## Creating and Concatenating Matrices

In this section...<br>"Overview" on page 1-2<br>"Constructing a Simple Matrix" on page 1-3<br>"Specialized Matrix Functions" on page 1-4<br>"Concatenating Matrices" on page 1-6<br>"Matrix Concatenation Functions" on page 1-7<br>"Generating a Numeric Sequence" on page 1-9

## Overview

The most basic MATLAB ${ }^{\circledR}$ data structure is the matrix: a two-dimensional, rectangularly shaped data structure capable of storing multiple elements of data in an easily accessible format. These data elements can be numbers, characters, logical states of true or false, or even other MATLAB structure types. MATLAB uses these two-dimensional matrices to store single numbers and linear series of numbers as well. In these cases, the dimensions are 1-by-1 and 1-by- n respectively, where n is the length of the numeric series. MATLAB also supports data structures that have more than two dimensions. These data structures are referred to as arrays in the MATLAB documentation.

MATLAB is a matrix-based computing environment. All of the data that you enter into MATLAB is stored in the form of a matrix or a multidimensional array. Even a single numeric value like 100 is stored as a matrix (in this case, a matrix having dimensions 1-by-1):

```
A = 100;
whos A
    Name Size Bytes Class
    A
    1x1
    8 \text { double array}
```

Regardless of the class being used, whether it is numeric, character, or logical true or false data, MATLAB stores this data in matrix (or array) form. For example, the string 'Hello World' is a 1-by-11 matrix of individual character
elements in MATLAB. You can also build matrices composed of more complex classes, such as MATLAB structures and cell arrays.

To create a matrix of basic data elements such as numbers or characters, see

- "Constructing a Simple Matrix" on page 1-3
- "Specialized Matrix Functions" on page 1-4

To build a matrix composed of other matrices, see

- "Concatenating Matrices" on page 1-6
- "Matrix Concatenation Functions" on page 1-7

This section also describes

- "Generating a Numeric Sequence" on page 1-9
- "Combining Unlike Classes"

## Constructing a Simple Matrix

The simplest way to create a matrix in MATLAB is to use the matrix constructor operator, []. Create a row in the matrix by entering elements (shown as E below) within the brackets. Separate each element with a comma or space:

```
row = [E , E E , ..., E Em row = [E [ E E . .. E Em
```

For example, to create a one row matrix of five elements, type

$$
A=\left[\begin{array}{llll}
12 & 62 & 93 & -8 \\
22
\end{array}\right] ;
$$

To start a new row, terminate the current row with a semicolon:

$$
A=\left[\operatorname{row}_{1} ; \operatorname{row}_{2} ; \ldots ; \operatorname{row}_{n}\right]
$$

This example constructs a 3 row, 5 column (or 3 -by- 5 ) matrix of numbers. Note that all rows must have the same number of elements:

```
A = [12 62 93 -8 22; 16 2 87 43 91; -4 17 -72 95 6]
A =
```

| 12 | 62 | 93 | -8 | 22 |
| ---: | ---: | ---: | ---: | ---: |
| 16 | 2 | 87 | 43 | 91 |
| -4 | 17 | -72 | 95 | 6 |

The square brackets operator constructs two-dimensional matrices only, (including 0 -by-0, 1-by-1, and 1-by-n matrices). To construct arrays of more than two dimensions, see "Creating Multidimensional Arrays" on page 1-52.

For instructions on how to read or overwrite any matrix element, see "Matrix Indexing" on page 1-12.

## Entering Signed Numbers

When entering signed numbers into a matrix, make sure that the sign immediately precedes the numeric value. Note that while the following two expressions are equivalent,

| $7-2+5$ | $7-2+5$ |
| :---: | :---: |
| ans $=$ | ans $=$ |
| 10 | 10 |

the next two are not:

```
[7 -2 +5]
ans =
    7 -2 5
```

[7-2 + 5]
ans $=$
10

## Specialized Matrix Functions

MATLAB has a number of functions that create different kinds of matrices. Some create specialized matrices like the Hankel or Vandermonde matrix. The functions shown in the table below create matrices for more general use.

| Function | Description |
| :--- | :--- |
| ones | Create a matrix or array of all ones. |
| zeros | Create a matrix or array of all zeros. |
| eye | Create a matrix with ones on the diagonal and zeros <br> elsewhere. |

| Function | Description |
| :--- | :--- |
| accumarray | Distribute elements of an input matrix to specified <br> locations in an output matrix, also allowing for <br> accumulation. |
| diag | Create a diagonal matrix from a vector. |
| magic | Create a square matrix with rows, columns, and diagonals <br> that add up to the same number. |
| rand | Create a matrix or array of uniformly distributed random <br> numbers. |
| randn | Create a matrix or array of normally distributed random <br> numbers and arrays. |
| randperm | Create a vector (1-by-n matrix) containing a random <br> permutation of the specified integers. |

Most of these functions return matrices of type double (double-precision floating point). However, you can easily build basic arrays of any numeric type using the ones, zeros, and eye functions.

