Function Reference

Data Import and Processing (p. 1-3)	Represent, process, analyze, and manipulate data
Linear Model Identification (p. 1-5)	Estimate time response, frequency response, transfer function, input-output polynomial, and state-space models from time and frequency domain data
Nonlinear Black-Box Model Identification (p. 1-8)	Estimate nonlinear ARX and Hammerstein-Wiener models
ODE Parameter Estimation (p. 1-12)	Estimate parameters of linear and nonlinear ordinary differential or difference equations (grey-box models)
Recursive Model Identification (p. 1-12)	Recursively estimate input-output linear models, such as AR, ARX, ARMAX, Box-Jenkins, and Output-Error models
Model Analysis (p. 1-13)	Validate and analyze models by comparing model output, computing parameter confidence intervals and prediction errors, and getting advice on estimated models

Simulation and Prediction (p. 1-16)	Simulate and predict linear and nonlinear model output, and estimate initial states
System Identification Tool GUI (p. 1-17)	Start System Identification Toolbox™ GUI and customize preferences

Data Import and Processing

`advice`	Analysis and recommendations for data or estimated linear polynomial and state-space models
`covf`	Estimate covariance functions for time-domain iddata object
`delayest`	Estimate time delay (dead time) from data
`detrend`	Subtract offset or trend from data signals
`diff`	Difference signals in iddata objects
`fcat`	Concatenate frequency-domain signals in data objects
`feedback`	Identify possible feedback data
`fft`	Transform `iddata` object to frequency domain data
`fselect`	Frequencies from frequency response data
`get`	Query properties of data and model objects
`getexp`	Specific experiments from multiple-experiment data set
`getTrend`	Data offset and trend information
`iddata`	Time- or frequency-domain data
`idfilt`	Filter data using user-defined passbands, general filters, or Butterworth filters
`idfrd`	Frequency-response data or model
`idinput`	Generate input signals
`idresamp`	Resample time-domain data by decimation or interpolation

`ifft`	Transform iddata objects from frequency to time domain
`isreal`	Determine whether model parameters or data values are real
`merge (iddata)`	Merge data sets into iddata object
`misdata`	Reconstruct missing input and output data
`nkshift`	Shift data sequences
`pexcit`	Level of excitation of input signals
`plot`	Plot iddata or model objects
`realdata`	Determine whether `iddata` is based on real-valued signals
`resample`	Resample time-domain data by decimation or interpolation (requires Signal Processing Toolbox™ software)
`set`	Set properties of data and model objects
`size`	Dimensions of data and model objects
`timestamp`	Return date and time when object was created or last modified
`TrendInfo`	Offset and linear trend slope values for detrending data

Linear Model Identification

`ar`	Estimate parameters of AR model for scalar time series
`armax`	Estimate parameters of ARMAX or ARMA model
`arx`	Estimate parameters of ARX or AR model using least squares
`arxdata`	ARX parameters from multiple-output models with variance information
`arxstruc`	Compute and compare loss functions for single-output ARX models
`balred`	Reduce model order (requires Control System Toolbox™ product)
`bj`	Box-Jenkins (BJ) model estimation
`c2d`	Transform linear model from continuous to discrete time
`cra`	Estimate impulse response using prewhitened-based correlation analysis
`d2c`	Transform linear model from discrete to continuous time
`delayest`	Estimate time delay (dead time) from data
`etfe`	Estimate empirical transfer functions and periodograms
`feedback`	Identify possible feedback data
`frd`	Convert `idfrd` objects to Control System Toolbox frequency-response LTI model
`freqresp`	Frequency response data from linear models

`get`	Query properties of data and model objects
`idarx`	Multiple-output ARX polynomials, impulse response, or step response model
`idfrd`	Frequency-response data or model
`idgrey`	Linear ODE (grey-box model) with known and unknown parameters
`idmodel`	Superclass for linear models
`idpoly`	Linear polynomial input-output model
`idproc`	Linear, low-order, continuous-time transfer function
`idss`	State-space model
`impulse`	Plot impulse response with confidence interval
`init`	Set or randomize initial parameter values
`iv4`	Estimate ARX model using four-stage instrumental variable method
`ivar`	Estimate AR model using instrumental variable method
`ivstruc`	Loss functions for sets of ARX model structures
`ivx`	Estimate parameters of ARX model using instrumental variable method with arbitrary instruments
`LTI Commands`	Apply Control System Toolbox commands to linear model
`merge`	Merge estimated models

`n4sid`	Estimate state-space models using subspace method
`nuderst`	Set step size for numerical differentiation
`oe`	Output-error (OE) model parameter estimation
`pem`	Estimate model parameters using iterative prediction-error minimization method
`pexcit`	Level of excitation of input signals
`polydata`	Parameters from single-input and single-output polynomial model
`selstruc`	Select model order for single-output ARX models
`set`	Set properties of data and model objects
`setpname`	Set mnemonic parameter names for linear black-box model structures
`setPolyFormat`	Specify format for B and F polynomials of multi-input polynomial model for backward compatibility
`setstruc`	Set matrix structure for idss model objects
`size`	Dimensions of data and model objects
`spa`	Estimate frequency response with fixed frequency resolution using spectral analysis
`spafdr`	Estimate frequency response and spectrum using spectral analysis with frequency-dependent resolution

`ss`	Convert linear models to Control System Toolbox LTI models
`ssdata`	State-space matrices from parametric linear model
`step`	Plot step response with confidence interval
`struc`	Generate model-order combinations for single-output ARX model estimation
`tf`	Convert linear models to transfer-function Control System Toolbox LTI models
`tfdata`	Numerator and denominator of transfer function from linear model
`timestamp`	Return date and time when object was created or last modified
`zpk`	Convert linear model to Control System Toolbox state-space LTI models
`zpkdata`	Zeros, poles, and gains of transfer function from linear model

Nonlinear Black-Box Model Identification

`addreg`	Add custom regressors to nonlinear ARX model
`customnet`	Custom nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models
`customreg`	Custom regressor for nonlinear ARX models

`data2state(idnlarx)`	Map past input/output data to current states of nonlinear ARX model
`deadzone`	Class representing dead-zone nonlinearity estimator for Hammerstein-Wiener models
`evaluate`	Value of nonlinearity estimator at given input
`findop(idnlarx)`	Compute operating point for nonlinear ARX model
`findop(idnlhw)`	Compute operating point for Hammerstein-Wiener model
`get`	Query properties of data and model objects
`getDelayInfo`	Get input/output delay information for `idnlarx` model structure
`getreg`	Regressor expressions and numerical values in nonlinear ARX model
`idnlarx`	Nonlinear ARX model
`idnlhw`	Hammerstein-Wiener model
`idnlmodel`	Superclass for nonlinear models
`init`	Set or randomize initial parameter values
`linapp`	Linear approximation of nonlinear ARX and Hammerstein-Wiener models for given input
`linear`	Specify to estimate nonlinear ARX model that is linear in (nonlinear) custom regressors
`linearize(idnlarx)`	Linearize nonlinear ARX model
`linearize(idnlhw)`	Linearize Hammerstein-Wiener model

`neuralnet`	Class representing neural network object created in Neural Network Toolbox™ product for estimating nonlinear ARX and Hammerstein-Wiener models
`nlarx`	Estimate nonlinear ARX model
`nlhw`	Estimate Hammerstein-Wiener model
`operspec(idnlarx)`	Construct operating point specification object for `idnlarx` model
`operspec(idnlhw)`	Construct operating point specification object for `idnlhw` model
`pem`	Estimate model parameters using iterative prediction-error minimization method
`poly1d`	Class representing single-variable polynomial nonlinear estimator for Hammerstein-Wiener models
`polyreg`	Powers and products of standard regressors
`pwlinear`	Class representing piecewise-linear nonlinear estimator for Hammerstein-Wiener models
`saturation`	Class representing saturation nonlinearity estimator for Hammerstein-Wiener models
`set`	Set properties of data and model objects
`sigmoidnet`	Class representing sigmoid network nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models

`treepartition`	Class representing binary-tree nonlinearity estimator for nonlinear ARX models
`unitgain`	Specify absence of nonlinearities for specific input or output channels in Hammerstein-Wiener models
`wavenet`	Class representing wavelet network nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models

ODE Parameter Estimation

`get`	Query properties of data and model objects
`getinit`	Values of `idnlgrey` model initial states
`getpar`	Parameter values and properties of `idnlgrey` model parameters
`idgrey`	Linear ODE (grey-box model) with known and unknown parameters
`idnlgrey`	Nonlinear ODE (grey-box model) with unknown parameters
`idnlmodel`	Superclass for nonlinear models
`init`	Set or randomize initial parameter values
`pem`	Estimate model parameters using iterative prediction-error minimization method
`set`	Set properties of data and model objects
`setinit`	Set initial states of `idnlgrey` model object
`setpar`	Set initial parameter values of `idnlgrey` model object

Recursive Model Identification

`rarmax`	Estimate recursively parameters of ARMAX or ARMA models
`rarx`	Estimate parameters of ARX or AR models recursively

`rbj`	Estimate recursively parameters of Box-Jenkins models
`roe`	Estimate recursively output-error models (IIR-filters)
`rpem`	Estimate general input-output models using recursive prediction-error minimization method
`rplr`	Estimate general input-output models using recursive pseudolinear regression method
`segment`	Segment data and estimate models for each segment

Model Analysis

`advice`	Analysis and recommendations for data or estimated linear polynomial and state-space models
`aic`	Akaike Information Criterion for estimated model
`arxdata`	ARX parameters from multiple-output models with variance information
`balred`	Reduce model order (requires Control System Toolbox product)
`bode`	Compute and plot frequency response magnitude and phase for logarithmic frequencies
`compare`	Compare model output and measured output

`ffplot`	Compute and plot frequency response magnitude and phase for linear frequencies
`fpe`	Akaike Final Prediction Error for estimated model
`freqresp`	Frequency response data from linear models
`fselect`	Frequencies from frequency response data
`impulse`	Plot impulse response with confidence interval
`isreal`	Determine whether model parameters or data values are real
`ivstruc`	Loss functions for sets of ARX model structures
`noisecnv`	Transform `idmodel` object with noise channels to model with measured channels only
`nyquist`	Plot Nyquist curve of frequency response with confidence interval
`pe`	Prediction errors associated with model and data set
`plot`	Plot iddata or model objects
`polydata`	Parameters from single-input and single-output polynomial model
`predict`	Predict output *k* steps ahead
`predict(idnlarx)`	Predict output *k* steps ahead for nonlinear ARX model
`predict(idnlgrey)`	Predict output *k* steps ahead for nonlinear ODE model
`predict(idnlhw)`	Predict output *k* steps ahead for Hammerstein-Wiener model

`present`	Display model information, including estimated uncertainty
`pzmap`	Plot zeros and poles with confidence interval
`resid`	Compute and test model residuals (prediction errors)
`selstruc`	Select model order for single-output ARX models
`sim`	Simulate linear models with confidence interval
`sim(idnlarx)`	Simulate nonlinear ARX model
`sim(idnlgrey)`	Simulate nonlinear ODE model
`sim(idnlhw)`	Simulate Hammerstein-Wiener model
`simsd`	Simulate models with uncertainty using Monte Carlo method
`ssdata`	State-space matrices from parametric linear model
`step`	Plot step response with confidence interval
`tfdata`	Numerator and denominator of transfer function from linear model
`view`	Plot model characteristics using Control System Toolbox LTI Viewer GUI
`zpkdata`	Zeros, poles, and gains of transfer function from linear model

Simulation and Prediction

`findstates(idmodel)`	Estimate initial states of linear model from data
`findstates(idnlarx)`	Estimate initial states of nonlinear ARX model from data
`findstates(idnlgrey)`	Estimate initial states of nonlinear grey-box model from data
`findstates(idnlhw)`	Estimate initial states of nonlinear Hammerstein-Wiener model from data
`predict`	Predict output k steps ahead
`predict(idnlarx)`	Predict output k steps ahead for nonlinear ARX model
`predict(idnlgrey)`	Predict output k steps ahead for nonlinear ODE model
`predict(idnlhw)`	Predict output k steps ahead for Hammerstein-Wiener model
`retrend`	Add offsets or trends to data signals
`sim`	Simulate linear models with confidence interval
`sim(idnlarx)`	Simulate nonlinear ARX model
`sim(idnlgrey)`	Simulate nonlinear ODE model
`sim(idnlhw)`	Simulate Hammerstein-Wiener model
`simsd`	Simulate models with uncertainty using Monte Carlo method

System Identification Tool GUI

`ident`	Open System Identification Tool GUI
`midprefs`	Set folder for storing `idprefs.mat` containing GUI startup information

2

Functions – Alphabetical List

addreg

Purpose

Add custom regressors to nonlinear ARX model

Syntax

```
m = addreg(model,regressors)
m = addreg(model,regressors,output)
```

Description

`m = addreg(model,regressors)` adds custom regressors to a nonlinear ARX model by appending the `CustomRegressors` *`model`* property. *`model`* and *`m`* are `idnalrx` objects. For single-output models, *`regressors`* is an object array of regressors you create using `customreg` or `polyreg`, or a cell array of string expressions. For multiple-output models, *`regressors`* is 1-by-`ny` cell array of `customreg` objects or 1-by-`ny` cell array of cell arrays of string expressions. `addreg` adds each element of the `ny` cells to the corresponding *`model`* output channel. If *`regressors`* is a single regressor, `addreg` adds this regressor to all output channels.

`m = addreg(model,regressors,output)` adds regressors *`regressors`* to specific output channels *`output`* of a multiple-output model. *`output`* is a scalar integer or vector of integers, where each integer is the index of a model output channel. Specify several pairs of *`regressors`* and *`output`* values to add different regressor variables to the corresponding output channels.

Examples

Add regressors to a nonlinear ARX model as a cell array of strings:

```
% Create nonlinear ARX model with standard regressors:
  m1 = idnlarx([4 2 1],'wavenet','nlr',[1:3]);
% Create model with additional custom regressors:
  m2 = addreg(m1,{'y1(t-2)^2';'u1(t)*y1(t-7)'})
% List all standard and custom regressors of m2:
  getreg(m2)
```

Add regressors to a nonlinear ARX model as `customreg` objects:

```
% Create nonlinear ARX model with standard regressors:
  m1 = idnlarx([4 2 1],'wavenet','nlr',[1:3]);
% Create a model based on m1 with custom regressors:
```

```
r1 = customreg(@(x)x^2, {'y1'}, 2)
r2 = customreg(@(x,y)x*y, {'u1','y1'}, [0 7])
m2 = addreg(m1,[r1 r2]);
```

`customreg` | `getreg` | `nlarx` | `polyreg`

How To

- "Identifying Nonlinear ARX Models"

advice

Purpose

Analysis and recommendations for data or estimated linear polynomial and state-space models

Syntax

```
advice(model)
advice(data)
```

Inputs

`model`
: Name of the `idarx`, `idgrey`, `idpoly`, `idproc`, or `idss` model object. These model objects belong to the `idmodel` abstract class, representing linear polynomial and state-space models.

`data`
: Name of the `iddata` object.

Description

`advice(model)` displays the following information about the estimated model in the MATLAB® Command Window:

- Does the model capture essential dynamics of the system and the disturbance characteristics?
- Is the model order higher than necessary?
- Is there potential output feedback in the validation data?
- Would a nonlinear ARX model perform better than a linear ARX model?

`advice(data)` displays the following information about the data in the MATLAB Command Window:

- What are the excitation levels of the signals and how does this affects the model orders? See also `pexcit`.
- Does it make sense to remove constant offsets and linear trends from the data? See also `detrend`.
- Is there an indication of output feedback in the data? See also `feedback`.

See Also

`detrend`

`feedback`

`iddata`

`pexcit`

Purpose

Akaike Information Criterion for estimated model

Syntax

```
am = aic(model)
am = aic(model1,model2,...)
```

Arguments

`model`
: Name of an `idarx`, `idgrey`, `idpoly`, `idproc`, `idss`, `idnlarx`, `idnlhw`, or `idnlgrey` model object.

Description

`am = aic(model)` returns a scalar value of the Akaike's Information Criterion (AIC) for the estimated `model`.

`am = aic(model1,model2,...)` returns a row vector containing AIC values for the estimated models `model1,model2,...`.

Remarks

Akaike's Information Criterion (AIC) provides a measure of model quality by simulating the situation where the model is tested on a different data set. After computing several different models, you can compare them using this criterion. According to Akaike's theory, the most accurate model has the smallest AIC.

Note If you use the same data set for both model estimation and validation, the fit always improves as you increase the model order and, therefore, the flexibility of the model structure.

Akaike's Information Criterion (AIC) is defined by the following equation:

$$AIC = \log V + \frac{2d}{N}$$

where V is the loss function, d is the number of estimated parameters, and N is the number of values in the estimation data set.

The loss function V is defined by the following equation:

$$V = \det\left(\frac{1}{N}\sum_{1}^{N}\varepsilon\left(t,\theta_N\right)\left(\varepsilon\left(t,\theta_N\right)\right)^T\right)$$

where θ_N represents the estimated parameters.

For $d<<N$:

$$AIC = \log\left(V\left(1+\frac{2d}{N}\right)\right)$$

Note *AIC* is approximately equal to log(*FPE*).

AIC is formally defined as the negative log-likelihood function Λ, evaluated at the estimated parameters, plus the number of estimated parameters. You can derive AIC from this definition, as follows:

If the disturbance source is Gaussian with the covariance matrix Λ, the logarithm of the likelihood function is

$$L(\theta,\Lambda) = -\frac{1}{2}\sum_{1}^{N}\varepsilon(t,\theta)^T\Lambda^{-1}\varepsilon(t,\theta) - \frac{N}{2}\log\left(\det\Lambda\right) + const$$

Maximizing this analytically with respect to Λ, and then maximizing the result with respect to θ, gives

$$L(\theta,\Lambda) = const + \frac{Np}{2} + \frac{N}{2}\log(V)$$

where p is the number of outputs.

`EstimationInfo`

`fpe`

Purpose

Algorithm properties affecting estimation process for linear models

Syntax

```
idprops idmodel algorithm
Model.algorithm.PropertyName='PropertyValue'
```

Description

`Algorithm` is a property of the `idmodel` class that specifies the estimation algorithm. The `idmodel` subclasses are used to define various linear models, including `idarx`, `idss`, `idpoly`, `idproc`, and `idgrey`. These models inherit the `idmodel` `Algorithm` property.

Note For a description of nonlinear model `Algorithm` property, see the corresponding nonlinear model reference page.

Property names are not case sensitive. When you type a property name, you only need to enter enough characters to uniquely identify the property. The Algorithm fields can be accessed and modified as for any structure using dot syntax. For example, you can access the `SearchMethod` field by typing `Model.Algorithm.SearchMethod`.

Note You can use the `get` function or dot notation to fetch fields of `Algorithm` as if they were the properties of the model itself. Similarly you can use `set` or dot notation to set a particular field. This shortcut access is available for the fields of `Algorithm` only (not for deeper level struct fields such as Search or Threshold options). For example:

```
method = Model.SearchMethod;
Model.MaxIter = 100;
```

is equivalent to

```
get(Model, 'SearchMethod')
set(Model, 'maxiter', 100);
```

Algorithm Properties

When you create a new model by refining an existing model `m`, the algorithm properties of `m` are inherited by the new model.

Note You can estimate a model with specific algorithm settings and define a structure variable to store the algorithm values. For example:

```
model = n4sid(data,order)
myalg = model.Algorithm;
myalg.Focus='Simulation';
m = pem(data,model,'alg',myalg)
```

You can also specify the algorithm properties (except advanced properties) as property-value pairs when creating the linear model (using `idpoly`, `idss`, etc.) or when estimating them (using `pem`, `n4sid`, `armax`, `oe` etc.).

Algorithm Properties

- `Criterion`: Specifies criterion used during minimization. `Criterion` can have the following values:
  - `'Det'`: Minimize $\det(E'*E)$, where E represents the prediction error. This is the optimal choice in a statistical sense and leads to the maximum likelihood estimates in case nothing is known about the variance of the noise. It uses the inverse of the estimated noise variance as the weighting function. This is the default criterion used for all models, except `idnlgrey` which uses `'Trace'` by default.
  - `'Trace'`: Minimize the trace of the weighted prediction error matrix `trace(E'*E*W)`, where `E` is the matrix of prediction errors, with one column for each output, and `W` is a positive semi-definite symmetric matrix of size equal to the number of outputs. By default, `W` is an identity matrix of size equal to the number of model outputs (so the minimization criterion becomes `trace(E'*E)`, or the traditional least-sum-of-squared-errors criterion. You can

specify the relative weighting of prediction errors for each output using the `Weighting` field of the Algorithm property.

Note The difference between the two criteria is meaningful in multiple-output cases only. In single-output models, the two criteria are equivalent. Both the `Det` and `Trace` criteria are derived from a general requirement of minimizing a weighted sum of squares of prediction errors. The `Det` criterion can be interpreted as estimating the covariance matrix of the noise source and using the inverse of that matrix as the weighting. When using the `Trace` criterion, you must specify the weighting using the `Weighting` property.

If you want to achieve better accuracy for a particular channel in multiple-input multiple-output models, you should use `Trace` with weighting that favors that channel. Otherwise it is natural to use the `Det` criterion. When using `Det`, you can check `cond(model.NoiseVariance)` after estimation. If the matrix is ill-conditioned, it may be more robust to use the `Trace` criterion. You can also use `compare` on validation data to check whether the relative error for different channels corresponds to your needs or expectations. Use the `Trace` criterion if you need to modify the relative errors, and check `model.NoiseVariance` to determine what weighting modifications to specify.

The search method of `lsqnonlin` supports the `Trace` criterion only.

- `Focus`: Defines how the errors e between the measured and the modeled outputs are weighed at specific frequencies during the minimization of the following loss function:

$$V = \sum_i \lambda_i e_i^2$$

Higher weighting at specific frequencies emphasizes the requirement for a good fit at these frequencies. `Focus` can have the following values:

- `'Prediction'`: (Default) Automatically calculates the weighting function as a product of the input spectrum and the inverse of the noise model. This minimizes the one-step-ahead prediction, which typically favors fitting small time intervals (higher frequency range). From a statistical-variance point of view, this is the optimal weighting function. However, this method neglects the approximation aspects (bias) of the fit. Might not result in a stable model. Use `'Stability'` when you want to ensure a stable model.
- `'Simulation'`: Estimates the model using the frequency weighting of the transfer function that is given by the input spectrum. Typically, this method favors the frequency range where the input spectrum has the most power. In other words, the resulting model will produce good simulations for inputs that have the same spectra as used for estimation. For models that have no disturbance model, there is no difference between `'Simulation'` and `'Prediction'`. In this case, $y = Gu + He$ with H=1, which is equivalent to `A=C=D=1` for `idpoly` models and `K = 0` for `idss` models.

  For models that have a disturbance model, G is first estimated with H=1, and then H is estimated using a prediction-error method with a fixed estimated transfer function $\hat{G}$. This guarantees a stable transfer function G.
- `'Stability'`: This weighting is the same as for `'Prediction'`, but the model is forced to be stable. Use only when you know the system is stable. In some cases, forcing the model to be stable can result in a bad model.
- Enter a row vector or a matrix containing frequency values that define desired passbands. For example:

  ```
  [wl,wh]
  [w1l,w1h;w2l,w2h;w3l,w3h;...]
  ```

where `wl` and `wh` represent upper and lower limits of a passband. For a matrix with several rows defining frequency passbands, the algorithm uses union of frequency ranges to define the estimation passband.

- Enter any SISO linear filter in any of the following ways:

  A single-input-single-output (SISO) `idmodel` object.

  An `ss`, `tf`, or `zpk` model from the Control System Toolbox product.

  Using the format `{A,B,C,D}`, which specifies the state-space matrices of the filter.

  Using the format `{numerator, denominator}`, which specifies the numerator and denominator of the filter transfer function

  This calculates the weighting function as a product of the filter and the input spectrum to estimate the transfer function from input to output, *G*. To obtain a good model fit for a specific frequency range, you must choose the filter with a passband in this range. After estimating *G*, the algorithm computes the disturbance model using a prediction-error method and keeping the estimated transfer function fixed (similar to the `'Simulation'` case). For a model that has no disturbance model, the estimation result is the same if you first prefilter the data using `idfilt`.

- For frequency-domain data only, enter a column vector of weights for `'Focus'`. This vector must have the same size as length of the frequency vector of the data set, `Data.Frequency`. Each input and output response in the data is multiplied by the corresponding weight at that frequency.

• `Maxsize`: A positive integer, specified such that the input-output data is split into segments where each contains fewer than `MaxSize` elements. Setting `MaxSize` can improve computational performance. The default value of `MaxSize` is `'Auto'`, which uses the file `idmsize` to set the value. You can edit this file to optimize computational speed on a particular computer. `MaxSize` does not affect the numerical properties of the estimate except when you use `InitialState = 'backcast'` for frequency-domain data. In this case, the frequency

ranges where backcasting takes place might depend on `MaxSize` and affects estimates.

- `FixedParameter`: Vector of integers containing the indices of parameters that are not estimated and remain fixed at nominal or initial values. Parameter indices refer to their position in the list, stored in the property `'ParameterVector'`. You can also specify parameter names as values from the property `'PName'`. To specify fixed parameters using parameter names, enter `Fixedparameter` as a cell array of strings. For example, to fix parameters with names `'a'` and `'b'`, type `m.FixedParameter = {'a','b','c'}`. Strings can contain wildcards, such as `'*'` to specify the automatic completion of a string, or `'?'` to represent an arbitrary character. For example, to fix three parameters in a disturbance model that start with `'k'`, such as `'k1'`, `'k2'`,`'k3'`, use `FixedParameter = {'k*'}`. For structured state-space models, you can fix and free parameters by specifying structure matrices, such as `As` and `Bs` (see `idss`).

Note By default, the property `'PName'` is empty. Use `setpname` to assign default parameter names. For example, `m = setpname(m)`.

- `Weighting`: Positive semi-definite symmetric matrix `W` to use as weighting for minimization of the trace criterion `trace(E'*E*W)`. `Weighting` can be used to specify relative importance of outputs in multiple-input multiple-output models (or reliability of corresponding data) by specifying `W` as a diagonal matrix of non-negative values. `Weighting` is not useful in single-input single-output models. By default, `Weighting` is the identity matrix of size equal to the number of model outputs, assigning equal importance to each output during estimation.

- `Display`: Specifies what information displays in the MATLAB Command Window about the iterative search during estimation.
  - `'Off'`: Displays no information.
  - `'On'`: Displays the loss-function values for each iteration.

- 'Full': Displays the same information as 'On' and also include the current parameter values and the search direction (except when the Advanced SSParameterization model property is set to 'Free' for idss models and the list of parameters can change between iterations).

- LimitError: Specifies when to adjust the weight of large errors from quadratic to linear. Default value is 0. Errors larger than LimitError times the estimated standard deviation have a linear weight in the criteria. The standard deviation is estimated robustly as the median of the absolute deviations from the median and divided by 0.7. (See the section about choosing a robust norm in [2].) LimitError = 0 disables the robustification and leads to a purely quadratic criterion. When estimating with frequency-domain data, LimitError is set to zero.

  Note You can estimate the model with the default value of LimitError (zero) and plot the prediction errors using pe(data.model). If the resulting plot shows occasional large values, repeat the estimation with model.Algorithm.LimitError set to a value between 1 and 2.

- MaxIter: Specifies the maximum number of iterations during loss-function minimization. The iterations stop when MaxIter is reached or another stopping criterion is satisfied, such as the Tolerance. The default value of MaxIter is 20. Setting MaxIter = 0 returns the result of the startup procedure. Use EstimationInfo.Iterations to get the actual number of iterations during an estimation.

- Tolerance: Specifies the minimum percentage difference (divided by 100) between the current value of the loss function and its expected improvement after the next iteration: When the percentage of expected improvement is less than Tolerance, the iterations are stopped. Default value is 0.01. The estimate of the expected

loss-function improvement at the next iteration is made based on the Gauss-Newton vector computed for the current parameter value.

- `SearchMethod`: The search method used for iterative parameter estimation. It can take one of the following values:
  - `'gn'`: The subspace Gauss-Newton direction. Singular values of the Jacobian matrix less than `GnPinvConst*eps*max(size(J))*norm(J)` are discarded when computing the search direction, where `J` is the Jacobian matrix. The Hessian matrix is approximated by J^TJ. If there is no improvement along this direction, the gradient direction is also tried.
  - `'gna'`: An adaptive version of subspace Gauss-Newton approach, suggested by Wills and Ninness (IFAC World congress, Prague 2005). Eigenvalues less than `gamma*max(sv)` of the Hessian are neglected , where `sv` are the singular values of the Hessian. The Gauss-Newton direction is computed in the remaining subspace. `gamma` has the initial value `InitGnaTol` (see below) and is increased by the factor `LmStep` each time the search fails to find a lower value of the criterion in less than 5 bisections. It is decreased by the factor `2*LmStep` each time a search is successful without any bisections.
  - `'lm'`: Uses the Levenberg-Marquardt method. This means that the next parameter value is `-pinv(H+d*I)*grad` from the previous one, where `H` is the Hessian, `I` is the identity matrix, and `grad` is the gradient. `d` is a number that is increased until a lower value of the criterion is found.
  - `'Auto'`: A choice among the above is made in the algorithm. This is the default choice.
  - `'lsqnonlin'`: Uses `lsqnonlin` optimizer from Optimization Toolbox™ software. You must have Optimization Toolbox installed to use this option. This search method can only handle the `Trace` criterion.

- `Advanced`: Structure that specifies advanced algorithm options and has the following fields:
  - `Search`: Uses the following fields to specify options for the iterative search:
    1. `GnPinvConst`: Must be a positive real value. Specifies that singular values of the Jacobian that are smaller than `GnPinvConst*max(size(J)*norm(J)*eps` are discarded when computing the search direction using the `'gn'` method. Default value is `1e4`.
    2. `InitGnaTol`: The initial value of `gamma` in the `gna` search algorithm. See `SearchMethod` for description of `gna`. Default is `10^-4`.
    3. `LmStep`: The size of the Levenberg-Marquardt step. The next value of the search-direction length `d` in the Levenberg-Marquardt method is `LmStep` times the previous one. Default is `2`.
    4. `StepReduction`: For search directions other than the Levenberg-Marquardt direction, the step is reduced by the factor `StepReduction` after each iteration. Default is `2`.
    5. `MaxBisection`: The maximum number of bisections used by the line search along the search direction. Default is `25`.
    6. `LmStartValue`: The starting value of search-direction length `d` in the Levenberg-Marquardt method. Default is `0.001`.
    7. `RelImprovement`: The iterations are stopped if the relative improvement of the criterion is less than `RelImprovement`. Default is `RelImprovement = 0`. This property is different from `Tolerance` in that it uses the actual improvement of the loss function, as opposed to the expected improvement.
  - `Threshold`: Contains fields with thresholds for several tests:
    1. `Sstability`: Specifies the location of the rightmost pole to test the stability of continuous-time models. A model is considered stable when its rightmost pole is to the left of `Sstability`. Default is `0`.

2 `Zstability`: Specifies the maximum distance of all poles from the origin to test stability of discrete-time models. A model is considered stable if all poles are within the distance `Zstability` from the origin. Default is `1+sqrt(eps)`.

- `AutoInitialState`: Specifies when to automatically estimate the initial state. When `InitialState = 'Auto'`, the initial state is estimated when the ratio of the prediction-error norm with a zero initial state to the norm with an estimated initial state exceeds `AutoInitialState`. Default is `1.05`.

Properties Relevant to Estimation of n4sid, State-Space (idss) Models

---

Note These properties apply to `n4sid`. Since `pem` commonly uses `n4sid` to initialize a model for iterative estimation, these properties affect the results of `pem` too.

- `N4Weight`: Calculates the weighting matrices used in the singular-value decomposition step of the algorithm and has three possible values:
  - `'Auto'`: (Default) Automatically chooses between `'MOESP'` and `'CVA'` .
  - `'MOESP'`: Uses the MOESP algorithm by Verhaegen.
  - `'CVA'`: Uses the canonical variable algorithm by Larimore.

  For more information about setting this property, see the `n4sid` reference page.
- `N4Horizon`: Determines the forward and backward prediction horizons used by the algorithm. Enter a row vector with three elements: `N4Horizon=[r sy su]`, where `r` is the maximum forward prediction horizon; that is, the algorithm uses up to `r` step-ahead predictors. `sy` is the number of past outputs, and `su` is the number of past inputs used for predictions. For an exact definition of these integers, see the section about subspace methods in [2], where they

are called *r*, *s1*, and *s2*. These numbers can have a substantial influence on the quality of the resulting model and there are no simple rules for choosing them. Making `'N4Horizon'` a `k`-by-`3` matrix means that the algorithm tries each row of `'N4Horizon'` and selects the value that gives the best (prediction) fit to the data. Choosing the best row is not available when you also specify to select the best model order. When you specify one column in `'N4Horizon'`, the interpretation is `r=sy=su`. The default choice is `'N4Horizon' = 'Auto'`, which uses an Akaike Information Criterion (AIC) for the selection of `sy` and `su`.

Note For algorithm properties of nonlinear models, see the reference pages for `idnlarx`, `idnlhw`, and `idnlgrey`.

`armax`

`bj`

`EstimationInfo`

`idpoly`

`idss`

`n4sid`

`oe`

`pem`

Purpose

Estimate parameters of AR model for scalar time series

Syntax

```
m = ar(y,n)
[m,refl] = ar(y,n,approach,window)
[m,refl] = ar(y,n,approach,window,'P1',V1,...,'PN',VN)
```

Arguments

`y`

`iddata` object that contains the time-series data (one output channel).

`n`

Scalar that specifies the order of the model you want to estimate (the number of A parameters in the AR model).

`approach`

Lets you choose the algorithm for computing the least squares AR model from the following options:

- `'burg'`: Burg's lattice-based method. Solves the lattice filter equations using the harmonic mean of forward and backward squared prediction errors.
- `'fb'`: (Default) Forward-backward approach. Minimizes the sum of a least- squares criterion for a forward model, and the analogous criterion for a time-reversed model.
- `'gl'`: Geometric lattice approach. Similar to Burg's method, but uses the geometric mean instead of the harmonic mean during minimization.
- `'ls'`: Least-squares approach. Minimizes the standard sum of squared forward-prediction errors.
- `'yw'`: Yule-Walker approach. Solves the Yule-Walker equations, formed from sample covariances.

`window`

Lets you specify how to use information about the data outside the measured time interval (past and future values). The following windowing options are available:

- `'now'`: (Default) No windowing. This value is the default except when the `approach` argument is `'yw'`. Only measured data is used to form regression vectors. The summation in the criteria starts at the sample index equal to `n+1`.
- `'pow'`: Postwindowing. Missing end values are replaced with zeros and the summation is extended to time `N+n` (`N` is the number of observations).
- `'ppw'`: Pre- and postwindowing. Used in the Yule-Walker approach.
- `'prw'`: Prewindowing. Missing past values are replaced with zeros so that the summation in the criteria can start at time equal to zero.

`'P1',V1,...,'PN',VN`
Pairs of property names and property values can include any of the following.

Property Name	Property Value	Description
`'Covariance'`	• `'None'` Suppresses the calculation of the covariance matrix. • `[]` Empty. • Square matrix containing covariance values of size equal to the length of the parameter vector	Specifies calculation of uncertainties in parameter estimates.

Property Name	Property Value	Description
'MaxSize'	Integer	See Algorithm Properties for the description.
'Ts'	Real positive number	Sets the sampling time and overrides the sampling time of y.

Description

Note Use for scalar time series only. For multivariate data, use arx.

m = ar(y,n) returns an idpoly model m.

[m,refl] = ar(y,n,approach,window) returns an idpoly model m and the variable refl. For the two lattice-based approaches, 'burg' and 'gl', refl stores the reflection coefficients in the first row, and the corresponding loss function values in the second row. The first column of refl is the zeroth-order model, and the (2,1) element of refl is the norm of the time series itself.

[m,refl] = ar(y,n,approach,window,'P1',V1,...,'PN',VN) returns an idpoly model m and the variable refl using additional windowing criteria.

Remarks

The AR model structure is given by the following equation:

$$A(q)y(t) = e(t)$$

AR model parameters are estimated using variants of the least-squares method. The following table summarizes the common names for methods with a specific combination of approach and window argument values.

Method	Approach and Windowing
Modified Covariance Method	(Default) Forward-backward approach and no windowing.
Correlation Method	Yule-Walker approach, which corresponds to least squares plus pre- and postwindowing.
Covariance Method	Least squares approach with no windowing. `arx` uses this routine.

Examples

Given a sinusoidal signal with noise, compare the spectral estimates of Burg's method with those found from the forward-backward approach and no-windowing method on a Bode plot.

```
y = sin([1:300]') + 0.5*randn(300,1);
y = iddata(y);
mb = ar(y,4,'burg');
mfb = ar(y,4);
bode(mb,mfb)
```

step

Purpose

Estimate parameters of ARMAX or ARMA model

Syntax

```
m = armax(data,orders)
m = armax(data,orders,'P1',V1,...,'PN',VN)
m = armax(data,'na',na,'nb',nb,'nc',nc,'nk',nk)
```

Arguments

`data`
: `iddata` object that contains the input-output data.

`orders`
: Vector of integers, specified using the format

```
orders = [na nb nc nk]
```

For multiple-input systems, `nb` and `nk` are row vectors where the `i`th element corresponds to the order and delay associated with the `i`th input.

When `data` is a time series, which has no input and one output, then

```
orders = [na nc]
```

Tip When refining an estimated model `mi`, set the model orders as follows:

```
orders = mi
```

`'na',na,'nb',nb,'nc',nc,'nk',nk`
: `'na'`, `'nb'`, and `'nc'` are orders of the ARMAX model. `nk` is the delay. `na`, `nb`, `nc`, and `nk` are the corresponding integer values.

`'P1',V1,...,'PN',VN`
: Pairs of property names and property values can include any of the following `idmodel` properties:

`'Focus'`, `'InitialState'`, `'Display'`, `'MaxIter'`, `'Tolerance'`, `'LimitError'`, and `'FixedParameter'`.

See `Algorithm Properties`, `idpoly`, and `idmodel` for more information.

Description

Note `armax` only supports time-domain data with single or multiple inputs and single output. For frequency-domain data, use `oe`. For the multiple-output case, use ARX or a state-space model (see `n4sid` and `pem`).

`m = armax(data,orders)` returns an `idpoly` model `m` with estimated parameters and covariances (parameter uncertainties). Estimates the parameters using the prediction-error method and specified `orders`.

`m = armax(data,orders,'P1',V1,...,'PN',VN)` returns an `idpoly` model `m`. Use additional property-value pairs to specify the estimation algorithm properties.

`m = armax(data,'na',na,'nb',nb,'nc',nc,'nk',nk)` returns an `idpoly` model `m` with orders and delays specified as parameter-value pairs.

Remarks

The ARMAX model structure is

$$\begin{aligned} y(t) + a_1 y(t-1) + \ldots + a_{n_a} y(t-n_a) = \\ b_1 u(t-n_k) + \ldots + b_{n_b} u(t-n_k-n_b+1) + \\ c_1 e(t-1) + \ldots + c_{n_c} e(t-n_c) + e(t) \end{aligned}$$

A more compact way to write the difference equation is

$$A(q)y(t) = B(q)u(t-n_k) + C(q)e(t)$$

where

- $y(t)$ — Output at time t.
- n_a — Number of poles.
- n_b — Number of zeroes plus 1.
- n_c — Number of C coefficients.
- n_k — Number of input samples that occur before the input affects the output, also called the *dead time* in the system. For discrete systems with no dead time, there is a minimum 1–sample delay because the output depends on the previous input and $n_k = 1$.
- $y(t-1)\dots y(t-n_a)$ — Previous outputs on which the current output depends.
- $u(t-n_k)\dots u(t-n_k-n_b+1)$ — Previous and delayed inputs on which the current output depends.
- $e(t-1)\dots e(t-n_c)$ — White-noise disturbance value.

The parameters `na`, `nb`, and `nc` are the orders of the ARMAX model, and `nk` is the delay. q is the delay operator. Specifically,

$$A(q) = 1 + a_1 q^{-1} + \dots + a_{n_a} q^{-n_a}$$

$$B(q) = b_1 + b_2 q^{-1} + \dots + b_{n_b} q^{-n_b+1}$$

$$C(q) = 1 + c_1 q^{-1} + \dots + c_{n_c} q^{-n_c}$$

If `data` is a time series, which has no input channels and one output channel, then `armax` calculates an ARMA model for the time series

$$A(q)y(t) = e(t)$$

In this case

```
orders = [na nc]
```

Algorithm

An iterative search algorithm with the properties 'SearchMethod', 'MaxIter', 'Tolerance', and 'Advanced' minimizes a robustified quadratic prediction error criterion. The iterations are terminated either when MaxIter is reached, or when the expected improvement is less than Tolerance, or when a lower value of the criterion cannot be found. You can get information about the search criteria using m.EstimationInfo.

When you do not specify initial parameter values for the iterative search in orders, they are constructed in a special four-stage LS-IV algorithm.

The cutoff value for the robustification is based on the property LimitError and on the estimated standard deviation of the residuals from the initial parameter estimate. It is not recalculated during the minimization.

To ensure that only models corresponding to stable predictors are tested, the algorithm performs a stability test of the predictor. Generally, both $C(q)$ and $F(q)$ (if applicable) must have all zeros inside the unit circle.

Minimization information is displayed on the screen when the property 'Display' is 'On' or 'Full'. With 'Display' ='Full', both the current and the previous parameter estimates are displayed in column-vector form, listing parameters in alphabetical order. Also, the values of the criterion function are given and the Gauss-Newton vector and its norm are also displayed. With 'Display' = 'On' only the criterion values are displayed.

`Algorithm Properties`

`EstimationInfo`

`idpoly`

`pem`

Purpose

Estimate parameters of ARX or AR model using least squares

Syntax

```
m = arx(data,orders)
m = arx(data,orders,'P1',V1,...,'PN',VN)
m = arx(data,'na',na,'nb',nb,'nc',nc,'nk',nk)
```

Arguments

`data`
: An `iddata` object, an `frd` object, or an `idfrd` frequency-response-data object.

`orders`
: Vector of integers, specified using the format

```
orders = [na nb nk]
```

For multiple-input systems, `nb` and `nk` are row vectors where the `i`th element corresponds to the order and delay associated with the `i`th input.

When `data` is a time series, which has no input and one output, then

```
orders = [na]
```

Note When refining an estimated model `mi`, set the model orders as follows:

```
orders = mi
```

`'na',na,'nb',nb,'nc',nc,'nk',nk`
: `'na'`, `'nb'`, and `'nc'` are orders of the ARMAX model. `nk` is the delay. `na`, `nb`, `nc`, and `nk` are the corresponding integer values.

`'P1',V1,...,'PN',VN`
Pairs of property names and property values can include any of the following `idmodel` properties:

`'Focus'`, `'InitialState'`, `'Display'`, `'MaxIter'`, `'Tolerance'`, `'LimitError'`, and `'FixedParameter'`.

See `Algorithm Properties`, `idpoly`, and `idmodel` for more information.

Description

Note `arx` does not support multiple-output continuous-time models. Use state-space model structure instead. When the true noise term $e(t-1)\ldots e(t-n_c)$ in the ARX model structure is not white noise and `na` is nonzero, the model estimate is incorrect. In this case, use `armax`, `bj`, `iv4`, or `oe`.

`m = arx(data,orders)` returns a model `m` as an `idpoly` or `idarx` object with estimated parameters and covariances (parameter uncertainties). For single-output data, the model is an `idpoly` object. For multiple-output data, the model is an `idarx` object. Uses the least-squares method and specified `orders`.

`m = arx(data,orders,'P1',V1,...,'PN',VN)` returns a model `m`. Use additional property-value pairs to specify the estimation algorithm properties.

`m = arx(data,'na',na,'nb',nb,'nc',nc,'nk',nk)` returns a model `m` with orders and delays specified as parameter-value pairs.

Remarks

`arx` estimates the parameters of the ARX model structure:

$$y(t)+a_1 y(t-1)+\ldots+a_{na} y(t-na)=$$
$$b_1 u(t-nk)+\ldots+b_{nb} u(t-nb-nk+1)+e(t)$$

The parameters `na` and `nb` are the orders of the ARX model, and `nk` is the delay.

- $y(t)$ — Output at time t.
- n_a — Number of poles.
- n_b — Number of zeroes plus 1.
- n_k — Number of input samples that occur before the input affects the output, also called the *dead time* in the system. For discrete systems with no dead time, there is a minimum 1–sample delay because the output depends on the previous input and $n_k = 1$.
- $y(t-1)\ldots y(t-n_a)$ — Previous outputs on which the current output depends.
- $u(t-n_k)\ldots u(t-n_k-n_b+1)$ — Previous and delayed inputs on which the current output depends.
- $e(t-1)\ldots e(t-n_c)$ — White-noise disturbance value.

A more compact way to write the difference equation is

$$A(q)y(t) = B(q)u(t-n_k) + e(t)$$

q is the delay operator. Specifically,

$$A(q) = 1 + a_1 q^{-1} + \ldots + a_{n_a} q^{-n_a}$$

$$B(q) = b_1 + b_2 q^{-1} + \ldots + b_{n_b} q^{-n_b+1}$$

Time Series Models

For time-series data that contains no inputs, one output and `orders = na`, the model has AR structure of order `na`.

The AR model structure is

$$A(q)y(t) = e(t)$$

Multiple Inputs and Single-Output Models

For multiple-input systems, `nb` and `nk` are row vectors where the `i`th element corresponds to the order and delay associated with the `i`th input.

$$y(t) + A_1 y(t-1) + A_2 y(t-2) + \ldots + A_{na} y(t-na) = B_0 u(t) + B_1 u(t-1) + \ldots + B_{nb} u(t-nb) + e(t)$$

Multi-Output Models

For models with multiple inputs and multiple outputs, `na`, `nb`, and `nk` contain one row for each output signal.

In the multiple-output case, `arx` minimizes the trace of the prediction error covariance matrix, or the norm

$$\sum_{t=1}^{N} e^T(t)e(t)$$

To transform this to an arbitrary quadratic norm using a weighting matrix `Lambda`

$$\sum_{t=1}^{N} e^T(t)\Lambda^{-1}e(t)$$

use the syntax

```
m = arx(data,orders,'NoiseVariance', Lambda)
```

You can use `arx` to refine an existing model `m_initial` as an argument.

```
m = arx(data,m_initial)
```

The new model `m` uses the orders and the weighting matrix for the prediction errors from `m_initial`. You can further modify `m_initial` by adding a list of property name and value pairs as arguments. This is especially useful when some parameters must be fixed using `'FixedParameter'` property.

Continuous-Time Models

For models with one output, continuous-time models can be estimated from continuous-time frequency-domain data. In this case, `na` is the number of estimated denominator coefficients and `nb` is number of estimated numerator coefficients.

Note For continuous-time models, omit the delay parameter `nk` because it has no meaning in this case. Because estimating continuous-time ARX models often produces bias, you might get better results by using the `oe` method.

For example, when `na = 4`, `nb = 2`, the model structure is:

$$G(s) = \frac{b_1 s + b_2}{s^4 + a_1 s^3 + a_2 s^2 + a_3 s + a_4}$$

Tip When using continuous-time data, limit the fit to a smaller frequency range using the `'Focus'` `idmodel` property:

```
m = arx(datac,[na nb],'focus',[0 wh])
```

Estimating Initial Conditions

For time-domain data, the signals are shifted such that unmeasured signals are never required in the predictors. Therefore, there is no need to estimate initial conditions.

For frequency-domain data, it might be necessary to adjust the data by initial conditions that support circular convolution.

You can set the property `'InitialState'` to one of the following values:

- `'zero'` — No adjustment.
- `'estimate'` — Perform adjustment to the data by initial conditions that support circular convolution.
- `'auto'` — Automatically choose between `'zero'` and `'estimate'` based on the data.

See `Algorithm Properties` for more information on model properties.

Algorithm

QR factorization solves the overdetermined set of linear equations that constitutes the least-squares estimation problem.

The regression matrix is formed so that only measured quantities are used (no fill-out with zeros). When the regression matrix is larger than `MaxSize`, data is segmented and QR factorization is performed iteratively on these data segments.

Examples

This example generates input data based on a specified ARX model, and then uses this data to estimate an ARX model.

```
A = [1  -1.5  0.7]; B = [0 1 0.5];
m0 = idpoly(A,B);
u = iddata([],idinput(300,'rbs'));
e = iddata([],randn(300,1));
y = sim(m0, [u e]);
z = [y,u];
m = arx(z,[2 2 1]);
```

How To

- “Using Linear Model for Nonlinear ARX Estimation”

arxdata

Purpose

ARX parameters from multiple-output models with variance information

Syntax

```
[A,B] = arxdata(m)
[A,B,dA,dB] = arxdata(m)
```

Arguments

`m`

An `idarx` model object.

Also accepts single-output `idpoly` models with an underlying ARX structure with orders `nc=nd=nf=0`.

Description

`[A,B] = arxdata(m)` returns `A` and `B` as 3-D arrays.

Suppose *ny* is the number of outputs (the dimension of the vector *y(t)*) and *nu* is the number of inputs.

`A` is an `ny`-by-`ny`-by-`(na+1)` array such that

```
A(:,:,k+1) = Ak
A(:,:,1) = eye(ny)
```

where `k=0,1,...,na`.

`B` is an `ny`-by-`nu`-by-`(nb+1)` array with

```
B(:,:,k+1) = Bk
```

`A(0)` is always the identity matrix. The leading entries in `B` equal to zero, which means there are no delays in the model.

Note For a time series, `B = []`.

`[A,B,dA,dB] = arxdata(m)` returns `A` and `B` matrices, and `dA` and `dB` as the estimated standard deviations of `A` and `B`, respectively.

Remarks

A and B are 2-D or 3-D arrays and are returned in the standard multivariable ARX format (see `idarx`), describing the model.

$$y(t) + A_1 y(t-1) + A_2 y(t-2) + \ldots + A_{na} y(t-na) =$$
$$B_0 u(t) + B_1 u(t-1) + \ldots + B_{nb} u(t-nb) + e(t)$$

where A_k and B_k matrices have dimensions *ny*-by-*ny* and *ny*-by-*nu*, respectively. *ny* is the number of outputs (the dimension of the vector *y(t)*) and *nu* is the number of inputs.

`idpoly`

Purpose

Compute and compare loss functions for single-output ARX models

Syntax

```
V = arxstruc(ze,zv,NN)
V = arxstruc(ze,zv,NN,maxsize)
```

Arguments

`ze`
: Estimation data set can be `iddata` or `idfrd` object.

`zv`
: Validation data set can be `iddata` or `idfrd` object.

`NN`
: Matrix defines the number of different ARX-model structures. Each row of `NN` is of the form:

```
nn = [na nb nk]
```

`maxsize`
: Specified maximum data size. See `Algorithm Properties` for an explanation.

Description

Note Use `arxstruc` for single-output systems only. `arxstruc` supports both single-input and multiple-input systems.

`V = arxstruc(ze,zv,NN)` returns `V`, which contains the loss functions in its first row. The remaining rows of `V` contain the transpose of `NN`, so that the orders and delays are given just below the corresponding loss functions. The last column of `V` contains the number of data points in `ze`.

`V = arxstruc(ze,zv,NN,maxsize)` uses the additional specification of the maximum data size.

with the same interpretation as described for `arx`. See `struc` for easy generation of typical `NN` matrices.

The output argument V is best analyzed using selstruc. The selection of a suitable model structure based on the information in v is normally done using selstruc.

Remarks

Each of ze and zv is an iddata object containing output-input data. Frequency-domain data and idfrd objects are also supported. Models for each of the model structures defined by NN are estimated using the data set ze. The loss functions (normalized sum of squared prediction errors) are then computed for these models when applied to the validation data set zv. The data sets ze and zv need not be of equal size. They could, however, be the same sets, in which case the computation is faster.

Examples

This example uses the simulation data from a second-order idpoly model with additive noise. The data is split into two parts, where one part is the estimation data and the other is the validation data. You select the best model by comparing the output of models with orders ranging between 1 and 5 with the validating data. All models have an input-to-output delay of 1.

```
% Create an ARX model for generaing data:
A = [1 -1.5 0.7]; B = [0 1 0.5];
m0 = idpoly(A,B);
% Generate a random input signal:
u = iddata([],idinput(400,'rbs'));
e = iddata([],0.1*randn(400,1));
% Simulate the output signal from the model m0:
y = sim(m0, [u e]);
z = [y,u]; % analysis data
NN = struc(1:5,1:5,1);
V = arxstruc(z(1:200),z(201:400),NN);
nn = selstruc(V,0);
m = arx(z,nn);
```

Purpose

Reduce model order (requires Control System Toolbox product)

Syntax

```
MRED = balred(M)
MRED = balred(M,ORDER,'DisturbanceModel','None')
```

Description

This function reduces the order of any model `M` given as an `idmodel` object. The resulting reduced-order model, `MRED`, is an `idss` model.

The function requires routines from the Control System Toolbox product.

`ORDER`: The desired order (dimension of the state-space representation). If `ORDER = []`, which is the default, a plot shows how the diagonal elements of the observability and controllability Gramians of a balanced realization decay with the order of the representation. You are then prompted to select an order based on this plot. The idea is that such a small element has a negligible influence on the input-output behavior of the model. We recommend that you choose an order such that only large elements in these matrices are retained.

`'DisturbanceModel'`: If the property `DisturbanceModel` is set to `'None'`, then an output-error model `MRED` is produced: that is, one with the Kalman gain K equal to zero. Otherwise (default), the disturbance model is also reduced.

The function recognizes whether `M` is a continuous- or discrete-time model and performs the reduction accordingly. The resulting model, `MRED`, is similar to `M` in this respect.

There are several options for how the reduction is performed: `AbsTol, RelTol, Offset, Elimination`.

Algorithm

The function uses the `balred` algorithm in Control System Toolbox. The plot, in case `ORDER = []`, shows the vector `g` returned by `balreal`.

Examples

Build a high-order multivariable ARX model, reduce its order to `3`, and compare the frequency responses of the original and reduced models:

```
M = arx(data,[4*ones(3,3),4*ones(3,2),ones(3,2)]);
```

```
MRED = balred(M,3);
bode(M,MRED)
```

Use the reduced-order model as an initial condition for a third-order state-space model.

```
M2 = pem(data,MRED);
```

balreal

Purpose

Box-Jenkins (BJ) model estimation

Syntax

```
m = bj(data,[nb nc nd nf nk])
m = bj(data,[nb nc nd nf nk],'PropertyName',PropertyValue)
m = bj(data,m_initial)
```

Description

`m = bj(data,[nb nc nd nf nk])` estimates Box-Jenkins model parameters and their covariances from input-output data. `m` is an `idpoly` object. `data` is a time-domain, single-output `iddata` object. `nb, nc, nd,` and `nf` are orders of the *B*, *C*, *D*, and *F* polynomials, respectively. `nk` is the input delay, specified as the number of samples. Orders and delay are scalar for single-input data, and row vectors for multiple-input data with the same size as the number of input channels.

`m = bj(data,[nb nc nd nf nk],'PropertyName',PropertyValue)` estimates Box-Jenkins model using algorithm options specified by `idpoly` property name-value pairs. See `Algorithm Properties`.

`m = bj(data,m_initial)` refines previously estimated model `m_initial`, which is an `idpoly` object.

`bj` does not support frequency-domain and multiple-output data.

Definitions

The general Box-Jenkins model structure is:

$$y(t) = \sum_{i=1}^{nu} \frac{B_i(q)}{F_i(q)} u_i\left(t - nk_i\right) + \frac{C(q)}{D(q)} e(t)$$

where nu is the number of input channels.

The orders of Box-Jenkins model are defined as follows:

$$nb\text{:}\quad B(q) = b_1 + b_2 q^{-1} + \ldots + b_{nb} q^{-nb+1}$$

$$nc\text{:}\quad C(q) = 1 + c_1 q^{-1} + \ldots + c_{nc} q^{-nc}$$

$$nd\text{:}\quad D(q) = 1 + d_1 q^{-1} + \ldots + d_{nd} q^{-nd}$$

$$nf\text{:}\quad F(q) = 1 + f_1 q^{-1} + \ldots + f_{nf} q^{-nf}$$

Examples

Estimate parameters of a single-input single-output Box-Jenkins model:

```
% Load SISO data.
  load iddata1;
% Estimate model parameters
  mbj = bj(z1,[2 2 2 2 1])
```

Estimate parameters of a multi-input single-output Box-Jenkins model:

```
% Load MISO data.
  load iddata8;
% Estimate model parameters
  mbj = bj(z8,[[2 1 1] 1 1 [2 1 2] [5 10 15]])
```

Estimate parameters of a single-input single-output Box-Jenkins model using estimation algorithm properties:

```
% Generate estimation data using simulation.
  B = [0 1 0.5];
  C = [1 -1 0.2];
  D = [1 1.5 0.7];
  F = [1 -1.5 0.7];
  m0 = idpoly(1,B,C,D,F,0.1);
  e = iddata([],randn(200,1));
  u = iddata([],idinput(200));
  y = sim(m0,[u e]);
  z = [y u];
% Estimate model parameters.
  mbj_i = bj(z,[2 2 2 2 1]);
% Repeat the estimation with more iterations.
  mbj = bj(z,mbj_i,'MaxIter',50)
% View the estimation results.
  mbj.EstimationInfo
% Compare initial and refined model parameters.
  compare(z,mbj,mbj_i)
```

Purpose

Compute and plot frequency response magnitude and phase for logarithmic frequencies

Syntax

```
bode(m)
bode(m,w)
bode(m('noise')
bode(m1,...,mN,'sd',sd,'mode','same','ap',ap,'fill')
[mag,phase,w] = bode(m)
[mag,phase,w,sdmag,sdphase] = bode(m)
```

Description

`bode(m)` plots a Bode plot for the model `m`, which can be an `idpoly`, `idss`, `idarx`, `idgrey`, or `idfrd` object. This frequency response is a function of logarithmic frequencies in radians per unit time (stored as the `TimeUnit` model property). Default frequency values are computed from the model dynamics. For time series spectra, phase plots are omitted. For MIMO models, press **Enter** to view the next plot in the sequence of different I/O channel pairs, annotated using the `InputNames` and `OuputNames` model properties.

`bode(m,w)` plots a Bode plot at specified frequencies `w` in radians per unit time, which can be

- A vector of values.
- `{wmin,wmax}`, which specifies 100 logarithmically spaced frequency values ranging from a minimum value `wmin` and a maximum value `wmax`.
- `{wmin,wmax,np}`, which specifies `np` logarithmically spaced frequency values.

Note For `idfrd` models, you cannot specify individual frequencies and can only limit the frequencies range for the internally stored frequencies using `{wmin,wmax}`.

`bode(m('noise')` plots a Bode plot of the output noise spectra when the model contains noise spectrum information.

`bode(m1,...,mN,'sd',sd,'mode','same','ap',ap,'fill')` plots a Bode plot for several models. `sd` specifies the confidence region as a positive number that represents the number of standard deviations. The argument `'fill'` indicates that the confidence region is color filled. `mode = 'same'` displays all I/O channels in the same plot. Set `ap = 'A'` to show only amplitude plots, or `ap = 'P'` to show only phase plots.

`[mag,phase,w] = bode(m)` computes the magnitude `mag` and `phase` values of the frequency response, which are 3-D arrays with dimensions (number of outputs)-by-(number of inputs)-by-(length of w). `w` specifies the frequency values for computing the response even if you did not specify it as an input. For SISO systems, `mag(1,1,k)` and `phase(1,1,k)` are the magnitude and phase (in degrees) at the frequency w(k). For MIMO systems, `mag(i,j,k)` is the magnitude of the frequency response at frequency `w(k)` from input `j` to output `i`, and similarly for `phase(i,j,k)`. When `m` is a time series, `mag` is its power spectrum and `phase` is zero.

`[mag,phase,w,sdmag,sdphase] = bode(m)` computes the standard deviations of the magnitude `sdmag` and the phase `sdphase`. `sdmag` is an array of the same size as `mag`, and `sdphase` is an array of the same size as `phase`.

Purpose

Compare model output and measured output

Syntax

```
compare(data,m);
compare(data,m,k)
compare(data,m,k,'Samples',sampnr,'InitialState',init,'OutputPlots
',Yplots)
compare(data,m1,m2,...,mN)
compare(data,m1,'PlotStyle1',...,mN,'PlotStyleN')
[yh,fit,x0] = compare(data,m1,'PlotStyle1',...,mN,'PlotStyleN',k)
```

Description

`data` is the output-input data in the usual `iddata` object format. `data` can also be an `idfrd` object with frequency-response data.

`compare` computes the output `yh` that results when the model `m` is simulated with the input `u`. *m* can be any `idmodel` or `idnlmodel` model object. The result is plotted together with the corresponding measured output `y`. The percentage of the output variation that is explained by the model

```
fit = 100*(1 - norm(yh - y)/norm(y-mean(y)))
```

is also computed and displayed. For multiple-output systems, this is done separately for each output. For frequency-domain data (or in general for complex valued data) the `fit` is still calculated as above, but only the absolute values of `y` and `yh` are plotted.

When the argument `k` is specified, the k step-ahead prediction of `y` according to the model `m` are computed instead of the simulated output. In the calculation of $yh(t)$, the model can use outputs up to time $t–k$: $y(s), s = t-k, t-k-1, \ldots$ (and inputs up to the current time t). The default value of `k` is `inf`, which gives a pure simulation from the input only. Note that for frequency-domain data, only simulation (`k = inf`) is allowed, and for time-series data (no input) only prediction (`k` not `inf`) is possible.

Property Name/Property Value Pairs

The optional property name/property value pairs `'Samples'/sampnr`, `'InitialState'/init`, and `'OutputPlots'/Yplots` can be given in any order.

The argument `Yplots` can be a cell array of strings. Only the outputs with `OutputName` in this array are plotted, while all are used for the necessary computations. If `Yplots` is not specified, all outputs are plotted.

The argument `sampnr` indicates that only the sample numbers in this row vector are plotted and used for the calculation of the fit. The whole data record is used for the simulation/prediction.

The argument `init` determines how to handle initial conditions in the models:

- `init = 'e'` (for `'estimate'`) estimates the initial conditions for best fit.
- `init = 'm'` (for `'model'`) uses internally stored initial state of the model.
- `init = 'z'` (for `'zero'`) uses zero initial conditions.
- `init = x0`, where `x0` is a column vector of the same size as the state vector of the models, uses `x0` as the initial state.
- `init = 'e'` is the default.

Several Models

When several models are specified, as in `compare(data,m1,m2,...,mN)`, the plots show responses and fits for all models. In that case `data` should contain all inputs and outputs that are required for the different models. However, some models might correspond to subselections of channels and might not need all channels in `data`. In that case the proper handling of signals is based on the `InputNames` and `OutputNames` of `data` and the models.

With `compare(data,m1,'PlotStyle1',...mN,'PlotStyle2')`, the color, line style, and/or marker can be specified for the curves associated with the different models. The markers are the same as for the regular `plot` command. For example,

```
compare(data,m1,'g_*',m2,'r:')
```

If `data` contains several experiments, separate plots are given for the different experiments. In this case `sampnr`, if specified, must be a cell array with as many entries as there are experiments.

Arguments

When output arguments `[yh,fit,x0] = compare(data,m1,..,mN)` are specified, no plots are produced.

`yh` is a cell array of length equal to the number of models. Each cell contains the corresponding model output as an `iddata` object.

`fit` is, in the general case, a 3-D array with `fit(kexp,kmod,ky)` containing the fit (computed as above) for output `ky`, model `kmod`, and experiment `kexp`.

`x0` is a cell array, such that `x0{kmod}` is the estimated initial state for model number `kmod`. If data is multiexperiment, `X0{kmod}` is a matrix whose column number `kexp` is the initial state vector for experiment number `kexp`.

Examples

Split the data record into two parts. Use the first one for estimating a model and the second one to check the model's ability to predict six steps ahead.

```
ze = z(1:250);
zv = z(251:500);
m= armax(ze,[2 3 1 0]);
compare(zv,m,6);
compare(zv,m,6,'Init','z') % No estimation of
                           % the initial state.
```

Purpose

Estimate covariance functions for time-domain iddata object

Syntax

```
R = covf(data,M)
R = covf(data,M,maxsize)
```

Description

`data` is an `iddata` object and `M` is the maximum delay -1 for which the covariance function is estimated. The routine is intended for time-domain data only.

Let `z` contain the output and input channels

$$z(t) = \begin{bmatrix} y(t) \\ u(t) \end{bmatrix}$$

where y and u are the rows of `data.OutputData` and `data.InputData`, respectively, with a total of `nz` channels.

`R` is returned as an nz^2 -by- M matrix with entries

$$R(i+(j-1)nz, k+1) = \frac{1}{N}\sum_{t=1}^{N} z_i(t) z_j(t+k) = \hat{R}_{ij}(k)$$

where z_j is the `j`th row of z, and missing values in the sum are replaced by zero.

The optional argument `maxsize` controls the memory size as explained under `Algorithm Properties`.

The easiest way to describe and unpack the result is to use

```
reshape(R(:,k+1),nz,nz) = E z(t)*z'(t+k)
```

Here `'` is complex conjugate transpose, which also explains how complex data is handled. The expectation symbol `E` corresponds to the sample means.

Algorithm

When `nz` is at most two, and when permitted by `maxsize`, a fast Fourier transform technique is applied. Otherwise, straightforward summing is used.

`spa`

Purpose

Estimate impulse response using prewhitened-based correlation analysis

Syntax

```
cra(data);
[ir,R,cl] = cra(data,M,na,plot);
cra(R);
```

Description

`data` is the output-input data given as an `iddata` object. The routine is intended for time-domain data only.

The routine only handles single-input-single-output data pairs. (For the multivariate case, apply `cra` to two signals at a time, or use `impulse`.) `cra` prewhitens the input sequence; that is, `cra` filters `u` through a filter chosen so that the result is as uncorrelated (white) as possible. The output `y` is subjected to the same filter, and then the covariance functions of the filtered `y` and `u` are computed and graphed. The cross correlation function between (prewhitened) input and output is also computed and graphed. Positive values of the lag variable then correspond to an influence from `u` to later values of `y`. In other words, significant correlation for negative lags is an indication of feedback from `y` to `u` in the data.

A properly scaled version of this correlation function is also an estimate of the system's impulse response `ir`. This is also graphed along with 99% confidence levels. The output argument `ir` is this impulse response estimate, so that its first entry corresponds to lag zero. (Negative lags are excluded in `ir`.) In the plot, the impulse response is scaled so that it corresponds to an impulse of height $1/T$ and duration T, where T is the sampling interval of the data.

The output argument `R` contains the covariance/correlation information as follows:

- The first column of `R` contains the lag indices.
- The second column contains the covariance function of the (possibly filtered) output.

- The third column contains the covariance function of the (possibly prewhitened) input.
- The fourth column contains the correlation function. The plots can be redisplayed by `cra(R)`.

The output argument `cl` is the 99% confidence level for the impulse response estimate.

The optional argument `M` defines the number of lags for which the covariance/correlation functions are computed. These are from `-M` to `M`, so that the length of `R` is `2M+1`. The impulse response is computed from `0` to `M`. The default value of `M` is `20`.

For the prewhitening, the input is fitted to an AR model of order `na`. The third argument of `cra` can change this order from its default value `na = 10`. With `na = 0` the covariance and correlation functions of the original data sequences are obtained.

`plot:  plot = 0` gives no plots. `plot = 1` (the default) gives a plot of the estimated impulse response together with a 99% confidence region. `plot = 2` gives a plot of all the covariance functions.

An often better alternative to `cra` is the functions `impulse` and `step`, which use a high-order FIR model to estimate the impulse response.

Examples

Compare a second-order ARX model's impulse response with the one obtained by correlation analysis.

```
ir = cra(z);
m = arx(z,[2 2 1]);
imp = [1;zeros(19,1)];
irth = sim(m,imp);
subplot(211)
plot([ir irth])
title('impulse responses')
subplot(212)
plot([cumsum(ir),cumsum(irth)])
title('step responses')
```

Purpose

Custom nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models

Syntax

```
C=customnet(H)
C=customnet(H,PropertyName,PropertyValue)
```

Description

`customnet` is an object that stores a custom nonlinear estimator with a user-defined unit function. This custom unit function uses a weighted sum of inputs to compute a scalar output.

Construction

`C=customnet(H)` creates a nonlinearity estimator object with a user-defined unit function using the function handle `H`. `H` must point to a function of the form `[f,g,a] = gaussunit(x)`, where `f` is the value of the function, `g=df/dx`, and `a` indicates the unit function active range. Name the function `gaussunit.m`. `g` is significantly nonzero in the interval `[-a a]`. Hammerstein-Wiener models require that your custom nonlinearity have only one input and one output.

`C=customnet(H,`*`PropertyName`*`,`*`PropertyValue`*`)` creates a nonlinearity estimator using property-value pairs defined in "customnet Properties" on page 2-58.

