order.

$$\text{thm}(k,:) = [b_1, \dots, b_{nb}, c_1, \dots, c_{nc}, d_1, \dots, d_{nd}, f_1, \dots, f_{nf}]$$

$\text{yhat}$  is the predicted value of the output, according to the current model; that is, row  $k$  of  $\text{yhat}$  contains the predicted value of  $y(k)$  based on all past data.

The actual algorithm is selected with the two arguments  $\text{adm}$  and  $\text{adg}$ . These are described under  $\text{rarx}$ .

The input argument  $\text{th0}$  contains the initial value of the parameters, a row vector consistent with the rows of  $\text{thm}$ . The default value of  $\text{th0}$  is all zeros.

The arguments  $\text{P0}$  and  $\text{P}$  are the initial and final values, respectively, of the scaled covariance matrix of the parameters. See  $\text{rarx}$ . The default value of  $\text{P0}$  is  $10^4$  times the unit matrix. The arguments  $\text{phi0}$ ,  $\text{psi0}$ ,  $\text{phi}$ , and  $\text{psi}$  contain initial and final values of the data vector and the gradient vector, respectively. The sizes of these depend on the chosen model orders. The normal choice of  $\text{phi0}$  and  $\text{psi0}$  is to use the outputs from a previous call to  $\text{rbj}$  with the same model orders. (This call could be a dummy call with default input arguments.) The default values of  $\text{phi0}$  and  $\text{psi0}$  are all zeros.

Note that the function requires that the delay  $n_k$  be larger than 0. If you want  $n_k = 0$ , shift the input sequence appropriately and use  $n_k = 1$ .

## Algorithm

The general recursive prediction error algorithm (11.44) of Ljung (1999) is implemented. See also “Algorithms for Recursive Estimation”.

# realdata

---

**Purpose** Determine whether iddata is based on real-valued signals

**Syntax** `realdata(data)`

**Description** `realdata` returns 1 if

- `data` contains only real-valued signals.
- `data` contains frequency-domain signals, obtained by Fourier transformation of real-valued signals.

Otherwise `realdata` returns 0.

Notice the difference with `isreal`:

```
load iddata1
isreal(z1); % returns 1
zf = fft(z1);
isreal(zf) % returns 0
realdata(zf) % returns 1
zf = complex(zf) % adds negative frequencies to zf
realdata(zf) % still returns 1
```

<b>Purpose</b>	Resample time-domain data by decimation or interpolation (requires Signal Processing Toolbox software)
<b>Syntax</b>	<code>resample(data,P,Q)</code> <code>resample(data,P,Q,order)</code>
<b>Description</b>	<p><code>resample(data,P,Q)</code> resamples data such that the data is interpolated by a factor <math>P</math> and then decimated by a factor <math>Q</math>. <code>resample(z,1,Q)</code> results in decimation by a factor <math>Q</math>.</p> <p><code>resample(data,P,Q,order)</code> filters the data by applying a filter of specified order before interpolation and decimation.</p>
<b>Input</b>	<p><code>data</code> Name of time-domain <code>iddata</code> object. Can be input-output or time-series data.</p> <p>Data must be sampled at equal time intervals.</p> <p><code>P, Q</code> Integers that specify the resampling factor, such that the new sampling interval is <math>Q/P</math> times the original one.</p> <p><math>(Q/P) &gt; 1</math> results in decimation and <math>(Q/P) &lt; 1</math> results in interpolation.</p> <p><code>order</code> Order of the filters applied before interpolation and decimation.</p> <p>Default: 10</p>
<b>Algorithm</b>	If you have installed the Signal Processing Toolbox software, <code>resample</code> calls the Signal Processing Toolbox <code>resample</code> function. The algorithm takes into account the intersample characteristics of the input signal, as described by <code>data.InterSample</code> .
<b>Examples</b>	In this example, you increase the sampling rate by a factor of 1.5 and compare the resampled and the original data signals.

# resample

---

```
plot(u)
ur = resample(u,3,2);
plot(u,ur)
```

idresamp

**Purpose**

Compute and test model residuals (prediction errors)

**Syntax**

```
resid(m,data)
resid(m,data,Type)
resid(m,data,Type,M)
e = resid(m,data);
```

**Description**

`data` contains the output-input data as an `iddata` object. Both time-domain and frequency-domain data are supported. `data` can also be an `idfrd` object.

`m` is any `idmodel` or `idnlmodel` object.

In all cases the residuals  $e$  associated with the data and the model are computed. This is done as in the command `pe` with a default choice of `init`.

When called without output arguments, `resid` produces a plot. The plot can be one of three kinds depending on the argument `Type`:

- `Type = 'Corr'` (only available for time-domain data): The autocorrelation function of  $e$  and the cross correlation between  $e$  and the input(s)  $u$  are computed and displayed. The 99% confidence intervals for these values are also computed and shown as a yellow region. The computation of the confidence region is done assuming  $e$  to be white and independent of  $u$ . The functions are displayed up to lag  $M$ , which is 25 by default.
- `Type = 'ir'`: The impulse response (up to lag  $M$ , which is 25 by default) from the input to the residuals is plotted with a 99% confidence region around zero marked as a yellow area. Negative lags up to  $M/4$  are also included to investigate feedback effects. The result is the same as `impulse(e, 'sd', 2.58, M)`.
- `Type = 'fr'`: The frequency response from the input to the residuals (based on a high-order FIR model) is shown as a Bode plot. A 99% confidence region around zero is also marked as a yellow area.

The default for time-domain data is `Type = 'Corr'`. For frequency-domain data, the default is `Type = 'fr'`.

With an output argument, no plot is produced, and `e` is returned with the residuals (prediction errors) associated with the model and the data. It is an `iddata` object with the residuals as outputs and the input in `data` as inputs. That means that `e` can be directly used to build model error models, that is, models that describe the dynamics from the input to the residuals (which should be negligible if `m` is a good description of the system).

## Examples

Here are some typical model validation commands.

```
e = resid(m,data);  
plot(e)  
compare(data,m);
```

To compute a model error model, that is, a model from the input to the residuals to see if any essential unmodeled dynamics are left, do the following:

```
e = resid(m,data);  
me = arx(e,[10 10 0]);  
bode(me,'sd',3,'fill')
```

## References

Ljung (1999), Section 16.6.

## See Also

`compare`  
`predict`  
`sim`  
`simsd`

**Purpose**

Estimate recursively output-error models (IIR-filters)

**Syntax**

```
t hm = roe(z,nn,adm,adg)
[ t hm,yhat,P,phi,psi] = roe(z,nn,adm,adg,th0,P0,phi0,psi0)
```

**Description**

The parameters of the output-error model structure

$$y(t) = \frac{B(q)}{F(q)}u(t - nk) + e(t)$$

are estimated using a recursive prediction error method.

The input-output data are contained in `z`, which is either an `iddata` object or a matrix  $z = [y \ u]$  where `y` and `u` are column vectors. `nn` is given as

$$nn = [nb \ nf \ nk]$$

where `nb` and `nf` are the orders of the output-error model, and `nk` is the delay. Specifically,

$$nb: \quad B(q) = b_1 + b_2q^{-1} + \dots + b_{nb}q^{-nb+1}$$

$$nf: \quad F(q) = 1 + f_1q^{-1} + \dots + f_{nf}q^{-nf}$$

See “What Are Black-Box Polynomial Models?” for more information.

Only single-input, single-output models are handled by `roe`. Use `rpm` for the multiple-input case.

The estimated parameters are returned in the matrix `t hm`. The `k`th row of `t hm` contains the parameters associated with time `k`; that is, they are based on the data in the rows up to and including row `k` in `z`.

Each row of `t hm` contains the estimated parameters in the following order.

$$t hm(k,:) = [b1, \dots, bnb, f1, \dots, fnf]$$

$\hat{y}$  is the predicted value of the output, according to the current model; that is, row  $k$  of  $\hat{y}$  contains the predicted value of  $y(k)$  based on all past data.

The actual algorithm is selected with the two arguments `adg` and `adm`. These are described under `rarx`.

The input argument `th0` contains the initial value of the parameters, a row vector consistent with the rows of `thm`. The default value of `th0` is all zeros.

The arguments `P0` and `P` are the initial and final values, respectively, of the scaled covariance matrix of the parameters. See `rarx`. The default value of `P0` is  $10^4$  times the unit matrix. The arguments `phi0`, `psi0`, `phi`, and `psi` contain initial and final values of the data vector and the gradient vector, respectively. The sizes of these depend on the chosen model orders. The normal choice of `phi0` and `psi0` is to use the outputs from a previous call to `roe` with the same model orders. (This call could be a dummy call with default input arguments.) The default values of `phi0` and `psi0` are all zeros.

Note that the function requires that the delay  $n_k$  be larger than 0. If you want  $n_k = 0$ , shift the input sequence appropriately and use  $n_k = 1$ .

## Algorithm

The general recursive prediction error algorithm (11.44) of Ljung (1999) is implemented. See also “Algorithms for Recursive Estimation”.

## See Also

`nkshift`  
`rarmax`  
`rarx`  
`rbj`  
`rpem`  
`rplr`

**Purpose** Estimate general input-output models using recursive prediction-error minimization method

**Syntax** `thm = rpem(z,nn,adm,adg)`  
`[thm,yhat,P,phi,psi] = rpem(z,nn,adm,adg,th0,P0,phi0,psi0)`

**Description** The parameters of the general linear model structure

$$A(q)y(t) = \frac{B_1(q)}{F_1(q)}u_1(t-nk_1) + \dots + \frac{B_{nu}(q)}{F_{nu}(q)}u_{nu}(t-nk_{nu}) + \frac{C(q)}{D(q)}e(t)$$

are estimated using a recursive prediction error method.

The input-output data is contained in `z`, which is either an `iddata` object or a matrix `z = [y u]` where `y` and `u` are column vectors. (In the multiple-input case, `u` contains one column for each input.) `nn` is given as

$$nn = [na \ nb \ nc \ nd \ nf \ nk]$$

where `na`, `nb`, `nc`, `nd`, and `nf` are the orders of the model, and `nk` is the delay. For multiple-input systems, `nb`, `nf`, and `nk` are row vectors giving the orders and delays of each input. See “What Are Black-Box Polynomial Models?” for an exact definition of the orders.

The estimated parameters are returned in the matrix `thm`. The `k`th row of `thm` contains the parameters associated with time `k`; that is, they are based on the data in the rows up to and including row `k` in `z`. Each row of `thm` contains the estimated parameters in the following order.

$$thm(k,:) = [a_1, a_2, \dots, a_n, b_1, \dots, b_n, \dots, \\ c_1, \dots, c_n, d_1, \dots, d_n, f_1, \dots, f_n]$$

For multiple-input systems, the  $B$  part in the above expression is repeated for each input before the  $C$  part begins, and the  $F$  part is also repeated for each input. This is the same ordering as in `m.par`.

$\hat{y}$  is the predicted value of the output, according to the current model; that is, row  $k$  of  $\hat{y}$  contains the predicted value of  $y(k)$  based on all past data.

The actual algorithm is selected with the two arguments `adg` and `adm`. These are described under `rarx`.

The input argument `th0` contains the initial value of the parameters, a row vector consistent with the rows of `thm`. The default value of `th0` is all zeros.

The arguments `P0` and `P` are the initial and final values, respectively, of the scaled covariance matrix of the parameters. See `rarx`. The default value of `P0` is  $10^4$  times the unit matrix. The arguments `phi0`, `psi0`, `phi`, and `psi` contain initial and final values of the data vector and the gradient vector, respectively. The sizes of these depend on the chosen model orders. The normal choice of `phi0` and `psi0` is to use the outputs from a previous call to `rpem` with the same model orders. (This call could be a dummy call with default input arguments.) The default values of `phi0` and `psi0` are all zeros.

Note that the function requires that the delay `nk` be larger than 0. If you want `nk = 0`, shift the input sequence appropriately and use `nk = 1`.

## Algorithm

The general recursive prediction error algorithm (11.44) of Ljung (1999) is implemented. See also “Algorithms for Recursive Estimation”.

For the special cases of ARX/AR models, and of single-input ARMAX/ARMA, Box-Jenkins, and output-error models, it is more efficient to use `rarx`, `rarmax`, `rbj`, and `roe`.

`rbj`

roe

rplr

**Purpose** Estimate general input-output models using recursive pseudolinear regression method

**Syntax**  
`thm = rplr(z,nn,adm,adg)`  
`[thm,yhat,P,phi] = rplr(z,nn,adm,adg,th0,P0,phi0)`

**Description** This is a direct alternative to `rpem` and has essentially the same syntax. See `rpem` for an explanation of the input and output arguments.

`rplr` differs from `rpem` in that it uses another gradient approximation. See Section 11.5 in Ljung (1999). Several of the special cases are well-known algorithms.

When applied to ARMAX models, (`nn = [na nb nc 0 0 nk]`), `rplr` gives the extended least squares (ELS) method. When applied to the output-error structure (`nn = [0 nb 0 0 nf nk]`), the method is known as HARF in the `adm = 'ff'` case and SHARF in the `adm = 'ng'` case.

`rplr` can also be applied to the time-series case in which an ARMA model is estimated with

$$\begin{aligned} z &= y \\ nn &= [na \ nc] \end{aligned}$$

You can thus use `rplr` as an alternative to `rarmax` for this case.

**References** For more information about HARF and SHARF, see Chapter 11 in Ljung (1999).

<b>Purpose</b>	Class representing saturation nonlinearity estimator for Hammerstein-Wiener models
<b>Syntax</b>	<code>s=saturation(LinearInterval,L)</code>
<b>Description</b>	<p>saturation is an object that stores the saturation nonlinearity estimator for estimating Hammerstein-Wiener models.</p> <p>You can use the constructor to create the nonlinearity object, as follows:</p> <p><code>s=saturation(LinearInterval,L)</code> creates a saturation nonlinearity estimator object, initialized with the linear interval L.</p> <p>Use <code>evaluate(s,x)</code> to compute the value of the function defined by the saturation object s at x.</p>
<b>Remarks</b>	<p>Use saturation to define a nonlinear function <math>y = F(x)</math>, where <math>F</math> is a function of <math>x</math> and has the following characteristics:</p> $\begin{array}{ll} a \leq x < b & F(x) = x \\ a > x & F(x) = a \\ b \leq x & F(x) = b \end{array}$ <p><math>y</math> and <math>x</math> are scalars.</p>
<b>saturation Properties</b>	<p>You can specify the property value as an argument in the constructor to specify the object.</p> <p>After creating the object, you can use <code>get</code> or dot notation to access the object property values. For example:</p> <pre>% List LinearInterval property value get(s) s.LinearInterval</pre> <p>You can also use the <code>set</code> function to set the value of particular properties. For example:</p>

# saturation

---

```
set(s, 'LinearInterval', [-1.5 1.5])
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
LinearInterval	<p>1-by-2 row vector that specifies the initial interval of the saturation.</p> <p>Default=[NaN NaN].</p> <p>For example:</p> <pre>saturation('LinearInterval',[-1.5 1.5])</pre>

## Examples

Use `saturation` to specify the saturation nonlinearity estimator in Hammerstein-Wiener models. For example:

```
m=nlhw(Data,Orders,saturation([-1 1]),[]);
```

The saturation nonlinearity is initialized at the interval `[-1 1]`. The interval values are adjusted to the estimation data by `nlhw`.

## See Also

`nlhw`

**Purpose**

Segment data and estimate models for each segment

**Syntax**