To do this, specify the MATLAB class name as the last argument:

```
A = zeros(4, 6, 'uint32')
A =
```

| 0 | 0 | 0 | 0 | 0 | 0 |
| :--- | :--- | :--- | :--- | :--- | :--- |
| 0 | 0 | 0 | 0 | 0 | 0 |
| 0 | 0 | 0 | 0 | 0 | 0 |
| 0 | 0 | 0 | 0 | 0 | 0 |

## Examples

Here are some examples of how you can use these functions.
Creating a Magic Square Matrix. A magic square is a matrix in which the sum of the elements in each column, or each row, or each main diagonal is the same. To create a 5 -by- 5 magic square matrix, use the magic function as shown.

| $A=$ | magic (5) |  |  |  |
| ---: | :--- | ---: | ---: | ---: |
| $A=$ |  |  |  |  |
|  |  |  |  |  |
|  | 24 | 1 | 8 | 15 |
| 23 | 5 | 7 | 14 | 16 |
| 4 | 6 | 13 | 20 | 22 |
| 10 | 12 | 19 | 21 | 3 |
| 11 | 18 | 25 | 2 | 9 |

Note that the elements of each row, each column, and each main diagonal add up to the same value: 65 .

Creating a Diagonal Matrix. Use diag to create a diagonal matrix from a vector. You can place the vector along the main diagonal of the matrix, or on a diagonal that is above or below the main one, as shown here. The -1 input places the vector one row below the main diagonal:

| $\mathrm{A}=\left[\begin{array}{llll}12 & 62 & 93 & -822] ;\end{array}\right.$ |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $B=\operatorname{diag}(\mathrm{A},-1)$ |  |  |  |  |  |
| $B=$ |  |  |  |  |  |
| 0 | 0 | 0 | 0 | 0 | 0 |
| 12 | 0 | 0 | 0 | 0 | 0 |
| 0 | 62 | 0 | 0 | 0 | 0 |
| 0 | 0 | 93 | 0 | 0 | 0 |
| 0 | 0 | 0 | -8 | 0 | 0 |
| 0 | 0 | 0 | 0 | 22 | 0 |

## Concatenating Matrices

Matrix concatenation is the process of joining one or more matrices to make a new matrix. The brackets [ ] operator discussed earlier in this section serves not only as a matrix constructor, but also as the MATLAB concatenation operator. The expression $C=[A B]$ horizontally concatenates matrices $A$ and B. The expression $C=[A ; B]$ vertically concatenates them.

This example constructs a new matrix $C$ by concatenating matrices $A$ and $B$ in a vertical direction:

```
A = ones(2, 5) * 6; % 2-by-5 matrix of 6's
B = rand(3, 5); % 3-by-5 matrix of random values
```

```
C = [A; B] % Vertically concatenate A and B
C =
\begin{tabular}{lllll}
6.0000 & 6.0000 & 6.0000 & 6.0000 & 6.0000 \\
6.0000 & 6.0000 & 6.0000 & 6.0000 & 6.0000 \\
0.9501 & 0.4860 & 0.4565 & 0.4447 & 0.9218 \\
0.2311 & 0.8913 & 0.0185 & 0.6154 & 0.7382 \\
0.6068 & 0.7621 & 0.8214 & 0.7919 & 0.1763
\end{tabular}
```

## Keeping Matrices Rectangular

You can construct matrices, or even multidimensional arrays, using concatenation as long as the resulting matrix does not have an irregular shape (as in the second illustration shown below). If you are building a matrix horizontally, then each component matrix must have the same number of rows. When building vertically, each component must have the same number of columns.

This diagram shows two matrices of the same height (i.e., same number of rows) being combined horizontally to form a new matrix.

The next diagram illustrates an attempt to horizontally combine two matrices of unequal height. MATLAB does not allow this.