Remarks

Use `customnet` to define a nonlinear function $y = F(x)$, where y is scalar and x is an `m`-dimensional row vector. The unit function is based on the following function expansion with a possible linear term L:

$$F(x) = (x-r)PL + a_1 f\left((x-r)Qb_1 + c_1\right) + \ldots \\ + a_n f\left((x-r)Qb_n + c_n\right) + d$$

where f is a unit function that you define using the function handle H.

P and Q are `m`-*by*-`p` and `m`-*by*-`q` projection matrices, respectively. The projection matrices P and Q are determined by principal component analysis of estimation data. Usually, `p=m`. If the components of x in the estimation data are linearly dependent, then `p<m`. The number of columns of Q, `q`, corresponds to the number of components of `x` used in the unit function.

When used to estimate nonlinear ARX models, `q` is equal to the size of the `NonlinearRegressors` property of the `idnlarx` object. When used to estimate Hammerstein-Wiener models, `m=q=1` and Q is a scalar.

r is a 1-*by*-`m` vector and represents the mean value of the regressor vector computed from estimation data.

d, a, and c are scalars.

L is a `p`-*by*-1 vector.

b represents `q`-*by*-1 vectors.

The function handle of the unit function of the custom net must have the form `[f,g,a] = function_name(x)`. This function must be vectorized, which means that for a vector or matrix `x`, the output arguments `f` and `g` must have the same size as `x` and be computed element-by-element.

customnet Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
get(C)
% Get value of NumberOfUnits property
C.NumberOfUnits
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(C, 'LinearTerm', 'on')
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
NumberOfUnits	Integer specifies the number of nonlinearity units in the expansion. Default=10. For example: `customnet(H,'NumberOfUnits',5)`
LinearTerm	Can have the following values: • 'on'—Estimates the vector *L* in the expansion. • 'off'—Fixes the vector *L* to zero. For example: `customnet(H,'LinearTerm','on')`
Parameters	A structure containing the parameters in the nonlinear expansion, as follows: • RegressorMean: 1-*by*-m vector containing the means of x in estimation data, r. • NonLinearSubspace: m-*by*-q matrix containing *Q*. • LinearSubspace: m-*by*-p matrix containing *P*. • LinearCoef: p-*by*-1 vector *L*. • Dilation: q-*by*-1 matrix containing the values b_k. • Translation: 1-*by*-n vector containing the values c_k. • OutputCoef: n-*by*-1 vector containing the values a_k. • OutputOffset: scalar d. Typically, the values of this structure are set by estimating a model with a customnet nonlinearity.
UnitFcn	Stores the function handle that points to the unit function.

Algorithm

customnet uses an iterative search technique for estimating parameters.

Examples

Define custom unit function and save it in gaussunit.m:

```
function [f, g, a] = GAUSSUNIT(x)
% x: unit function variable
% f: unit function value
% g: df/dx
% a: unit active range (g(x) is significantly
% nonzero in the interval [-a a])

% The unit function must be "vectorized": for
% a vector or matrix x, the output arguments f and g
% must have the same size as x,
% computed element-by-element.

% GAUSSUNIT customnet unit function example
[f, g, a] = gaussunit(x)
f =  exp(-x.*x);
if nargout>1
  g = - 2*x.*f;
  a = 0.2;
end
```

Use custom networks in nlarx and nlhw model estimation commands:

```
% Define handle to example unit function.
H = @gaussunit;
% Estimate nonlinear ARX model using
% Gauss unit function with 5 units.
m = nlarx(Data,Orders,customnet(H,'NumberOfUnits',5));
```

How To

- "Identifying Nonlinear ARX Models"

- “Identifying Hammerstein-Wiener Models”

Purpose Custom regressor for nonlinear ARX models

Syntax

```
C=customreg(Function,Variables)
C=customreg(Function,Variables,Delays,Vectorized)
```

Description

`customreg` class represents arbitrary functions of past inputs and outputs, such as products, powers, and other MATLAB expressions of input and output variables.

You can specify custom regressors in addition to or instead of standard regressors for greater flexibility in modeling your data using nonlinear ARX models. For example, you can define regressors like *tan(u(t-1))*, $u(t-1)^2$, and *u(t-1)*y(t-3)*.

For simpler regressor expressions, specify custom regressors directly in the GUI or in the `nlarx` estimation command. For more complex expressions, create a `customreg` object for each custom regressor and specify these objects as inputs to the estimation. Regardless of how you specify custom regressors, the toolbox represents these regressors as `customreg` objects. Use `getreg` to list the expressions of all standard and custom regressors in your model.

A special case of custom regressors involves polynomial combinations of past inputs and outputs. For example, it is common to capture nonlinearities in the system using polynomial expressions like $y(t-1)2$, $u(t-1)2$, $y(t-2)2$, $y(t-1)*y(t-2)$, $y(t-1)*u(t-1)$, $y(t-2)*u(t-1)$. At the command line, use the `polyreg` command to generate polynomial-type regressors automatically by computing all combinations of input and output variables up to a specified degree. `polyreg` produces `customreg` objects that you specify as inputs to the estimation.

The nonlinear ARX model (`idnlarx` object) stores all custom regressors as the `CustomRegressors` property. You can list all custom regressors using `m.CustomRegressors`, where `m` is a nonlinear ARX model. For MIMO models, to retrieve the `r`th custom regressor for output `ky`, use `m.CustomRegressors{ky}(r)`.

Use the `Vectorized` property to specify whether to compute custom regressors using vectorized form during estimation. If you know

that your regressor formulas can be vectorized, set `Vectorized` to `1` to achieve better performance. To better understand vectorization, consider the custom regressor function handle `z=@(x,y)x^2*y`. `x` and `y` are vectors and each variable is evaluated over a time grid. Therefore, `z` must be evaluated for each `(xi,yi)` pair, and the results are concatenated to produce a `z` vector:

```
for k = 1:length(x)
   z(k) = x(k)^2*y(k)
end
```

The above expression is a nonvectorized computation and tends to be slow. Specifying a `Vectorized` computation uses MATLAB vectorization rules to evaluate the regressor expression using matrices instead of the `FOR`-loop and results in faster computation:

```
% ".*" indicates element-wise operation
z=(x.^2).*y
```

Construction

C=customreg(*Function*,*Variables*) specifies a custom regressor for a nonlinear ARX model. *C* is a `customreg` object that stores custom regressor. *Function* is a handle or string representing a function of input and output variables. *Variables* is a cell array of strings that represent the names of model inputs and outputs in the function *Function*. Each input and output name must coincide with the strings in the `InputName` and `OutputName` properties of the corresponding `idnlarx` object. The size of *Variables* must match the number of *Function* inputs. For multiple-output models with `p` outputs, the custom regressor is a `p`-by-1 cell array or an array of `customreg` object, where the `ky`th entry defines the custom regressor for output `ky`. You must add these regressors to the *model* by assigning the `CustomRegressors` *model* property or by using `addreg`.

C=customreg(*Function*,*Variables*,*Delays*,*Vectorized*) create a custom regressor that includes the delays corresponding to inputs or outputs in `Arguments`. *Delays* is a vector of positive integers that represent the delays of *Variables* variables (default is 1 for each vector element). The size of *Delays* must match the size of *Variables*.

Vectorized value of 1 uses MATLAB vectorization rules to evaluate the regressor expression *Function*. By default, *Vectorized* value is 0 (false).

Properties

After creating the object, you can use get or dot notation to access the object property values. For example:

```
% List all property values
get(C)
% Get value of Arguments property
C.Arguments
```

You can also use the set function to set the value of particular properties. For example:

```
set(C,'Vectorized',1)
```

Property Name	Description
Function	Function handle or string representing a function of standards regressors. For example: `cr = @(x,y) x*y`
Variables	Cell array of strings that represent the names of model input and output variables in the function Function. Each input and output name must coincide with the strings in the InputName and OutputName properties of the idnlarx object—the model for which you define custom regressors. The size of Variables must match the number of Function inputs. For example, Variables correspond to {'y1','u1'} in: `C = customreg(cr,{'y1','u1'},[2 3])`

Property Name	Description
Delays	Vector of positive integers representing the delays of `Variables`. The size of `Delays` must match the size of `Arguments`. Default: `1` for each vector element. For example, `Delays` are `[2 3]` in: `C = customreg(cr,{'y1','u1'},[2 3])`
Vectorized	Assignable values: • `0` (default)—`Function` is not computed in vectorized form. • `1`—`Function` is computed in vectorized form when called with vector arguments.

Examples

Define custom regressors as a cell array of strings:

```
load iddata1
m = nlarx(z1,[2 2 1]);
C={'u1(t-1)*sin(y1(t-3))','u1(t-2)^3'};
% u1 and y1 are system input and output

m.CustomRegressors = C;
m=pem(z1,m)
```

Define custom regressors directly in the estimation command `nlarx`:

```
m = nlarx(data,[na nb nk],'linear',...
          'CustomRegressors',...
          {'u1(t-1)*sin(y1(t-3))','u1(t-2)^3'});
```

Define custom regressors as an object array of `customreg` objects:

```
cr1=@(x,y) x*sin(y);
cr2=@(x) x^3;
C=[customreg(cr1,{'u' 'y'},[1 3]),...
   customreg(cr2,{'u'},2)];
m=addreg(m,C);
```

Use vectorization rules to evaluate regressor expression during estimation:

```
C = customreg(@(x,y) x*sin(y),{'u' 'y'},[1 3])
set(C,'Vectorized',1)
m = nlarx(data,[na nb nk],'sigmoidnet','CustomReg',C)
```

How To

- “Identifying Nonlinear ARX Models”

Purpose

Transform linear model from continuous to discrete time

Syntax

```
md = c2d(mc,T)
md = c2d(mc,T,method)
[md,G] = c2d(mc,T,method)
```

Description

`mc` is a continuous-time model such as any `idmodel` object (`idgrey`, `idproc`, `idpoly`, or `idss`). `md` is the model that is obtained when it is sampled with sampling interval `T`.

`method = 'zoh'` (default) makes the translation to discrete time under the assumption that the input is piecewise constant (zero-order hold).

`method = 'foh'` assumes the input to be piecewise linear between the sampling instants (first-order hold).

When you have the Control System Toolbox product installed, you can also use the following methods: `'tustin'`, and `'matched'`. In these cases, no translation of the covariance matrix takes place.

Note that the innovations variance λ of the continuous-time model is interpreted as the intensity of the spectral density of the noise spectrum. The noise variance in `md` is thus given as λ/T.

`idpoly` and `idss` models are returned in the same format. `idgrey` structures are preserved if their `CDMfile` property is equal to `'cd'`. Otherwise they are transformed to `idss` objects. `idproc` models are returned as `idgrey` objects.

For `idpoly` models, the covariance matrix is translated by the use of numerical derivatives. The step sizes used for the differentiation are given by the function `nuderst`. For `idss, idproc,` and `idgrey` models, the covariance matrix is not translated, but covariance information about the input-output properties is included in `md`. To inhibit the translation of covariance information (which may take some time), use `c2d(mc,T,'covariance','none')`.

The output argument `G` is a matrix that transforms the initial state `x0` of `mc` to the initial state of `md` as

```
X0d=G * [X0; u(0)],
```

where u(0) is the input at time 0. For idproc models, the state variables correspond to those of idgrey(mc). For idpoly models, G is returned as the empty matrix.

Examples

Define a continuous-time system and study the poles and zeros of the sampled counterpart.

```
mc = idpoly(1,1,1,1,[1 1 0],'Ts',0);
md = c2d(mc,0.5);
pzmap(md)
```

See Also

d2c

Purpose

Map past input/output data to current states of nonlinear ARX model

Syntax

```
X = data2state(MODEL,IOSTRUCT)
X = data2state(MODEL,DATA)
```

Description

`X = data2state(MODEL,IOSTRUCT)` maps the input and output samples in `IOSTRUCT` to the current states of `MODEL`, `X`. For a definition of the states of `idnlarx` models, see "Definition of idnlarx States" on page 2-189. The data in `IOSTRUCT` is interpreted as past samples of data, so that the returned state values must be interpreted as values at the time immediately after the time corresponding to the last (most recent) sample in the data.

`X = data2state(MODEL,DATA)` maps the input and output samples from `DATA` to the current states, `X`, of the model.

Input

- `MODEL`: `idnlarx` model.
- `IOSTRUCT`: Structure with fields `Input` and `Output`. Samples in `IOSTRUCT` must be in the order of increasing time (the last row of values corresponds to the most recent time). Each field contains data samples corresponding to the past input and output of `MODEL` respectively.
  - `Input`: Matrix of `NU` columns, where `NU` is the number of inputs. The number of rows can be equal to either of the following:
    - Maximum input delay in `MODEL` (maximum across all input variables).
    - 1 to specify steady-state (constant) input values.
  - `Output`: Matrix of `NY` columns, where `NY` is the number of outputs. The number of rows can be equal to either of the following:
    - Maximum input delay in `MODEL` (maximum across all output variables).
    - 1 to specify steady-state (constant) output values.

- DATA: iddata object containing data samples. Samples in DATA must be in the order of increasing time (the last row of values corresponds to the most recent time). The number of samples in DATA must be greater than or equal to the maximum delay in the model across all input and output variables.

Note To determine maximum delay in each input and output channel of MODEL, use the getDelayInfo command. For more information, see the getDelayInfo reference page.

Output

X is the state vector of MODEL corresponding to the time after the most recent sample in the input data (IOSTRUCT or DATA).

Examples

In this example you determine the current state of an idnlarx model.

1. Load your data and create a data object.

```
load motorizedcamera;
z = iddata(y,u,0.02,'Name','Motorized Camera', ...
                       'TimeUnit','s');
```

2. Estimate an idnlarx model from the data. The model has 6 inputs and 2 outputs.

```
mw1 = nlarx(z,[ones(2,2),ones(2,6),ones(2,6)],wavenet);
```

3. Compute the maximum delays across all output variables in mw1.

```
MaxDelays =  getDelayInfo(mw1);
```

4. Represent the past input and output samples:

```
IOData = struct('Input', ...
                 rand(max(MaxDelays(3+1:end)),6),...
                'Output', ...
```

```
                    rand(max(MaxDelays(1:3)),2));
```

5 Compute the current states of mw1 based on the past data in IOSTRUCT.

```
X = data2state(mw1,IOData)
```

The previous command computes the state vector.

Note You can specify constant input levels with scalar values (10,20,30,40,50,60) for the input variables by setting IOSTRUCT.Input = [10, 20, 30, 40, 50, 60] instead of a matrix of values.

getDelayInfo

deadzone

Purpose

Class representing dead-zone nonlinearity estimator for Hammerstein-Wiener models

Syntax

```
s=deadzone(ZeroInterval,I)
```

Description

`deadzone` is an object that stores the dead-zone nonlinearity estimator for estimating Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`s=deadzone(ZeroInterval,I)` creates a dead-zone nonlinearity estimator object, initialized with the zero interval `I`.

Use `evaluate(d,x)` to compute the value of the function defined by the `deadzone` object `d` at `x`.

Remarks

Use `deadzone` to define a nonlinear function $y = F(x)$, where F is a function of x and has the following characteristics:

$a \le x < b$	$F(x) = 0$
$x < a$	$F(x) = x - a$
$x \ge b$	$F(x) = x - b$

y and x are scalars.

Properties

You can specify the property value as an argument in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List ZeroInterval property value
get(d)
d.ZeroInterval
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(d, 'ZeroInterval', [-1.5 1.5])
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
`ZeroInterval`	1-*by*-2 row vector that specifies the initial zero interval of the nonlinearity. Default=`[NaN NaN]`. For example: `deadzone('ZeroInterval',[-1.5 1.5])`

Examples

Use `deadzone` to specify the dead-zone nonlinearity estimator in Hammerstein-Wiener models. For example:

```
m=nlhw(Data,Orders,deadzone([-1 1]),[]);
```

The dead-zone nonlinearity is initialized at the interval `[-1 1]`. The interval values are adjusted to the estimation data by `nlhw`.

See Also

`nlhw`

delayest

Purpose

Estimate time delay (dead time) from data

Syntax

```
nk = delayest(Data)
nk = delayest(Data,na,nb,nkmin,nkmax,maxtest)
```

Description

`Data` is an `iddata` object containing the input-output data. It can also be an `idfrd` object defining frequency-response data. Only single-output data can be handled.

`nk` is returned as an integer or a row vector of integers, containing the estimated time delay in samples from the input(s) to the output in `Data`.

The estimate is based on a comparison of ARX models with different delays:

$$y(t) + a_1 y(t-1) + \ldots + a_{na} y(t-na) =$$
$$b_1 u(t-nk) + \ldots + b_{nb} u(t-nb-nk+1) + e(t)$$

The integer `na` is the order of the A polynomial (default 2). `nb` is a row vector of length equal to the number of inputs, containing the order(s) of the B polynomial(s) (default all 2).

`nkmin` and `nkmax` are row vectors of the same length as the number of inputs, containing the smallest and largest delays to be tested. Defaults are `nkmin = 0` and `nkmax = nkmin+20`.

If `nb`, `nkmax`, and/or `nkmin` are entered as scalars in the multiple-input case, all inputs will be assigned the same values.

`maxtest` is the largest number of tests allowed (default 10,000).

Purpose

Subtract offset or trend from data signals

Syntax

```
data_d = detrend(data)
data_d = detrend(data,Type)
[data_d,T] = detrend(data,Type)
data_d = detrend(data,1,brkp)
```

Description

`data_d = detrend(data)` subtracts the mean value from each time-domain or time-series signal `data`. `data_d` and `data` are `iddata` objects.

`data_d = detrend(data,Type)` subtracts a mean value from each signal when `Type = 0`, a linear trend (least-squares fit) when `Type = 1`, or a trend specified by a `TrendInfo` object when `Type = T`.

`[data_d,T] = detrend(data,Type)` stores the trend information as a `TrendInfo` object `T`.

`data_d = detrend(data,1,brkp)` subtracts a piecewise linear trend at one or more breakpoints `brkp`. `brkp` is a data index where discontinuities between successive linear trends occur. When `brkp` contains breakpoints that match the time vector, `detrend` subtracts a continuous piecewise linear trend. You cannot store piecewise linear trend information as an output argument.

Examples

Subtract mean values from input and output signals and store the trend information:

```
% Load SISO data containing vectors u2 and y2.
load dryer2
% Create data object with sampling interval of 0.08 sec.
data=iddata(y2,u2,0.08)
% Plot data on a time plot. Data has a nonzero mean.
plot(data)
% Remove the mean from the data.
[data_d,T] = detrend(data,0)
% Plot detrended data on the same plot.
hold on
```

```
plot(data_d)
```

Remove specified offset from input and output signals:

```
% Load SISO data containing vectors u2 and y2.
load dryer2
% Create data object with sampling time of 0.08 sec.
data=iddata(y2,u2,0.08)
plot(data)
% Create a TrendInfo object for storing offsets and trends.
T = getTrend(data)
% Assign offset values to the TrendInfo object.
T.InputOffset=5;
T.OutputOffset=5;
% Subtract offset from the data.
data_d = detrend(data,T)
% Plot detrended data on the same plot.
hold on
plot(data_d)
```

Subtract several linear trends that connect at three breakpoints `[30 60 90]`:

```
data = detrend(data,1,[30 60 90]);
% [30 60 90] are data indexes where breakpoints occur.
```

Subtract a mean value from the input signal and a V-shaped trend from the output signal, such that the V peak occurs at the breakpoint value of `119`:

```
zd1 = z(:,:,[]); zd2 = z(:,[],:);
zd1(:,1,[]) = detrend(z(:,1,[]),1,119);
zd2(:,[],1) = detrend(z(:,[],1));
zd = [zd1,zd2];
```

See Also

`getTrend` | `retrend` | `TrendInfo`

How To

- “Handling Offsets and Trends in Data”

Purpose Difference signals in iddata objects

Syntax

```
zdi = diff(z)
zdi = diff(z,n)
```

Description `z` is a time-domain `iddata` object. `diff(z)` and `diff(z,n)` apply this command to each of the input/output signals in `z`.

Purpose

Transform linear model from discrete to continuous time

Syntax

```
mc = d2c(md)
mc = d2c(md,method)
mc = d2c(md,'CovarianceMatrix',cov,'InputDelay',inpd)
```

Description

The discrete-time model `md`, given as any `idmodel` object, is converted to a continuous-time counterpart `mc`. The covariance matrix of the parameters in the model is also translated using the Gauss approximation formula and numerical derivatives of the transformation. The step sizes in the numerical derivatives are determined by the function `nuderst`. To inhibit the translation of the covariance matrix and save time, enter among the input arguments `(...,'CovarianceMatrix,'None,....)`) (any abbreviations will do).

`method` is one of the input intersample behaviors `'zoh'` (zero-order hold) or `'foh'` (first-order hold). If `method` is not specified, the `InterSample` behavior of the data from which `md` was estimated is used.

When you have Control System Toolbox installed, you can also use the following methods: `'tustin'`, and `'matched'`. In these cases, no translation of the covariance matrix takes place.

If the discrete-time model contains pure time delays, that is, $nk>1$, then these are first removed before the transformation is made. These delays are appended as pure time delay (dead time) to the continuous-time model as the property `InputDelay`. To have the time delay approximated by a finite-dimensional continuous system, enter among the input arguments `(...,'InputDelay',0,...)`.

If the noise variance is λ in `md`, and its sampling interval is T, then the continuous-time model has an indicated level of noise spectral density equal to $T\lambda$.

While `idpoly` and `idss` models are returned in the same format, `idarx` models are returned as `idss` models `mc`. The reason is that the transformation does not preserve the special structure of `idarx`. The `idgrey` structures are preserved if their `CDMfile` property is equal to `cd`. Otherwise they are transformed to `idss` objects.

Note The transformation from discrete to continuous time is not unique. d2c selects the continuous-time counterpart with the slowest time constants consistent with the discrete-time model. The lack of uniqueness also means that the transformation can be ill-conditioned or even singular. In particular, poles on the negative real axis, in the origin, or in the point 1, are likely to cause problems. Interpret the results with care.

Examples

Transform an identified model to continuous time and compare the frequency responses of the two models.

```
m = n4sid(data,3)
mc = d2c(m);
bode(m,mc,'sd',3)
```

Note that you can include the transformation to continuous time in the n4sid command by specifying the model to be continuous time.

```
mc = n4sid(data,3,'Ts',0)
```

nuderst

EstimationInfo

Purpose

Information about linear model estimation results

Syntax

```
m.EstimationInfo
m.es
m.es.DataLength, etc
```

Description

`EstimationInfo` for linear models is a structure whose fields give information about the results of model estimation. Depending on whether it is an estimated parametric `idmodel` or an estimated frequency response `idfrd`, `EstimationInfo` contains different fields.

Note For a description of nonlinear model `EstimationInfo` property, see the corresponding nonlinear model reference page.

---

idmodel Case

The model structure will contain the properties `ParameterVector`, `CovarianceMatrix`, and `NoiseVariance`, which are all calculated in the estimation process (see the reference page for `idmodel`). In addition, `EstimationInfo` contains the following fields:

- `Status`: Information whether the model has been estimated, or modified after being estimated.
- `Method`: Name of the estimation command that produced the model.
- `LossFcn`: Value of the identification criterion at the estimate. Normally equal to the determinant of the covariance matrix of the prediction errors, that is, the determinant of `NoiseVariance`. Note that the loss function for the minimization might be different due to `LimitError`. The value of the nonrobustified loss function is always stored in `LossFcn`.
- `FPE`: Akaike's Final Prediction Error, defined as `LossFcn *(1+d/N}/(1-d/N)`, where `d` is the number of estimated parameters and `N` is the length of the data record.

- `DataName`: Name of the data set from which the model was estimated. This is equal to the property `name` of the `iddata` object. If this was not defined, the name of the `iddata` variable is used.
- `DataLength`: Length of the data record.
- `DataTs`: Sampling interval of the data.
- `DataDomain`: `'Time'` or `'Frequency'`, depending on the data domain.
- `DataInterSample`: Intersample behavior of the data from which the model was estimated. This equals the property `InterSample` of the `iddata` object. (See `iddata`.)
- `WhyStop`: For models that have been estimated by iterative search. The stopping rule that caused the iterations to terminate. Assumes values such as`'MaxIter reached'`, `'No improvement possible along the search vector'`, or `'Near (local) minimum'`. The latter means that the expected improvement is less than `Tolerance` (see `Algorithm Properties`).
- `UpdateNorm`: Norm of the Gauss-Newton vector at the last iteration.
- `LastImprovement`: Relative improvement of the criterion value at the last iteration.
- `Iterations`: Number of iterations used in the search.
- `InitialState`: Option actually used when `Model.InitialState = 'auto'`.
- `N4Weight`: For `n4sid` estimates, or estimates that have been initialized by `n4sid`: the actual value of `N4Weight` used.
- `N4Horizon`: For `n4sid` estimates, or estimates that have been initialized by `n4sid`: the actual value of `N4Horizon` used. See `n4sid` and `Algorithm Properties`.

idfrd Case

If the `idfrd` model is obtained from an estimated parametric model,

```
g = idfrd(Model)
```

g.EstimationInfo is the same as Model.EstimationInfo as described above.

For an idfrd model that has been estimated from etfe, spa, or spafdr, EstimationInfo contains the following fields:

- Status: Whether the model is estimated or directly constructed.
- Method: etfe, spa, or spafdr
- WindowSize: Resolution parameter (or vector) used for the estimation
- DataName, DataLength, DataTs, DataDomain, DataInterSample: Properties of the estimation data as above.

See Also

Algorithm Properties

idpoly

idss

Purpose

Estimate empirical transfer functions and periodograms

Syntax

```
g = etfe(data)
g = etfe(data,M,N)
```

Description

`etfe` estimates the transfer function `g` as an `idfrd` object of the general linear model:

$$y(t) = G(q)u(t) + v(t)$$

`data` contains the output-input data and is an `iddata` object (time or frequency domain).

`g` is given as an `idfrd` object with the estimate of $G\left(e^{i\omega}\right)$ at the frequencies

```
w = [1:N]/N*pi/T
```

The default value of `N` is `128`.

In case `data` contains a time series (no input channels), `g` is returned as the periodogram of `y`.

When `M` is specified other than the default value `M = []`, a smoothing operation is performed on the raw spectral estimates. The effect of `M` is then similar to the effect of `M` in `spa`. This can be a useful alternative to `spa` for narrowband spectra and systems, which require large values of `M`.

When `etfe` is applied to time series, the corresponding spectral estimate is normalized in the way that is defined in "Spectrum Normalization". `etfe` normalization differs from the `spectrum` normalization in the Signal Processing Toolbox product.

If the (input) data is marked as periodic (`data.Period = integer`) and contains an even number of periods, the response is computed at the frequencies `k*2*pi/period` for `k = 0` up to the Nyquist frequency.

Examples

Compare an empirical transfer function estimate to a smoothed spectral estimate.

```
ge = etfe(z);
gs = spa(z);
bode(ge,gs)
```

Generate a periodic input, simulate a system with it, and compare the frequency response of the estimated model with the true system at the excited frequency points.

```
m = idpoly([1 -1.5 0.7],[0 1 0.5]);
u = iddata([],idinput([50,1,10],'sine'));
u.Period = 50;
y = sim(m,u);
me = etfe([y u])
bode(me,'b*',m)
```

Algorithm

The empirical transfer function estimate is computed as the ratio of the output Fourier transform to the input Fourier transform, using `fft`. The periodogram is computed as the normalized absolute square of the Fourier transform of the time series.

You obtain the smoothed versions (`M` less than the length of `z`) by applying a Hamming window to the output fast Fourier transform (FFT) times the conjugate of the input FFT, and to the absolute square of the input FFT, respectively, and subsequently forming the ratio of the results. The length of this Hamming window is equal to the number of data points in `z` divided by `M`, plus one.

evaluate

Purpose

Value of nonlinearity estimator at given input

Syntax

```
value = evaluate(nl,x)
```

Arguments

`nl`
: Nonlinearity estimator object.

`x`
: Value at which to evaluate the nonlinearity.

  If `nl` is a single nonlinearity estimator, then `x` is a `1`-by-`nx` row vector or an `nv`-by-`nx` matrix, where `nx` is the dimension of the regression vector input to `nl` (`size(nl)`) and `nv` is the number of points where `nl` is evaluated.

  If `nl` is an array of `ny` nonlinearity estimators, then `x` is a `1`-by-`ny` cell array of `nv`-by-`nx` matrices.

Description

`value = evaluate(nl,x)` computes the value of a nonlinear estimator object of type `customnet`, `deadzone`, `linear`, `neuralnet`, `pwlinear`, `saturation`, `sigmoidnet`, `treepartition`, or `wavenet`.

Example

The following syntax evaluates the nonlinearity of an estimated nonlinear ARX model `m`:

```
value = evaluate(m.Nonlinearity,x)
```

where `m.Nonlinearity` accesses the nonlinearity estimator of the nonlinear ARX model.

See Also

`idnlarx`

`idnlhw`

Purpose

Concatenate frequency-domain signals in data objects

Syntax

```
Mc = fcat(M1,M2,...Mn)
```

Description

`M1`, `M2`, etc., are all `idfrd` objects or `iddata` frequency-domain objects.

`Mc` is the corresponding object obtained by concatenation of the responses at all the frequencies in `Mk`.

Note that for `iddata` objects, this is the same as vertical concatenation (`vertcat`).

```
Mc = [M1;M2;..;Mn].
```

See Also

`fselect`

`iddata`

`idfrd`

Purpose

Identify possible feedback data

Syntax

```
[fbck,fbck0,nudir] = feedback(Data)
```

Description

`Data` is an `iddata` set with *Ny* outputs and *Nu* inputs.

`fbck` is an *Ny*-by-*Nu* matrix indicating the feedback. The *ky,ku* entry is a measure of feedback from output *ky* to input *ku*. The value is a probability *P* in percent. Its interpretation is that if the hypothesis that there is no feedback from output *ky* to input *ku* were tested at the level *P*, it would have been rejected. An intuitive but technically incorrect way of thinking about this is to see *P* as "the probability of feedback." Often only values above 90% are taken as indications of feedback. When `fbck` is calculated, direct dependence at lag zero between $u(t)$ and $y(t)$ is not regarded as a feedback effect.

`fbck0`: Same as `fbck`, but direct dependence at lag 0 between $u(t)$ and $y(t)$ is viewed as feedback effect.

`nudir`: A vector containing those input numbers that appear to have a direct effect on some outputs, that is, no delay from input to output.

`iddata`

`idmodel`

Purpose

Compute and plot frequency response magnitude and phase for linear frequencies

Syntax

```
ffplot(m)
ffplot(m,w)
ffplot(m('noise')
ffplot(m1,...,mN,'sd',sd,'mode','same','ap',ap,'fill')
[mag,phase,w] = ffplot(m)
[mag,phase,w,sdmag,sdphase] = ffplot(m)
```

Description

`ffplot(m)` plots a frequency response plot for the model `m`, which can be an `idpoly`, `idss`, `idarx`, `idgrey`, or `idfrd` object. This frequency response is a function of linear frequencies in units of inverse time (stored as the `TimeUnit` model property). The default frequency values are determined from the model dynamics. For time series spectra, phase plots are omitted. For MIMO models, press **Enter** to view the next plot in the sequence of different I/O channel pairs, annotated using the `InputNames` and `OuputNames` model properties.

`ffplot(m,w)` plots a frequency response plot at specified frequencies `w` in inverse time units, which can be:

- A vector of values.
- `{wmin,wmax}`, which specifies 100 linearly spaced frequency values ranging from a minimum value `wmin` and a maximum value `wmax`.
- `{wmin,wmax,np}`, which specifies `np` linearly spaced frequency values.

Note For `idfrd` models, you cannot specify individual frequencies and can only limit the frequencies range for the internally stored frequencies using `{wmin,wmax}`.

`ffplot(m('noise')` plots a frequency response plot of the output noise spectra when the model contains noise spectrum information.

`ffplot(m1,...,mN,'sd',sd,'mode','same','ap',ap,'fill')` plots a frequency response plot for several models. `sd` specifies the confidence region as a positive number that represents the number of standard deviations. The argument `'fill'` indicates that the confidence region is color filled. `mode = 'same'` displays all I/O channels in the same plot. Set `ap = 'A'` to show only amplitude plots, or `ap = 'P'` to show only phase plots.

`[mag,phase,w] = ffplot(m)` computes the magnitude `mag` and `phase` values of the frequency response, which are 3-D arrays with dimensions (number of outputs)-by-(number of inputs)-by-(length of w). `w` specifies the frequency values for computing the response even if you did not specify it as an input. For SISO systems, `mag(1,1,k)` and `phase(1,1,k)` are the magnitude and phase (in degrees) at the frequency w(k). For MIMO systems, `mag(i,j,k)` is the magnitude of the frequency response at frequency `w(k)` from input `j` to output `i`, and similarly for `phase(i,j,k)`. When `m` is a time series, `mag` is its power spectrum and `phase` is zero.

`[mag,phase,w,sdmag,sdphase] = ffplot(m)` computes the standard deviations of the magnitude `sdmag` and the phase `sdphase`. `sdmag` is an array of the same size as `mag`, and `sdphase` is an array of the same size as `phase`.

Purpose

Transform `iddata` object to frequency domain data

Syntax

```
Datf = fft(Data)
Datf = fft(Data,N)
Datf = fft(Data,N,'complex')
```

Description

If `Data` is a time-domain `iddata` object with real-valued signals and with constant sampling interval `Ts`, `Datf` is returned as a frequency-domain `iddata` object with the frequency values equally distributed from frequency 0 to the Nyquist frequency. Whether the Nyquist frequency actually is included or not depends on the signal length (even or odd). Note that the FFTs are normalized by dividing each transform by the square root of the signal length. That is in order to preserve the signal power and noise level.

In the default case, the length of the transformation is determined by the signal length. A second argument `N` will force FFT transformations of length `N`, padding with zeros if the signals in `Data` are shorter and truncating otherwise. Thus the number of frequencies in the real signal case will be `N/2` or `(N+1)/2`. If `Data` contains several experiments, `N` can be a row vector of corresponding length.

For real signals, the default is that `Datf` only contains nonnegative frequencies. For complex-valued signals, negative frequencies are also included. To enforce negative frequencies in the real case, add a last argument, `'Complex'`.

Purpose

Compute operating point for nonlinear ARX model

Syntax

```
[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)
[X,U] = findop(SYS,SPEC)
[X,U] = findop(SYS,'snapshot',T,UIN,X0)
[X,U,REPORT] = findop(...)
findop(SYS,...,PVPairs)
```

Description

`[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)` computes operating-point state values, `X`, and input values, `U`, from steady-state specifications for an `idnlarx` model. For more information about the states of an `idnlarx` model, see "Definition of idnlarx States" on page 2-189.

`[X,U] = findop(SYS,SPEC)` computes the equilibrium operating point using the specifications in the object `SPEC`. Whereas the previous command only lets you specify the input and output level, `SPEC` provides additional specification for computing the steady-state operating point.

`[X,U] = findop(SYS,'snapshot',T,UIN,X0)` computes the operating point at a simulation snapshot of time `T` using the specified input and initial state values.

`[X,U,REPORT] = findop(...)` creates a structure, `REPORT`, containing information about the algorithm for computing an operating point.

`findop(SYS,...,PVPairs)` specifies property-value pairs for setting algorithm options.

Input

- `SYS`: `idnlarx` (nonlinear ARX) model.
- `'steady'`: Computes operating point using steady-state input and output levels.
- `'snapshot'`: Computes operating point at simulating snapshot of model `SYS` at time `T`.
- `InputLevel`: Steady-state input level for computing operating point. Use `NaN` when the value is unknown.

- `OutputLevel`: Steady-state output level for computing the operating point. Use `NaN` when the value is unknown.
- `SPEC`: Operating point specifications object. Use `SPEC = OPERSPEC(SYS)` to construct the `SPEC` object for model `SYS`. Then, configure `SPEC` options, such as signal bounds, known values, and initial guesses. See `operspec(idnlarx)` for more information.
- `T`: Simulation snapshot time at which to compute the operating point.
- `UIN`: Input for simulating the model. `UIN` is a double matrix or an `iddata` object. The number of input channels in `UIN` must match the number of `SYS` inputs.
- `X0`: Initial states for model simulation.

  Default: Zero.
- `PVPairs`: Property-value pairs for customizing the model `Algorithm` property fields, such as `SearchMethod`, `MaxSize`, and `Tolerance`.

Output

- `X`: Operating point state values.
- `U`: Operating point input value.
- `REPORT`: Structure containing the following fields:
  - `SearchMethod`: String indicating the value of the `SearchMethod` property of `MODEL.Algorithm`.
  - `WhyStop`: String describing why the estimation stopped.
  - `Iterations`: Number of estimation iterations.
  - `FinalCost`: Final value of the sum of squared errors that the algorithm minimizes.
  - `FirstOrderOptimality`: Measure of the gradient of the search direction at the final parameter values when the search algorithm terminates. It is equal to the ∞-norm of the gradient vector.
  - `SignalLevels`: Structure containing fields `Input` and `Output`, which are the input and output signal levels of the operating point.

Algorithm

`findop` computes the operating point from steady-state operating point specifications or at a simulation snapshot.

Computing the Operating Point from Steady-State Specifications

You specify to compute the steady-state operating point by calling `findop` in either of the following ways:

```
[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)
[X,U] = findop(SYS,SPEC)
```

When you use the syntax `[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)`, the algorithm assumes the following operating-point specifications:

- All finite input values are fixed values. Any `NaN` values specify an unknown input signal with the initial guess of `0`.
- All finite output values are initial guess values. Any `NaN` values specify an unknown output signal with the initial guess of `0`.
- The minimum and maximum bounds have default values (-/+ `Inf`) for both `Input` and `Output` properties in the specification object.

Using the syntax `[X,U] = findop(SYS,SPEC)`, you can specify additional information, such as the minimum and maximum constraints on the input/output signals and whether certain inputs are known (fixed).

To compute the states, `X`, and the input, `U`, of the steady-state operating point, `findop` uses the algorithm specified in the `SearchMethod` property of `MODEL.Algorithm` to minimize the norm of the error $e(t) = y(t)-f(x(t), u(t))$, where f is the nonlinearity estimator, $x(t)$ are the model states, and $u(t)$ is the input.

The algorithm uses the following independent variables for minimization:

- Unknown (unspecified) inputs

- Output signals

Because the states of a nonlinear ARX (`idnlarx`) model are delayed samples of the input and output variables, the values of all the states are the constant values of the corresponding steady-state inputs and outputs. For more information about the definition of nonlinear ARX model states, see "Definition of idnlarx States" on page 2-189.

Computing the Operating Point at a Simulation Snapshot

When you use the syntax `[X,U] = findop(SYS,'snapshot',T,UIN,X0)`, the algorithm simulates the model output until the snapshot time, `T`. At the snapshot time, the algorithm passes the input and output samples to the `data2state` command to map these values to the current state vector.

Note For snapshot-based computations, `findop` does not perform numerical optimization.

Examples

In this example, you compute the operating point of an `idnlarx` model for a steady-state input level of 1.

1. Estimate an `idnlarx` model from sample data `iddata2`.

   ```
   load iddata2;
   M = nlarx(z2,[4 3 2],'wavenet');
   ```

2. Compute the steady-state operating point for an input level of 1.

   ```
   x0 = findop(M,'steady',1,NaN)
   ```

Purpose

Compute operating point for Hammerstein-Wiener model

Syntax

```
[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)
[X,U] = findop(SYS,SPEC)
[X,U] = findop(SYS,'snapshot',T,UIN,X0)
[X,U,REPORT] = findop(...)
findop(SYS,...,PVPairs)
```

Description

`[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)` computes operating-point state values, `X`, and input values, `U`, from steady-state specifications for an `idnlhw` model. For more information about the states of an `idnlhw` model, see "idnlhw States" on page 2-223.

`[X,U] = findop(SYS,SPEC)` computes the equilibrium operating point using the specifications in the object `SPEC`. Whereas the previous command only lets you specify the input and output level, `SPEC` provides additional specification for computing the steady-state operating point.

`[X,U] = findop(SYS,'snapshot',T,UIN,X0)` computes the operating point at a simulation snapshot of time `T` using the specified input and initial state values.

`[X,U,REPORT] = findop(...)` creates a structure, `REPORT`, containing information about the algorithm for computing an operating point.

`findop(SYS,...,PVPairs)` specifies property-value pairs for setting algorithm options.

Input

- `SYS`: `idnlhw` (Hammerstein-Wiener) model.
- `'steady'`: Computes operating point using steady-state input and output levels.
- `'snapshot'`: Computes operating point at simulating snapshot of model `SYS` at time `T`.
- `InputLevel`: Steady-state input level for computing operating point. Use `NaN` when the value is unknown. Do not enter `OutputLevel` when `InputLevel` does not contain any `NaN` values.

- `OutputLevel`: Steady-state output level for computing the operating point. Use `NaN` when the value is unknown.
- `SPEC`: Operating point specifications object. Use `SPEC = OPERSPEC(SYS)` to construct the `SPEC` object for model `SYS`. Then, configure `SPEC` options, such as signal bounds, known values, and initial guesses. See `operspec(idnlhw)` for more information.
- `T`: Simulation snapshot time at which to compute the operating point.
- `UIN`: Input for simulating the model. `UIN` is a double matrix or an `iddata` object. The number of input channels in `UIN` must match the number of `SYS` inputs.
- `X0`: Initial states for model simulation.

  Default: Zero.
- `PVPairs`: Property-value pairs for customizing the model `Algorithm` property fields, such as `SearchMethod`, `MaxSize`, and `Tolerance`.

Output

- `X`: Operating point state values.
- `U`: Operating point input value.
- `REPORT`: Structure containing the following fields:
  - `SearchMethod`: String indicating the value of the `SearchMethod` property of `MODEL.Algorithm`.
  - `WhyStop`: String describing why the estimation stopped.
  - `Iterations`: Number of estimation iterations.
  - `FinalCost`: Final value of the sum of squared errors that the algorithm minimizes.
  - `FirstOrderOptimality`: Measure of the gradient of the search direction at the final parameter values when the search algorithm terminates. It is equal to the ∞-norm of the gradient vector.
  - `SignalLevels`: Structure containing fields `Input` and `Output`, which are the input and output signal levels of the operating point.

Algorithm

`findop` computes the operating point from steady-state operating point specifications or at a simulation snapshot.

Computing the Operating Point from Steady-State Specifications

You specify to compute the steady-state operating point by calling `findop` in either of the following ways:

```
[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)
[X,U] = findop(SYS,SPEC)
```

When you use the syntax `[X,U] = findop(SYS,'steady',InputLevel,OutputLevel)`, the algorithm assumes the following operating-point specifications:

- All finite input values are fixed values. Any `NaN` values specify an unknown input signal with the initial guess of `0`.
- All finite output values are initial guess values. Any `NaN` values specify an unknown output signal with the initial guess of `0`.
- The minimum and maximum bounds have default values (-/+ `Inf`) for both `Input` and `Output` properties in the specification object.

Using the syntax `[X,U] = findop(SYS,SPEC)`, you can specify additional information, such as the minimum and maximum constraints on the input/output signals and whether certain inputs are known (fixed).

`findop` uses a different approach to compute the steady-state operating point depending on how much information you provide for this computation:

- When you specify values for all input levels (no `NaN` values). For a given input level, U, the equilibrium state values are X = inv(I-A)*B*$f(U)$, where `[A,B,C,D] = ssdata(model.LinearModel)`, and $f()$ is the input nonlinearity.

- When you specify known and unknown input levels. `findop` uses numerical optimization to minimize the norm of the error and compute the operating point. The total error is the union of contributions from e_1 and e_2 , $e(t) = (e_1(t)e_2(t))$, such that:
  - e_1 applies for known outputs and the algorithm minimizes $e_1 = y-g(L(x,f(u)))$, where f is the input nonlinearity, $L(x,u)$ is the linear model with states x, and g is the output nonlinearity.
  - e_2 applies for unknown outputs and the error is a measure of whether these outputs are within the specified minimum and maximum bounds. If a variable is within its specified bounds, the corresponding error is zero. Otherwise, the error is equal to the distance from the nearest bound. For example, if a free output variable has a value z and its minimum and maximum bounds are L and U, respectively, then the error is $e_2= \max[z-U, L-z, 0]$.

  The independent variables for the minimization problem are the unknown inputs. In the error definition e, both the input u and the states x are free variables. To get an error expression that contains only unknown inputs as free variables, the algorithm `findop` specifies the states as a function of inputs by imposing steady-state conditions: $x = \text{inv}(I\text{-A})^*\text{B}^*f(\text{U})$, where [A,B,C,D] are state-space parameters corresponding to the linear model $L(x,u)$. Thus, substituting $x = \text{inv}(I\text{-A})^*\text{B}^*f(\text{U})$ into the error function results in an error expression that contains only unknown inputs as free variables computed by the optimization algorithm.

Computing the Operating Point at a Simulation Snapshot

When you use the syntax `[X,U] = findop(SYS,'snapshot',T,UIN,X0)`, the algorithm simulates the model output until the snapshot time, `T`. At the snapshot time, the algorithm computes the inputs for the linear model block of the Hammerstein-Wiener model (`LinearModel` property of `the idnlhw` object) by transforming the given inputs using the input nonlinearity: $w = f(u)$. `findop` uses the resulting w to compute `x` until the snapshot time using the following equation: $x(\text{t+1}) = Ax(\text{t}) + Bw(\text{t})$, where `[A,B,C,D] = ssdata(model.LinearModel)`.

Note For snapshot-based computations, `findop` does not perform numerical optimization.

Examples

In this example, you compute the operating point of an `idnlhw` model for a steady-state input level of 1.

1. Estimate an `idnlhw` model from sample data `iddata2`.

```
load iddata2;
M = nlhw(z2,[4 3 2],'wavenet','pwl');
```

2. Compute the steady-state operating point for an input level of 1.

```
x0 =  findop(M,'steady',1,NaN)
```

`sim(idnlhw)`

findstates(idmodel)

Purpose

Estimate initial states of linear model from data

Syntax

```
X0 = findstates(MODEL,DATA)
X0 = findstates(MODEL,DATA,INIT)
```

Description

`X0 = findstates(MODEL,DATA)` estimates the initial states of `MODEL` that provide the best fit to output signal in `DATA`.

`X0 = findstates(MODEL,DATA,INIT)` specifies how the initial states should be estimated using the flag `INIT`.

Input

- `MODEL`: `idmodel` object. If `MODEL` is not in state-space form, initial states must be interpreted as state values corresponding to `idss(MODEL)`.
- `DATA`: `iddata` object with matching input/output dimensions.
- `INIT`: Flag indicating how the initial states should be estimated. This flag can have the following values:
  - `'e'`: (Default) Estimate initial state so that the norm of prediction error is minimized.
  - `'d'`: (Only available for discrete-time models) Same as `'e'`, but if `MODEL.InputDelay` is non-zero, these delays are first converted to explicit model delays, and the extra initial states (those corresponding to the delays) are also estimated and returned.

Output

- `X0`: Estimated initial state vector corresponding to time `DATA.TStart`. For multi-experiment data, `X0` is a matrix with as many columns as there are experiments.

Examples

In this example you estimate an `idpoly` model and simulate it such that the response of the estimated model matches the estimation data's output signal as closely as possible.

1 Load sample data.

```
load iddata1 % estimation data z1;
```

2 Estimate a linear model from the data.

```
model = arx(z1, [2 2 1]); % idpoly model
```

3 Estimate the value of the initial states to best fit the measured output `z1.y`.

```
x0est = findstates(model, z1);
```

4 Simulate the model.

```
sim(model, z1.u, 'init', x0est)
```

`sim`

findstates(idnlarx)

Purpose

Estimate initial states of nonlinear ARX model from data

Syntax

```
X0 = findstates(MODEL,DATA)
X0 = findstates(MODEL,DATA,X0INIT)
X0 = findstates(MODEL,DATA,X0INIT,PRED_OR_SIM)
X0 = findstates(MODEL,DATA,X0INIT,PRED_OR_SIM,PVPairs)
[X0, REPORT] = findstates(...)
```

Description

`X0 = findstates(MODEL,DATA)` estimates the initial states of an `idnlarx` model that minimize the error between the output measurements in `DATA` and the predicted output of the model. The states of an `idnlarx` model are defined as the delayed samples of input and output variables. For more information about the definition of states for `idnlarx` models, see “Definition of idnlarx States” on page 2-189.

`X0 = findstates(MODEL,DATA,X0INIT)` specifies an initial guess for estimating the initial states.

`X0 = findstates(MODEL,DATA,X0INIT,PRED_OR_SIM)` allows switching between prediction-error (default) and simulation-error minimization.

`X0 = findstates(MODEL,DATA,X0INIT,PRED_OR_SIM,PVPairs)` lets you specify the algorithm properties that control the numerical optimization process as property-value pairs.

`[X0, REPORT] = findstates(...)` creates a report to summarize results of numerical optimization that is performed to search for the model states.

Input

- `MODEL`: `idnlarx` model.
- `DATA`: `iddata` object from which to estimate the initial states of `MODEL`.
- `X0INIT`: Initial guess for value of `X0`. Must be a vector of length equal to the number of the states of `MODEL` (`sum(getDelayInfo(MODEL))`).
- `PRED_OR_SIM`: Specifies minimization criteria using one of the following values:

- `'prediction'`: (Default) Estimation of initial states by minimizing the difference between the measured output data and 1-step-ahead predicted response of the model.
- `'simulation'`: Estimation of initial states by minimizing the difference between the measured output and the simulated response of the model. This estimation algorithm can be slower than `'prediction'`.

- `PVPairs`: Property-value pairs that specify the algorithm properties that control numerical optimization process. By default, algorithm properties are read from the `Algorithm` property of `MODEL`. You can override `MODEL.Algorithm` properties using property-value pairs. For example you might set `SearchMethod`, `MaxSize`, `Tolerance`, and `Display`.

Output

- `X0`: Estimated initial state vector corresponding to time `DATA.TStart`. For multi-experiment data, `X0` is a matrix with as many columns as there are experiments.
- `REPORT`: Structure containing the following fields:
  - `'EstimationCriterion'`: String containing the minimization method used.
  - `'SearchMethod'`: String indicating the value of the `SearchMethod` property of `MODEL.Algorithm`.
  - `'WhyStop'`: String describing why the estimation was stopped.
  - `'Iterations'`: Number of iterations carried out during estimation.
  - `'FinalCost'`: The final value of the sum of squared errors that the search method attempts to minimize
  - `'FirstOrderOptimality'`: Measure of the gradient of the search direction at the final value of the parameter set when the search algorithm terminates. It is equal to the ∞-norm of the gradient vector.

Examples

Estimating Initial States

In this example, you use sample data z1 to create a nonlinear ARX model. You use findstates to compute the initial states of the model such that the difference between the predicted output of the model and the output data in z2 is minimized.

1 Load the sample data and create two data objects z1 and z2.

```
load twotankdata
% Create data objects z1 and z2.
z = iddata(y,u,0.2,'Name','Two tank system');
z1 = z(1:1000); z2 = z(1001:2000);
```

2 Estimate the idnlarx model.

```
% Estimate a nonlinear ARX model from data in z1.
mw1 = nlarx(z1,[5 1 3],wavenet('NumberOfUnits',8));
```

3 Estimate the initial states of the model.

```
% Find the initial states X0 of mw1 that minimize
% the error between the output data of z2 and the
% simulated output of mw1.
X0 = findstates(mw1,z2,[],'sim')
```

Estimating Initial States for Multiple-Experiment Data

In this example, you estimate the initial states for each data set in a multiple-experiment data object.

1 Create a multi-experiment data set from z1 and z2:

```
% Create a multi-experiment data set.
zm = merge(z1,z2);
```

2 Estimate the initial states for each experiment in the data set, such that the one-step-ahead prediction error is minimized for each data set.

```
% Estimate initial states for each data set in zm.
X0 = findstates(mw1,zm)
```

findstates(idmodel)

findstates(idnlhw)

Purpose

Estimate initial states of nonlinear grey-box model from data

Syntax

```
X0 = findstates(NLSYS,DATA);
[X0,ESTINFO] = findstates(NLSYS,DATA);
[X0,ESTINFO] = findstates(NLSYS,DATA,X0INIT);
```

Description

`X0 = findstates(NLSYS,DATA);` estimates the initial states of an `idnlgrey` model from given data. For more information about the states of `idnlgrey` models, see "Definition of idnlgrey States" on page 2-209.

`[X0,ESTINFO] = findstates(NLSYS,DATA);` returns basic information about the estimation.

`[X0,ESTINFO] = findstates(NLSYS,DATA,X0INIT);` specifies an initial guess for `X0`.

Input

- `NLSYS`: `idnlgrey` model whose output is to be predicted.
- `DATA`: Input/output data `DATA = [Y U]`, where `U` and `Y` are the following:
  - `U`: Input data that can be given either as an `iddata` object or as a matrix `U = [U1 U2 ...Um]`, where the kth column vector is input `Uk`
  - `Y`: Either an `iddata` object or a matrix of outputs (with as many columns as there are outputs).

Note For time-continuous `idnlgrey` models, `DATA` passed as a matrix will cause the data sample interval Ts to be assumed to be equal to 1.

- `X0INIT`: Initial state strategy to use:
  - `'zero'`: Use zero initial state and estimate all states (`NLSYS.InitialStates.Fixed` is thus ignored). Notice that all states are estimated, whereas they are fixed in `predict`.

- 'estimate': NLSYS.InitialStates determines the values of the states, but all initial states are estimated (NLSYS.InitialStates.Fixed is thus ignored).
- 'model': (Default) NLSYS.InitialStates determines the values of the initial states, which initial states to estimate, as well as their maximum and minimum values.
- vector/matrix: Column vector of appropriate length to be used as an initial guess for initial states. For multiple experiment DATA, X0INIT may be a matrix whose columns give different initial states for each experiment. With this option, all initial states are estimated (and not fixed as in predict) (NLSYS.InitialStates.Fixed is thus ignored).
- struct array: Nx-by-1 structure array with fields:
  - Name: Name of the state (a string).
  - Unit: Unit of the state (a string).
  - Value: Value of the states (a finite real 1-by-Ne vector, where Ne is the number of experiments).
  - Minimum: Minimum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same minimum value).
  - Maximum: Maximum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same maximum value).
  - Fixed: Boolean 1-by-Ne vector, or a scalar Boolean (applicable for all states) specifying whether the initial state is fixed or not.

Output

- X0: Matrix containing the initial states. In the single experiment case it is a column vector of length Nx. For multi-experiment data, X0 is a matrix with as many columns as there are experiments.
- ESTINFO: Structure or Ne-by-1 structure array containing basic information about the estimation result (some of the fields normally stored in NLSYS.EstimationInfo). For multi-experiment data,

ESTINFO is an Ne-by-1 structure array with elements providing initial state estimation information related to each experiment.

Examples

Estimating Individual Initial States Selectively

In this example you estimate the initial states of a model selectively, fixing the first state and allowing the second state of the model to be estimated. First you create a model from sample data and set the Fixed property of the model such that the second state is free and the first is fixed.

1 Specify the file describing the model structure, the model orders, and model parameters.

```
% Specify the file describing the model structure:
FileName = 'dcmotor_m';
% Specify the model orders [ny nu nx]
Order = [2 1 2];
% Specify the model parameters
% (see idnlgreydemo1 for more information)
Parameters = [0.24365; 0.24964];
```

2 Estimate the model parameters and set the model properties:

```
nlgr = idnlgrey(FileName, Order, Parameters);
set(nlgr, 'InputName', 'Voltage','OutputName', ...
  {'Angular position', 'Angular velocity'});
```

3 Free the second state while keeping the first one fixed.

```
setinit(nlgr,'Fixed',{1 0});
```

4 Load the estimation data.

```
load(fullfile(matlabroot,'toolbox','ident',...
     'iddemos','data','dcmotordata'));
z = iddata(y,u,0.1,'Name','DC-motor',...
     'InputName', 'Voltage', 'OutputName',...
     {'Angular position','Angular velocity'});
```

5. Estimate the free states of the model.

   ```
   [X0,EstInfo] = findstates(nlgr,z)
   ```

Estimating Initial States Starting from States Stored in Model

This example shows how you can estimate all of the initial states, starting from the initial state 0, then from the initial states stored in the model nlgr, and finally using a numerical initial states vector as the initial guess.

1. Estimate all the initial states starting from 0.

   ```
   X0 = findstates(nlgr,z,'zero');
   ```

2. Estimate the free initial states specified by nlgr, starting from the initial state stored in nlgr.

   ```
   X0 = findstates(nlgr, z, 'mod');
   ```

3. Estimate all the initial states, starting from an initial state vector that you specify.

   ```
   nlgr.Algorithm.Display = 'full';

   % Starting from an initial state vector [10;10]
   X0 = findstates(nlgr,z,[10;10])
   ```

Advanced Use of findstates(idnlgrey)

The following example shows advanced use of findstates. Here you estimate states for multi-experiment data, such that the states of model nlgr are estimated separately for each experiment. After creating a 3-experiment data set z3, you estimate individual initial states separately.

1. Create a three-experiment data set.

```
z3 = merge(z, z, z); % 3-experiment data
```

2 Fix some initial states and only estimate the free initial states starting of with the initial state in `nlgr`. This means that both elements of state vector 1 will be estimated, that no state of the second state vector will be estimated, and that only the first state of state vector 3 is estimated.

```
% prepare model for 3-experiment data
nlgr = pem(z3, nlgr, 'Display', 'off');
```

3 Specify which initial states to fix, and set the `Display` property of `Algorithm` to `'full'`.

```
nlgr.InitialStates(1).Fixed = [true false true];
nlgr.InitialStates(2).Fixed = [true false false];
nlgr.Algorithm.Display = 'full';
```

4 Estimate the initial states and obtain information about the estimation.

```
[X0, EstInfo] = findstates(nlgr, z3);
```

`predict`

`sim`

Purpose

Estimate initial states of nonlinear Hammerstein-Wiener model from data

Syntax

```
X0 = findstates(MODEL,DATA)
X0 = findstates(MODEL,DATA,X0INIT)
X0 = findstates(MODEL,DATA,X0INIT,PVPairs)
[X0, REPORT] = findstates(...)
```

Description

`X0 = findstates(MODEL,DATA)` estimates the initial states of an `idnlhw` model from given data. The states of an `idnlhw` model are defined as the states of its embedded linear model (`Model.LinearModel`). For more information about the states of `idnlhw` models, see "idnlhw States" on page 2-223.

`X0 = findstates(MODEL,DATA,X0INIT)` specifies an initial guess for value of `X0` using `X0INIT`.

`X0 = findstates(MODEL,DATA,X0INIT,PVPairs)` specifies property-value pairs representing the algorithm properties that control the numerical optimization process.

`[X0, REPORT] = findstates(...)` creates a report to summarize results of numerical optimization that is performed to search for the model states.

Input

- `MODEL`: `idnlhw` model.
- `DATA`: `iddata` object from which to estimate the initial states of `MODEL`.
- `X0INIT`: Initial guess for value of `X0`. Must be a vector of length equal to the number of the states of `MODEL`.
- `PVPairs`: Property-value pairs that specify the algorithm properties that control numerical optimization process. By default, algorithm properties are read from the `Algorithm` property of `MODEL`. You can override `MODEL.Algorithm` properties using property-value pairs. For example you might set `SearchMethod`, `MaxSize`, `Tolerance`, and `Display`.

Output

- X0: Estimated initial state vector corresponding to time DATA.TStart. For multi-experiment data, X0 is a matrix with as many columns as there are experiments.
- REPORT: Structure containing the following fields:
  - 'EstimationCriterion': String containing the minimization method used.
  - 'SearchMethod': String indicating the value of the SearchMethod property of MODEL.Algorithm.
  - 'WhyStop': String describing why the estimation was stopped.
  - 'Iterations': Number of iterations carried out during estimation.
  - 'FinalCost': The final value of the sum of squared errors that the search method attempts to minimize
  - 'FirstOrderOptimality': Measure of the gradient of the search direction at the final value of the parameter set when the search algorithm terminates. It is equal to the ∞-norm of the gradient vector.

Examples

In this example, you create an idnlarx model from sample data and estimate initial states using another data set. Next you jointly estimate the states for separate data sets contained in multi-experiment data.

1. Load the data and create iddata objects z1 and z2.

```
load twotankdata

z = iddata(y, u, 0.2,'Name','Two tank system');
z1 = z(1:1000); z2 = z(1001:2000);
```

2. Estimate an idnlhw model from data.

```
m1=nlhw(z1,[4 2 1], 'unitgain' , 'pwlinear')
```

3. Estimate the initial states of m1 using data z2.

```
% Estimate initial states. View estimation trace and use
% only 5 iterations in the search algorithm
X0 = findstates(m1,z2,[],'MaxIter',5,'Display','on')
```

4. Estimate states using multiple-experiment data. There are separate sets of initial states for each experiment. The states of all data experiments are jointly estimated, and X0 is returned as a matrix with as many columns as there are data experiments.

```
zm = merge(z1,z2);
X0 = findstates(m1, zm)
```

`findstates(idmodel)`

`findop(idnlhw)`

Purpose

Convert idfrd objects to Control System Toolbox frequency-response LTI model

Syntax

```
sys = frd(mod)
```

Description

mod is an idfrd object. sys is returned as an frd object.

The fields Frequency, ResponseData, Units, Ts, InputDelay, InputName, OutputName and Notes in mod are transferred to sys. The remaining fields (SpectrumData, CovarianceData and NoiseCovariance) are ignored. The command, therefore, cannot be applied to a time-series idfrd model object.

ss

tf

zpk

Purpose

Frequency response data from linear models

Alternative

`idfrd` computes the same information as `freqresp` and stores it in the `idfrd` model object.

Syntax

```
H = freqresp(m)
[H,w,covH] = freqresp(m,w)
```

Description

`H = freqresp(m)` returns the frequency response `H` of the model `m` at default frequencies determined from the dynamics of the model. For `idmodel` models, computes the frequency response of the model. For `idfrd` models, extracts the frequency data from the model object. If `m` contains nonzero delays (stored as `m.InputDelay`), these delays are absorbed into the returned frequency response.

`[H,w,covH] = freqresp(m,w)` returns the frequency response `H` of the model `m`

at frequencies `w`. For `idfrd` models with input channels, the frequency response is `H = m.ResponseData` and the covariance of the response is `covH = m.CovarianceData`. For time-series `idfrd` models (power spectra), the frequency response is `H = m.SpectrumData` and the covariance of the response is `covH = m.NoiseCovariance`.

Tip For a SISO model, use `H(:)` to obtain a vector of the frequency response. If models containing input channels, you can get the spectrum information of the noise (output disturbance) signal using `freqresp(m('n'))`.

Inputs

`m`

Name of the `idmodel` or `idfrd` model object.

`w`

Frequencies for computing the frequency response, specified as a vector of real values in rad/s.

Note If you do not specify `w`, `freqresp` returns the frequency response at default frequencies determined from the dynamics of the model.

Outputs

`H`

Frequency response data of the model.

If `m` has `ny` outputs and `nu` inputs, and `w` contains `Nw` frequencies, the output `H` is an `ny`-by-`nu`-by-`Nw` array such that `H(:,:,k)` is a complex-valued response at frequency `w(k)`.

`w`

Frequencies of the response, returned as a vector of real values in rad/s.

`covH`

For a model with input channels, covariance of the response of a model that is a 5-D array. `covH(ky,ku,k,:,:)` is the 2-by-2 covariance matrix of the response from the input `ku` to the output `ky` at frequency `w(k)`. The (1,1) element is the variance of the real part, the (2,2) element is the variance of the imaginary part, and the (1,2) and (2,1) elements are the covariance between the real and imaginary parts.

Tip `squeeze(covH(ky,ku,k,:,:))` returns the covariance matrix of the corresponding response.

For a time-series model (no input channels), `H` is an `ny`-by-`ny`-by-`Nw` array of the power spectrum of the outputs. Thus, `H(:,:,k)` is the spectrum matrix at frequency `w(k)`. The element `H(k1,k2,k)` is the cross spectrum between outputs `k1` and `k2` at frequency `w(k)`. When `k1 = k2`, this is the real-valued power spectrum of output `k1`.

`covH` is then the covariance of the estimated spectrum `H` such that `covH(k1,k1,k)` is the variance of the power spectrum estimate of output `k1` at frequency `w(k)`. No information about the variance of the cross spectra is given; that is, `covH(k1,k2,k) = 0` for `k1` not equal to `k2`.

Purpose

Akaike Final Prediction Error for estimated model

Syntax

```
fp = fpe(Model1,Model2,Model3,...)
```

Description

`Model` is the name of an `idarx`, `idgrey`, `idpoly`, `idproc`, `idss`, `idnlarx`, `idnlhw`, or `idnlgrey` model object.

`fp` is returned as a row vector containing the values of the Akaike Final Prediction Error (FPE) for the different models.

Definition

Akaike's Final Prediction Error (FPE) criterion provides a measure of model quality by simulating the situation where the model is tested on a different data set. After computing several different models, you can compare them using this criterion. According to Akaike's theory, the most accurate model has the smallest FPE.

Note If you use the same data set for both model estimation and validation, the fit always improves as you increase the model order and, therefore, the flexibility of the model structure.

Akaike's Final Prediction Error (FPE) is defined by the following equation:

$$FPE = V\left(\frac{1 + d/N}{1 - d/N}\right)$$

where V is the loss function, d is the number of estimated parameters, and N is the number of values in the estimation data set.

The toolbox assumes that the final prediction error is asymptotic for $d \ll N$ and uses the following approximation to compute FPE:

$$FPE = V\left(1 + 2d/N\right)$$

The loss function V is defined by the following equation:

$$V = \det\left(\frac{1}{N}\sum_{1}^{N}\varepsilon\left(t,\theta_N\right)\left(\varepsilon\left(t,\theta_N\right)\right)^T\right)$$

where θ_N represents the estimated parameters.

`EstimationInfo`

`aic`

Purpose

Frequencies from frequency response data

Syntax

```
idfm = fselect(idf,index)
idfm = fselect(idf,Fmin,Fmax)
```

Description

`idf` is any `idfrd` object. `index` is a row vector of frequency indices, so that `idfm` is the `idfrd` object that contains the response at frequencies `idf.Frequency(Index)`.

If `Fmin` and `Fmax` are specified, `idfm` contains responses at frequencies between `Fmin` and `Fmax`.

Note that the operation is the same as `dat(index)` for an `iddata` object.

Examples

Select every fifth frequency:

```
idfm = fselect(idf,5:5:100)
```

Select the response in the third quadrant:

```
ph = angle(squeeze(idf.response));
idfm = fselect(idf,find(ph>-pi & ph <-pi/2))
```

See Also

`fcat`

`iddata`

`idfrd`

Purpose

Query properties of data and model objects

Syntax

```
Value = get(m,'PropertyName')
get(m)
Struct = get(m)
```

Description

`value = get(m,'PropertyName')` returns the current value of the property `PropertyName` of the `iddata` object or `idfrd` object, or `idmodel` object (`idgrey`, `idarx`, `idpoly`, `idss`), or `idnlgrey`, `idnlarx`, or `idnlhw` model object.

The string `'PropertyName'` can be the full property name (for example, `'SSParameterization'`) or any unambiguous case-insensitive abbreviation (for example, `'ss'`).

`Struct = get(m)` converts the object `m` into a standard MATLAB structure with the property names as field names and the property values as field values.

Without an output argument

```
get(m)
```

displays all properties of `m` and their values.

Remarks

An alternative to the syntax

```
Value = get(m,'PropertyName')
```

is the structure-like referencing

```
Value = m.PropertyName
```

idpoly

idproc

idss

Purpose

Get input/output delay information for `idnlarx` model structure

Syntax

```
DELAYS = getDelayInfo(MODEL)
DELAYS = getDelayInfo(MODEL,TYPE)
```

Description

`DELAYS = getDelayInfo(MODEL)` obtains the maximum delay in each input and output variable of an `idnlarx` model.

`DELAYS = getDelayInfo(MODEL,TYPE)` lets you choose between obtaining maximum delays across all input and output variables or maximum delays for each output variable individually. When delays are obtained for each output variable individually a matrix is returned, where each row is a vector containing n_y+n_u maximum delays for each output variable, and:

- n_y is the number of outputs of `MODEL`.
- n_u is the number of inputs of `MODEL`.

Delay information is useful for determining the number of states in the model. For nonlinear ARX models, the states are related to the set of delayed input and output variables that define the model structure (regressors). For example, if an input or output variable p has a maximum delay of D samples, then it contributes D elements to the state vector:

$p(t\text{-}1)$, $p(t\text{-}2)$, ...$p(t\text{-}D)$

The number of states of a nonlinear ARX model equals the sum of the maximum delays of each input and output variable. For more information about the definition of states for `idnlarx` models, see “Definition of idnlarx States” on page 2-189

Input

`getDelayInfo` accepts the following arguments:

- `MODEL`: `idnlarx` model.