```
segm = segment(z,nn)
[segm,V,thm,R2e] = segment(z,nn,R2,q,R1,M,th0,P0,ll,mu)
```

**Description**

segment builds models of AR, ARX, or ARMAX/ARMA type,

$$A(q)y(t) = B(q)u(t-nk) + C(q)e(t)$$

assuming that the model parameters are piecewise constant over time. It results in a model that has split the data record into segments over which the model remains constant. The function models signals and systems that might undergo abrupt changes.

The input-output data is contained in *z*, which is either an `iddata` object or a matrix  $z = [y \ u]$  where *y* and *u* are column vectors. If the system has several inputs, *u* has the corresponding number of columns.

The argument *nn* defines the model order. For the ARMAX model

$$nn = [na \ nb \ nc \ nk]$$

where *na*, *nb*, and *nc* are the orders of the corresponding polynomials. See “What Are Black-Box Polynomial Models?”. Moreover, *nk* is the delay. If the model has several inputs, *nb* and *nk* are row vectors, giving the orders and delays for each input.

For an ARX model (*nc* = 0) enter

$$nn = [na \ nb \ nk]$$

For an ARMA model of a time series

$$z = y$$

$$nn = [na \ nc]$$

and for an AR model

$$nn = na$$

## segment

---

The output argument `segm` is a matrix, where the  $k$ th row contains the parameters corresponding to time  $k$ . This is analogous to the output argument `thm` in `rarx` and `rarmax`. The output argument `thm` of `segment` contains the corresponding model parameters that have not yet been segmented. That is, they are not piecewise constant, and therefore correspond to the outputs of the functions `rarmax` and `rarx`. In fact, `segment` is an alternative to these two algorithms, and has a better capability to deal with time variations that might be abrupt.

The output argument `V` contains the sum of the squared prediction errors of the segmented model. It is a measure of how successful the segmentation has been.

The input argument `R2` is the assumed variance of the innovations  $e(t)$  in the model. The default value of `R2`, `R2 = []`, is that it is estimated. Then the output argument `R2e` is a vector whose  $k$ th element contains the estimate of `R2` at time  $k$ .

The argument `q` is the probability that the model exhibits an abrupt change at any given time. The default value is 0.01.

`R1` is the assumed covariance matrix of the parameter jumps when they occur. The default value is the identity matrix with dimension equal to the number of estimated parameters.

`M` is the number of parallel models used in the algorithm (see below). Its default value is 5.

`th0` is the initial value of the parameters. Its default is zero. `P0` is the initial covariance matrix of the parameters. The default is 10 times the identity matrix.

`l1` is the guaranteed life of each of the models. That is, any created candidate model is not abolished until after at least `l1` time steps. The default is `l1 = 1`. `Mu` is a forgetting parameter that is used in the scheme that estimates `R2`. The default is 0.97.

The most critical parameter for you to choose is `R2`. It is usually more robust to have a reasonable guess of `R2` than to estimate it. Typically, you need to try different values of `R2` and evaluate the results. (See the example below.)  $\sqrt{R2}$  corresponds to a change in the value  $y(t)$

that is normal, giving no indication that the system or the input might have changed.

## Algorithm

The algorithm is based on  $M$  parallel models, each recursively estimated by an algorithm of Kalman filter type. Each model is updated independently, and its posterior probability is computed. The time-varying estimate  $\mathbf{thm}$  is formed by weighting together the  $M$  different models with weights equal to their posterior probability. At each time step the model (among those that have lived at least 11 samples) that has the lowest posterior probability is abolished. A new model is started, assuming that the system parameters have changed, with probability  $q$ , a random jump from the most likely among the models. The covariance matrix of the parameter change is set to  $R1$ .

After all the data are examined, the surviving model with the highest posterior probability is tracked back and the time instances where it jumped are marked. This defines the different segments of the data. (If no models had been abolished in the algorithm, this would have been the maximum likelihood estimates of the jump instances.) The segmented model  $\mathbf{segm}$  is then formed by smoothing the parameter estimate, assuming that the jump instances are correct. In other words, the last estimate over a segment is chosen to represent the whole segment.

## Examples

Check how the algorithm segments a sinusoid into segments of constant levels. Then use a very simple model  $y(t) = b_1 * 1$ , where  $1$  is a fake input and  $b_1$  describes the piecewise constant level of the signal  $y(t)$  (which is simulated as a sinusoid).

```
y = sin([1:50]/3)';
thm = segment([y,ones(length(y),1)],[0 1 1],0.1);
plot([thm,y])
```

By trying various values of  $R2$  (0.1 in the above example), more levels are created as  $R2$  decreases.

# selstruc

---

**Purpose** Select model order for single-output ARX models

**Syntax**  
`nn = selstruc(v)`  
`[nn,vmod] = selstruc(v,c)`

## Description

---

**Note** Use `selstruc` for single-output systems only. `selstruc` supports both single-input and multiple-input systems.

---

`selstruc` is a function to help choose a model structure (order) from the information contained in the matrix `v` obtained as the output from `arxstruc` or `ivstruc`.

The default value of `c` is `'plot'`. The plot shows the percentage of the output variance that is not explained by the model as a function of the number of parameters used. Each value shows the best fit for that number of parameters. By clicking in the plot you can examine which orders are of interest. When you click **Select**, the variable `nn` is exported to the workspace as the optimal model structure for your choice of number of parameters. Several choices can be made.

`c = 'aic'` gives no plots, but returns in `nn` the structure that minimizes Akaike's Information Criterion (AIC),

$$V_{mod} = V\left(1 + \frac{2d}{N}\right)$$

where  $V$  is the loss function,  $d$  is the total number of parameters in the structure in question, and  $N$  is the number of data points used for the estimation. See `aic` for more details.

`c = 'mdl'` returns in `nn` the structure that minimizes Rissanen's Minimum Description Length (MDL) criterion.

$$V_{mod} = V\left(1 + \frac{d \log(N)}{N}\right)$$

When `c` equals a numerical value, the structure that minimizes

$$V_{mod} = V\left(1 + \frac{cd}{N}\right)$$

is selected.

The output argument `vmod` has the same format as `v`, but it contains the logarithms of the accordingly modified criteria.

## Examples

```
V = arxstruc(data(1:200),data(201:400),...  
            struc(1:10,1:10,1:10))  
nn = selstruc(V,0); %best fit to validation data  
m = arx(data,nn)
```

# set

---

## Purpose

Set properties of data and model objects

## Syntax

```
set(m, 'Property', Value)
set(m, 'Property1', Value1, ... 'PropertyN', ValueN)
set(m, 'Property')
set(m)
```

## Description

set is used to set or modify the properties of any of the objects in the toolbox (iddata, idmodel, idgrey, idarx, idpoly, idss, idnlrx, idnlgrey, idnlhw). See the corresponding reference pages for a complete list of properties.

set(m, 'Property', Value) assigns the value Value to the property of the object m specified by the string 'Property'. This string can be the full property name (for example, 'SSParameterization') or any unambiguous case-insensitive abbreviation (for example, 'ss').

set(m, 'Property1', Value1, ... 'PropertyN', ValueN) sets multiple properties with a single statement. In certain cases this might be necessary, since the model m must, for example, have state-space matrices of consistent dimensions after each set statement.

set(m, 'Property') displays admissible values for the property specified by 'Property'.

set(m) displays all assignable values of m and their admissible values. The same result is also obtained by subassignment.

```
m.Property = Value
```

---

<b>Purpose</b>	Set initial states of idnlgrey model object
<b>Syntax</b>	<code>setinit(model,property,values)</code>
<b>Input</b>	<code>model</code> Name of the idnlgrey model object. <code>property</code> Name of the InitialStates model property field, such as 'Name', 'Unit', 'Value', 'Minimum', 'Maximum', and 'Fixed'. <code>values</code> Values of the specified property Property. <code>values</code> are an Nx-by-1 cell array of values, where Nx is the number of states.
<b>Description</b>	<code>setinit(model,property,values)</code> sets the values of the property field of the InitialStates model property. <code>property</code> can be 'Name', 'Unit', 'Value', 'Minimum', 'Maximum', and 'Fixed'.
<b>See Also</b>	<code>getinit</code> <code>getpar</code> <code>idnlgrey</code> <code>setpar</code>

# setpar

---

<b>Purpose</b>	Set initial parameter values of idnlgrey model object
<b>Syntax</b>	<code>setpar(model,property,values)</code>
<b>Input</b>	<code>model</code> Name of the idnlgrey model object. <code>property</code> Name of the Parameters model property field, such as 'Name', 'Unit', 'Value', 'Minimum', or 'Maximum'. Default: 'Value'. <code>values</code> Values of the specified property Property. values are an Np-by-1 cell array of values, where Np is the number of parameters.
<b>Description</b>	<code>setpar(model,property,values)</code> sets the model parameter values in the property field of the Parameters model property. property can be 'Name', 'Unit', 'Value', 'Minimum', and 'Maximum'.
<b>See Also</b>	<code>getinit</code> <code>getpar</code> <code>idnlgrey</code> <code>setinit</code>

---

<b>Purpose</b>	Set mnemonic parameter names for linear black-box model structures
<b>Syntax</b>	<code>model = setpname(model)</code>
<b>Description</b>	<p><code>model</code> is an <code>idmodel</code> object of <code>idarx</code>, <code>idpoly</code>, <code>idproc</code>, or <code>idss</code> type. The returned model has the 'PName' property set to a cell array of strings that correspond to the symbols used in this manual to describe the parameters.</p> <p>For single-input <code>idpoly</code> models, the parameters are called 'a1', 'a2', ..., 'fn'.</p> <p>For multiple-input <code>idpoly</code> models, the <math>b</math> and <math>f</math> parameters have the output/input channel number in parentheses, as in 'b1(1,2)', 'f3(1,2)', etc.</p> <p>For <code>idarx</code> models, the parameter names are as in '-A(ky,ku)' for the negative value of the <math>ky</math>-<math>ku</math> entry of the matrix in <math>A(q)</math> polynomial of the multiple-output ARX equation, and similarly for the <math>B</math> parameters.</p> <p>For <code>idss</code> models, the parameters are named for the matrix entries they represent, such as 'A(4,5)', 'K(2,3)', etc.</p> <p>For <code>idproc</code> models, the parameter names are as described under <code>idproc</code>.</p> <p>This function is particularly useful when certain parameters are to be fixed. See the property <code>FixedParameter</code> under <code>Algorithm Properties</code>.</p>

# setstruc

---

**Purpose** Set matrix structure for idss objects

**Syntax** `setstruc(M,As,Bs,Cs,Ds,Ks,X0s)`  
`setstruc(M,Mods)`

**Description** `setstruc(M,As,Bs,Cs,Ds,Ks,X0s)`

is the same as

`set(M,'As',As,'Bs',Bs,'Cs',Cs,'Ds',Ds,'Ks',Ks,'X0s',X0s)`

Use empty matrices for structure matrices that should not be changed. You can omit trailing arguments.

In the alternative syntax, `Mods` is a structure with field names `As`, `Bs`, etc., with the corresponding values of the fields.

**See Also** `idss`

**Purpose** Class representing sigmoid network nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models

**Syntax**  
`s=sigmoidnet('NumberOfUnits',N)`  
`s=sigmoidnet(Property1,Value1,...PropertyN,ValueN)`

**Description** `sigmoidnet` is an object that stores the sigmoid network nonlinear estimator for estimating nonlinear ARX and Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`s=sigmoidnet('NumberOfUnits',N)` creates a sigmoid nonlinearity estimator object with  $N$  terms in the sigmoid expansion.

`s=sigmoidnet(Property1,Value1,...PropertyN,ValueN)` creates a sigmoid nonlinearity estimator object specified by properties in “sigmoidnet Properties” on page 2-372.

Use `evaluate(s,x)` to compute the value of the function defined by the `sigmoidnet` object `s` at `x`.

**Remarks** Use `sigmoidnet` to define a nonlinear function  $y = F(x)$ , where  $y$  is scalar and  $x$  is an  $m$ -dimensional row vector. The sigmoid network function is based on the following expansion:

$$F(x) = (x - r)PL + a_1 f((x - r)Qb_1 - c_1) + \dots + a_n f((x - r)Qb_n - c_n) + d$$

where  $f$  is the sigmoid function, given by the following equation:

$$f(z) = \frac{1}{e^{-z} + 1}$$

$P$  and  $Q$  are  $m$ -by- $p$  and  $m$ -by- $q$  projection matrices. The projection matrices  $P$  and  $Q$  are determined by principal component analysis of estimation data. Usually,  $p=m$ . If the components of  $x$  in the estimation data are linearly dependent, then  $p < m$ . The number of columns of  $Q$ ,

# sigmoidnet

---

$q$ , corresponds to the number of components of  $x$  used in the sigmoid function.

When used in a nonlinear ARX model,  $q$  is equal to the size of the NonlinearRegressors property of the `idnlarx` object. When used in a Hammerstein-Wiener model,  $m=q=1$  and  $Q$  is a scalar.

$r$  is a 1-by- $m$  vector and represents the mean value of the regressor vector computed from estimation data.

$d$ ,  $a_k$ , and  $c_k$  are scalars.

$L$  is a  $p$ -by-1 vector.

$b_k$  are  $q$ -by-1 vectors.

## sigmoidnet Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
get(s)
% Get value of NumberOfUnits property
s.NumberOfUnits
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(s, 'LinearTerm', 'on')
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
NumberOfUnits	<p>Integer specifies the number of nonlinearity units in the expansion. Default=10.</p> <p>For example:</p> <pre>sigmoidnet(H, 'NumberOfUnits', 5)</pre>
LinearTerm	<p>Can have the following values:</p> <ul style="list-style-type: none"> <li>• 'on'—Estimates the vector <math>L</math> in the expansion.</li> <li>• 'off'—Fixes the vector <math>L</math> to zero.</li> </ul> <p>For example:</p> <pre>sigmoidnet(H, 'LinearTerm', 'on')</pre>
Parameters	<p>A structure containing the parameters in the nonlinear expansion, as follows:</p> <ul style="list-style-type: none"> <li>• RegressorMean: 1-by-m vector containing the means of <math>x</math> in estimation data, <math>r</math>.</li> <li>• NonLinearSubspace: m-by-q matrix containing <math>Q</math>.</li> <li>• LinearSubspace: m-by-p matrix containing <math>P</math>.</li> <li>• LinearCoef: p-by-1 vector <math>L</math>.</li> <li>• Dilation: q-by-n matrix containing the values <math>b_k</math>.</li> <li>• Translation: 1-by-n vector containing the values <math>c_k</math>.</li> <li>• OutputCoef: n-by-1 vector containing the values <math>a_k</math>.</li> <li>• OutputOffset: scalar <math>d</math>.</li> </ul> <p>Typically, the values of this structure are set by estimating a model with a sigmoidnet nonlinearity.</p>

# sigmoidnet

---

## Examples

Use `sigmoidnet` to specify the nonlinear estimator in nonlinear ARX and Hammerstein-Wiener models. For example:

```
m=nlarx(Data,Orders,sigmoidnet('num',5));
```

## See Also

`nlarx`

`nlhw`

**Purpose**

Simulate linear models with confidence interval

**Syntax**

```
y = sim(m,u)
y = sim(m,u,'noise')
[y, ysd] = sim(m,u,'InitialState',init)
```

**Description**

`m` is any `idmodel`.

`u` is an `iddata` object, containing inputs only. (Any outputs are ignored). Both time-domain and frequency-domain signals are supported. The number of input channels in `u` must either be equal to the number of inputs of the model `m` or equal to the sum of the number of inputs and noise sources (number of outputs). In the latter case the last inputs in `u` are regarded as noise sources and a noise-corrupted simulation is obtained. The noise is scaled according to the property `m.NoiseVariance` in `m`. To obtain the right noise level according to the model, the noise inputs should be white noise with zero mean and unit covariance matrix. A simpler way of obtaining a noise-corrupted simulation with Gaussian noise is to add the argument `'noise'`. If no noise sources are contained in `u`, a noise-free simulation is obtained. `sim` applies both to time-domain and frequency-domain `iddata` objects, but no standard deviations are obtained for frequency-domain signals.

`sim` returns `y`, containing the simulated output, as an `iddata` object.

`init` gives access to the initial states:

- `init = 'm'` (default) uses the internally stored initial state of model `m`.
- `init = 'z'` uses zero initial state.
- `init = x0`, where `x0` is a column vector of appropriate length, uses this value as the initial state. For multi-experiment inputs, `x0` has as many columns as there are experiments to allow for different initial conditions. For a continuous-time model `m`, `x0` is the initial state for this model. Any modifications of the initial state that sampling might require are automatically handled. If `m` has a non-zero `InputDelay`,

and you need to access the values of the inputs during this delay, you must first apply `inpd2nk(m)`. If `m` is a continuous-time model, it must first be sampled before `inpd2nk` can be applied.

The second output argument `ysd` is the standard deviation of the simulated output. This is not available for frequency-domain data.

`u` can also be given as a matrix with the number of columns being either the number of inputs in `m` or the sum of the number of inputs and outputs. Then `y` and `ysd` are returned as matrices. Continuous-time models, however, require `u` to be given as `iddata`.

If `m` is a continuous-time model, it is first converted to discrete time with the sampling interval given by `ue`, taking into account the inter-sample behavior of the input (`ue.InterSample`).

## Examples

Simulate a given system `m0` (for example, created by `idpoly`).

```
e = iddata([],randn(500,1));
u = iddata([],idinput(500,'prbs'));
y = sim(m0,[u e]);
% iddata object with output y and input u.
z = [y u];
```

The same result is obtained by

```
u = iddata([],idinput(500,'prbs'));
y = sim(m0,u,'noise');
z = [y u];
```

or

```
u = idinput(500,'prbs');
y = sim(m0,u,'noise');
z = iddata(y,u);
```

Validate a model by comparing a measured output `y` with one simulated using an estimated model `m`.

```
yh = sim(m,u);  
plot(y,yh)
```

# sim(idnlarx)

---

**Purpose** Simulate nonlinear ARX model

**Syntax**  
YS = sim(MODEL,U)  
YS = sim(MODEL,U,'Noise')  
YS = sim(MODEL,U,'InitialState',INIT)

**Description** YS = sim(MODEL,U) simulates a dynamic system with an idnlarx model.

YS = sim(MODEL,U,'Noise') produces a noise corrupted simulation with an additive Gaussian noise scaled according to the value of the NoiseVariance property of MODEL.

YS = sim(MODEL,U,'InitialState',INIT) specifies the initial conditions for simulation using various options, such as numerical initial state vector or past I/O data.

To simulate the model with user-defined noise, set the input U = [UIN E], where UIN is the input signal and E is the noise signal. UIN and E must both be one of the following:

- iddata objects: E stores the noise signals as inputs, where the number of inputs matches the number of model outputs.
- Matrices: E has as many columns as there are noise signals, corresponding to the number of model outputs.

## Input

- MODEL: idnlarx model object.
- U: Input data for simulation, an iddata object (where only the input channels are used) or a matrix. For simulations with noisy data, U contains both input and noise channels.
- INIT: Initial condition specification. INIT can be one of the following:
  - A real column vector X0, for the state vector corresponding to an appropriate number of output and input data samples prior to the simulation start time. To build an initial state vector from a given set of input-output data or to generate equilibrium states, see data2state(idnlarx), findstates(idnlarx) and

`findop(idnlarx)`. For multi-experiment data, `X0` may be a matrix whose columns give different initial states for different experiments.

- `'z'`: (Default) Zero initial state, equivalent to a zero vector of appropriate size.
- `iddata` object containing output and input data samples prior to the simulation start time. If it contains more data samples than necessary, only the last samples are taken into account. This syntax is equivalent to `sim(MODEL,U,'InitialState',data2state(MODEL,INIT))`, where `data2state(idnlarx)` transforms the `iddata` object `INIT` to a state vector.

## Output

- `YS`: Simulated output. An `iddata` object if `U` is an `iddata` object, a matrix otherwise.

---

**Note** If `sim` is called without an output argument, MATLAB software displays the simulated output(s) in a plot window.

---

## Examples

### Simulation of a SISO `idnlarx` model

In this example you simulate a single-input single-output `idnlarx` model `M` around a known equilibrium point, with an input level of 1 and output level of 10.

- 1 Load the sample data.

```
load iddata2;
```

- 2 Estimate an `idnlarx` model from the data.

```
M = nlarx(z2, [2 2 1], 'tree');
```

- 3 Estimate current states of model based on past data.

## sim(idnlarx)

---

```
x0 = data2state(M, struct('Input',1, 'Output', 10));
```

- 4 Simulate the model using the initial states returned by data2state.

```
sim(M, z2, 'init', x0);
```

### Continuing from End of Previous Simulation

In this example you continue the simulation of a model from the end of a previous simulation run.

- 1 Estimate the idnlarx model from data.

```
load iddata2  
M = nlarx(z2, [2 2 1], 'tree'); % idnlarx model
```

- 2 Simulate the model using first half of input data of z2

```
u1 = z2(1:200, []);  
% Simulate starting from zero initial states  
ys1 = sim(M, u1, 'init', 'z');
```

- 3 Start another simulation, using the same states of the model from when the first simulation ended. For the second simulation, you use the second half of the input data of z2.

```
u2 = z2(201:end, []);
```

- 4 In order to set the initial states for second simulation correctly, package input u1 and output ys1 from the first simulation into one iddata object.

```
firstSimData = [ys1,u1];
```

- 5 Pass this data as initial conditions for the next simulation.

```
ys2 = sim(M, u2, 'init', firstSimData);
```

- 6 Verify the two simulations by comparing to a complete simulation using all the input data of z2.

```

uTotal = z2(:,[]); % extract the whole input data
ysTotal = sim(M, uTotal, 'init', 'z');

% Compare the values of ys1, ys2 and ysTotal.
% ys1 should be equal to first half of ysTotal.
% ys2 should be equal to the second half of ysTotal
%
% plot the three responses
plot(ys1,'b', ys2, 'g', ysTotal, 'k*')

```

MATLAB software responds with a plot showing the three responses, with `ysTotal` overlaying `ys1` and `ys2` to verify that they match.

## Matching Model Response to Output Data

In this example, you estimate initial states of model `M` such that the response best matches the output in data set `z2`.

- 1 Load the sample data and create data object `z2`.

```

load iddata2;
z2 = z2(1:50);

```

- 2 Estimate `idnlarx` model from data.

## sim(idnlarx)

---

```
M = nlarx(z2,[4 3 2], 'wave');
```

- 3 Estimate initial states of M to best fit z2.y in the simulated response.

```
x0 = findstates(M,z2,[], 'sim');
```

- 4 Simulate the model.

```
ysim = sim(M, z2.u, 'init', x0)
```

- 5 Compare ysim with the output signal in z2:

```
time = z2.SamplingInstants;  
plot(time, ysim, time, z2.y, '.')
```

### Simulation Near Steady State with Known Input and Unknown Output

In this example you start simulation of a model near steady state, where the input is known to be 1, but the output is unknown.

- Load sample data and create data object z2.

```
load iddata2  
z2 = z2(1:50);
```

- Estimate idnlarx model from data.

```
M = nlarx(z2, [4 3 2], 'wave');
```

- Determine equilibrium state values for input 1 and the unknown target output.

```
x0 = findop(M, 'steady', 1, NaN);
```

- Simulate the model using initial states x0.

```
sim(M, z2.u, 'init', x0)
```

# sim(idnlgrey)

---

**Purpose** Simulate nonlinear ODE model

**Syntax**

```
YS = sim(NLSYS,DATA)
YS = sim(NLSYS,DATA,'Noise');
YS = sim(NLSYS,DATA,XOINIT);
YS = sim(NLSYS,DATA,'Noise',XOINIT);
YS = sim(NLSYS,DATA,'Noise','InitialState',XOINIT);
[YS, YSD, XFINAL] = sim(NLSYS,DATA,'Noise','InitialState',
    XOINIT);
```

**Description**

YS = sim(NLSYS,DATA) simulates the output of an idnlgrey model.

YS = sim(NLSYS,DATA,'Noise'); simulates the model with Gaussian noise added to YS.

YS = sim(NLSYS,DATA,XOINIT); simulates the model with the specified initial states.

YS = sim(NLSYS,DATA,'Noise',XOINIT); simulates the model with the specified initial states and with Gaussian noise added.

YS = sim(NLSYS,DATA,'Noise','InitialState',XOINIT); simulates the model with the specified initial states.

[YS, YSD, XFINAL] = sim(NLSYS,DATA,'Noise','InitialState',XOINIT); performs simulation starting with the specified initial states and with Gaussian noise added, and returns the final states of the model after the simulation is completed.

To simulate the model with user-defined noise, set the input DATA = [UIN E], where UIN is the input signal and E is the noise signal. UIN and E must both be one of the following:

- **iddata** objects: E stores the noise signals as inputs, where the number of inputs matches the number of model outputs.
- **Matrices**: E has as many columns as there are noise signals, corresponding to the number of model outputs.

## Input

- NLSYS: idnlgrey model object.
- DATA: Input-noise data [U E]. If E is omitted and 'Noise' is not given as an input argument, then a noise-free simulation is obtained. If E is omitted and 'Noise' is given as an input argument, then Gaussian noise created by `randn(size(YS))*sqrtm(NLSYS.NoiseVariance)` will be added to YS. If both E and 'Noise' are given, then E specifies the noise to add to YS. For time-continuous idnlgrey objects, DATA passed as a matrix will lead to that the data sample interval, Ts, is set to one.
- X0INIT: Initial states. Can have the following values:
  - 'zero' : Zero initial state x(0) with all states fixed (`nlsys.InitialStates.Fixed` is thus ignored).
  - (Default) 'fixed': (or `NLSYS.InitialState`) Determines the values of the model initial states, but all states are fixed (`NLSYS.InitialStates.Fixed` is ignored).
  - 'model': `NLSYS.InitialState` determines the value of the initial states, which initial states to estimate, and minimum and maximum state values.
  - vector/matrix: Column vector of initial state values. For multiple experiment DATA, X0INIT may be a matrix whose columns give different initial states for each experiment. All initial states are kept fixed (`nlsys.InitialStates.Fixed` is thus ignored).
  - struct array : Nx-by-1 structure array with fields:
    - Name: Name of the state (a string).
    - Unit: Unit of the state (a string).
    - Value: Value of the states (a finite real 1-by-Ne vector, where Ne is the number of experiments.)

# sim(idnlgrey)

---

- **Minimum:** Minimum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same minimum value).
- **Maximum:** Maximum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same maximum value).
- **(Default) Fixed:** True (or a 1-by-Ne vector of True values). Any false value is ignored.

## Output

- **YS:** Simulated output. If DATA is an iddata object, then YS will also be an iddata object. Otherwise, YS will be a matrix where the k:th output is found in the k:th column of YS. If DATA is a multiple-experiment iddata object, then YS will be a multiple experiment object as well.
- **YSD:** Empty vector ([ ] .) In the future, it will contain the estimated standard deviation of the simulated output.
- **XFINAL:** Final states computed. In the single experiment case it is a column vector of length Nx. For multi-experiment data, XFINAL is an Nx-by-Ne matrix with the ith column specifying the initial state of experiment i.

---

**Note** If sim is called without an output argument, MATLAB software displays the simulated output(s) in a plot window.

---

## Examples

In this example you simulate an idnlgrey model for a data set z. This example uses the nlgr model created in idnlgreydemo2.

**1** Load the data set and create an idnlgrey model.

```
load twotankdata;
```

**2** Estimate the idnlgrey model.

```
% Specify file.
FileName = 'twotanks_c';
% Specify model orders [ny nu nx].
Order = [1 1 2];
% Specify initial parameters.
Parameters = {0.5; 0.0035; 0.019; ...
              9.81; 0.25; 0.016};
% Specify initial states.
InitialStates = [0; 0.1];
Ts = 0;
nlgr = idnlgrey(FileName, Order, Parameters, ...
               InitialStates, Ts, ...
               'Name', 'Two tanks');
```

- 3** Create an iddata object z from data z (from twotankdata.mat).

```
z = iddata([], u, 0.2, 'Name', 'Two tanks');
```

- 4** Simulate the model using the input signal from the data z.

```
sim(nlgr,z)
```

# sim(idnlhw)

---

**Purpose** Simulate Hammerstein-Wiener model

**Syntax**  
YS = sim(MODEL,U)  
YS = sim(MODEL,U,'Noise')  
YS = sim(MODEL,U,'InitialState',INIT)

**Description** YS = sim(MODEL,U) simulates the output of an idnlhw model.  
YS = sim(MODEL,U,'Noise') simulates the model output with an additive Gaussian noise scaled according to the value of the NoiseVariance property of MODEL.  
YS = sim(MODEL,U,'InitialState',INIT) specifies initial conditions for starting the simulation.  
To simulate the model with user-defined noise, set the input U = [UIN E], where UIN is the input signal and E is the noise signal. UIN and E must both be one of the following:

- **iddata** objects: E stores the noise signals as inputs, where the number of inputs matches the number of model outputs.
- **Matrices**: E has as many columns as there are noise signals, corresponding to the number of model outputs.

**Input**

- **MODEL**: idnlhw model object.
- **U**: Input data for simulation, which is an iddata object (where only the input channels are used) or a matrix. For simulations with noisy data, U contains both input and noise channels.
- **INIT**: Initial condition for simulation. INIT has one of the following values:
  - **Vector of initial state values**. To estimate an initial state vector from input-output data or to generate equilibrium states, see the findstates(idnlhw) and findop(idnlhw) reference pages. For multiple-experiment data, enter a matrix with the same number of columns as the number of experiments.

- 'z': (Default) Vector containing zeros and corresponding to a system starting from rest.

## Output

- YS: Simulated output, which is an iddata object when U is an iddata object, or a matrix otherwise.

---

**Note** If `sim` is called without an output argument, MATLAB software displays the simulated output(s) in a plot window.

---

## Examples

### Simulation Using Initial States to Best Fit Model Response to Measured Output

In this example you simulate the model output using initial states that minimize the error between the simulated and the measured output. `z2` is the measured data.

- 1 Load the sample data.

```
load iddata2
```

- 2 Create a Hammerstein-Wiener model.

```
M = n1hw(z2,[4 3 2], 'wave', 'pw1');
```

- 3 Compute the initial states that best fit the model response to the measured output.

```
x0 = findstates(M,z2);
```

- 4 Simulate the model using the estimated initial states.

```
ysim = sim(M,z2.u,'init',x0)
```

- 5 Compare `ysim` to output signal in `z2`:

```
t = z2.samp;
```

```
plot(t, ysim, t, z2.y)
```

### Simulating a Hammerstein-Wiener Model at Steady-State with Known Input and Unknown Output

In this example, you simulate a single-input single-output `idnlhw` model about a steady-state operating point, where the input level is known to be 1 and the output level is unknown.

- 1 Load the sample data.

```
load iddata2
```

- 2 Create a Hammerstein-Weiner model.

```
M = n1hw(z2,[4 3 2], 'wave', 'pw1');
```

- 3 Compute steady-state operating point values corresponding to an input level of 1 and an unknown output level.

```
x0 = findop(M, 'steady', 1, NaN);
```

- 4 Simulate the model using the estimated initial states.

```
sim(M, z2.u, 'init', x0)
```

### See Also

```
findop(idnlhw)  
finstates(idnlhw)  
predict(idnlhw)
```

**Purpose**

Simulate models with uncertainty using Monte Carlo method

**Syntax**

```
simsd(m,u)
simsd(m,u,N, 'noise',Ky)
[y,yzd] = simsd(m,u)
```

**Description**

`u` is an `iddata` object containing the inputs. `m` is a model given as any `idmodel` object. `N` random models are created according to the covariance information given in `m`. The responses of each of these models to the input `u` are computed and graphed in the same diagram. If the argument `'noise'` is included, noise is added to the simulation in accordance with the noise model of `m` and its own uncertainty. `Ky` denotes the output numbers to be plotted. (The default is `all`).

The default value is `N=10`.

With output arguments

```
[y,yzd] = simsd(m,u)
```

No plots are produced, but `y` is returned as a cell array with the simulated outputs, and `yzd` is the estimated standard deviation of `y`, based on the `N` different simulations. If `u` is an `iddata` object, so are the contents of the cells of `y` and `yzd`; otherwise, they are returned as vectors/matrices. In the `iddata` case,

```
plot(y{:})
```

thus plots all the responses.

`sim` and `simsd` have similar syntaxes. Note that `simsd` computes the standard deviation by Monte Carlo simulation, while `sim` uses differential approximations (the Gauss approximation formula). They might give different results.

**Examples**

Plot the step response of the model `m` and evaluate how it varies in view of the model's uncertainty.