- `TYPE`: (Optional) Specifies whether to obtain channel delays `'channelwise'` or `'all'` as follows:
  - `'all'`: Default value. `DELAYS` contains the maximum delays across each output (vector of n_y+n_u entries, where `[ny, nu] = size(MODEL)`).
  - `'channelwise'`: `DELAYS` contains delay values separated for each output (n_y-by-(n_y+n_u) matrix).

Output

- `DELAYS`: Contains delay information in a vector of length n_y+n_u arranged with output channels preceding the input channels, i.e., `[y1, y2,.., u1, u2,..]`.

Examples

In the following example you create a 2-output, 3-input nonlinear ARX model, then verify the number of delays using `getDelayInfo`.

1 Create an `idnlarx` model.

```
M = idnlarx([2 0 2 2 1 1 0 0; 1 0 1 5 0 1 1 0],...
            'linear');
```

2 Compute the maximum delays for each output variable individually.

```
Del = getDelayInfo(M,'channelwise')

Del =

     2     0     2     1     0
     1     0     1     5     0
```

The matrix `Del` contains the maximum delays for the first and second output of the model `M`. You can interpret the contents of matrix `Del` as follows:

- In the dynamics for the output 1 (y_1) of model `M`, the maximum delays for each input/output channel are as follows: y_1: 2, y_2: 0, u_1: 2, u_2: 1, u_3:0.

- Similarly, in the dynamics for the output 2 (y_2) of the model, the maximum delays in channels y_1, y_2, u_1, u_2, u_3 are 1, 0, 1, 5, and 0 respectively.

You can find the maximum delays for all the input and output variables in the order (y_1, y_2, u_1, u_2, u_3) by executing the command

```
Del=getDelayInfo(M, 'all')
```

which returns

```
Del =

     2     0     2     5     0
```

Note The maximum delay across all output equations can be obtained by executing `MaxDel = max(Del,[],1)`. Since input u_2 has 5 delays (the 4th entry in `Del`, there are 5 terms corresponding to u_5 in the state vector (($u_5(t\text{-}1)$, ...$u_5(t\text{-}5)$. Applying this definition to all I/O channels, the complete state vector for model `M` becomes:

$X(t)$ = [$y_1(t\text{-}1)$, $y_1(t\text{-}2)$, $u_1(t\text{-}1)$, $u_1(t\text{-}2)$, $u_2(t\text{-}1)$, $u_2(t\text{-}2)$, $u_2(t\text{-}3)$, $u_2(t\text{-}4)$, $u_2(t\text{-}5)$]

`idnlarx`

getexp

Purpose

Specific experiments from multiple-experiment data set

Syntax

```
d1 = getexp(data,ExperimentNumber)
d1 = getexp(data,ExperimentName)
```

Description

`data` is an `iddata` object that contains several experiments. `d1` is another `iddata` object containing the indicated experiment(s). The reference can either be by `ExperimentNumber`, as in `d1 = getexp(data,3)` or `d1 = getexp(data,[4 2])`; or by `ExperimentName`, as in `d1 = getexp(data,'Period1')` or `d1 = getexp(data,{'Day1','Day3'})`.

See `merge (iddata)` and `iddata` for how to create multiple-experiment data objects.

You can also retrieve the experiments using a fourth subscript, as in `d1 = data(:,:,:,ExperimentNumber)`. Type `help iddata/subsref` for details on this.

Purpose

Values of `idnlgrey` model initial states

Syntax

```
getinit(model)
getinit(model,prop)
```

Arguments

`model`
: Name of the `idnlgrey` model object.

`Property`
: Name of the `InitialStates` model property field, such as `'Name'`, `'Unit'`, `'Value'`, `'Minimum'`, `'Maximum'`, and `'Fixed'`.

  Default: `'Value'`.

Description

`getinit(model)` gets the initial-state values in the `'Value'` field of the `InitialStates` model property.

`getinit(model,prop)` gets the initial-state values of the `prop` field of the `InitialStates` model property. `prop` can be `'Name'`, `'Unit'`, `'Value'`, `'Minimum'`, `'Maximum'`, and `'Fixed'`.

The returned values are an `Nx`-by-1 cell array of values, where `Nx` is the number of states.

See Also

`setinit`

`setpar`

Purpose

Parameter values and properties of `idnlgrey` model parameters

Syntax

```
getpar(model)
getpar(model,prop)
```

Arguments

`model`
: Name of the `idnlgrey` model object.

`Property`
: Name of the `Parameters` model property field, such as `'Name'`, `'Unit'`, `'Value'`, `'Minimum'`, `'Maximum'`, or `'Fixed'`.

  Default: `'Value'`.

Description

`getpar(model)` gets the model parameter values in the `'Value'` field of the `Parameters` model property.

`getpar(model,prop)` gets the model parameter values in the `prop` field of the `Parameters` model property. `prop` can be `'Name'`, `'Unit'`, `'Value'`, `'Minimum'`, and `'Maximum'`.

The returned values are an `Np`-by-1 cell array of values, where `Np` is the number of parameters.

`getinit`

`idnlgrey`

`setinit`

`setpar`

Purpose

Regressor expressions and numerical values in nonlinear ARX model

Syntax

```
Rs = getreg(model)
Rs = getreg(model,subset)
Rm = getreg(model,subset,data)
Rm = getreg(model,subset,data,init)
```

Description

`Rs = getreg(model)` returns expressions for computing regressors in the nonlinear ARX model. `Rs` is a cell array of strings. `model` is an `idnlarx` object.

`Rs = getreg(model,subset)` returns regressor expressions for a specified subset of regressors. `subset` is a string.

`Rm = getreg(model,subset,data)` returns regressor values as a matrix for a specified subset of regressors.

`Rm = getreg(model,subset,data,init)` returns regressor values as matrices for a specified subset of regressors. The first `N` rows of each regressor matrix depend on the initial states `init`, where `N` is the maximum delay in the regressors (see `getDelayInfo`). For multiple-output models, `Rm` is a cell array of cell arrays.

Inputs

`data`

`iddata` object containing measured data.

`init`

Initial conditions of your data:

- `'z'` (default) specifies zero initial state.
- Real column vector containing the initial state values. input and output data values at a time instant before the first sample in `data`. To create the initial state vector from the input-output data, use the `data2state` method of the `idnlarx` class. For multiple-experiment data, this is a matrix where each column specifies the initial state of the model corresponding to that experiment.

- `iddata` object containing input and output samples at time instants before to the first sample in `data`. When the `iddata` object contains more samples than the maximum delay in the model, only the most recent samples are used. The minimum number of samples required is equal to `max(getDelayInfo(model))`.

`model`
: `iddata` object representing nonlinear ARX model.

`subset`
: String that represents a subset of all regressors:

- (Default) `'all'` — All regressors.
- `'custom'`—Only custom regressors.
- `'input'`—Only standard regressors computed from input data.
- `'linear'`—Only regressors not used in the nonlinear block.
- `'nonlinear'`—Only regressors used in the nonlinear block.

Note You can use `'nl'` as an abbreviation of `'nonlinear'`.

- `'output'`—Only regressors computed from output data.
- `'standard'`—Only standard regressors (excluding any custom regressors).

Outputs

`Rm`
: Matrix of regressor values for all or a specified subset of regressors. Each matrix in `Rm` contains as many rows as there are data samples. For a model with `ny` outputs, `Rm` is an `ny`-by-1 cell array of matrices. When `data` contains multiple experiments, `Rm` is a cell array where each element corresponds to a matrix of regressor values for an experiment.

`Rs`

Regressor expressions represented as a cell array of strings. For a model with `ny` outputs, `Rs` is an `ny`-by-1 cell array of cell arrays of strings. For example, the expression `'u1(t-2)'` computes the regressor by delaying the input signal `u1` by two time samples. Similarly, the expression `'y2(t-1)'` computes the regressor by delaying the output signal `y2` by one time sample.

The order of regressors in `Rs` corresponds to regressor indices in the `idnlarx` object property `model.NonlinearRegressors`.

Examples

Get regressor expressions and values, and evaluate the predicted model output:

```
% Load sample data u and y:
  load twotankdata;
  Ts = 0.2; % Sampling interval is 0.2 min
% Create data object:
  z = iddata(y,u,Ts);
% Use first 1000 samples for estimation:
  ze = z(1:1000);
% Estimate nonlinear ARX model
  model = nlarx(ze,[3 2 1]);
% Get regressor expressions:
  Rs = getreg(model)
% Get regressor values:
  Rm = getreg(model,'all',ze)
% Evaluate model output for one-step-prediction:
  Y = evaluate(model.Nonlinearity,Rm)
% The previous result is equivalent to:
  Y_p = predict(model,ze,1,'z')
```

How To

- “Identifying Nonlinear ARX Models”

getTrend

Purpose

Data offset and trend information

Syntax

```
T = getTrend(data)
T = getTrend(data,0)
T = getTrend(data,1)
```

Description

`T = getTrend(data)` constructs a `TrendInfo` object to store offset, mean, or linear trend information for detrending or retrending data. You can assign specific offset and slope values to `T`.

`T = getTrend(data,0)` computes the means of input and output signals and stores them as `InputOffset` and `OutputOffset` properties of `T`, respectively.

`T = getTrend(data,1)` computes a best-fit straight line for both input and output signals and stores them as properties of `T`.

Examples

Compute input-output signal means, store them, and detrend the data:

```
% Load SISO data containing vectors u2 and y2
load dryer2
% Create data object with sampling time of 0.08 sec
data=iddata(y2,u2,0.08)
% Plot data on a time plot - it has a nonzero mean
plot(data)
% Compute the mean of the data
T = getTrend(data,0)
% Remove the mean from the data
data_d = detrend(data,T)
% Plot detrended data on the same plot
hold on
plot(data_d)
```

Remove a specific offset from input and output data signals:

```
% Load SISO data containing vectors u2 and y2
load dryer2
% Create data object with sampling time of 0.08 sec
```

```
data=iddata(y2,u2,0.08)
plot(data)
% Create a TrendInfo object for storing offsets and trends
T = getTrend(data)
% Assign offset values to the TrendInfo object
T.InputOffset=5;
T.OutputOffset=5;
% Subtract specific offset from the data
data_d = detrend(data,T)
% Plot detrended data on the same plot
hold on
plot(data_d)
```

See Also

`detrend`

`retrend`

`TrendInfo`

"Handling Offsets and Trends in Data"

Purpose

Multiple-output ARX polynomials, impulse response, or step response model

Syntax

```
m = idarx(A,B,Ts)
m = idarx(A,B,Ts,'Property1',Value1,...,,'PropertyN',ValueN)
```

Description

`idarx` creates an object containing parameters that describe the general multiple-input, multiple-output model structure of ARX type.

$$y(t) + A_1 y(t-1) + A_2 y(t-2) + \ldots + A_{na} y(t-na) =$$
$$B_0 u(t) + B_1 u(t-1) + \ldots + B_{nb} u(t-nb) + e(t)$$

Here A_k and B_k are matrices of dimensions *ny*-by-*ny* and *ny*-by-*nu*, respectively. (*ny* is the number of outputs, that is, the dimension of the vector $y(t)$, and *nu* is the number of inputs.)

The arguments `A` and `B` are 3-D arrays that contain the `A` matrices and the `B` matrices of the model in the following way.

`A` is an `ny`-by-`ny`-by-`(na+1)` array such that:

```
A(:,:,k+1) = Ak
A(:,:,1) = eye(ny)
```

Similarly `B` is an `ny`-by-`nu`-by-`(nb+1)` array with:

```
B(:,:,k+1) = Bk
```

Note that `A` always starts with the identity matrix, and that delays in the model are defined by setting the corresponding leading entries in `B` to zero. For a multivariate time series, take `B = []`.

The optional property `NoiseVariance` sets the covariance matrix of the driving noise source $e(t)$ in the model above. The default value is the identity matrix.

The argument `Ts` is the sampling interval. Note that continuous-time models (`Ts` = 0) are not supported.

The use of `idarx` is twofold. You can use it to create models that are simulated (using `sim`) or analyzed (using `bode`, `pzmap`, etc.). You can also use it to define initial value models that are further adjusted to data (using `arx`). The free parameters in the structure are consistent with the structure of `A` and `B`; that is, leading zeros in the rows of `B` are regarded as fixed delays, and trailing zeros in `A` and `B` are regarded as a definition of lower-order polynomials. These zeros are fixed, while all other parameters are free.

For a model with one output, ARX models can be described both as `idarx` and `idpoly` models. The internal representation is different, however.

idarx Properties

- `A`, `B`: The `A` and `B` polynomials as 3-D arrays, described above.
- `dA`, `dB`: The standard deviations of `A` and `B`. Same format as `A` and `B`. Cannot be set.
- `na`, `nb`, `nk`: The orders and delays of the model. `na` is an `ny`-by-`ny` matrix whose *i-j* entry is the order of the polynomial corresponding to the *i-j* entry of `A`. Similarly `nb` is an `ny`-by-`nu` matrix with the orders of `B`. `nk` is also an `ny`-by-`nu` matrix, whose *i-j* entry is the delay from input *j* to output *i*, that is, the number of leading zeros in the *i-j* entry of `B`.
- `InitialState`: This describes how the initial state (initial values in filtering, etc.) should be handled. For time-domain applications, this is typically handled by starting the filtering when all data are available. For frequency-domain data, you must estimate initial states. The possible values of `InitialState` are `'zero'`, `'estimate'`, and `'auto'` (which makes a data-dependent choice between zero and estimate).

In addition to these properties, `idarx` objects also have all the properties of the `idmodel` object. See `idmodel`, `Algorithm Properties`, and `EstimationInfo`.

Note that you can set and retrieve all properties either with the `set` and `get` commands or by subscripts. Autofill applies to all properties and values, and they are case insensitive.

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`. See also `idprops idarx`.

idarx Definition of States

The states of an `idarx` model are defined as those corresponding to the model obtained by converting them to the state-space format using the `idss` command. For example, if you have an `idarx` model defined by `m1 = idarx(A,B,1)`, then the initial states of this model correspond to those of `m2 = idss(m1)`. The concept of states is useful for functions such as `sim`, `predict`, `compare` and `findstates`.

Examples

Simulate a second-order ARX model with one input and two outputs, and then estimate a model using the simulated data.

```
A = zeros(2,2,3);
B = zeros(2,1,3)
A(:,:,1) =eye(2);
A(:,:,2) = [-1.5 0.1;-0.2 1.5];
A(:,:,3) = [0.7 -0.3;0.1 0.7];
B(:,:,2) = [1;-1];
B(:,:,3) = [0.5;1.2];
m0 = idarx(A,B,1);
u = iddata([],idinput(300));
e = iddata([],randn(300,2));
y = sim(m0,[u e]);
m = arx([y u],[[2 2;2 2],[2;2],[1;1]]);
```

How To

- "Using Linear Model for Nonlinear ARX Estimation"

Purpose

Time- or frequency-domain data

Syntax

```
data = iddata(y,[],Ts)
data = iddata(y,u,Ts)
data = iddata(y,u,Ts,'Frequency',W)
data = iddata(y,u,Ts,'P1',V1,...,'PN',VN)
data = iddata(idfrd_object)
```

Arguments

`y`

Name of MATLAB variable that represents the output signal from a system. Sets the `OutputData` `iddata` property. For a single-output system, this is a column vector. For a multiple-output system with N_y output channels and N_T time samples, this is an N_T-by-N_y matrix.

Note Output data must be in the same domain as input data.

`u`

Name of MATLAB variable that represents the input signal to a system. Sets the `InputData` `iddata` property. For a single-input system, this is a column vector. For a multiple-output system with N_u output channels and N_T time samples, this is an N_T-by-N_u matrix.

Note Input data must be in the same domain as output data.

`Ts`

Time interval between successive data samples in seconds. Default value is `1`. For continuous-time data in the frequency domain, set `Ts` to `0`.

`'P1',V1,...,'PN',VN`

Pairs of `iddata` property names and property values.

`idfrd_object`
: Name of `idfrd` data object.

Description

`data = iddata(y,[],Ts)` creates an `iddata` object for time-series data, containing a time-domain output signal `y` and an empty input signal `[]`, respectively. `Ts` specifies the sampling interval of the experimental data.

`data = iddata(y,u,Ts)` creates an `iddata` object containing a time-domain output signal `y` and input signal `u`, respectively. `Ts` specifies the sampling interval of the experimental data.

`data = iddata(y,u,Ts,'Frequency',W)` creates an `iddata` object containing a frequency-domain output signal `y` and input signal `u`, respectively.`Ts` specifies the sampling interval of the experimental data. `W` specifies the `iddata` property `'frequency'` as a vector of frequencies.

`data = iddata(y,u,Ts,'P1',V1,...,'PN',VN)` creates an `iddata` object containing a time-domain or frequency-domain output signal `y` and input signal `u`, respectively. `Ts` specifies the sampling interval of the experimental data. `'P1',V1,...,'PN',VN` are property-value pairs, as described in “iddata Properties” on page 2-141.

`data = iddata(idfrd_object)` transforms an `idfrd` object to a frequency-domain `iddata` object.

iddata Properties

The following table describes `iddata` object properties and their values. These properties are specified as property-value arguments `'P1',V1,...,'PN',VN`’ in the `iddata` constructor, or you can set them using the `set` command or dot notation. In the list below, `N` denotes the number of data samples in the input and output signals, `ny` is the number of output channels, `nu` is the number of input channels, and `Ne` is the number of experiments.

Tip Property names are not case sensitive. You do not need to type the entire property name. However, the portion you enter must by enough to uniquely identify the property.

Property Name	Description	Value
`Domain`	Specifies whether the data is in the time domain or frequency domain.	• `'Frequency'` — Frequency-domain data. • `'Time'` (Default) — Time-domain data.
`ExperimentName`	Name of each data set contained in the `iddata` object.	For `Ne` experiments, a `1`-by-`Ne` cell array of strings. Each cell contains the name of the corresponding experiment. Default names are `{'Exp1', 'Exp2',...}`.
`Frequency`	(Frequency-domain data only) Frequency values for defining the Fourier Transforms of the signals.	For a single experiment, this is an `N`-by-`1` vector. For `Ne` experiments, a `1`-by-`Ne` cell array and each cell contains the frequencies of the corresponding experiment.
`InputData`	Name of MATLAB variable that stores the input signal to a system.	For `nu` input channels and `N` data samples, this is an `N`-by-`nu` matrix.
`InputName`	Specifies the names of individual input channels.	Cell array of length `nu`-by-`1` contains the name string of each input channel. Default names are `{'u1';'u2';...}`.
`InputUnit`	Specifies the units of each input channel.	Cell array of length `nu`-by-`1`. Each cell contains a string that specifies the units of each input channel.

Property Name	Description	Value
`InterSample`	Specifies the behavior of the input signals between samples for transformations between discrete-time and continuous-time.	For a single experiment: • `zoh`— (Default) Zero-order hold maintains a piecewise-contant input signal between samples. • `foh`— First-order hold maintains a piecewise-linear input signal between samples. • `bl`— Band-limited behavior specifies that the continuous-time input signal has zero power above the Nyquist frequency. For `Ne` experiments, `InterSample` is an `nu`-by-`Ne` cell array. Each cell contains one of these values corresponding to each experiment.
`Name`	Name of the data set.	Text string.
`Notes`	Comments about the data set.	Text string.
`OutputData`	Name of MATLAB variable that stores the output signal from a system.	For `ny` output channels and `N` samples, this is an `N`-by-`ny` matrix.

Property Name	Description	Value
OutputName	For a multiple-output system, specifies the names of individual output channels.	Cell array of length ny-by-1 contains the name string of each output channel. Default names are {'y1';'y2';...}.
OutputUnit	Specifies the units of each output channel.	For ny output channels, a cell array of length ny-by-1. Each cell contains a string that specifies the units of the corresponding output channel.
Period	Period of the input signal.	(Default) For a nonperiodic signal, set to inf. For a multiple-input signal, this is an nu-by-1 vector and the kth entry contains the period of the kth input. For Ne experiments, this is a 1-by-Ne cell array and each cell contains a scalar or vector of periods for the corresponding experiment.
SamplingInstants	(Time-domain data only) The time values in the time vector calculated from the properties Tstart and Ts.	For a single experiment, this is an N-by-1 vector. For Ne experiments, this is a 1-by-Ne cell array and each cell contains the sampling instants of the corresponding experiment.
TimeUnit	(Time-domain data only) Time unit.	A string that specifies the time unit for the time vector.

Property Name	Description	Value
`Ts`	Time interval between successive data samples in seconds. Must be specified for both time- and frequency-domain data. For frequency-domain, it is used to compute Fourier transforms of the signals as discrete-time Fourier transforms (DTFT) with the indicated sampling interval. **Note** Your data must be uniformly sampled.	Default value is `1`. For continuous-time data in the frequency domain, set to `0`; the inputs and outputs are interpreted as continuous-time Fourier transforms of the signals. Note that `Ts` is essential also for frequency-domain data, for proper interpretation of how the Fourier transforms were computed: They are interpreted as discrete-time Fourier transforms (DTFT) with the indicated sampling interval.. For multiple-experiment data, `Ts` is a `1`-by-`Ne` cell array and each cell contains the sampling interval of the corresponding experiment.
`Tstart`	(Time-domain data only) Specifies the start time of the time vector.	For a single experiment, this is a scalar. For `Ne` experiments, `Tstart` is a `1`-by-`Ne` cell array and each cell contains the starting time of the corresponding experiment.

Property Name	Description	Value
Units	(Frequency-domain data only) Frequency unit.	Specified as rad/s or Hz.For multiexperiement data with Ne experiments, Units is a 1-by-Ne cell array and each cell contains the frequency unit for each experiment.
UserData	Additional comments.	Text string.

Purpose

Open System Identification Tool GUI

Syntax

```
ident
ident(session,path)
```

Description

`ident` opens the System Identification Tool GUI.

`ident(session,path)` opens the saved session `session` in the System Identification Tool GUI. `path` specifies the location of this file. Omit `path` when the session file is on `MATLABPATH`.

Examples

Open a saved session `iddata1`:

```
ident('iddata1.sid')
```

Open a saved session `mydata` in a specified folder:

```
ident('mydata.sid','\matlab\data\cdplayer\')
```

"System Identification Tool GUI"

Purpose

Filter data using user-defined passbands, general filters, or Butterworth filters

Syntax

```
Zf = idfilt(Z,filter)
Zf = idfilt(Z,filter,causality)
Zf = idfilt(Z,filter,'FilterOrder',NF)
```

Description

`Z` is the data, defined as an `iddata` object. `Zf` contains the filtered data as an `iddata` object. The filter can be defined in three ways:

- As an explicit system that defines the filter,

  ```
  filter = idm or filter = {num,den} or filter = {A,B,C,D}
  ```

  `idm` can be any SISO `idmodel` or LTI model object. Alternatively the filter can be defined as a cell array `{A,B,C,D}` of SISO state-space matrices or as a cell array `{num,den}` of numerator/denominator filter coefficients.

- As a vector or matrix that defines one or several passbands,

  ```
  filter=[[wp1l,wp1h];[ wp2l,wp2h]; ....;[wpnl,wpnh]]
  ```

  The matrix is `n`-by-2, where each row defines a passband in rad/s. A filter is constructed that gives the union of these passbands. For time-domain data, it is computed as cascaded Butterworth filters or order NF. The default value of NF is `5`.

  For example, to define a stopband between `ws1` and `ws2`, use

  ```
  filter = [0 ws1; ws2,Nyqf]
  ```

  where `Nyqf` is the Nyquist frequency.

- For frequency-domain data, only the frequency response of the filter can be specified:

  ```
  filter = Wf
  ```

Here `Wf` is a vector of possibly complex values that define the filter's frequency response, so that the inputs and outputs at frequency `Z.Frequency(kf)` are multiplied by `Wf(kf)`. `Wf` is a column vector of length = number of frequencies in `Z`. If the data object has several experiments, `Wf` is a cell array of length = # of experiments in `Z`.

For time-domain data, the filtering is carried out in the time domain as causal filtering as default. This corresponds to a last argument `causality = 'causal'`. With `causality = 'noncausal'`, a noncausal, zero-phase filter is used for the filtering (corresponding to `filtfilt` in the Signal Processing Toolbox product).

For frequency-domain data, the signals are multiplied by the frequency response of the filter. With the filters defined as passband, this gives ideal, zero-phase filtering ("brickwall filters"). Frequencies that have been assigned zero weight by the filter (outside the passband, or via the frequency response) are removed from the `iddata` object `Zf`.

It is common practice in identification to select a frequency band where the fit between model and data is concentrated. Often this corresponds to bandpass filtering with a passband over the interesting breakpoints in a Bode diagram. For identification where a disturbance model is also estimated, it is better to achieve the desired estimation result by using the property `'Focus'` (see `Algorithm Properties`) than just to prefilter the data. The proper values for `'Focus'` are the same as the argument `filter` in `idfilt`.

Algorithm

The Butterworth filter is the same as `butter` in the Signal Processing Toolbox product. Also, the zero-phase filter is equivalent to `filtfilt` in that toolbox.

`iddata`

idfrd

Purpose

Frequency-response data or model

Syntax

```
h = idfrd(Response,Freq,Ts)
h = idfrd(Response,Freq,Ts,...
     'CovarianceData',Covariance,'SpectrumData',Spec,...
     'NoiseCovariance',Speccov)
h = idfrd(Response,Freq,Ts,...
     'P1',V1,'PN',VN)
h = idfrd(mod)
h = idfrd(mod,Freqs)
```

Description

`h = idfrd(Response,Freq,Ts)` constructs an `idfrd` object that stores the frequency response `Response` of a linear system at frequency values `Freq`. `Ts` is the sampling time interval. For a continuous-time system, set `Ts=0`.

`h = idfrd(Response,Freq,Ts,... 'CovarianceData',Covariance,'SpectrumData',Spec,... 'NoiseCovariance',Speccov)` also stores the uncertainty of the response `Covariance`, the spectrum of the additive disturbance (noise) `Spec`, and the uncertainty of the noise `Speccov`.

`h = idfrd(Response,Freq,Ts,... 'P1',V1,'PN',VN)` constructs an `idfrd` object that stores a frequency-response model with properties specified by the `idfrd` model property-value pairs.

`h = idfrd(mod)` converts a System Identification Toolbox or Control System Toolbox linear model to frequency-response data at default frequencies, including the output noise spectra and their covariance. If the linear model has an input-to-output delay, this delay is converted to a phase lag.

`h = idfrd(mod,Freqs)` converts a System Identification Toolbox or Control System Toolbox linear model to frequency-response data at frequencies `Freqs`.

For a model

$$y(t) = G(q)u(t) + H(q)e(t)$$

stores the transfer function estimate $G(e^{i\omega})$, as well as the spectrum of the additive noise (Φ_v) at the output

$$\Phi_v(\omega) = \lambda T \left| H(e^{i\omega T}) \right|^2$$

where λ is the estimated variance of $e(t)$, and T is the sampling interval.

Creating idfrd from Given Responses

`Response` is a 3-D array of dimension `ny`-by-`nu`-by-`Nf`, with `ny` being the number of outputs, `nu` the number of inputs, and `Nf` the number of frequencies (that is, the length of `Freqs`). `Response(ky,ku,kf)` is thus the complex-valued frequency response from input `ku` to output `ky` at frequency `ω=Freqs(kf)`. When defining the response of a SISO system, `Response` can be given as a vector.

`Freqs` is a column vector of length `Nf` containing the frequencies of the response.

`Ts` is the sampling interval. `T = 0` means a continuous-time model.

`Covariance` is a 5-D array containing the covariance of the frequency response. It has dimension `ny`-by-`nu`-by-`Nf`-by-2-by-2. The structure is such that `Covariance(ky,ku,kf,:,:)` is the 2-by-2 covariance matrix of the response `Response(ky,ku,kf)`. The 1-1 element is the variance of the real part, the 2-2 element is the variance of the imaginary part, and the 1-2 and 2-1 elements are the covariance between the real and imaginary parts. `squeeze(Covariance(ky,ku,kf,:,:))` thus gives the covariance matrix of the corresponding response.

The information about spectrum is optional. The format is as follows:

`spec` is a 3-D array of dimension `ny`-by-`ny`-by-`Nf`, such that `spec(ky1,ky2,kf)` is the cross spectrum between the noise at output `ky1` and the noise at output `ky2`, at frequency `Freqs(kf)`. When `ky1 = ky2` the (power) spectrum of the noise at output `ky1` is thus obtained. For a single-output model, `spec` can be given as a vector.

speccov is a 3-D array of dimension ny-by-ny-by-Nf, such that speccov(ky1,ky1,kf) is the variance of the corresponding power spectrum. Normally, no information is included about the covariance of the nondiagonal spectrum elements.

If only SpectrumData is to be packaged in the idfrd object, set Response = [].

Creating idfrd from a Given Model

idfrd can also be computed from a given model mod (defined as any idmodel object).

If the frequencies Freqs are not specified, a default choice is made based on the dynamics of the model mod.

If mod has InputDelay different from zero, these are appended as phase lags, and h will then have an InputDelay of 0.

The estimated covariances are computed using the Gauss approximation formula from the uncertainty information in mod. For models with complicated parameter dependencies, numerical differentiation is applied. The step sizes for the numerical derivatives are determined by nuderst.

Frequency responses for submodels can be obtained by the standard subreferencing, h = idfrd(m(2,3)). See idmodel. In particular, h = idfrf(m('measured')) gives an h that just contains the ResponseData (G) and no spectra. Also h = idfrd(m('noise')) gives an h that just contains SpectrumData.

The idfrd models can be graphed with bode, ffplot, and nyquist, which all accept mixtures of idmodel and idfrd models as arguments. Note that spa, spafdr, and etfe return their estimation results as idfrd objects.

idfrd Properties

- ResponseData: 3-D array of the complex-valued frequency response as described above. For SISO systems use Response(1,1,:) to obtain a vector of the response data.

- `Frequency`: Column vector containing the frequencies at which the responses are defined.
- `CovarianceData`: 5-D array of the covariance matrices of the response data as described above.
- `SpectrumData`: 3-D array containing power spectra and cross spectra of the output disturbances (noise) of the system.
- `NoiseCovariance`: 3-D array containing the variances of the power spectra, as explained above.
- `Units`: Unit of the frequency vector. Can assume the values `'rad/s'` and `'Hz'`.
- `Ts`: Scalar denoting the sampling interval of the model whose frequency response is stored. `'Ts' = 0` means a continuous-time model.
- `Name`: An optional name for the object.
- `InputName`: String or cell array containing the names of the input channels. It has as many entries as there are input channels.
- `OutputName`: Correspondingly for the output channels.
- `InputUnit`: Units in which the input channels are measured. It has the same format as `'InputName'`.
- `OutputUnit`: Correspondingly for the output channels.
- `InputDelay`: Row vector of length equal to the number of input channels. Contains the delays from the input channels. These should thus be appended as phase lags when the response is calculated. This is done automatically by `freqresp`, `bode`, `ffplot`, and `nyquist`. Note that if the `idfrd` is calculated from an `idmodel`, possible input delays in that model are converted to phase lags, and the `InputDelay` of the `idfrd` model is set to zero.
- `Notes`: An arbitrary field to store extra information and notes about the object.
- `UserData`: An arbitrary field for any possible use.

- `EstimationInfo`: Structure that contains information about the estimation process that is behind the frequency data. It contains the following fields (see also the reference page for `EstimationInfo`).
  - `Status`: Gives the status of the model, for example, `'Not estimated'`.
  - `Method`: The identification routine that created the model.
  - `WindowSize`: If the model was estimated by `spa`, `spafdr`, or `etfe`, the size of window (input argument `M`, the resolution parameter) that was used. This is scalar or a vector.
  - `DataName`: Name of the data set from which the model was estimated.
  - `DataLength`: Length of this data set.

Note that you can set or retrieve all properties either with the `set` and `get` commands or by subscripts. Autofill applies to all properties and values, and these are case insensitive:

```
h.ts = 0
loglog(h.fre,squeeze(h.spe(2,2,:)))
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`. See also `idprops idfrd`.

Subreferencing

The different channels of the `idfrd` are retrieved by subreferencing.

```
h(outputs,inputs)
```

`h(2,3)` thus contains the response data from input channel 3 to output channel 2, and, if applicable, the output spectrum data for output channel 2. The channels can also be referred to by their names, as in `h('power',{'voltage', 'speed'})`.

```
h('m')
```

contains the information for measured inputs only, that is, just `ResponseData`, while

```
h('n')
```

(`'n'` for `'noise'`) just contains `SpectrumData`.

Horizontal Concatenation

Adding input channels,

```
h = [h1,h2,...,hN]
```

creates an `idfrd` model `h`, with `ResponseData` containing all the input channels in `h1,...,hN`. The output channels of `hk` must be the same, as well as the frequency vectors. `SpectrumData` is ignored.

Vertical Concatenation

Adding output channels,

```
h = [h1;h2;... ;hN]
```

creates an `idfrd` model `h` with `ResponseData` containing all the output channels in `h1, h2,...,hN`. The input channels of `hk` must all be the same, as well as the frequency vectors. `SpectrumData` is also appended for the new outputs. The cross spectrum between output channels is then set to zero.

Converting to iddata

You can convert an `idfrd` object to a frequency-domain `iddata` object by

```
Data = iddata(Idfrdmodel)
```

See `iddata`.

Examples

Compare the results from spectral analysis and an ARMAX model.

```
m = armax(z,[2 2 2 1]);
g = spa(z)
g = spafdr(z,[],{0,10})
bode(g,m)
```

Compute separate `idfrd` models, one containing the frequency function and the other the noise spectrum.

```
g = idfrd(m('m'))
phi = idfrd(m('n'))
```

idgrey

Purpose

Linear ODE (grey-box model) with known and unknown parameters

Syntax

```
m = idgrey(MfileName,ParameterVector,CDmfile)
m = idgrey(MfileName,ParameterVector,CDmfile,FileArgument,Ts,...
'Property1',Value1,...,'PropertyN',ValueN)
```

Description

The function `idgrey` is used to create arbitrarily parameterized state-space models as `idgrey` objects.

`MfileName` is the name of a MATLABfile that defines how the state-space matrices depend on the parameters to be estimated. The format of this file is given by

```
[A,B,C,D,K,X0] = mymfile(pars,Tsm,Auxarg)
```

and is further discussed below.

`ParameterVector` is a column vector of the nominal/initial parameters. Its length must be equal to the number of free parameters in the model (that is, the argument `pars` in the example below).

The argument `CDmfile` describes how the user-written file handles continuous and discrete-time models. It takes the following values:

- `CDmfile = 'cd'`: The file returns the continuous-time state-space matrices when called with the argument `Tsm = 0`. When called with a value `Tsm > 0`, the file returns the discrete-time state-space matrices, obtained by sampling the continuous-time system with sampling interval `Tsm`. The file must consequently in this case include the sampling procedure.
- `CDmfile = 'c'`. The file always returns the continuous-time state-space matrices, no matter the value of `Tsm`. In this case the toolbox's estimation routines will provide the sampling when you are fitting the model to discrete-time data.
- `CDmfile = 'd'`. The file always returns discrete-time state-space matrices that may or may not depend on `Tsm`.

The argument `FileArgument` corresponds to the auxiliary argument `Auxarg` in the user-written file. It can be used to handle several variants of the model structure, without having to edit the file. If it is not used, enter `FileArgument = []`. (Default.)

`Ts` denotes the sampling interval of the model. Its default value is `Ts = 0`, that is, a continuous-time model.

The `idgrey` object is a child of `idmodel`. Therefore any `idmodel` properties can be set as property name/property value pairs in the `idgrey` command. They can also be set by the command `set`, or by subassignment, as in

```
m.InputName = {'speed','voltage'}
m.FileArgument = 0.23
```

There are also two properties, `DisturbanceModel` and `InitialState`, that can be used to affect the parameterizations of *K* and *X0*, thus overriding the outputs from the file.

idgrey Properties

- `MfileName`: Name of the user-written function.
- `CDmfile`: How this file handles continuous and discrete-time models depending on its second argument, `T`.
  - `CDmfile = 'cd'` means that the file returns the continuous-time state-space model matrices when the argument `T = 0`, and the discrete-time model, obtained by sampling with sampling interval `T`, when `T > 0`.
  - `CDmfile = 'c'` means that the file always returns continuous-time model matrices, no matter the value of T.
  - `CDmfile = 'd'` means that the file always returns discrete-time model matrices that may or may not depend on the value of `T`.
- `FileArgument`: Possible extra input arguments to the user-written file.
- `DisturbanceModel`: Affects the parameterization of the K matrix. It can assume the following values:

  - 'Model': This is the default. It means that the K matrix obtained from the user-written file is used.
  - 'Estimate': The K matrix is treated as unknown and all its elements are estimated as free parameters.
  - 'Fixed': The K matrix is fixed to a given value.
  - 'None': The K matrix is fixed to zero, thus producing an output-error model.

  Note that in the three last cases the output K from the user-written file is ignored. The estimated/fixed value is stored internally and does not change when the model is sampled, resampled, or converted to continuous time. Note also that this estimated value is tailored only to the sampling interval of the data.

- InitialState: Affects the parameterization of the X0 vector. It can assume the following values:
  - 'Model': This is the default. It means that the X0 vector is obtained from the user-written file.
  - 'Estimate': The X0 matrix is treated as unknown and all its elements are estimated as free parameters.
  - 'Fixed': The X0 vector is fixed to a given value.
  - 'Backcast': The X0 vector is estimated using a backcast operation analogous to the idss case.
  - 'Auto': Makes a data-dependent choice among 'Estimate', 'Backcast', and 'Model'.
- A, B, C, D, K, and X0: The state-space matrices. For idgrey models, only 'K' and 'X0' can be set; the others can only be retrieved. The set 'K' and 'X0' are relevant only when DisturbanceModel/InitialState are Estimate or Fixed.
- dA, dB, dC, dD, dK, and dX0: The estimated standard deviations of the state-space matrices. These cannot be set, only retrieved.

In addition, any `idgrey` object also has all the properties of `idmodel`. See `Algorithm Properties` and the reference page for `idmodel`.

Note that you can set or retrieve all properties using either the `set` and `get` commands or subscripts. Autofill applies to all properties and values, and they are case insensitive.

```
m.fi = 10;
set(m,'search','gn')
p = roots(m.a)
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`.

MATLAB File Details

The model structure corresponds to the general linear state-space structure

$$\tilde{x}(t) = A(\theta)x(t) + B(\theta)u(t) + K(\theta)e(t)$$
$$x(0) = x_0(\theta)$$
$$y(t) = C(\theta)x(t) + D(\theta)u(t) + e(t)$$

Here $\tilde{x}(t)$ is the time derivative $\dot{x}(t)$ for a continuous-time model and $x(t + Ts)$ for a discrete-time model.

The matrices in this time-discrete model can be parameterized in an arbitrary way by the vector θ. Write the format for the file as follows:

```
[A,B,C,D,K,x0] = mymfile(pars,T,Auxarg)
```

Here the vector `pars` contains the parameters θ, and the output arguments `A`, `B`, `C`, `D`, `K`, and `x0` are the matrices in the model description that correspond to this value of the parameters and this value of the sampling interval `T`.

`T` is the sampling interval, and `Auxarg` is any variable of auxiliary quantities with which you want to work. (In that way you can change certain constants and other aspects in the model structure without having to edit the file.) Note that the two arguments `T` and `Auxarg`

must be included in the function head of the file, even if they are not used within the file.

A comment about `CDmfile`: If a continuous-time model is sought, it is easiest to let the file deliver just the continuous-time model, that is, have `CDmfile = 'c'` and rely upon the toolbox's routines for the proper sampling. Similarly, if the underlying parameterization is indeed discrete time, it is natural to deliver the discrete-time model matrices and let `CDmfile = 'd'.` If the underlying parameterization is continuous, but you prefer for some reason to do your own sampling inside the file in accordance with the value of `T`, then let your file deliver the continuous-time model when called with `T = 0`, that is, the alternative `CMmfile = 'cd'`. This avoids sampling and then transforming back (using `d2c`) to find the continuous-time model.

idgrey Definition of States

The states of an `idgrey` model are defined explicitly by the user in the function or MEX-file (as specified in *`MfileName`* property) storing the model structure. The concept of states is useful for functions such as `sim`, `predict`, `compare` and `findstates`.

Examples

In this example, you use the file `mynoise` given in "Example – Estimating a Discrete-Time Grey-Box Model with Parameterized Disturbance" to obtain a physical parameterization of the Kalman gain. You estimate the unknown parameters of this model using the estimation data `z`.

```
mn = idgrey('mynoise',[0.1,-2,1,3,0.2]','d',1)
m = pem(z,mn)
```

idinput

Purpose

Generate input signals

Syntax

```
u = idinput(N)
u = idinput(N,type,band,levels)
[u,freqs] = idinput(N,'sine',band,levels,sinedata)
```

Description

`idinput` generates input signals of different kinds, which are typically used for identification purposes. `u` is returned as a matrix or column vector.

For further use in the toolbox, we recommend that you create an `iddata` object from `u`, indicating sampling time, input names, periodicity, and so on:

```
u = iddata([],u);
```

`N` determines the number of generated input data. If `N` is a scalar, `u` is a column vector with this number of rows.

`N = [N nu]` gives an input with `nu` input channels each of length `N`.

`N = [P nu M]` gives a periodic input with `nu` channels, each of length `M*P` and periodic with period `P`.

Default is `nu = 1` and `M = 1`.

`type` defines the type of input signal to be generated. This argument takes one of the following values:

- `type = 'rgs'`: Gives a random, Gaussian signal.
- `type = 'rbs'`: Gives a random, binary signal. This is the default.
- `type = 'prbs'`: Gives a pseudorandom, binary signal.
- `type = 'sine'`: Gives a signal that is a sum of sinusoids.

The frequency contents of the signal is determined by the argument `band`. For the choices `type = 'rs'`, `'rbs'`, and `'sine'`, this argument is a row vector with two entries

```
band = [wlow, whigh]
```

that determine the lower and upper bound of the passband. The frequencies `wlow` and `whigh` are expressed in fractions of the Nyquist frequency. A white noise character input is thus obtained for `band = [0 1]`, which is also the default value.

For the choice `type = 'prbs'`,

```
band = [0, B]
```

where `B` is such that the signal is constant over intervals of length `1/B` (the clock period). In this case the default is `band = [0 1]`.

The argument `levels` defines the input level. It is a row vector

```
levels = [minu, maxu]
```

such that the signal `u` will always be between the values `minu` and `maxu` for the choices `type = 'rbs'`, `'prbs'`, and `'sine'`. For `type = 'rgs'`, the signal level is such that `minu` is the mean value of the signal, minus one standard deviation, while `maxu` is the mean value plus one standard deviation. Gaussian white noise with zero mean and variance one is thus obtained for `levels = [-1, 1]`, which is also the default value.

Some PRBS Aspects

If more than one period is demanded (that is, `M > 1`), the length of the data sequence and the period of the PRBS signal are adjusted so that an integer number of maximum length PRBS periods is always obtained. If `M = 1`, the period of the PRBS signal is chosen to that it is longer than `P = N`. In the multiple-input case, the signals are maximally shifted. This means `P/nu` is an upper bound for the model orders that can be estimated with such a signal.

Some Sine Aspects

In the `'sine'` case, the sinusoids are chosen from the frequency grid

```
freq = 2*pi*[1:Grid_Skip:fix(P/2)]/P
```

intersected with `pi*[band(1) band(2)]`. For `Grid_Skip`, see below. For multiple-input signals, the different inputs use different frequencies from this grid. An integer number of full periods is always delivered. The selected frequencies are obtained as the second output argument, `freqs`, where row `ku` of `freqs` contains the frequencies of input number `ku`. The resulting signal is affected by a fifth input argument, `sinedata`

```
sinedata = [No_of_Sinusoids, No_of_Trials, Grid_Skip]
```

meaning that `No_of_Sinusoids` is equally spread over the indicated `band`. `No_of_Trials` (different, random, relative phases) are tried until the lowest amplitude signal is found.

```
Default: sinedata = [10,10,1];
```

`Grid_Skip` can be useful for controlling odd and even frequency multiples, for example, to detect nonlinearities of various kinds.

Algorithm

Very simple algorithms are used. The frequency contents are achieved for `'rgs'` by an eighth-order Butterworth, noncausal filter, using `idfilt`. This is quite reliable. The same filter is used for the `'rbs'` case, before making the signal binary. This means that the frequency contents are not guaranteed to be precise in this case.

For the `'sine'` case, the frequencies are selected to be equally spread over the chosen grid, and each sinusoid is given a random phase. A number of trials are made, and the phases that give the smallest signal amplitude are selected. The amplitude is then scaled so as to satisfy the specifications of `levels`.

References

See Söderström and Stoica (1989), Chapter C5.3. For a general discussion of input signals, see Ljung (1999), Section 13.3.

Examples

Create an input consisting of five sinusoids spread over the whole frequency interval. Compare the spectrum of this signal with that of its square. The frequency splitting (the square having spectral support at other frequencies) reveals the nonlinearity involved:

```
u = idinput([100 1 20],'sine',[],[],[5 10 1]);
u = iddata([],u,1,'per',100);
u2 = u.u.^2;
u2 = iddata([],u2,1,'per',100);
ffplot(etfe(u),'r*',etfe(u2),'+')
```

idmodel

Purpose

Superclass for linear models

Description

`idmodel` is an object that you do not deal with directly. It contains all the common properties of the model objects `idarx`, `idgrey`, `idpoly`, `idproc`, and `idss`, which are returned by the different estimation routines.

Basic Use

If you just estimate models from data, the model objects should be transparent. All parametric estimation routines return `idmodel` results.

```
m = arx(Data,[2 2 1])
```

The model `m` contains all relevant information. Just typing `m` will give a brief account of the model. `present(m)` also gives information about the uncertainties of the estimated parameters. `get(m)` gives a complete list of model properties.

Most of the interesting properties can be directly accessed by subreferencing:

```
m.a
m.da
```

See the property list obtained by `get(m)`, as well as the property lists of `idgrey`, `idarx`, `idpoly`, and `idss` in Chapter 2, “Functions – Alphabetical List” for more details on this. See also `idprops`.

The characteristics of the model `m` can be directly examined and displayed by commands like `impulse`, `step`, `bode`, `nyquist`, and `pzmap`. The quality of the model is assessed by commands like `compare` and `resid`. When you have Control System Toolbox software installed, you can use `view(m)` to access various display functions.

To extract state-space matrices, transfer function polynomials, etc., use the commands `arxdata`, `polydata`, `tfdata`, `ssdata`, and `zpkdata`.

To compute the frequency response of the model, use the commands `idfrd` and `freqresp`.

Creating and Modifying Model Objects

If you want to define a model to use, for example, for simulating data, you need to use the model creator functions:

- `idarx`, for multivariable ARX models
- `idgrey`, for user-defined grey-box state-space models
- `idpoly`, for single-output polynomial models
- `idproc`, for simple, continuous-time process models
- `idss`, for state-space models

If you want to estimate a state-space model with a specific internal parameterization, you need to create an `idss` model or an `idgrey` model. See the reference pages for these functions.

Dealing with Input and Output Channels

For multivariable models, you construct submodels containing a subset of inputs and outputs by simple subreferencing. The outputs and input channels can be referenced according to

```
m(outputs,inputs)
```

Use a colon (:) to denote all channels and an empty matrix (`[]`) to denote no channels. The channels can be referenced by number or by name. For several names, you must use a cell array, such as

```
m3 = m('position',{'power','speed'})
```

or

```
m3 = m(3,[1 4])
```

Thus `m3` is the model obtained from `m` by looking at the transfer functions from input numbers 1 and 4 (with input names 'power' and 'speed') to output number `3` (with name `position`).

For a single-output model m,

```
m4 = m(inputs)
```

selects the corresponding input channels, and for a single-input model,

```
m5 = m(outputs)
```

selects the indicated output channels.

Subreferencing is quite useful, for example, when a plot of just some channels is desired.

Noise Channels

The estimated models have two kinds of input channels: the measured inputs u and the noise inputs e. For a general linear model m, we have

$$y(t) = G(q)u(t) + H(q)e(t)$$

where u is the nu-dimensional vector of measured input channels and e is the ny-dimensional vector of noise channels. The covariance matrix of e is given by the property 'NoiseVariance'. Occasionally this matrix Λ is written in factored form,

$$\Lambda = LL^T$$

This means that e can be written as

$$e = Lv$$

where v is white noise with identity covariance matrix (independent noise sources with unit variances).

If m is a time series (nu = 0), G is empty and the model is given by

$$y(t) = H(q)e(t)$$

For the model m, the restriction to the transfer function matrix G is obtained by

```
m1 = m('measured') or just m1 = m('m')
```

Then `e` is set to `0` and `H` is removed.

Analogously,

```
m2 = m('noise') or just m2 = m('n')
```

creates a time-series model `m2` from `m` by ignoring the measured input. That is, `m2` describes the signal *He*.

For a system with measured inputs, `bode`, `step`, and other transformation and display functions deal with the transfer function matrix *G*. To obtain or graph the properties of the disturbance model *H*, it is therefore important to make the transformations `m('n')`. For example,

```
bode(m('n'))
```

plots the additive noise spectra according to the model `m`, while

```
bode(m)
```

just plots the frequency responses of *G*.

To study the noise contributions in more detail, it is useful to convert the noise channels to measured channels, using the command `noisecnv`.

```
m3 = noisecnv(m)
```

This creates a model `m3` with all input channels, both measured `u` and noise sources `e`, treated as measured signals. That is, `m3` is a model from `u` and `e` to `y`, describing the transfer functions *G* and *H*. The information about the variance of the innovations `e` is lost. For example, studying the step response from the noise channels does not take into consideration how large the noise contributions actually are.

To include that information, `e` should first be normalized, $e = Lv$, so that v becomes white noise with an identity covariance matrix.

```
m4 = noisecnv(m,'Norm')
```

This creates a model m4 where u and v are treated as measured signals.

$$y(t) = G(q)u(t) + H(q)Lv(t) = [G\ HL]\begin{bmatrix} u \\ v \end{bmatrix}$$

For example, the step responses from v to y will now reflect the typical size of the disturbance influence because of the scaling by L. In both cases, the previous noise sources that have become regular inputs will automatically get input names that are related to the corresponding output. The unnormalized noise sources e have names like 'e@ynam1' (noise e at output channel ynam1), while the normalized sources v are called 'v@ynam1'.

Retrieving Transfer Functions

The functions that retrieve transfer function properties, ssdata, tfdata, and zpkdata, behave, as follows, for a model with measured inputs. (fcn is ssdata, tfdata, or zpkdata.)

fcn(m) returns the properties of G (ny outputs and nu inputs).

fcn(m('n')) returns the properties of the transfer function H (ny outputs and ny inputs).

fcn(noisecnv(m,'Norm')) returns the properties of the transfer function [G HL} (ny outputs and ny+nu inputs). Analogously,

```
m1 = m('n');
fcn(noisecnv(m1,'Norm'))
```

returns the properties of the transfer function HL (ny outputs and ny inputs).

If m is a time-series model, fcn(m) returns the properties of H, while

```
fcn(noisecnv(m,'Norm'))
```

returns the properties of HL.

Note that the estimated covariance matrix NoiseVariance itself is uncertain. This means that the uncertainty information about *H* is different from that of *HL*.

idmodel Properties

In the list below, ny is the number of output channels, and nu is the number of input channels:

- Name: An optional name for the data set. An arbitrary string.
- OutputName, InputName: Cell arrays of length ny-by-1 and nu-by-1 containing the names of the output and input channels. For estimated models, these are inherited from the data. If not specified, they are given default names {'y1','y2',...} and {'u1','u2',...}.
- OutputUnit, InputUnit: Cell arrays of length ny-by-1 and nu-by-1 containing the units of the output and input channels. Inherited from data for estimated models.
- TimeUnit: Unit for the sampling interval.
- Ts: Sampling interval. A nonnegative scalar. Ts = 0 denotes a continuous-time model. Note that changing just Ts will not recompute the model parameters. Use c2d and d2c for recomputing the model to other sampling intervals.
- ParameterVector: Vector of adjustable parameters in the model structure. Initial/nominal values or estimated values, depending on the status of the model. A column vector.
- PName: The names of the parameters. A cell array of the length of the parameter vector. If not specified, it will contain empty strings. See also setpname.
- CovarianceMatrix: Estimated covariance matrix of the parameter vector. For a nonestimated model this is the empty matrix. For state-space models in the 'Free' parameterization the covariance matrix is also the empty matrix, since the individual matrix elements are not identifiable then. Instead, in this case, the covariance information is hidden (in the hidden property 'Utility') and retrieved by the relevant functions when necessary. Setting

CovarianceMatrix to 'None' inhibits calculation of covariance and uncertainty information. This can save substantial time for certain models.

- NoiseVariance: Covariance matrix of the noise source e. An ny-by-ny matrix.
- InputDelay: Vector of size nu-by-1, containing the input delay from each input channel. For a continuous-time model (Ts = 0) the delay is measured in TimeUnit, while for discrete-time models (Ts > 0) the delay is measured as the number of samples. Note the difference between InputDelay and nk (which is a property of idarx, idss, and idpoly). 'Nk' is a model structure property that tells the model structure to include such an input delay. In that case, the corresponding state-space matrices and polynomials will explicitly contain Nk input delays. The property InputDelay, on the other hand, is an indication that in addition to the model as defined, the inputs should be shifted by the given amount. InputDelay is used by sim and the estimation routines to shift the input data. When computing frequency responses, the InputDelay is also respected. Note that InputDelay can be both positive and negative.
- Algorithm: See the reference page for Algorithm Properties.
- EstimationInfo: See the reference page for EstimationInfo.
- Notes: An arbitrary field to store extra information and notes about the object.
- UserData: An arbitrary field for any possible use.

Note All properties can be set or retrieved either by these commands or by subscripts. Autofill applies to all properties and values, and is case insensitive.

For a complete list of property values, use get(m). To see possible value assignments, use set(m).

Subreferencing

The outputs and input channels can be referenced according to

```
m(outputs,inputs)
```

Use a colon (:) to denote all channels and an empty matrix ([ ]) to denote no channels. The channels can be referenced by number or by name. For several names, you must use a cell array.

```
m2 = m('y3',{'u1','u4'})
m3 = m(3,[1 4])
```

For a single output model `m`,

```
m4 = m(inputs)
```

selects the corresponding input channels, and for a single input model,

```
m5 = m(outputs)
```

selects the indicated output channels.

The string `'measured'` (or any abbreviation like `'m'`) means the measured input channels.

```
m4 = m(3,'m')
m('m') is the same as m(:,'m')
```

Similarly, the string `'noise'` (or any abbreviation) refers to the noise input channels. See “Noise Channels” on page 2-168 for more details.

Horizontal Concatenation

Adding input channels,

```
m = [m1,m2,...,mN]
```

creates an `idmodel` object `m`, consisting of all the input channels in `m1,...  mN`. The output channels of `mk` must be the same.

Vertical Concatenation

Adding output channels,

```
m = [m1;m2;... ;mN]
```

creates an `idmodel` object `m` consisting of all the output channels in `m1, m2, ..mN`. The input channels of `mk` must all be the same.

Purpose

Nonlinear ARX model

Syntax

```
m = idnlarx([na nb nk])
m = idnlarx([na nb nk],Nonlinearity)
m = idnlarx([na nb nk],Nonlinearity,'PropertyName',
   PropertyValue)
m = idnlarx(LinModel)
m = idnlarx(LinModel,Nonlinearity)
m = idnlarx(LinModel,Nonlinearity,'PropertyName',
   PropertyValue)
```

Description

Represents nonlinear ARX model. The nonlinear ARX structure is an extension of the linear ARX structure and contains linear and nonlinear functions. For more information, see “Nonlinear ARX Model Extends the Linear ARX Structure”.

Typically, you use the `nlarx` command to both construct the `idnlarx` object and estimate the model parameters. You can configure the model properties directly in the `nlarx` syntax.

You can also use the `idnlarx` constructor to create the nonlinear ARX model structure and then estimate the parameters of this model using `nlarx` or `pem`.

For `idnlarx` object properties, see:

- “idnlarx Model Properties” on page 2-177
- “idnlarx Algorithm Properties” on page 2-180
- “idnlarx Advanced Algorithm Properties” on page 2-184
- “idnlarx EstimationInfo Properties” on page 2-186

Construction

`m = idnlarx([na nb nk])` creates an `idnlarx` object using a default wavelet network as its nonlinearity estimator. *na*, *nb*, and *nk* are positive integers that specify model orders and delays.

`m = idnlarx([na nb nk],Nonlinearity)` specifies a nonlinearity estimator `Nonlinearity`, as a nonlinearity estimator object or string representing the nonlinearity estimator type.

`m = idnlarx([na nb nk],Nonlinearity,'PropertyName',PropertyValue)` creates the object using options specified as `idnlarx` property name and value pairs. Specify `PropertyName` inside single quotes.

`m = idnlarx(LinModel)` creates an `idnlarx` object using a linear model (in place of [`na nb nk`]), and a wavelet network as its nonlinearity estimator. `LinModel` is a discrete time input-output polynomial model of ARX structure (`idpoly`) for single-output systems and `idarx` object for multi-output systems. `LinModel` sets the model orders, input delay, input-output channel names and units, sample time, and time unit of `m`, and the polynomials initialize the linear function of the nonlinearity estimator.

`m = idnlarx(LinModel,Nonlinearity)` specifies a nonlinearity estimator `Nonlinearity`.

`m = idnlarx(LinModel,Nonlinearity,'PropertyName',PropertyValue)` creates the object using options specified as `idnlarx` property name and value pairs.

Input Arguments

`na nb nk`

Positive integers that specify the model orders and delays.

For `ny` output channels and `nu` input channels, `na` is an `ny`-by-`ny` matrix whose *i*-*j*th entry gives the number of delayed *j*th outputs used to compute the *i*th output. `nb` and `nk` are `ny`-by-`nu` matrices, where each row defines the orders for the corresponding output.

`Nonlinearity`

Nonlinearity estimator, specified as a nonlinearity estimator object or string representing the nonlinearity estimator type.

`'wavenet'` or `wavenet` object (default)	Wavelet network
`'sigmoidnet'` or `sigmoidnet` object	Sigmoid network
`'treepartition'` or `treepartition` object	Binary-tree
`'linear'` or `[ ]` or `linear` object	Linear function
`neuralnet` object	Neural network
`customnet` object	Custom network

Specifying a string creates a nonlinearity estimator object with default settings. Use object representation to configure the properties of a nonlinearity estimator.

For `ny` output channels, you can specify nonlinear estimators individually for each output channel by setting *`Nonlinearity`* to an `ny`-by-1 cell array or object array of nonlinearity estimators. To specify the same nonlinearity for all outputs, specify *`Nonlinearity`* as a single nonlinearity estimator.

`LinModel`

Discrete time input-output polynomial model of ARX structure, typically estimated using the `arx` command:

- `idpoly` object for single-output systems
- `idarx` object for multi-output systems

idnlarx Model Properties

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% Get the model time unit
get(m,'TimeUnit')
% Get value of Nonlinearity property
m.Nonlinearity
```

You can specify property name-value pairs in the model estimator or constructor to configure the model structure and estimation algorithm.

The following table summarizes `idnlarx` model properties. The general `idnlmodel` properties also apply to this nonlinear model object (see the corresponding reference page).

Property Name	Description
`Algorithm`	A structure that specifies the estimation algorithm options, as described in "idnlarx Algorithm Properties" on page 2-180.
`CustomRegressors`	Custom expression in terms of standard regressors. Assignable values: • Cell array of strings. For example: `{'y1(t-3)^3','y2(t-1)*u1(t-3)','sin(u3(t-2))'}`. • Object array of `customreg` objects. Create these objects using commands such as `customreg` and `polyreg`. For more information, see the corresponding reference pages.
`EstimationInfo`	A read-only structure that stores estimation settings and results, as described in "idnlarx EstimationInfo Properties" on page 2-186.
`Focus`	Specifies `'Prediction'` or `'Simulation'`. Assignable values: • `'Prediction'` (default) — The estimation algorithm minimizes $\|y - \hat{y}\|$, where $\hat{y}$ is the 1–step ahead predicted output. This algorithm does not necessarily minimize the simulation error. • `'Simulation'` — The estimation algorithm minimizes the simulation error and optimizes the results of `compare(data,model,Inf)`. That is, when computing $\hat{y}$, y in the regressors in F are replaced by values simulated

Property Name	Description
	from the input only. `'Simulation'` requires that the model include only differentiable nonlinearities. **Note** If your model includes the `treepartition` or `neuralnet` nonlinearity, the algorithm always uses `'prediction'`, regardless of the `Focus` value. If your model includes the `wavenet` nonlinearity, the first estimation of this model uses `'prediction'`.
`NonlinearRegressors`	Specifies which standard or custom regressors enter the nonlinear block. For multiple-output models, use cell array of n_y elements (n_y = number of model outputs). For each output, assignable values are: • `'all'` — All regressors enter the nonlinear block. • `'search'` — Specifies that the estimation algorithm searches for the best regressor combination. This is useful when you want to reduce a large number of regressors entering the nonlinear function block or the nonlinearity estimator. • `'input'` — Input regressors only. • `'output'` — Output regressors only. • `'standard'` — Standard regressors only. • `'custom'` — Custom regressors only. • `'[]'` — No regressors enter the nonlinear block. • A vector of indices: Specifies the indices of the regressors that should be used in the nonlinear estimator. To determine the order of regressors, use `getreg`.

Property Name	Description
Nonlinearity	Nonlinearity estimator object. Assignable values include wavenet (default), sigmoidnet, treepartition, customnet, neuralnet, and linear. If the model contains only one regressor, you can also use saturation, deadzone, pwlinear, or poly1d. For ny outputs, Nonlinearity is an ny-by-1 array. For example, [sigmoidnet;wavenet] for a two-output model. When you specify a scalar object, this nonlinearity applies to all outputs.
na nb nk	Nonlinear ARX model orders and input delays, where na is the number of output terms, nb is the number of input terms, and nk is the delay from input to output in terms of the number of samples. For ny outputs and nu inputs, na is an ny-by-ny matrix whose *i*-*j*th entry gives the number of delayed *j*th outputs used to compute the *i*th output. nb and nk are ny-by-nu matrices.

idnlarx Algorithm Properties

The following table summarizes the fields of the Algorithm idnlarx model properties. Algorithm is a structure that specifies the estimation-algorithm options.

Property Name	Description
Advanced	A structure that specifies additional estimation algorithm options, as described in “idnlarx Advanced Algorithm Properties” on page 2-184.
Criterion	The search method of lsqnonlin supports the Trace criterion only. Use for multiple-output models only. Criterion can have the following values:

Property Name	Description
	• 'Det': Minimize det(E'*E), where E represents the prediction error. This is the optimal choice in a statistical sense and leads to the maximum likelihood estimates in case nothing is known about the variance of the noise. It uses the inverse of the estimated noise variance as the weighting function. This is the default criterion used for all models, except idnlgrey which uses 'Trace' by default. • 'Trace': Minimize the trace of the weighted prediction error matrix trace(E'*E*W), where E is the matrix of prediction errors, with one column for each output, and W is a positive semi-definite symmetric matrix of size equal to the number of outputs. By default, W is an identity matrix of size equal to the number of model outputs (so the minimization criterion becomes trace(E'*E), or the traditional least-squares criterion). You can specify the relative weighting of prediction errors for each output using the Weighting field of the Algorithm property. If the model contains neuralnet or treepartition as one of its nonlinearity estimators, weighting is not applied because estimations are independent for each output. Both the Det and Trace criteria are derived from a general requirement of minimizing a weighted sum of least squares of prediction errors. Det can be interpreted as estimating the covariance matrix of the noise source and using the inverse of that matrix as the weighting. You should specify the weighting when using the Trace criterion. If you want to achieve better accuracy for a particular channel in MIMO models, use Trace with weighting that favors that channel. Otherwise, use Det. If you use Det, check cond(model.NoiseVariance) after estimation. If the matrix is ill-conditioned, try using the Trace criterion. You can also use compare on validation data to check whether the relative

Property Name	Description
	error for different channels corresponds to your needs or expectations. Use the `Trace` criterion if you need to modify the relative errors, and check `model.NoiseVariance` to determine what weighting modifications to specify.
`IterWavenet`	(For `wavenet` nonlinear estimator only) Toggles performing iterative or noniterative estimation. Default: `'auto'`. Assignable values: • `'auto'` — First estimation is noniterative and subsequent estimation are iterative. • `'On'` — Perform iterative estimation only. • `'Off'` — Perform noniterative estimation only.
`LimitError`	Robustification criterion that limits the influence of large residuals, specified as a positive real value. Residual values that are larger than `'LimitError'` times the estimated residual standard deviation have a linear cost instead of the usual quadratic cost. Default: `0` (no robustification).
`MaxIter`	Maximum number of iterations for the estimation algorithm, specified as a positive integer. Default: `20`.

Property Name	Description
MaxSize	The number of elements (size) of the largest matrix to be formed by the algorithm. Computational loops are used for larger matrices. Use this value for memory/speed trade-off.MaxSize can be any positive integer. Default: 250000. **Note** The original data matrix of *u* and *y* must be smaller than MaxSize.
SearchMethod	Method used by the iterative search algorithm. Assignable values: • 'Auto' — Automatically chooses from the following methods. • 'gn' — Subspace Gauss-Newton method. • 'gna' — Adaptive Gauss-Newton method. • 'grad' — A gradient method. • 'lm' — Levenberg-Marquardt method. • 'lsqnonlin' — Nonlinear least-squares method (requires the Optimization Toolbox product). This method only handles the 'Trace' criterion.
Tolerance	Specifies to terminate the iterative search when the expected improvement of the parameter values is less than Tolerance, specified as a positive real value in %. Default: 0.01.

Property Name	Description
Display	Toggles displaying or hiding estimation progress information in theMATLAB Command Window. Default: 'Off'. Assignable values: • 'Off' — Hide estimation information. • 'On' — Display estimation information.
Weighting	(For multiple-output models only) Specifies the relative importance of outputs in MIMO models (or reliability of corresponding data) as a positive semi-definite matrix W. Use when Criterion = 'Trace' for weighted trace minimization. By default, Weighting is an identity matrix of size equal to the number of outputs.

idnlarx Advanced Algorithm Properties

The following table summarizes the fields of the Algorithm.Advanced model properties. The fields in the Algorithm.Advanced structure specify additional estimation-algorithm options.

Property Name	Description
GnPinvConst	When the search direction is computed, the algorithm discards the singular values of the Jacobian that are smaller than GnPinvConst*max(size(J))*norm(J)*eps. Singular values that are closer to 0 are included when GnPinvConst is decreased. Default: 1e4. Assign a positive, real value.
LMStartValue	(For Levenberg-Marquardt search algorithm) The starting level of *regularization* when using the Levenberg-Marquardt search method (Algorithm.SearchMethod='lm'). Default: 0.001. Assign a positive real value.

Property Name	Description
`LMStep`	(For Levenberg-Marquardt search algorithm) Try this next level of *regularization* to get a lower value of the criterion function. The level of regularization is `LMStep` times the previous level. At the start of a new iteration, the level of regularization is computed as `1/LMStep` times the value from the previous iteration. Default: `10`. Assign a real value `>1`.
`MaxBisections`	Maximum number of bisections performed by the line search algorithm along the search direction (number of rotations of search vector for `'lm'`). Used by `'gn'`, `'lm'`, `'gna'` and `'grad'` search methods (`Algorithm.SearchMethod` property) Default: `10`. Assign a positive integer value.
`MaxFunEvals`	The iterations are stopped if the number of calls to the model file exceeds this value. Default: `Inf`. Assign a positive integer value.
`MinParChange`	The smallest parameter update allowed per iteration. Default: `1e-16`. Assign a positive, real value.
`RelImprovement`	The iterations are stopped if the relative improvement of the criterion function is less than `RelImprovement`. Default: `0`. Assign a positive real value. **Note** Does not apply to `Algorithm.SearchMethod='lsqnonlin'`
`StepReduction`	(For line search algorithm) The suggested parameter update is reduced by the factor `'StepReduction'` after each try until either `'MaxBisections'` tries are completed or a lower value

Property Name	Description
	of the criterion function is obtained. Default: `2`. Assign a positive, real value `>1`. **Note** Does not apply to `Algorithm.SearchMethod='lsqnonlin'`

idnlarx EstimationInfo Properties

The following table summarizes the fields of the `EstimationInfo` model properties. The read-only fields of the `EstimationInfo` structure store estimation settings and results.

Property Name	Description
`Status`	Shows whether the model parameters were estimated.
`Method`	Shows the estimation method.
`LossFcn`	Value of the loss function, equal to `det(E'*E/N)`, where `E` is the residual error matrix (one column for each output) and `N` is the total number of samples.
`FPE`	Value of Akaike's Final Prediction Error (see `fpe`).
`DataName`	Name of the data from which the model is estimated.
`DataLength`	Length of the estimation data.
`DataTs`	Sampling interval of the estimation data.
`DataDomain`	`'Time'` means time domain data. `'Frequency'` is not supported.

Property Name	Description
`DataInterSample`	Intersample behavior of the input estimation data used for interpolation: • `'zoh'` means zero-order-hold, or piecewise constant. • `'foh'` means first-order-hold, or piecewise linear.
`EstimationTime`	Duration of the estimation.
`InitRandState`	The value of `randn('state')` at the last randomization of the initial parameter vector.
`Iterations`	Number of iterations performed by the estimation algorithm.
`UpdateNorm`	Norm of the Gauss-Newton in the last iteration. Empty when `'lsqnonlin'` is the search method.
`LastImprovement`	Criterion improvement in the last iteration, shown in %. Empty when `'lsqnonlin'` is the search method.
`Warning`	Any warnings encountered during parameter estimation.
`WhyStop`	Reason for terminating parameter estimation iterations.

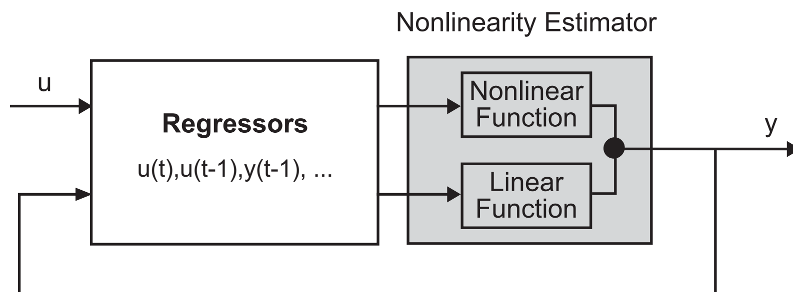
Nonlinear ARX Model Structure

This block diagram represents the structure of a nonlinear ARX model:



The nonlinear ARX model computes the output y in two stages:

1. Computes regressors from the current and past input values and past output data.

   In the simplest case, regressors are delayed inputs and outputs, such as *u(t-1)* and *y(t-3)*—called *standard* regressors. You can also specify *custom* regressors, which are nonlinear functions of delayed inputs and outputs. For example, $\tan(u(t\text{-}1))$ or $u(t\text{-}1)*y(t\text{-}3)$.

   By default, all regressors are inputs to both the linear and the nonlinear function blocks of the nonlinearity estimator. You can choose a subset of regressors as inputs to the nonlinear function block.

2. The nonlinearity estimator block maps the regressors to the model output using a combination of nonlinear and linear functions. You can select from available nonlinearity estimators, such as tree-partition networks, wavelet networks, and multi-layer neural networks. You can also exclude either the linear or the nonlinear function block from the nonlinearity estimator.

The nonlinearity estimator block can include linear and nonlinear blocks in parallel. For example:

$$F(x) = L^T(x-r) + d + g\left(Q(x-r)\right)$$

x is a vector of the regressors. $L^T(x) + d$ is the output of the linear function block and is affine when d≠0. d is a scalar offset. $g\left(Q(x-r)\right)$ represents the output of the nonlinear function block. r is the mean of the regressors x. Q is a projection matrix that makes the calculations well conditioned. The exact form of $F(x)$ depends on your choice of the nonlinearity estimator.

Estimating a nonlinear ARX model computes the model parameter values, such as L, r, d, Q, and other parameters specifying g. Resulting models are `idnlarx` objects that store all model data, including model regressors and parameters of the nonlinearity estimator. See the `idnlarx` reference page for more information.

Definition of idnlarx States

The states of an `idnlarx` object are delayed input and output variables that define the structure of the model. This toolbox requires states for simulation and prediction using `sim(idnlarx)`, `predict(idnlarx)`, and `compare`. States are also necessary for linearization of nonlinear ARX models using `linearize(idnlarx)`.

This toolbox provides a number of options to facilitate how you specify the initial states. For example, you can use `findstates` and `data2state` to automatically search for state values in simulation and prediction applications. For linearization, use `findop`. You can also specify the states manually.

The states of an `idnlarx` model are defined by the maximum delay in each input and output variable used by the regressors. If a variable p has a maximum delay of D samples, then it contributes D elements to the state vector at time t: $p(t\text{-}1)$, $p(t\text{-}2)$, ..., $p(t\text{-}D)$.

For example, if you have a single-input, single-output `idnlarx` model:

```
m = idnlarx([2 3 0],'wavenet', ...
                    'CustomRegressors', ...
                    {'y1(t-10)*u1(t-1)'});
```

This model has these regressors:

```
getreg(m)

Regressors:
    y1(t-1)
    y1(t-2)
    u1(t)
    u1(t-1)
    u1(t-2)
    y1(t-10)*u1(t-1)
```

The regressors show that the maximum delay in the output variable `y1` is 10 samples and the maximum delay in the input `u1` is 2 samples. Thus, this model has a total of 12 states:

```
X(t) = [y1(t-1),y2(t-2), ,y1(t-10),u1(t-1),u1(t-2)]
```

Note The state vector includes the output variables first, followed by input variables.

As another example, consider the 2-output and 3-input model:

```
m = idnlarx([2 0 2 2 1 1 0 0; 1 0 1 5 0 1 1 0], ...
            [wavenet; linear])
```

`getreg` lists these regressors:

```
getreg(m)

Regressors:
  For output 1:
    y1(t-1)
    y1(t-2)
    u1(t-1)
    u1(t-2)
    u2(t)
    u2(t-1)
    u3(t)
  For output 2:
    y1(t-1)
    u1(t-1)
    u2(t-1)
    u2(t-2)
    u2(t-3)
    u2(t-4)
    u2(t-5)
```

The maximum delay in output variable y1 is 2 samples, which occurs in regressor set for output 1. The maximum delays in the three input variables are 2, 5, and 0, respectively. Thus, the state vector is:

```
X(t) = [y1(t-1), y1(t-2), u1(t-1), u1(t-2), u2(t-1),
            u2(t-2), u2(t-3), u2(t-4), u2(t-5)]
```

Variables y2 and u3 do not contribute to the state vector because the maximum delay in these variables is zero.

A simpler way to determine states by inspecting regressors is to use getDelayInfo, which returns the maximum delays in all I/O variables across all model outputs. For the multiple-input multiple-output model m, getDelayInfo returns:

```
maxDel = getDelayInfo(m)
maxDel =
     2     0     2     5     0
```

maxDel contains the maximum delays for all input and output variables in the order (y1, y2, u1, u2, u3). The total number of model states is sum(maxDel) = 9.

The set of states for an idnlarx model are not required to be minimal.

Examples

Create nonlinear ARX model structure with (default) wavelet network nonlinearity:

```
m = idnlarx([2 2 1]) % na=nb=2 and nk=1
```

Create nonlinear ARX model structure with sigmoid network nonlinearity:

```
m=idnlarx([2 3 1],sigmoidnet('Num',15))
% number of units is 15
```

Create nonlinear ARX model structure with no nonlinear function in nonlinearity estimator:

```
m=idnlarx([2 2 1],[])
```

Construct a nonlinear ARX model using a linear ARX model:

```
% Construct a linear ARX model.
A = [1 -1.2 0.5];
B = [0.8 1];
LinearModel = idpoly(A, B, 'Ts', 0.1);

% Construct nonlinear ARX model using the linear ARX model.
m1 = idnlarx(LinearModel)
```

How To

- “Identifying Nonlinear ARX Models”
- “Using Linear Model for Nonlinear ARX Estimation”

Purpose

Nonlinear ODE (grey-box model) with unknown parameters

Syntax

```
m = idnlgrey('filename',Order,Parameters)
m = idnlgrey('filename',Order,Parameters,InitialStates)
m = idnlgrey('filename',Order,Parameters,InitialStates,Ts)
m = idnlgrey('filename',Order,Parameters,InitialStates,
Ts,P1,V1,...,PN,VN)
```

Description

`idnlgrey` is an object that represents the nonlinear grey-box model.

For information about the nonlinear grey-box models, see "Estimating Nonlinear Grey-Box Models".

The information in these reference pages summarizes the `idnlgrey` model constructor and properties. It discusses the following topics:

- "idnlgrey Constructor" on page 2-193
- "idnlgrey Properties" on page 2-194
- "idnlgrey Advanced Algorithm Properties" on page 2-201
- "idnlgrey Simulation Options" on page 2-203
- "idnlgrey Gradient Options" on page 2-206
- "idnlgrey EstimationInfo Properties" on page 2-207

idnlgrey Constructor

Use the following syntax to define the `idnlgrey` model object:

```
m = idnlgrey('filename',Order,Parameters)
```

```
m = idnlgrey('filename',Order,Parameters,InitialStates)
```

```
m = idnlgrey('filename',Order,Parameters,InitialStates,Ts)
```

```
m =
idnlgrey('filename',Order,Parameters,InitialStates,Ts,P1,V1,...,PN,VN)
```

The `idnlgrey` arguments are defined as follows:

- `'filename'` — Name of the function or MEX-file storing the model structure (ODE file).
- `Order` — Vector with three entries `[Ny Nu Nx]`, specifying the number of model outputs `Ny`, the number of inputs `Nu`, and the number of states `Nx`.
- `Parameters` — Parameters, specified as `struct` arrays, cell arrays, or double arrays.
- `InitialStates` — Specified in a same way as parameters. Must be fourth input to the `idnlgrey` constructor.
- The command

  ```
  m = idnlgrey('filename',Order,Parameters,...
                InitialStates,Ts,P1,V1,...,PN,VN)
  ```

  specifies `idnlgrey` property-value pairs. See information on properties of `idnlgrey` objects below.

Estimate the parameters of this object using `pem`.

idnlgrey Properties

You can include property-value pairs in the model estimator or constructor to specify the model structure and estimation algorithm properties.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% Get the model time unit
get(m,'TimeUnit')
m.TimeUnit
```

The following table summarizes `idnlgrey` model properties. The general `idnlmodel` properties also apply to this nonlinear model object (see the corresponding reference pages).