```
step1 = [zeros(5,1); ones(20,1)];
```

# simsd

---

`simsd(m,step1)`

`sim`

**Purpose**

Dimensions of `iddata`, `idmodel`, `idnlmodel`, and `idfrd` objects

**Syntax**

```
d = size(m)
[ny,nu,Npar,Nx] = size(model)
[N, ny, nu, Nexp] = size(data)
ny = size(data,2)
ny = size(data,'ny')
size(model)
size(idfrd_object)
```

**Description**

`size` describes the dimensions of `iddata`, `idmodel`, `idnlmodel`, and `idfrd` objects.

**iddata**

For `iddata` objects, the sizes returned are, in this order,

- `N` = the length of the data record. For multiple-experiment data, `N` is a row vector with as many entries as there are experiments.
- `ny` = the number of output channels.
- `ny` = the number of input channels.
- `Ne` = the number of experiments.

To access a specific `size` output, use syntax similar to the following: `size(data,k)` for the `k` `size(data,'N')`, `size(data,'ny')`.

When called with one output argument, `d = size(data)` returns

- `d = [N ny nu]` if the number of experiments is 1.
- `d = [sum(N) ny nu Ne]` if the number of experiments is `Ne > 1`.

**idmodel**

For `idmodel` objects the sizes returned are, in this order,

- `ny` = the number of output channels.
- `nu` = the number of input channels.

## size

---

- Npar = the length of the ParameterVector (number of estimated parameters).
- Nx = the number of states for idss and idgrey models.

To access a specific size output, use syntax similar to the following: `size(mod,2)`, `size(mod, 'Npar')`.

When `size` is called with one output argument, `d = size(mod)`, `d` is given by

```
[ny nu Npar]
```

### **idfrd**

For `idfrd` models, the sizes returned are, in this order,

- `ny` = the number of output channels.
- `nu` = the number of input channels.
- `Nf` = the number of frequencies.
- `Ns` = the number of spectrum channels.

To access a specific size output, use syntax similar to the following: `size(mod,2)` or `size(mod, 'Nf')`.

When `size` is called with one output argument, `d = size(fre)`, `d` is given by

```
[ny nu Nf Ns]
```

When `size` is called with no output arguments, in any of these cases, the information is displayed in the MATLAB Command Window.

### **idnlarx or idnlhw**

For `idmodel` objects the sizes returned are, in this order,

- `ny` = the number of output channels.

- nu = the number of input channels.

To access a specific size output, use one of the following:

```
NY = SIZE(NLSYS, 1)
NU = SIZE(NLSYS, 2)
NY = SIZE(NLSYS, 'Ny')
NU = SIZE(NLSYS, 'Nu')
```

When called with only one output argument, `N = SIZE(NLSYS)` returns the vector `N = [NY NU]`.

When called with no output argument, the information is displayed in the MATLAB Command Window.

### **idnlgrey**

For `idnlgrey` objects the sizes returned are, in this order,

- Ny = the number of output channels.
- Nu = the number of input channels.
- Nx = the number of states.
- Np = the number of parameters.
- Npo = the number of parameter variables (number of estimated parameters).
- Npf = the number of fixed parameters.
- Ne = the number of experiments associated with the states.

Ny, Nu, Nx, Np, Npo, Npf and Ne are set to NaN if NLSYS is inconsistent.

To access a specific size output, use one of the following:

```
NY = SIZE(NLSYS, 1)
NU = SIZE(NLSYS, 2)
NX = SIZE(NLSYS, 3)
NP = SIZE(NLSYS, 4)
NPO = size(NLSYS, 5)
```

## size

---

```
NPF = (NLSYS, 6)
NE = (NLSYS, 7)
NY = SIZE(NLSYS, 'Ny')
NU = SIZE(NLSYS, 'Nu')
```

When called with only one output argument, `N = SIZE(NLSYS)` returns the vector `N = [NY NU NP NX NPO NPF NE]`.

When called with no output argument, the information is displayed in the MATLAB Command Window.

**Purpose**

Estimate frequency response and spectrum using spectral analysis returning idfrd object

**Syntax**

```
g = spa(data)
g = spa(data,M,w,maxsize)
[g,phi,spe] = spa(data)
```

**Description**

spa estimates the transfer function  $g$  and the noise spectrum  $\Phi_v$  of the general linear model

$$y(t) = G(q)u(t) + v(t)$$

where  $\Phi_v(\omega)$  is the spectrum of  $v(t)$ .

`data` contains the output-input data as an `iddata` object. The data can be complex valued. `data` can be both time domain and frequency domain. `data` can also be an `idfrd` object.

$g$  is returned as an `idfrd` object (see `idfrd`) with the estimate of  $G(e^{i\omega})$  at the frequencies  $\omega$  specified by row vector  $w$ . The default value of  $w$  is

$$w = [1:128]/128*\pi/Ts$$

Here  $Ts$  is the sampling interval of `data`.

$g$  also includes information about the spectrum estimate of  $\Phi_v(\omega)$  at the same frequencies. Both outputs are returned with estimated covariances, included in  $g$ . See `idfrd`.

$M$  is the length of the lag window used in the calculations. The default value is

$$M = \min(30, \text{length}(\text{data})/10)$$

Changing the value of  $M$  controls the frequency resolution of the estimate. The resolution corresponding to  $M$  is approximately  $\pi/M$  rad/sampling interval. The value of  $M$  exchanges bias for variance in the spectral estimate. As  $M$  is increased, the estimated functions show more detail, but are more corrupted by noise. The sharper peaks a

true frequency function has, the higher  $M$  it needs. See `etfe` as an alternative for narrowband signals and systems. The function `spafdr` allows the frequency resolution to depend on the frequency. See also “Identifying Frequency-Response Models”.

`maxsize` controls the memory-speed tradeoff (see Algorithm Properties).

For time series, where `data` contains no input channels, `g` is returned with the estimated output spectrum and its estimated standard deviation.

When `spa` is called with two or three output arguments,

- `g` is returned as an `idfrd` model with just the estimated frequency response from input to output and its uncertainty.
- `phi` is returned as an `idfrd` model, containing just the spectrum data for the output spectrum  $\Phi_y(\omega)$  and its uncertainty.
- `spe` is returned as an `idfrd` model containing spectrum data for all output-input channels in `data`. That is, if  $z = [\text{data.OutputData}, \text{data.InputData}]$ , `spe` contains as spectrum data the matrix-valued power spectrum of  $z$ .

$$S = \sum_{m=-M}^M E z(t+m)z(t)' \exp(-iWmT) \text{win}(m)$$

Here  $\text{win}(m)$  is weight at lag  $m$  of an  $M$ -size Hamming window and  $W$  is the frequency value  $i$  rad/s. Note that  $'$  denotes complex-conjugate transpose.

The normalization of the spectrum differs from the normalization used by the Signal Processing Toolbox `spectrum` function. See “Understanding Spectrum Normalization” for a more precise definition.

## Algorithm

The covariance function estimates are computed using `covf`. These are multiplied by a Hamming window of lag size  $M$  and then transformed using a Fourier transform. The relevant ratios and differences are then

formed. For the default frequencies, this is done using a fast Fourier transform, which is more efficient than for user-defined frequencies. For multivariable systems, a straightforward for loop is used.

Note that  $M = \Upsilon$  is in Table 6.1 of Ljung (1999). The standard deviations are computed as on pages 184 and 188 in Ljung (1999).

## Examples

With default frequencies,

```
g = spa(z);  
% z is a data object with Ts=1  
bode(g)
```

With logarithmically spaced frequencies,

```
w = logspace(-2,pi,128);  
g= spa(z,[],w);  
% The empty matrix specifies the default lag window size.  
bode(g,'sd',3)  
bode(g('noise'),'sd',3) % noise spectrum with confidence  
interval of 3 standard deviations.
```

**Purpose** Estimate frequency response and spectrum using spectral analysis with frequency-dependent resolution returning `idfrd` object

**Syntax**  
`g = spafdr(data)`  
`g = spafdr(data,Resol,w)`

**Description** `spafdr` estimates the transfer function  $g$  and the noise spectrum  $\Phi_v$  of the general linear model

$$y(t) = G(q)u(t) + v(t)$$

where  $\Phi_v(\omega)$  is the spectrum of  $v(t)$ .

`data` contains the output-input data as an `iddata` object. The data can be complex valued, and either time or frequency domain. It can also be an `idfrd` object containing frequency-response data.

`g` is returned as an `idfrd` object (see `idfrd`) with the estimate of  $G(e^{i\omega})$  at the frequencies  $\omega$  specified by row vector `w`. `g` also includes information about the spectrum estimate of  $\Phi_v(\omega)$  at the same frequencies. Both results are returned with estimated covariances, included in `g`. See `idfrd`. The normalization of the spectrum is the same as described under `spa`.

## Frequencies

The frequency variable `w` is either specified as a row vector of frequencies, or as a cell array `{wmin,wmax}`. In the latter case the covered frequencies will be 50 logarithmically spaced points from `wmin` to `wmax`. You can change the number of points to `NP` by entering `{wmin,wmax,NP}`.

Omitting `w` or entering it as an empty matrix gives the default value, which is 100 logarithmically spaced frequencies between the smallest and largest frequency in data. For time-domain data, this means from  $1/N \cdot T_s$  to  $\pi \cdot T_s$ , where  $T_s$  is the sampling interval of data and  $N$  is the number of data.

## Resolution

The argument `Resol` defines the frequency resolution of the estimates. The resolution (measured in rad/s) is the size of the smallest detail in the frequency function and the spectrum that is resolved by the estimate. The resolution is a tradeoff between obtaining estimates with fine, reliable details, and suffering from spurious, random effects: The finer the resolution, the higher the variance in the estimate. `Resol` can be entered as a scalar (measured in rad/s), which defines the resolution over the whole frequency interval. It can also be entered as a row vector of the same length as `w`. Then `Resol(k)` is the local, frequency-dependent resolution around frequency `w(k)`.

The default value of `Resol`, obtained by omitting it or entering it as the empty matrix, is `Resol(k) = 2(w(k+1) - w(k))`, adjusted upwards, so that a reasonable estimate is guaranteed. In all cases, the resolution is returned in the variable `g.EstimationInfo.WindowSize`.

## Algorithm

If the data is given in the time domain, it is first converted to the frequency domain. Then averages of  $Y(w)\text{Conj}(U(w))$  and  $U(w)\text{Conj}(U(w))$  are formed over the frequency ranges `w`, corresponding to the desired resolution around the frequency in question. The ratio of these averages is then formed for the frequency-function estimate, and corresponding expressions define the noise spectrum estimate.

**Purpose** Convert idmodel objects to Control System Toolbox LTI models

**Syntax**  
`sys = ss(mod)`  
`sys = ss(mod, 'm')`

**Description** `mod` is any idmodel object: `idgrey`, `idarcx`, `idpoly`, `idproc`, `idss`, or `idmodel`.  
`sys` is returned as an `ss` LTI model object. The noise input channels in `mod` are treated as follows: consider a model `mod` with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$y = Gu + HLv$$
$$\text{cov}(v) = I$$

Both measured input channels  $u$  and normalized noise input channels  $v$  in `mod` are input channels in `sys`. The noise input channels belong to the InputGroup 'Noise', while the others belong to the InputGroup 'Measured'. The names of the noise input channels are `v@yname`, where `yname` is the name of the corresponding output channel. This means that the LTI object realizes the transfer function  $[G \ HL]$ .

To transform only the measured input channels in `sys`, use

```
sys = ss(mod('m')) or sys = ss(mod, 'm')
```

This gives a representation of  $G$  only.

For a time series (no measured input channels,  $nu = 0$ ), the LTI representations in `ss` contains the transfer functions from the normalized noise sources  $v$  to the outputs, that is,  $HL$ . If the model `mod` has both measured and noise inputs, `sys = ss(mod('n'))` gives a representation of the additive noise.

In addition, the normal subreferencing can be used.

```
sys = ss(mod(1, [3 4]))
```

---

If you want to describe  $[G H]$  or  $H$  (unnormalized noise), from  $e$  to  $y$ , first use

```
mod = noisecnv(mod)
```

to convert the noise channels  $e$  to regular input channels. These channels are assigned the names  $e@yname$ .

**Purpose** State-space matrices from idmodel object

**Syntax**  
 $[A, B, C, D, K, X0] = \text{ssdata}(m)$   
 $[A, B, C, D, K, X0, dA, dB, dC, dD, dK, dX0] = \text{ssdata}(m)$

**Description**  $m$  is the model given as any idmodel object.  $A$ ,  $B$ ,  $C$ ,  $D$ ,  $K$ , and  $X0$  are the matrices in the state-space description

$$\tilde{x}(t) = Ax(t) + Bu(t) + Ke(t)$$

$$x(0) = x0$$

$$y(t) = Cx(t) + Dx(t) + e(t)$$

where  $\tilde{x}(t)$  is  $\dot{x}(t)$  or  $x(t + Ts)$  depending on whether  $m$  is a continuous-time or discrete-time model.

$dA$ ,  $dB$ ,  $dC$ ,  $dD$ ,  $dK$ , and  $dX0$  are the standard deviations of the state-space matrices.

If the underlying model itself is a state-space model, the matrices correspond to the same basis. If the underlying model is an input-output model, an observer canonical form representation is obtained.

For a time-series model (no measured input channels,  $u = []$ ),  $B$  and  $D$  are returned as the empty matrices.

Subreferencing models in the usual way (see idmodel properties) will give the state-space representation of the chosen channels. Notice in particular that

$$[A, B, C, D] = \text{ssdata}(m('m'))$$

gives the response from the measured inputs. This is a model without a disturbance description. Moreover,

$$[A, B, C, D, K] = \text{ssdata}(m('n'))$$

('n' as in "noise") gives the disturbance description, that is, a time-series description of the additive noise with no measured inputs, so that  $B = []$  and  $D = []$ .

To obtain state-space descriptions that treat all input channels, both  $u$  and  $e$ , as measured inputs, first apply the conversion

```
m = noisecnv(m)
```

or

```
m = noisecnv(m, 'norm')
```

where the latter case first normalizes  $e$  to  $v$ , where  $v$  has a unit covariance matrix. See the reference page for `noisecnv`.

## Algorithm

The computation of the standard deviations in the input-output case assumes that an  $A$  polynomial is not used together with an  $F$  or  $D$  polynomial in the general polynomial equation (see "What Are Black-Box Polynomial Models?" in the User's Guide. For the computation of standard deviations in the case that the state-space parameters are complicated functions of the parameters, the Gauss approximation formula is used together with numerical derivatives. The step sizes for this differentiation are determined by `nuderst`.

## Purpose

Plot step response with confidence interval

## Syntax

```
step(m)
step(data)
step(m, 'sd', sd, Time)
step(data, 'sd', sd, 'PW', na, Time)
step(m1, m2, ..., dat1, ..., mN, Time, 'sd', sd)
step(m1, 'PlotStyle1', m2, 'PlotStyle2', ..., dat1, 'PlotStylek', ..., mN,
'PlotStyleN', Time, 'sd', sd)
[y, t, ysd] = step(m)
mod = step(data)
```

## Description

`step` can be applied both to any `idmodel` or `idn1model` object and to `iddata` sets.

For a discrete-time `idmodel` `m`, the step response `y` and, when required, its estimated standard deviation `ysd`, are computed using `sim`. When called with output arguments, `y`, `ysd`, and the time vector `t` are returned. When `step` is called without output arguments, a plot of the step response is shown. If `sd` is given a value larger than zero, a confidence region around the response is drawn. It corresponds to the confidence of `sd` standard deviations. If the input argument list contains `'fill'`, this region is plotted as a filled area.

### Setting the Time Interval

The start time `T1` and the end time `T2` can be specified by `Time = [T1 T2]`. If `T1` is not given, it is set to `-T2/4`. The negative time lags (the step is always assumed to occur at time 0) show possible feedback effects in the data when the step is estimated directly from data. If `Time` is not specified, a default value is used.

### Estimating the Step Response from the Data

For an `iddata` set `data`, `step(data)` estimates a high-order, noncausal FIR model after first having prefiltered the data so that the input is “as white as possible.” The step response of this FIR model and, when asked for, its confidence region, are then plotted. Note that it might not be possible always to deliver the demanded time interval in

this case, because of lack of excitation in the data. A warning is then issued. When called with an output argument, `step`, in the `iddata` case, returns this FIR model, stored as an `idarx` model. The order of the prewhitening filter can be specified as `na`. The default value is `na = 10`.

### Several Models/Data Sets

Any number and any mixture of models and data sets can be used as input arguments. The responses are plotted with each input/output channel (as defined by the models and data sets `InputName` and `OutputName`) as a separate plot. Colors, line styles, and marks can be defined by `PlotStyle` values, as in

```
step(m1, 'b-*', m2, 'y--', m3, 'g')
```

### Noise Channels

The noise input channels in `m` are treated as follows: Consider a model `m` with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$y = Gu + He$$

$$\text{cov}(e) = \Lambda = LL'$$

where  $L$  is a lower triangular matrix. Note that `m.NoiseVariance =  $\Lambda$` . The model can also be described with a unit variance, using a normalized noise source  $v$ :

$$y = Gu + HLv$$

$$\text{cov}(v) = I$$

- `step(m)` plots the step response of the transfer function  $G$ .
- `step(m('n'))` plots the step response of the transfer function  $H$  ( $ny$  inputs and  $ny$  outputs). The input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- If `m` is a time series, that is,  $nu = 0$ , `step(m)` plots the step response of the transfer function  $H$ .

- `step(noiseconv(m))` plots the step response of the transfer function  $[G H]$  ( $nu+ny$  inputs and  $ny$  outputs). The noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- `step(noiseconv(m, 'norm'))` plots the step response of the transfer function  $[G HL]$  ( $nu+ny$  inputs and  $ny$  outputs). The noise input channels have names `v@yname`, where `yname` is the name of the corresponding output.

## Arguments

If `step` is called with a single `idmodel` `m`, the output argument `y` is a 3-D array of dimension `Nt`-by-`ny`-by-`nu`. Here `Nt` is the length of the time vector `t`, `ny` is the number of output channels, and `nu` is the number of input channels. Thus `y(:, ky, ku)` is the response in the `kyth` output channel to a step in the `kuth` input channel. No plot is produced when output arguments are used.

`ysd` has the same dimensions as `y` and contains the standard deviations of `y`. This is normally computed using `sim`. However, when the model `m` contains an estimated delay (dead time) as in certain process models, the standard deviation is estimated with Monte Carlo techniques, using `simsd`.

If `step` is called with an output argument and a single data set in the input arguments, the output is returned as an `idarx` model `mod` containing the high-order FIR model, and its uncertainty. By calling `step` with `mod`, the responses can be displayed and returned without your having to redo the estimation.

## Examples

```
% Estimate and plot the step response
step(data, 'sd', 3)
mod = step(data)
step(mod, 'sd', 3)
```

**Purpose**                   Generate model structure matrices for single-input and single-output systems

**Syntax**                   NN = struc(NA,NB,NK)

**Description**           struc returns in NN the set of model structures composed of all combinations of the orders and delays given in row vectors NA, NB, and NK. The format of NN is consistent with the input format used by arxstruc and ivstruc. The command is intended for single-input systems only.

**Examples**               The statement

```
    NN = struc(1:2,1:2,4:5);
```

produces

```
    NN =
          1      1      4
          1      1      5
          1      2      4
          1      2      5
          2      1      4
          2      1      5
          2      2      4
          2      2      5
```

**See Also**               arxstruc  
                  ivstruc  
                  selstruc

**Purpose** Convert `idmodel` objects to transfer-function Control System Toolbox LTI models

**Syntax**  
`sys = tf(mod)`  
`sys = tf(mod, 'm')`

**Description** `mod` is any `idmodel` object: `idgrey`, `idarcx`, `idpoly`, `idproc`, `idss`, or `idmodel`.

`sys` is returned as a transfer function `tf` LTI model object. The noise input channels in `mod` are treated as follows:

Consider a model `mod` with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$y = Gu + He$$

$$\text{cov}(e) = \Lambda = LL'$$

where  $L$  is a lower triangular matrix. `mod.NoiseVariance =  $\Lambda$` . The model can also be described with a unit variance, using a normalized noise source  $v$ .

$$y = Gu + HLv$$

$$\text{cov}(v) = I$$

Both measured input channels  $u$  and normalized noise input channels  $v$  in `mod` are input channels in `sys`. The noise input channels belong to the `InputGroup` 'Noise', while the others belong to the `InputGroup` 'Measured'. The names of the noise input channels will be `v@yname`, where `yname` is the name of the corresponding output channel. This means that the LTI object realizes the transfer function  $[G \ HL]$ .

To transform only the measured input channels in `mod`, use

$$\text{sys} = \text{tf}(\text{mod}('m')) \text{ or } \text{sys} = \text{tf}(\text{mod}, 'm')$$

This gives a representation of  $G$  only.

---

For a time series, (no measured input channels,  $nu = 0$ ), the LTI representation contains the transfer functions from the normalized noise sources  $v$  to the outputs, that is,  $HL$ . If the model `mod` has both measured and noise inputs, `sys = tf(mod('n'))` gives a representation of the additive noise.

In addition, you can use normal subreferencing.

```
sys = tf(mod(1,[3 4]))
```

If you want to describe  $[G H]$  or  $H$  (unnormalized noise), from  $e$  to  $y$ , first use

```
mod = noisecnv(mod)
```

to convert the noise channels  $e$  to regular input channels. These channels are assigned the names `e@yname`.

`frd`

`ss`

`zpk`

**Purpose** Numerator and denominator of transfer function from `idmodel` object

**Syntax**

```
[num,den] = tfdata(m)
[num,den,sdnum,sdden] = tfdata(m)
[num,den,sdnum,sdden] = tfdata(m, 'v')
```

**Description** `m` is a model given as any `idmodel` object with `ny` output channels and `nu` input channels.

`num` is a cell array of dimension `ny-by-nu`. `num{ky,ku}` (note the curly braces) contains the numerator of the transfer function from input `ku` to output `ky`. This numerator is a row vector whose interpretation is described below.

Similarly, `den` is an `ny-by-nu` cell array of the denominators.

`sdnum` and `sdden` have the same formats as `num` and `den`. They contain the standard deviations of the numerator and denominator coefficients.

If `m` is a SISO model, adding an extra input argument `'v'` (for vector) will return `num` and `den` as vectors rather than cell arrays.

The formats of `num` and `den` are the same as those used by the Signal Processing Toolbox and Control System Toolbox products, both for continuous-time and discrete-time models.

The noise input channels in `m` are treated as follows: Consider a model `m` with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$y = Gu + He$$
$$\text{cov}(e) = \Lambda = LL'$$

where  $L$  is a lower triangular matrix. Note that `m.NoiseVariance` =  $\Lambda$ . The model can also be described with a unit variance, using a normalized noise source  $v$ :

$$y = Gu + HLv$$
$$\text{cov}(v) = I$$

- `tfdata(m)` returns the transfer function  $G$ .
- `tfdata(m('n'))` returns the transfer function  $H$  ( $n_y$  inputs and  $n_y$  outputs).
- If  $m$  is a time series, that is,  $nu = 0$ , `tfdata(m)` returns the transfer function  $H$ .
- `tfdata(noiseconv(m))` returns the transfer function  $[G H]$  ( $nu+n_y$  inputs and  $n_y$  outputs).
- `tfdata(noiseconv(m, 'norm'))` returns the transfer function  $[G HL]$  ( $nu+n_y$  inputs and  $n_y$  outputs).

## Examples

For a continuous-time model,

```
num = [1 2]
den = [1 3 0]
```

corresponds to the transfer function

$$G(s) = \frac{s + 2}{s^2 + 3s}$$

For a discrete-time model,

```
num = [2 4 0]
den = [1 2 3 5]
```

corresponds to the transfer function

$$H(z) = \frac{2z^2 + 4z}{z^3 + 2z^2 + 3z + 5}$$

which is the same as

$$H(q) = \frac{2q^{-1} + 4q^{-2}}{1 + 2q^{-1} + 3q^{-2} + 5q^{-3}}$$

# tfdata

---

Note that for discrete-time models, `idpoly` and `polydata` have a different interpretation of the numerator vector, in case it does not have the same length as the denominator vector. To avoid confusion, fill out with zeros to make numerator and denominator vectors the same length. Do this with `tfdata`.

## See Also

`idpoly`  
`noisecnv`

**Purpose** Return date and time when object was created or last modified

**Syntax** `timestamp(obj)`  
`ts = timestamp(obj)`

**Description** `obj` is any `idmodel`, `iddata`, or `idfrd` object. `timestamp` returns or displays a string with information about when the object was created and last modified.

# treepartition

---

**Purpose** Class representing binary-tree nonlinearity estimator for nonlinear ARX models

**Syntax** `t=treepartition(Property1,Value1,...PropertyN,ValueN)`  
`t=treepartition('NumberOfUnits',N)`

**Description** `treepartition` is an object that stores the binary-tree nonlinearity estimator for estimating nonlinear ARX models.

You can use the constructor to create the nonlinearity object, as follows:

`t=treepartition(Property1,Value1,...PropertyN,ValueN)` creates a binary tree nonlinearity estimator object specified by properties in “`treepartition Properties`” on page 2-417. The tree has the number of leaves equal to  $2^{(J+1)} - 1$ , where  $J$  is the number of nodes in the tree and set by the property `NumberOfUnits`. The default value of `NumberOfUnits` is computed automatically.

---

**Note** `NumberOfUnits` sets an upper limit on the actual number of tree nodes used by the estimator.

---

`t=treepartition('NumberOfUnits',N)` creates a binary tree nonlinearity estimator object with  $N$  terms in the binary tree expansion (the number of nodes in the tree). When you estimate a model containing `t`, the value of the `NumberOfUnits` property,  $N$ , in `t` is automatically changed to show the actual number of leaves used—which is the largest integer of the form  $2^n - 1$  and less than or equal to  $N$ .

Use `evaluate(t,x)` to compute the value of the function defined by the `treepartition` object `t` at  $x$ . At this stage, an adaptive *pruning algorithm* is used to select an active partition  $D_a (= D_a(x))$  on the branch of tree partitions that contain  $x$ .

**Remarks** Use `treepartition` to define a nonlinear function  $y = F(x)$ , where  $F$  is a piecewise-linear (affine) function of  $x$ ,  $y$  is scalar, and  $x$  is a

1-by-m vector.  $F$  is a local linear mapping, where  $x$ -space partitioning is determined by a binary tree.

The binary-tree network function is based on the following function expansion:

$$F(x) = xL + [1, x]C_a + d$$

$x$  belongs to the active partition  $D_a$ .  $D_k$  is a partition of  $x$ -space.  $L$  is 1-by-m vector.

$C_k$  is a 1-by-(m+1) vector.

$d$  is a scalar.

The active partition  $D_a$  is computed as an intersection of half-spaces by a binary tree, as follows:

- 1** Tree with N nodes and J levels is initialized.
- 2** Node at level J is a terminating leaf and a node at level  $j < J$  has two descendants at level  $j+1$ . The number of leaves in the tree is  $N = 2^{(J+1)} - 1$ , which is determined by the NumberOfUnits property of the treepartition object.
- 3** Partition at node  $r$  is based on  $[1, x] * B_r > 0$  or  $\leq 0$  (move to left or right descendant), where  $B_r$  is chosen to improve the stability of least-square computation on the partitions at the descendant nodes.
- 4** Compute at each node  $r$  the coefficients  $C_r$  of best linear approximation of unknown regression function on  $D_r$  using penalized least-squares algorithm.

## treepartition Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
```

# treepartition

---

```
get(t)
% Get value of NumberOfUnits property
t.NumberOfUnits
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(t, 'NumberOfUnits', 5)
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
NumberOfUnits	<p>Integer specifies the number of nodes in the tree. Default='auto' selects the number of nodes from the data using the pruning algorithm.</p> <p>When you estimate a model containing a <code>treepartition</code> nonlinearity, the value of <code>NumberOfUnits</code> is automatically changed to show the actual number of leaves used—which is the largest integer of the form <math>2^n - 1</math> and less than or equal to <math>N</math> (the integer value of units you specify).</p> <p>For example:</p> <pre>treepartition('NumberOfUnits',5)</pre>

# treepartition

Property Name	Description
Options	<p>Structure containing the following fields that affect the initial model:</p> <ul style="list-style-type: none"><li>• <b>FinestCell</b>: Integer or string specifying the minimum number of data points in the smallest partition. Default: 'auto', which computes the value from the data.</li><li>• <b>Threshold</b>: Threshold parameter used by the adaptive pruning algorithm. Smaller threshold value corresponds to a shorter branch that is terminated by the active partition <math>D_a</math>. Higher threshold value results in a longer branch. Default: 1.0.</li><li>• <b>Stabilizer</b>: Penalty parameter of the penalized least-squares algorithm used to compute local parameter vectors <math>C_k</math>. Higher stabilizer value improves stability, but may deteriorate the accuracy of the least-square estimate. Default: <math>1e-6</math>.</li></ul>

## Examples

Use treepartition to specify the nonlinear estimator in nonlinear ARX models. For example:

```
m=nlarx(Data,Orders,treepartition('num',5));
```

The following commands provide an example of using advanced treepartition options:

```
% Define the treepartition object  
t=treepartition('num',100);  
% Set the Threshold, which is a field  
% in the Options structure  
t.Options.Threshold=2;  
% Estimate the nonlinear ARX model  
m=nlarx(Data,Orders,t);
```

deadzone

nlhw

saturation

sigmoidnet

**Purpose** Plot model characteristics using Control System Toolbox LTI Viewer GUI

**Syntax**

```
view(m)
view(m('n'))
view(m1,...,mN,Plotttype)
view(m1,PlotStyle1,...,mN,PlotStyleN)
```

**Description**  $m$  is the output-input data to be graphed, given as any `idfrd` or `idmodel` object. After appropriate model transformations, the Control System Toolbox LTI Viewer opens. This allows `bode`, `nyquist`, `impulse`, `step`, and `zero/poles` plots.

To compare several models  $m_1, \dots, m_N$ , use `view(m1, ..., mN)`. With `PlotStyle`, the color, line style, and marker of each model can be specified.