Property Name	Description
`Algorithm`	A structure that specifies the estimation algorithm options, as described in "idnlgrey Algorithm Properties" on page 2-198.
`CovarianceMatrix`	Covariance matrix of the estimated `Parameters`. Assignable values: • `'None'` to omit computing uncertainties and save time during parameter estimation. • `'Estimate'` to estimation covariance. Symmetric and positive N_p-by-N_p matrix (or `[]`) where N_p is the number of free model parameters.
`EstimationInfo`	A read-only structure that stores estimation settings and results, as described in "idnlgrey EstimationInfo Properties" on page 2-207.
`FileArgument`	Contains auxiliary variables passed to the ODE file (function or MEX-file) specified in `FileName`. These variables may be used as extra inputs for specifying the state and/or output equations. `FileArgument` should be specified as a cell array. Default: `{}`.
`FileName`	File name string (without extension) or a function handle for computing the states and the outputs. If `'FileName'` is a string, then it must point to an MATLAB file or MEX-file. For more information about the file variables, see "Specifying the Nonlinear Grey-Box Model Structure".

Property Name	Description

`InitialStates`	An `Nx`-by-1 structure array with fields as follows. Here, `Nx` is the number of states of the model.
	
	• `Name`: Name of the state (a string). Default value is `'x#i'`, where `#i` is an integer in `[1, Nx]`.
	• `Unit`: Unit of the state (a string). Default value is `''`.
	• `Value`: Initial value of the initial state(s). Assignable values are:
	  - A finite real scalar
	  - A finite real 1-by-Ne vector, where `Ne` is the number of experiments in the data set to be used for estimation
	• `Minimum`: Minimum value of the initial state(s). Must be a real scalar/1-by-`Ne` vector of the same size as Value and such that Minimum <= Value for all components. Default value: `-Inf(size(Value))`.
	• `Maximum`: Maximum value of the initial state(s). Must be a real scalar/1-by-`Ne` vector of the same size as `Value` and such that `Value` <= `Maximum` for all components. Default value: `Inf(size(Value))`.
	• `Fixed`: Specifies which component(s) of the initial state(s) are fixed to their known values. Must be a Boolean scalar/1-by-`Ne` vector of the same size as `Value`. Default value: `true(size(Value))` (that is, do not estimate the initial states).
	
	For an `idnlgrey` model `M`, the `i`th initial state is accessed through `M.InitialStates(i)` and its subfields as `M.InitialStates(i).FIELDNAME`.

Property Name	Description
`Order`	Structure with following fields: • `ny` — Number of outputs of the model structure. • `nu` — Number of inputs of the model structure. • `nx` — Number of states of the model structure. For time series, `nu` is 0. For static model structures, `nx` is 0.

`Parameters`	`Np`-by-1 structure array with information about the model parameters containing the following fields:
	
	• `Name`: Name of the parameter (a string). Default value is `'p#i'`, where `#i` is an integer in `[1, Np]`.
	• `Unit`: Unit of the parameter (a string). Default value is `''`.
	• `Value`: Initial value of the parameter(s). Assignable values are:
	  - A finite real scalar
	  - A finite real column vector
	  - A 2-dimensional real matrix
	• `Minimum`: Minimum value of the parameter(s). Must be a real scalar/column vector/matrix of the same size as `Value` and such that `Minimum` <= `Value` for all components. Default value: `-Inf(size(Value))`.
	• `Maximum`: Maximum value of the parameter(s). Must be a real scalar/column vector/matrix of the same size as `Value` and such that `Value` <= `Maximum` for all components. Default value: `Inf(size(Value))`.
	• `Fixed`: Specifies which component(s) of the parameter(s) are fixed to their known values. Must be a Boolean scalar/column vector/matrix of the same size as `Value`.

Property Name	Description
	Default value: `false(size(Value))`, (estimate all parameter components). For an `idnlgrey` model `M`, the `i`th parameter is accessed through `M.Parameters(i)` and its subfields as `M.Parameters(i).FIELDNAME`.

idnlgrey Algorithm Properties

The following table summarizes the fields of the `Algorithm` `idnlgrey` model properties. `Algorithm` is a structure that specifies the estimation-algorithm options.

Property Name	Description
`Advanced`	A structure that specifies additional estimation algorithm options, as described in "idnlgrey Advanced Algorithm Properties" on page 2-201.
`Criterion`	Specifies criterion used during minimization. `Criterion` can have the following values: • `'Det'`: Minimize `det(E'*E)` where `E` represents the prediction error. This is the optimal choice in a statistical sense and leads to the maximum likelihood estimates in case nothing is known about the variance of the noise. It uses the inverse of the estimated noise variance as the weighting function. This is the default criterion used for all models, except `idnlgrey` which uses `'Trace'` by default. • `'Trace'`: Minimize the trace of the weighted prediction error matrix `trace(E'*E*W)`, where `E` is the matrix of prediction errors, with one column for each output, and `W` is a positive semi-definite symmetric matrix of size equal to the number of outputs. By default, `W` is an identity matrix of size equal to the number of model outputs (so the minimization criterion becomes `trace(E'*E)`, or the traditional least-sum-of-squared-errors criterion. You can

Property Name	Description
	specify the relative weighting of prediction errors for each output using the `Weighting` field of the `Algorithm` property.
`LimitError`	Robustification criterion that limits the influence of large residuals, specified as a positive real value. Residual values that are larger than `'LimitError'` times the estimated residual standard deviation have a linear cost instead of the usual quadratic cost. Default: `0` (no robustification).
`MaxIter`	Maximum number of iterations for the estimation algorithm, specified as a positive integer. Default: `20`.
`SearchMethod`	Method used by the iterative search algorithm. Assignable values: • `'Auto'` — Automatically chooses from the following methods. • `'gn'` — Gauss-Newton method. • `'gna'` — Adaptive Gauss-Newton method. • `'grad'` — A gradient method. • `'lm'` — Levenberg-Marquardt method. • `'lsqnonlin'` — Nonlinear least-squares method (requires the Optimization Toolbox product). This method handles only the `'Trace'` criterion.
`Tolerance`	Specifies to terminate the iterative search when the expected improvement of the parameter values is less than `Tolerance`, specified as a positive real value in %. Default: `0.01`.
`GradientOptions`	A structure that specifies the options related to calculation of gradient of the cost, "idnlgrey Gradient Options" on page 2-206.

Property Name	Description
SimulationOptions	A structure that specifies the simulation method and related options, as described in "idnlgrey Simulation Options" on page 2-203.
Display	Toggles displaying or hiding estimation progress information in the MATLAB Command Window. Default: 'Off'. Assignable values: • 'Off' — Hide estimation information. • 'On' — Display estimation information.
Weighting	Positive semi-definite matrix W used for weighted trace minimization. When Criterion = 'Trace', trace(E'*E*W) is minimized. Weighting can be used to specify relative importance of outputs in multiple-input multiple-output models (or reliability of corresponding data) when W is a diagonal matrix of nonnegative values. Weighting is not useful in single-output models. By default, Weighting is an identity matrix of size equal to the number of outputs.

Note The `Criterion` property setting is meaningful in multiple-output cases only. In single-output models, the two criteria are equivalent. Both the `Det` and `Trace` criteria are derived from a general requirement of minimizing a weighted sum of least squares of prediction errors. The `Det` criterion can be interpreted as estimating the covariance matrix of the noise source and using the inverse of that matrix as the weighting. You should specify the weighting when using the `Trace` criterion.

If you want to achieve better accuracy for a particular channel in multiple-input multiple-output models, you should use `Trace` with weighting that favors that channel. Otherwise it is natural to use `Det`. When using `Det` you can check `cond(model.NoiseVariance)` after estimation. If the matrix is ill-conditioned, it may be more robust to use the `Trace` criterion. You can also use `compare` on validation data to check whether the relative error for different channels corresponds to your needs or expectations. Use the `Trace` criterion if you need to modify the relative errors, and check `model.NoiseVariance` to determine what weighting modifications to specify.

The search method of `lsqnonlin` supports the `Trace` criterion only.

idnlgrey Advanced Algorithm Properties

The following table summarizes the fields of the `Algorithm.Advanced` model properties. The fields in the `Algorithm.Advanced` structure specify additional estimation-algorithm options.

Property Name	Description
GnPinvConst	When the search direction is computed, the algorithm discards the singular values of the Jacobian that are smaller than GnPinvConst*max(size(J))*norm(J)*eps. Singular values that are closer to 0 are included when GnPinvConst is decreased. Default: 1e4. Assign a positive, real value.
LMStartValue	(For Levenberg-Marquardt search algorithm) The starting level of *regularization* when using the Levenberg-Marquardt search method (Algorithm.SearchMethod='lm'). Default: 0.001. Assign a positive real value.
LMStep	(For Levenberg-Marquardt search algorithm) Try this next level of *regularization* to get a lower value of the criterion function. The level of regularization is LMStep times the previous level. At the start of a new iteration, the level of regularization is computed as 1/LMStep times the value from the previous iteration. Default: 10. Assign a real value >1.
MaxBisections	Maximum number of bisections performed by the line search algorithm along the search direction (number of rotations of search vector for 'lm'). Used by 'gn', 'lm', 'gna' and 'grad' search methods (Algorithm.SearchMethod property) Default: 25. Assign a positive integer value.
MaxFunEvals	The iterations are stopped if the number of calls to the model file exceeds this value. Default: Inf. Assign a positive integer value.

Property Name	Description
`MinParChange`	The smallest parameter update allowed per iteration. Default: `1e-16`. Assign a positive, real value.
`RelImprovement`	The iterations are stopped if the relative improvement of the criterion function is less than `RelImprovement`. Default: `0`. Assign a positive real value. **Note** Does not apply to `Algorithm.SearchMethod='lsqnonlin'`
`StepReduction`	(For line search algorithm) The suggested parameter update is reduced by the factor `'StepReduction'` after each try until either `'MaxBisections'` tries are completed or a lower value of the criterion function is obtained. Default: `2`. Assign a positive, real value `>1`. **Note** Does not apply to `Algorithm.SearchMethod='lsqnonlin'`

idnlgrey Simulation Options

The following table summarizes the fields of `Algorithm.SimulationOptions` model properties.

Property Name	Description
`AbsTol`	Absolute error tolerance. This scalar applies to all components of the state vector. `AbsTol` applies only to the variable step solvers. Default: `1e-6`. Assignable value: A positive real value.
`FixedStep`	(For fixed-step time-continuous solvers) Step size used by the solver. Default: `'Auto'`. Assignable values: • `'Auto'` — Automatically chooses the initial step. • A real value such that `0<FixedStep<=1`.
`InitialStep`	(For variable-step time-continuous solvers) Specifies the initial step at which the ODE solver starts. Default: `'Auto'`. Assignable values: • `'Auto'` — Automatically chooses the initial step. • A positive real value such that `MinStep<=InitialStep<=MaxStep`.
`MaxOrder`	(For ode15s) Specifies the order of the Numerical Differentiation Formulas (NDF). Default: `5`. Assignable values: 1, 2, 3, 4 or 5.
`MaxStep`	(For variable-step time-continuous solvers) Specifies the largest time step of the ODE solver. Default: `'Auto'` — 1/15 of the simulation interval. Assignable values: • `'Auto'` — Automatically chooses the time step. • A positive real value > `MinStep`.

<table>
<tr><th>Property Name</th><th>Description</th></tr>
<tr><td>MinStep</td><td>(For variable-step time-continuous solvers) Specifies the smallest time step of the ODE solver.
Default: 'Auto'.
Assignable values:
• 'Auto' — Automatically chooses the time step.
• A positive real value < MaxStep.</td></tr>
<tr><td>RelTol</td><td>(For variable-step time-continuous solvers) Relative error tolerance that applies to all components of the state vector. The estimated error in each integration step satisfies |e(i)| <= max(RelTol*abs(x(i)), AbsTol(i)).
Default: 1e-3 (0.1% accuracy).
Assignable value: A positive real value.</td></tr>
<tr><td>Solver</td><td>ODE (Ordinary Differential/Difference Equation) solver for solving state space equations.
A. Variable-step solvers for time-continuous idnlgrey models:
• 'ode45' — Runge-Kutta (4,5) solver for nonstiff problems.
• 'ode23' — Runge-Kutta (2,3) solver for nonstiff problems.
• 'ode113' — Adams-Bashforth-Moulton solver for nonstiff problems.
• 'ode15s' — Numerical Differential Formula solver for stiff problems.
• 'ode23s' — Modified Rosenbrock solver for stiff problems.
• 'ode23t' — Trapezoidal solver for moderately stiff problems.
• 'ode23tb' — Implicit Runge-Kutta solver for stiff problems.
B. Fixed-step solvers for time-continuous idnlgrey models:
• 'ode5' — Dormand-Prince solver.</td></tr>
</table>

Property Name	Description
	• 'ode4' — Fourth-order Runge-Kutta solver. • 'ode3' — Bogacki-Shampine solver. • 'ode2' — Heun or improved Euler solver. • 'ode1' — Euler solver. C. Fixed-step solvers for time-discrete `idnlgrey` models: `'FixedStepDiscrete'` D. General: `'Auto'` — Automatically chooses one of the previous solvers (default).

idnlgrey Gradient Options

The following table summarizes the fields of the `Algorithm.GradientOptions` model properties. `Algorithm` is a structure that specifies the estimation-algorithm options.

Property Name	Description
`DiffMaxChange`	Largest allowed parameter perturbation when computing numerical derivatives. Default: `Inf`. Assignable value: A positive real value `>'DiffMinChange'`.
`DiffMinChange`	Smallest allowed parameter perturbation when computing numerical derivatives. Default: `0.01*sqrt(eps)`. Assignable value: A positive real value `<'DiffMaxChange'`.

Property Name	Description
`DiffScheme`	Method for computing numerical derivatives with respect to the components of the parameters and/or the initial state(s) to form the Jacobian. Default: `'Auto'` Assignable values: • `'Auto'` - Automatically chooses from the following methods. • `'Central approximation'` • `'Forward approximation'` • `'Backward approximation'`
`GradientType`	Method used when computing derivatives (Jacobian) of the parameters or the initial states to be estimated. Default: `'Auto'`. Assignable values: • `'Auto'` — Automatically chooses from the following methods. • `'Basic'` — Individually computes all numerical derivatives required to form each column of the Jacobian. • `'Refined'` — Simultaneously computes all numerical derivatives required to form each column of the Jacobian.

idnlgrey EstimationInfo Properties

The following table summarizes the fields of the `EstimationInfo` model properties. The read-only fields of the `EstimationInfo` structure store estimation settings and results.

Property Name	Description
Status	Shows whether the model parameters were estimated.
Method	Names of the solver and the optimizer used during estimation.
LossFcn	Value of the loss function, equal to det(E'*E/N), where E is the residual error matrix (one column for each output) and N is the total number of samples. Provides a quantitative description of the model quality.
FPE	Value of Akaike's Final Prediction Error (see fpe).
DataName	Name of the data from which the model is estimated.
DataLength	Length of the estimation data.
DataTs	Sampling interval of the estimation data.
DataDomain	'Time' means time domain data. 'Frequency' is not supported.
DataInterSample	Intersample behavior of the input estimation data used for interpolation: • 'zoh' means zero-order-hold, or piecewise constant. • 'foh' means first-order-hold, or piecewise linear.
EstimationTime	Duration of the estimation.
InitialGuess	Structure with the fields InitialStates and Parameters, specifying the values of these quantities before the last estimation.
Iterations	Number of iterations performed by the estimation algorithm.
LastImprovement	Criterion improvement in the last iteration, shown in %. Empty when SearchMethod='lsqnonlin' is the search method.

Property Name	Description
`UpdateNorm`	Norm of the search vector (Gauss-Newton vector) at the last iteration. Empty when `'lsqnonlin'` is the search method.
`Warning`	Any warnings encountered during parameter estimation.
`WhyStop`	Reason for terminating parameter estimation iterations.

Definition of idnlgrey States

The states of an `idnlgrey` model are defined explicitly by the user in the function or MEX-file (as specified in the `FileName` property of the model) storing the model structure . The concept of states is useful for functions such as `sim`, `predict`, `compare`, and `findstates`.

Note The initial values of the states are configured by the `InitialStates` property of the `idnlgrey` model.

m = idnlhw(LinModel,InputNL,OutputNL,'PropertyName',
   PropertyValue)
```

Description

Represents Hammerstein-Wiener models. The Hammerstein-Wiener structure represents a linear model with input-output nonlinearities.

Typically, you use the `nlhw` command to both construct the `idnlhw` object and estimate the model parameters. You can configure the model properties directly in the `nlhw` syntax. For information about the Hammerstein-Wiener model structure, see "Structure of Hammerstein-Wiener Models".

You can also use the `idnlhw` constructor to create the Hammerstein-Wiener model structure and then estimate the parameters of this model using `pem`.

For `idnlhw` object properties, see:

- "idnlhw Model Properties" on page 2-213
- "idnlhw Algorithm Properties" on page 2-214
- "idnlhw Advanced Algorithm Properties" on page 2-218
- "idnlhw EstimationInfo Properties" on page 2-220

Construction

`m = idnlhw([nb nf nk])` creates an `idnlhw` object using default piecewise linear functions for the input and output nonlinearity estimators. *`nb`*, *`nf`*, and *`nk`* are positive integers that specify model orders and delays. *`nb`* is the number of zeros plus 1, *`nf`* is the number of poles, and *`nk`* is the input delay.

m = `idnlhw([`*nb nf nk*`],`*InputNL*`,`*OutputNL*`)` specifies input nonlinearity *InputNL* and output nonlinearity *OutputNL*, as a nonlinearity estimator object or string representing the nonlinearity estimator type.

m = `idnlhw([`*nb nf nk*`],`*InputNL*`,`*OutputNL*`,'`*PropertyName*`',`*PropertyValue*`)` creates the object using options specified as `idnlhw` property name and value pairs. Specify *PropertyName* inside single quotes.

m = `idnlhw(`*LinModel*`)` uses a linear model (in place of [*nb nf nk*]) and default piecewise linear functions for the input and output nonlinearity estimators. *LinModel* is a discrete time input-output polynomial model of Output-Error (OE) structure (`idpoly`) or state-space model with no disturbance component (`idss` with $K = 0$) for single-output systems, and `idss` model with $K = 0$ for multi-output systems. *LinModel* sets the model orders, input delay, B and F polynomial values, input-output names and units, sampling time, and time units of *m*.

m = `idnlhw(`*LinModel*`,`*InputNL*`,`*OutputNL*`)` specifies input nonlinearity *InputNL* and output nonlinearity *OutputNL*.

m = `idnlhw(`*LinModel*`,`*InputNL*`,`*OutputNL*`,'`*PropertyName*`',`*PropertyValue*`)` creates the object using options specified as `idnlhw` property name and value pairs.

Input Arguments

nb, *nf*, *nk*

Model orders and input delay, where *nb* is the number of zeros plus 1, *nf* is the number of poles, and *nk* is the input delay.

For `nu` inputs and `ny` outputs, `nb`, `nf`, and, `nk` are `ny`-by-`nu` matrices whose *i*-*j*th entry specifies the orders and delay of the transfer function from the *j*th input to the *i*th output.

InputNL, *OutputNL*

Input and output nonlinearity estimators, respectively, specified as a nonlinearity estimator object or string representing the nonlinearity estimator type.

`'pwlinear'` or `pwlinear` object (default)	Piecewise linear function
`'sigmoidnet'` or `sigmoidnet` object	Sigmoid network
`'wavenet'` or `wavenet` object	Wavelet network
`'saturation'` or `saturation` object	Saturation
`'deadzone'` or `deadzone` object	Dead zone
`'poly1d'` or `poly1d` object	One-dimensional polynomial
`'unitgain'` or `unitgain` object	Unit gain
`customnet` object	Custom network

Specifying a string creates a nonlinearity estimator object with default settings. Use object representation to configure the properties of a nonlinearity estimator.

For `ny` output channels, you can specify nonlinear estimators individually for each output channel by setting *`InputNL`* or *`OutputNL`* to an `ny`-by-1 cell array or object array of nonlinearity estimators. To specify the same nonlinearity for all outputs, specify a single input and output nonlinearity estimator.

`LinModel`

Discrete time linear model, typically estimated using the `oe` or `n4sid` command:

- Input-output polynomial model of Output-Error (OE) structure (`idpoly`) or state-space model with no disturbance component (`idss` with $K = 0$), for single-output systems

- State-space model with no disturbance component (`idss` model with $K = 0$), for multi-output systems

idnlhw Model Properties

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% Get the model B parameters
get(m,'b')
% Get value of InputNonlinearity property
m.InputNonlinearity
```

You can specify property name-value pairs in the model estimator or constructor to specify the model structure and estimation algorithm.

The following table summarizes `idnlhw` model properties. The general `idnlmodel` properties also apply to this nonlinear model object (see the corresponding reference page).

Property Name	Description
`Algorithm`	A structure that specifies the estimation algorithm options, as described in "idnlhw Algorithm Properties" on page 2-214.
`b`	B polynomial as a cell array of `Ny`-by-`Nu` elements, where `Ny` is the number of outputs and `Nu` is the number of inputs. An element `b{i,j}` is a row vector representing the numerator polynomial for the `j`th input to `i`th output transfer function. It contains as many leading zeros as there are input delays.
`f`	F polynomial as a cell array of `Ny`-by-`Nu` elements, where `Ny` is the number of outputs and `Nu` is the number of inputs. An element `f{i,j}` is a row vector representing the denominator polynomial for the `j`:th input to `i`th output transfer function.
`LinearModel`	(Read only) The linear model in the linear block. For single output, represented as an `idpoly` object. For multiple output, represented as an `idss` object.

Property Name	Description
`EstimationInfo`	(Read-only) Structure that stores estimation settings and results, as described in "idnlhw EstimationInfo Properties" on page 2-220.
`InputNonlinearity`	Nonlinearity estimator object. Assignable values include `pwlinear` (default), `deadzone`, `wavenet`, `saturation`, `customnet`, `sigmoidnet`, `poly1d`, and `unitgain`. For more information, see the corresponding reference pages. For `ny` outputs, `Nonlinearity` is an `ny`-by-1 array, such as `[sigmoidnet;wavenet]`. However, if you specify a scalar object, this nonlinearity object applies to all outputs.
`OutputNonlinearity`	Same as `InputNonlinearity`.

`nb`
`nf`
`nk`
	Model orders and input delays, where `nb` is the number of zeros plus 1, `nf` is the number of poles, and `nk` is the delay from input to output in terms of the number of samples.
	
	For `nu` inputs and `ny` outputs, `nb`, `nf` and, `nk` are `ny`-by-`nu` matrices whose *i*-*j*th entry specifies the orders and delay of the transfer function from the *j*th input to the *i*th output.

idnlhw Algorithm Properties

The following table summarizes the fields of the `Algorithm` `idnlhw` model properties. `Algorithm` is a structure that specifies the estimation-algorithm options.

Property Name	Description
`Advanced`	A structure that specifies additional estimation algorithm options, as described in "idnlhw Advanced Algorithm Properties" on page 2-218.
`Criterion`	The search method of `lsqnonlin` supports the `Trace` criterion only. Use for multiple-output models only. `Criterion` can have the following values: • `'Det'`: Minimize `det(E'*E)`, where `E` represents the prediction error. This is the optimal choice in a statistical sense and leads to the maximum likelihood estimates in case nothing is known about the variance of the noise. It uses the inverse of the estimated noise variance as the weighting function. This is the default criterion used for all models, except `idnlgrey` which uses `'Trace'` by default. • `'Trace'`: Minimize the trace of the weighted prediction error matrix `trace(E'*E*W)`, where `E` is the matrix of prediction errors, with one column for each output, and `W` is a positive semi-definite symmetric matrix of size equal to the number of outputs. By default, `W` is an identity matrix of size equal to the number of model outputs (so the minimization criterion becomes `trace(E'*E)`, or the traditional least-squares criterion). You can specify the relative weighting of prediction errors for each output using the `Weighting` field of the `Algorithm` property. If the model contains `neuralnet` or `treepartition` as one of its nonlinearity estimators, weighting is not applied because estimations are independent for each output. Both the `Det` and `Trace` criteria are derived from a general requirement of minimizing a weighted sum of least squares of prediction errors. `Det` can be interpreted as estimating the covariance matrix of the noise source and using the inverse of

Property Name	Description
	that matrix as the weighting. You should specify the weighting when using the `Trace` criterion. If you want to achieve better accuracy for a particular channel in MIMO models, use `Trace` with weighting that favors that channel. Otherwise, use `Det`. If you use `Det`, check `cond(model.NoiseVariance)` after estimation. If the matrix is ill-conditioned, try using the `Trace` criterion. You can also use `compare` on validation data to check whether the relative error for different channels corresponds to your needs or expectations. Use the `Trace` criterion if you need to modify the relative errors, and check `model.NoiseVariance` to determine what weighting modifications to specify.
`IterWavenet`	(For `wavenet` nonlinear estimator only) Implicitly set to perform iterative estimation. Changing this setting does not impact the algorithm. Default: `'On'`.
`LimitError`	Robustification criterion that limits the influence of large residuals, specified as a positive real value. Residual values that are larger than `'LimitError'` times the estimated residual standard deviation have a linear cost instead of the usual quadratic cost. Default: `0` (no robustification).
`MaxIter`	Maximum number of iterations for the estimation algorithm, specified as a positive integer. Default: `20`.

Property Name	Description
`MaxSize`	The number of elements (size) of the largest matrix to be formed by the algorithm. Computational loops are used for larger matrices. Use this value for memory/speed trade-off. `MaxSize` can be any positive integer. Default: `250000`. **Note** The original data matrix of *u* and *y* must be smaller than `MaxSize`.
`SearchMethod`	Method used by the iterative search algorithm. Assignable values: • `'Auto'` — Automatically chooses from the following methods. • `'gn'` — Gauss-Newton method. • `'gna'` — Adaptive Gauss-Newton method. • `'grad'` — A gradient method. • `'lm'` — Levenberg-Marquardt method. • `'lsqnonlin'` — Nonlinear least-squares method (requires the Optimization Toolbox product). This method handles only the `'Trace'` criterion.
`Tolerance`	Specifies to terminate the iterative search when the expected improvement of the parameter values is less than `Tolerance`, specified as a positive real value in %. Default: `0.01`.

Property Name	Description
Display	Toggles displaying or hiding estimation progress information in the MATLAB Command Window. Default: 'Off'. Assignable values: • 'Off' — Hide estimation information. • 'On' — Display estimation information.
Weighting	Positive semi-definite matrix W used for weighted trace minimization. When Criterion = 'Trace', trace(E'*E*W) is minimized. Weighting can be used to specify relative importance of outputs in multiple-input multiple-output models (or reliability of corresponding data) when W is a diagonal matrix of nonnegative values. Weighting is not useful in single-output models. By default, Weighting is an identity matrix of size equal to the number of outputs.

idnlhw Advanced Algorithm Properties

The following table summarizes the fields of the Algorithm.Advanced model properties. The fields in the Algorithm.Advanced structure specify additional estimation-algorithm options.

Property Name	Description
GnPinvConst	When the search direction is computed, the algorithm discards the singular values of the Jacobian that are smaller than GnPinvConst*max(size(J))*norm(J)*eps. Singular values that are closer to 0 are included when GnPinvConst is decreased. Default: 1e4. Assign a positive, real value.
LMStartValue	(For Levenberg-Marquardt search algorithm) The starting level of *regularization* when using the Levenberg-Marquardt search method (Algorithm.SearchMethod='lm').

Property Name	Description
	Default: `0.001`. Assign a positive real value.
`LMStep`	(For Levenberg-Marquardt search algorithm) Try this next level of *regularization* to get a lower value of the criterion function. The level of regularization is `LMStep` times the previous level. At the start of a new iteration, the level of regularization is computed as `1/LMStep` times the value from the previous iteration. Default: `10`. Assign a real value `>1`.
`MaxBisections`	Maximum number of bisections performed by the line search algorithm along the search direction (number of rotations of search vector for `'lm'`). Used by `'gn'`, `'lm'`, `'gna'` and `'grad'` search methods (`Algorithm.SearchMethod` property). Default: `10`. Assign a positive integer value.
`MaxFunEvals`	The iterations are stopped if the number of calls to the model file exceeds this value. Default: `Inf`. Assign a positive integer value.
`MinParChange`	The smallest parameter update allowed per iteration. Default: `1e-16`. Assign a positive, real value.

Property Name	Description
`RelImprovement`	The iterations are stopped if the relative improvement of the criterion function is less than `RelImprovement`. Default: `0`. Assign a positive real value. **Note** This does not apply when `Algorithm.SearchMethod='lsqnonlin'`.
`StepReduction`	(For line search algorithm) The suggested parameter update is reduced by the factor `'StepReduction'` after each try until either `'MaxBisections'` tries are completed or a lower value of the criterion function is obtained. Default: `2`. Assign a positive, real value `>1`. **Note** This does not apply when `Algorithm.SearchMethod='lsqnonlin'`.

idnlhw EstimationInfo Properties

The following table summarizes the fields of the `EstimationInfo` model properties. The read-only fields of the `EstimationInfo` structure store estimation settings and results.

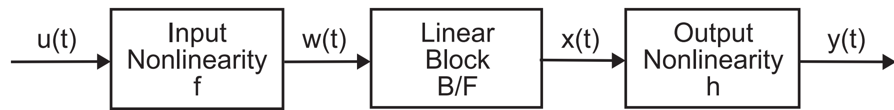
Property Name	Description
`Status`	Shows whether the model parameters were estimated.
`Method`	Shows the estimation method.
`LossFcn`	Value of the loss function, equal to `det(E'*E/N)`, where `E` is the residual error matrix (one column for each output) and `N` is the total number of samples.

Property Name	Description
FPE	Value of Akaike's Final Prediction Error (see fpe).
DataName	Name of the data from which the model is estimated.
DataLength	Length of the estimation data.
DataTs	Sampling interval of the estimation data.
DataDomain	'Time' means time domain data. 'Frequency' is not supported.
DataInterSample	Intersample behavior of the input estimation data used for interpolation: • 'zoh' means zero-order-hold, or piecewise constant. • 'foh' means first-order-hold, or piecewise linear.
WhyStop	Reason for terminating parameter estimation iterations.
UpdateNorm	Norm of the search vector (gn-vector) in the last iteration. Empty when 'lsqnonlin' is the search method.
LastImprovement	Criterion improvement in the last iteration, shown in %. Empty when 'lsqnonlin' is the search method.
Iterations	Number of iterations performed by the estimation algorithm.
Warning	Any warnings encountered during parameter estimation.
InitRandState	The value of random number type and seed at the last randomization of the initial parameter vector.
EstimationTime	Duration of the estimation.

Definitions

Hammerstein-Wiener Model Structure

This block diagram represents the structure of a Hammerstein-Wiener model:



where:

- $w(t) = f(u(t))$ is a nonlinear function transforming input data $u(t)$. $w(t)$ has the same dimension as $u(t)$.
- $x(t) = (B/F)w(t)$ is a linear transfer function. $x(t)$ has the same dimension as $y(t)$.

  where B and F are similar to polynomials in the linear Output-Error model, as described in "What Are Black-Box Polynomial Models?".

  For ny outputs and nu inputs, the linear block is a transfer function matrix containing entries:

  $$\frac{B_{j,i}(q)}{F_{j,i}(q)}$$

  where $j = 1,2,...,ny$ and $i = 1,2,...,nu$.
- $y(t) = h(x(t))$ is a nonlinear function that maps the output of the linear block to the system output.

w(t) and *x(t)* are internal variables that define the input and output of the linear block, respectively.

Because *f* acts on the input port of the linear block, this function is called the *input nonlinearity*. Similarly, because *h* acts on the output port of the linear block, this function is called the *output nonlinearity*. If system contains several inputs and outputs, you must define the functions *f* and *h* for each input and output signal.

You do not have to include both the input and the output nonlinearity in the model structure. When a model contains only the input nonlinearity *f*, it is called a *Hammerstein* model. Similarly, when the model contains only the output nonlinearity *h*), it is called a *Wiener* model.

The nonlinearities f and h are scalar functions, one nonlinear function for each input and output channel.

The Hammerstein-Wiener model computes the output y in three stages:

1. Computes $w(t) = f(u(t))$ from the input data.

   $w(t)$ is an input to the linear transfer function B/F.

   The input nonlinearity is a static (*memoryless*) function, where the value of the output a given time t depends only on the input value at time t.

   You can configure the input nonlinearity as a sigmoid network, wavelet network, saturation, dead zone, piecewise linear function, one-dimensional polynomial, or a custom network. You can also remove the input nonlinearity.

2. Computes the output of the linear block using $w(t)$ and initial conditions: $x(t) = (B/F)w(t)$.

   You can configure the linear block by specifying the numerator B and denominator F orders.

3. Compute the model output by transforming the output of the linear block $x(t)$ using the nonlinear function h: $y(t) = h(x(t))$.

   Similar to the input nonlinearity, the output nonlinearity is a static function. Configure the output nonlinearity in the same way as the input nonlinearity. You can also remove the output nonlinearity, such that $y(t) = x(t)$.

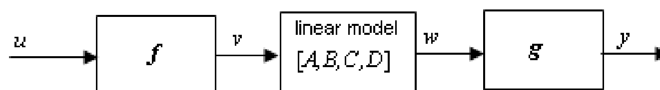
Resulting models are `idnlhw` objects that store all model data, including model parameters and nonlinearity estimator. See the `idnlhw` reference page for more information.

idnlhw States

This toolbox requires states for simulation and prediction using `sim(idnlhw)`, `predict(idnlhw)`, and `compare`. States are also

necessary for linearization of nonlinear ARX models using `linearize(idnlhw)`. This toolbox provides a number of options to facilitate how you specify the initial states. For example, you can use `findstates` and `data2state` to automatically search for state values in simulation and prediction applications. For linearization, use `findop`. You can also specify the states manually.

The states of the Hammerstein-Wiener model correspond to the states of the linear block in the Hammerstein-Wiener model structure:



The linear block contains all the dynamic elements of the model. If this linear model is not a state-space structure, the states are defined as those of model `Mss`, where `Mss = idss(Model.LinearModel)` and `Model` is the `idnlhw` object.

Examples

Create default Hammerstein-Wiener model structure:

```
  m = idnlhw([2 2 1]) % na=nb=2 and nk=1
% m has piecewise linear input and output nonlinearity
```

Create nonlinear ARX model structure with sigmoid network nonlinearity:

```
m=idnlarx([2 3 1],sigmoidnet('Num',15))
% number of units is 15
```

Create Hammerstein-Wiener model with specific input-output nonlinearities:

```
  m=idnlhw([2 2 1],'sigmoidnet','deadzone')
% Equivalent to m=idnlhw([2 2 1],'sig','dead')
% Nonlinearities have default configuration
```

Create Hammerstein-Wiener model and configure the nonlinearity objects:

```
m=idnlhw([2 2 1],sigmoidnet('num',5),deadzone([-1,2]))
```

Create a Hammerstein model (no output nonlinearity):

```
m=idnlhw([2 2 1],'saturation',[])
% [] specifies unitgain output nonlinearity
```

Configure the Hammerstein-Wiener model and estimate models parameters:

```
m0 = idnlhw([nb,nf,nk],[sigmoidnet;pwlinear],[]);
m = pem(data,m0); % equivalent to m=nlhw(data,m0)
```

Construct default Hammerstein-Wiener model using an input-output polynomial model of Output-Error structure:

```
% Construct an input-output polynomial model of OE structure.
B = [0.8 1];
F = [1 -1.2 0.5];
LinearModel = idpoly(1, B, 1,1, F, 'Ts', 0.1);

% Construct Hammerstein-Wiener model using OE model
% as its linear component.
m1 = idnlhw(LinearModel, 'saturation', [])
```

How To

- "Identifying Hammerstein-Wiener Models"
- "Using Linear Model for Hammerstein-Wiener Estimation"

Purpose

Superclass for nonlinear models

Description

You do not use the `idnlmodel` class directly. Instead, `idnlmodel` defines the common properties and methods inherited by its subclasses, `idnlarx`, `idnlgrey`, and `idnlhw`.

idnlmodel Properties

The following table lists the properties shared by the `idnlarx`, `idnlgrey`, and `idnlhw`, defined in terms of `Ny` outputs and `Nu` inputs.

Property Name	Description
`InputName`	Specifies the names of individual input channels. Default: `{'u1';'u2';...;'uNu'}`. Assignable values: • For single-output models, a string. For example, `'torque'`. • For multiple-output models, an `nu`-by-`1` cell array. For example: `{'thrust'; 'aileron deflection'}`
`InputUnit`	Specifies the units of each input channel. Default: `''`. Assignable values: • For single-output models, a string. For example, `'m/s'`. • For multiple-output models, an `nu`-by-`1` cell array.
`Name`	Name of the model, specified as a string.
`NoiseVariance`	Noise variance (covariance matrix) of the model innovations *e*. Assignable value is an `ny`-by-`ny` matrix. Typically set automatically by the estimation algorithm.

Property Name	Description
OutputName	Specifies the names of individual output channels. Default: {'y1';'y2';...;'yNy'}. Assignable values: • For single-output models, a string. For example, 'torque'. • For multiple-output models, an ny-by-1 cell array. For example: {'thrust'; 'aileron deflection'}
OutputUnit	Specifies the units of each output channel. Default: ''. Assignable values: • For single-output models, a string. For example, 'm/s'. • For multiple-output models, an ny-by-1 cell array.
TimeUnit	Unit of the sampling interval and time vector, specified as a string. Default: ''.
TimeVariable	Independent variable for the inputs, outputs, and—when available—internal states, specified as a string. Default: 't' (time).
Ts	Sampling interval with the unit specified by TimeUnit. Default: 1. Assignable values: • For discrete-time models, positive scalar value of the sampling interval. • For continuous-time models, 0.

`idnlhw`

idpoly

Purpose

Linear polynomial input-output model

Syntax

```
m = idpoly(A,B)
m = idpoly(A,B,C,D,F,NoiseVariance,Ts)
m = idpoly(A,B,C,D,F,NoiseVariance,Ts,'Property1',Value1,...
      'PropertyN',ValueN)
m = idpoly(mi)
```

Description

`idpoly` creates a model object containing parameters that describe the general multiple-input single-output model structure.

$$A(q)y(t) = \frac{B_1(q)}{F_1(q)} u_1(t - nk_1) + \ldots + \frac{B_{nu}(q)}{F_{nu}(q)} u_{nu}(t - nk_{nu}) + \frac{C(q)}{D(q)} e(t)$$

A, B, C, D, and F are the polynomial coefficients. For more information, see “What Are Black-Box Polynomial Models?”.

Specify A, C, and D as row vectors that start with 1. For example,

```
A = [1 a1 a2 ... ana]
```

consequently describes

$$A(q) = 1 + a_1 q^{-1} + \ldots + a_{na} q^{-na}$$

For single-input systems, specify B as a row vector that contains leading zeros to indicate the delays and F as a row vector that starts with 1.

For multiple-input systems, specify B and F using cell arrays of Nu row vectors or double matrices with Nu rows, where Nu is the number of inputs. Double matrix support will be removed in a future version. Use cell array format instead. You can switch between double and cell array formats after creating the model using the `setPolyFormat` command.

For time series, enter B and F as empty matrices.

```
B = [];  F = [];
```

`NoiseVariance` is the variance of the white noise sequence $e(t)$, while `Ts` is the sampling interval.

Trailing arguments C, D, F, `NoiseVariance`, and `Ts` can be omitted, in which case they are taken as 1. (If `B = []`, then F is taken as `[]`.) The property name/property value pairs can start directly after B.

`Ts = 0` means that the model is a continuous-time one. Then the interpretation of the arguments is that

```
A = [1 2 3 4]
```

corresponds to the polynomial s^3+2s^2+3s+4 in the Laplace variable s, and so on. For continuous-time systems, `NoiseVariance` indicates the level of the spectral density of the innovations. A sampled version of the model has the innovations variance `NoiseVariance/Ts`, where `Ts` is the sampling interval. The continuous-time model must have a white noise component in its disturbance description. See "Spectrum Normalization".

For discrete-time models (`Ts > 0`), note the following: `idpoly` strips any trailing zeros from the polynomials when determining the orders. It also strips leading zeros from the B polynomial to determine the delays. Keep this in mind when you use `idpoly` and `polydata` to modify earlier estimates to serve as initial conditions for estimating new structures.

`idpoly` can also take any single-output `idmodel` or LTI object `mi` as an input argument. If an LTI system has an input group with name `'Noise'`, these inputs are interpreted as white noise with unit variance, and the noise model of the `idpoly` model is computed accordingly.

Properties

`na, nb, nc, nd, nf, nk`

Orders and delays of the polynomials, specified as integers or row vectors of integers.

`a, c, d`

A, C, and D polynomials, specified as row vectors.

`b, f`

B and *F* polynomials, specified as:

- Row vectors for single-input systems.
- Multi-row double matrices or cell arrays for multi-input systems, depending on how you specify the polynomials during construction. Double matrix support will be removed in a future version. Use cell array format instead. You can switch between double and cell array formats after creating the model using `setPolyFormat`.

`da, db, dc, dd, df`

The estimated standard deviation of the polynomials. Cannot be set.

`'InitialState'`

How to deal with the initial conditions that are required to compute the prediction of the output. Possible values are:

`'Estimate'`	The necessary initial states are estimated from data as extra parameters.
`'Backcast'`	The necessary initial states are estimated by a backcasting (backward filtering) process, described in Knudsen (1994).
`'Zero'`	All initial states are taken as zero.
`'Auto'` (default)	An automatic choice among the above is made, guided by the data.

In addition, any `idpoly` object also has all the properties of `idmodel`. See `idmodel` properties and `Algorithm Properties`.

Note that you can set or retrieve all properties either with the set and get commands or by subscripts. Autofill applies to all properties and values, and these are case insensitive.

```
m.a=[1 -1.5 0.7];
set(m,'ini','b')
p = roots(m.a)
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`.

Examples

Create a polynomial model of ARMAX structure:

```
A = [1 -1.5 0.7];
B = [0 1 0.5];
C = [1 -1 0.2];
m0 = idpoly(A,B,C);
```

This gives a system with one delay (`nk = 1`).

Create, discretize and simulate the following continuous-time multi-input polynomial model:

$$y(t) = \frac{1}{s(s+1)} u_1(t) + \frac{s+3}{s^2+2s+4} u_2(t) + e(t)$$

```
% Create multi-input Output Error (OE) model.
B={[0 1],[1 3]};
F={[1 1 0],[1 2 4]}
m = idpoly(1,B,1,1,F,1,0)

% Discretize the model using sampling time T = 0.1s.
md = c2d(m,0.1)

% Simulate the model without noise.
% u1 and u2 are double vectors representing input signals.
y = sim(md,[u1 u2])
```

Note that, when you simulate the model, the continuous-time model is automatically sampled to the sampling interval of the data. So the discretization and simulation operations are also achieved using the following commands:

```
u = iddata([],[u1 u2],0.1)
y = sim(m,u)
```

idpoly Definition of States

The states of an `idpoly` model are defined as those corresponding to the model obtained by converting them to the state-space format using the `idss` command. For example, if you have an `idpoly` model defined by `m1 = idpoly([1 2 1],[2 2])`, then the initial states of this model correspond to those of `m2 = idss(m1)`. The concept of states is useful for functions such as `sim`, `predict`, `compare` and `findstates`.

How To

- "Identifying Input-Output Polynomial Models"
- "Extracting Parameter Values from Linear Models"
- "Using Linear Model for Nonlinear ARX Estimation"
- "Using Linear Model for Hammerstein-Wiener Estimation"

Purpose

Linear, low-order, continuous-time transfer function

Syntax

```
m = idproc(Type)
m = idproc(Type,'Property1',Value1,...,'PropertyN',ValueN)
m = pem(Data,Type) % to directly estimate an idproc model
```

Description

The function `idproc` is used to create typical simple, continuous-time process models as `idproc` objects. The model has one output, but can have several inputs.

The character of the model is defined by the argument `Type`. This is an acronym made up of the following symbols:

- P: All `'Type'` acronyms start with this letter.
- 0, 1, 2, or 3: This integer denotes the number of time constants (poles) to be modeled. Possible integrations (poles in the origin) are not included in this number.
- I: The letter I is included to mark that an integration is enforced (self-regulation process).
- D: The letter D is used to mark that the model contains a time delay (dead time).
- Z: The letter Z is used to mark an extra numerator term: a zero.
- U: The letter U is included to mark that underdamped modes (complex-valued poles) are permitted. If U is not included, all poles are restricted to be real.

This means, for example, that `Type = 'P1D'` corresponds to the model with transfer function

$$G(s) = \frac{K_p}{1 + sT_{p1}} e^{-T_d s}$$

while `Type = 'P0I'` is

$$G(s) = \frac{K_p}{s}$$

and `Type = 'P3UZ'` is

$$G(s) = K_p \frac{1 + T_z s}{(1 + 2\varsigma T_\omega s + (T_\omega s)^2)(1 + T_{p3} s)}$$

For multiple-input systems, `Type` is a cell array where each cell describes the character of the model from the corresponding input, like `Type = {'P1D' 'POI'}` for the two-input model

$$Y(s) = \frac{K_p(1)}{1 + sT_{p1}(1)} e^{-T_d s} U_1(s) + \frac{K_p(2)}{s} U_2(s)$$

The parameters of the model are

- `Kp`: The static gain
- `Tp1`, `Tp2`, `Tp3`: The real-time constants (corresponding to poles in `1/Tp1`, etc.)
- `Tw` and `Zeta`: The "resonance time constant" and the damping factor corresponding to a denominator factor `(1+2 Zeta Tw s + (Tw s)^2)`. If underdamped modes are allowed, `Tw` and `Zeta` replace `Tp1` and `Tp2`. A third real pole, `Tp3`, could still be included.
- `Td`: The time delay
- `Tz`: The numerator zero

These properties contain fields that give the values of the parameters, upper and lower bounds, and information whether they are locked to zero, have a fixed value, or are to be estimated. For multiple-input models, the number of entries in these fields equals the number of inputs. This is described in more detail below.

The `idproc` object is a child of `idmodel`. Therefore any `idmodel` properties can be set as property name/property value pairs in the

idproc command. They can also be set by the command set, or by subassignment, as in

```
m.InputName = {'speed','voltage'}
m.kp = 12
```

In the multiple-input case, models for specific inputs can be obtained by regular subreferencing.

```
m(ku)
```

There are also two properties, DisturbanceModel and InitialState, that can be used to expand the model. See below.

idproc Properties

- Type: A string or a cell array of strings with as many elements as there are inputs. The string is an acronym made up of the characters P, Z, I, U, D and an integer between 0 and 3. The string must start with P, followed by the integer, while possible other characters can follow in any order. The integer is the number of poles (not counting a possible integration), Z means the inclusion of a numerator zero, D means inclusion of a time delay, while U marks that the modes can be underdamped (a pair of complex conjugated poles). I means that an integration in the model is enforced.
- Kp, Tp1, Tp2, Tp3, Tw, Zeta, Tz, Td: These are the parameters as explained above. Each of these is a structure with the following fields:
  - value: Numerical value of the parameter.
  - max: Maximum allowed value of the parameter when it is estimated.
  - min: Minimum allowed value of the parameter when it is estimated. For multiple-input models, these are row vectors.
  - status: Assumes one of 'Estimate', 'Fixed', or 'Zero'.

    'Zero' means that the parameter is locked to zero and not included in the model. Assigning, for example, Type = 'P1' means that the status of Tp2, Tp3, Tw, and Zeta will be 'Zero'.

The value `'Fixed'` means that the parameter is fixed to its value, and will not be estimated.

The value `'Estimate'` means that the parameter value should be estimated.

For multiple-input modes, `status` is a cell array with one element for each input, while `value`, `max`, and `min` are row vectors.

- `DisturbanceModel`: Allows an additive disturbance model as in

  $$y(t) = G(s)u(t) + \frac{C(s)}{D(s)}e(t)$$

  where $G(s)$ is a process model and $e(t)$ is white noise, and C/D is a first- or second-order transfer function.

  `DisturbanceModel` can assume the following values:

  - `'None'`: This is the default. No disturbance model is included (that is, $C=D=1$).
  - `'arma1'`: The disturbance model is a first-order ARMA model (that is, C and D are first-order polynomials).
  - `'arma2'` or `'Estimate'`: The disturbance model is a second-order ARMA model (that is, C and D are second-order polynomials).

  When a disturbance model has been estimated, the property `DisturbanceModel` is returned as a cell array, with the first entry being the status as just defined, and the second entry being the actual model, delivered as a continuous-time `idpoly` object.

- `InitialState`: Affects the parameterization of the initial values of the states of the model. It assumes the same values as for other models:

  - `'Zero'`: The initial states are fixed to zero.
  - `'Estimate'`: The initial states are treated as parameters to be estimated.

- 'Backcast': The initial state vector is adjusted, during the parameter estimation step, to a suitable value, but it is not stored.
- 'Auto': Makes a data-dependent choice among the values above.

• InputLevel: The offset level of the input signal(s). This is of particular importance for those input channels that contain an integration. InputLevel will then define the level from which the integration takes place, and that cannot be handled by estimating initial states. InputLevel has the same structure as the model parameters Kp, etc., and thus contains the following fields:

  - value: Numerical value of the parameter. For multiple-input models, this is a row vector.
  - max: Maximum allowed value of the parameter when it is estimated.
  - min: Minimum allowed value of the parameter when it is estimated. For multiple-input models, these are row vectors.
  - status: Assumes one of 'Estimate', 'Fixed', or 'Zero' with the same interpretations.

In addition, any idproc object also has all the properties of idmodel. See Algorithm Properties, EstimationInfo, and idmodel.

Note that all properties can be set or retrieved using either the set and get commands or subscripts. Autofill applies to all properties and values, and these are case insensitive. Also 'u' and 'y' are short for 'Input' and 'Output', respectively. You can also set all properties at estimation time as property name/property value pairs in the call to pem. An extended syntax allows direct setting of the fields of the parameter values, so that assigning a numerical value is automatically attributed to the value field, while a string is attributed to the status field.

```
m.kp = 10  % Alternative for m.Kp.value = 10
m.Tp1 = 'estimate'  % Alternative for
                    % m.Tp1.status = {'estimate'}
% Initializing the parameter Kp at the value 10
m = pem(Data,'P1D','kp',10)
```

```
% Fixing the parameter Kp to the value 10
m = pem(Data,'P1D','kp',10,'kp','fix')
% constraining Kp to lie between 3 and 4
m = pem(Data,'P2U','kp',{'max',4},'kp',{'min',3})
% For two inputs, estimate the offset level
% of the first input
m = pem(Data,{'P2I','P1D'},'ulevel',{'est','zer'})
% estimate a noise model
m = pem(Data,'P2U','dist','est')
% Use a fixed noisemodel,
% given by the continuous-time idpoly model noimod
m = pem(Data,'P2U','dist',{'fix',noimod})
% (minimum Kp for the second input)
m.kp.min(2) = 12
% fixing the gain for the second input.
m.kp.status{2} = 'fix'
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`.

idproc Definition of States

The states of an `idproc` model are defined as those corresponding to the model obtained by converting them to the state-space format using the `idss` command. For example, if you have an `idproc` model defined by `m1 = idproc('P1D');`, then the initial states of this model correspond to those of `m2 = idss(m1)`. The concept of states is useful for functions such as `sim`, `predict`, `compare` and `findstates`.

Examples

In this example, you estimate a process model with two real poles and dead time, including an ARMA1 model to capture disturbance dynamics:

```
m = pem(Data,'P2D','dist','arma1')
```

Purpose

Resample time-domain data by decimation or interpolation

Syntax

```
datar = idresamp(data,R)
datar = idresamp(data,R,order,tol)
[datar,res_fact] = idresamp(data,R,order,tol)
```

Description

`datar = idresamp(data,R)` resamples data on a new sample interval `R` and stores the resampled data as `datar`.

`datar = idresamp(data,R,order,tol)` filters the data by applying a filter of specified `order` before interpolation and decimation. Replaces `R` by a rational approximation that is accurate to a tolerance `tol`.

`[datar,res_fact] = idresamp(data,R,order,tol)` returns `res_fact`, which corresponds to the value of `R` approximated by a rational expression.

Input

`data`

Name of time-domain `iddata` object or a matrix of data. Can be input-output or time-series data.

Data must be sampled at equal time intervals.

`R`

Resampling factor, such that `R>1` results in decimation and `R<1` results in interpolation.

Any positive number you specify is replaced by the rational approximation, `Q/P`.

`order`

Order of the filters applied before interpolation and decimation.

Default: `8`

`tol`

Tolerance of the rational approximation for the resampling factor `R`.

Smaller tolerance might result in larger P and Q values, which produces more accurate answers at the expense of slower computation.

Default: 0.1

Output

datar
: Name of the resampled data variable. datar class matches the data class, as specified.

res_fact
: Rational approximation for the specified resampling factor R and tolerance tol.

  Any positive number you specify is replaced by the rational approximation, Q/P, where the data is interpolated by a factor P and then decimated by a factor Q.

resample

Purpose

State-space model

Syntax

```
m = idss(A,B,C,D)
m = idss(A,B,C,D,K,x0,Ts,'Property1',Value1,...
           'PropertyN',ValueN)
mss = idss(m1)
```

Description

The function `idss` is used to construct state-space model structures with various parameterizations. It is a complement to `idgrey` and deals with parameterizations that do not require the user to write a special function. Instead it covers parameterizations that are either `'Free'`, that is, all parameters in the A, B, and C matrices can be adjusted freely, or `'Canonical'`, meaning that the matrices are parameterized as canonical forms. The parameterization can also be `'Structured'`, which means that certain elements in the state-space matrices are free to be adjusted, while others are fixed. This is explained below.

`Ts` is the sampling interval. `Ts = 0` means a continuous-time model. The default is `Ts = 1`.

The `idss` object `m` describes state-space models in innovations form of the following kind:

$$\tilde{x}(t) = A(\theta)x(t) + B(\theta)u(t) + K(\theta)e(t)$$
$$x(0) = x_0(\theta)$$
$$y(t) = C(\theta)x(t) + D(\theta)u(t) + e(t)$$

Here $\tilde{x}(t)$ is the time derivative $\dot{x}(t)$ for a continuous-time model and $x(t+Ts)$ for a discrete-time model.

The model `m` will contain information both about the nominal/initial values of the A, B, C, D, K, and X0 matrices and about how these matrices are parameterized by the parameter vector θ (to be estimated).

The nominal model is defined by `idss(A,B,C,D,K,X0)`. If `K` and `X0` are omitted, they are taken as zero matrices of appropriate dimensions.

Defining an `idss` object from a given model,

```
mss = idss(m1)
```

constructs an `idss` model from any `idmodel` or LTI system `m1`.

If `m1` is an LTI system (`ss`, `tf`, or `zpk`) that has no `InputGroup` called `'Noise'`, the corresponding state-space matrices *A*, *B*, *C*, *D* are used to define the `idss` object. The Kalman gain *K* is then set to zero.

If the LTI system has an `InputGroup` called `'Noise'`, these inputs are interpreted as white noise with a covariance matrix equal to the identity matrix. The corresponding Kalman gain and noise variance are then computed and entered into the `idss` model together with *A*, *B*, *C*, and *D*.

Parameterizations

There are several different ways to define the parameterization of the state-space matrices. The parameterization determines which parameters can be adjusted to data by the parameter estimation routine `pem`.

- Free black-box parameterizations: This is the default situation and corresponds to letting all parameters in *A*, *B*, and *C* be freely adjustable. You do this by setting the property `'SSParameterization' = 'Free'`. The parameterizations of *D*, *K*, and *X0* are then determined by the following properties:
  - `'nk'`: A row vector of the same length as the number of inputs. The `ku`th element is the delay from input channel number `ku`. Thus `nk = [0,...,0]` means that there is no delay from any of the inputs, and that consequently all elements of the *D* matrix should be estimated. `nk =[1,...,1]` means that there is a delay of 1 from each input, so that the *D* matrix is fixed to be zero.
  - `'DisturbanceModel'`: This property affects the parameterization of K and can assume the following values:

    `'Estimate'`: All elements of the *K* matrix are to be estimated.

    `'None'`: All elements of *K* are fixed to zero.

    `'Fixed'`: All elements of *K* are fixed to their nominal/initial values.

- 'InitialState': Affects the parameterization of *X0* and can assume the following values:

  'Auto': An automatic choice of the following is made, depending on data (default).

  'Estimate': All elements of *X0* are to be estimated.

  'Zero': All elements of *X0* are fixed to zero.

  'Fixed': All elements of *X0* are fixed to their nominal/initial values.

  'Backcast': The vector *X0* is adjusted, during the parameter estimation step, to a suitable value, but it is not stored as an estimation result.

- Canonical black-box parameterizations: You do this by setting the property 'SSParameterization' = 'Canonical'. The matrices *A*, *B*, and *C* are then parameterized as an observer canonical form, which means that ny (number of output channels) rows of *A* are fully parameterized while the others contain 0's and 1's in a certain pattern. The *C* matrix is built up of 0's and 1's while the *B* matrix is fully parameterized. See Equation (A.16) in Ljung (1999) for details. The exact form of the parameterization is affected by the property 'CanonicalIndices'. The default value 'Auto' is a good choice. The parameterization of the *D*, *K*, and *X0* matrices in this case is determined by the properties 'nk', 'DisturbanceModel', and 'InitialState'.

- Arbitrarily structured parameterizations: The general case, where arbitrary elements of the state-space matrices are fixed and others can be freely adjusted, corresponds to the case 'SSParameterization' = 'Structured'. The parameterization is determined by the idss properties As, Bs, Cs, Ds, Ks, and X0s. These are the *structure matrices* that are "shadows" of the state-space matrices, so that an element in these matrices that is equal to NaN indicates a freely adjustable parameter, while a numerical value in these matrices indicates that the corresponding system matrix element is fixed (nonadjustable) to this value.

idss Properties

- `SSParameterization` has the following possible values:
  - `'Free'`: Means that all parameters in *A*, *B*, and *C* are freely adjustable, and the parameterizations of *D*, *K*, and *X0* depend on the properties `'nk'`, `'DisturbanceModel'`, and `'InitialState'`.
  - `'Canonical'`: Means that *A* and *C* are parameterized as an observer canonical form. The details of this parameterization depend on the property `'CanonicalIndices'`. The *B* matrix is always fully parameterized, and the parameterizations of *D*, *K*, and *X0* depend on the properties `'nk'`, `'DisturbanceModel'`, and `'InitialState'`.
  - `'Structured'`: Means that the parameterization is determined by the properties (the structure matrices) `'As'`, `'Bs'`, `'Cs'`, `'Ds'`, `'Ks'`, and `'X0s'`. A `NaN` in any position in these matrices denotes a freely adjustable parameter, and a numeric value denotes a fixed and nonadjustable parameter.
- `nk`: A row vector with as many entries as the number of input channels. The entry number `k` denotes the time delay from input number `k` to `y(t)`. This property is relevant only for `'Free'` and `'Canonical'` parameterizations. If any delay is larger than `1`, the structure of the *A*, *B*, and *C* matrices will accommodate this delay, at the price of a higher-order model.
- `DisturbanceModel` has the following possible values:
  - `'Estimate'`: Means that the *K* matrix is fully parameterized.
  - `'None'`: Means that the *K* matrix is fixed to zero. This gives a so-called output-error model, since the model output depends on past inputs only.
  - `'Fixed'`: Means that the *K* matrix is fixed to the current nominal values.
- `InitialState` has the following possible values:
  - `'Estimate'`: Means that *X0* is fully parameterized.
  - `'Zero'`: Means that *X0* is fixed to zero.

  - 'Fixed': Means that *X0* is fixed to the current nominal value.
  - 'Backcast': The value of *X0* is estimated by the identification routines as the best fit to data, but it is not stored.
  - 'Auto': Gives an automatic and data-dependent choice among 'Estimate', 'Zero', and 'Backcast'.
- A, B, C, D, K, and X0: The state-space matrices that can be set and retrieved at any time. These contain both fixed values and estimated/nominal values.
- dA, dB, dC, dD, dK, and dX0: The estimated standard deviations of the state-space matrices. These cannot be set, only retrieved. Note that these are not defined for an idss model with 'Free' SSParameterization. You can then convert the parameterization to 'Canonical' and study the uncertainties of the matrix elements in that form.
- As, Bs, Cs, Ds, Ks, and X0s: These are the structure matrices that have the same sizes as A, B, C, etc., and show the freely adjustable parameters as NaNs in the corresponding position. These properties are used to define the model structure for 'SSParameterization' = 'Structured'. They are always defined, however, and can be studied also for the other parameterizations.
- CanonicalIndices: Determines the details of the canonical parameterization. It is a row vector of integers with as many entries as there are outputs. They sum up to the system order. This is the so-called pseudocanonical multiindex with an exact definition, for example, on page 132 in Ljung (1999). A good default choice is 'Auto'. This property is relevant only for the canonical parameterization case. Note however, that for 'Free' parameterizations, the estimation algorithms also store a canonically parameterized model to handle the model uncertainty.

In addition to these properties, idss objects also have all the properties of the idmodel object. See idmodel properties, Algorithm Properties, and EstimationInfo.

Note that all properties can be set and retrieved either by the `set` and `get` commands or by subscripts. Autofill applies to all properties and values, and these are case insensitive.

```
m.ss='can'
set(m,'ini','z')
p = eig(m.a)
```

For a complete list of property values, use `get(m)`. To see possible value assignments, use `set(m)`.

Examples

Define a continuous-time model structure corresponding to

$$\dot{x} = \begin{bmatrix} \theta_1 & 0 \\ 0 & \theta_2 \end{bmatrix} x + \begin{bmatrix} \theta_3 \\ \theta_4 \end{bmatrix} u$$
$$y = [1 \ \ 1] x + e$$

with initial values

$$\theta = \begin{bmatrix} -0.2 \\ -0.3 \\ 2 \\ 4 \end{bmatrix}$$

and estimate the free parameters.

```
A = [-0.2, 0; 0, -0.3]; B = [2;4]; C=[1, 1]; D = 0
m0 = idss(A,B,C,D);
m0.As = [NaN,0;0,NaN];
m0.Bs = [NaN;NaN];
m0.Cs = [1,1];
m0.Ts = 0;
m = pem(z,m0);
```

Estimate a model in free parameterization. Convert it to continuous time, then convert it to canonical form and continue to fit this model to data.

```
m1 = n4sid(data,3);
m1 = d2c(m1);
m1.ss ='can';
m = pem(data,m1);
```

All of this can be done at once by

```
m = pem(data,3,'ss','can','ts',0)
```

How To

- “Using Linear Model for Hammerstein-Wiener Estimation”

Purpose

Transform iddata objects from frequency to time domain

Syntax

```
dat = ifft(Datf)
```

Description

`ifft` transforms a frequency-domain `iddata` object to the time domain. It requires the frequencies on `Datf` to be equally spaced from frequency 0 to the Nyquist frequency. This means that if there are `N` frequencies in `Datf` and the time sampling interval is `Ts`, then

`Datf.Frequency = [0:df:F]`, where `F` is `pi/Ts` if `N` is odd and `F = pi/Ts*(1-1/N)` if `N` is even.

See Also

`iddata`

`fft`

Purpose

Plot impulse response with confidence interval

Syntax

```
impulse(m)
impulse(data)
impulse(m,'sd',sd,Time)
impulse(m,'sd',sd,Time,'fill')
impulse(data,'sd',sd,'pw',na,Time)
impulse(m1,m2,...,dat1, ...,mN,Time,'sd',sd)
impulse(m1,'PlotStyle1',m2,'PlotStyle2',...,dat1,'PlotStylek',...,
mN,'PlotStyleN',Time,'sd',sd)
[y,t,ysd] = impulse(m)
mod = impulse(data)
```

Description

`impulse` can be applied both to `idmodels` and to `iddata` sets, as well as to any mixture.

For a discrete-time `idmodel` `m`, the impulse response `y` and, when required, its estimated standard deviation `ysd`, are computed using `sim`. When called with output arguments, `y`, `ysd`, and the time vector `t` are returned. When `impulse` is called without output arguments, a plot of the impulse response is shown. If `sd` is given a value larger than zero, a confidence region around zero is drawn. It corresponds to the confidence of `sd` standard deviations. In the plots, the impulse is inversely scaled with the sampling interval so that it has the same energy regardless of the sampling interval.

Adding an argument `'fill'` among the input arguments gives an uncertainty region marked by a filled area rather than by dash-dotted lines.

Setting the Time Interval

You can specify the start time `T1` and the end time `T2` using `Time= [T1 T2]`. If `T1` is not given, it is set to `-T2/4`. The negative time lags (the impulse is always assumed to occur at time 0) show possible feedback effects in the data when the impulse is estimated directly from data. If `Time` is not specified, a default value is used.

Estimating the Impulse Response from Data

For an `iddata` object, `impulse(data)` estimates a high-order, noncausal FIR model after first having prefiltered the data so that the input is "as white as possible." The impulse response of this FIR model and, when asked for, its confidence region, are then plotted. Note that it is not always possible to deliver the demanded time interval when the response is estimated. A warning is then issued. When called with an output argument, `impulse`, in the `iddata` case, returns this FIR model, stored as an `idarx` model. The order of the prewhitening filter can be specified by the property name/property value pair `'pw'/na`. The default value is `na = 10`.

Several Models/Data Sets

Any number and any mixture of models and data sets can be used as input arguments. The responses are plotted with each input/output channel (as defined by the model and data set `InputName` and `OutputName` properties) as a separate plot. Colors, line styles, and marks can be defined by `PlotStyle` values. These are the same as for the regular `plot` command, as in

```
impulse(m1,'b-*',m2,'y--',m3,'g')
```

Noise Channels

The noise input channels in `m` are treated as follows:

Consider a model `m` with both measured input channels u (nu channels) and noise channels e (ny channels) with covariance matrix Λ

$$y = Gu + He$$
$$\mathrm{cov}(e) = \Lambda = LL'$$

where L is a lower triangular matrix. Note that `m.NoiseVariance` = Λ. The model can also be described with unit variance, using a normalized noise source v:

$$y = Gu + HLv$$
$$\mathrm{cov}(v) = I$$

- `impulse(m)` plots the impulse response of the transfer function *G*.
- `impulse(m('n'))` plots the impulse response of the transfer function *H* (*ny* inputs and *ny* outputs). The input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- If `m` is a time series, that is *nu* `= 0,impulse(m)`, plots the impulse response of the transfer function *H*.
- `impulse(noisecnv(m))` plots the impulse response of the transfer function [*G H*] (*nu*+*ny* inputs and *ny* outputs). The noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- `impulse(noisecnv(m,'norm'))` plots the impulse response of the transfer function [*G HL*] (*nu*+*ny* inputs and *ny* outputs). The noise input channels have names `v@yname`, where `yname` is the name of the corresponding output.

Arguments

If `impulse` is called with a single `idmodel m`, the output argument `y` is a 3-D array of dimension `Nt`-by-`ny`-by-`nu`. Here `Nt` is the length of the time vector `t`, `ny` is the number of output channels, and `nu` is the number of input channels. Thus `y(:,ky,ku)` is the response in output `ky` to an impulse in the `ku`th input channel.

`ysd` has the same dimensions as `y` and contains the standard deviations of `y`.

If `impulse` is called with an output argument and a single data set in the input arguments, the output is returned as an `idarx` model `mod` containing the high-order FIR model and its uncertainty. By calling `impulse` with `mod`, the responses can be displayed and returned without your having to redo the estimation.

Examples

Suppose that you have a two-input and three-output data set. To estimate and plot the impulse response for all I/O pairs, including

the confidence region corresponding to 3 standard deviations, use the following command:

```
impulse(data,'sd',3)  % Response from input 3 to output 2
```

To take a closer look at the subsystems, do the following:

```
mod = impulse(data)
impulse(mod(2,3),'sd',3)
```

See Also

`cra`

`step`

Purpose

Set or randomize initial parameter values

Syntax

```
m = init(m0)
m = init(m0,R,pars,sp)
```

Description

This function randomizes initial parameter estimates for model structures `m0` for any `idmodel`, `idnlarx`, and `idnlhw` model object. It does not support `idnlgrey` models. `m` is the same model structure as `m0`, but with a different nominal parameter vector. This vector is used as the initial estimate by `pem`.

The parameters are randomized around `pars` with variances given by the row vector `R`. Parameter number k is randomized as `pars(k) + e*sqrt(R(k))`, where `e` is a normal random variable with zero mean and a variance of 1. The default value of `R` is all ones, and the default value of `pars` is the nominal parameter vector in `m0`.

Only models that give stable predictors are accepted. If `sp = 'b'`, only models that are both stable and have stable predictors are accepted.

`sp = 's'` requires stability only of the model, and `sp = 'p'` requires stability only of the predictor. `sp = 'p'` is the default.

Sufficiently free parameterizations can be stabilized by direct means without any random search. To just stabilize such an initial model, set `R = 0`. With `R > 0`, randomization is also done.

For model structures where a random search is necessary to find a stable model/predictor, a maximum of 100 trials is made by `init`. It can be difficult to find a stable predictor for high-order systems by trial and error.

`pem`

isreal

Purpose

Determine whether model parameters or data values are real

Syntax

```
isreal(Data)
isreal(Model)
```

Description

`Data` is an `iddata` set and `Model` is any `idmodel`. The `isreal` function returns `1` if all parameters of the model are real and if all signals of the data set are real.

See Also

`realdata`

Purpose

Estimate AR model using instrumental variable method

Syntax

```
m = ivar(y,na)
m = ivar(y,na,nc,maxsize)
```

Description

Estimate AR model using the instrumental variable method and returning `idpoly` object. The parameters of an AR model structure

$$A(q)y(t) = e(t)$$

are estimated using the instrumental variable method. `y` is the signal to be modeled, entered as an `iddata` object (outputs only). `na` is the order of the A polynomial (the number of A parameters). The resulting estimate is returned as an `idpoly` model `m`. The routine is for scalar time-domain signals only.

In the above model, *e(t)*(*t*) is an arbitrary process, assumed to be a moving average process of order `nc`, possibly time varying. (Default is `nc = na`.) Instruments are chosen as appropriately filtered outputs, delayed `nc` steps.

The optional argument `maxsize` is explained under `Algorithm Properties`.

Examples

Compare spectra for sinusoids in noise, estimated by the IV method and by the forward-backward least squares method.

```
y = iddata(sin([1:500]'*1.2) + sin([1:500]'*1.5) + ...
           0.2*randn(500,1),[]);
miv = ivar(y,4);
mls = ar(y,4);
bode(miv,mls)
```

`pem`

`spa`

`step`

Purpose

Loss functions for sets of ARX model structures

Syntax

```
v = ivstruc(ze,zv,NN)
v = ivstruc(ze,zv,NN,p,maxsize)
```

Description

`NN` is a matrix that defines a number of different structures of the ARX type. Each row of `NN` is of the form

```
nn = [na nb nk]
```

with the same interpretation as described for `arx`. See `struc` for easy generation of typical `NN` matrices.

`ze` and `zv` are `iddata` objects containing output-input data. Only time-domain data is supported. Models for each model structure defined in `NN` are estimated using the instrumental variable (IV) method on data set `ze`. The estimated models are simulated using the inputs from data set `zv`. The normalized quadratic fit between the simulated output and the measured output in `zv` is formed and returned in `v`. The rows below the first row in `v` are the transpose of `NN`, and the last row contains the logarithms of the condition numbers of the IV matrix

$$\sum \varsigma(t)\varphi^T(t)$$

A large condition number indicates that the structure is of unnecessarily high order (see Ljung, L. *System Identification: Theory for the User*, Upper Saddle River, NJ, Prentice-Hal PTR, 1999, p. 498).

The information in `v` is best analyzed using `selstruc`.

If `p` is equal to zero, the computation of condition numbers is suppressed. For the use of `maxsize`, see `Algorithm Properties`.

The routine is for single-output systems only.

Note The IV method used does not guarantee that the models obtained are stable. The output-error fit calculated in `v` can then be misleading.

Examples

Compare the effect of different orders and delays, using the same data set for both the estimation and validation.

```
v = ivstruc(z,z,struc(1:3,1:2,2:4));
nn = selstruc(v)
m = iv4(z,nn);
```

Algorithm

A maximum-order ARX model is computed using the least squares method. Instruments are generated by filtering the input(s) through this model. The models are subsequently obtained by operating on submatrices in the corresponding large IV matrix.

`struc`

Purpose

Estimate parameters of ARX model using instrumental variable method with arbitrary instruments

Syntax

```
m = ivx(data,orders,x)
m = ivx(data,orders,x,maxsize)
```

Description

Estimate parameters of ARX model using instrumental variable method with arbitrary instruments and returning `idpoly` or `idarx` objects. `ivx` is a routine analogous to the `iv4` routine, except that you can use arbitrary instruments. These are contained in the matrix `x`. Make this the same size as the output, `data.y`. In particular, if data contains several experiments, `x` must be a cell array with one matrix/vector for each experiment. The instruments used are then analogous to the regression vector itself, except that `y` is replaced by `x`.

Note that `ivx` does not return any estimated covariance matrix for `m`, since that requires additional information. `m` is returned as an `idpoly` object for single-output systems and as an `idarx` object for multiple-output systems.

Use `iv4` as the basic IV routine for ARX model structures. The main interest in `ivx` lies in its use for nonstandard situations, for example, when there is feedback present in the data, or when other instruments need to be tried out. Note that there is also an IV version that automatically generates instruments from certain filters you define (type `help iv`).

`idpoly`

iv4

pem

Purpose

Estimate ARX model using four-stage instrumental variable method

Syntax

```
m = iv4(data,orders)
m = iv4(data,'na',na,'nb',nb,'nk',nk)
m= iv4(data,orders,'Property1',Value1,...,'PropertyN',ValueN)
```

Description

Returns `idpoly` or `idarx` object. This function is an alternative to `arx` and the use of the arguments is entirely analogous to the `arx` function. The main difference is that the procedure is not sensitive to the color of the noise term $e(t)$ in the model equation.

Examples

Here is an example of a two-input, one-output system with different delays on the inputs u_1 and u_2.

```
z = iddata(y, [u1 u2]);
nb = [2 2];
nk = [0 2];
m= iv4(z,[2 nb nk]);
```

Algorithm

The first stage uses the `arx` function. The resulting model generates the instruments for a second-stage IV estimate. The residuals obtained from this model are modeled as a high-order AR model. At the fourth stage, the input-output data is filtered through this AR model and then subjected to the IV function with the same instrument filters as in the second stage.

For the multiple-output case, optimal instruments are obtained only if the noise sources at the different outputs have the same color. The estimates obtained with the routine are reasonably accurate, however, even in other cases.

Purpose

Linear approximation of nonlinear ARX and Hammerstein-Wiener models for given input

Syntax

```
lm = linapp(nlmodel,u)
lm = linapp(nlmodel,umin,umax,nsample)
```

Input

`nlmodel`
: Name of the `idnlarx` or `idnlhw` model object you want to linearize.

`u`
: Input signal as an iddata object or a real matrix.

  Dimensions of `u` must match the number of inputs in `nlmodel`.

`[umin,umax]`
: Minimum and maximum input values for generating white-noise input with a magnitude in this rectangular range. The sample length of this signal is `nsample`.

`nsample`
: Optional argument when you specify `[umin,umax]`. Specifies the length of the white-noise input. Default: `1024`.

Description

`lm = linapp(nlmodel,u)` computes a linear approximation of a nonlinear ARX or Hammerstein-Wiener model by simulating the model output for the input signal `u`, and estimating a linear model `lm` from `u` and the simulated output signal.

`lm = linapp(nlmodel,umin,umax,nsample)` computes a linear approximation of a nonlinear ARX or Hammerstein-Wiener model by first generating the input signal as a uniformly distributed white noise from the magnitude range `umin` and `umax` and (optionally) the number of samples.

The following table summarizes the linear model objects that store the linear approximation for each type of nonlinear model and the number of outputs.

Nonlinear Model Type	Number of Outputs	Linear Model Object
idnlarx	Single output	idpoly
idnlarx	Multiple outputs	idarx
idnlhw	Single output	idpoly
idnlhw	Multiple outputs	idss

How To

- "Linear Approximation of Nonlinear Black-Box Models"

Purpose

Specify to estimate nonlinear ARX model that is linear in (nonlinear) custom regressors

Syntax

```
lin=linear
lin=linear('Parameters',Par)
```

Description

`linear` is an object that specifies that the nonlinear ARX model is linear in custom (nonlinear) regressors. You define custom regressors using `customreg`.

`lin=linear` instantantiates the `linear` object.

`lin=linear('Parameters',Par)` instantantiates the `linear` object and specifies optional values in the `Par` structure. For more information about this structure, see "linear Properties" on page 2-267.

Remarks

`linear` is a linear (affine) function $y = F(x)$, defined as follows:

$$F(x) = xL + d$$

y is scalar, and x is a 1-*by*-`m` vector.

Use `evaluate(lin,x)` to compute the value of the function defined by the `linear` object `lin` at `x`.

linear Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List Parameters values
get(lin)
% Get value of Parameters property
lin.Parameters
```

Property Name	Description
`Parameters`	Structure containing the following fields: • `LinearCoef`: m-*by*-1 vector *L*. • `OutputOffset`: Scalar d.

Examples

To specify that the nonlinear ARX model is linear in custom regressors, first specify one or more `customreg` objects. Then, include the `linear` object in the `nlarx` estimator command.

For example, to estimate a nonlinear ARX model linear in the custom regressors, use the following syntax:

```
m=nlarx(Data,Orders,linear,'custom',{'y(t-1)*u(t-2)'});
```

Note In this example, the custom regressor is a nonlinear function of input and output variables.

Algorithm

When the `idnlarx` property `Focus` is `'Prediction'`, `linear` uses a fast, noniterative initialization and iterative search technique for estimating parameters. In most cases, iterative search requires only a few iterations.

When the `idnlarx` property `Focus='Simulation'`, `linear` uses an iterative technique for estimating parameters.

`customreg`

`nlarx`

Purpose

Linearize nonlinear ARX model

Syntax

```
SYS = linearize(NLSYS,U0,X0)
```

Description

`SYS = linearize(NLSYS,U0,X0)` linearizes a nonlinear ARX model about the specified operating point `U0` and `X0`. The linearization is based on tangent linearization. For more information about the definition of states for `idnlarx` models, see "Definition of idnlarx States" on page 2-189.

Input

- `NLSYS`: `idnlarx` model.
- `U0`: Matrix containing the constant input values for the model.
- `X0`: Model state values. The states of a nonlinear ARX model are defined by the time-delayed samples of input and output variables. For more information about the states of nonlinear ARX models, see the `getDelayInfo` reference page.

Note To estimate `U0` and `X0` from operating point specifications, use the `findop(idnlarx)` command.

Output

- `SYS` is an `idss` model.

  When the Control System Toolbox product is installed, `SYS` is an LTI object.

Algorithm

The following equations govern the dynamics of an `idnlarx` model:

$$X(t+1) = AX(t) + B\tilde{u}(t)$$
$$y(t) = f(X,u)$$

where $X(t)$ is a state vector, $u(t)$ is the input, and $y(t)$ is the output. A and B are constant matrices. $\tilde{u}(t)$ is $[y(t), u(t)]^T$.

The output at the operating point is given by

$y^* = f(X^*, u^*)$

where X^* and u^* are the state vector and input at the operating point.

The linear approximation of the model response is as follows:

$$\Delta X(t+1) = (A + B_1 f_X)\Delta X(t) + (B_1 f_u + B_2)\Delta u(t)$$
$$\Delta y(t) = f_X \Delta X(t) + f_u \Delta u(t)$$

where

- $\Delta X(t) = X(t) - X^*(t)$
- $\Delta u(t) = u(t) - u^*(t)$
- $\Delta y(t) = y(t) - y^*(t)$
- $B\tilde{U} = [B_1, B_2]\begin{bmatrix} Y \\ U \end{bmatrix} = B_1 Y + B_2 U$
- $f_X = \frac{\partial}{\partial X} f(X,U)\Big|_{X^*,U^*}$
- $f_U = \frac{\partial}{\partial U} f(X,U)\Big|_{X^*,U^*}$

Note For linear approximations over larger input ranges, use `linapp`. For more information, see the `linapp` reference page.

Example

Linearize a nonlinear ARX model around an operating point corresponding to a simulation snapshot at a specific time. Create an `idnlarx` model estimated using sample data.

1 Load sample data:

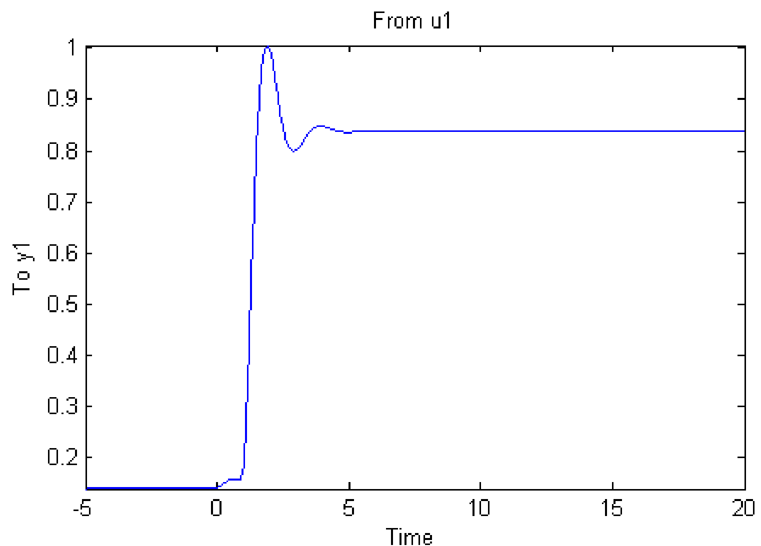
```
load iddata2
```

2 Estimate `idnlarx` model from sample data:

```
nlsys = nlarx(z2,[4 3 10],'tree','custom',...
  {'sin(y1(t-2)*u1(t))+y1(t-2)*u1(t)+u1(t).*u1(t-13)',...
   'y1(t-5)*y1(t-5)*y1(t-1)'},'nlr',[1:5, 7 9]);
```

3 Plot the response of the model for a step input:

```
step(nlsys, 20)
```



The model step response is a steady-state value of `0.8383` at `T = 20` seconds.

4 Compute the operating point corresponding to `T = 20`.

```
stepinput = iddata([],[zeros(10,1);ones(200,1)],...
                    nlsys.Ts);
% Compute operating point.
[x,u] = findop(nlsys,'snapshot',20,stepinput);
```

5 Linearize the model about the operating point corresponding to the model snapshot at `T=20`.

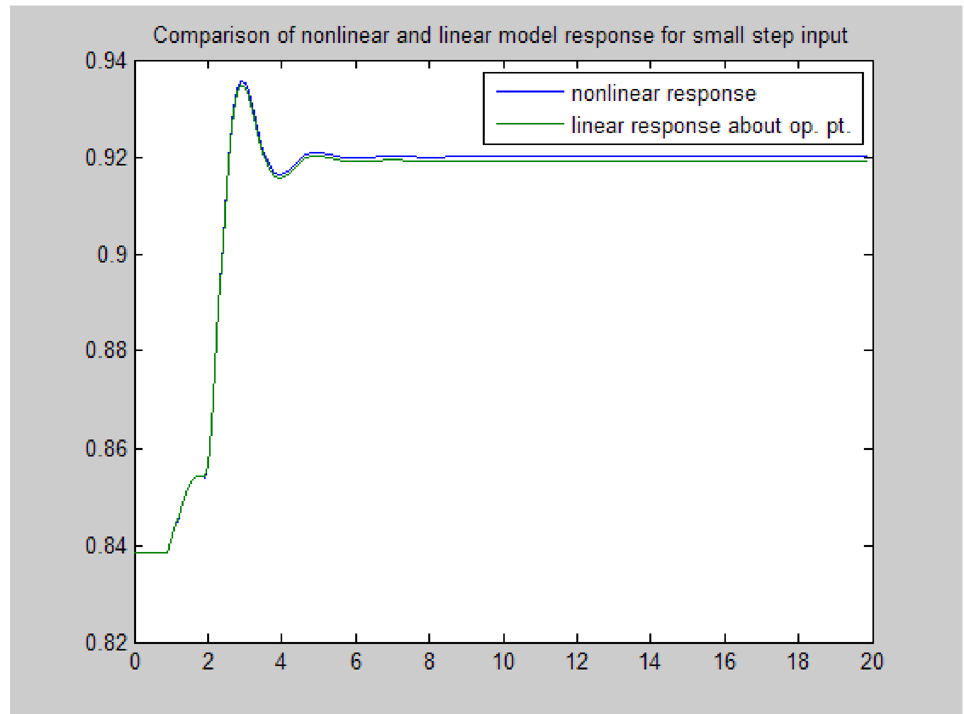
```
sys = linearize(nlsys,u,x)
```

6 To validate the linear model, apply a small perturbation `delta_u` to the steady-state input of the nonlinear model `nlsys`. If the linear approximation is accurate, the following should match:

- The response of the nonlinear model `y_nl` to an input that is the sum of the equilibrium level and the perturbation `delta_u`.
- The sum of the response of the linear model to a perturbation input `delta_u` and the output equilibrium level.

```
% Generate a 200-sample step signal with amplitude 0.1
% This is the perturbation signal.
delta_u = [zeros(10,1); 0.1*ones(190,1)];
%
% For a nonlinear system with a steady-state input of 1
% and a steady-state output of 0.8383,
% compute the steady-state response
% y_nl to the perturbed input u_nl. Use equilibrium state
% values x as initial conditions (see Step 4).
u_nl = 1 + delta_u;
y_nl = sim(nlsys,u_nl,x);
%
% Compute response of linear model to perturbation input
% and add it to the output equilibrium level:
y_lin = 0.8383 + lsim(sys,delta_u);
%
% Compare the response of nonlinear and linear models:
time = [0:0.1:19.9]';
plot(time,y_nl,time,y_lin)
legend('Nonlinear response',...
       'Linear response about op. pt.')
```

```
title(['Nonlinear and linear model response'...
       ' for small step input'])
```



The linearized model response tracks the nonlinear model output.

How To

- "Linear Approximation of Nonlinear Black-Box Models"

linearize(idnlhw)

Purpose

Linearize Hammerstein-Wiener model

Syntax

```
SYS = linearize(NLSYS,U0)
SYS = linearize(NLSYS,U0,X0)
```

Description

`SYS = linearize(NLSYS,U0)` linearizes a Hammerstein-Wiener model around the equilibrium operating point. When using this syntax, equilibrium state values for the linearization are calculated automatically using `U0`.

`SYS = linearize(NLSYS,U0,X0)` linearizes the `idnlhw` model `NLSYS` around the operating point specified by the input `U0` and state values `X0`. In this usage, `X0` need not contain equilibrium state values. For more information about the definition of states for `idnlhw` models, see "idnlhw States" on page 2-223.

The output is a linear model that is the best linear approximation for inputs that vary in a small neighborhood of a constant input $u(t) = U$. The linearization is based on tangent linearization.

Input

- `NLSYS`: `idnlhw` model.
- `U0`: Matrix containing the constant input values for the model.
- `X0`: Operating point state values for the model.

Note To estimate `U0` and `X0` from operating point specifications, use the `findop(idnlhw)` command.

Output

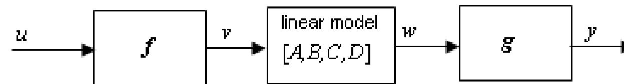
- `SYS` is an `idss` model.

  When the Control System Toolbox product is installed, `SYS` is an LTI object.

Algorithm

The `idnlhw` model structure represents a nonlinear system using a linear system connected in series with one or two static nonlinear

systems. For example, you can use a static nonlinearity to simulate saturation or dead-zone behavior. The following figure shows the nonlinear system as a linear system that is modified by static input and output nonlinearities, where function ***f*** represents the input nonlinearity, ***g*** represents the output nonlinearity, and [*A*,*B*,*C*,*D*] represents a state-space parameterization of the linear model.



The following equations govern the dynamics of an `idnlhw` model:

$v(t) = f(u(t))$

$X(t+1) = AX(t)+Bv(t)$

$w(t) = CX(t)+Dv(t)$

$y(t) = g(w(t))$

where

- u is the input signal
- v and w are intermediate signals (outputs of the input nonlinearity and linear model respectively)
- y is the model output

The linear approximation of the Hammerstein-Weiner model around an operating point (X^*, u^*) is as follows:

$$\Delta X(t+1) = A\Delta X(t) + Bf_u \Delta u(t)$$
$$\Delta y(t) \approx g_w C\Delta X(t) + g_w D f_u \Delta u(t)$$

where

- $\Delta X(t) = X(t) - X^*(t)$
- $\Delta u(t) = u(t) - u^*(t)$

- $\Delta y(t) = y(t) - y^*(t)$
- $f_u = \frac{\partial}{\partial u} f(u)\Big|_{u=u^*}$
- $g_w = \frac{\partial}{\partial w} g(w)\Big|_{w=w^*}$

where y^* is the output of the model corresponding to input u^* and state vector X^*, $v^* = f(u^*)$, and w^* is the response of the linear model for input v^* and state X^*.

Note For linear approximations over larger input ranges, use `linapp`. For more information, see the `linapp` reference page.

Examples

Linearize a Hammerstein-Wiener model with two inputs at an equilibrium point, and compare the linearized model response to the original model response.

1. Load the sample data to create `iddata` object `z`.

```
load iddata2
load iddata3
z2.Ts = z3.Ts;
z = [z2(1:300),z3]; % Estimation data
```

2. Estimate an `idnlhw` model using a combination of `pwlinear`, `poly1d`, `sigmoidnet` and `customnet` nonlinearities.

```
orders = [2 2 3 4 1 5; 2 5 1 2 5 2];
nlsys = nlhw(z,orders,[pwlinear;poly1d],...
             [sigmoidnet;customnet(@gaussunit)]);
```

3. Linearize the model at an equilibrium operating point corresponding to input levels of `10` and `5` respectively. To do this you first compute

the operating point using `findop`, then linearize the model around the computed input and state values.

```
[x,u_s,report] = findop(nlsys,'steady',[10,5]);
sys = linearize(nlsys,u_s,x);
% sys is a state-space model
```

4. To validate the linear model, apply a small perturbation `delta_u` to the steady-state input of the nonlinear model `nlsys`. If the linear approximation is accurate, the following should match:

   - The response of the nonlinear model `y_nl` to an input that is the sum of the equilibrium level and the perturbation `delta_u`.
   - The sum of the response of the linear model to a perturbation input `delta_u` and the output equilibrium level.

```
% Generate a 300-sample step signal with amplitude 0.1
% This is the perturbation input signal.
delta_u = [zeros(20,2); 0.1*ones(280,2)];
%
% Compute the response of the linear model delta_y_lin
% to the perturbed input signal delta_u:
delta_y_lin = lsim(sys,delta_u);
%
% For the nonlinear system with a steady-state input u_s,
% compute the steady-state output y_s from the
% SignalLevels field of the findop report (see Step 3):
y_s = report.SignalLevels.Output;
%
% Compute the perturbed input to the nonlinear system
% as the sum of the steady-state input u_s and
% the perturbation signal delta_u:
u_nl = bsxfun(@plus,delta_u,u_s);

% Compute the steady-state response of the
% nonlinear system y_nl to the perturbed input u_nl.
% Use equilibrium state values x as initial conditions.
```

```
y_nl = sim(nlsys,u_nl,x);
%
% Compare the response of nonlinear and linear models:
time = (0:299)';
subplot(211)
plot(time,y_nl(:,1),time,delta_y_lin(:,1)+y_s(1),'.')
legend('Nonlinear response',...
       'Linear response about op. pt.')
title('Comparison of signal values for output 1')

subplot(212)
plot(time,y_nl(:,2),time,delta_y_lin(:,2)+y_s(2),'.')
legend('Nonlinear response',...
       'Linear response about op. pt.')
title('Comparison of signal values for output 2')
```

How To

- "Linear Approximation of Nonlinear Black-Box Models"

LTI Commands

Purpose

Apply Control System Toolbox commands to linear model

Syntax

```
append, augstate, balreal, canon, d2d, feedback, inv, minreal,
modred, norm, parallel, series, ss2ss
```

Description

When you have the Control System Toolbox product installed, you can apply the listed LTI commands to `idmodel` objects, including `idarx`, `idgrey`, `idpoly`, and `idss` models. You can also use the overloaded operations `+`, `-`, and `*`. The same operations are performed and the result is delivered as an `idmodel`. The original covariance information is lost most of the time, however.

Examples

You have two more or less identical processes connected in series. Estimate a model for one of them, and use that to form an initial estimate for a model of the connected process.

```
% data concerns one of the processes
m = pem(data)
% data2 is from the entire connected process
m2 = pem(data2,m*m)
```

merge (iddata)

Purpose

Merge data sets into iddata object

Syntax

```
dat = merge(dat1,dat2,....,datN)
```

Description

`dat` collects the data sets in `dat1, ...,datN` into one `iddata` object, with several *experiments*. The number of experiments in `dat` will be the sum of the number of experiments in `datk`. For the merging to be allowed, a number of conditions must be satisfied:

- All of `datk` must have the same number of input channels, and the `InputNames` must be the same.
- All of `datk` must have the same number of output channels, and the `OutputNames` must be the same. If some input or output channel is lacking in one experiment, it can be replaced by a vector of `NaN`s to conform with these rules.
- If the `ExperimentNames` of `datk` have been specified as something other than the default `'Exp1'`, `'Exp2'`, etc., they must all be unique. If default names overlap, they are modified so that `dat` will have a list of unique `ExperimentNames`.

The sampling intervals, the number of observations, and the input properties (`Period`, `InterSample`) might be different in the different experiments.

You can retrieve the individual experiments by using the command `getexp`. You can also retrieve them by subreferencing with a fourth index.

```
dat1 = dat(:,:,:,ExperimentNumber)
```

or

```
dat1 = dat(:,:,:,ExperimentName)
```

Storing multiple experiments as one `iddata` object can be very useful for handling experimental data that has been collected on different

occasions, or when a data set has been split up to remove "bad" portions of the data. All the toolbox routines accept multiple-experiment data.

Examples

Bad portions of data have been detected around sample 500 and between samples 720 to 730. Cut out these bad portions and form a multiple-experiment data set that can be used to estimate models without the bad data destroying the estimate.

```
dat = merge(dat(1:498),dat(502:719),dat(731:1000))
m = pem(dat)
```

Use the first two parts to estimate the model and the third one for validation.

```
m = pem(getexp(dat,[1,2]));
compare(getexp(dat,3),m)
```

See also `iddemo` #9.

See Also

`iddata`

`getexp`

Purpose

Merge estimated models

Syntax

```
m = merge(m1,m2,....,mN)
[m,tv] = merge(m1,m2)
```

Description

The models `m1,m2,...,mN` must all be of the same structure, just differing in parameter values and covariance matrices. Then `m` is the merged model, where the parameter vector is a statistically weighted mean (using the covariance matrices to determine the weights) of the parameters of `mk`.

When two models are merged,

```
[m, tv] = merge(m1,m2)
```

returns a test variable `tv`. It is χ^2 distributed with `n` degrees of freedom, if the parameters of `m1` and `m2` have the same means. Here `n` is the length of the parameter vector. A large value of `tv` thus indicates that it might be questionable to merge the models.

For `idfrd` models, `merge` is a statistical average of two responses in the individual models, weighted using inverse variances. You can only merge two `idfrd` models with responses at the same frequencies and nonzero covariances.

Merging models is an alternative to merging data sets and estimating a model for the merged data.

```
m1 = arx(z1,[2 3 4]);
m2 = arx(z2,[2 3 4]);
ma = merge(m1,m2);
```

and

```
mb = arx(merge(z1,z2),[2 3 4]);
```

result in models `ma` and `mb` that are related and should be close. The difference is that merging the data sets assumes that the signal-to-noise ratios are about the same in the two experiments. Merging the models

allows one model to be much more uncertain, for example, due to more disturbances in that experiment. If the conditions are about the same, we recommend that you merge data rather than models, since this is more efficient and typically involves better conditioned calculations.

Purpose

Set folder for storing `idprefs.mat` containing GUI startup information

Syntax

```
midprefs
midprefs(path)
```

Description

The graphical user interface `ident` allows a large number of variables for customized choices. These include the window layout, the default choices of plot options, and names and directories of the four most recent sessions with `ident`. This information is stored in the file `idprefs.mat`, which should be placed on the user's `MATLABPATH`. The default, automatic location for this file is in the same folder as the user's `startup.m` file.

`midprefs` is used to select or change the folder where you store `idprefs.mat`. Either type `midprefs` and follow the instructions, or give the folder name as the argument. Include all folder delimiters, as in the PC case

```
midprefs('c:\matlab\toolbox\local\')
```

or in the UNIX® case

```
midprefs('/home/ljung/matlab/')
```

See Also

`ident`

misdata

Purpose

Reconstruct missing input and output data

Syntax

```
Datae = misdata(Data)
Datae = misdata(Data,Model)
Datae = misdata(Data,Maxiter,Tol)
```

Description

`Data` is time-domain input-output data in the `iddata` object format. Missing data samples (both in inputs and in outputs) are entered as `NaN`s.

`Datae` is an `iddata` object where the missing data has been replaced by reasonable estimates.

`Model` is any `idmodel` (`idarx`, `idgrey`, `idpoly`, `idss`) used for the reconstruction of missing data.

If no suitable model is known, it is estimated in an iterative fashion using default order state-space models.

`Maxiter` is the maximum number of iterations carried out (the default is 10). The iterations are terminated when the difference between two consecutive data estimates differs by less than `Tol`%. The default value of `Tol` is `1`.

Algorithm

For a given model, the missing data is estimated as parameters so as to minimize the output prediction errors obtained from the reconstructed data. See Section 14.2 in Ljung (1999). Treating missing outputs as parameters is not the best approach from a statistical point of view, but is a good approximation in many cases.

When no model is given, the algorithm alternates between estimating missing data and estimating models, based on the current reconstruction.

Purpose

Class representing neural network object created in Neural Network Toolbox product for estimating nonlinear ARX and Hammerstein-Wiener models

Syntax

```
n=neuralnet(Network)
```

Description

`neuralnet` is an object that stores the neural network nonlinearity estimator for estimating nonlinear ARX and Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`n=neuralnet(Network)` creates a neural network nonlinearity estimator based on the network object you created using the Neural Network Toolbox product.

The neural network must meet the following requirements:

- Neural network must be created using the Neural Network Toolbox `newff` or `newcf` command (feedforward networks used for function approximation).
- Neural network must represent a static mapping between the inputs and the output. It should not contain I/O delays or feedback.
- Neural network must have one output. If you want to use neural networks for multiple-output nonlinear ARX model, you must assign a separate `neuralnet` estimator for each output—that is, each estimator must represent a single-output network object.

Use `evaluate(n,x)` to compute the value of the function defined by the `neuralnet` object `n` at `x`.

Remarks

Use `neuralnet` to define a nonlinear function $y = F(x)$, where F is a multilayer feedforward neural network, as defined in the Neural Network Toolbox documentation.

y is a scalar and x is an `m`-dimensional row vector.

When you have installed the Neural Network Toolbox product, you can create a multilayer feedforward neural network using the Neural Network Toolbox function `newff`:

```
ff = newff(P,T,[nL_1,nL_2,..,nL_r],{tf_1,tf_2,...,tf_r})
```

where `P` is an `m`-*by*-`N` matrix containing inputs `x`, and `T` is a `1`-*by*-`N` matrix containing output (target) values for one of the model outputs. You can also use the Neural Network Toolbox function `newcf`.

There are `r+1` layers and `nL_k` neurons in the `k`th layer, except for the last layer. The last layer has one neuron assigned automatically, such that `nL_(r+1)=1`. The transfer function (or unit function) in the `k`th layer is `tf_k`.

If `m` is unknown at the time of creation of the network, use `P = zeros(0,N)` with arbitrary `N>0`. After this initialization, `m` is adjusted to the estimation data by `nlarx` or `nlhw`. Similarly, you can set `T` to any vector (number of rows=1).

neuralnet Properties

You include the property as an argument in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List Network property value
get(n)
n.Network
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(d, 'Network', net_obj)
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
`Network`	Neural network object. You must use the Neural Network Toolbox `newff` or `newcf` command to create such an object.

The `newff` and `newcf` commands automatically create a network object configured for use with the System Identification Toolbox software. When you manually configure the network object (`net`), specify its properties as follows:

- `net.numInputs=1`

  The single input can be a vector.

- `net.numLayers`

  Must be a positive integer (`nL`).

- `net.inputConnect=[1;zeros(nL-1,1)]`

  The first layer must be connected to the input.

- `net.outputConnect=[zeros(1,nL-1) 1]`

  The last layer must be connected to the output.

- `net.layerConnect`

  Must be an `nL`-*by*-`nL` logical matrix that satisfies the following conditions:

  - Each layer, except the last one, must have its output connected to another layer `all(any(net.layerConnect(:,1:end-1),1),2) == true`
  - Each layer, except the first one, must have its input connected to another layer `all(any(net.layerConnect(2:end,:),2),1) == true`

  Typical value is `diag(true(1,nL-1),-1)` and represents a series connection from the first layer to the last layer.

- `net.trainFcn`

Must be set to the MATLAB training function name (MATLAB file, MEX-file, built-in, or P-file).

```
all(any(net.layerConnect(2:end,:),2),1) == true
```

- `net.inputs{1}.size`

  Must be set zero (undetermined) or a positive integer equal to the number of regressors.

- `net.initFcn='initlay'`

  Indicates the use of layer initialization functions.

- `net.gradientFcn='calcjx'`
- `net.performFcn`

  Must be set to the MATLAB performance function name (MATLAB file, MEX-file, built-in, or P-file).

  ```
  any(exist(net.performFcn)==[2 3 5 6]) == true
  ```

  Typical value is `'mse'`.

- `net.trainParam`

  Must be a structure with fields:

  ```
  epochs
  goal
  max_fail
  mem_reduc
  min_grad
  mu
  mu_dec
  mu_inc
  mu_max
  show
  showCommandLine
  showWindow
  time
  ```

- `net.layers(k).initFcn` for `k=1:nL`

  Must be set to the MATLAB initialization function name (MATLAB file, MEX-file, built-in, or P-file).

  ```
  any(exist(net.layers{k}.initFcn)==[2 3 5 6]) == true
  ```

  Typical value is `'initnw'`.

- `net.biasConnect=logical(net.biasConnect)`

  Must be a logical value.

Note The layer numbers, namely the values of `k` in `net.layers{k}`, are labels referring to the different layers. The layers are not necessarily connected in the natural order indicated by `k`. It means that, in principle, `net.layers{1}` is not necessarily the input layer, and `net.layers{end}` is not necessarily the output layer. However, topologically, there is no loss of generality to assume that `net.layers{1}` is the input layer and `net.layers{end}` is the output layer. The previous requirements make these assumptions to simplify how you can validate your network object.

Algorithm

When the `idnlarx` property `Focus` is `'Prediction'`, `neuralnet` uses the `train` method of the `network` object in the Neural Network Toolbox software for estimating parameters.

You cannot use `nerualnet` when `Focus` is `'Simulation'` because this nonlinearity estimator is not differentiable. Minimization of simulation error requires differentiable nonlinear functions.

Examples

Use `neuralnet` to specify the neural network nonlinearity estimator in nonlinear ARX and Hammerstein-Wiener models. For example:

```
% Create network object using Neural Network Toolbox
net_obj=newff(zeros(0,10),rand(1,10),[6 8 2],...
                  {'logsig','logsig','purelin'})
% Estimate nonlinear ARX model using
```

```
% net_obj as the neural network
m=nlarx(z1,[2,6,10],neuralnet(net_obj));
```

See Also

`nlarx`

`nlhw`

Purpose

Shift data sequences

Syntax

```
Datas = nkshift(Data,nk)
```

Description

`Data` contains input-output data in the `iddata` format.

`nk` is a row vector with the same length as the number of input channels in `Data`.

`Datas` is an `iddata` object where the input channels in `Data` have been shifted according to `nk`. A positive value of `nk(ku)` means that input channel number `ku` is delayed `nk(ku)` samples.

`nkshift` supports both frequency- and time-domain data. For frequency-domain data it multiplies with $e^{ink\omega T}$ to obtain the same effect as shifting in the time domain. For continuous-time frequency-domain data (`Ts = 0`), `nk` should be interpreted as the shift in seconds.

`nkshift` lives in symbiosis with the `InputDelay` property of `idmodel`:

```
m1 = pem(dat,4,'InputDelay',nk)
```

is related to

```
m2 = pem(nkshift(dat,nk),4);
```

such that `m1` and `m2` are the same models, but `m1` stores the delay information and uses this information when computing the frequency response, for example. When using `m2`, the delay value must be accounted for separately when computing time and frequency responses.

Note the difference from the `idss` and `idpoly` property `nk`.

```
m3 = pem(dat,4,'nk',nk)
```

gives a model that itself explicitly contains a delay of `nk` samples. In contrast, `m1` contains a total delay of `m1.nk + m1.InputDelay = 4`.

`idss`

Purpose

Estimate nonlinear ARX model

Syntax

```
m = nlarx(data,[na nb nk])
m = nlarx(data,[na nb nk],Nonlinearity)
m = nlarx(data,[na nb nk],'PropertyName',PropertyValue)
m = nlarx(data,LinModel)
m = nlarx(data,LinModel,Nonlinearity)
m = nlarx(data,LinModel,Nonlinearity,'PropertyName',
   PropertyValue)
```

Description

`m = nlarx(data,[na nb nk])` creates and estimates a nonlinear ARX model using a default wavelet network as its nonlinearity estimator. `data` is an `iddata` object. *na*, *nb*, and *nk* are positive integers that specify the model orders and delays.

`m = nlarx(data,[na nb nk],Nonlinearity)` specifies a nonlinearity estimator *Nonlinearity*, as a nonlinearity estimator object or string representing the nonlinearity estimator type.

`m = nlarx(data,[na nb nk],'PropertyName',PropertyValue)` constructs and estimates the model using options specified as `idnlarx` property name and value pairs. Specify *PropertyName* inside single quotes.

`m = nlarx(data,LinModel)` creates and estimates a nonlinear ARX model using a linear model (in place of [*na nb nk*]), and a wavelet network as its nonlinearity estimator. *LinModel* is a discrete time input-output polynomial model of ARX structure (`idpoly`) for single-output systems, and `idarx` object, for multi-output systems. *LinModel* sets the model orders, input delay, input-output channel names and units, sample time, and time unit of *m*, and the polynomials initialize the linear function of the nonlinearity estimator.

`m = nlarx(data,LinModel,Nonlinearity)` specifies a nonlinearity estimator *Nonlinearity*.

`m = nlarx(data,LinModel,Nonlinearity,'PropertyName',PropertyValue)`,

constructs and estimates the model using options specified as `idnlarx` property name and value pairs.

Input Arguments

`data`

Time-domain `iddata` object.

`na nb nk`

Positive integers that specify the model orders and delays.

For `ny` output channels and `nu` input channels, `na` is an `ny`-by-`ny` matrix whose *i*-*j*th entry gives the number of delayed *j*th outputs used to compute the *i*th output. `nb` and `nk` are `ny`-by-`nu` matrices, where each row defines the orders for the corresponding output.

`Nonlinearity`

Nonlinearity estimator, specified as a nonlinearity estimator object or string representing the nonlinearity estimator type.

`'wavenet'` or `wavenet` object (default)	Wavelet network
`'sigmoidnet'` or `sigmoidnet` object	Sigmoid network
`'treepartition'` or `treepartition` object	Binary-tree
`'linear'` or `[]` or `linear` object	Linear function
`neuralnet` object	Neural network
`customnet` object	Custom network

Specifying a string creates a nonlinearity estimator object with default settings. Use object representation to configure the properties of a nonlinearity estimator.

For `ny` output channels, you can specify nonlinear estimators individually for each output channel by setting *`Nonlinearity`* to an `ny`-by-1 cell array or object array of nonlinearity estimators. To specify the same nonlinearity for all outputs, specify *`Nonlinearity`* as a single nonlinearity estimator.

LinModel

Discrete time input-output polynomial model of ARX structure, typically estimated using the arx command:

- idpoly object for single-output systems
- idarx object for multi-output systems

Examples

Estimate nonlinear ARX model with default settings:

```
load twotankdata
Ts = 0.2; % Sampling interval is 0.2 min
z = iddata(y,u,Ts);  % constructs iddata object
m = nlarx(z,[4 4 1]) % na=nb=4 and nk=1
```

Estimate nonlinear ARX model with a specific nonlinearity:

```
  NL =  wavenet('NumberOfUnits',5);
% Wavelet network has 5 units
  m = nlarx(z,[4 4 1],NL)
```

Estimate nonlinear ARX model with a custom network nonlinearity:

```
% Define custom unit function and save it as gaussunit.m.
function [f, g, a] = GAUSSUNIT(x)
[f, g, a] = gaussunit(x)
f =  exp(-x.*x);
if nargout>1
  g = - 2*x.*f;
  a = 0.2;
end

% Estimate nonlinear ARX model using the custom
% Gauss unit function.
H = @gaussunit;
```

```
CNetw = customnet(H);
m = nlarx(data,[na nb nk],CNetw)
```

Estimate nonlinear ARX model with specific algorithm settings:

```
  m = nlarx(z,[4 4 1],'sigmoidnet','MaxIter',50,...
                      'Focus','Simulation')
% Maximum number of estimation iterations is 50.
% Estimation focus 'simulation' optimizes model for
% simulation applications.
```

Estimate nonlinear ARX model from time series data:

```
t = 0:0.01:10;
y = 10*sin(2*pi*10*t)+rand(size(t));
z = iddata(y',[],0.01);
m = nlarx(z,2,'sigmoid')
compare(z,m,1) % compare 1-step-ahead
               % prediction pf response
```

Estimate nonlinear ARX model and avoid local minima:

```
% Estimate initial model.
  load iddata1
  m1=nlarx(z1,[4 2 1],'wave','nlr',[1:3])
% Perturb parameters slightly to avoid local minima:
  m2=init(m1)
% Estimate model with perturbed initial parameter values:
  m2=nlarx(z1,m2)
```

Estimate nonlinear ARX model with custom regressors:

```
% Load sample data z1 (iddata object).
  load iddata1
% Estimate the model parameters:
  m = nlarx(z1,[0 0 0],'linear','CustomReg',...
                              {'y1(t-1)^2',...
                              'y1(t-2)*u1(t-3)'})
% na=nb=nk=0 means there are no standard regressors.
% 'linear' means that the nonlinear estimator has only
% the linear function.
```

Estimate nonlinear ARX model with custom regressor object:

```
% Load sample data z1 (iddata object):
  load iddata1
% Define custom regressors as customreg objects:
  C1 = customreg(@(x)x^2,{`y1'}, [1]); % y1(t-1)^2
  C2 = customreg(@(x,y)x*y,{`y1', `u1'},...
                         [2 3]); % y1(t-2)*u1(t-3)
  C = [C1, C2]; % object array of custom regressors
% Estimate model with custom regressors:
  m = nlarx(z1,[0 0 0],`linear',`CustomReg',C);
% List all model regressors:
  getreg(m)
```

Estimate nonlinear ARX model and search for optimum regressors for input to the nonlinear function:

```
load iddata1
m = nlarx(z1,[4 4 1],'sigmoidnet',...
          'NonlinearRegressors','search');
m.NonlinearRegressors
% regressors indices in nonlinear function
```

Estimate nonlinear ARX model with selected regressors as inputs to the nonlinear function:

```
  load iddata1
  m = nlarx(z1,[4 4 1],'sigmoidnet',...
                       'NonlinearReg','input');
% Only input regressors enter the nonlinear function.
% m is linear in past outputs.
```

Estimate nonlinear ARX model with no linear term in the nonlinearity estimator:

```
  load iddata1
  SNL = sigmoidnet('LinearTerm','off')
  m = nlarx(z1,[2 2 1],SNL);
```

Estimate MIMO nonlinear ARX model that has the same nonlinearity estimator for all output channels:

```
  m = nlarx(data,[[2 1;0 1] [2;1] [1;1]],...
               sigmoidnet('num',7))
% m uses a sigmoid network with 7 units
% for all output channels.
```

Estimate MIMO nonlinear ARX model with different nonlinearity estimator for each output channel:

```
  m = nlarx(data,[[2 1;0 1] [2;1] [1;1]],...
               ['wavenet'; sigmoidnet('num',7)])
% first output channel uses a wavelet network
% second output channel uses a sigmoid network with 7 units
```

Estimate a nonlinear ARX model using an ARX model:

```
% Estimate  linear ARX model.
load throttledata.mat
Tr = getTrend(ThrottleData);
Tr.OutputOffset = 15;
DetrendedData = detrend(ThrottleData, Tr);
LinearModel = arx(DetrendedData, [2 1 1], 'Focus', 'Simulation');

% Estimate nonlinear ARX model using linear model to model
% output saturation in data.
NonlinearModel = nlarx(ThrottleData, LinearModel, 'sigmoidnet',...
 'Focus', 'Simulation')
```

- “Using Linear Model for Nonlinear ARX Estimation”

Purpose

Estimate Hammerstein-Wiener model

Syntax

```
m = nlhw(data,[nb nf nk])
m = nlhw(data,[nb nf nk],InputNL,OutputNL)
m = nlhw(data,[nb nf nk],InputNL,OutputNL,'PropertyName',
   PropertyValue)
m = nlhw(data,LinModel)
m = idnlhw(LinModel,InputNL,OutputNL)
m = idnlhw(LinModel,InputNL,OutputNL,'PropertyName',
   PropertyValue)
```

Description

`m = nlhw(data,[nb nf nk])` creates and estimates a Hammerstein-Wiener model using piecewise linear functions as its input and output nonlinearity estimators. *`data`* is a time-domain `iddata` object. *`nb`*, *`nf`*, and *`nk`* are positive integers that specify the model orders and delay. *`nb`* is the number of zeros plus 1, *`nf`* is the number of poles, and *`nk`* is the input delay.

`m = nlhw(data,[nb nf nk],InputNL,OutputNL)` specifies input nonlinearity *`InputNL`* and output nonlinearity *`OutputNL`*, as a nonlinearity estimator object or string representing the nonlinearity estimator type.

`m = nlhw(data,[nb nf nk],InputNL,OutputNL,'PropertyName',PropertyValue)` creates and estimates the model using options specified as `idnlhw` property name and value pairs. Specify *`PropertyName`* inside single quotes.

`m = nlhw(data,LinModel)` creates and estimates a Hammerstein-Wiener model using a linear model (in place of [*`nb nf nk`*]), and default piecewise linear functions for the input and output nonlinearity estimators. *`LinModel`* is a discrete-time input-output polynomial model of Output-Error (OE) structure (`idpoly`) or state-space model with no disturbance component (`idss` with $K = 0$) for single-output systems, and `idss` model with $K = 0$ for multi-output systems. *`LinModel`* sets the model orders, input delay, B and F polynomial values, input-output names and units, sampling time and time units of *`m`*.

m = idnlhw(*LinModel*,*InputNL*,*OutputNL*) specifies input nonlinearity *InputNL* and output nonlinearity *OutputNL*.

m = idnlhw(*LinModel*,*InputNL*,*OutputNL*,'*PropertyName*',*PropertyValue*) creates and estimates the model using options specified as idnlhw property name and value pairs.

Input Arguments

data

Time-domain iddata object.

nb, *nf nk*

Order of the linear transfer function, where *nb* is the number of zeros plus 1, *nf* is the number of poles, and *nk* is the input delay.

For nu inputs and ny outputs, nb, nf and, nk are ny-by-nu matrices whose *i-j*th entry specifies the orders and delay of the transfer function from the *j*th input to the *i*th output.

InputNL, *OutputNL*

Input and output nonlinearity estimators, respectively, specified as a nonlinearity estimator object or string representing the nonlinearity estimator type.

'pwlinear' or pwlinear object (default)	Piecewise linear function
'sigmoidnet' or sigmoidnet object	Sigmoid network
'wavenet' or wavenet object	Wavelet network
'saturation' or saturation object	Saturation
'deadzone' or deadzone object	Dead zone
'poly1d' or poly1d object	One-dimensional polynomial

`'unitgain'` or `unitgain` object	Unit gain
`customnet` object	Custom network

Specifying a string creates a nonlinearity estimator object with default settings. Use object representation to configure the properties of a nonlinearity estimator.

For `ny` output channels, you can specify nonlinear estimators individually for each output channel by setting *`InputNL`* or *`OutputNL`* to an `ny`-by-1 cell array or object array of nonlinearity estimators. To specify the same nonlinearity for all outputs, specify a single input and output nonlinearity estimator.

`LinModel`

Discrete time linear model, typically estimated using the `oe` or `n4sid` command:

- Input-output polynomial model of Output-Error (OE) structure (`idpoly`) or state-space model with no disturbance component (`idss` with $K = 0$), for single-output systems
- State-space model with no disturbance component (`idss` model with $K = 0$), for multi-output systems

Examples

Estimate a Hammerstein-Wiener model:

```
load iddata3
m1=nlhw(z3,[4 2 1],'sigmoidnet','deadzone')
```

Estimate a Hammerstein model with saturation:

```
  load iddata1
% Create a saturation object with lower limit of 0
% and upper limit of 5:
  InputNL = saturation('LinearInterval', [0 5]);
% Estimate model with no output nonlinearity.
```

```
m = nlhw(z1,[2 3 0],InputNL,[]);
```

Estimate a Wiener model with a nonlinearity containing 5 sigmoid units:

```
load iddata1
m2 = nlhw(z1,[2 3 0],[],sigmoidnet('num', 5))
```

Estimate a Hammerstein-Wiener model with a custom network nonlinearity:

```
% Define custom unit function and save it as gaussunit.m.
function [f, g, a] = GAUSSUNIT(x)
[f, g, a] = gaussunit(x)
f =  exp(-x.*x);
if nargout>1
  g = - 2*x.*f;
  a = 0.2;
end

% Estimate Hammerstein-Wiener model using the custom
% Gauss unit function.
H = @gaussunit;
CNetw = cutomnet(H);
m = nlhw(data,[na nb nk],CNetw)
```

Estimate a MISO Hammerstein model with a different nonlinearity for each input:

```
m = nlhw(data,[nb,nf,nk],...
              [sigmoidnet;pwlinear],...
              [])
```

Refine a Hammerstein-Wiener model using successive calls of `nlhw`:

```
load iddata3
m3 = nlhw(z3,[4 2 1],'sigmoidnet','deadzone')
m3 = nlhw(z3,m3)
LinearBlock = m3.LinearModel % retrieves the linear block
```

Estimate a Hammerstein-Wiener model and avoid local minima:

```
load iddata3
M1 = nlhw(z3, [2 2 1], 'sigm','wave'); % original model
M1p = init(M1); % randomly perturbs parameters about nominal values
M2 = pem(z3, M1p);  % estimates parameters of perturbed model
```

Estimate default Hammerstein-Wiener model using an input-output polynomial model of Output-Error (OE) structure:

```
% Estimate linear OE model.
load throttledata.mat
Tr = getTrend(ThrottleData);
Tr.OutputOffset = 15;
DetrendedData = detrend(ThrottleData, Tr);
LinearModel = oe(DetrendedData, [1 2 1], 'Focus', 'Simulation');

% Estimate Hammerstein-Wiener model using OE model as
% its linear component and saturation as its output nonlinearity.
NonlinearModel = nlhw(ThrottleData, LinearModel, [], 'saturation')
```

How To

- "Identifying Hammerstein-Wiener Models"
- "Using Linear Model for Hammerstein-Wiener Estimation"

Purpose

Transform `idmodel` object with noise channels to model with measured channels only

Syntax

```
mod1 = noisecnv(mod)
mod2 = noisecnv(mod,'norm')
```

Description

`mod` is any `idmodel`, `idarx`, `idgrey`, `idpoly`, or `idss`.

The noise input channels in `mod` are converted as follows: Consider a model with both measured input channels *u* (*nu* channels) and noise channels *e* (*ny* channels) with covariance matrix *Λ*:

$$y = Gu + He$$
$$\mathrm{cov}(e) = \Lambda = LL'$$

where *L* is a lower triangular matrix. Note that `mod.NoiseVariance` = *Λ*. The model can also be described with unit variance, using a normalized noise source *v*:

$$y = Gu + HLv$$
$$\mathrm{cov}(v) = I$$

- `mod1 = noisecnv(mod)` converts the model to a representation of the system [*G H*] with *nu*+*ny* inputs and *ny* outputs. All inputs are treated as measured, and `mod1` does not have any noise model. The former noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- `mod2 = noisecnv(mod,'norm')` converts the model to a representation of the system [*G HL*] with *nu*+*ny* inputs and *ny* outputs. All inputs are treated as measured, and `mod2` does not have any noise model. The former noise input channels have names `v@yname`, where `yname` is the name of the corresponding output. Note that the noise variance matrix factor *L* typically is uncertain (has a nonzero covariance). This is taken into account in the uncertainty description of `mod2`.

- If `mod` is a time series, that is, nu `= 0`, `mod1` is a model that describes the transfer function H with measured input channels. Analogously, `mod2` describes the transfer function HL.

Note the difference with subreferencing:

- `mod('m')` gives a description of G only.
- `mod('n')` gives a description of the noise model characteristics as a time-series model, that is, it describes H and also the covariance of e. In contrast, `noisecnv(m('n'))` describes just the transfer function H. To obtain a description of the normalized transfer function HL, use `noisecnv(m('n'),'norm')`.

Converting the noise channels to measured inputs is useful to study the properties of the individual transfer functions from noise to output. It is also useful for transforming `idmodel` objects to representations that do not handle disturbance descriptions explicitly.

nuderst

Purpose

Set step size for numerical differentiation

Syntax

```
nds = nuderst(pars)
```

Description

The function `pem` uses numerical differentiation with respect to the model parameters when applied to state-space structures. The same is true for many functions that transform model uncertainties to other representations.

The step size used in these numerical derivatives is determined by the `nuderst` command. The output argument `nds` is a row vector whose `k`th entry gives the increment to be used when differentiating with respect to the `k`th element of the parameter vector `pars`.

The default version of `nuderst` uses a very simple method. The step size is the maximum of 10^{-4} times the absolute value of the current parameter and 10^{-7}. You can adjust this to the actual value of the corresponding parameter by editing `nuderst`. Note that the nominal value, for example 0, of a parameter might not reflect its normal size.

Purpose

Plot Nyquist curve of frequency response with confidence interval

Syntax

```
nyquist(m)
[fr,w] = nyquist(m)
[fr,w,covfr] = nyquist(m)
nyquist(m1,m2,m3,...,w)
nyquist(m1,'PlotStyle1',m2,'PlotStyle2',...)
nyquist(m1,m2,m3,..'sd*5',sd,'mode',mode)
```

Description

`nyquist` computes the complex-valued frequency response of `idmodel` and `idfrd` models. When invoked without output arguments, `nyquist` produces a Nyquist plot on the screen, that is, a graph of the frequency response's imaginary part against its real part.

The argument `m` is an arbitrary `idmodel` or `idfrd` model. This model can be continuous or discrete, and SISO or MIMO. The `InputNames` and `OuputNames` of the models are used to plot the responses for different I/O channels in separate plots. Pressing the **Enter** key advances the plot from one input-output pair to the next one. You can select specific I/O channels with normal subreferencing: `m(ky,ku)`. With `mode = 'same'`, all plots are given in the same diagram.

`nyquist(m,w)` explicitly specifies the frequency range or frequency points to be used for the plot. To focus on a particular frequency interval `[wmin,wmax]`, set `w = {wmin,wmax}`. To use particular frequency points, set `w` to the vector of desired frequencies. Use `logspace` to generate logarithmically spaced frequency vectors. All frequencies should be specified in rad/s.

`nyquist(m1,m2,...,mN)` or `nyquist(m1,m2,...mN,w)` plots the Bode responses of several `idmodels` or `idfrd` models on a single figure. The models can be mixes of different sizes, and continuous or discrete. The sorting of the plots is based on the `InputNames` and `OutputNames`.

`nyquist(m1,'PlotStyle1',...,mN,'PlotStyleN')` further specifies which color, line style, and/or marker should be used to plot each system, as in

```
nyquist(m1,'r--',m2,'gx')
```

When sd is specified as a number larger than zero, confidence regions are also plotted. These are ellipses in the complex plane and correspond to the region where the true response at the frequency in question is to be found with a confidence corresponding to sd standard deviations (of the Gaussian distribution).

If the argument indicating standard deviations is given as in 'sd+5', a confidence region is plotted for every 5:th frequency, marking the center point by '+'. The default is 'sd+10'.

Note that the frequencies cannot be specified for idfrd objects. For those, the plot and response are calculated for the internally stored frequencies. If the frequencies w are specified when several models are treated, they will apply to all non-idfrd models in the list. If you want different frequencies for different models, you should first convert them to idfrd objects using the idfrd command.

For time-series models (no input channels), the Nyquist plot is not defined.

Input

When nyquist is called with a single system and output arguments,

```
fr = nyquist(m,w) or [fr,w,covfr] = nyquist(m)
```

no plot is drawn on the screen. If m has ny outputs and nu inputs, and w contains Nw frequencies, then fr is an ny-by-nu-by-Nw array such that fr(ky,ku,k) gives the complex-valued frequency response from input ku to output ky at the frequency w(k). For a SISO model, use fr(:) to obtain a vector of the frequency response. The uncertainty information covfr is a 5-D array where covfr(ky,ku,k,:,:)) is the 2-by-2 covariance matrix of the response from input ku to output ky at frequency w(k). The 1,1 element is the variance of the real part, the 2,2 element is the variance of the imaginary part, and the 1,2 and 2,1 elements are the covariance between the real and imaginary parts.

squeeze(covfr(ky,ku,k,:,:)) gives the covariance matrix of the corresponding response.

If m is a time series (no input), fr is returned as the (power) spectrum of the outputs, an ny-by-ny-by-Nw array. Hence fr(:,:,k) is the spectrum matrix at frequency w(k). The element fr(k1,k2,k) is the cross spectrum between outputs k1 and k2 at frequency w(k). When k1 = k2, this is the real-valued power spectrum of output k1. The covfr is then the covariance of the spectrum fr, so that covfr(k1,k1,k) is the variance of the power spectrum of output k1 at frequency w(k). No information about the variance of the cross spectra is normally given. (That is, covfr(k1,k2,k) = 0 for k1 not equal to k2.)

If the model m is not a time series, use fr = nyquist(m('n')) to obtain the spectrum information of the noise (output disturbance) signals.

Examples

```
g = spa(data)
m = n4sid(data,3)
nyquist(g,m,'sd',3)

n4sid

Purpose

Estimate state-space models using subspace method

Syntax

```
m = n4sid(data)
m = n4sid(data,order,'Property1',Value1,...,'PropertyN',ValueN)
```

Description

`n4sid` estimates models in state-space form and returns an `idss` object `m`. `n4sid` handles an arbitrary number of inputs and outputs, including the time-series case (no input). The state-space model is in the innovations form

$$x(t+Ts) = Ax(t) + Bu(t) + Ke(t)$$
$$y(t) = Cx(t) + Du(t) + e(t)$$

If `data` is continuous-time (frequency-domain) data, a corresponding continuous-time state-space model is estimated.

`data`: An `iddata` object containing the output-input data. Both time-domain and frequency-domain signals are supported. `data` can also be a `frd` or `idfrd` frequency-response data object.

`order`: The desired order of the state-space model. If `order` is entered as a row vector (as in `order = [1:10]`), preliminary calculations for all the indicated orders are carried out. A plot is then given that shows the relative importance of the dimension of the state vector. More precisely, the singular values of the Hankel matrices of the impulse response for different orders are graphed. You are prompted to select the order, based on this plot. The idea is to choose an order such that the singular values for higher orders are comparatively small. If `order = 'best'`, a model of "best" (default choice) order is computed among the orders 1:10. This is the default choice of `order`.

Estimating the D Matrix

Whether the D matrix is estimated or not is governed by the property `nk`, which is further described below. The default is that D is not estimated. By setting the `k`th entry of `nk` to 0, the `k`th column of D (corresponding to the `k`th input) is estimated. To estimate a full D matrix thus, let `nk = zeros(1,nu)` as in

```
m = n4sid(data,order,'nk',[0 .. 0])
```

This holds for both discrete- and continuous-time models.

Properties

The list of property name/property value pairs can contain any `idss` and algorithm properties. See `idss` and `Algorithm Properties`.