```
view(m1,'y:*',m2,'b')
```

Adding `Plotttype` as a last argument specifies the type of plot in which `view` is initialized. `Plotttype` is any of `'impulse'`, `'step'`, `'bode'`, `'nyquist'`, `'nichols'`, `'sigma'`, or `'pzmap'`. It can also be given as a cell array containing any collection of these strings (up to 6) in which case a multiplot is shown.

`view` does not display confidence regions. For that, use `bode`, `nyquist`, `impulse`, `step`, and `pzmap`.

The noise input channels in  $m$  are treated as follows: Consider a model  $m$  with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$y = Gu + He$$
$$\text{cov}(e) = \Lambda = LL^T$$

where  $L$  is a lower triangular matrix. Note that `m.NoiseVariance` =  $\Lambda$ . The model can also be described with a unit variance, using a normalized noise source  $v$ :

$$y = Gu + HLv$$

$$\text{cov}(v) = I$$

- `view(m)` plots the characteristics of the transfer function  $G$ .
- `view(m('n'))` plots the characteristics of the transfer function  $HL$  ( $ny$  inputs and  $ny$  outputs). The input channels have names `v@yname`, where `yname` is the name of the corresponding output.
- If `m` is a time series, that is,  $nu = 0$ , `view(m)` plots the characteristics of the transfer function  $HL$ .
- `view(noiseconv(m))` plots the characteristics of the transfer function  $[G H]$  ( $nu+ny$  inputs and  $ny$  outputs). The noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- `view(noiseconv(m,'norm'))` plots the characteristics of the transfer function  $[G HL]$  ( $nu+ny$  inputs and  $ny$  outputs). The noise input channels have names `v@yname`, where `yname` is the name of the corresponding output.

`view` does not give access to all of the features of `ltiview`. Use

```
m1 = ss(m), ltiview(Plotttype,m1,...)
```

to reach these options.

**Purpose** Class representing wavelet network nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models

**Syntax**  
`s=wavenet('NumberOfUnits',N)`  
`s=wavenet(Property1,Value1,...PropertyN,ValueN)`

**Description** `wavenet` is an object that stores the wavelet network nonlinear estimator for estimating nonlinear ARX and Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`s=wavenet('NumberOfUnits',N)` creates a wavelet nonlinearity estimator object with  $N$  terms in the wavelet expansion.

`s=wavenet(Property1,Value1,...PropertyN,ValueN)` creates a wavelet nonlinearity estimator object specified by properties in “wavenet Properties” on page 2-427.

Use `evaluate(s,x)` to compute the value of the function defined by the `wavenet` object `s` at `x`.

**Remarks** Use `wavenet` to define a nonlinear function  $y = F(x)$ , where  $y$  is scalar and  $x$  is an  $m$ -dimensional row vector. The wavelet network function is based on the following function expansion:

$$\begin{aligned} F(x) = & (x-r)PL + a_{s1}f((b_{s1}(x-r))Q - c_{s1}) + \dots \\ & + a_{sn}f((b_{sn}(x-r))Q - c_{sn}) \\ & + a_{w1}g((b_{w1}(x-r))Q - c_{w1}) + \dots \\ & + a_{wn}wg((b_{wn}(x-r))Q - c_{wn}) + d \end{aligned}$$

where  $f$  is a scaling function and  $g$  is the wavelet function.  $P$  and  $Q$  are  $m$ -by- $p$  and  $m$ -by- $q$  projection matrices, respectively. The projection matrices  $P$  and  $Q$  are determined by principal component analysis of estimation data. Usually,  $p=m$ . If the components of  $x$  in the estimation data are linearly dependent, then  $p < m$ . The number of columns of  $Q$ ,  $q$ ,

corresponds to the number of components of  $x$  used in the scaling and wavelet function.

When used in a nonlinear ARX model,  $q$  is equal to the size of the `NonlinearRegressors` property of the `idnlarx` object. When used in a Hammerstein-Wiener model,  $m=q=1$  and  $Q$  is a scalar.

$r$  is a 1-by- $m$  vector and represents the mean value of the regressor vector computed from estimation data.

$d$ ,  $a_s$ ,  $b_s$ ,  $a_w$ , and  $b_w$  are scalars. Parameters with the  $s$  subscript are scaling parameters, and parameters with the  $w$  subscript are wavelet parameters.

$L$  is a  $p$ -by-1 vector.

$c_s$  and  $c_w$  are 1-by- $q$  vectors.

The scaling function  $f$  and the wavelet function  $g$  are both radial functions, as follows:

$$f(x) = e^{-0.5x'x}$$

$$g(x) = (\dim(x) - x'x)e^{-0.5x'x}$$

## wavenet Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
get(w)
% Get value of NumberOfUnits property
w.NumberOfUnits
```

You can also use the `set` function to set the value of particular properties. For example:

```
h set(w, 'LinearTerm', 'on')
```

# wavenet

---

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
NumberOfUnits	<p>Integer specifies the number of nonlinearity units in the expansion. Default='auto'.</p> <p>For example:</p> <pre>wavenet('NumberOfUnits',5)</pre>
LinearTerm	<p>Can have the following values:</p> <ul style="list-style-type: none"><li>• 'on' — (Default) Estimates the vector <math>L</math> in the expansion.</li><li>• 'off' — Fixes the vector <math>L</math> to zero and omits the term <math>(x-r)PL</math>.</li></ul> <p>For example:</p> <pre>wavenet(H,'LinearTerm','on')</pre>

Property Name	Description
Parameters	<p>Structure containing the parameters in the nonlinear expansion, as follows:</p> <ul style="list-style-type: none"> <li>• <b>RegressorMean</b>: 1-by-m vector containing the means of <math>x</math> in estimation data, <math>r</math>.</li> <li>• <b>NonLinearSubspace</b>: m-by-q matrix containing <math>Q</math>.</li> <li>• <b>LinearSubspace</b>: m-by-p matrix containing <math>P</math>.</li> <li>• <b>LinearCoef</b>: p-by-1 vector <math>L</math>.</li> <li>• <b>ScalingDilation</b>: ns-by-1 matrix containing the values <math>bs_k</math>.</li> <li>• <b>WaveletDilation</b>: nw-by-1 matrix containing the values <math>bw_k</math>.</li> <li>• <b>ScalingTranslation</b>: ns-by-q matrix containing the values <math>cs_k</math>.</li> <li>• <b>WaveletTranslation</b>: nw-by-q matrix containing the values <math>cw_k</math>.</li> <li>• <b>ScalingCoef</b>: ns-by-1 vector containing the values <math>as_k</math>.</li> <li>• <b>WaveletCoef</b>: nw-by-1 vector containing the values <math>aw_k</math>.</li> <li>• <b>OutputOffset</b>: scalar <math>d</math>.</li> </ul>

Default: 2.</li><li>• <b>TranslationStep</b>: Real scalar specifying the translation step size. Default: 1.</li></ul>

## Examples

Use `wavenet` to specify the nonlinear estimator in nonlinear ARX and Hammerstein-Wiener models. For example:

```
m=nlarx(Data,Orders,wavenet);
```

## See Also

`nlarx`  
`nlhw`

**Purpose**

Convert `idmodel` objects to Control System Toolbox state-space LTI models

**Syntax**

```
sys = zpk(mod)
sys = zpk(mod, 'm')
```

**Description**

`mod` is any `idmodel` object: `idgrey`, `idarcx`, `idpoly`, `idproc`, `idss`, or `idmodel`.

`sys` is returned as a `zpk` LTI model object. The noise input channels in `mod` are treated as follows: consider a model `mod` with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$y = Gu + He$$

$$\text{cov}(e) = \Lambda = LL'$$

where  $L$  is a lower triangular matrix. Note that `mod.NoiseVariance` =  $\Lambda$ . The model can also be described with a unit variance, using a normalized noise source  $v$ .

$$y = Gu + HLv$$

$$\text{cov}(v) = I$$

Both measured input channels  $u$  and normalized noise input channels  $v$  in `mod` are input channels in `sys`. The noise input channels belong to the `InputGroup` 'Noise', while the others belong to the `InputGroup` 'Measured'. The names of the noise input channels are given by `v@yname`, where `yname` is the name of the corresponding output channel. This means that the LTI object realizes the transfer function  $[G \ HL]$ .

To transform only the measured input channels in `sys`, use

```
sys = zpk(mod('m')) or sys = zpk(mod, 'm')
```

This gives a representation of  $G$  only.

For a time series, (no measured input channels,  $nu = 0$ ), the LTI representation contains the transfer functions from the normalized

noise sources  $v$  to the outputs, that is,  $HL$ . If the model `mod` has both measured and noise inputs, `sys = zpk(mod('n'))` gives a representation of the additive noise.

In addition, the normal subreferencing can be used.

```
sys = zpk(mod(1,[3 4]))
```

If you want to describe  $[GH]$  or  $H$  (unnormalized noise), from  $e$  to  $y$ , first use

```
mod = noiseconv(mod)
```

to convert the noise channels  $e$  to regular input channels. These channels are assigned the names `e@yname`.

`frd`

`ss`

`tf`

**Purpose**

Zeros, poles, and gains of transfer function from `idmodel` object

**Syntax**

```
[z,p,k] = zpkdata(m)
[z,p,k,dz,dp,dk] = zpkdata(m)
[z,p,k,dz,dp,dk] = zpkdata(m,'v')
```

**Description**

`m` is a model given as any `idmodel` object with `ny` output channels and `nu` input channels.

`z` is a cell array of dimension `ny-by-nu`. `z{ky,ku}` (note the curly braces) contains the zeros of the transfer function from input `ku` to output `ky`. This is a column vector of possibly complex numbers.

Similarly, `p` is an `ny-by-nu` cell array containing the poles.

`k` is a `ny-by-nu` matrix whose `ky-ku` entry is the transfer function gain of the transfer function from input `ku` to output `ky`. Note that the transfer function gain is the value of the leading coefficient of the numerator when the leading coefficient of the denominator is normalized to 1. It thus differs from the static gain. The static gain can be retrieved as `Ks = freqresp(m,0)`.

`dz` contains the covariance matrices of the zeros in the following way: `dz` is a `ny-by-nu` cell array. `dz{ky,ku}` contains the covariance information about the zeros of the transfer function from `ku` to `ky`. It is a 3-D array of dimension 2-by-2-by-`Nz`, where `Nz` is the number of zeros. `dz{ky,ku}(:, :, kz)` is the covariance matrix of the zero `z{ky,ku}(kz)`, so that the 1-1 element is the variance of the real part, the 2-2 element is the variance of the imaginary part, and the 1-2 and 2-1 elements contain the covariance between the real and imaginary parts.

`dp` contains the covariance matrices of the poles in the same way.

`dk` is a matrix containing the variances of the elements of `k`.

If `m` is a SISO model, adding an extra input argument `'v'` (for vector) returns `z` and `p` as vectors rather than cell arrays.

Note that the zeros and the poles are associated with the different channel combinations. To obtain the so-called transmission zeros, use `tzero`.

The noise input channels in  $m$  are treated as follows: Consider a model  $m$  with both measured input channels  $u$  ( $nu$  channels) and noise channels  $e$  ( $ny$  channels) with covariance matrix  $\Lambda$

$$y = Gu + He$$
$$\text{cov}(e) = \Lambda = LL'$$

where  $L$  is a lower triangular matrix. Note that  $m.\text{NoiseVariance} = \Lambda$ . The model can also be described with a unit variance, using a normalized noise source  $v$ .

$$y = Gu + HLv$$
$$\text{cov}(v) = I$$

Then,

- `zpkdata(m)` returns the zeros and poles of  $G$ .
- `zpkdata(m('n'))` returns the zeros and poles of  $H$  ( $ny$  inputs and  $ny$  outputs).
- If  $m$  is a time series, that is,  $nu = 0$ , `zpkdata(m)` returns the zeros and poles of  $H$ .
- `zpkdata(noisecnv(m))` returns the zeros and poles of the transfer function  $[G H]$  ( $nu+ny$  inputs and  $ny$  outputs).
- `zpkdata(noisecnv(m, 'norm'))` returns the zeros and poles of the transfer function  $[G HL]$  ( $nu+ny$  inputs and  $ny$  outputs).

The procedure handles both models in continuous and discrete time.

Note that you cannot rely on information about zeros and poles at the origin and at infinity for discrete-time models. (This is a somewhat confusing issue anyway.)

## Algorithm

The poles and zeros are computed using `ss2zp`. The covariance information is computed using the Gauss approximation formula, using the parameter covariance matrix contained in  $m$ . When the transfer function depends on the parameters, numerical differentiation is

applied. The step sizes for the differentiation are determined in the M-file `nuderst`.

## Purpose

Estimate parameters of AR model from scalar time series in Simulink software returning `idpoly` object

## Library

System Identification Toolbox

## Description

The AR Estimator block estimates the parameters of an AR model for a scalar time series and returns the model as an `idpoly` object. A time series is time-domain data consisting of one or more outputs  $y(t)$  and no corresponding measured input.

For information about the default algorithm settings used for model estimation, see the [Algorithm Properties](#) reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

## Model Definition

The AR model is defined, as follows:

$$y(t) + a_1 y(t-1) + \dots + a_{n_a} y(t-n_a) = e(t)$$

where

- $y(t)$  is the output at time  $t$ .
- $a_1 \dots a_n$  are the parameters to be estimated from the data.
- $n_a$  is the number of poles of the system.
- $y(t-1) \dots y(t-n_a)$  are the previous outputs on which the current output depends.
- $e(t)$  is white-noise disturbance.

The AR model can be written compactly for a single output  $y(t)$  using the following notation:

$$A(q)y(t) = e(t)$$

where  $A(q) = 1 + a_1q^{-1} + \dots + a_{n_a}q^{-n_a}$  and  $q^{-1}$  is the backward shift operator defined by  $q^{-1}u(t) = u(t-1)$ .

The following block diagram shows the AR model structure.

## Input

Time-series signal.

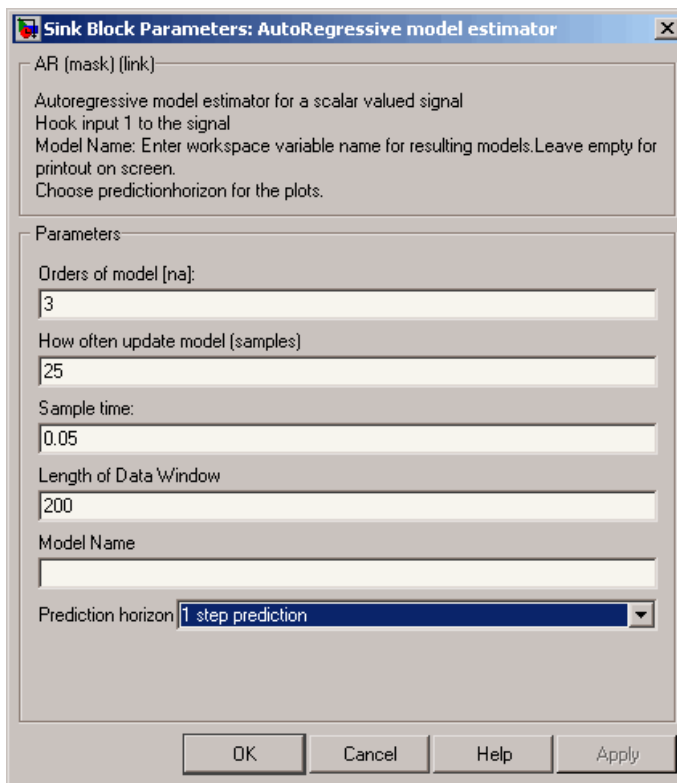

## Output

The AR Estimator block outputs a sequence of multiple models (idpoly objects), estimated at regular intervals during the simulation. The **Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

# AR Estimator

## Dialog Box

### Orders of model [na]

Integer  $n_a$  corresponds to the number of  $a$  parameters (poles) in the AR model.

### How often to update model (samples)

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

### Sample time

Sampling time for the model.

---

**Note** If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

---

## Length of Data Window

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

## Model Name

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

## Prediction horizon

Specifies the forward-prediction horizon for computing the response K steps in the future, where K is 1, 5, or 10.

## Examples

This example shows how you can use the AR Estimator block in a Simulink model.

- 1 Generate sample input and output data.

```
y = sin([1:300]') + 0.5*randn(300,1);  
y = iddata(y);
```

- 2 Create a new Simulink model, as follows:

# AR Estimator

---

- Add the IDDATA Source block and specify  $y$  in the **Iddata object** field of the IDDATA Source block parameter dialog box.
- Add the AR Estimator block to the model and accept default block parameter values.
- Connect the Output port of the IDDATA Source block to the  $y$  port of the AR Estimator block.

### 3 Run the estimation.

The estimated models appear in the MATLAB Command Window every 25 samples.

"Time Series Model Identification"

## Purpose

Estimate parameters of ARMAX model from SISO data in Simulink software returning `idpoly` object

## Library

System Identification Toolbox

## Description

The ARMAX Estimator block estimates the parameters of a single-input and single-output ARMAX model and returns the model as an `idpoly` object.