`idss` properties that are of particular interest for `n4sid` are

- `nk`: For time-domain data, this gives delays from the inputs to the outputs, a row vector with the same number of entries as the number of input channels. Default is `nk = [1 1... 1]`. Note that delays of 0 or 1 show up as zeros or estimated parameters in the D matrix. Delays larger than 1 mean that a special structure of the A, B, and C matrices is used to accommodate the delays. This also means that the actual order of the state-space model will be larger than `order`. For continuous-time models estimated from continuous-time (frequency-domain) data, the elements of `nk` are restricted to the values 1 and 0.
- `CovarianceMatrix` (can be abbreviated to `'co'`): Setting `CovarianceMatrix` to `'None'` blocks all calculations of uncertainty measures. These can take the major part of the computation time. Note that, for a `'Free'` parameterization, the individual matrix elements cannot be associated with any variance. (These parameters are not identifiable.) Instead, the resulting model `m` stores a hidden state-space model in canonical form that contains covariance information. This is used when the uncertainty of various input-output properties is calculated. It can also be retrieved by `m.ss = 'can'`. The actual covariance properties of `n4sid` estimates are not known today. Instead the Cramer-Rao bound is computed and stored as an indication of the uncertainty.
- `DisturbanceModel`: Setting `DisturbanceModel` to `'None'` will deliver a model with `K = 0`. This has no direct effect on the dynamics model other than that the default choice of `N4Horizon` will not involve past outputs.

- `InitialState`: The initial state is always estimated for better accuracy. However, it is returned with `m` only if `InitialState = 'Estimate'`.

Algorithm properties that are of special interest are

- `Focus`: Assumes the values `'Prediction'` (default), `'Simulation'`, `'Stability'`, passbands, or any SISO linear filter (given as an LTI or `idmodel` object, or as filter coefficients. See `Algorithm Properties`.) Setting `'Focus'` to `'Simulation'` chooses weights that should give a better simulation performance for the model. In particular, a stable model is guaranteed. Selecting a linear filter focuses the fit to the frequency ranges that are emphasized by this filter.
- `N4Weight`: This property determines some weighting matrices used in the singular-value decomposition that is a central step in the algorithm. Two choices are offered: `'MOESP'`, corresponding to the MOESP algorithm by Verhaegen, and `'CVA'`, which is the canonical variable algorithm by Larimore. The default value is `'N4Weight' = 'Auto'`, which gives an automatic choice between the two options. `m.EstimationInfo.N4Weight` tells you what the actual choice turned out to be.
- `N4Horizon`: Determines the prediction horizons forward and backward used by the algorithm. This is a row vector with three elements: `N4Horizon = [r sy su]`, where `r` is the maximum forward prediction horizon. That is, the algorithm uses up to `r` step-ahead predictors. `sy` is the number of past outputs, and `su` is the number of past inputs that are used for the predictions. See pages 209 and 210 in Ljung (1999) for the exact meaning of this. These numbers can have a substantial influence on the quality of the resulting model, and there are no simple rules for choosing them. Making `'N4Horizon'` a `k`-by-3 matrix means that each row of `'N4Horizon'` is tried, and the value that gives the best (prediction) fit to data is selected. (This option cannot be combined with selection of model order.) If the property `'Display'` is `'On'`, information about the results is given in the MATLAB Command Window.

If you specify only one column in `'N4Horizon'`, the interpretation is `r=sy=su`. The default choice is `'N4Horizon' = 'Auto'`, which uses an Akaike Information Criterion (AIC) for the selection of `sy` and `su`. If `'DisturbanceModel' = 'None'`, `sy` is set to 0. Typing `m.EstimationInfor.N4Horizon` will tell you what the final choices of horizons were.

Algorithm

The algorithm is described in Section 10.6 in Ljung (1999).

Examples

Build a fifth-order model from data with three inputs and two outputs. Try several choices of auxiliary orders. Look at the frequency response of the model.

```
z = iddata([y1 y2],[ u1 u2 u3]);
m = n4sid(z,5,'n4h',[7:15]','Display','on');
bode(m,'sd',3)
```

Estimate a continuous-time model, in a canonical form parameterization, focusing on the simulation behavior. Determine the order yourself after seeing the plot of singular values.

```
m = n4sid(z,[1:10],'foc','sim','ssp','can','ts',0)
bode(m)
```

Purpose

Output-error (OE) model parameter estimation

Syntax

```
m = oe(data,[nb nc nk])
m = oe(data,[nb nc nk],'PropertyName',PropertyValue)
m = oe(data,m_initial)
```

Description

`m = oe(data,[nb nc nk])` estimates output-error model parameters and their covariances from input-output data. `data` is frequency-domain or time-domain `iddata`, `idfrd`, or `frd` object. `m` is an `idpoly` object. `nb` and `nc` are orders of the *B* and *C* polynomials, respectively. `nk` is the input delay. Orders and delay are scalar for single-input data, and row vectors for multiple-input data with the same size as the number of input channels.

`m = oe(data,[nb nc nk],'PropertyName',PropertyValue)` estimates Box-Jenkins model using algorithm options specified by `idpoly` property name-value pairs. See `Algorithm Properties`.

`m = oe(data,m_initial)` refines previously estimated model `m_initial`, which is an `idpoly` object.

For multiple-input systems, `nb`, `nf`, and `nk` are row vectors with as many entries as there are input channels. Entry number `i` then describes the orders and delays associated with the `i`th input.

`oe` does not support multiple-output models.

Properties

The structure and the estimation algorithm are affected by any property name/property value pairs that are set in the input argument list. Useful properties are `'Focus'`, `'InitialState'`, `'InputDelay'`, `'SearchMethod'`, `'MaxIter'`, `'Tolerance'`, `'LimitError'`, `'FixedParameter'`, and `'Display'`.

See `Algorithm Properties`, `idpoly`, and `idmodel` for details of these properties and their possible values.

Use a state-space model for this case (see `n4sid` and `pem`).

Definitions

Output-Error (OE) Model

The general Output-Error model structure is:

$$y(t) = \frac{B(q)}{F(q)} u(t - nk) + e(t)$$

The orders of the Output-Error model are:

$$nb: \quad B(q) = b_1 + b_2 q^{-1} + \ldots + b_{nb} q^{-nb+1}$$

$$nf: \quad F(q) = 1 + f_1 q^{-1} + \ldots + f_{nf} q^{-nf}$$

Continuous-Time Output-Error Model

If `data` is continuous-time (frequency-domain) data, `oe` estimates a continuous-time model with transfer function:

$$G(s) = \frac{B(s)}{F(s)} = \frac{b_{nb} s^{(nb-1)} + b_{nb-1} s^{(nb-2)} + \ldots + b_1}{s^{nf} + f_{nf} s^{(nf-1)} + \ldots + f_1}$$

The orders of the numerator and denominator are `nb` and `nf`, similar to the discrete-time case. However, the delay `nk` has no meaning and you should omit it.

Algorithm

Algorithm minimizes prediction errors. `oe` algorithm is similar to `armax`, but `oe` uses slightly different methods for computing prediction errors and gradients.

Examples

Estimating Output-Error (OE) model of the type

$$G(s) = \frac{b}{s^3 + f_1 s^2 + f_2 s + f_3}:$$

```
% Use fast sampled data (Ts = 0.001)
% from a plant with bandwidth of about 500 rad/s.
z = iddata(y,u,0.001);
zf = fft(z);
```

```
zf.ts = 0;
m = oe(zf,[1 3],'foc',[0 500])
```

How To

- "Using Linear Model for Hammerstein-Wiener Estimation"

operspec(idnlarx)

Purpose Construct operating point specification object for `idnlarx` model

Syntax `SPEC = operspec(NLSYS)`

Description `SPEC = operspec(NLSYS)` creates an operating point specification object for the `idnlarx` model `NLSYS`. The object encapsulates constraints on input and output signal values. These specifications are used to determine an operating point of the `idnlarx` model using `findop(idnlarx)`.

Input

- `NLSYS`: `idnlarx` model.

Output

- `SPEC`: Operating point specification object. `SPEC` contains the following properties:
  - `Input`: Structure with fields:
    - `Value`: Initial guess for the values of the input signals. Specify a vector of length equal to number of model inputs. Default value: Vector of zeros.
    - `Min`: Minimum value constraint on values of input signals for the model. Default: `-Inf` for all channels.
    - `Max`: Maximum value constraint on values of input signals for the model. Default: `Inf` for all channels.
    - `Known`: Specifies when `Value` is known (fixed) or is an initial guess. Use a logical vector to denote which signals are known (logical `1`, or `true`) and which have to be estimated using `findop` (logical `0`, or `false`). Default value: `true`.
  - `Output`: Structure with fields:
    - `Value`: Initial guess for the values of the output signals. Default value: Vector of zeros.
    - `Min`: Minimum value constraint on values of output signals for the model. Default value: `-Inf`.

- `Max`: Maximum value constraint on values of output signals for the model. Default value: `-Inf`.

See Also

`findop(idnlarx)`

operspec(idnlhw)

Purpose

Construct operating point specification object for `idnlhw` model

Syntax

```
SPEC = operspec(NLSYS)
```

Description

`SPEC = operspec(NLSYS)` creates an operating point specification object for the `idnlhw` model `NLSYS`. The object encapsulates constraints on input and output signal values. These specifications are used to determine an operating point of the `idnlhw` model using `findop(idnlhw)`.

Input

- `NLSYS`: `idnlhw` model.

Output

- `SPEC`: Operating point specification object. `SPEC` contains the following fields:
  - `Value`: Initial guess for the values of the input signals. Specify a vector of length equal to number of model inputs. Default value: Vector of zeros.
  - `Min`: Minimum value constraint on values of input signals for the model. Default: `-Inf` for all channels.
  - `Max`: Maximum value constraint on values of input signals for the model. Default: `Inf` for all channels.
  - `Known`: Specifies when `Value` is known (fixed) or is an initial guess. Use a logical vector to denote which signals are known (logical `1`, or `true`) and which have to be estimated using `findop` (logical `0`, or `false`). Default value: `true`.

Note

1. If the input is completely known (`'Known'` field is set to `true` for all input channels), then the initial state values are determined using input values only. In this case, `findop(idnlhw)` ignores the output signal specifications.

2. If the input values are not completely known, `findop(idnlhw)` uses the output signal specifications to achieve the following objectives:

   - Match target values of known output signals (output channels with `Known` = `true`).
   - Keep the free output signals (output channels with `Known` = `false`) within the specified min/max bounds.

See Also

`findop(idnlhw)`

Purpose

Prediction errors associated with model and data set

Syntax

```
e = pe(m,data)
[e,x0] = pe(m,data,init)
```

Description

`data` is the output-input data set, given as an `iddata` object, and `m` is any `idmodel` or `idnlmodel` object. Both time-domain and frequency-domain data are supported, and `data` can also be an `idfrd` object.

`e` is returned as an `iddata` object, so that `e.OutputData` contains the prediction errors that result when model `m` is applied to the data.

$e(t) = H^{-1}(q)[y(t)–G(q)u(t)]$

The argument `init` determines how to deal with the initial conditions:

- `init = 'e(stimate)'` means that the initial state is chosen so that the norm of prediction error is minimized. This initial state is returned as `x0`.
- `init = `d(elayexpand)':` Same as `'estimate'`, but for a model with nonzero `InputDelay`, the delays are first converted to explicit model delays (using `inpd2nk`) so that they are contained in x0.
- `init = 'z(ero)'` sets the initial state to zero.
- `init = 'm(odel)'` uses the model's internally stored initial state.
- `init = x0i`, where `x0i` is a column vector of appropriate dimension, uses that value as initial state. For multiexperiment data, `x0i` may be a matrix whose columns give different initial states for each experiment. For a continuous-time model `m`, `x0` is the initial state for this model. Any modifications of the initial state that sampling might require are automatically handled. If `m` has a non-zero `InputDelay`, and you need to access the values of the inputs during this delay, you must first apply `inpd2nk(m)`. If `m` is continuous in time, it must first be sampled before `inpd2nk` can be applied.

If `init` is not specified for linear models, its value is determined, as follows:

- If `m.InitialState` is `'Estimate'`, `'Backcast'`, and `'Auto'`, `init = 'Estimate'`.
- If `m.InitialState` is `'Zero'`, `init = 'zero'`.
- If `m.InitialState` is `'Model'` or `'Fixed'`, `init = 'model'`. For `idss`, `idproc`, and `idgrey` models, `init` corresponds to the `m.x0` values. For other linear models, `init = 'zero'`.

If `init` is not specified for `idnlgrey` models, `init = 'Model'` is the default. The values and their estimation behavior are inherited from `m.InitialStates`.

If `init` is not specified for `idnlarx` models, `init = 'Estimate'` is the default. This corresponds to the first few samples of predicted outputs exactly matching the first few output samples in the data set.

If `init` is not specified for `idnlhw` models, `init = 'Estimate'` is the default. This computes initial states by minimizing the prediction errors over the available data range.

The output argument `x0` is the value of the initial state used. If `data` contains several experiments, `x0` is a matrix containing the initial states from each experiment.

`sim`

`simsd`

Purpose

Estimate model parameters using iterative prediction-error minimization method

Syntax

```
m = pem(data)
m = pem(data,mi)
m = pem(data,mi,'Property1',Value1,...,'PropertyN',ValueN)
m = pem(data,orders)
m = pem(data,'P1D')
m = pem(data,'nx',ssorder)
m = pem(data,'na',na,'nb',nb,'nc',nc,'nd',nd,'nf',nf,'nk',nk)
m = pem(data,orders,'Property1',Value1,...,'PropertyN',ValueN)
```

How to Use

If you are using the System Identification Tool GUI, you can specify PEM for low-order continuous-time process models, linear state-space, and polynomial models. If you are working in the MATLAB Command Window, you can use the `pem` command to both construct and estimate these linear models and to also estimate linear and nonlinear grey-box models.

Alternatively, you can use PEM to try to refine initial parameter estimates for all linear and nonlinear parametric models. For more information about refining initial model estimates, see Refining Linear Parametric Models.

Description

`pem` is the basic estimation command in the toolbox and covers a variety of situations.

`data` is always an `iddata` object that contains the input/output data. Both time-domain and frequency-domain signals are supported. `data` can also be an `frd` or `idfrd` frequency-response data object. Estimation of noise models (`K` in state-space models and `A`, `C`, and `D` in polynomial models) is not supported for frequency-domain data.

With Initial Model

`mi` is any `idmodel` or `idnlmodel` object. It could be a result of another estimation routine, or constructed and modified by the constructors (`idarx`, `idpoly`, `idss`, `idgrey`, `idproc`) and `set`. The properties of `mi`

can also be changed by any property name/property value pairs in `pem` as indicated in the syntax.

`m` is then returned as the best fitting model in the model structure defined by `mi`. The iterative search is initialized at the parameters of the initial/nominal model `mi`. `m` will be of the same class as `mi`.

Black-Box State-Space Models

With `m = pem(data,n)`, where `n` is a positive integer, or `m = pem(data,'nx',n)`, a state-space model of order `n` is estimated.

$$x(t+Ts) = Ax(t) + Bu(t) + Ke(t)$$
$$y(t) = Cx(t) + Du(t) + e(t)$$

If `data` is continuous-time (frequency-domain) data, a corresponding continuous-time state space model is estimated.

The default is that it is estimated in a `'Free'` parameterization that can be further modified by the properties `'nk'`, `'DisturbanceModel'`, and `'InitialState'` (see the corresponding reference pages for `idss` and `n4sid`). The model is initialized by `n4sid` and then further adjusted by optimizing the prediction error fit.

You can choose among several different orders by

```
m = pem(data,'nx',[n1,n2,...nN])
```

and you are then prompted for the “best” order. By

```
m = pem(data,'best')
```

an automatic choice of order among 1:10 is made.

```
m = pem(data)
```

is short for `m = pem(data,'best')`. To work with other delays, use, for example, `m = pem(data,'best','nk',[0,...0])`.

In this case `m` is returned as an `idss` model.

Estimating the D, K, and X0 Matrices

Whether the D matrix is estimated or not is governed by the property nk, which is further described below. The default is that D is not estimated. By setting the kth entry of nk to 0, the kth column of D (corresponding to the kth input) is estimated. To estimate a full D matrix, let nk = zeros(1,nu), as in

```
m = pem(data,order,'nk',[0 .. 0])
```

This holds for both discrete- and continuous-time models.

For frequency-domain data, K is always fixed to 0. For time-domain data, K is estimated by default. To fix K to 0 in this case, use

```
m = pem(data,order,'DisturbanceModel','none')
```

Similarly, X0 is estimated if 'InitialState' is set to 'Estimate', and fixed to 0 if 'InitialState' is set to 'Zero'.

Black-Box Multiple-Input-Single-Output Models

The function pem also handles the general multiple-input-single-output structure

$$A(q)y(t) = \frac{B_1(q)}{F_1(q)}u_1(t-nk_1) + \ldots + \frac{B_{nu}(q)}{F_{nu}(q)}u_{nu}(t-nk_{nu}) + \frac{C(q)}{D(q)}e(t)$$

The orders of this general model are given either as

```
orders = [na nb nc nd nf nk]
```

or with (...'na',na,'nb',nb,...) as shown in the syntax. Here na, nb, nc, nd, and nf are the orders of the model, and nk is the delay(s). For multiple-input systems, nb, nf, and nk are row vectors giving the orders and delays of each input. (See “What Are Black-Box Polynomial Models?” in the User’s Guide for a definition of the orders.) When the orders are specified with separate entries, those not given are taken as zero.

For frequency-domain data, only estimation of B and F is supported. It is simpler to use oe in that case.

In this case, m is returned as an idpoly object.

Continuous-Time Process Models

Entering for the initial model an acronym for a process model, as in

```
m = pem(data,'P2UI')
```

will estimate a continuous-time process model of the indicated type. See the reference page for idproc for details of possible model types and associated property name/property value pairs.

In this case, m is returned as an idproc model.

Properties

In all cases the algorithm is affected by the properties (see Algorithm Properties for details):

- Focus can be set to 'Prediction' (default), 'Simulation', or a passband range.
- MaxIter and Tolerance govern the stopping criteria for the iterative search.
- LimitError deals with how the criterion can be made less sensitive to outliers and bad data.
- MaxSize determines the largest matrix ever formed by the algorithm. The algorithm goes into for loops to avoid larger matrices, which can be more efficient than using virtual memory.
- Display, with possible values 'Off', 'On', and 'Full', governs the information sent to the MATLAB Command Window.

For black-box state-space models, 'N4Weight' and 'N4Horizon' will also affect the result, since these models are initialized with an n4sid estimate. See the reference page for n4sid.

Typical idmodel properties are (see idmodel properties for more details):

- Ts is the sampling interval. Set 'Ts'= 0 to obtain a continuous-time state-space model. For discrete-time models, 'Ts' is automatically set to the sampling interval of the data. Note that, in the black-box case, it is usually better to first estimate a discrete-time model, and then convert that to continuous time using d2c.
- nk is the time delays from the inputs (not applicable to structured state-space models). Time delays specified by 'nk' will be included in the model.
- DisturbanceModel determines the parameterization of K for free and canonical state-space parameterizations, as well as for idgrey models. It also determines whether a noise model should be included for idproc models.
- InitialState: The initial state can have a substantial influence on the estimation result for systems with slow responses. It is most pronounced for output-error models (K = 0 for state-space and na = nc = nd =0 for input/output models). The default value 'Auto'" estimates the influence of the initial state and sets the value to 'Estimate', 'Backcast', or 'Zero' based on this effect. Possible values of 'InitialState' are 'Auto', 'Estimate', 'Backcast', 'Zero', and 'Fixed'.

Examples

Here is an example of a system with three inputs and two outputs. A canonical form state-space model of order 5 is sought.

```
z = iddata([y1 y2],[ u1 u2 u3]);
m = pem(z,5,'ss','can')
```

Building an ARMAX model for the response to output 2,

```
ma = pem(z(:,2,:),'na',2,'nb',[2 3 1],'nc',2,'nk',[1 2 0])
```

Comparing the models (compare automatically matches the channels using the channel names),

```
compare(z,m,ma)
```

Algorithm

`pem` uses essentially the same algorithm as `armax`, with modifications to the computation of prediction errors and gradients.

PEM uses optimization to minimize the *cost function*, defined as follows for scalar outputs:

$$V_N(G,H) = \sum_{t=1}^{N} e^2(t)$$

where *e(t)* is the difference between the measured output and the predicted output of the model. For a linear model, this error is defined by the following equation:

$$e(t) = H^{-1}(q)[y(t) - G(q)u(t)]$$

e(t) is a vector and the cost function $V_N(G,H)$ is a scalar value. The subscript N indicates that the cost function is a function of the number of data samples and becomes more accurate for larger values of N. For multiple-output models, the previous equation is more complex.

For black-box models, PEM estimates an initial model and then varies the parameter values along a specific direction to decrease the cost function. As with any nonlinear optimization algorithm, there is a chance that the model might find a local minimum that is not accurate for a specific system.

`bj`

`oe`

Purpose

Level of excitation of input signals

Syntax

```
Ped = pexcit(Data)
[Ped.Maxnr] = pexcit(Data,Maxnr,Threshold)
```

Description

`Data` is an `iddata` object with time- or frequency-domain signals.

`Ped` is the degree or order of excitation of the inputs in `Data`. A row vector of integers with as many components as there are inputs in `Data`. The intuitive interpretation of the degree of excitation in an input is the order of a model that the input is capable of estimating in an unambiguous way.

`Maxnr` is the maximum order tested. Default is `min(N/3,50)`, where `N` is the number of input data.

`Threshold` is the threshold level used to measure which singular values are significant. Default is `1e-9`.

`advice`

`iddata`

Purpose

Plot iddata or model objects

Syntax

```
plot(data)
plot(d1,...,dN)
plot(d1,PlotStyle1,...,dN,PlotStyleN)
plot(model)
```

Description

`data` is the output-input data to be graphed, given as an `iddata` object. A split plot is obtained with the outputs on top and the inputs at the bottom.

One plot for each I/O channel combination is produced. Pressing the **Enter** key advances the plot. Typing **Ctrl+C** aborts the plotting in an orderly fashion.

To plot a specific interval, use `plot(data(200:300))`. To plot specific input/output channels, use `plot(data(:,ky,ku))`, consistent with the subreferencing of `iddata` objects.

If `data.intersample = 'zoh'`, the input is piecewise constant between sampling points, and it is then graphed accordingly.

To plot several`iddata` sets `d1,...,dN`, use `plot(d1,...,dN)`. I/O channels with the same experiment name, input name, and output name are always plotted in the same plot.

With `PlotStyle`, the color, line style, and marker of each data set can be specified

```
plot(d1,'y:*',d2,'b')
```

just as in the regular `plot` command.

`model` is an `idmodel`, `idnlarx`, or `idnlhw` object.

`iddata`

polydata

Purpose

Parameters from single-input and single-output polynomial model

Syntax

```
[A,B,C,D,F] = polydata(m)
[A,B,C,D,F,dA,dB,dC,dD,dF] = polydata(m)
```

Description

This is essentially the inverse of the `idpoly` constructor. It returns the polynomials of the general model

$$A(q)y(t) = \frac{B_1(q)}{F_1(q)}u_1(t - nk_1) + \ldots + \frac{B_{nu}(q)}{F_{nu}(q)}u_{nu}(t - nk_{nu}) + \frac{C(q)}{D(q)}e(t)$$

as contained in the model `m`.

`dA`, `dB`, etc. are the standard deviations of `A`, `B`, etc.

`m` can be any single-output `idmodel`, that is, not just `idpoly`. For multiple-output models you can use `[A,B,C,D,F] = polydata(m(ky,:))` to obtain the polynomials for the `ky`th output.

`idmodel`

`idpoly`

`tfdata`

Purpose

Powers and products of standard regressors

Syntax

```
R = polyreg(model)
R = polyreg(model,'MaxPower',n)
R = polyreg(model,'MaxPower',n,'CrossTerm',CrossTermVal)
```

Description

`R = polyreg(model)` creates an array *R* of polynomial regressors up to the power 2. If a model order has input `u` and output `y`, `na=nb=2`, and delay `nk=1`, polynomial regressors are $y(t-1)^2$, $u(t-1)^2$, $y(t-2)^2$, $u(t-2)^2$. *`model`* is an `idnlarx` object. You must add these regressors to the *`model`* by assigning the `CustomRegressors` *`model`* property or by using `addreg`.

`R = polyreg(model,'MaxPower',n)` creates an array *R* of polynomial regressors up to the power *n*. Excludes terms of power `1` and cross terms, such as $y(t-1)*u(t-1)$.

`R = polyreg(model,'MaxPower',n,'CrossTerm',CrossTermVal)` creates an array *R* of polynomial regressors up to the power *n* and includes cross terms (products of standards regressors) when *`CrossTermVal`* is `'on'`. By default, *`CrossTermVal`* is `'off'`.

Examples

Create polynomial regressors up to order 2:

```
% Estimate a nonlinear ARX model with
% na=nb=2 and nk=1.
% Nonlinearity estimator is wavenet.
  load iddata1
  m = nlarx(z1,[2 2 1])
% Create polynomial regressors:
  R = polyreg(m);
% Estimate model:
  m = nlarx(z1,[2 2 1],'wavenet','CustomReg',R);
% View all model regressors (standard and custom):
  getreg(m)
```

Create polynomial regressors up to order 3:

```
R = polyreg(m,'MaxPower',3,'CrossTerm','on')
```

If the model `m` that has three standard regressors `a`, `b` and `c` , `R` includes `a^2`, `b^2`, `c^2`, `a*b`, `a*c`, `b*c`, `a^2*b`, `a^2*c`, `a*b^2`, `a*b*c`, `a*c^2`, `b^2*c`, `b*c^2`, `a^3`, `b^3`, and `c^3`.

How To

- “Identifying Nonlinear ARX Models”

Purpose

Class representing single-variable polynomial nonlinear estimator for Hammerstein-Wiener models

Syntax

```
t=poly1d('Degree',n)
t=poly1d('Coefficients',C)
t=poly1d(n)
```

Description

`poly1d` is an object that stores the single-variable polynomial nonlinear estimator for Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`t=poly1d('Degree',n)` creates a polynomial nonlinearity estimator object of `n`th degree.

`t=poly1d('Coefficients',C)` creates a polynomial nonlinearity estimator object with coefficients `C`.

`t=poly1d(n)` a polynomial nonlinearity estimator object of `n`th degree.

Use `evaluate(p,x)` to compute the value of the function defined by the `poly1d` object `p` at `x`.

Remarks

Use `poly1d` to define a nonlinear function $y = F(x)$, where F is a single-variable polynomial function of x:

$$F(x) = c(1)x^n + c(2)x^{(n-1)} + \ldots + c(n)x + c(n+1)$$

poly1d Properties

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
get(p)
% Get value of Coefficients property
p.Coefficients
```

poly1d

Property Name	Description
`Degree`	Positive integer specifies the degree of the polynomial Default=`1`. For example: `poly1d('Degree',3)`
`Coefficients`	1-*by*-`(n+1)` matrix containing the polynomial coefficients.

Examples

Use `poly1s` to specify the single-variable polynomial nonlinearity estimator in Hammerstein-Wiener models. For example:

```
m=nlhw(Data,Orders,poly1d('deg',3),[]);
```

where `'deg'` is an abbreviation for the property `'Degree'`.

See Also

`nlhw`

Purpose

Predict output *k* steps ahead

Syntax

```
yp = predict(m,data)
[yp,x0p,mpred] = predict(m,data,k,'InitialState',init)
```

Description

`data` is the output-input data as an `iddata` object, and `m` is any `idmodel` or `idnlmodel` object. `predict` is meaningful only for time-domain data.

The argument `k` indicates that the k step-ahead prediction of `y` according to the model `m` is computed. In the calculation of $yp(t)$, the model can use outputs up to time

$t–k$: $y(s)$, $s = t–k$, $t–k–1$,...

and inputs up to the current time t. The default value of `k` is `1`.

The output `yp` is an `iddata` object containing the predicted values as `OutputData`.

`x0p` is the used (estimated) initial state vector. For multiexperiment data, `x0p` is a matrix, whose columns contain the initial states for each experiment.

The output argument `mpred` contains the k step-ahead predictor. This is given as a cell array, whose kth entry is an `idpoly` model for the predictor of output number k. Note that these predictor models have as input both input and output signals in the data set. The channel names indicate how the predictor model and the data fit together.

`init` determines how to deal with the initial state:

- `init ='e(stimate)`': The initial state is set to a value that minimizes the norm of the prediction error associated with the model and the data.
- `init = 'd(elayexpand)':` Same as `'estimate'`, but for a model with nonzero `InputDelay`, the delays are first converted to explicit model delays (using `inpd2nk`) so that they are contained in `x0p`.
- `init = 'z(ero)'` sets the initial state to zero.
- `init = 'm(odel)'` uses the model's internally stored initial state.

- `init = x0`, where `x0` is a column vector of appropriate dimension, uses that value as initial state. For multiexperiment data, `x0` can be a matrix whose columns give different initial states for each experiment. For a continuous-time model `m`, `x0` is the initial state for this model. Any modifications of the initial state that sampling might require are automatically handled. If `m` has a non-zero `InputDelay`, and you need to access the values of the inputs during this delay, you must first apply `inpd2nk(m)`. When `m` is a continuous-time model, it must first be sampled before `inpd2nk` can be applied.

If `init` is not specified for linear models, its value is determined, as follows:

- If `m.InitialState` is `'Estimate'`, `'Backcast'`, and `'Auto'`, `init = 'Estimate'`.
- If `m.InitialState` is `'Zero'`, `init = 'zero'`.
- If `m.InitialState` is `'Model'` or `'Fixed'`, `init = 'model'`. For `idss`, `idproc`, and `idgrey` models, `init` corresponds to the `m.x0` values. For other linear models, `init = 'zero'`.

If `init` is not specified for `idnlgrey` models, `init = 'Model'` is the default. The values and their estimation behavior are inherited from `m.InitialStates`.

If `init` is not specified for `idnlarx` models, `init = 'Estimate'` is the default. This corresponds to the first few samples of predicted outputs exactly matching the first few output samples in the data set.

If `init` is not specified for `idnlhw` models, `init = 'Estimate'` is the default. This computes initial states by minimizing the prediction errors over the available data range.

An important use of `predict` is to evaluate a model's properties in the mid-frequency range. Simulation with `sim` (which conceptually corresponds to `k = inf`) can lead to levels that drift apart, since the low-frequency behavior is emphasized. One step-ahead prediction is not a powerful test of the model's properties, since the high-frequency

behavior is stressed. The trivial predictor $\hat{y}(t) = y(t-1)$ can give good predictions in case the sampling of the data is fast.

Another important use of `predict` is to evaluate time-series models. The natural way of studying a time-series model's ability to reproduce observations is to compare its k step-ahead predictions with actual data.

Note that for output-error models, there is no difference between the k step-ahead predictions and the simulated output, since, by definition, output-error models only use past inputs to predict future outputs.

Algorithm

The model is evaluated in state-space form, and the state equations are simulated k steps ahead with initial value $x(t-k) = \hat{x}(t-k)$, where $\hat{x}(t-k)$ is the Kalman filter state estimate.

Examples

Simulate a time series, estimate a model based on the first half of the data, and evaluate the four step-ahead predictions on the second half.

```
m0 = idpoly([1 -0.99],[],[1 -1 0.2]);
e = iddata([],randn(400,1));
y = sim(m0,e);
m = armax(y(1:200),[1 2]);
yp = predict(m,y,4);
plot(y(201:400),yp(201:400))
```

Note that the last two commands are also achieved by

```
compare(y,m,4,201:400);
```

`pe`

`sim`

`simsd`

predict(idnlarx)

Purpose Predict output *k* steps ahead for nonlinear ARX model

Syntax

```
YP = predict(MODEL,DATA,K)
YP = predict(SYS,DATA,K,INIT)
YP = predict(MODEL,DATA,K,'InitialState',INIT)
```

Description

`YP = predict(MODEL,DATA,K)` predicts the *k*-step ahead output with an `idnlarx` model.

`YP = predict(SYS,DATA,K,INIT)` or `YP = predict(MODEL,DATA,K,'InitialState',INIT)` specifies the initialization.

Input

- `MODEL`: `idnlarx` model object.
- `DATA`: `iddata` object.
- `K`: Prediction horizon. Old outputs up to time *t-K* are used to predict the output at time t. All relevant inputs are used. Default value: `K` = 1).
- `INIT`: initialization specification. `INIT` can be the following:
  - `'e'`: Assume the initial states of the model are such that the first `N` values of the predicted output match the first `N` samples of the measured output exactly, where `N` is the maximum channel delay in the model (`N = max(getDelayInfo(model))`). The initial states are not computed explicitly, but are assumed to exist. The prediction starts at the (`N+1`)th sample, while a perfect match is assumed for the first `N` samples. If you want prediction of response values starting from the first data sample, you must estimate and provide the initial state vector explicitly as described in the following option for `INIT` = `X0`.
  - Real column vector `X0`, for the state vector corresponding to an appropriate number of output and input data samples prior to the simulation start time. To build an initial state vector from a given set of input-output data or to generate equilibrium states, use `data2state(idnlarx)`, `findstates(idnlarx)` or

`findop(idnlarx)`. For multi-experiment data, `X0` may be a matrix whose columns give different initial states for different experiments.

- `'z'`: (Default) Zero initial state, equivalent to a zero vector of appropriate size.
- `iddata` object containing output and input data samples prior to the simulation start time. If it contains more data samples than necessary, only the last samples are taken into account. This syntax is equivalent to `sim(MODEL, U, 'InitialState', data2state(MODEL,INIT))` where `data2state(idnlarx)` transforms the `iddata` object `INIT` to a state vector.

Output

`YP`: Predicted output as an `iddata` object. If `DATA` contains multiple experiments, so will `YP`.

Note If `predict` is called without an output argument, MATLAB software displays the predicted output(s) in a plot window.

predict(idnlgrey)

Purpose

Predict output *k* steps ahead for nonlinear ODE model

Syntax

```
YP  = predict(NLSYS,DATA);
[YP,X0,XFINAL] = predict(NLSYS,DATA);
[YP,X0,XFINAL] = predict(NLSYS,DATA,K);
[YP,X0,XFINAL] = predict(NLSYS,DATA,K,X0INIT);
```

Description

`YP = predict(NLSYS,DATA);` predicts the *k*-step ahead output with an `idnlgrey` model.

`[YP,X0,XFINAL] = predict(NLSYS,DATA);` returns the initial states used in the prediction as well as the final states computed, in addition to the predicted output.

`[YP,X0,XFINAL] = predict(NLSYS,DATA,K);` specifies the prediction horizon to use during prediction.

`[YP,X0,XFINAL] = predict(NLSYS,DATA,K,X0INIT);` specifies the initialization for the *k*-step ahead prediction.

Input

- `NLSYS`: `idnlgrey` model for which output is to be predicted.
- `DATA`: Input-output data `[Y U]`. `U` is the input data that can be given either as an `iddata` object or as a matrix `U = [U1 U2 ...  Um]`, where the `k`:th column vector is input U_k. Similarly, `Y` is either an `iddata` object or a matrix of outputs (with as many columns as there are outputs). For time-continuous `idnlgrey` objects, `DATA` passed as a matrix will lead to that the data sample interval, `Ts`, is set to one.
- `K`: Prediction horizon. `K` and can be set to an integer between 1 and `inf` (pure simulation). As `idnlgrey` assumes an output error model structure, where prediction and simulation coincide, `K` has no meaning.
- `X0INIT`: Initial state to use. It can take the following values:
  - `'zero'` : Zero initial state $x(0)$ with all states fixed (`nlsys.InitialStates.Fixed` is thus ignored).

- 'fixed': (or NLSYS.InitialState) Determines the values of the model initial states, but all states are fixed (NLSYS.InitialStates.Fixed is ignored).
- 'estimate': NLSYS.InitialState determines the value of the initial states and all initial states are estimated (NLSYS.InitialStates.Fixed is ignored).
- (Default) 'model': NLSYS.InitialState determines the value of the initial states, which initial states to estimate, and minimum and maximum state values.
- vector/matrix: Column vector of initial states. For multiple-experiment DATA, $x(0)$ can be a matrix where each column contains initial states for the corresponding experiment. All initial states are fixed (nlsys.InitialStates.Fixed is ignored).
- struct array : An Nx-by-1 structure array with fields:
  - Name: Name of the state (a string).
  - Unit: Unit of the state (a string).
  - Value: Value of the states (a finite real 1-by-Ne vector, where Ne is the number of experiments.)
  - Minimum: Minimum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same minimum value).
  - Maximum: Maximum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same maximum value).
  - (Default) Fixed: Uses initial state values from NLSYS.InitialState.Value. Ignores NLSYS.InitialState.Fixed.

The initial state can also be specified using the property-value pair InitialState or X0, followed by the value X0INIT. For example: predict(NLSYS,DATA,K,'InitialState',X0INIT).

Output

- `YP`: Predicted output. If `DATA` is an `iddata` object, then `YP` will also be an `iddata` object. Otherwise, `YP` will be a matrix where the `k`:th output is found in the `k`:th column of `YP`. If `DATA` is a multiple experiment `iddata` object, then `YP` will be as well.
- `X0`: Initial states. In the single experiment case it is a column vector of length `Nx`. For multi-experiment data, `X0` is an `Nx`-by-`Ne` matrix with the `i`th column specifying the initial state of experiment `i`.
- `XFINAL`: Final states computed. In the single experiment case it is a column vector of length `Nx`. For multi-experiment data, `XFINAL` is an `Nx`-by-`Ne` matrix with the `i`th column specifying the initial state of experiment `i`.

Note If `predict` is called without an output argument, MATLAB software displays the predicted output(s) in a plot window.

Purpose

Predict output k steps ahead for Hammerstein-Wiener model

Syntax

```
YP = predict(MODEL,DATA,K)
YP = predict(MODEL,DATA,K,INIT)
YP = predict(MODEL,DATA,K,'InitialState',INIT)
```

Description

`YP = predict(MODEL,DATA,K)` predicts the k-step ahead output with an `idnlhw` model.

`YP = predict(MODEL,DATA,K,INIT)` or `YP = predict(MODEL,DATA,K,'InitialState',INIT)` specifies the initialization.

Input

- `MODEL`: `idnlhw` model object.
- `DATA`: `iddata` object.
- `K`: Prediction horizon. Old outputs up to time t-`K` are used to predict the output at time t. All relevant inputs are used. Default value: `K` = 1).
- `INIT`: Initialization specification. `INIT` can be the following:
  - `'e'`: Estimate initial states minimizing the sum of squared prediction errors. To compute the initial state estimates explicitly, use `findstates(idnlhw)`.
  - Real column vector `X0` for the initial state vector. To build an initial state vector from a given set of input-output data or to generate equilibrium states, see `findstates(idnlhw)` and `findop(idnlhw)`. For multi-experiment data, `X0` may be a matrix whose columns give different initial states for different experiments.
  - `'z'`: (Default) Zero initial state, equivalent to a zero vector of appropriate size.

Output

`YP`: Predicted output as an `iddata` object. If `DATA` contains multiple experiments, so will `YP`.

Note If `predict` is called without an output argument, MATLAB software displays the predicted output(s) in a plot window.

`findstates(idnlhw)`

`sim(idnlhw)`

Purpose

Display model information, including estimated uncertainty

Syntax

```
present(m)
```

Description

The `present` function displays the model `m`, together with the estimated standard deviations of the parameters, loss function, and Akaike's Final Prediction Error (FPE) Criterion (which essentially equals the AIC). It also displays information about how `m` was created.

`m` is any `idmodel` or `idnlmodel` object.

`present` thus gives more detailed information about the model than the standard `display` function.

Purpose

Class representing piecewise-linear nonlinear estimator for Hammerstein-Wiener models

Syntax

```
t=pwlinear('NumberOfUnits',N)
t=pwlinear('BreakPoints',BP)
t=pwlinear(Property1,Value1,...PropertyN,ValueN)
```

Description

`pwlinear` is an object that stores the piecewise-linear nonlinear estimator for estimating Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`t=pwlinear('NumberOfUnits',N)` creates a piecewise-linear nonlinearity estimator object with `N` breakpoints.

`t=pwlinear('BreakPoints',BP)` creates a piecewise-linear nonlinearity estimator object with breakpoints at values `BP`.

`t=pwlinear(Property1,Value1,...PropertyN,ValueN)` creates a piecewise-linear nonlinearity estimator object specified by properties in "pwlinear Properties" on page 2-353.

Use `evaluate(p,x)` to compute the value of the function defined by the `pwlinear` object `p` at `x`.

Remarks

Use `pwlinear` to define a nonlinear function $y = F(x)$, where F is a piecewise-linear (affine) function of x and there are `n` breakpoints `(x_k,y_k), k=1,...,n. y_k = F(x_k)`. F is linearly interpolated between the breakpoints.

y and x are scalars.

F is also linear to the left and right of the extreme breakpoints. The slope of these extension is a function of `x_i` and `y_i` breakpoints. The breakpoints are ordered by ascending `x`-values, which is important when you set a specific breakpoint to a different value.

There are minor deviations from the breakpoint values you set and the values actually stored in the object because the toolbox represent breakpoints differently internally.

pwlinear Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
get(p)
% Get value of NumberOfUnits property
p.NumberOfUnits
```

Property Name	Description
`NumberOfUnits`	Integer specifies the number of breakpoints. Default=`10`. For example: `pwlinear('NumberOfUnits',5)`
`BreakPoints`	2-by-`n` matrix containing the breakpoint `x` and `y` value, specified using the following format: `[x_1,x_2,...,x_n;y_1,y_2,...,y_n]` If set to a 1-by-`n` vector, the values are interpreted as `x`-values and the corresponding `y`-values are set to zero.

Examples

Use `pwlinear` to specify the piecewise nonlinearity estimator in Hammerstein-Wiener models. For example:

```
m=nlhw(Data,Orders,pwlinear('Br',[-1:0.1:1]),[]);
```

The piecewise nonlinearity is initialized at the specified breakpoints. The breakpoint values are adjusted to the estimation data by `nlhw`.

`nlhw`

Purpose

Plot zeros and poles with confidence interval

Syntax

```
pzmap(m)
pzmap(m,'sd',sd)
pzmap(m1,m2,m3,...)
pzmap(m1,'PlotStyle1',m2,'PlotStyle2',...,'sd',sd)
pzmap(m1,m2,m3,..,'sd',sd,'mode',mode,'axis',axis)
```

Description

`m` is any `idmodel` object: `idarx`, `idgrey`, `idss`, `idproc`, or `idpoly`.

The zeros and poles of `m` are graphed, with `o` denoting zeros and `x` denoting poles. Poles and zeros at infinity are ignored. For discrete-time models, zeros and poles at the origin are also ignored.

The Property/Value pairs `'sd'/sd, 'mode'/mode` and `` `axis'/axis `` can appear in any order. They are explained below.

If `sd` has a value larger than zero, confidence regions around the poles and zeros are also graphed. The regions corresponding to `sd` standard deviations are marked. The default value is `sd = 0`. Note that the confidence regions might sometimes stretch outside the plot, but they are always symmetric around the indicated zero or pole.

If the poles and zeros are associated with a discrete-time model, a unit circle is also drawn. For continuous-time models, the real and imaginary axes are drawn.

When `mi` contains information about several different input/output channels, you have the following options:

`mode = 'sub'` splits the screen into several plots, one for each input/output channel. These are based on the `InputName` and `OutputName` properties associated with the different models.

`mode = 'same'` gives all plots in the same diagram. Pressing the **Enter** key advances the plots.

`mode = 'sep'` erases the previous plot before the next channel pair is treated.

The default value is `mode = 'sub'`.

`axis = [x1 x2 y1 y2]` fixes the axis scaling accordingly. `axis = s` is the same as

```
axis = [-s s -s s]
```

You can select the colors associated with the different models by using the argument `PlotStyle`. Use `PlotStyle = 'b'`, `'g'`, etc. Markers and line styles are not used.

The noise input channels in `m` are treated as follows: Consider a model `m` with both measured input channels u (nu channels) and noise channels e (ny channels) with covariance matrix Λ:

$$y = Gu + He$$
$$\mathrm{cov}(e) = \Lambda = LL'$$

where L is a lower triangular matrix. Note that `m.NoiseVariance` $= \Lambda$. The model can also be described with a unit variance, using a normalized noise source v.

$$y = Gu + HLv$$
$$\mathrm{cov}(v) = I$$

Then,

- `pzmap(m)` plots the zeros and poles of the transfer function G.
- `pzmap(m('n'))` plots the zeros and poles of the transfer function H (ny inputs and ny outputs). The input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- If `m` is a time series, that is nu `= 0`, `pzmap(m)` plots the zeros and poles of the transfer function H.
- `pzmap(noisecnv(m))` plots the zeros and poles of the transfer function [G H] (nu+ny inputs and ny outputs). The noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.

- `pzmap(noisecnv(m,'norm')` plots the zeros and poles of the transfer function [*G HL*] (*nu*+*ny* inputs and *ny* outputs). The noise input channels have names `v@yname`, where `yname` is the name of the corresponding output.

Examples

```
mbj = bj(data,[2 2 1 1 1]);
mar = armax(data,[2 2 2 1]);
pzmap(mbj,mar,'sd',3)
```

shows all zeros and poles of two models along with the confidence regions corresponding to three standard deviations.

`idmodel`

`zpkdata`

Purpose

Estimate recursively parameters of ARMAX or ARMA models

Syntax

```
thm = rarmax(z,nn,adm,adg)
[thm,yhat,P,phi,psi] = rarmax(z,nn,adm,adg,th0,P0,phi0,psi0)
```

Description

The parameters of the ARMAX model structure

$$A(q)y(t) = B(q)u(t-nk) + C(q)e(t)$$

are estimated using a recursive prediction error method.

The input-output data is contained in `z`, which is either an `iddata` object or a matrix `z = [y u]` where `y` and `u` are column vectors. `nn` is given as

```
nn = [na nb nc nk]
```

where `na`, `nb`, and `nc` are the orders of the ARMAX model, and `nk` is the delay. Specifically,

$$na: \quad A(q) = 1 + a_1 q^{-1} + \ldots + a_{na} q^{-na}$$

$$nb: \quad B(q) = b_1 + b_2 q^{-1} + \ldots + b_{nb} q^{-nb+1}$$

$$nc: \quad \mathrm{C}(q) = 1 + c_1 q^{-1} + \ldots + c_{nc} q^{-nc}$$

See “What Are Black-Box Polynomial Models?” for more information.

If `z` represents a time series `y` and `nn = [na nc]`, `rarmax` estimates the parameters of an ARMA model for `y`.

$$A(q)y(t) = C(q)e(t)$$

Only single-input, single-output models are handled by `rarmax`. Use `rpem` for the multiple-input case.

The estimated parameters are returned in the matrix `thm`. The `k`th row of `thm` contains the parameters associated with time `k`; that is, they are based on the data in the rows up to and including row `k` in `z`. Each row of `thm` contains the estimated parameters in the following order:

```
thm(k,:) = [a1,a2,...,ana,b1,...,bnb,c1,...,cnc]
```

yhat is the predicted value of the output, according to the current model; that is, row *k* of yhat contains the predicted value of y(k) based on all past data.

The actual algorithm is selected with the two arguments adm and adg. These are described under rarx.

The input argument th0 contains the initial value of the parameters, a row vector consistent with the rows of thm. The default value of th0 is all zeros.

The arguments P0 and P are the initial and final values, respectively, of the scaled covariance matrix of the parameters. See rarx. The default value of P0 is 10^4 times the unit matrix. The arguments phi0, psi0, phi, and psi contain initial and final values of the data vector and the gradient vector, respectively. The sizes of these depend on the chosen model orders. The normal choice of phi0 and psi0 is to use the outputs from a previous call to rarmax with the same model orders. (This call could be a dummy call with default input arguments.) The default values of phi0 and psi0 are all zeros.

Note that the function requires that the delay nk be larger than 0. If you want nk = 0, shift the input sequence appropriately and use nk = 1.

Algorithm

The general recursive prediction error algorithm (11.44), (11.47) through (11.49) of Ljung (1999) is implemented. See "Algorithms for Recursive Estimation" for more information.

Examples

Compute and plot, as functions of time, the four parameters in a second-order ARMA model of a time series given in the vector y. The forgetting factor algorithm with a forgetting factor of 0.98 is applied.

```
thm = rarmax(y,[2 2],'ff',0.98);
plot(thm)
```

Purpose

Estimate parameters of ARX or AR models recursively

Syntax

```
thm = rarx(z,nn,adm,adg)
[thm,yhat,P,phi] = rarx(z,nn,adm,adg,th0,P0,phi0)
```

Description

`thm = rarx(z,nn,adm,adg)` estimates the parameters `thm` of single-output ARX model from input-output data `z` and model orders `nn` using the algorithm specified by `adm` and `adg`. If `z` is a time series `y` and `nn = na`, `rarx` estimates the parameters of a single-output AR model.

`[thm,yhat,P,phi] = rarx(z,nn,adm,adg,th0,P0,phi0)` estimates the parameters `thm`, the predicted output `yhat`, final values of the scaled covariance matrix of the parameters `P`, and final values of the data vector `phi` of single-output ARX model from input-output data `z` and model orders `nn` using the algorithm specified by `adm` and `adg`. If `z` is a time series `y` and `nn = na`, `rarx` estimates the parameters of a single-output AR model.

Definitions

The general ARX model structure is:

$$A(q)y(t) = B(q)u(t - nk) + e(t)$$

The orders of the ARX model are:

$$na: \quad A(q) = 1 + a_1 q^{-1} + \ldots + a_{na} q^{-na}$$

$$nb: \quad B(q) = b_1 + b_2 q^{-1} + \ldots + b_{nb} q^{-nb+1}$$

Models with several inputs are defined, as follows:

$$A(q)y(t) = B_1(q)u_1(t - nk_1) + \ldots + B_{nu}u_{nu}(t - nk_{nu}) + e(t)$$

Inputs

`z`

Name of the matrix `iddata` object that represents the input-output data or a matrix `z = [y u]`, where `y` and `u` are column vectors.

For multiple-input models, the `u` matrix contains each input as a column vector:

```
u = [u1 ... unu]
```

`nn`

For input-output models, specifies the structure of the ARX model as:

```
nn = [na nb nk]
```

where `na` and `nb` are the orders of the ARX model, and `nk` is the delay.

For multiple-input models, `nb` and `nk` are row vectors that define orders and delays for each input.

For time-series models, `nn = na`, where `na` is the order of the AR model.

Note The delay `nk` must be larger than `0`. If you want `nk = 0`, shift the input sequence appropriately and use `nk = 1` (see `nkshift`).

`adm` and `adg`

`adm = 'ff'` and `adg` = `lam` specify the *forgetting factor* algorithm with the forgetting factor λ=`lam`. This algorithm is also known as recursive least squares (RLS). In this case, the matrix `P` has the following interpretation: R_2/2 * `P` is approximately equal to the covariance matrix of the estimated parameters.R_2 is the variance of the innovations (the true prediction errors $e(t)$).

`adm ='ug'` and `adg = gam` specify the *unnormalized gradient* algorithm with gain *gamma* = `gam`. This algorithm is also known as the normalized least mean squares (LMS).

`adm ='ng'` and `adg = gam` specify the *normalized gradient* or normalized least mean squares (NLMS) algorithm. In these cases, `P` is not applicable.

`adm ='kf'` and `adg =R1` specify the *Kalman filter based* algorithm with R_2=`1` and R_1 = `R1`. If the variance of the innovations $e(t)$ is not unity but R_2; then R_2* `P` is the covariance matrix of the parameter estimates, while R_1 = `R1` /R_2 is the covariance matrix of the parameter changes.

`th0`

Initial value of the parameters in a row vector, consistent with the rows of `thm`.

Default: All zeros.

`P0`

Initial values of the scaled covariance matrix of the parameters.

Default: 10^4 times the identity matrix.

`phi0`

The argument `phi0` contains the initial values of the data vector:

$\varphi(t) = [y(t-1),...,y(t-na),u(t-1),...,u(t-nb-nk+1)]$

If `z = [y(1),u(1); ... ;y(N),u(N)]`, phi0 = $\varphi(1)$ and phi = $\varphi(N)$. For online use of `rarx`, use `phi0`, `th0`, and `P0` as the previous outputs `phi`, `thm` (last row), and `P`.

Default: All zeros.

Outputs

`thm`

Estimated parameters of the model. The `k`th row of `thm` contains the parameters associated with time `k`; that is, the estimate parameters are based on the data in rows up to and including row `k` in `z`. Each row of `thm` contains the estimated parameters in the following order:

```
thm(k,:) = [a1,a2,...,ana,b1,...,bnb]
```

For a multiple-input model, the *b* are grouped by input. For example, the *b* parameters associated with the first input are listed first, and the *b* parameters associated with the second input are listed next.

`yhat`

Predicted value of the output, according to the current model; that is, row `k` of `yhat` contains the predicted value of `y(k)` based on all past data.

`P`

Final values of the scaled covariance matrix of the parameters.

`phi`

`phi` contains the final values of the data vector:

$$\varphi(t) = [y(t-1),\ldots,y(t-na),u(t-1),\ldots,u(t-nb-nk+1)]$$

Examples

Adaptive noise canceling: The signal *y* contains a component that originates from a known signal *r*. Remove this component by recursively estimating the system that relates *r* to *y* using a sixth-order FIR model and the NLMS algorithm.

```
z = [y r];
[thm,noise] = rarx(z,[0 6 1],'ng',0.1);
% noise is the adaptive estimate of the noise
% component of y
plot(y-noise)
```

If this is an online application, you can plot the best estimate of the signal `y - noise` at the same time as the data *y* and *u* become available, use the following code:

```
phi = zeros(6,1);
P=1000*eye(6);
th = zeros(1,6);
```

```
axis([0 100 -2 2]);
plot(0,0,'*'), hold on
% Use a while loop
while ~abort
[y,r,abort] = readAD(time);
[th,ns,P,phi] = rarx([y r],'ff',0.98,th,P,phi);
plot(time,y-ns,'*')
time = time + Dt
end
```

This example uses a forgetting factor algorithm with a forgetting factor of 0.98. `readAD` is a function that reads the value of an A/D converter at the indicated time instant.

"Algorithms for Recursive Estimation"

Purpose

Estimate recursively parameters of Box-Jenkins models

Syntax

```
thm = rbj(z,nn,adm,adg)
[thm,yhat,P,phi,psi] = rbj(z,nn,adm,adg,th0,P0,phi0,psi0)
```

Description

The parameters of the Box-Jenkins model structure

$$y(t) = \frac{B(q)}{F(q)}u(t-nk) + \frac{C(q)}{D(q)}e(t)$$

are estimated using a recursive prediction error method.

The input-output data is contained in `z`, which is either an `iddata` object or a matrix `z = [y u]` where `y` and `u` are column vectors. `nn` is given as

```
nn = [nb nc nd nf nk]
```

where `nb`, `nc`, `nd`, and `nf` are the orders of the Box-Jenkins model, and `nk` is the delay. Specifically,

$$nb\colon\ B(q) = b_1 + b_2q^{-1} + \ldots + b_{nb}q^{-nb+1}$$

$$nc\colon\ C(q) = 1 + c_1q^{-1} + \ldots + c_{nc}q^{-nc}$$

$$nd\colon\ D(q) = 1 + d_1q^{-1} + \ldots + d_{nd}q^{-nd}$$

$$nf\colon\ F(q) = 1 + f_1q^{-1} + \ldots + f_{nf}q^{-nf}$$

See “What Are Black-Box Polynomial Models?” for more information.

Only single-input, single-output models are handled by `rbj`. Use `rpem` for the multiple-input case.

The estimated parameters are returned in the matrix `thm`. The `k`th row of `thm` contains the parameters associated with time `k`; that is, they are based on the data in the rows up to and including row `k` in `z`. Each row of `thm` contains the estimated parameters in the following order.

```
thm(k,:) = [b1,...,bnb,c1,...,cnc,d1,...,dnd,f1,...,fnf]
```

`yhat` is the predicted value of the output, according to the current model; that is, row `k` of `yhat` contains the predicted value of `y(k)` based on all past data.

The actual algorithm is selected with the two arguments `adm` and `adg`. These are described under `rarx`.

The input argument `th0` contains the initial value of the parameters, a row vector consistent with the rows of `thm`. The default value of `th0` is all zeros.

The arguments `P0` and `P` are the initial and final values, respectively, of the scaled covariance matrix of the parameters. See `rarx`. The default value of `P0` is 10^4 times the unit matrix. The arguments `phi0`, `psi0`, `phi`, and `psi` contain initial and final values of the data vector and the gradient vector, respectively. The sizes of these depend on the chosen model orders. The normal choice of `phi0` and `psi0` is to use the outputs from a previous call to `rbj` with the same model orders. (This call could be a dummy call with default input arguments.) The default values of `phi0` and `psi0` are all zeros.

Note that the function requires that the delay `nk` be larger than `0`. If you want `nk = 0`, shift the input sequence appropriately and use `nk = 1`.

Algorithm

The general recursive prediction error algorithm (11.44) of Ljung (1999) is implemented. See also "Algorithms for Recursive Estimation".

`nkshift`

`rarmax`

`rarx`

`roe`

`rpem`

`rplr`

realdata

Purpose

Determine whether `iddata` is based on real-valued signals

Syntax

```
realdata(data)
```

Description

`realdata` returns 1 if

- `data` contains only real-valued signals.
- `data` contains frequency-domain signals, obtained by Fourier transformation of real-valued signals.

Otherwise `realdata` returns `0`.

Notice the difference with `isreal`:

```
load iddata1
isreal(z1); % returns 1
zf = fft(z1);
isreal(zf) % returns 0
realdata(zf) % returns 1
zf = complex(zf) % adds negative frequencies to zf
realdata(zf) % still returns 1
```

Purpose

Resample time-domain data by decimation or interpolation (requires Signal Processing Toolbox software)

Syntax

```
resample(data,P,Q)
resample(data,P,Q,order)
```

Description

`resample(data,P,Q)` resamples data such that the data is interpolated by a factor `P` and then decimated by a factor `Q`. `resample(z,1,Q)` results in decimation by a factor `Q`.

`resample(data,P,Q,order)` filters the data by applying a filter of specified `order` before interpolation and decimation.

Input

`data`

Name of time-domain `iddata` object. Can be input-output or time-series data.

Data must be sampled at equal time intervals.

`P`, `Q`

Integers that specify the resampling factor, such that the new sampling interval is `Q/P` times the original one.

`(Q/P)>1` results in decimation and `(Q/P)<1` results in interpolation.

`order`

Order of the filters applied before interpolation and decimation.

Default: `10`

Algorithm

If you have installed the Signal Processing Toolbox software, `resample` calls the Signal Processing Toolbox `resample` function. The algorithm takes into account the intersample characteristics of the input signal, as described by `data.InterSample`.

Examples

In this example, you increase the sampling rate by a factor of `1.5` and compare the resampled and the original data signals.

```
plot(u)
ur = resample(u,3,2);
plot(u,ur)
```

See Also

`idresamp`

resid

Purpose

Compute and test model residuals (prediction errors)

Syntax

```
resid(m,data)
resid(m,data,Type)
resid(m,data,Type,M)
e = resid(m,data);
```

Description

`data` contains the output-input data as an `iddata` object. Both time-domain and frequency-domain data are supported. `data` can also be an `idfrd` object.

`m` is any `idmodel` or `idnlmodel` object.

In all cases the residuals *e* associated with the data and the model are computed. This is done as in the command `pe` with a default choice of `init`.

When called without output arguments, `resid` produces a plot. The plot can be one of three kinds depending on the argument `Type`:

- `Type = 'Corr'` (only available for time-domain data): The autocorrelation function of `e` and the cross correlation between `e` and the input(s) `u` are computed and displayed. The 99% confidence intervals for these values are also computed and shown as a yellow region. The computation of the confidence region is done assuming `e` to be white and independent of `u`. The functions are displayed up to lag `M`, which is 25 by default.
- `Type = 'ir'`: The impulse response (up to lag `M`, which is 25 by default) from the input to the residuals is plotted with a 99% confidence region around zero marked as a yellow area. Negative lags up to `M/4` are also included to investigate feedback effects. The result is the same as `impulse(e,'sd',2.58,M)`.
- `Type = 'fr'`: The frequency response from the input to the residuals (based on a high-order FIR model) is shown as a Bode plot. A 99% confidence region around zero is also marked as a yellow area.

The default for time-domain data is `Type = 'Corr'`. For frequency-domain data, the default is `Type = 'fr'`.

With an output argument, no plot is produced, and `e` is returned with the residuals (prediction errors) associated with the model and the data. It is an `iddata` object with the residuals as outputs and the input in `data` as inputs. That means that `e` can be directly used to build model error models, that is, models that describe the dynamics from the input to the residuals (which should be negligible if `m` is a good description of the system).

Examples

Here are some typical model validation commands.

```
e = resid(m,data);
plot(e)
compare(data,m);
```

To compute a model error model, that is, a model from the input to the residuals to see if any essential unmodeled dynamics are left, do the following:

```
e = resid(m,data);
me = arx(e,[10 10 0]);
bode(me,'sd',3,'fill')
```

See Also

`compare`

`predict`

`sim`

`simsd`

Purpose

Add offsets or trends to data signals

Syntax

```
data = retrend(data_d,T)
```

Description

`data = retrend(data_d,T)` returns a data object `data` by adding the trend information `T` to each signal in `data_d`. `data_d` is a time-domain `iddata` object. `T` is an `TrendInfo` object.

Examples

Subtract means from input-output signals, estimate a linear model, and retrend the simulated output:

```
% Load SISO data containing vectors u2 and y2
load dryer2
% Create data object with sampling time of 0.08 sec
data=iddata(y2,u2,0.08)
% Remove the mean from the data
[data_d,T] = detrend(data,0)
% Estimate a linear ARX model
m = arx(data_d,[2 2 1])
% Simulate the model output
% with zero initial states
y_sim = sim(m,data_d(:,[],:));
% Retrend the simulated model output
y_tot = retrend(y_sim,T);
```

"Handling Offsets and Trends in Data"

Purpose

Estimate recursively output-error models (IIR-filters)

Syntax

```
thm = roe(z,nn,adm,adg)
[thm,yhat,P,phi,psi] = roe(z,nn,adm,adg,th0,P0,phi0,psi0)
```

Description

The parameters of the output-error model structure

$$y(t) = \frac{B(q)}{F(q)}u(t-nk) + e(t)$$

are estimated using a recursive prediction error method.

The input-output data are contained in `z`, which is either an `iddata` object or a matrix `z = [y u]` where `y` and `u` are column vectors. `nn` is given as

```
nn = [nb nf nk]
```

where `nb` and `nf` are the orders of the output-error model, and `nk` is the delay. Specifically,

$$nb: \quad B(q) = b_1 + b_2 q^{-1} + \ldots + b_{nb} q^{-nb+1}$$
$$nf: \quad F(q) = 1 + f_1 q^{-1} + \ldots + f_{nf} q^{-nf}$$

See “What Are Black-Box Polynomial Models?” for more information.

Only single-input, single-output models are handled by `roe`. Use `rpem` for the multiple-input case.

The estimated parameters are returned in the matrix `thm`. The `k`th row of `thm` contains the parameters associated with time `k`; that is, they are based on the data in the rows up to and including row `k` in `z`.

Each row of `thm` contains the estimated parameters in the following order.

```
thm(k,:) = [b1,...,bnb,f1,...,fnf]
```

`yhat` is the predicted value of the output, according to the current model; that is, row `k` of `yhat` contains the predicted value of `y(k)` based on all past data.

The actual algorithm is selected with the two arguments `adg` and `adm`. These are described under `rarx`.

The input argument `th0` contains the initial value of the parameters, a row vector consistent with the rows of `thm`. The default value of `th0` is all zeros.

The arguments `P0` and `P` are the initial and final values, respectively, of the scaled covariance matrix of the parameters. See `rarx`. The default value of `P0` is 10^4 times the unit matrix. The arguments `phi0`, `psi0`, `phi`, and `psi` contain initial and final values of the data vector and the gradient vector, respectively. The sizes of these depend on the chosen model orders. The normal choice of `phi0` and `psi0` is to use the outputs from a previous call to `roe` with the same model orders. (This call could be a dummy call with default input arguments.) The default values of `phi0` and `psi0` are all zeros.

Note that the function requires that the delay `nk` be larger than `0`. If you want `nk = 0`, shift the input sequence appropriately and use `nk = 1`.

Algorithm

The general recursive prediction error algorithm (11.44) of Ljung (1999) is implemented. See also “Algorithms for Recursive Estimation”.

Purpose

Estimate general input-output models using recursive prediction-error minimization method

Syntax

```
thm = rpem(z,nn,adm,adg)
[thm,yhat,P,phi,psi] = rpem(z,nn,adm,adg,th0,P0,phi0,psi0)
```

Description

The parameters of the general linear model structure

$$A(q)y(t) = \frac{B_1(q)}{F_1(q)}u_1(t-nk_1) + \ldots + \frac{B_{nu}(q)}{F_{nu}(q)}u_{nu}(t-nk_{nu}) + \frac{C(q)}{D(q)}e(t)$$

are estimated using a recursive prediction error method.

The input-output data is contained in `z`, which is either an `iddata` object or a matrix `z = [y u]` where `y` and `u` are column vectors. (In the multiple-input case, `u` contains one column for each input.) `nn` is given as

```
nn = [na nb nc nd nf nk]
```

where `na`, `nb`, `nc`, `nd`, and `nf` are the orders of the model, and `nk` is the delay. For multiple-input systems, `nb`, `nf`, and `nk` are row vectors giving the orders and delays of each input. See “What Are Black-Box Polynomial Models?” for an exact definition of the orders.

The estimated parameters are returned in the matrix `thm`. The `k`th row of `thm` contains the parameters associated with time `k`; that is, they are based on the data in the rows up to and including row `k` in `z`. Each row of `thm` contains the estimated parameters in the following order.

```
thm(k,:) = [a1,a2,...,ana,b1,...,bnb,...
  c1,...,cnc,d1,...,dnd,f1,...,fnf]
```

For multiple-input systems, the B part in the above expression is repeated for each input before the C part begins, and the F part is also repeated for each input. This is the same ordering as in `m.par`.

`yhat` is the predicted value of the output, according to the current model; that is, row `k` of `yhat` contains the predicted value of `y(k)` based on all past data.

The actual algorithm is selected with the two arguments `adg` and `adm`. These are described under `rarx`.

The input argument `th0` contains the initial value of the parameters, a row vector consistent with the rows of `thm`. The default value of `th0` is all zeros.

The arguments `P0` and `P` are the initial and final values, respectively, of the scaled covariance matrix of the parameters. See `rarx`. The default value of `P0` is 10^4 times the unit matrix. The arguments `phi0`, `psi0`, `phi`, and `psi` contain initial and final values of the data vector and the gradient vector, respectively. The sizes of these depend on the chosen model orders. The normal choice of `phi0` and `psi0` is to use the outputs from a previous call to `rpem` with the same model orders. (This call could be a dummy call with default input arguments.) The default values of `phi0` and `psi0` are all zeros.

Note that the function requires that the delay `nk` be larger than `0`. If you want `nk = 0`, shift the input sequence appropriately and use `nk = 1`.

Algorithm

The general recursive prediction error algorithm (11.44) of Ljung (1999) is implemented. See also "Algorithms for Recursive Estimation".

For the special cases of ARX/AR models, and of single-input ARMAX/ARMA, Box-Jenkins, and output-error models, it is more efficient to use `rarx`, `rarmax`, `rbj`, and `roe`.

See Also

`nkshift`

`rarmax`

`rarx`

`rbj`

`roe`

`rplr`

Purpose

Estimate general input-output models using recursive pseudolinear regression method

Syntax

```
thm = rplr(z,nn,adm,adg)
[thm,yhat,P,phi] = rplr(z,nn,adm,adg,th0,P0,phi0)
```

Description

This is a direct alternative to `rpem` and has essentially the same syntax. See `rpem` for an explanation of the input and output arguments.

`rplr` differs from `rpem` in that it uses another gradient approximation. See Section 11.5 in Ljung (1999). Several of the special cases are well-known algorithms.

When applied to ARMAX models, (`nn = [na nb nc 0 0 nk]`), `rplr` gives the extended least squares (ELS) method. When applied to the output-error structure (`nn = [0 nb 0 0 nf nk]`), the method is known as HARF in the `adm = 'ff'` case and SHARF in the `adm = 'ng'` case.

`rplr` can also be applied to the time-series case in which an ARMA model is estimated with

```
z = y
nn = [na nc]
```

You can thus use `rplr` as an alternative to `rarmax` for this case.

References

For more information about HARF and SHARF, see Chapter 11 in Ljung (1999).

Purpose

Class representing saturation nonlinearity estimator for Hammerstein-Wiener models

Syntax

```
s=saturation(LinearInterval,L)
```

Description

`saturation` is an object that stores the saturation nonlinearity estimator for estimating Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`s=saturation(LinearInterval,L)` creates a saturation nonlinearity estimator object, initialized with the linear interval `L`.

Use `evaluate(s,x)` to compute the value of the function defined by the `saturation` object `s` at `x`.