For information about the default algorithm settings used for model estimation, see the [Algorithm Properties](#) reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

## Model Definition

The ARMAX model is defined, as follows:

$$y(t) + a_1 y(t-1) + \dots + a_{n_a} y(t-n_a) = b_1 u(t-1) + \dots + b_{n_b} u(t-n_b) + e(t) + c_1 e(t-1) + \dots + c_{n_c} e(t-n_c)$$

where

- $y(t)$  is the output at time  $t$ .
- $a_1 \dots a_n$ ,  $b_1 \dots b_n$ , and  $c_1 \dots c_n$  are the parameters to be estimated.
- $n_a$  is the number of poles of the system.
- $n_b - 1$  is the number of zeros of the system.
- $n_c$  is the number of previous error terms on which the current output depends.

# ARMAX Estimator

---

- $n_k$  is the number of input samples that occur before the inputs affecting the current output.
- $y(t-1)\dots y(t-n_a)$  are the previous outputs on which the current output depends.
- $u(t-n_k)\dots u(t-n_k-n_b+1)$  are the previous inputs on which the current output depends.
- $e(t), e(t-1), \dots, e(t-n_c)$  are the white-noise disturbance values on which the current output depends.

The ARMAX model can also be written in a compact way using the following notation:

$$A(q)y(t) = B(q)u(t) + C(q)e(t)$$

where

$$A(q) = 1 + a_1q^{-1} + \dots + a_{n_a}q^{-n_a}$$

$$B(q) = b_1 + b_2q^{-1} + \dots + b_{n_b}q^{-n_b+1}$$

$$C(q) = 1 + c_1q^{-1} + \dots + c_{n_c}q^{-n_c}$$

and  $q^{-1}$  is the backward shift operator, defined by  $q^{-1}u(t) = u(t-1)$ .

The following block diagram shows the ARMAX model structure.

## Input

The block accepts two inputs, corresponding to the measured input-output data for estimating the model.

First input: Input signal.

Second input: Output signal.

## Output

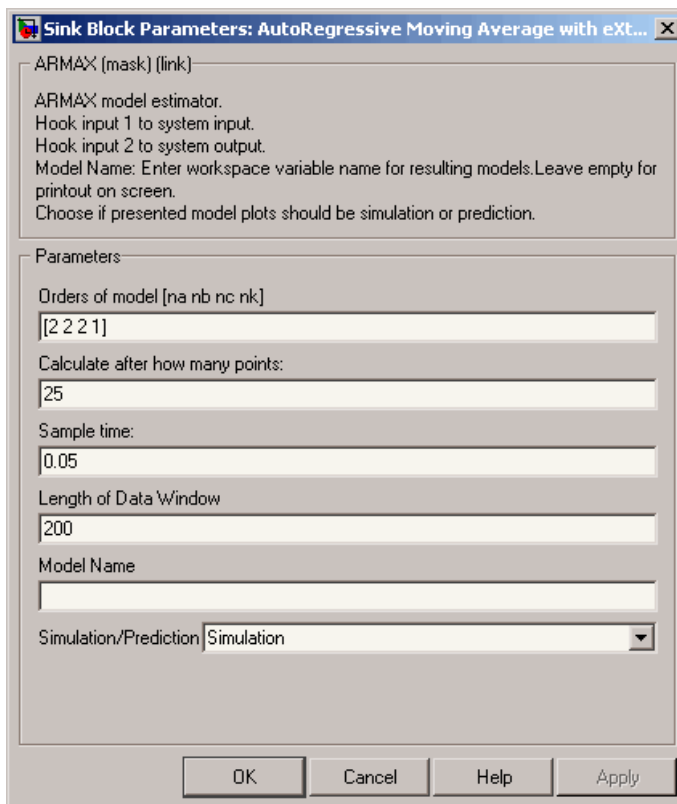

The ARMAX Estimator block outputs a sequence of multiple models (idpoly objects), estimated at regular intervals during the simulation.

The **Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

# ARMAX Estimator

## Dialog Box

### Orders of model [na nb nc nk]

Integers  $n_a$ ,  $n_b$ ,  $n_c$ , and  $n_k$  specify the number of  $A$ ,  $B$ , and  $C$  model parameters and  $n_k$  is input-output delay, respectively.

### Calculate after how many points

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

### Sample time

Sampling time for the model.

---

**Note** If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

---

## Length of Data Window

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

## Model Name

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

## Simulation/Prediction

**Simulation:** The algorithm uses only measured input data to simulate the response of the model.

**Prediction:** Specifies the forward-prediction horizon for computing the response K steps in the future, where K is 1, 5, or 10.

## Examples

This example shows how you can use the ARMAX Estimator block in a Simulink model.

- 1 Generate sample input and output data.

```
u = sin([1:300]') + 0.6*(rand(300,1)-0.5);
```

# ARMAX Estimator

---

```
y = cos(u) + 0.1*rand(300,1);  
IODEATA = iddata(y,u,1);
```

**2** Create a new Simulink model, as follows.

Add the IODEATA Source block and specify IODEATA in the **Iddata object** field of the IODEATA Source block parameters dialog box.

Add the ARMAX Estimator block to the model and set the model orders to [4 4 4 0] and set the sample time to 1.

Connect the Input and Output ports of the IODEATA Source block to the u and y ports of the ARMAX Estimator block, respectively. Set the simulation end time to 300 seconds.

**3** Run the simulation.

The estimated models display in the MATLAB Command Window every 25 samples.

## Topics in the System Identification Toolbox User's Guide

"Identifying Input-Output Polynomial Models"

## Purpose

Estimate parameters of ARX model from SISO data in Simulink software returning `idpoly` object

## Library

System Identification Toolbox

## Description

The ARX block uses least-squares analysis to estimate the parameters of an ARX model and returns the estimated model as an `idpoly` object.

For information about the default algorithm settings used for model estimation, see the [Algorithm Properties](#) reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

## Model Definition

The ARX model is defined, as follows:

$$y(t) + a_1 y(t-1) + \dots + a_{n_a} y(t-n_a) = b_1 u(t-1) + \dots + b_{n_b} u(t-n_k - n_b + 1) + e(t)$$

where

- $y(t)$  is the output at time  $t$ .
- $a_1 \dots a_n$  and  $b_1 \dots b_n$  are the parameters to be estimated.
- $n_a$  is the number of poles of the system.
- $n_b - 1$  is the number of zeros of the system.
- $n_k$  is the number of input samples that occur before the inputs that affect the current output.
- $y(t-1) \dots y(t-n_a)$  are the previous outputs on which the current output depends.

# ARX Estimator

---

- $u(t - n_k) \dots u(t - n_k - n_b + 1)$  are the previous inputs on which the current output depends.
- $e(t)$  is a white-noise disturbance value.

The ARX model can also be written in a compact way using the following notation:

$$A(q)y(t) = B(q)u(t - n_k) + e(t)$$

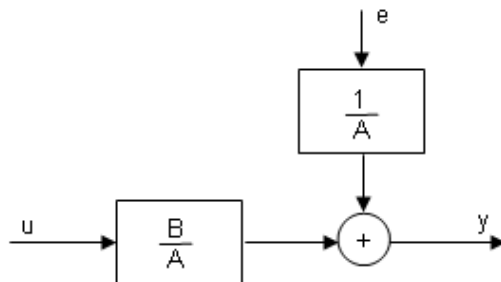

where

$$A(q) = 1 + a_1q^{-1} + \dots + a_{n_a}q^{-n_a}$$

$$B(q) = b_1 + b_2q^{-1} + \dots + b_{n_b}q^{-n_b+1}$$

and  $q^{-1}$  is the backward shift operator, defined by  $q^{-1}u(t) = u(t - 1)$ .

The following block diagram shows the ARX model structure.

## Input

The block accepts two inputs, corresponding to the measured input-output data for estimating the model.

First input: Input signal.

Second input: Output signal.

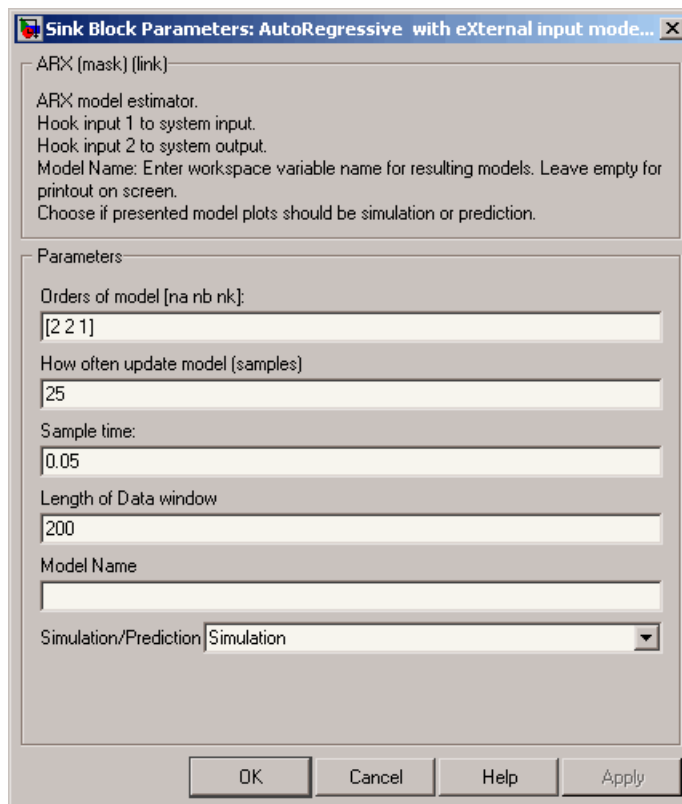

## Output

The ARX Estimator block outputs a sequence of multiple models (idpoly objects), estimated at regular intervals during the simulation.

The **Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

## Dialog Box

The dialog box is titled "Sink Block Parameters: AutoRegressive with external input mode...". It contains the following fields and options:

- ARX (mask) (link):** ARX model estimator.  
Hook input 1 to system input.  
Hook input 2 to system output.  
Model Name: Enter workspace variable name for resulting models. Leave empty for printout on screen.  
Choose if presented model plots should be simulation or prediction.
- Parameters:**
  - Orders of model [na nb nk]: [2 2 1]
  - How often update model (samples): 25
  - Sample time: 0.05
  - Length of Data window: 200
  - Model Name: (empty text field)
  - Simulation/Prediction: Simulation (dropdown menu)

Buttons at the bottom: OK, Cancel, Help, Apply.

## Orders of model [na nb nk]

Integers  $n_a$ ,  $n_b$ , and  $n_k$  specify the number of  $A$  and  $B$  model parameters and  $n_k$  is input-output delay, respectively.

## How often to update model [samples]

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

## Sample time

Sampling time for the model.

---

**Note** If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

---

## Length of Data window

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

## Model Name

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

## Simulation/Prediction

**Simulation:** The algorithm uses only measured input data to simulate the response of the model.

**Prediction:** Specifies the forward-prediction horizon for computing the response K steps in the future, where K is 1, 5, or 10.

## Examples

This example shows how you can use the ARX Estimator block in a Simulink model.

- 1 Specify the data from `iddata1.mat` for estimation:

```
load iddata1;  
IODEATA = z1;
```

- 2 Create a new Simulink model, as follows:

- Add the IODEATA Source block and specify IODEATA in the **Iddata object** field of the IODEATA Source block parameters dialog box.
- Add the ARX Estimator block to the model. Set the sample time in the block to 0.1 seconds and the simulation end time to 30 seconds.
- Connect the Input and Output ports of the IODEATA Source block to the `u` and `y` ports of the ARX Estimator block, respectively.

- 3 Run the simulation.

“Identifying Input-Output Polynomial Models”

## Purpose

Estimate parameters of Box-Jenkins model from SISO data in Simulink software returning `idpoly` object

## Library

System Identification Toolbox

## Description

The BJ Estimator block estimates the parameters of a Box-Jenkins model, and returns the estimated model as an `idpoly` object.

For information about the default algorithm settings used for model estimation, see the [Algorithm Properties](#) reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

## Model Definition

The Box-Jenkins model is defined, as follows:

$$y(t) = \frac{B(q)}{F(q)} u(t - n_k) + \frac{C(q)}{D(q)} e(t)$$

where the coefficients of

$$B(q) = b_1 + b_2 q^{-1} + \dots + b_{n_b} q^{-n_b + 1}$$

$$F(q) = 1 + f_1 q^{-1} + \dots + f_{n_f} q^{-n_f}$$

$$C(q) = 1 + c_1 q^{-1} + \dots + c_{n_c} q^{-n_c}$$

$$D(q) = 1 + d_1 q^{-1} + \dots + d_{n_d} q^{-n_d}$$

are the parameters being estimated, and  $q^{-1}$  is the backward shift operator defined by  $q^{-1}u(t) = u(t - 1)$ .

The following block diagram shows the Box-Jenkins model structure.

# BJ Estimator

---

## Input

The block accepts two inputs, corresponding to the measured input-output data for estimating the model.

First input: Input signal.

Second input: Output signal.

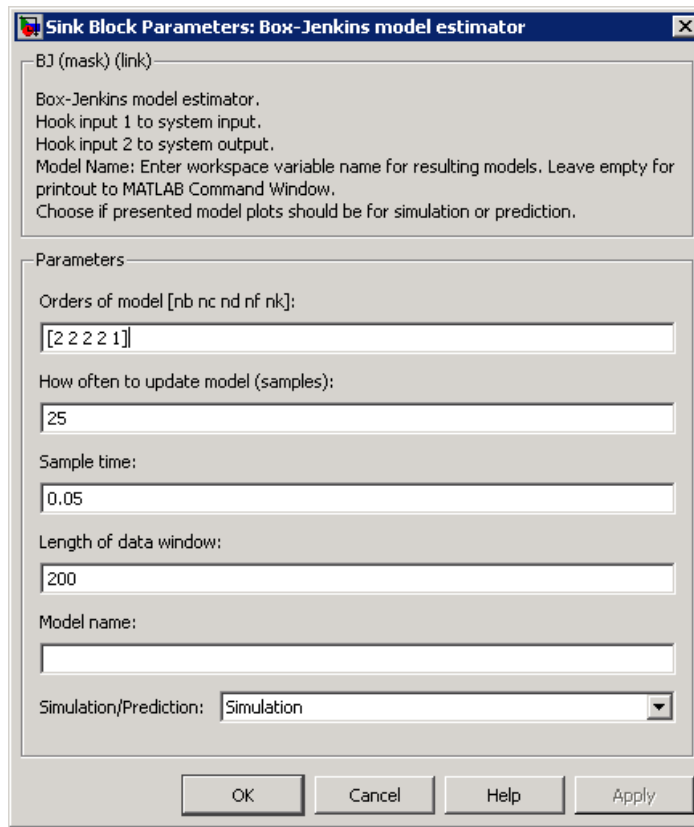

## Output

The BJ Estimator block outputs a sequence of multiple models (`idpoly`), estimated at regular intervals during the simulation.

The **Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

## Dialog Box

### Orders of model [nb nc nd nf nk]

Integers  $n_b$ ,  $n_c$ ,  $n_d$ , and  $n_f$  specify the number of  $B$ ,  $C$ ,  $D$ , and  $F$  model parameters, respectively.

Integer  $n_k$  specifies the input-output delay.

### Calculate after how many points

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

## **Sample time**

Sampling time for the model.

---

**Note** If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

---

## **Length of data window**

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

## **Model name**

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

## **Simulation/Prediction**

**Simulation:** The algorithm uses only measured input data to simulate the response of the model.

**Prediction:** Specifies the forward-prediction horizon for computing the response  $K$  steps in the future, where  $K$  is 1, 5, or 10.

## Examples

This example shows how you can use the BJ Estimator block in a Simulink model.

- 1 Specify the data in `iddata1.mat` for estimation:

```
load iddata1;  
IODATA = z1;
```

- 2 Create a new Simulink model, as follows:

- Add the IDDATA Source block and specify IODATA in the **Iddata object** field of the IDDATA Source block parameters dialog box.
- Add the BJ Estimator block to the model. Set the sample time in the block to 0.1 seconds and the simulation end time to 30 seconds.
- Connect the Input and Output ports of the IDDATA Source block to the `u` and `y` ports of the BJ Estimator block, respectively.