Remarks

Use `saturation` to define a nonlinear function $y = F(x)$, where F is a function of x and has the following characteristics:

$$
\begin{array}{ll}
a \le x < b & F(x) = x \\
a > x & F(x) = a \\
b \le x & F(x) = b
\end{array}
$$

y and x are scalars.

saturation Properties

You can specify the property value as an argument in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List LinearInterval property value
get(s)
s.LinearInterval
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(s, 'LinearInterval', [-1.5 1.5])
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
`LinearInterval`	1-*by*-2 row vector that specifies the initial interval of the saturation. Default=`[NaN NaN]`. For example: `saturation('LinearInterval',[-1.5 1.5])`

Examples

Use `saturation` to specify the saturation nonlinearity estimator in Hammerstein-Wiener models. For example:

```
m=nlhw(Data,Orders,saturation([-1 1]),[]);
```

The saturation nonlinearity is initialized at the interval `[-1 1]`. The interval values are adjusted to the estimation data by `nlhw`.

`nlhw`

segment

Purpose

Segment data and estimate models for each segment

Syntax

```
segm = segment(z,nn)
[segm,V,thm,R2e] = segment(z,nn,R2,q,R1,M,th0,P0,ll,mu)
```

Description

`segment` builds models of AR, ARX, or ARMAX/ARMA type,

$$A(q)y(t) = B(q)u(t-nk) + C(q)e(t)$$

assuming that the model parameters are piecewise constant over time. It results in a model that has split the data record into segments over which the model remains constant. The function models signals and systems that might undergo abrupt changes.

The input-output data is contained in `z`, which is either an `iddata` object or a matrix `z = [y u]` where `y` and `u` are column vectors. If the system has several inputs, `u` has the corresponding number of columns.

The argument `nn` defines the model order. For the ARMAX model

```
nn = [na nb nc nk]
```

where `na`, `nb`, and `nc` are the orders of the corresponding polynomials. See “What Are Black-Box Polynomial Models?”. Moreover, `nk` is the delay. If the model has several inputs, `nb` and `nk` are row vectors, giving the orders and delays for each input.

For an ARX model (`nc = 0`) enter

```
nn = [na nb nk]
```

For an ARMA model of a time series

```
z = y
nn = [na nc]
```

and for an AR model

```
nn = na
```

The output argument segm is a matrix, where the kth row contains the parameters corresponding to time k. This is analogous to the output argument thm in rarx and rarmax. The output argument thm of segment contains the corresponding model parameters that have not yet been segmented. That is, they are not piecewise constant, and therefore correspond to the outputs of the functions rarmax and rarx. In fact, segment is an alternative to these two algorithms, and has a better capability to deal with time variations that might be abrupt.

The output argument V contains the sum of the squared prediction errors of the segmented model. It is a measure of how successful the segmentation has been.

The input argument R2 is the assumed variance of the innovations $e(t)$ in the model. The default value of R2, R2 = [], is that it is estimated. Then the output argument R2e is a vector whose kth element contains the estimate of R2 at time k.

The argument q is the probability that the model exhibits an abrupt change at any given time. The default value is 0.01.

R1 is the assumed covariance matrix of the parameter jumps when they occur. The default value is the identity matrix with dimension equal to the number of estimated parameters.

M is the number of parallel models used in the algorithm (see below). Its default value is 5.

th0 is the initial value of the parameters. Its default is zero. P0 is the initial covariance matrix of the parameters. The default is 10 times the identity matrix.

ll is the guaranteed life of each of the models. That is, any created candidate model is not abolished until after at least ll time steps. The default is ll = 1. Mu is a forgetting parameter that is used in the scheme that estimates R2. The default is 0.97.

The most critical parameter for you to choose is R2. It is usually more robust to have a reasonable guess of R2 than to estimate it. Typically, you need to try different values of R2 and evaluate the results. (See the

example below.) `sqrt(R2)` corresponds to a change in the value $y(t)$ that is normal, giving no indication that the system or the input might have changed.

Algorithm

The algorithm is based on `M` parallel models, each recursively estimated by an algorithm of Kalman filter type. Each model is updated independently, and its posterior probability is computed. The time-varying estimate `thm` is formed by weighting together the `M` different models with weights equal to their posterior probability. At each time step the model (among those that have lived at least `ll` samples) that has the lowest posterior probability is abolished. A new model is started, assuming that the system parameters have changed, with probability `q`, a random jump from the most likely among the models. The covariance matrix of the parameter change is set to `R1`.

After all the data are examined, the surviving model with the highest posterior probability is tracked back and the time instances where it jumped are marked. This defines the different segments of the data. (If no models had been abolished in the algorithm, this would have been the maximum likelihood estimates of the jump instances.) The segmented model `segm` is then formed by smoothing the parameter estimate, assuming that the jump instances are correct. In other words, the last estimate over a segment is chosen to represent the whole segment.

Examples

Check how the algorithm segments a sinusoid into segments of constant levels. Then use a very simple model $y(t) = b_1 * 1$, where `1` is a fake input and b_1 describes the piecewise constant level of the signal $y(t)$ (which is simulated as a sinusoid).

```
y = sin([1:50]/3)';
thm = segment([y,ones(length(y),1)],[0 1 1],0.1);
plot([thm,y])
```

By trying various values of `R2` (`0.1` in the above example), more levels are created as `R2` decreases.

selstruc

Purpose

Select model order for single-output ARX models

Syntax

```
nn = selstruc(v)
[nn,vmod] = selstruc(v,c)
```

Description

Note Use `selstruc` for single-output systems only. `selstruc` supports both single-input and multiple-input systems.

`selstruc` is a function to help choose a model structure (order) from the information contained in the matrix `v` obtained as the output from `arxstruc` or `ivstruc`.

The default value of `c` is `'plot'`. The plot shows the percentage of the output variance that is not explained by the model as a function of the number of parameters used. Each value shows the best fit for that number of parameters. By clicking in the plot you can examine which orders are of interest. When you click **Select**, the variable `nn` is exported to the workspace as the optimal model structure for your choice of number of parameters. Several choices can be made.

`c = 'aic'` gives no plots, but returns in `nn` the structure that minimizes

$$
\begin{aligned}
V_{\text{mod}} &= \log\left(V\left(1+\frac{2d}{N}\right)\right) \\
&= \log(V)+\frac{2d}{N}, N \gg d
\end{aligned}
$$

where V is the loss function, d is the total number of parameters in the structure in question, and N is the number of data points used for the estimation. $\log(V)+\frac{2d}{N}$ is the Akaike's Information Criterion (AIC). See `aic` for more details.

`c = 'mdl'` returns in `nn` the structure that minimizes Rissanen's Minimum Description Length (MDL) criterion.

$$V_{\text{mod}} = V\left(1 + \frac{d\log(N)}{N}\right)$$

When `c` equals a numerical value, the structure that minimizes

$$V_{\text{mod}} = V\left(1 + \frac{cd}{N}\right)$$

is selected.

The output argument `vmod` has the same format as `v`, but it contains the logarithms of the accordingly modified criteria.

Examples

```
V = arxstruc(data(1:200),data(201:400),...
             struc(1:10,1:10,1:10))
nn = selstruc(V,0); %best fit to validation data
m = arx(data,nn)
```

Purpose

Set properties of data and model objects

Syntax

```
set(m,'Property',Value)
set(m,'Property1',Value1,...'PropertyN',ValueN)
set(m,'Property')
set(m)
```

Description

`set` is used to set or modify the properties of any of the objects in the toolbox (`iddata`, `idmodel`, `idgrey`, `idarx`, `idpoly`, `idss`, `idnlarx`, `idnlgrey`, `idnlhw`). See the corresponding reference pages for a complete list of properties.

`set(m,'Property',Value)` assigns the value `Value` to the property of the object `m` specified by the string `'Property'`. This string can be the full property name (for example, `'SSParameterization'`) or any unambiguous case-insensitive abbreviation (for example, `'ss'`).

`set(m,'Property1',Value1,...'PropertyN',ValueN)` sets multiple properties with a single statement. In certain cases this might be necessary, since the model `m` must, for example, have state-space matrices of consistent dimensions after each `set` statement.

`set(m,'Property')` displays admissible values for the property specified by `'Property'`.

`set(m)` displays all assignable values of `m` and their admissible values.

The same result is also obtained by subassignment.

```
m.Property = Value
```

setinit

Purpose

Set initial states of `idnlgrey` model object

Syntax

```
setinit(model,property,values)
```

Input

`model`
: Name of the `idnlgrey` model object.

`property`
: Name of the `InitialStates` model property field, such as `'Name'`, `'Unit'`, `'Value'`, `'Minimum'`, `'Maximum'`, and `'Fixed'`.

`values`
: Values of the specified property `Property`. `values` are an `Nx`-by-1 cell array of values, where `Nx` is the number of states.

Description

`setinit(model,property,values)` sets the `values` of the `property` field of the `InitialStates` model property. `property` can be `'Name'`, `'Unit'`, `'Value'`, `'Minimum'`, `'Maximum'`, and `'Fixed'`.

See Also

`getinit`

`idnlgrey`

`setpar`

Purpose

Set initial parameter values of idnlgrey model object

Syntax

```
setpar(model,property,values)
```

Input

model
: Name of the idnlgrey model object.

property
: Name of the Parameters model property field, such as 'Name', 'Unit', 'Value', 'Minimum', or 'Maximum'.

  Default: 'Value'.

values
: Values of the specified property Property. values are an Np-by-1 cell array of values, where Np is the number of parameters.

Description

setpar(model,property,values) sets the model parameter values in the property field of the Parameters model property. property can be 'Name', 'Unit', 'Value', 'Minimum', and 'Maximum'.

See Also

getinit

getpar

idnlgrey

setinit

setpname

Purpose

Set mnemonic parameter names for linear black-box model structures

Syntax

```
model = setpname(model)
```

Description

`model` is an `idmodel` object of `idarx`, `idpoly`, `idproc`, or `idss` type. The returned model has the `'PName'` property set to a cell array of strings that correspond to the symbols used in this manual to describe the parameters.

For single-input `idpoly` models, the parameters are called `'a1', 'a2', ...,'fn'`.

For multiple-input `idpoly` models, the *b* and *f* parameters have the output/input channel number in parentheses, as in `'b1(1,2)'`, `'f3(1,2)'`, etc.

For `idarx` models, the parameter names are as in `'-A(ky,ku)'` for the negative value of the *ky-ku* entry of the matrix in *A(q)* polynomial of the multiple-output ARX equation, and similarly for the *B* parameters.

For `idss` models, the parameters are named for the matrix entries they represent, such as `'A(4,5)'`, `'K(2,3)'`, etc.

For `idproc` models, the parameter names are as described under `idproc`.

This function is particularly useful when certain parameters are to be fixed. See the property `FixedParameter` under `Algorithm Properties`.

Purpose

Specify format for B and F polynomials of multi-input polynomial model for backward compatibility

Syntax

```
model= setPolyFormat(model, 'cell')
model= setPolyFormat(model, 'double')
```

Description

`model= setPolyFormat(model, 'cell')` converts the B and F polynomials of a multi-input polynomial model, `model`, from double matrices to cell arrays. Each cell array has Nu-elements of double vectors, where Nu is the number of inputs.

`model= setPolyFormat(model, 'double')` allows you to continue using double matrices for the B and F polynomials. The model displays a message that it is in backward compatibility mode.

Tips

- The *B* and *F* polynomials, represented by `b` and `f` properties of `idpoly` object, are currently double matrices. For multi-input polynomial models, these polynomials will be cell arrays in a future version. Using `setPolyFormat` allows you to either change to using cell arrays immediately or continue using double arrays without errors in a future version.
- After using `model = setPolyFormat(model, 'cell')`, update your code to use cell array syntax for operations on the `b` and `f` properties.
- After using `model = setPolyFormat(model, 'double')`, you can continue using double matrix syntax for operations on the `b` and `f` properties.
- `setPolyFormat` has no effect on single-input `idpoly` models, where the `b` and `f` properties continue to be represented by double row vectors.

Examples

Convert the `B` and `F` polynomials of an estimated multi-input ARX model to cell arrays:

1. Estimate a 3-input ARX model.

```
% Load estimation data.
load iddata8
% Estimate model.
m = arx(z8, [3 [2 2 1] [1 1 1]]);
```

The software computes the B and F polynomials and stores their values as double matrices in the `b` and `f` properties. Operations on the B and F polynomials, such as `m.b`, produce an incompatibility warning.

2 Convert the `B` and `F` polynomials to cell arrays.

```
m=setPolyFormat(m,'cell');
```

To verify that the B and F polynomials are cell arrays, type `class(m.b)`, which returns:

```
ans =

cell
```

3 Extract pole and zero information from the model using cell array syntax.

```
Poles1 = roots(m.f{1});
Zeros1 = roots(m.b{1});
```

Continue using double matrices for B and F polynomials of an estimated multi-input ARX model:

1 Estimate a 3-input ARX model.

```
% Load estimation data.
load iddata8
% Estimate model.
m = arx(z8, [3 [2 2 1] [1 1 1]]);
```

The software computes the B and F polynomials, and stores their values in double matrices in the `b` and `f` properties. Operations on the B and F polynomials, such as `m.b`, produce an incompatibility warning.

2 Designate the model to continue using double matrices for the B and F polynomials for backward compatibility.

```
m=setPolyFormat(m,'double')
```

The following message at the MATLAB prompt indicates that the model is backward compatible:

```
(model configured to operate in backward compatibility mode)
```

3 Extract pole and zero information from the model using matrix syntax.

```
Poles1 = roots(m.f(1,:))
Zeros1 = roots(m.b(1,:))
```

How To

- “Extracting Parameter Values from Linear Models”

setstruc

Purpose

Set matrix structure for idss model objects

Syntax

```
setstruc(M,As,Bs,Cs,Ds.Ks,X0s)
setstruc(M,Mods)
```

Description

```
setstruc(M,As,Bs,Cs,Ds.Ks,X0s)
```

is the same as

```
set(M,'As',As,'Bs',Bs,'Cs',Cs,'Ds',Ds,'Ks',Ks,'X0s',X0s)
```

Use empty matrices for structure matrices that should not be changed. You can omit trailing arguments.

In the alternative syntax, `Mods` is a structure with field names `As`, `Bs`, etc., with the corresponding values of the fields.

See Also

`idss`

Purpose

Class representing sigmoid network nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models

Syntax

```
s=sigmoidnet('NumberOfUnits',N)
s=sigmoidnet(Property1,Value1,...PropertyN,ValueN)
```

Description

`sigmoidnet` is an object that stores the sigmoid network nonlinear estimator for estimating nonlinear ARX and Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`s=sigmoidnet('NumberOfUnits',N)` creates a sigmoid nonlinearity estimator object with `N` terms in the sigmoid expansion.

`s=sigmoidnet(Property1,Value1,...PropertyN,ValueN)` creates a sigmoid nonlinearity estimator object specified by properties in "sigmoidnet Properties" on page 2-394.

Use `evaluate(s,x)` to compute the value of the function defined by the `sigmoidnet` object `s` at `x`.

Remarks

Use `sigmoidnet` to define a nonlinear function $y = F(x)$, where y is scalar and x is an `m`-dimensional row vector. The sigmoid network function is based on the following expansion:

$$F(x) = (x-r)PL + a_1 f\left((x-r)Qb_1 - c_1\right) + \dots$$
$$+ a_n f\left((x-r)Qb_n - c_n\right) + d$$

where f is the sigmoid function, given by the following equation:

$$f(z) = \frac{1}{e^{-z} + 1}$$

P and Q are `m`-*by*-`p` and `m`-*by*-`q` projection matrices. The projection matrices P and Q are determined by principal component analysis of estimation data. Usually, `p=m`. If the components of x in the estimation data are linearly dependent, then `p<m`. The number of columns of Q,

q, corresponds to the number of components of x used in the sigmoid function.

When used in a nonlinear ARX model, q is equal to the size of the NonlinearRegressors property of the idnlarx object. When used in a Hammerstein-Wiener model, m=q=1 and Q is a scalar.

r is a 1-*by*-m vector and represents the mean value of the regressor vector computed from estimation data.

d, a_k, and c_k are scalars.

L is a p-*by*-1 vector.

b_k are q-*by*-1 vectors.

sigmoidnet Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use get or dot notation to access the object property values. For example:

```
% List all property values
get(s)
% Get value of NumberOfUnits property
s.NumberOfUnits
```

You can also use the set function to set the value of particular properties. For example:

```
set(s, 'LinearTerm', 'on')
```

The first argument to set must be the name of a MATLAB variable.

<table>
<tr><th>Property Name</th><th>Description</th></tr>
<tr><td><code>NumberOfUnits</code></td><td>Integer specifies the number of nonlinearity units in the expansion.
Default=<code>10</code>.

For example:

<code>sigmoidnet(H,'NumberOfUnits',5)</code></td></tr>
<tr><td><code>LinearTerm</code></td><td>Can have the following values:
<code>'on'</code>—Estimates the vector L in the expansion.
<code>'off'</code>—Fixes the vector L to zero.
For example:

<code>sigmoidnet(H,'LinearTerm','on')</code></td></tr>
<tr><td><code>Parameters</code></td><td>A structure containing the parameters in the nonlinear expansion, as follows:
<code>RegressorMean</code>: 1-by-<code>m</code> vector containing the means of <code>x</code> in estimation data, <code>r</code>.

<code>OutputOffset</code>: scalar <code>d</code>.
Typically, the values of this structure are set by estimating a model with a <code>sigmoidnet</code> nonlinearity.</td></tr>
</table>

sigmoidnet

Algorithm

`sigmoidnet` uses an iterative search technique for estimating parameters.

Examples

Use `sigmoidnet` to specify the nonlinear estimator in nonlinear ARX and Hammerstein-Wiener models. For example:

```
m=nlarx(Data,Orders,sigmoidnet('num',5));
```

See Also

`nlarx`

`nlhw`

Purpose

Simulate linear models with confidence interval

Syntax

```
y = sim(m,u)
y = sim(m,u,'noise')
[y, ysd] = sim(m,u,'InitialState',init)
```

Description

`m` is any `idmodel`.

`u` is an `iddata` object, containing inputs only. (Any outputs are ignored). Both time-domain and frequency-domain signals are supported. The number of input channels in `u` must either be equal to the number of inputs of the model `m` or equal to the sum of the number of inputs and noise sources (number of outputs). In the latter case the last inputs in `u` are regarded as noise sources and a noise-corrupted simulation is obtained. The noise is scaled according to the property `m.NoiseVariance` in `m`. To obtain the right noise level according to the model, the noise inputs should be white noise with zero mean and unit covariance matrix. A simpler way of obtaining a noise-corrupted simulation with Gaussian noise is to add the argument `'noise'`. If no noise sources are contained in `u`, a noise-free simulation is obtained. `sim` applies both to time-domain and frequency-domain `iddata` objects, but no standard deviations are obtained for frequency-domain signals.

`sim` returns `y`, containing the simulated output, as an `iddata` object.

`init` gives access to the initial states:

- `init = 'm'` (default) uses the internally stored initial state of model `m`.
- `init = 'z'` uses zero initial state.
- `init = x0`, where `x0` is a column vector of appropriate length, uses this value as the initial state. For multi-experiment inputs, `x0` has as many columns as there are experiments to allow for different initial conditions. For a continuous-time model `m`, `x0` is the initial state for this model. Any modifications of the initial state that sampling might require are automatically handled. If `m` has a non-zero `InputDelay`,

and you need to access the values of the inputs during this delay, you must first apply `inpd2nk(m)`. If `m` is a continuous-time model, it must first be sampled before `inpd2nk` can be applied.

The second output argument `ysd` is the standard deviation of the simulated output. This is not available for frequency-domain data.

`u` can also be given as a matrix with the number of columns being either the number of inputs in `m` or the sum of the number of inputs and outputs. Then `y` and `ysd` are returned as matrices. Continuous-time models, however, require `u` to be given as `iddata`.

If `m` is a continuous-time model, it is first converted to discrete time with the sampling interval given by `ue`, taking into account the inter-sample behavior of the input (`ue.InterSample`).

Examples

Simulate a given system `m0` (for example, created by `idpoly`).

```
e = iddata([],randn(500,1));
u = iddata([],idinput(500,'prbs'));
y = sim(m0,[u e]);
% iddata object with output y and input u.
z = [y u];
```

The same result is obtained by

```
u = iddata([],idinput(500,'prbs'));
y = sim(m0,u,'noise');
z = [y u];
```

or

```
u = idinput(500,'prbs');
y = sim(m0,u,'noise');
z = iddata(y,u);
```

Validate a model by comparing a measured output `y` with one simulated using an estimated model `m`.

```
yh = sim(m,u);
plot(y,yh)
```

`simsd`

Purpose

Simulate nonlinear ARX model

Syntax

```
YS = sim(MODEL,U)
YS = sim(MODEL,U,'Noise')
YS = sim(MODEL,U,'InitialState',INIT)
```

Description

`YS = sim(MODEL,U)` simulates a dynamic system with an `idnlarx` model.

`YS = sim(MODEL,U,'Noise')` produces a noise corrupted simulation with an additive Gaussian noise scaled according to the value of the `NoiseVariance` property of `MODEL`.

`YS = sim(MODEL,U,'InitialState',INIT)` specifies the initial conditions for simulation using various options, such as numerical initial state vector or past I/O data.

To simulate the model with user-defined noise, set the input `U = [UIN E]`, where `UIN` is the input signal and `E` is the noise signal. `UIN` and `E` must both be one of the following:

- `iddata` objects: `E` stores the noise signals as inputs, where the number of inputs matches the number of model outputs.
- Matrices: `E` has as many columns as there are noise signals, corresponding to the number of model outputs.

Input

- `MODEL`: `idnlarx` model object.
- `U`: Input data for simulation, an `iddata` object (where only the input channels are used) or a matrix. For simulations with noisy data, `U` contains both input and noise channels.
- `INIT`: Initial condition specification. `INIT` can be one of the following:
  - A real column vector `X0`, for the state vector corresponding to an appropriate number of output and input data samples prior to the simulation start time. To build an initial state vector from a given set of input-output data or to generate equilibrium states, see `data2state(idnlarx)`, `findstates(idnlarx)` and

findop(idnlarx). For multi-experiment data, X0 may be a matrix whose columns give different initial states for different experiments.

- 'z': (Default) Zero initial state, equivalent to a zero vector of appropriate size.
- iddata object containing output and input data samples prior to the simulation start time. If it contains more data samples than necessary, only the last samples are taken into account. This syntax is equivalent to sim(MODEL,U,'InitialState',data2state(MODEL,INIT)), where data2state(idnlarx) transforms the iddata object INIT to a state vector.

Output

- YS: Simulated output. An iddata object if U is an iddata object, a matrix otherwise.

Note If sim is called without an output argument, MATLAB software displays the simulated output(s) in a plot window.

Examples

Simulation of a SISO idnlarx model

In this example you simulate a single-input single-output idnlarx model M around a known equilibrium point, with an input level of 1 and output level of 10.

1. Load the sample data.

```
load iddata2;
```

2. Estimate an idnlarx model from the data.

```
M = nlarx(z2, [2 2 1], 'tree');
```

3. Estimate current states of model based on past data.

```
x0 = data2state(M, struct('Input',1, 'Output', 10));
```

4. Simulate the model using the initial states returned by `data2state`.

   ```
   sim(M, z2, 'init', x0);
   ```

Continuing from End of Previous Simulation

In this example you continue the simulation of a model from the end of a previous simulation run.

1. Estimate the `idnlarx` model from data.

   ```
   load iddata2
   M = nlarx(z2, [2 2 1], 'tree'); % idnlarx model
   ```

2. Simulate the model using first half of input data of `z2`

   ```
   u1 = z2(1:200,[]);
   % Simulate starting from zero initial states
   ys1 = sim(M, u1, 'init', 'z');
   ```

3. Start another simulation, using the same states of the model from when the first simulation ended. For the second simulation, you use the second half of the input data of `z2`.

   ```
   u2 = z2(201:end, []);
   ```

4. In order to set the initial states for second simulation correctly, package input `u1` and output `ys1` from the first simulation into one `iddata` object.

   ```
   firstSimData = [ys1,u1];
   ```

5. Pass this data as initial conditions for the next simulation.

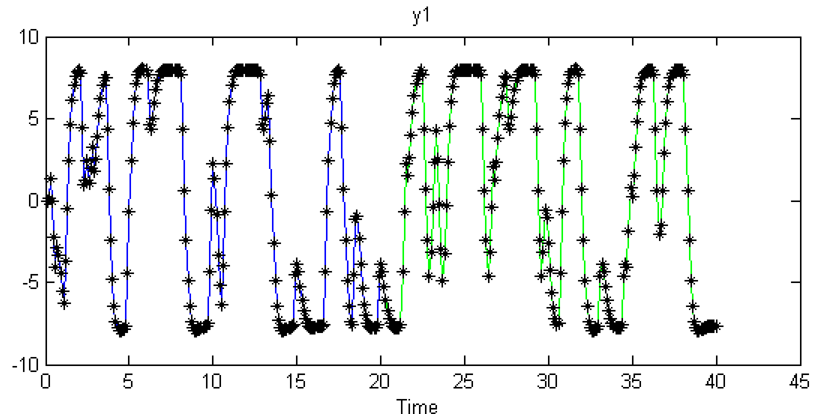
   ```
   ys2 = sim(M, u2, 'init', firstSimData);
   ```

6. Verify the two simulations by comparing to a complete simulation using all the input data of `z2`.

```
uTotal = z2(:,[]); % extract the whole input data
ysTotal = sim(M, uTotal, 'init', 'z');

% Compare the values of ys1, ys2 and ysTotal.
% ys1 should be equal to first half of ysTotal.
% ys2 should be equal to the second half of ysTotal
%
% plot the three responses
plot(ys1,'b', ys2, 'g', ysTotal, 'k*')
```

MATLAB software responds with a plot showing the three responses, with `ysTotal` overlaying `ys1` and `ys2` to verify that they match.



Matching Model Response to Output Data

In this example, you estimate initial states of model `M` such that the response best matches the output in data set `z2`.

1 Load the sample data and create data object `z2`.

```
load iddata2;
z2 = z2(1:50);
```

2 Estimate `idnlarx` model from data.

```
M = nlarx(z2,[4 3 2],'wave');
```

3. Estimate initial states of M to best fit z2.y in the simulated response.

```
x0 = findstates(M,z2,[],'sim');
```

4. Simulate the model.

```
ysim = sim(M, z2.u, 'init', x0)
```

5. Compare ysim with the output signal in z2:

```
time = z2.SamplingInstants;
plot(time, ysim, time, z2.y,'.')
```

Simulation Near Steady State with Known Input and Unknown Output

In this example you start simulation of a model near steady state, where the input is known to be 1, but the output is unknown.

- Load sample data and create data object z2.

```
load iddata2
z2 = z2(1:50);
```

- Estimate idnlarx model from data.

```
M = nlarx(z2, [4 3 2], 'wave');
```

- Determine equilibrium state values for input 1 and the unknown target output.

```
x0 = findop(M, 'steady', 1, NaN);
```

- Simulate the model using initial states x0.

```
sim(M, z2.u, 'init', x0)
```

sim(idnlgrey)

Purpose

Simulate nonlinear ODE model

Syntax

```
YS = sim(NLSYS,DATA)
YS = sim(NLSYS,DATA,'Noise');
YS = sim(NLSYS,DATA,XOINIT);
YS = sim(NLSYS,DATA,'Noise',XOINIT);
YS = sim(NLSYS,DATA,'Noise','InitialState',XOINIT);
[YS, YSD, XFINAL] = sim(NLSYS,DATA,'Noise','InitialState',
   XOINIT);
```

Description

`YS = sim(NLSYS,DATA)` simulates the output of an `idnlgrey` model.

`YS = sim(NLSYS,DATA,'Noise');` simulates the model with Gaussian noise added to `YS`.

`YS = sim(NLSYS,DATA,XOINIT);` simulates the model with the specified initial states.

`YS = sim(NLSYS,DATA,'Noise',XOINIT);` simulates the model with the specified initial states and with Gaussian noise added.

`YS = sim(NLSYS,DATA,'Noise','InitialState',XOINIT);` simulates the model with the specified initial states.

`[YS, YSD, XFINAL] = sim(NLSYS,DATA,'Noise','InitialState',XOINIT);` performs simulation starting with the specified initial states and with Gaussian noise added, and returns the final states of the model after the simulation is completed.

To simulate the model with user-defined noise, set the input `DATA = [UIN E]`, where `UIN` is the input signal and `E` is the noise signal. `UIN` and `E` must both be one of the following:

- `iddata` objects: `E` stores the noise signals as inputs, where the number of inputs matches the number of model outputs.
- Matrices: `E` has as many columns as there are noise signals, corresponding to the number of model outputs.

Input

- NLSYS: idnlgrey model object.
- DATA: Input-noise data [U E]. If E is omitted and 'Noise' is not given as an input argument, then a noise-free simulation is obtained. If E is omitted and 'Noise' is given as an input argument, then Gaussian noise created by randn(size(YS))*sqrtm(NLSYS.NoiseVariance) will be added to YS. If both E and 'Noise' are given, then E specifies the noise to add to YS. For time-continuous idnlgrey objects, DATA passed as a matrix will lead to that the data sample interval, Ts, is set to one.
- XOINIT: Initial states. Can have the following values:
  - 'zero' : Zero initial state x(0) with all states fixed (nlsys.InitialStates.Fixed is thus ignored).
  - 'fixed' (default): Struct array (NLSYS.InitialState) determines the values of the model initial states and all states are fixed. (NLSYS.InitialStates.Fixed is ignored). Same as 'model'.
  - vector/matrix: Column vector of initial state values. For multiple experiment DATA, XOINIT may be a matrix whose columns give different initial states for each experiment. All initial states are kept fixed (nlsys.InitialStates.Fixed is thus ignored).
  - struct array : Nx-by-1 structure array with fields:
    - Name: Name of the state (a string).
    - Unit: Unit of the state (a string).
    - Value: Value of the states (a finite real 1-by-Ne vector, where Ne is the number of experiments.)
    - Minimum: Minimum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same minimum value).

- Maximum: Maximum values of the states (a real 1-by-Ne vector or a real scalar, in which case all initial states have the same maximum value).
- Fixed: True (or a 1-by-Ne vector of True values). Any false value is ignored.

Output

- YS: Simulated output. If DATA is an iddata object, then YS will also be an iddata object. Otherwise, YS will be a matrix where the k:th output is found in the k:th column of YS. If DATA is a multiple-experiment iddata object, then YS will be a multiple experiment object as well.
- YSD: Empty vector ([].) In the future, it will contain the estimated standard deviation of the simulated output.
- XFINAL: Final states computed. In the single experiment case it is a column vector of length Nx. For multi-experiment data, XFINAL is an Nx-by-Ne matrix with the ith column specifying the initial state of experiment i.

Note If sim is called without an output argument, MATLAB software displays the simulated output(s) in a plot window.

Examples

In this example you simulate an idnlgrey model for a data set z. This example uses the nlgr model created in idnlgreydemo2.

1. Load the data set and create an idnlgrey model.

```
load twotankdata;
```

2. Estimate the idnlgrey model.

```
% Specify file.
FileName = 'twotanks_c';
```

```
% Specify model orders [ny nu nx].
Order = [1 1 2];
% Specify initial parameters.
Parameters = {0.5; 0.0035; 0.019; ...
              9.81; 0.25; 0.016};
% Specify initial states.
InitialStates = [0; 0.1];
Ts = 0;
nlgr = idnlgrey(FileName, Order, Parameters, ...
                InitialStates, Ts, ...
                'Name', 'Two tanks');
```

3. Create an `iddata` object `z` from data `z` (from `twotankdata.mat`).

   ```
   z = iddata([], u, 0.2, 'Name', 'Two tanks');
   ```

4. Simulate the model using the input signal from the data `z`.

   ```
   sim(nlgr,z)
   ```

`pem`

`predict(idnlgrey)`

Purpose

Simulate Hammerstein-Wiener model

Syntax

```
YS = sim(MODEL,U)
YS = sim(MODEL,U,'Noise')
YS = sim(MODEL,U,'InitialState',INIT)
```

Description

`YS = sim(MODEL,U)` simulates the output of an `idnlhw` model.

`YS = sim(MODEL,U,'Noise')` simulates the model output with an additive Gaussian noise scaled according to the value of the `NoiseVariance` property of `MODEL`.

`YS = sim(MODEL,U,'InitialState',INIT)` specifies initial conditions for starting the simulation.

To simulate the model with user-defined noise, set the input `U = [UIN E]`, where `UIN` is the input signal and `E` is the noise signal. `UIN` and `E` must both be one of the following:

- `iddata` objects: `E` stores the noise signals as inputs, where the number of inputs matches the number of model outputs.
- Matrices: `E` has as many columns as there are noise signals, corresponding to the number of model outputs.

Input

- `MODEL`: `idnlhw` model object.
- `U`: Input data for simulation, which is an `iddata` object (where only the input channels are used) or a matrix. For simulations with noisy data, `U` contains both input and noise channels.
- `INIT`: Initial condition for simulation. `INIT` has one of the following values:
  - Vector of initial state values. To estimate an initial state vector from input-output data or to generate equilibrium states, see the `findstates(idnlhw)` and `findop(idnlhw)` reference pages. For multiple-experiment data, enter a matrix with the same number of columns as the number of experiments.

- `'z'`: (Default) Vector containing zeros and corresponding to a system starting from rest.

Output

- `YS`: Simulated output, which is an `iddata` object when `U` is an `iddata` object, or a matrix otherwise.

Note If `sim` is called without an output argument, MATLAB software displays the simulated output(s) in a plot window.

Examples

Simulation Using Initial States to Best Fit Model Response to Measured Output

In this example you simulate the model output using initial states that minimize the error between the simulated and the measured output. `z2` is the measured data.

1. Load the sample data.

   ```
   load iddata2
   ```

2. Create a Hammerstein-Wiener model.

   ```
   M = nlhw(z2,[4 3 2],'wave','pwl');
   ```

3. Compute the initial states that best fit the model response to the measured output.

   ```
   x0 = findstates(M,z2);
   ```

4. Simulate the model using the estimated initial states.

   ```
   ysim = sim(M,z2.u,'init',x0)
   ```

5. Compare `ysim` to output signal in `z2`:

   ```
   t = z2.samp;
   ```

```
plot(t, ysim, t, z2.y)
```

Simulating a Hammerstein-Wiener Model at Steady-State with Known Input and Unknown Output

In this example, you simulate a single-input single-output `idnlhw` model about a steady-state operating point, where the input level is known to be 1 and the output level is unknown.

1. Load the sample data.

   ```
   load iddata2
   ```

2. Create a Hammerstein-Weiner model.

   ```
   M = nlhw(z2,[4 3 2],'wave','pwl');
   ```

3. Compute steady-state operating point values corresponding to an input level of 1 and an unknown output level.

   ```
   x0 = findop(M,'steady',1,NaN);
   ```

4. Simulate the model using the estimated initial states.

   ```
   sim(M,z2.u,'init',x0)
   ```

See Also

`findop(idnlhw)`

`finstates(idnlhw)`

`predict(idnlhw)`

Purpose

Simulate models with uncertainty using Monte Carlo method

Syntax

```
simsd(m,u)
simsd(m,u,N,'noise',Ky)
[y,ysd] = simsd(m,u)
```

Description

u is an iddata object containing the inputs. m is a model given as any idmodel object. N random models are created according to the covariance information given in m. The responses of each of these models to the input u are computed and graphed in the same diagram. If the argument 'noise' is included, noise is added to the simulation in accordance with the noise model of m and its own uncertainty. Ky denotes the output numbers to be plotted. (The default is all).

The default value is N=10.

With output arguments

```
[y,ysd] = simsd(m,u)
```

No plots are produced, but y is returned as a cell array with the simulated outputs, and ysd is the estimated standard deviation of y, based on the N different simulations. If u is an iddata object, so are the contents of the cells of y and ysd; otherwise, they are returned as vectors/matrices. In the iddata case,

```
plot(y{:})
```

thus plots all the responses.

sim and simsd have similar syntaxes. Note that simsd computes the standard deviation by Monte Carlo simulation, while sim uses differential approximations (the Gauss approximation formula). They might give different results.

Examples

Plot the step response of the model m and evaluate how it varies in view of the model's uncertainty.

```
step1 = [zeros(5,1); ones(20,1)];
```

```
simsd(m,step1)
```

`sim`

size

Purpose

Dimensions of data and model objects

Syntax

```
d = size(m)
[ny,nu,Npar,Nx] = size(model)
[N, ny, nu, Nexp] = size(data)
ny = size(data,2)
ny = size(data,'ny')
size(model)
size(idfrd_object)
```

Description

`size` describes the dimensions of `iddata`, `idmodel`, `idnlmodel`, and `idfrd` objects.

iddata

For `iddata` objects, the sizes returned are, in this order,

- `N` = the length of the data record. For multiple-experiment data, `N` is a row vector with as many entries as there are experiments.
- `ny` = the number of output channels.
- `nu` = the number of input channels.
- `Ne` = the number of experiments.

To access a specific `size` output, use syntax similar to the following: `size(data,k)` for the `k` `size(data,'N')`,`size(data,'ny')`.

When called with one output argument, `d = size(data)` returns

- `d = [N ny nu]` if the number of experiments is `1`.
- `d = [sum(N) ny nu Ne]` if the number of experiments is `Ne > 1`.

idmodel

For `idmodel` objects the sizes returned are, in this order,

- `ny` = the number of output channels.
- `nu` = the number of input channels.

- `Npar` = the length of the `ParameterVector` (number of estimated parameters).
- `Nx` = the number of states for `idss` and `idgrey` models.

To access a specific `size` output, use syntax similar to the following: `size(mod,2)`, `size(mod,'Npar')`.

When `size` is called with one output argument, `d = size(mod)`, `d` is given by

```
[ny nu Npar]
```

idfrd

For `idfrd` models, the sizes returned are, in this order,

- `ny` = the number of output channels.
- `nu` = the number of input channels.
- `Nf` = the number of frequencies.
- `Ns` = the number of spectrum channels.

To access a specific `size` output, use syntax similar to the following: `size(mod,2)` or `size(mod,'Nf')`.

When `size` is called with one output argument, `d = size(fre)`, `d` is given by

```
[ny nu Nf Ns]
```

When `size` is called with no output arguments, in any of these cases, the information is displayed in the MATLAB Command Window.

idnlarx or idnlhw

For `idmodel` objects the sizes returned are, in this order,

- `ny` = the number of output channels.

- `nu` = the number of input channels.

To access a specific `size` output, use one of the following:

```
NY = SIZE(NLSYS,1)
NU = SIZE(NLSYS,2)
NY = SIZE(NLSYS,'Ny')
NU = SIZE(NLSYS,'Nu')
```

When called with only one output argument, `N = SIZE(NLSYS)` returns the vector `N = [NY NU]`.

When called with no output argument, the information is displayed in the MATLAB Command Window.

idnlgrey

For `idnlgrey` objects the sizes returned are, in this order,

- `Ny` = the number of output channels.
- `Nu` = the number of input channels.
- `Nx` = the number of states.
- `Np` = the number of parameters.
- `Npo` = the number of parameter variables (number of estimated parameters).
- `Npf` = the number of fixed parameters.
- `Ne` = the number of experiments associated with the states.

`Ny`, `Nu`, `Nx`, `Np`,`Npo`, `Npf` and `Ne` are set to `NaN` if NLSYS is inconsistent.

To access a specific `size` output, use one of the following:

```
NY = SIZE(NLSYS, 1)
NU = SIZE(NLSYS, 2)
NX = SIZE(NLSYS, 3)
NP = SIZE(NLSYS, 4)
NPO = size(NLSYS, 5)
```

```
NPF = (NLSYS, 6)
NE = (NLSYS, 7)
NY = SIZE(NLSYS, 'Ny')
NU = SIZE(NLSYS, 'Nu')
```

When called with only one output argument, `N = SIZE(NLSYS)` returns the vector `N = [NY NU NP NX NPO NPF NE]`.

When called with no output argument, the information is displayed in the MATLAB Command Window.

Purpose

Estimate frequency response with fixed frequency resolution using spectral analysis

Syntax

```
G = spa(data)
G = spa(data,winSize,freq)
G = spa(data,winSize,freq,MaxSize)
[G,phi,spectrum] = spa(data)
```

Description

`G = spa(data)` estimates frequency response (with uncertainty) and noise spectrum from time- or frequency-domain data. `data` is an `iddata` or `idfrd` object and can be complex valued. `G` is as an `idfrd` object. For time-series `data`, `G` is the estimated spectrum and standard deviation.

`G = spa(data,winSize,freq)` estimates frequency response at frequencies `freq`. `freq` is a row vector of values in rad/sec. `winSize` is a scalar integer that sets the size of the Hann window.

`G = spa(data,winSize,freq,MaxSize)` can improve computational performance using `MaxSize` to split the input-output data such that each segment contains fewer than `MaxSize` elements. `MaxSize` is a positive integer.

`[G,phi,spectrum] = spa(data)` estimates `phi`, which is the output disturbance $\Phi_v(\omega)$ and its uncertainty, and `spetrum`, which is the spectrum matrix for both the output and the input channels. For example, if `z = [data.OutputData, data.InputData]`, `spe` contains the power spectrum estimate of `z`. `G`, `phi`, and `spectrum` are `idfrd` objects.

Definitions

Frequency Response Function

Frequency response function describes the steady-state response of a system to sinusoidal inputs. For a linear system, a sinusoidal input of a specific frequency results in an output that is also a sinusoid with the same frequency, but with a different amplitude and phase. The frequency response function describes the amplitude change and phase shift as a function of frequency.

To better understand the frequency response function, consider the following description of a linear, dynamic system:

$$y(t) = G(q)u(t) + v(t)$$

where *u(t)* and *y(t)* are the input and output signals, respectively. *G(q)* is called the transfer function of the system—it captures the system dynamics that take the input to the output. The notation *G(q)u(t)* represents the following operation:

$$G(q)u(t) = \sum_{k=1}^{\infty} g(k)u(t-k)$$

q is the *shift operator*, defined by the following equation:

$$G(q) = \sum_{k=1}^{\infty} g(k)q^{-k} \qquad q^{-1}u(t) = u(t-1)$$

G(q) is the *frequency-response function*, which is evaluated on the unit circle, $G(q=e^{iw})$.

Together, $G(q=e^{iw})$ and the output noise spectrum $\hat{\Phi}_v(\omega)$ are the frequency-domain description of the system.

The frequency-response function estimated using the Blackman-Tukey approach is given by the following equation:

$$\hat{G}_N\left(e^{i\omega}\right) = \frac{\hat{\Phi}_{yu}(\omega)}{\hat{\Phi}_u(\omega)}$$

In this case, ^ represents approximate quantities. For a derivation of this equation, see the chapter on nonparametric time- and frequency-domain methods in *System Identification: Theory for the User*, Second Edition, by Lennart Ljung, Prentice Hall PTR, 1999.

Output Noise Spectrum

The output noise spectrum (spectrum of *v(t)*) is given by the following equation:

$$\hat{\Phi}_v(\omega) = \hat{\Phi}_y(\omega) - \frac{\left|\hat{\Phi}_{yu}(\omega)\right|^2}{\hat{\Phi}_u(\omega)}$$

This equation for the noise spectrum is derived by assuming the linear relationship $y(t) = G(q)u(t) + v(t)$, that *u(t)* is independent of *v(t)*, and the following relationships between the spectra:

$$\Phi_y(\omega) = \left|G\left(e^{i\omega}\right)\right|^2 \Phi_u(\omega) + \Phi_v(\omega)$$

$$\Phi_{yu}(\omega) = G\left(e^{i\omega}\right)\Phi_u(\omega)$$

where the noise spectrum is given by the following equation:

$$\Phi_v(\omega) \equiv \sum_{\tau=-\infty}^{\infty} R_v(\tau)e^{-iw\tau}$$

$\hat{\Phi}_{yu}(\omega)$ is the output-input cross-spectrum and $\hat{\Phi}_u(\omega)$ is the input spectrum.

Alternatively, the disturbance *v(t)* can be described as filtered white noise:

$$v(t) = H(q)e(t)$$

where *e(t)* is the white noise with variance λ and the noise power spectrum is given by the following equation:

$$\Phi_v(\omega) = \lambda\left|H\left(e^{i\omega}\right)\right|^2$$

Examples

Estimate frequency response with fixed resolution at 128 equally spaced, logarithmic frequency values between 0 (excluded) and π:

```
g = spa(z); % z is an iddata object with Ts=1
bode(g)
```

Estimate frequency response with fixed resolution at logarithmically spaced frequencies:

```
% Define frequency vector
w = logspace(-2,pi,128);
% Compute frequency response
g= spa(z,[],w); % [] specifies the default lag window size
bode(g,'sd',3) % Bode plot of the transfer function
bode(g('noise'),'sd',3) % Noise spectrum
% Bode plots include confidence interval
% of 3 standard deviations
```

Algorithm

`spa` applies the Blackman-Tukey spectral analysis method by following these steps:

1 Computes the covariances and cross-covariance from $u(t)$ and $y(t)$:

$$\hat{R}_y(\tau) = \frac{1}{N}\sum_{t=1}^{N} y(t+\tau)y(t)$$

$$\hat{R}_u(\tau) = \frac{1}{N}\sum_{t=1}^{N} u(t+\tau)u(t)$$

$$\hat{R}_{yu}(\tau) = \frac{1}{N}\sum_{t=1}^{N} y(t+\tau)u(t)$$

This portion of the algorithm uses the `covf` function.

2 Computes the Fourier transforms of the covariances and the cross-covariance:

$$\hat{\Phi}_y(\omega) = \sum_{\tau=-M}^{M} \hat{R}_y(\tau) W_M(\tau) e^{-i\omega\tau}$$

$$\hat{\Phi}_u(\omega) = \sum_{\tau=-M}^{M} \hat{R}_u(\tau) W_M(\tau) e^{-i\omega\tau}$$

$$\hat{\Phi}_{yu}(\omega) = \sum_{\tau=-M}^{M} \hat{R}_{yu}(\tau) W_M(\tau) e^{-i\omega\tau}$$

where $W_M(\tau)$ is the Hann window with a width (lag size) of M. You can specify `M` to control the frequency resolution of the estimate, which is approximately equal 2π/`M` rad/sampling interval.

By default, this operation uses 128 equally spaced frequency values between 0 (excluded) and π, where `w = [1:128]/128*pi/Ts` and `Ts` is the sampling interval of that data set. The default lag size of the Hann window is `M = min(length(data)/10,30)`. For default frequencies, uses fast Fourier transforms (FFT)—which is more efficient than for user-defined frequencies.

Note `M` =γ is in Table 6.1 of Ljung (1999). Standard deviations are on pages 184 and 188 in Ljung (1999).

---

3 Compute the frequency-response function $\hat{G}_N\left(e^{i\omega}\right)$ and the output noise spectrum $\hat{\Phi}_v(\omega)$.

$$\hat{G}_N\left(e^{i\omega}\right) = \frac{\hat{\Phi}_{yu}(\omega)}{\hat{\Phi}_u(\omega)}$$

$$\Phi_v(\omega) \equiv \sum_{\tau=-\infty}^{\infty} R_v(\tau) e^{-iw\tau}$$

`spectrum` is the spectrum matrix for both the output and the input channels. That is, if `z = [data.OutputData, data.InputData]`, `spectrum` contains as spectrum data the matrix-valued power spectrum of `z`.

$$S = \sum_{m=-M}^{M} Ez(t+m)z(t)' W_M(T_s)\exp(-i\omega m)$$

`'` is a complex-conjugate transpose.

How To

- "Identifying Frequency-Response Models"
- "Spectrum Normalization"

Purpose

Estimate frequency response and spectrum using spectral analysis with frequency-dependent resolution

Syntax

```
g = spafdr(data)
g = spafdr(data,Resol,w)
```

Description

`spafdr` estimates the `idfrd` object containing transfer function and the noise spectrum Φ_v of the general linear model

$$y(t) = G(q)u(t) + v(t)$$

where $\Phi_v(\omega)$ is the spectrum of $v(t)$.

`data` contains the output-input data as an `iddata` object. The data can be complex valued, and either time or frequency domain. It can also be an `idfrd` object containing frequency-response data.

`g` is returned as an `idfrd` object (see `idfrd`) with the estimate of $G\left(e^{i\omega}\right)$ at the frequencies ω specified by row vector `w`. `g` also includes information about the spectrum estimate of $\Phi_v(\omega)$ at the same frequencies. Both results are returned with estimated covariances, included in `g`. See `idfrd`. The normalization of the spectrum is the same as described under `spa`.

Frequencies

The frequency variable `w` is either specified as a row vector of frequencies, or as a cell array `{wmin,wmax}`. In the latter case the covered frequencies will be 50 logarithmically spaced points from `wmin` to `wmax`. You can change the number of points to `NP` by entering `{wmin,wmax,NP}`.

Omitting `w` or entering it as an empty matrix gives the default value, which is 100 logarithmically spaced frequencies between the smallest and largest frequency in data. For time-domain data, this means from `1/N*Ts` to `pi*Ts`, where `Ts` is the sampling interval of data and `N` is the number of data.

Resolution

The argument `Resol` defines the frequency resolution of the estimates. The resolution (measured in rad/s) is the size of the smallest detail in the frequency function and the spectrum that is resolved by the estimate. The resolution is a tradeoff between obtaining estimates with fine, reliable details, and suffering from spurious, random effects: The finer the resolution, the higher the variance in the estimate. `Resol` can be entered as a scalar (measured in rad/s), which defines the resolution over the whole frequency interval. It can also be entered as a row vector of the same length as `w`. Then `Resol(k)` is the local, frequency-dependent resolution around frequency `w(k)`.

The default value of `Resol`, obtained by omitting it or entering it as the empty matrix, is `Resol(k) = 2(w(k+1)-w(k))`, adjusted upwards, so that a reasonable estimate is guaranteed. In all cases, the resolution is returned in the variable `g.EstimationInfo.WindowSize`.

Algorithm

If the data is given in the time domain, it is first converted to the frequency domain. Then averages of `Y(w)Conj(U(w))` and `U(w)Conj(U(w))` are formed over the frequency ranges `w`, corresponding to the desired resolution around the frequency in question. The ratio of these averages is then formed for the frequency-function estimate, and corresponding expressions define the noise spectrum estimate.

`spa`

Purpose

Convert linear models to Control System Toolbox LTI models

Syntax

```
sys = ss(mod)
sys = ss(mod,'m')
```

Description

`mod` is any `idmodel` object: `idgrey`, `idarx`, `idpoly`, `idproc`, `idss`, or `idmodel`.

`sys` is returned as an `ss` LTI model object. The noise input channels in `mod` are treated as follows: consider a model `mod` with both measured input channels u (nu channels) and noise channels e (ny channels) with covariance matrix Λ

$$y = Gu + HLv$$
$$\mathrm{cov}(v) = I$$

Both measured input channels u and normalized noise input channels v in `mod` are input channels in `sys`. The noise input channels belong to the `InputGroup 'Noise'`, while the others belong to the `InputGroup 'Measured'`. The names of the noise input channels are `v@yname`, where `yname` is the name of the corresponding output channel. This means that the LTI object realizes the transfer function [G HL].

To transform only the measured input channels in `sys`, use

```
sys = ss(mod('m')) or sys = ss(mod,'m')
```

This gives a representation of G only.

For a time series (no measured input channels, nu = `0`), the LTI representations in `ss` contains the transfer functions from the normalized noise sources v to the outputs, that is, HL. If the model `mod` has both measured and noise inputs, `sys = ss(mod('n'))` gives a representation of the additive noise.

In addition, the normal subreferencing can be used.

```
sys = ss(mod(1,[3 4]))
```

If you want to describe [G H] or H (unnormalized noise), from e to y, first use

```
mod = noisecnv(mod)
```

to convert the noise channels e to regular input channels. These channels are assigned the names `e@yname`.

Purpose

State-space matrices from parametric linear model

Syntax

```
[A,B,C,D,K,X0] = ssdata(m)
[A,B,C,D,K,X0,dA,dB,dC,dD,dK,dX0] = ssdata(m)
```

Description

`m` is the model given as any `idmodel` object. `A`, `B`, `C`, `D`, `K`, and `X0` are the matrices in the state-space description

$$\tilde{x}(t) = Ax(t) + Bu(t) + Ke(t)$$
$$x(0) = x0$$
$$y(t) = Cx(t) + Dx(t) + e(t)$$

where $\tilde{x}(t)$ is $\dot{x}(t)$ or $x(t+Ts)$ depending on whether `m` is a continuous-time or discrete-time model.

`dA`, `dB`, `dC`, `dD`, `dK`, and `dX0` are the standard deviations of the state-space matrices.

If the underlying model itself is a state-space model, the matrices correspond to the same basis. If the underlying model is an input-output model, an observer canonical form representation is obtained.

For a time-series model (no measured input channels, u = `[]`), B and D are returned as the empty matrices.

Subreferencing models in the usual way (see `idmodel` properties) will give the state-space representation of the chosen channels. Notice in particular that

```
[A,B,C,D] = ssdata(m('m'))
```

gives the response from the measured inputs. This is a model without a disturbance description. Moreover,

```
[A,B,C,D,K] = ssdata(m('n'))
```

('n' as in “noise”) gives the disturbance description, that is, a time-series description of the additive noise with no measured inputs, so that `B = []` and `D = []`.

To obtain state-space descriptions that treat all input channels, both u and e, as measured inputs, first apply the conversion

```
m = noisecnv(m)
```

or

```
m = noisecnv(m,'norm')
```

where the latter case first normalizes e to v, where v has a unit covariance matrix. See the reference page for `noisecnv`.

Algorithm

The computation of the standard deviations in the input-output case assumes that an A polynomial is not used together with an F or D polynomial in the general polynomial equation (see “What Are Black-Box Polynomial Models?” in the User’s Guide. For the computation of standard deviations in the case that the state-space parameters are complicated functions of the parameters, the Gauss approximation formula is used together with numerical derivatives. The step sizes for this differentiation are determined by `nuderst`.

`nuderst`

Purpose

Plot step response with confidence interval

Syntax

```
step(m)
step(data)
step(m,'sd',sd,Time)
step(data,'sd',sd,'PW',na,Time)
step(m1,m2,...,dat1, ...,mN,Time,'sd',sd)
step(m1,'PlotStyle1',m2,'PlotStyle2',...,dat1,'PlotStylek',...,mN,
'PlotStyleN',Time,'sd',sd)
[y,t,ysd] = step(m)
mod = step(data)
```

Description

`step` can be applied both to any `idmodel` or `idnlmodel` object and to `iddata` sets.

For a discrete-time `idmodel` `m`, the step response `y` and, when required, its estimated standard deviation `ysd`, are computed using `sim`. When called with output arguments, `y`, `ysd`, and the time vector `t` are returned. When `step` is called without output arguments, a plot of the step response is shown. If `sd` is given a value larger than zero, a confidence region around the response is drawn. It corresponds to the confidence of `sd` standard deviations. If the input argument list contains `'fill'`, this region is plotted as a filled area.

Setting the Time Interval

The start time `T1` and the end time `T2` can be specified by `Time = [T1 T2]`. If `T1` is not given, it is set to `-T2/4`. The negative time lags (the step is always assumed to occur at time `0`) show possible feedback effects in the data when the step is estimated directly from data. If `Time` is not specified, a default value is used.

Estimating the Step Response from the Data

For an `iddata` set data, `step(data)` estimates a high-order, noncausal FIR model after first having prefiltered the data so that the input is "as white as possible." The step response of this FIR model and, when asked for, its confidence region, are then plotted. Note that it might not be possible always to deliver the demanded time interval in

this case, because of lack of excitation in the data. A warning is then issued. When called with an output argument, `step`, in the `iddata` case, returns this FIR model, stored as an `idarx` model. The order of the prewhitening filter can be specified as `na`. The default value is `na = 10`.

Several Models/Data Sets

Any number and any mixture of models and data sets can be used as input arguments. The responses are plotted with each input/output channel (as defined by the models and data sets `InputName` and `OutputName`) as a separate plot. Colors, line styles, and marks can be defined by `PlotStyle` values, as in

```
step(m1,'b-*',m2,'y--',m3,'g')
```

Noise Channels

he noise input channels in `m` are treated as follows: Consider a model `m` with both measured input channels u (nu channels) and noise channels e (ny channels) with covariance matrix Λ

$$y = Gu + He$$
$$\text{cov}(e) = \Lambda = LL'$$

where L is a lower triangular matrix. Note that m.NoiseVariance $= \Lambda$. The model can also be described with a unit variance, using a normalized noise source v:

$$y = Gu + HLv$$
$$\text{cov}(v) = I$$

- `step(m)` plots the step response of the transfer function G.
- `step(m('n'))` plots the step response of the transfer function H (ny inputs and ny outputs). The input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- If `m` is a time series, that is, nu `= 0`, `step(m)` plots the step response of the transfer function H.

- `step(noisecnv(m))` plots the step response of the transfer function [*G H*] (*nu*+*ny* inputs and *ny* outputs). The noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- `step(noisecnv(m,'norm'))` plots the step response of the transfer function [*G HL*] (*nu*+*ny* inputs and *ny* outputs). The noise input channels have names `v@yname`, where `yname` is the name of the corresponding output.

Arguments

If `step` is called with a single `idmodel` `m`, the output argument `y` is a 3-D array of dimension `Nt`-by-`ny`-by-`nu`. Here `Nt` is the length of the time vector `t`, `ny` is the number of output channels, and `nu` is the number of input channels. Thus `y(:,ky,ku)` is the response in the `ky`th output channel to a step in the `ku`th input channel. No plot is produced when output arguments are used.

`ysd` has the same dimensions as y and contains the standard deviations of `y`. This is normally computed using `sim`. However, when the model `m` contains an estimated delay (dead time) as in certain process models, the standard deviation is estimated with Monte Carlo techniques, using `simsd`.

If `step` is called with an output argument and a single data set in the input arguments, the output is returned as an `idarx` model `mod` containing the high-order FIR model, and its uncertainty. By calling `step` with `mod`, the responses can be displayed and returned without your having to redo the estimation.

Examples

```
% Estimate and plot the step response
step(data,'sd',3)
mod = step(data)
step(mod,'sd',3)
```

`impulse`

Purpose

Generate model-order combinations for single-output ARX model estimation

Syntax

```
nn = struc(na,nb,nk)
nn = struc(na,nb_1,...,nb_nu,nk_1,...,nk_nu)
```

Description

`nn = struc(na,nb,nk)` generates model-order combinations for single-input ARX model estimation. *na* and *nb* are row vectors that specify range of model orders. *nk* is a row vector that specifies range of model delays. *nn* is a matrix that contains all combinations of the orders and delays.

`nn = struc(na,nb_1,...,nb_nu,nk_1,...,nk_nu)` generates model-order combinations for ARX model with *nu* input channels.

Usage

- Use with `arxstruc` or `ivstruc` to compute loss functions for ARX models, one for each model order combination returned by `struc`.

Examples

Generate model-order combinations for single-input ARX model estimation:

```
% na and nb vary between 1 and 2, nk varies between 4 and 5.
NN = struc(1:2,1:2,4:5);
```

Generate model-order combinations, and estimate multi-input ARX model:

```
% Create estimation and validation data sets.
load co2data;
Ts = 0.5; % Sampling interval is 0.5 min
ze = iddata(Output_exp1,Input_exp1,Ts);
zv = iddata(Output_exp2,Input_exp2,Ts);

% Generate model-order combinations for na=2:4,
% nb=2:5 for the first input and 1 or 4 for the second input,
% nk=1:4 for the first input and 0 for the second input.
```

```
NN = struc(2:4, 2:5, [1 4], 1:4, 0);

% Estimate an ARX model for each model order.
V = arxstruc(ze, zv, NN);

% Select a model order.
order=selstruc(V,0);

% Estimate an ARX model of selected order.
M=arx(ze,order);
```

How To

- “Preliminary Step – Estimating Model Orders and Input Delays”

Purpose

Convert linear models to transfer-function Control System Toolbox LTI models

Syntax

```
sys = tf(mod)
sys = tf(mod,'m')
```

Description

`mod` is any `idmodel` object: `idgrey`, `idarx`, `idpoly`, `idproc`, `idss`, or `idmodel`.

`sys` is returned as a transfer function `tf` LTI model object. The noise input channels in `mod` are treated as follows:

Consider a model `mod` with both measured input channels u (nu channels) and noise channels e (ny channels) with covariance matrix Λ

$$y = Gu + He$$
$$\mathrm{cov}(e) = \Lambda = LL'$$

where L is a lower triangular matrix mod.NoiseVariance = Λ. The model can also be described with a unit variance, using a normalized noise source v.

$$y = Gu + HLv$$
$$\mathrm{cov}(v) = I$$

Both measured input channels u and normalized noise input channels v in `mod` are input channels in `sys`. The noise input channels belong to the `InputGroup 'Noise'`, while the others belong to the `InputGroup 'Measured'`. The names of the noise input channels will be `v@yname`, where `yname` is the name of the corresponding output channel. This means that the LTI object realizes the transfer function [G HL].

To transform only the measured input channels in `mod`, use

```
sys = tf(mod('m')) or sys = tf(mod,'m')
```

This gives a representation of G only.

For a time series, (no measured input channels, *nu* = `0`), the LTI representation contains the transfer functions from the normalized noise sources v to the outputs, that is, HL. If the model `mod` has both measured and noise inputs, `sys = tf(mod('n'))` gives a representation of the additive noise.

In addition, you can use normal subreferencing.

```
sys = tf(mod(1,[3 4]))
```

If you want to describe $[G\ H]$ or H (unnormalized noise), from e to y, first use

```
mod = noisecnv(mod)
```

to convert the noise channels e to regular input channels. These channels are assigned the names `e@yname`.

Purpose

Numerator and denominator of transfer function from linear model

Syntax

```
[num,den] = tfdata(m)
[num,den,sdnum,sdden] = tfdata(m)
[num,den,sdnum,sdden] = tfdata(m,'v')
```

Description

`m` is a model given as any `idmodel` object with `ny` output channels and `nu` input channels.

`num` is a cell array of dimension `ny`-by-`nu`. `num{ky,ku}` (note the curly braces) contains the numerator of the transfer function from input `ku` to output `ky`. This numerator is a row vector whose interpretation is described below.

Similarly, `den` is an `ny`-by-`nu` cell array of the denominators.

`sdnum` and `sdden` have the same formats as `num` and `den`. They contain the standard deviations of the numerator and denominator coefficients.

If `m` is a SISO model, adding an extra input argument `'v'` (for vector) will return `num` and `den` as vectors rather than cell arrays.

The formats of `num` and `den` are the same as those used by the Signal Processing Toolbox and Control System Toolbox products, both for continuous-time and discrete-time models.

The noise input channels in `m` are treated as follows: Consider a model `m` with both measured input channels u (nu channels) and noise channels e (ny channels) with covariance matrix Λ

$$y = Gu + He$$
$$\text{cov}(e) = \Lambda = LL'$$

where L is a lower triangular matrix. Note that m.NoiseVariance $= \Lambda$. The model can also be described with a unit variance, using a normalized noise source v:

$$y = Gu + HLv$$
$$\text{cov}(v) = I$$

- `tfdata(m)` returns the transfer function *G*.
- `tfdata(m('n'))` returns the transfer function *H* (*ny* inputs and *ny* outputs).
- If `m` is a time series, that is, *nu* `= 0`, `tfdata(m)` returns the transfer function *H*.
- `tfdata(noisecnv(m))` returns the transfer function [*G H*] (*nu*+*ny* inputs and *ny* outputs).
- `tfdata(noisecnv(m,'norm'))` returns the transfer function [*G HL*] (*nu*+*ny* inputs and *ny* outputs).

Examples

For a continuous-time model,

```
num = [1 2]
den = [1 3 0]
```

corresponds to the transfer function

$$G(s) = \frac{s+2}{s^2+3s}$$

For a discrete-time model,

```
num = [2 4 0]
den = [1 2 3 5]
```

corresponds to the transfer function

$$H(z) = \frac{2z^2+4z}{z^3+2z^2+3z+5}$$

which is the same as

$$H(q) = \frac{2q^{-1}+4q^{-2}}{1+2q^{-1}+3q^{-2}+5q^{-3}}$$

Note that for discrete-time models, `idpoly` and `polydata` have a different interpretation of the numerator vector, in case it does not have the same length as the denominator vector. To avoid confusion, fill out with zeros to make numerator and denominator vectors the same length. Do this with `tfdata`.

`idpoly`

`noisecnv`

Purpose

Return date and time when object was created or last modified

Syntax

```
timestamp(obj)
ts = timestamp(obj)
```

Description

`obj` is any `idmodel`, `iddata`, or `idfrd` object. `timestamp` returns or displays a string with information about when the object was created and last modified.

treepartition

Purpose

Class representing binary-tree nonlinearity estimator for nonlinear ARX models

Syntax

```
t=treepartition(Property1,Value1,...PropertyN,ValueN)
t=treepartition('NumberOfUnits',N)
```

Description

`treepartition` is an object that stores the binary-tree nonlinear estimator for estimating nonlinear ARX models.

You can use the constructor to create the nonlinearity object, as follows:

`t=treepartition(Property1,Value1,...PropertyN,ValueN)` creates a binary tree nonlinearity estimator object specified by properties in "treepartition Properties" on page 2-443. The tree has the number of leaves equal to `2^(J+1)-1`, where `J` is the number of nodes in the tree and set by the property `NumberOfUnits`. The default value of `NumberOfUnits` is computed automatically.

Note `NumberOfUnits` sets an upper limit on the actual number of tree nodes used by the estimator.

`t=treepartition('NumberOfUnits',N)` creates a binary tree nonlinearity estimator object with `N` terms in the binary tree expansion (the number of nodes in the tree). When you estimate a model containing `t`, the value of the `NumberOfUnits` property, `N`, in `t` is automatically changed to show the actual number of leaves used—which is the largest integer of the form `2^n-1` and less than or equal to `N`.

Use `evaluate(t,x)` to compute the value of the function defined by the `treepartition` object `t` at `x`. At this stage, an adaptive *pruning algorithm* is used to select an active partition `D_a(= D_a(x))` on the branch of tree partitions that contain `x`.

Remarks

Use `treepartition` to define a nonlinear function $y = F(x)$, where F is a piecewise-linear (affine) function of x, y is scalar, and x is a

1-*by*-`m` vector. F is a local linear mapping, where x-space partitioning is determined by a binary tree.

The binary-tree network function is based on the following function expansion:

$$F(x) = xL + [1, x]C_a + d$$

x belongs to the active partition D_a. D_k is a partition of x-space. L is 1-*by*-`m` vector.

C_k is a 1-*by*-`(m+1)` vector.

d is a scalar.

The active partition D_a is computed as an intersection of half-spaces by a binary tree, as follows:

1. Tree with `N` nodes and `J` levels is initialized.
2. Node at level `J` is a terminating leaf and a node at level `j<J` has two descendants at level `j+1`. The number of leaves in the tree is `N = 2^(J+1)-1`, which is determined by the `NumberOfUnits` property of the `treepartition` object.
3. Partition at node `r` is based on `[1,x]*B_r > 0` or <= 0 (move to left or right descendant), where `B_r` is chosen to improve the stability of least-square computation on the partitions at the descendant nodes.
4. Compute at each node `r` the coefficients `C_r` of best linear approximation of unknown regression function on `D_r` using penalized least-squares algorithm.

treepartition Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use `get` or dot notation to access the object property values. For example:

```
% List all property values
```

```
get(t)
% Get value of NumberOfUnits property
t.NumberOfUnits
```

You can also use the `set` function to set the value of particular properties. For example:

```
set(t, 'NumberOfUnits', 5)
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
`NumberOfUnits`	Integer specifies the number of nodes in the tree. Default=`'auto'` selects the number of nodes from the data using the pruning algorithm. When you estimate a model containing a `treepartition` nonlinearity, the value of `NumberOfUnits` is automatically changed to show the actual number of leaves used—which is the largest integer of the form `2^n-1` and less than or equal to `N` (the integer value of units you specify). For example: `treepartition('NumberOfUnits',5)`
`Parameters`	Structure containing the following fields: • `RegressorMean`: 1-by-`m` vector containing the means of `x` in estimation data, `r`. • `RegressorMinMax`: `m`-by-2 matrix containing the maximum and minimum estimation-data regressor values. • `OutputOffset`: scalar `d`. • `LinearCoef`: `m`-*by*-1 vector *L*. • `SampleLength`: Length of estimation data.

Property Name	Description
	• `NoiseVariance`: Estimated variance of the noise in estimation data. • `NonlinearParameters`: A structure containing the following tree parameters: - `TreeLevelPntr`: `N`-*by*-1 vector containing the levels `j` of each node. - `AncestorDescendantPntr`: `N`-*by*-3 matrix, such that the entry `(k,1)` is the ancestor of node `k`, and entries `(k,2)` and `(k,3)` are the left and right descendants, respectively. - `LocalizingVectors`: `N`-*by*-`(m+1)` matrix, such that the `r`th row is `B_r`. - `LocalParVector`: `N`-*by*-`(m+1)` matrix, such that the `k`th row is `C_k`. - `LocalCovMatrix`: `N`-*by*-`((m+1)m/2)` matrix such that the `k`th row is the covariance matrix of `C_k`. `C_k` is reshaped as a row vector.
`Options`	Structure containing the following fields that affect the initial model: • `FinestCell`: Integer or string specifying the minimum number of data points in the smallest partition. Default: `'auto'`, which computes the value from the data. • `Threshold`: Threshold parameter used by the adaptive pruning algorithm. Smaller threshold value corresponds to a shorter branch that is terminated by the active partition `D_a`. Higher threshold value results in a longer branch. Default: `1.0`. • `Stabilizer`: Penalty parameter of the penalized least-squares algorithm used to compute local parameter

Property Name	Description
	vectors C_k. Higher stabilizer value improves stability, but may deteriorate the accuracy of the least-square estimate. Default: 1e-6.

Algorithm

When the idnlarx property Focus is 'Prediction', treepartition uses a noniterative technique for estimating parameters. Iterative refinements are not possible for models containing this nonlinearity estimator.

You cannot use treepartition when Focus is 'Simulation' because this nonlinearity estimators is not differentiable. Minimization of simulation error requires differentiable nonlinear functions.

Examples

Use treepartition to specify the nonlinear estimator in nonlinear ARX models. For example:

```
m=nlarx(Data,Orders,treepartition('num',5));
```

The following commands provide an example of using advanced treepartition options:

```
% Define the treepartition object
t=treepartition('num',100);
% Set the Threshold, which is a field
% in the Options structure
t.Options.Threshold=2;
% Estimate the nonlinear ARX model
m=nlarx(Data,Orders,t);
```

Purpose

Offset and linear trend slope values for detrending data

Description

`TrendInfo` class represents offset and linear trend information of input and output data. Constructing the corresponding object lets you:

- Compute and store mean values or best-fit linear trends of input and output data signals.
- Define specific offsets and trends to be removed from input-output data.

By storing offset and trend information, you can apply it to multiple data sets.

After estimating a linear model from detrended data, you can simulate the model at original operation conditions by adding the saved trend to the simulated output using `retrend`.

Construction

For transient data, if you want to define a specific offset or trend to be removed from this data, create the `TrendInfo` object using `getTrend`. For example:

```
T=getTrend(data)
```

where data is the `iddata` object from which you will be removing the offset or linear trend, and `T` is the `TrendInfo` object. You must then assign specific offset and slope values as properties of this object before passing the object as an argument to `detrend`.

For steady-state data, if you want to detrend the data and store the trend information, use the `detrend` command with the output argument for storing trend information.

Properties

After creating the object, you can use `get` or dot notation to access the object property values.

Property Name	Default	Description
`DataName`	Empty string	Name of the `iddata` object from which trend information is derived (if any)
`InputOffset`	`zeros(1,nu)`, where `nu` is the number of inputs	• For transient data, the physical equilibrium offset you specify for each input signal. • For steady-state data, the mean of input values. Computed automatically when detrending the data. • If removing a linear trend from the input-output data, the value of the line at `t0`, where `t0` is the start time. For multiple experiment data, this is a cell array of size equal to the number of experiments in the data set.
`InputSlope`	`zeros(1,nu)`, where `nu` is the number of inputs	Slope of linear trend in input data, computed automatically when using the `detrend` command to remove the linear trend in the data. For multiple experiment data, this is a cell array of size equal to the number of experiments in the data set.

Property Name	Default	Description
OutputOffset	zeros(1,ny), where ny is the number of outputs	• For transient data, the physical equilibrium offset you specify for each output signal • For steady-state data, the mean of output values. Computed automatically when detrending the data. • If removing a linear trend from the intput-output data, the value of the line at t0, where t0 is the start time. For multiple experiment data, this is a cell array of size equal to the number of experiments in the data set.
OutputSlope	zeros(1,ny), where ny is the number of outputs	Slope of linear trend in output data, computed automatically when using the detrend command to remove the linear trend in the data. For multiple experiment data, this is a cell array of size equal to the number of experiments in the data set.

Examples

Construct the object that stores trend information as part of data detrending:

```
% Load SISO data containing vectors u2 and y2
load dryer2
% Create data object with sampling time of 0.08 sec
data=iddata(y2,u2,0.08)
% Plot data on a time plot - it has a nonzero mean
plot(data)
% Detrend the mean from the data
% Store the mean as TrendInfo object T
[data_d,T] = detrend(data,0)
% View mean value removed from the data
```

```
get(T)
```

Construct the object that stores input and output offsets to be removed from transient data:

```
% Load SISO data containing vectors u2 and y2
load dryer2
% Create data object with sampling time of 0.08 sec
data=iddata(y2,u2,0.08)
% Plot data on a time plot - it has a nonzero mean
plot(data)
% Create a TrendInfo object for storing offsets and trends
T = getTrend(data)
% Assign offset values to the TrendInfo object
T.InputOffset=5;
T.OutputOffset=5;
% Subtract specific offset from the data
data_d = detrend(data,T)
% View mean value removed from the data
get(T)
```

`retrend`

"Handling Offsets and Trends in Data"

Purpose

Specify absence of nonlinearities for specific input or output channels in Hammerstein-Wiener models

Syntax

```
unit=unitgain
```

Description

`unit=unitgain` instantiates an object that specifies an identity mapping *F(x)=x* to exclude specific input and output channels from being affected by a nonlinearity in Hammerstein-Wiener models.

Use the `unitgain` object as an argument in the `nlhw` estimator to set the corresponding channel nonlinearity to unit gain.

For example, for a two-input and one-output model, to exclude the second input from being affected by a nonlinearity, use the following syntax:

```
m = nlhw(data,orders,['saturation''unitgain'],'deadzone')
```

In this case, the first input saturates and the output has an associated `deadzone` nonlinearity.

Remarks

Use the `unitgain` object to exclude specific input and output channels from being affected by a nonlinearity in Hammerstein-Wiener models.

`unitgain` is a linear function $y = F(x)$, where *F(x)=x*.

unitgain Properties

`unitgain` does not have properties.

Examples

For example, for a one-input and one-output model, to exclude the output from being affected by a nonlinearity, use the following syntax:

```
m = nlhw(Data,Orders,'saturation','unitgain')
```

In this case, the input has a saturation nonlinearity.

If nonlinearities are absent in input or output channels, you can replace `unitgain` with an empty matrix. For example, to specify a Wiener

model with a sigmoid nonlinearity at the output and a unit gain at the input, use the following command:

```
m = nlhw(Data,Orders,[],'sigmoid');
```

See Also

`deadzone`

`nlhw`

`saturation`

`sigmoidnet`

Purpose

Plot model characteristics using Control System Toolbox LTI Viewer GUI

Syntax

```
view(m)
view(m('n'))
view(m1,...,mN,Plottype)
view(m1,PlotStyle1,...,mN,PlotStyleN)
```

Description

`m` is the output-input data to be graphed, given as any `idfrd` or `idmodel` object. After appropriate model transformations, the Control System Toolbox LTI Viewer opens. This allows `bode`, `nyquist`, `impulse`, `step`, and `zero/poles` plots.

To compare several models `m1,...,mN`, use `view(m1,...,mN)`. With `PlotStyle`, the color, line style, and marker of each model can be specified.

```
view(m1,'y:*',m2,'b')
```

Adding `Plottype` as a last argument specifies the type of plot in which `view` is initialized. `Plottype` is any of `'impulse'`,`'step'`,`'bode'`,`'nyquist'`,`'nichols'`,`'sigma'`, or `'pzmap'`. It can also be given as a cell array containing any collection of these strings (up to 6) in which case a multiplot is shown.

`view` does not display confidence regions. For that, use `bode`, `nyquist`, `impulse`, `step`, and `pzmap`.

The noise input channels in `m` are treated as follows: Consider a model `m` with both measured input channels u (nu channels) and noise channels e (ny channels) with covariance matrix Λ

$$y = Gu + He$$
$$\mathrm{cov}(e) = \Lambda = LL'$$

where L is a lower triangular matrix. Note that m.NoiseVariance $= \Lambda$. The model can also be described with a unit variance, using a normalized noise source v:

$$y = Gu + HLv$$
$$\text{cov}(v) = I$$

- `view(m)` plots the characteristics of the transfer function G.
- `view(m('n'))` plots the characteristics of the transfer function HL (ny inputs and ny outputs). The input channels have names `v@yname`, where `yname` is the name of the corresponding output.
- If `m` is a time series, that is, nu `= 0`, `view(m)` plots the characteristics of the transfer function HL.
- `view(noisecnv(m))` plots the characteristics of the transfer function $[G\ H]$ ($nu+ny$ inputs and ny outputs). The noise input channels have names `e@yname`, where `yname` is the name of the corresponding output.
- `view(noisecnv(m,'norm'))` plots the characteristics of the transfer function $[G\ HL]$ ($nu+ny$ inputs and ny outputs). The noise input channels have names `v@yname`, where `yname` is the name of the corresponding output.

`view` does not give access to all of the features of `ltiview`. Use

```
ml = ss(m), ltiview(Plottype,ml,...)
```

to reach these options.

Purpose

Class representing wavelet network nonlinearity estimator for nonlinear ARX and Hammerstein-Wiener models

Syntax

```
s=wavenet('NumberOfUnits',N)
s=wavenet(Property1,Value1,...PropertyN,ValueN)
```

Description

`wavenet` is an object that stores the wavelet network nonlinear estimator for estimating nonlinear ARX and Hammerstein-Wiener models.

You can use the constructor to create the nonlinearity object, as follows:

`s=wavenet('NumberOfUnits',N)` creates a wavelet nonlinearity estimator object with `N` terms in the wavelet expansion.

`s=wavenet(Property1,Value1,...PropertyN,ValueN)` creates a wavelet nonlinearity estimator object specified by properties in “wavenet Properties” on page 2-456.

Use `evaluate(s,x)` to compute the value of the function defined by the `wavenet` object `s` at `x`.

Remarks

Use `wavenet` to define a nonlinear function $y = F(x)$, where y is scalar and x is an `m`-dimensional row vector. The wavelet network function is based on the following function expansion:

$$
\begin{aligned}
F(x) = (x-r)PL + a_{s1} f\left(\left(b_{s1}(x-r)\right)Q - c_{s1}\right) + \ldots \\
+ a_{sn} f\left(\left(b_{sn} s(x-r)\right)Q - c_{sn}\right) \\
+ a_{w1} g\left(\left(b_{w1}(x-r)\right)Q - c_{w1}\right) + \ldots \\
+ a_{wn} w g\left(\left(b_{wn} w(x-r)\right)Q - c_{wn}\right) + d
\end{aligned}
$$

where f is a scaling function and g is the wavelet function. P and Q are `m`-*by*-`p` and `m`-*by*-`q` projection matrices, respectively. The projection matrices P and Q are determined by principal component analysis of estimation data. Usually, `p=m`. If the components of x in the estimation data are linearly dependent, then `p<m`. The number of columns of Q, `q`,

corresponds to the number of components of x used in the scaling and wavelet function.

When used in a nonlinear ARX model, q is equal to the size of the NonlinearRegressors property of the idnlarx object. When used in a Hammerstein-Wiener model, m=q=1 and Q is a scalar.

r is a 1-*by*-m vector and represents the mean value of the regressor vector computed from estimation data.

d, a_s, b_s, a_w, and b_w are scalars. Parameters with the s subscript are scaling parameters, and parameters with the w subscript are wavelet parameters.

L is a p-*by*-1 vector.

c_s and c_w are 1-*by*-q vectors.

The scaling function f and the wavelet function g are both radial functions, as follows:

$$f(x) = e^{-0.5x'x}$$

$$g(x) = (\dim(x) - x'x)e^{-0.5x'x}$$

wavenet Properties

You can include property-value pairs in the constructor to specify the object.

After creating the object, you can use get or dot notation to access the object property values. For example:

```
% List all property values
get(w)
% Get value of NumberOfUnits property
w.NumberOfUnits
```

You can also use the set function to set the value of particular properties. For example:

```
h set(w, 'LinearTerm', 'on')
```

The first argument to `set` must be the name of a MATLAB variable.

Property Name	Description
`NumberOfUnits`	Integer specifies the number of nonlinearity units in the expansion. Default=`'auto'`. For example: `wavenet('NumberOfUnits',5)`
`LinearTerm`	Can have the following values: • `'on'` — (Default) Estimates the vector L in the expansion. • `'off'` — Fixes the vector L to zero and omits the term $(x-r)PL$. For example: `wavenet(H,'LinearTerm','on')`
`Parameters`	Structure containing the parameters in the nonlinear expansion, as follows: • `RegressorMean`: 1-*by*-`m` vector containing the means of `x` in estimation data, `r`. • `NonLinearSubspace`: `m`-*by*-`q` matrix containing Q. • `LinearSubspace`: `m`-*by*-`p` matrix containing P. • `LinearCoef`: `p`-*by*-1 vector L. • `ScalingDilation`: `ns`-*by*-1 matrix containing the values `bs_k`. • `WaveletDilation`: `nw`-*by*-1 matrix containing the values `bw_k`.

Property Name	Description
	• `ScalingTranslation`: `ns`-*by*-`q` matrix containing the values `cs_k`. • `WaveletTranslation`: `nw`-*by*-`q` matrix containing the values `cw_k`. • `ScalingCoef`: `ns`-*by*-1 vector containing the values `as_k`. • `WaveletCoef`: `nw`-*by*-1 vector containing the values `aw_k`. • `OutputOffset`: scalar `d`.
`Options`	Structure containing the following fields that affect the initial model: • `FinestCell`: Integer or string specifying the minimum number of data points in the smallest cell. A *cell* is the area covered by the significantly nonzero portion of a wavelet. Default: `'auto'`, which computes the value from the data. • `MinCells`: Integer specifying the minimum number of cells in the partition. Default: `16`. • `MaxCells`: Integer specifying the maximum number of cells in the partition. Default: `128`. • `MaxLevels`: Integer specifying the maximum number of wavelet levels. Default: `10`. • `DilationStep`: Real scalar specifying the dilation step size. Default: `2`. • `TranslationStep`: Real scalar specifying the translation step size. Default: `1`.

Algorithm

When the `idnlarx` property `Focus` is `'Prediction'`, `wavenet` uses a fast, noniterative technique for estimating parameters. Successive refinements after the first estimation use an iterative algorithm.

When the idnlarx property Focus='Simulation', wavenet uses an iterative technique for estimating parameters.

To always use noniterative or iterative algorithm, specify the IterWavenet algorithm property of the idnlarx class.

Examples

Use wavenet to specify the nonlinear estimator in nonlinear ARX and Hammerstein-Wiener models. For example:

```
m=nlarx(Data,Orders,wavenet);
```

See Also

nlarx

nlhw

Purpose Convert linear model to Control System Toolbox state-space LTI models

Syntax

```
sys = zpk(mod)
sys = zpk(mod,'m')
```

Description

`mod` is any `idmodel` object: `idgrey`, `idarx`, `idpoly`, `idproc`, `idss`, or `idmodel`.

`sys` is returned as a `zpk` LTI model object. The noise input channels in `mod` are treated as follows: consider a model `mod` with both measured input channels u (nu channels) and noise channels e (ny channels) with covariance matrix Λ

$$y = Gu + He$$
$$\mathrm{cov}(e) = \Lambda = LL'$$

where L is a lower triangular matrix. Note that mod.NoiseVariance $= \Lambda$. The model can also be described with a unit variance, using a normalized noise source v.

$$y = Gu + HLv$$
$$\mathrm{cov}(v) = I$$

Both measured input channels u and normalized noise input channels v in `mod` are input channels in `sys`. The noise input channels belong to the `InputGroup 'Noise'`, while the others belong to the `InputGroup 'Measured'`. The names of the noise input channels are given by `v@yname`, where `yname` is the name of the corresponding output channel. This means that the LTI object realizes the transfer function [G HL].

To transform only the measured input channels in `sys`, use

```
sys = zpk(mod('m')) or sys = zpk(mod,'m')
```

This gives a representation of G only.

For a time series, (no measured input channels, nu `= 0`), the LTI representation contains the transfer functions from the normalized

noise sources v to the outputs, that is, HL. If the model `mod` has both measured and noise inputs, `sys = zpk(mod('n'))` gives a representation of the additive noise.

In addition, the normal subreferencing can be used.

```
sys = zpk(mod(1,[3 4]))
```

If you want to describe $[GH]$ or H (unnormalized noise), from e to y, first use

```
mod = noisecnv(mod)
```

to convert the noise channels e to regular input channels. These channels are assigned the names `e@yname`.

zpkdata

Purpose

Zeros, poles, and gains of transfer function from linear model

Syntax

```
[z,p,k] = zpkdata(m)
[z,p,k,dz,dp,dk] = zpkdata(m)
[z,p,k,dz,dp,dk] = zpkdata(m,'v')
```

Description

`m` is a model given as any `idmodel` object with `ny` output channels and `nu` input channels.

`z` is a cell array of dimension `ny`-by-`nu`. `z{ky,ku}` (note the curly braces) contains the zeros of the transfer function from input `ku` to output `ky`. This is a column vector of possibly complex numbers.

Similarly, `p` is an `ny`-by-`nu` cell array containing the poles.

`k` is a `ny`-by-`nu` matrix whose `ky`-`ku` entry is the transfer function gain of the transfer function from input `ku` to output `ky`. Note that the transfer function gain is the value of the leading coefficient of the numerator when the leading coefficient of the denominator is normalized to 1. It thus differs from the static gain. The static gain can be retrieved as `Ks = freqresp(m,0)`.

`dz` contains the covariance matrices of the zeros in the following way: `dz` is a `ny`-by-`nu` cell array. `dz{ky,ku}` contains the covariance information about the zeros of the transfer function from `ku` to `ky`. It is a 3-D array of dimension 2-by-2-by-`Nz`, where `Nz` is the number of zeros. `dz{ky,ku}(:,:,kz)` is the covariance matrix of the zero `z{ky,ku}(kz)`, so that the 1-1 element is the variance of the real part, the 2-2 element is the variance of the imaginary part, and the 1-2 and 2-1 elements contain the covariance between the real and imaginary parts.

`dp` contains the covariance matrices of the poles in the same way.

`dk` is a matrix containing the variances of the elements of `k`.

If `m` is a SISO model, adding an extra input argument `'v'` (for vector) returns `z` and `p` as vectors rather than cell arrays.

Note that the zeros and the poles are associated with the different channel combinations. To obtain the so-called transmission zeros, use `tzero`.

The noise input channels in `m` are treated as follows: Consider a model `m` with both measured input channels u (nu channels) and noise channels e (ny channels) with covariance matrix Λ

$$y = Gu + He$$
$$\mathrm{cov}(e) = \Lambda = LL'$$

where L is a lower triangular matrix. Note that mod.NoiseVariance = Λ. The model can also be described with a unit variance, using a normalized noise source v.

$$y = Gu + HLv$$
$$\mathrm{cov}(v) = I$$

Then,

- `zpkdata(m)` returns the zeros and poles of G.
- `zpkdata(m('n'))` returns the zeros and poles of H (ny inputs and ny outputs).
- If `m` is a time series, that is, nu `= 0`, `zpkdata(m)` returns the zeros and poles of H.
- `zpkdata(noisecnv(m))` returns the zeros and poles of the transfer function [G H] (nu+ny inputs and ny outputs).
- `zpkdata(noisecnv(m,'norm'))` returns the zeros and poles of the transfer function [G HL] (nu+ny inputs and ny outputs).

The procedure handles both models in continuous and discrete time.

Note that you cannot rely on information about zeros and poles at the origin and at infinity for discrete-time models. (This is a somewhat confusing issue anyway.)

Algorithm

The poles and zeros are computed using `ss2zp`. The covariance information is computed using the Gauss approximation formula, using the parameter covariance matrix contained in `m`. When the transfer

function depends on the parameters, numerical differentiation is applied. The step sizes for the differentiation are determined in the `nuderst` command.

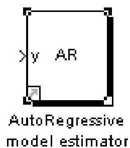
Purpose

Estimate parameters of AR model from scalar time series in Simulink software returning `idpoly` object

Library

System Identification Toolbox

Description



The AR Estimator block estimates the parameters of an AR model for a scalar time series and returns the model as an `idpoly` object. A time series is time-domain data consisting of one or more outputs *y(t)* and no corresponding measured input.

For information about the default algorithm settings used for model estimation, see the `Algorithm Properties` reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

Model Definition

The AR model is defined, as follows:

$$y(t) + a_1 y(t-1) + \cdots + a_{n_a} y(t-n_a) = e(t)$$

where

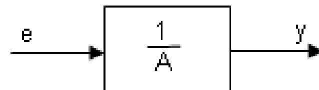
- $y(t)$ is the output at time t.
- $a_1 \cdots a_n$ are the parameters to be estimated from the data.
- n_a is the number of poles of the system.
- $y(t-1) \ldots y(t-n_a)$ are the previous outputs on which the current output depends.
- $e(t)$ is white-noise disturbance.

The AR model can be written compactly for a single output *y(t)* using the following notation:

$$A(q)y(t) = e(t)$$

where $A(q) = 1 + a_1 q^{-1} + \cdots + a_{n_a} q^{-n_a}$ and q^{-1} is the backward shift operator defined by $q^{-1}u(t) = u(t-1)$.

The following block diagram shows the AR model structure.



Input

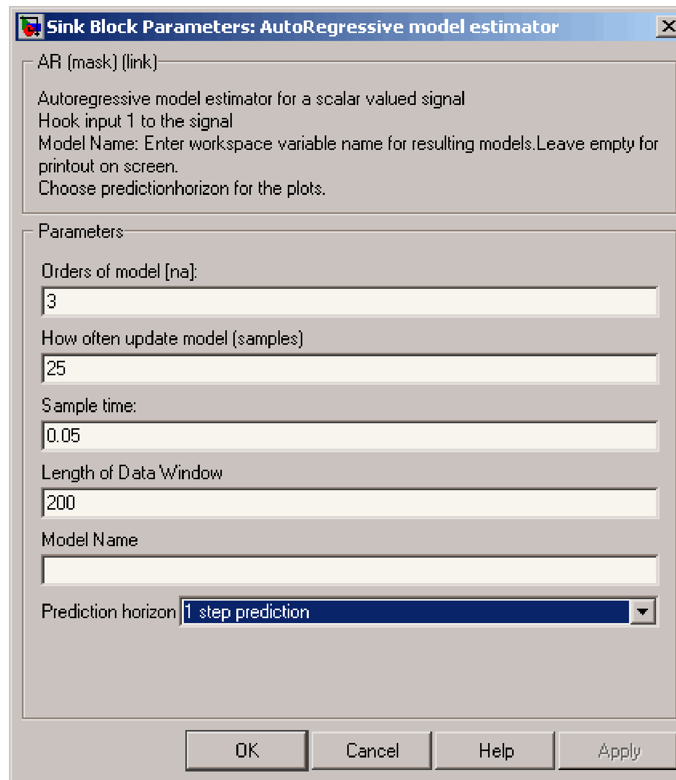
Time-series signal.

Output

The AR Estimator block outputs a sequence of multiple models (`idpoly` objects), estimated at regular intervals during the simulation. The **Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

Dialog Box



Orders of model [na]

Integer n_a corresponds to the number of a parameters (poles) in the AR model.

How often to update model (samples)

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

Sample time

Sampling time for the model.

> **Note** If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

Length of Data Window
Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

Model Name
Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

Prediction horizon
Specifies the forward-prediction horizon for computing the response `K` steps in the future, where `K` is 1, 5, or 10.

Examples

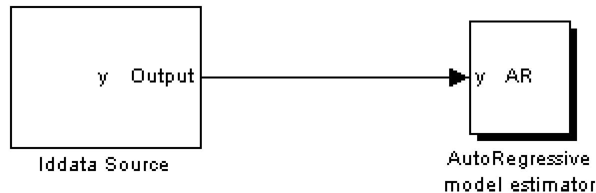
This example shows how you can use the AR Estimator block in a Simulink model.

1 Generate sample input and output data.

```
y = sin([1:300]') + 0.5*randn(300,1);
y = iddata(y);
```

2 Create a new Simulink model, as follows:

- Add the IDDATA Source block and specify y in the **Iddata object** field of the IDDATA Source block parameter dialog box.
- Add the AR Estimator block to the model and accept default block parameter values.
- Connect the Output port of the IDDATA Source block to the y port of the AR Estimator block.



3. Run the estimation.

   The estimated models appear in the MATLAB Command Window every 25 samples.

"Time Series Identification"

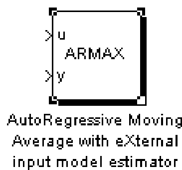
Purpose

Estimate parameters of ARMAX model from SISO data in Simulink software returning `idpoly` object

Library

System Identification Toolbox

Description



AutoRegressive Moving Average with eXternal input model estimator

The ARMAX Estimator block estimates the parameters of a single-input and single-output ARMAX model and returns the model as an `idpoly` object.

For information about the default algorithm settings used for model estimation, see the `Algorithm Properties` reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

Model Definition

The ARMAX model is defined, as follows:

$$y(t) + a_1 y(t-1) + \cdots + a_{n_a} y(t-n_a) =$$
$$b_1 u(t-1) + \cdots + b_{n_b} u(t-n_b) + e(t) + c_1 e(t-1) + \cdots + c_{n_c} e(t-n_c)$$

where

- $y(t)$ is the output at time t.
- $a_1 \cdots a_n$, $b_1 \cdots b_n$, and $c_1 \cdots c_n$ are the parameters to be estimated.
- n_a is the number of poles of the system.
- $n_b - 1$ is the number of zeros of the system.
- n_c is the number of previous error terms on which the current output depends.

- n_k is the number of input samples that occur before the inputs affecting the current output.
- $y(t-1)\ldots y(t-n_a)$ are the previous outputs on which the current output depends.
- $u(t-n_k)\ldots u(t-n_k-n_b+1)$ are the previous inputs on which the current output depends.
- $e(t), e(t-1), \cdots e(t-n_c)$ are the white-noise disturbance values on which the current output depends.

The ARMAX model can also be written in a compact way using the following notation:

$$A(q)y(t) = B(q)u(t) + C(q)e(t)$$

where

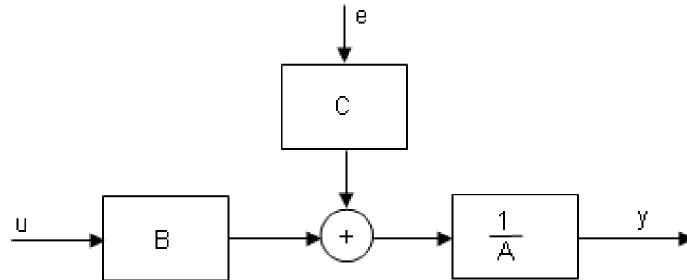
$$A(q) = 1 + a_1 q^{-1} + \cdots + a_{n_a} q^{-n_a}$$

$$B(q) = b_1 + b_2 q^{-1} + \cdots + b_{n_b} q^{-n_b+1}$$

$$C(q) = 1 + c_1 q^{-1} + \cdots a_{n_c} q^{-n_c}$$

and q^{-1} is the backward shift operator, defined by $q^{-1}u(t) = u(t-1)$.

The following block diagram shows the ARMAX model structure.



Input

The block accepts two inputs, corresponding to the measured input-output data for estimating the model.

First input: Input signal.

Second input: Output signal.

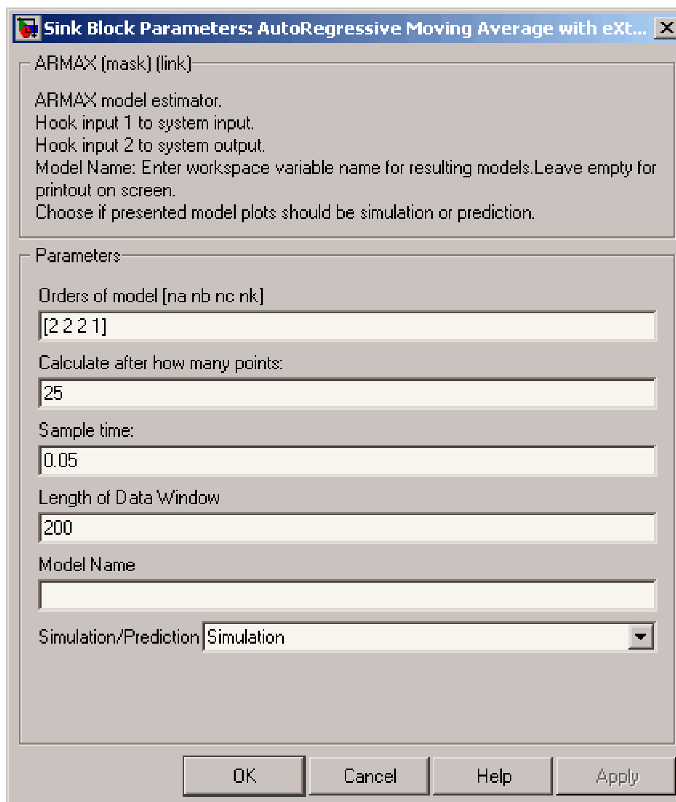
Output

The ARMAX Estimator block outputs a sequence of multiple models (`idpoly` objects), estimated at regular intervals during the simulation.

The **Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

Dialog Box



Orders of model [na nb nc nk]

Integers n_a, n_b, n_c, and n_k specify the number of A, B, and C model parameters and n_k is input-output delay, respectively.

Calculate after how many points

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

Sample time

Sampling time for the model.

Note If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

Length of Data Window

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

Model Name

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

Simulation/Prediction

`Simulation`: The algorithm uses only measured input data to simulate the response of the model.

`Prediction`: Specifies the forward-prediction horizon for computing the response `K` steps in the future, where `K` is 1, 5, or 10.

Examples

This example shows how you can use the ARMAX Estimator block in a Simulink model.

1 Generate sample input and output data.

```
u = sin([1:300]') + 0.6*(rand(300,1)-0.5);
```

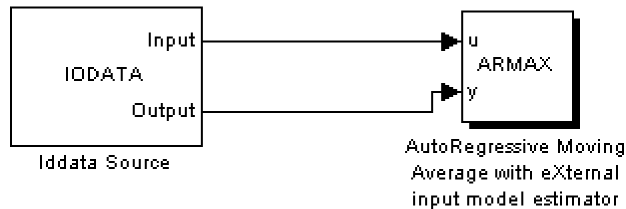
```
y = cos(u) + 0.1*rand(300,1);
IODATA = iddata(y,u,1);
```

2 Create a new Simulink model, as follows.

Add the IDDATA Source block and specify `IODATA` in the **Iddata object** field of the IDDATA Source block parameters dialog box.

Add the ARMAX Estimator block to the model and set the model orders to `[4 4 4 0]` and set the sample time to `1`.

Connect the Input and Output ports of the IDDATA Source block to the u and y ports of the ARMAX Estimator block, respectively. Set the simulation end time to `300` seconds.



3 Run the simulation.

The estimated models display in the MATLAB Command Window every 25 samples.

Topics in the System Identification Toolbox User's Guide

"Identifying Input-Output Polynomial Models"

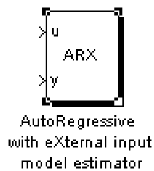
Purpose

Estimate parameters of ARX model from SISO data in Simulink software returning `idpoly` object

Library

System Identification Toolbox

Description



AutoRegressive with eXternal input model estimator

The ARX block uses least-squares analysis to estimate the parameters of an ARX model and returns the estimated model as an `idpoly` object.

For information about the default algorithm settings used for model estimation, see the `Algorithm Properties` reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

Model Definition

The ARX model is defined, as follows:

$$y(t)+a_1y(t-1)+\cdots+a_{n_a}y(t-n_a)=b_1u(t-1)+\cdots+b_{n_b}u(t-n_k-n_b+1)+e(t)$$

where

- $y(t)$ is the output at time t.
- $a_1 \cdots a_n$ and $b_1 \cdots b_n$ are the parameters to be estimated.
- n_a is the number of poles of the system.
- $n_b - 1$ is the number of zeros of the system.
- n_k is the number of input samples that occur before the inputs that affect the current output.
- $y(t-1)\ldots y(t-n_a)$ are the previous outputs on which the current output depends.

- $u(t-n_k)\ldots u(t-n_k-n_b+1)$ are the previous inputs on which the current output depends.
- *e(t)* is a white-noise disturbance value.

The ARX model can also be written in a compact way using the following notation:

$$A(q)y(t) = B(q)u(t-n_k) + e(t)$$

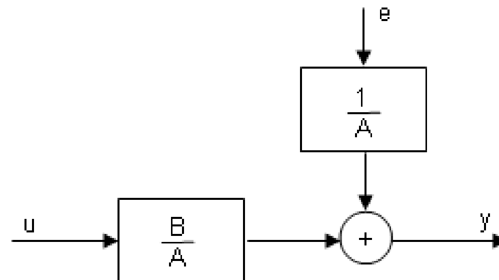
where

$$A(q) = 1 + a_1 q^{-1} + \cdots + a_{n_a} q^{-n_a}$$

$$B(q) = b_1 + b_2 q^{-1} + \cdots + b_{n_b} q^{-n_b+1}$$

and q^{-1} is the backward shift operator, defined by $q^{-1}u(t) = u(t-1)$.

The following block diagram shows the ARX model structure.



Input

The block accepts two inputs, corresponding to the measured input-output data for estimating the model.

First input: Input signal.

Second input: Output signal.

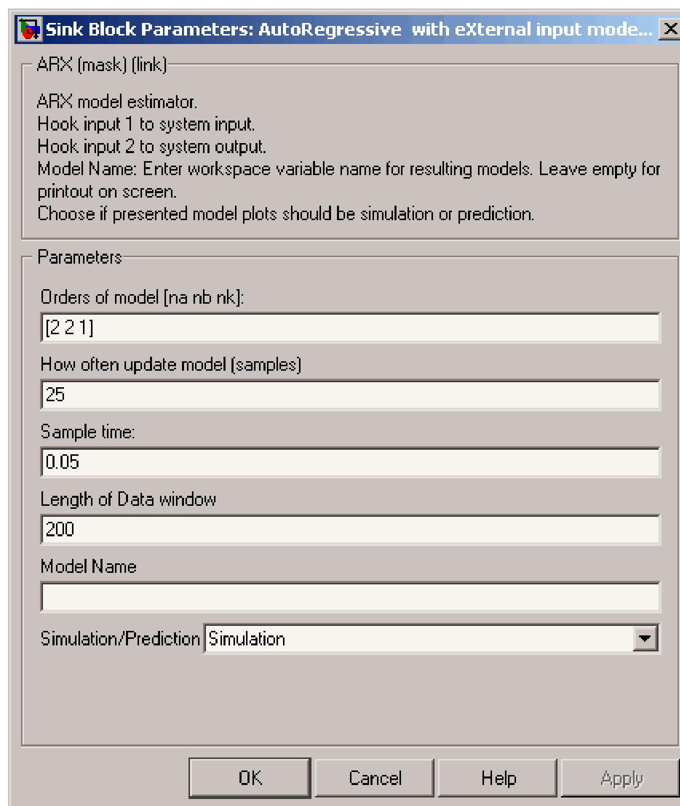
Output

The ARX Estimator block outputs a sequence of multiple models (`idpoly` objects), estimated at regular intervals during the simulation.

The **Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

Dialog Box



Orders of model [na nb nk]

Integers n_a, n_b, and n_k specify the number of A and B model parameters and n_k is input-output delay, respectively.

How often to update model [samples]

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

Sample time

Sampling time for the model.

Note If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

Length of Data window

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

Model Name

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

Simulation/Prediction

`Simulation`: The algorithm uses only measured input data to simulate the response of the model.

`Prediction`: Specifies the forward-prediction horizon for computing the response `K` steps in the future, where `K` is 1, 5, or 10.

Examples

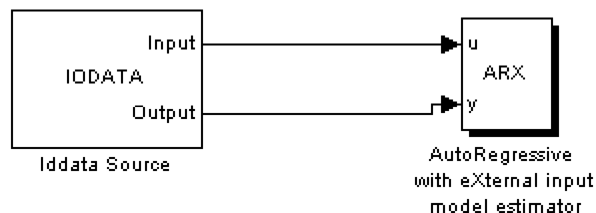
This example shows how you can use the ARX Estimator block in a Simulink model.

1 Specify the data from `iddata1.mat` for estimation:

```
load iddata1;
IODATA = z1;
```

2 Create a new Simulink model, as follows:

- Add the IDDATA Source block and specify `IODATA` in the **Iddata object** field of the IDDATA Source block parameters dialog box.
- Add the ARX Estimator block to the model. Set the sample time in the block to `0.1` seconds and the simulation end time to `30` seconds.
- Connect the Input and Output ports of the IDDATA Source block to the u and y ports of the ARX Estimator block, respectively.



3 Run the simulation.

"Identifying Input-Output Polynomial Models"

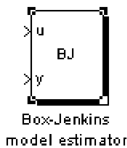
Purpose

Estimate parameters of Box-Jenkins model from SISO data in Simulink software returning `idpoly` object

Library

System Identification Toolbox

Description



The BJ Estimator block estimates the parameters of a Box-Jenkins model, and returns the estimated model as an `idpoly` object.

For information about the default algorithm settings used for model estimation, see the `Algorithm Properties` reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

Model Definition

The Box-Jenkins model is defined, as follows:

$$y(t) = \frac{B(q)}{F(q)}u(t-n_k) + \frac{C(q)}{D(q)}e(t)$$

where the coefficients of

$$B(q) = b_1 + b_2q^{-1} + \cdots + b_{n_b}q^{-n_b+1}$$

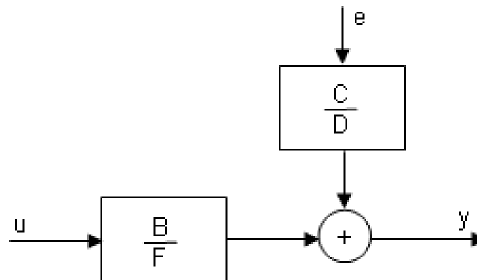
$$F(q) = 1 + f_1q^{-1} + \cdots + f_{n_f}q^{-n_f}$$

$$C(q) = 1 + c_1q^{-1} + \cdots + c_{n_c}q^{-n_c}$$

$$D(q) = 1 + d_1q^{-1} + \cdots + d_{n_d}q^{-n_d}$$

are the parameters being estimated, and q^{-1} is the backward shift operator defined by $q^{-1}u(t) = u(t-1)$.

The following block diagram shows the Box-Jenkins model structure.



Input

The block accepts two inputs, corresponding to the measured input-output data for estimating the model.

First input: Input signal.

Second input: Output signal.

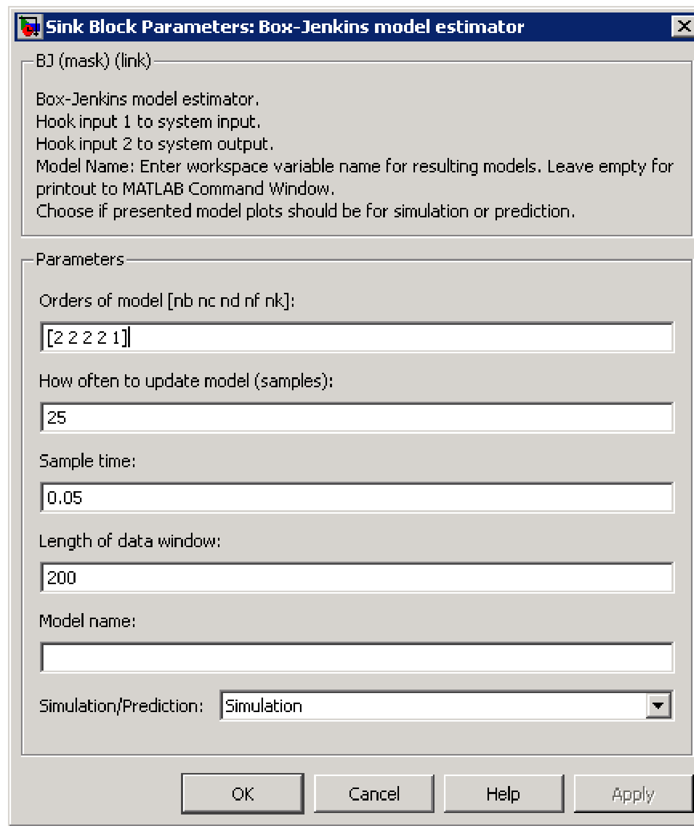
Output

The BJ Estimator block outputs a sequence of multiple models (`idpoly`), estimated at regular intervals during the simulation.

The **Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

Dialog Box



Orders of model [nb nc nd nf nk]

Integers n_b, n_c, n_d, and n_f specify the number of *B*, *C*, *D*, and *F* model parameters, respectively.

Integer n_k specifies the input-output delay.

Calculate after how many points

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

Sample time

Sampling time for the model.

Note If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

Length of data window

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

Model name

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

Simulation/Prediction

`Simulation`: The algorithm uses only measured input data to simulate the response of the model.

`Prediction`: Specifies the forward-prediction horizon for computing the response `K` steps in the future, where `K` is 1, 5, or 10.

Examples

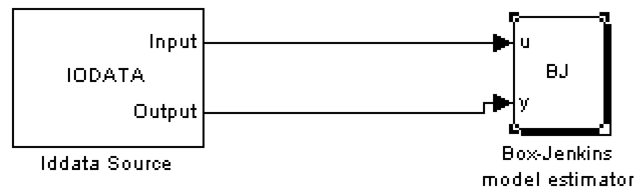
This example shows how you can use the BJ Estimator block in a Simulink model.

1 Specify the data in `iddata1.mat` for estimation:

```
load iddata1;
IODATA = z1;
```

2 Create a new Simulink model, as follows:

- Add the IDDATA Source block and specify `IODATA` in the **Iddata object** field of the IDDATA Source block parameters dialog box.
- Add the BJ Estimator block to the model. Set the sample time in the block to `0.1` seconds and the simulation end time to `30` seconds.
- Connect the Input and Output ports of the IDDATA Source block to the u and y ports of the BJ Estimator block, respectively.



3 Run the simulation.

The estimated models appear in the MATLAB Command Window every 25 samples.

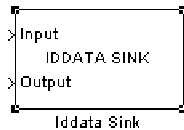
"Identifying Input-Output Polynomial Models"

Purpose Export `iddata` object to MATLAB workspace

Library System Identification Toolbox

Description The IDDATA Sink block exports an `iddata` object to the MATLAB workspace.



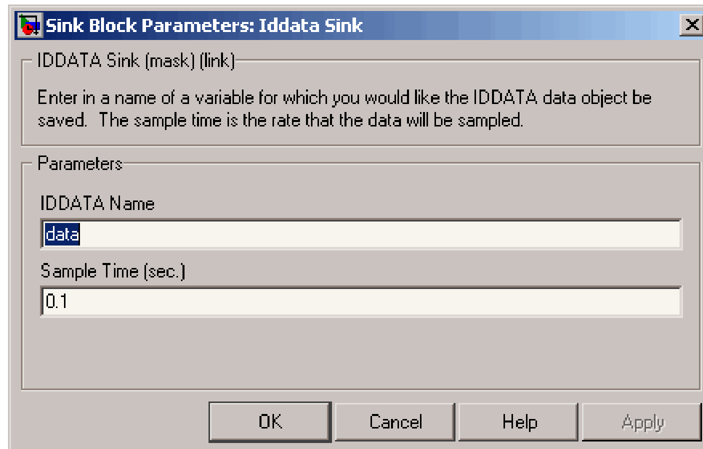
Input

The first block input is the input of specified `iddata` object in the MATLAB workspace. Similarly, the second block input is the output of the specified `iddata` object.

Output

None.

Dialog Box



IDDATA Name
Name of the `iddata` object in the MATLAB workspace.

Sample Time (sec.)
Time interval (in seconds) between successive data samples.

See Also IDDATA Source

Purpose

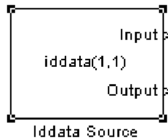
Import `iddata` object from MATLAB workspace

Library

System Identification Toolbox

Description

The IDDATA Source block imports an `iddata` object from the MATLAB workspace.



Input

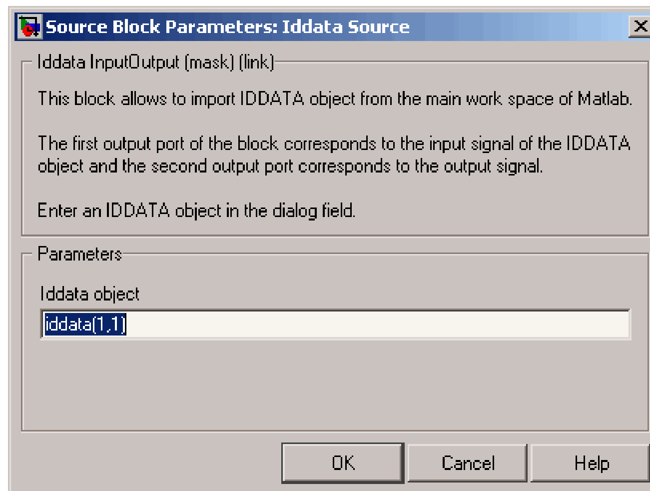
None.

Output

The first block output is the input signal of the `iddata` object imported from the MATLAB workspace.

The second block output is the output signal of this `iddata` object.

Dialog Box



Iddata object

Name of the `iddata` object imported from the MATLAB workspace.

The `iddata` object must contain only one experiment. For a multiple-experiment object, use `getexp(data,kexp)` to specify the experiment number `kexp`.

See Also

IDDATA Sink

Purpose

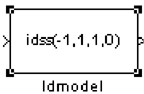
Simulate `idmodel` object in Simulink software

Library

System Identification Toolbox

Description

The IDMODEL block simulates a linear model in the MATLAB workspace.



Note For simulating nonlinear models, use the IDNLGREY, IDNLARX, or IDNLHW Model blocks.

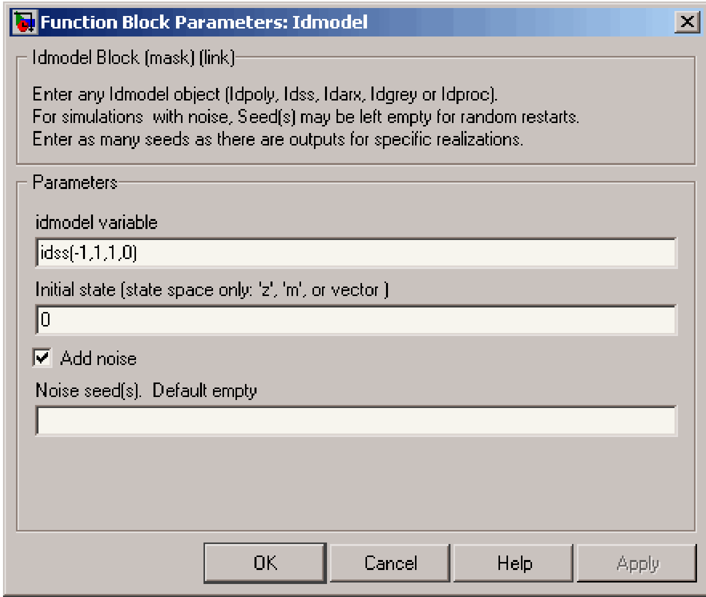
Input

Input signal to the model.

Output

Simulated output from the model.

Dialog Box



idmodel variable

Name of `idmodel` variable in the MATLAB workspace, which can be an `idpoly`, `idss`, `idgrey`, `idarx` or `idproc` model object that you estimated using System Identification Toolbox software.

This block supports both continuous-time and discrete-time models with or without input-output delays.

Initial state (state space only)

Initial state vector.

(Default) `'z'` (in quotation marks) specifies zero, which corresponds to a simulation starting from a state of rest.

Enter `'m'` to use the internal initial states of the model, stored by the `idss` or `idgrey` model property `X0`.

To specify your own initial states, enter one of the following:

- Enter known initial states for a state-space model directly, as a numerical vector.

Note For non-state-space models, the initial conditions are `0`.

- Compute the initial states using the `findstates(idmodel)` command to get the initial state values that produce the best fit between the model output and the measured output signal.

  For example, if the data set `z` and model `m` are already in the MATLAB workspace, you can enter `X0`, such that:

  ```
  X0 = findstates(m,z1)
  ```

Add noise

Select when you need to add noise, as specified by the model property `model.NoiseVariance` and the matrices or polynomials that determine the color of the additive noise.

For continuous-time models, the ideal variance of the noise term at any moment is infinite. In reality, you see a band-limited noise that takes into account the natural time constants of the system. You can interpret the resulting simulated output as filtered using a low-pass filter with a pass-band that does not distort the dynamics from the input.

Noise seed(s)

(Use when you select the **Add noise** check box.)

Enter an integer that specifies a seed that forces the simulation to add the same noise to the output every time you simulate the model. For more information about using seeds with functions that generate random number sequences, see the `rand` reference page in MATLAB documentation, for example.

`findstates(idmodel)`

`idmodel`

Purpose

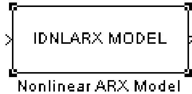
Simulate nonlinear ARX model in Simulink software

Library

System Identification Toolbox

Description

The IDNLARX Model block simulates a nonlinear ARX (`idnlarx`) model for time-domain input and output data.



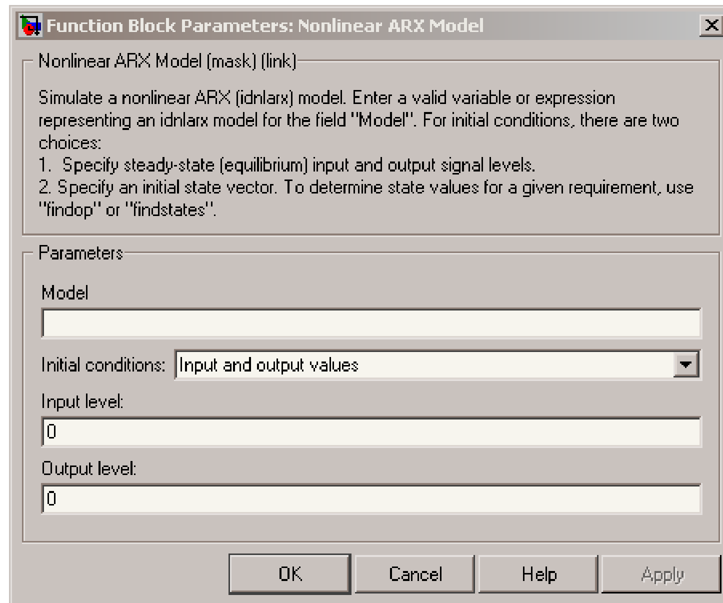
Input

Input signal to the model.

Output

Simulated output from the model.

Dialog Box



Model

Name of `idnlarx` variable in the MATLAB workspace.

Initial conditions

Specifies the initial states as one of the following:

- `Input and output values`: Specify the input and output levels, as follows:
  - **Input level**

    If known, enter a vector of length equal to the number of model inputs. If you enter a scalar, it is the signal value for all inputs.
  - **Output level**

    If known, enter a vector of length equal to the number of model's outputs. If you enter a scalar, it is the signal value for all outputs.
- `State values`: When selected, you must specify a vector of length equal to the number of states in the model in the **Vector of state values** field.

  If you do not know the initial states, you can estimate these states, as follows:
  - To simulate around a given input level when you do not know the corresponding output level, you can estimate the equilibrium state values using the `findop(idnlarx)` command.

    For example, to simulate a model `M` about a steady-state point where the input is `1` and the output is unknown, you can enter `X0`, such that:

    ```
    X0 = findop(M,'steady',1,NaN)
    ```
  - To estimate the initial states that provide a best fit between measured data and the simulated response of the model for the same input, use the `findstates(idnlarx)` command.

For example, to compute initial states such that the response of the model M matches the output data in the data set z, you can enter X0, such that:

```
X0 = findstates(M,z,[],'sim')
```

- To continue a simulation from a previous run, use the simulated input-output values from the previous simulation to compute the initial states X0 for the current simulation.

  For example, suppose that firstSimData is a variable that stores the input and output values from a previous simulation. For a model M, you can enter X0, such that:

```
X0 = data2state(M,firstSimData)
```

Examples

Example 1

In this example, you estimate a nonlinear ARX model from data and compare the model output of the model to the measured output of the system.

1. Load the sample data.

```
load twotankdata
```

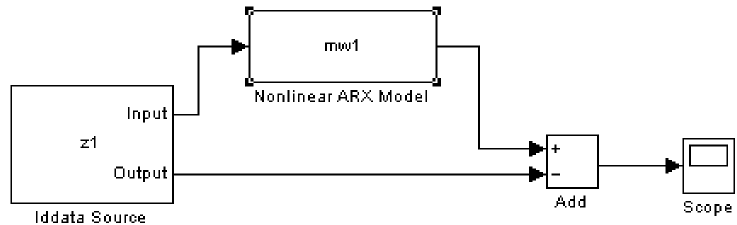
2. Create a data object from sample data.

```
z = iddata(y,u,0.2,'Name','Two tank system');
z1 = z(1:1000);
```

3. Estimate a nonlinear ARX model.

```
mw1 = nlarx(z1,[5 1 3],wavenet('NumberOfUnits',8));
```

4. Build the following Simulink model using the IDDATA Source, IDNLARX Model, and Scope blocks.



5 Double-click the IDDATA Source block and enter the following into the block parameter dialog box:

   IDDATA Object: `z1`

   Click **OK**.

6 Double-click the IDNLARX Model block and enter the following into the block parameter dialog box:

   - **Model**: `mw1`
   - **Initial conditions**: Select `Input and output values` and accept the default values.

7 Run the simulation.

   Click the Scope block to view the difference between the measured output and the model output. Use the **Autoscale** command to scale the axes.

Example 2

In this example, you reduce the difference between the measured and simulated responses. To achieve this, you use the `findstates` command to estimate an initial state vector for the model from the data.

1 Estimate initial states from the data `z1`.

```
x0 = findstates(mw1,z1,[],'simulation');
```

2. Set the **Initial Conditions** to `State Values`. Enter `x0` in the corresponding field.

3. Run the simulation.

"Estimating Nonlinear Grey-Box Models"

Purpose

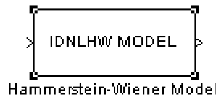
Simulate Hammerstein-Wiener model in Simulink software

Library

System Identification Toolbox

Description

The IDNLHW Model block simulates a Hammerstein-Wiener (`idnlhw`) model for time-domain input and output data.



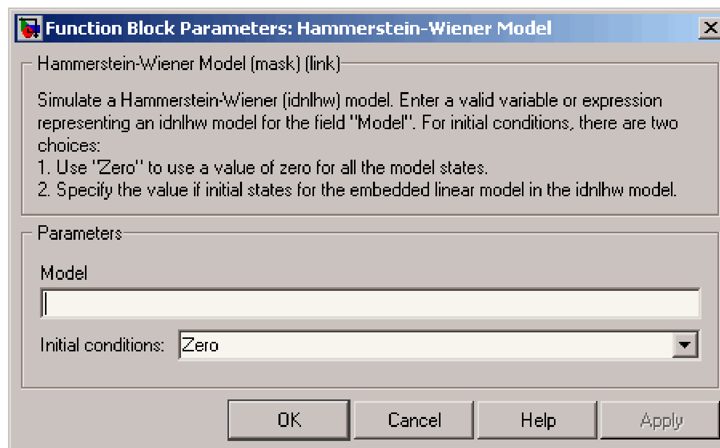
Input

Input signal to the model.

Output

Simulated output from the model.

Dialog Box



Model

Name of the `idnlhw` variable in the MATLAB workspace.

Initial conditions

Specifies the initial states as one of the following:

- `Zero`: Specifies zero, which corresponds to a simulation starting from a state of rest.
- `State values`: When selected, you must specify a vector of length equal to the number of states in the model in the **Specify a vector of state values** field.

  If you do not know the initial states, you can estimate these states, as follows:

  - To simulate around a given input level when you do not know the corresponding steady-state output level, you can estimate the equilibrium state values using the `findop(idnlhw)` command.

    For example, to simulate a model `M` about a steady-state point where the input is `1` and the output is unknown, you can enter `X0`, such that:

    ```
    X0 = findop(M,'steady',1,NaN)
    ```

  - To estimate the initial states such that the simulated response of the model matches specified output data for the same input, use the `findstates(idnlhw)`.

    For example, for the data set `z` and model `m`, you can enter `X0`, such that:

    ```
    X0 = findstates(m,z)
    ```

Examples

Example 1

In this example, you estimate a Hammerstein-Wiener model from data and compare the model output of the model to the measured output of the system.

1. Load the sample data.

   ```
   load twotankdata
   ```

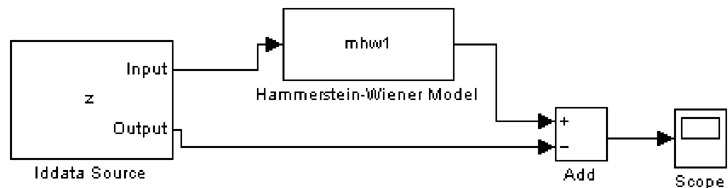
2. Create a data object from sample data.

```
z = iddata(y,u,0.2, ...
           'Name','Two tank system',...
           'Tstart',0);
```

3 Estimate a Hammerstein-Wiener model.

```
mhw1 = nlhw(z,[1 5 3],pwlinear,pwlinear);
```

4 Build the following Simulink model using the IDDATA Source, IDNLHW Model, and Scope blocks.



5 Double-click the IDDATA Source block and enter the following into the block parameter dialog box:

- **IDDATA Object**: z

Click **OK**.

6 Double-click the IDNLHW Model block and enter the following into the block parameter dialog box:

- **Model**: mhw1
- **Initial Conditions**: Zero

7 Run the simulation.

Click the Scope block to view the difference between the measured output and the model output. Use the **Autoscale** toolbar button to scale the axes.

Example 2

In this example, you reduce the difference between the measured and simulated responses using suitable initial state values. To achieve this, you use the `findstates` command to estimate an initial state vector for the model from the data.

1. Estimate initial states from the data `z`:

   ```
   x0 = findstates(mhw1,z,[],'maxiter',50);
   ```

2. Set the **Initial Conditions** to `State Values`. Enter `x0` in the corresponding field.

3. Run the simulation.

"Identifying Hammerstein-Wiener Models"

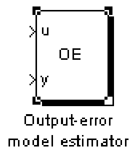
Purpose

Estimate parameters of Output-Error model from SISO data in Simulink software returning `idpoly` object

Library

System Identification Toolbox

Description



Output-error model estimator.

The OE block estimates the parameters of an Output-Error model, and returns the estimated model as an `idpoly` object.

For information about the default algorithm settings used for model estimation, see the `Algorithm Properties` reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

Model Definition

The output-error model is defined, as follows:

$$w(t) + f_1 w(t-1) + \cdots + f_{n_f} w(t-n_f) = b_1 u(t-1) + \cdots + b_{n_b} u(t-n_k-n_b+1)$$
$$y(t) = w(t) + e(t)$$

where

- w is the undisturbed output.
- $y(t)$ is the output at time t.
- $f_1 \cdots f_{n_f}$ and $b_1 \cdots b_{n_b}$ are the parameters to be estimated.
- n_f is the number of poles of the transfer function from the input to the undisturbed output.
- $n_b + 1$ is the number of zeros of the transfer function from the input to the undisturbed output.

- n_k is the number of input samples that occur before the inputs that affect the current output.
- $u(t-n_k)\ldots u(t-n_k-n_b+1)$ are the previous inputs on which the current output depends.
- *e(t)* is a white-noise disturbance value.

The OE model can also be written in a compact way using the following notation:

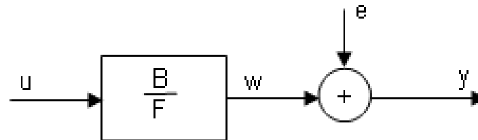
$$y(t) = \frac{B(q)}{F(q)}u(t-n_k) + e(t)$$

where

$$B(q) = b_1 + b_2q^{-1} + \cdots + b_{n_b}q^{-n_b+1}$$
$$F(q) = 1 + f_1q^{-1} + \cdots f_{n_f}q^{-n_f}$$

and q^{-1} is the backward shift operator, defined by $q^{-1}u(t) = u(t-1)$.

The following block diagram shows the ARX model structure.



Input

The block accepts two inputs, corresponding to the measured input-output data for estimating the model.

First input: Input signal.

Second input: Output signal.

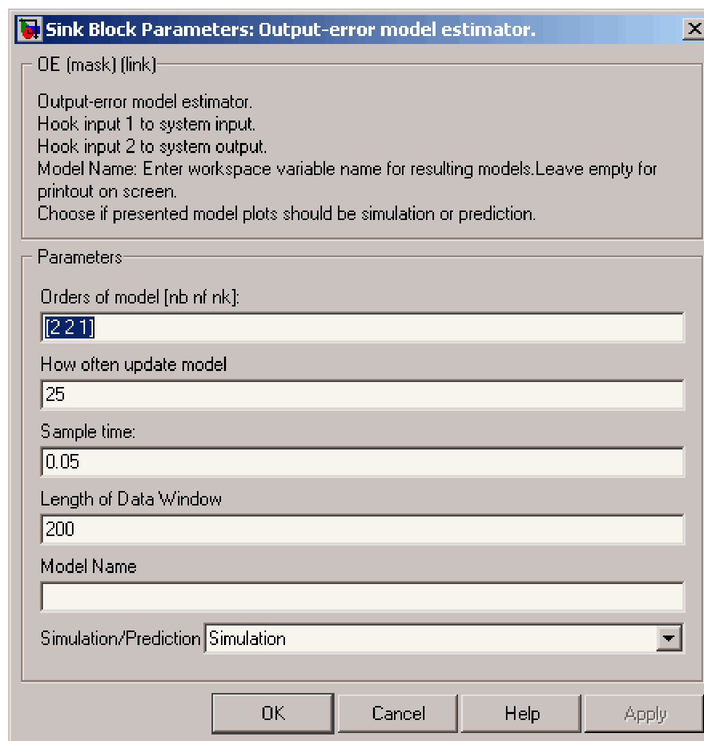
Output

The OE Estimator block outputs a sequence of multiple models (`idpoly`), estimated at regular intervals during the simulation.

The **Length of Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

Dialog Box



Orders of model [nb nf nk]

Integers n_b, n_f, and n_k specify the number of B and F model parameters and n_k is the input-output delay, respectively.

How often to update model

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

Sample time

Sampling time for the model.

Note If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

Length of Data Window

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

Model Name

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

Simulation/Prediction

`Simulation`: The algorithm uses only measured input data to simulate the response of the model.

`Prediction`: Specifies the forward-prediction horizon for computing the response `K` steps in the future, where `K` is 1, 5, or 10.

Examples

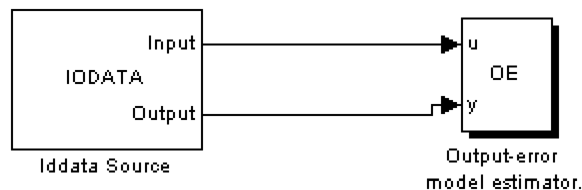
This example shows how you can use the OE Estimator block in a Simulink model.

1 Specify the data from `iddata1.mat` for estimation:

```
load iddata1;
IODATA = z1;
```

2 Create a new Simulink model, as follows:

- Add the IDDATA Source block and specify `IODATA` in the **Iddata object** field of the IDDATA Source block parameters dialog box.
- Add the OE Estimator block to the model. Set sample time in the block to `0.1` seconds and the simulation end time to `30` seconds.
- Connect the Input and Output ports of the IDDATA Source block to the u and y ports of the OE Estimator block, respectively.



3 Run the simulation.

The estimated models appear in the MATLAB Command Window every 25 samples.

"Identifying Input-Output Polynomial Models"

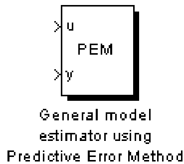
Purpose

Estimate generic input-output polynomial model parameters from SISO data using iterative prediction-error minimization method

Library

System Identification Toolbox

Description



General model estimator using Predictive Error Method

The PEM Estimator block estimates linear input-output polynomial models in Simulink software.

For information about the default algorithm settings used for model estimation, see the `Algorithm Properties` reference page.

Each estimation generates a figure with the following plots:

- Actual (measured) output versus the simulated or predicted model output.
- Error in simulated model, which is the difference between the measured output and the model output.

Model Definition

The input-output polynomial structure is defined, as follows:

$$Ay(t) = \frac{B}{F}u(t - Nk) + \frac{C}{D}e(t)$$

where

- $y(t)$ is the output at time t.
- A, B, F, C, and D are the parameters $a_1 \ldots a_{na}$, $b_1 \cdots b_{n_b}$, $f_1 \cdots f_{n_f}$, $c_1 \cdots c_{n_c}$ and $d_1 \cdots d_{n_d}$ to be estimated.
- $e(t)$ is a white-noise disturbance.

Input

The block accepts two inputs, corresponding to the measured input-output data for estimating the model.

First input: Input signal.

Second input: Output signal.

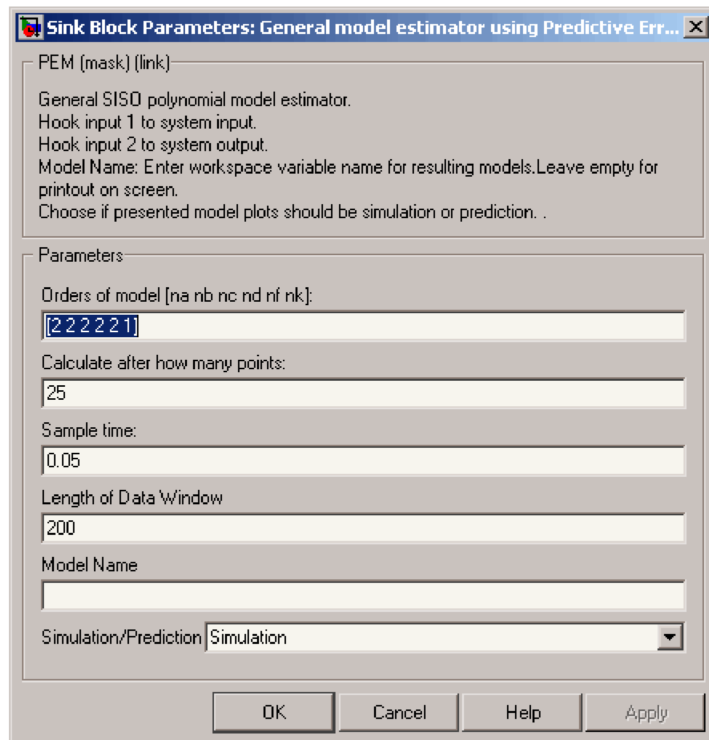
Output

The PEM Estimator block outputs a sequence of multiple models (`idpoly` objects), estimated at regular intervals during the simulation.

The **Data window** field in the block parameter dialog box specifies the number of data samples to use for estimation, as the simulation progresses.

The output format depends on whether you specify the **Model Name** in the block parameter dialog box.

Dialog Box



Orders of model [na nb nc nd nf nk]

Integers n_a, n_b, n_c, n_d, n_f, and n_k, specify the number of A, B, C, D, and F model parameters n_k is the input-output delay, respectively.

Calculate after how many points

Number of input data samples that specify the interval after which to estimate a new model.

Default: 25

Sample time

Sampling time for the model.

Note If you use a fixed step-size solver, the fixed step size must be consistent with this sample time.

Length of Data Window

Number of past data samples used to estimate each model. A longer data window should be used for higher-order models. Too small a value might cause poor estimation results, and too large a value leads to slower computation.

Default: 200.

Model Name

Name of the model.

Whether you specify the model name determines the output format of the resulting models, as follows:

- If you do not specify a model name, the estimated models display in the MATLAB Command Window in a transfer-function format.
- If you specify a model name, the resulting models are output to the MATLAB workspace as a cell array.

Simulation/Prediction

`Simulation`: The algorithm uses only measured input data to simulate the response of the model.

`Prediction`: Specifies the forward-prediction horizon for computing the response `K` steps in the future, where `K` is 1, 5, or 10.

Examples

This example shows how you can use the PEM Estimator block in a Simulink model.

1 Specify data in `iddata1.mat` for estimation:

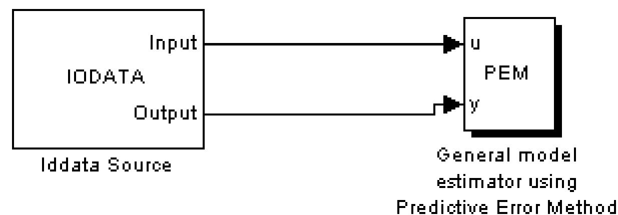
```
load iddata1;
IODATA = z1;
```

2 Create a new Simulink model, as follows.

Add the IDDATA Source block and specify `IODATA` in the **Iddata object** field of the IDDATA Source block parameters dialog box.

Add the PEM Estimator block to the model. Set the sample time in the block to `0.1` seconds and the simulation end time to `30` seconds.

Connect the Input and Output ports of the IDDATA Source block to the u and y ports of the PEM Estimator block, respectively.



3 Run the simulation.

The estimated models display in the MATLAB Command Window every 25 samples.