- 3 Run the simulation.

The estimated models appear in the MATLAB Command Window every 25 samples.

IDDATA Source

## Purpose

Import iddata object from MATLAB workspace

## Library

System Identification Toolbox

## Description

The IDDATA Source block imports an iddata object from the MATLAB workspace.

## Input

None.

## Output

The first block output is the input signal of the iddata object imported from the MATLAB workspace.

The second block output is the output signal of this iddata object.

## Dialog Box

## Iddata object

Name of the iddata object imported from the MATLAB workspace.

## IDDATA Source

---

The `iddata` object must contain only one experiment. For a multiple-experiment object, use `getexp(data, kexp)` to specify the experiment number `kexp`.

### **See Also**

IDDATA Sink

**Purpose** Simulate idmodel object in Simulink software

**Library** System Identification Toolbox

**Description** The IDMODEL block simulates a linear model in the MATLAB workspace.

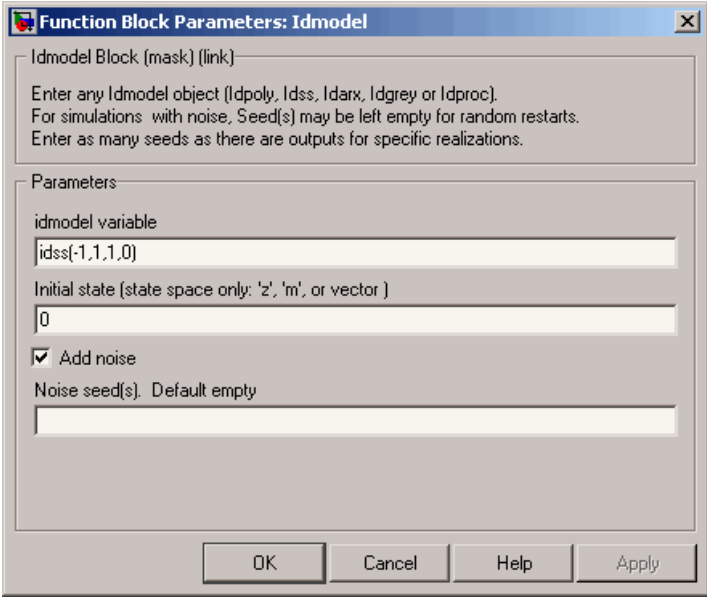

**Note** For simulating nonlinear models, use the IDNLGREY, IDNLARX, or IDNLHW Model blocks.

**Input**  
Input signal to the model.

**Output**  
Simulated output from the model.

## Dialog Box

## **idmodel variable**

Name of `idmodel` variable in the MATLAB workspace, which can be an `idpoly`, `idss`, `idgrey`, `idarx` or `idproc` model object that you estimated using System Identification Toolbox software.

This block supports both continuous-time and discrete-time models with or without input-output delays.

## **Initial state (state space only)**

Initial state vector.

(Default) 'z' (in quotation marks) specifies zero, which corresponds to a simulation starting from a state of rest.

Enter 'm' to use the internal initial states of the model, stored by the `idss` or `idgrey` model property `X0`.

To specify your own initial states, enter one of the following:

- Enter known initial states for a state-space model directly, as a numerical vector.

---

**Note** For non-state-space models, the initial conditions are 0.

---

- Compute the initial states using the `findstates(idmodel)` command to get the initial state values that produce the best fit between the model output and the measured output signal.

For example, if the data set `z` and model `m` are already in the MATLAB workspace, you can enter `X0`, such that:

```
X0 = findstates(m,z1)
```

## **Add noise**

Select when you need to add noise, as specified by the model property `model.NoiseVariance` and the matrices or polynomials that determine the color of the additive noise.

For continuous-time models, the ideal variance of the noise term at any moment is infinite. In reality, you see a band-limited noise that takes into account the natural time constants of the system. You can interpret the resulting simulated output as filtered using a low-pass filter with a pass-band that does not distort the dynamics from the input.

### Noise seed(s)

(Use when you select the **Add noise** check box.)

Enter an integer that specifies a seed that forces the simulation to add the same noise to the output every time you simulate the model. For more information about using seeds with functions that generate random number sequences, see the `rand` reference page in MATLAB documentation, for example.

# IDNLARX Model

**Purpose** Simulate nonlinear ARX model in Simulink software

**Library** System Identification Toolbox

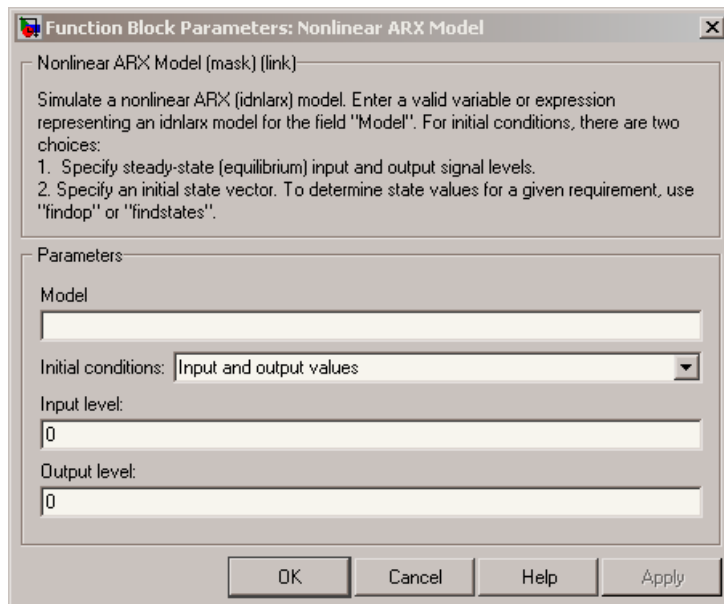

**Description** The IDNLARX Model block simulates a nonlinear ARX (idnlarx) model for time-domain input and output data.

**Input** Input signal to the model.

**Output** Simulated output from the model.

## Dialog Box

**Model** Name of idnlarx variable in the MATLAB workspace.

## Initial conditions

Specifies the initial states as one of the following:

- **Input and output values:** Specify the input and output levels, as follows:
  - **Input level**

If known, enter a vector of length equal to the number of model inputs. If you enter a scalar, it is the signal value for all inputs.
  - **Output level**

If known, enter a vector of length equal to the number of model's outputs. If you enter a scalar, it is the signal value for all outputs.
- **State values:** When selected, you must specify a vector of length equal to the number of states in the model in the **Vector of state values** field.

If you do not know the initial states, you can estimate these states, as follows:

- To simulate around a given input level when you do not know the corresponding output level, you can estimate the equilibrium state values using the `findop(idnlarx)` command.

For example, to simulate a model `M` about a steady-state point where the input is 1 and the output is unknown, you can enter `X0`, such that:

```
X0 = findop(M, 'steady', 1, NaN)
```

- To estimate the initial states that provide a best fit between measured data and the simulated response of the model for the same input, use the `findstates(idnlarx)` command.

# IDNLARX Model

---

For example, to compute initial states such that the response of the model `M` matches the output data in the data set `z`, you can enter `X0`, such that:

```
X0 = findstates(M,z,[],'sim')
```

- To continue a simulation from a previous run, use the simulated input-output values from the previous simulation to compute the initial states `X0` for the current simulation.

For example, suppose that `firstSimData` is a variable that stores the input and output values from a previous simulation. For a model `M`, you can enter `X0`, such that:

```
X0 = data2state(M,firstSimData)
```

## Examples

### Example 1

In this example, you estimate a nonlinear ARX model from data and compare the model output of the model to the measured output of the system.

- 1 Load the sample data.

```
load twotankdata
```

- 2 Create a data object from sample data.

```
z = iddata(y,u,0.2,'Name','Two tank system');  
z1 = z(1:1000);
```

- 3 Estimate a nonlinear ARX model.

```
mw1 = nlarx(z1,[5 1 3],wavenet('NumberOfUnits',8));
```

- 4 Build the following Simulink model using the `IDDATA` Source, `IDNLARX` Model, and `Scope` blocks.

- 5 Double-click the IDDATA Source block and enter the following into the block parameter dialog box:

**IDDATA Object:** z1

Click **OK**.

- 6 Double-click the IDNLARX Model block and enter the following into the block parameter dialog box:
  - **Model:** mw1
  - **Initial conditions:** Select Input and output values and accept the default values.

- 7 Run the simulation.

Click the Scope block to view the difference between the measured output and the model output. Use the **Autoscale** command to scale the axes.

## Example 2

In this example, you reduce the difference between the measured and simulated responses. To achieve this, you use the `findstates` command to estimate an initial state vector for the model from the data.

- 1 Estimate initial states from the data z1.

# IDNLARX Model

---

```
x0 = findstates(mw1,z1,[],'simulation');
```

**2** Set the **Initial Conditions** to State Values. Enter x0 in the corresponding field.

**3** Run the simulation.

"Estimating Nonlinear Grey-Box Models"

**Purpose** Simulate Hammerstein-Wiener model in Simulink software

**Library** System Identification Toolbox

**Description** The IDNLHW Model block simulates a Hammerstein-Wiener (idnlhw) model for time-domain input and output data.

**Input** Input signal to the model.

**Output** Simulated output from the model.

## Dialog Box

**Model**  
Name of the idnlhw variable in the MATLAB workspace.

**Initial conditions**  
Specifies the initial states as one of the following:

# IDNLHW Model

---

- **Zero:** Specifies zero, which corresponds to a simulation starting from a state of rest.
- **State values:** When selected, you must specify a vector of length equal to the number of states in the model in the **Specify a vector of state values** field.

If you do not know the initial states, you can estimate these states, as follows:

- To simulate around a given input level when you do not know the corresponding steady-state output level, you can estimate the equilibrium state values using the `findop(idnlhw)` command.

For example, to simulate a model `M` about a steady-state point where the input is 1 and the output is unknown, you can enter `X0`, such that:

```
X0 = findop(M,'steady',1,NaN)
```

- To estimate the initial states such that the simulated response of the model matches specified output data for the same input, use the `findstates(idnlhw)`.

For example, for the data set `z` and model `m`, you can enter `X0`, such that:

```
X0 = findstates(m,z)
```

## Examples

### Example 1

In this example, you estimate a Hammerstein-Wiener model from data and compare the model output of the model to the measured output of the system.

- 1 Load the sample data.

```
load twotankdata
```

- 2 Create a data object from sample data.

```
z = iddata(y,u,0.2, ...  
          'Name','Two tank system',...  
          'Tstart',0);
```

- 3 Estimate a Hammerstein-Wiener model.

```
mhw1 = nlhw(z,[1 5 3],pwlinear,pwlinear);
```

- 4 Build the following Simulink model using the IDDATA Source, IDNLHW Model, and Scope blocks.

- 5 Double-click the IDDATA Source block and enter the following into the block parameter dialog box:

- **IDDATA Object:** z

Click **OK**.

- 6 Double-click the IDNLHW Model block and enter the following into the block parameter dialog box:

- **Model:** mhw1
- **Initial Conditions:** Zero

- 7 Run the simulation.

Click the Scope block to view the difference between the measured output and the model output. Use the **Autoscale** toolbar button to scale the axes.

# IDNLHW Model

---

## Example 2

In this example, you reduce the difference between the measured and simulated responses using suitable initial state values. To achieve this, you use the `findstates` command to estimate an initial state vector for the model from the data.

**1** Estimate initial states from the data `z`:

```
x0 = findstates(mhw1,z,[],'maxiter',50);
```

**2** Set the **Initial Conditions** to State Values. Enter `x0` in the corresponding field.

**3** Run the simulation.

## Topics in the System Identification Toolbox User's Guide

“Identifying Hammerstein-Wiener Models”

## Purpose

Estimate parameters of Output-Error model from SISO data in Simulink software returning idpoly object

## Library

System Identification Toolbox

## Description

The OE block estimates the parameters of an Output-Error model, and returns the estimated model as an idpoly object.

For information about the default algorithm settings used for model estimation, see the [Algorithm Properties](#) reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

## Model Definition

The output-error model is defined, as follows:

$$w(t) + f_1 w(t-1) + \dots + f_{n_f} w(t-n_f) = b_1 u(t-1) + \dots + b_{n_b} u(t-n_b-n_b+1)$$

$$y(t) = w(t) + e(t)$$

where

- $w$  is the undisturbed output.
- $y(t)$  is the output at time  $t$ .
- $f_1 \dots f_{n_f}$  and  $b_1 \dots b_{n_b}$  are the parameters to be estimated.
- $n_f$  is the number of poles of the transfer function from the input to the undisturbed output.
- $n_b + 1$  is the number of zeros of the transfer function from the input to the undisturbed output.

# OE Estimator

---

- $n_k$  is the number of input samples that occur before the inputs that affect the current output.
- $u(t - n_k) \dots u(t - n_k - n_b + 1)$  are the previous inputs on which the current output depends.
- $e(t)$  is a white-noise disturbance value.

The OE model can also be written in a compact way using the following notation:

$$y(t) = \frac{B(q)}{F(q)} u(t - n_k) + e(t)$$

where

$$B(q) = b_1 + b_2 q^{-1} + \dots + b_{n_b} q^{-n_b + 1}$$

$$F(q) = 1 + f_1 q^{-1} + \dots + f_{n_f} q^{-n_f}$$

and  $q^{-1}$  is the backward shift operator, defined by  $q^{-1}u(t) = u(t - 1)$ .

The following block diagram shows the ARX model structure.

## Input

The block accepts two inputs, corresponding to the measured input-output data for estimating the model.

First input: Input signal.

Second input: Output signal.

## Output

The OE Estimator block outputs a sequence of multiple models (idpoly), estimated at regular intervals during the simulation.

The **Length of Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

## Dialog Box

### Orders of model [nb nf nk]

Integers  $n_b$ ,  $n_f$ , and  $n_k$  specify the number of  $B$  and  $F$  model parameters and  $n_k$  is the input-output delay, respectively.

## How often to update model

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

## Sample time

Sampling time for the model.

---

**Note** If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

---

## Length of Data Window

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

## Model Name

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

## Simulation/Prediction

**Simulation:** The algorithm uses only measured input data to simulate the response of the model.

**Prediction:** Specifies the forward-prediction horizon for computing the response K steps in the future, where K is 1, 5, or 10.

## Examples

This example shows how you can use the OE Estimator block in a Simulink model.

- 1 Specify the data from `iddata1.mat` for estimation:

```
load iddata1;  
IODEATA = z1;
```

- 2 Create a new Simulink model, as follows:

- Add the IDDATA Source block and specify IOEATA in the **Iddata object** field of the IDDATA Source block parameters dialog box.
- Add the OE Estimator block to the model. Set sample time in the block to 0.1 seconds and the simulation end time to 30 seconds.
- Connect the Input and Output ports of the IDDATA Source block to the `u` and `y` ports of the OE Estimator block, respectively.

- 3 Run the simulation.

The estimated models appear in the MATLAB Command Window every 25 samples.

**Prediction:** Specifies the forward-prediction horizon for computing the response K steps in the future, where K is 1, 5, or 10.

## Examples

This example shows how you can use the PEM Estimator block in a Simulink model.

- 1 Specify data in `iddata1.mat` for estimation:

```
load iddata1;  
IODATA = z1;
```

- 2 Create a new Simulink model, as follows.

Add the IDDATA Source block and specify `IODATA` in the **Iddata object** field of the IDDATA Source block parameters dialog box.

Add the PEM Estimator block to the model. Set the sample time in the block to 0.1 seconds and the simulation end time to 30 seconds.

Connect the Input and Output ports of the IDDATA Source block to the `u` and `y` ports of the PEM Estimator block, respectively.

- 3 Run the simulation.

The estimated models display in the MATLAB Command Window every 25 samples.