## Matrix Concatenation Functions

The following functions combine existing matrices to form a new matrix.

| Function | Description |
| :--- | :--- |
| cat | Concatenate matrices along the specified dimension |
| horzcat | Horizontally concatenate matrices |
| vertcat | Vertically concatenate matrices |
| repmat | Create a new matrix by replicating and tiling existing <br> matrices |
| blkdiag | Create a block diagonal matrix from existing matrices |

## Examples

Here are some examples of how you can use these functions.
Concatenating Matrices and Arrays. An alternative to using the [] operator for concatenation are the three functions cat, horzcat, and vertcat. With these functions, you can construct matrices (or multidimensional arrays) along a specified dimension. Either of the following commands accomplish the same task as the command $C=[A ; B]$ used in the section on "Concatenating Matrices" on page 1-6:

```
C = cat(1, A, B); % Concatenate along the first dimension
C = vertcat(A, B); % Concatenate vertically
```

Replicating a Matrix. Use the repmat function to create a matrix composed of copies of an existing matrix. When you enter

```
repmat(M, v, h)
```

MATLAB replicates input matrix $M v$ times vertically and $h$ times horizontally. For example, to replicate existing matrix $A$ into a new matrix $B$, use

```
A = [8 1 6; 3 5 7; 4 9 2]
A =
    8 1 6
    3
    4 9 2
B = repmat(A, 2, 4)
B =
```

| 8 | 1 | 6 | 8 | 1 | 6 | 8 | 1 | 6 | 8 | 1 | 6 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 3 | 5 | 7 | 3 | 5 | 7 | 3 | 5 | 7 | 3 | 5 | 7 |
| 4 | 9 | 2 | 4 | 9 | 2 | 4 | 9 | 2 | 4 | 9 | 2 |
| 8 | 1 | 6 | 8 | 1 | 6 | 8 | 1 | 6 | 8 | 1 | 6 |
| 3 | 5 | 7 | 3 | 5 | 7 | 3 | 5 | 7 | 3 | 5 | 7 |
| 4 | 9 | 2 | 4 | 9 | 2 | 4 | 9 | 2 | 4 | 9 | 2 |

Creating a Block Diagonal Matrix. The blkdiag function combines matrices in a diagonal direction, creating what is called a block diagonal matrix. All other elements of the newly created matrix are set to zero:

```
A = magic(3);
B = [-5 -6 -9; -4 -4 -2];
C = eye(2) * 8;
D = blkdiag(A, B, C)
D =
    8
    3
    4
    0
    0
    0
    0
```

## Generating a Numeric Sequence

Because numeric sequences can often be useful in constructing and indexing into matrices and arrays, MATLAB provides a special operator to assist in creating them.

This section covers

- "The Colon Operator" on page 1-10
- "Using the Colon Operator with a Step Value" on page 1-10

## The Colon Operator

The colon operator (first:last) generates a 1-by-n matrix (or vector) of sequential numbers from the first value to the last. The default sequence is made up of incremental values, each 1 greater than the previous one:

```
A = 10:15
A =
```

The numeric sequence does not have to be made up of positive integers. It can include negative numbers and fractional numbers as well:

```
A = -2.5:2.5
A =
    -2.5000 -1.5000 -0.5000 0.5000 1.5000 2.5000
```

By default, MATLAB always increments by exactly 1 when creating the sequence, even if the ending value is not an integral distance from the start:

```
A = 1:6.3
A =
    1 2 
```

Also, the default series generated by the colon operator always increments rather than decrementing. The operation shown in this example attempts to increment from 9 to 1 and thus MATLAB returns an empty matrix:

```
\(A=9: 1\)
A =
    Empty matrix: 1-by-0
```

The next section explains how to generate a nondefault numeric series.

## Using the Colon Operator with a Step Value

To generate a series that does not use the default of incrementing by 1 , specify an additional value with the colon operator (first:step:last). In between the starting and ending value is a step value that tells MATLAB how much to increment (or decrement, if step is negative) between each number it generates.

To generate a series of numbers from 10 to 50 , incrementing by 5 , use

```
A = 10:5:50
A =
    10
```

You can increment by noninteger values. This example increments by 0.2:
$A=3: 0.2: 3.8$
$A=$
3.0000
3.2000
3.4000
3.6000
3.8000

To create a sequence with a decrementing interval, specify a negative step value:

```
A = 9:-1:1
A =
    9
```

## Matrix Indexing

## In this section...

"Accessing Single Elements" on page 1-12
"Linear Indexing" on page 1-13
"Functions That Control Indexing Style" on page 1-13
"Accessing Multiple Elements" on page 1-14
"Using Logicals in Array Indexing" on page 1-17
"Single-Colon Indexing with Different Array Types" on page 1-20
"Indexing on Assignment" on page 1-21

## Accessing Single Elements

To reference a particular element in a matrix, specify its row and column number using the following syntax, where A is the matrix variable. Always specify the row first and column second:

```
A(row, column)
```

For example, for a 4-by-4 magic square A,

```
A = magic(4)
A =
\begin{tabular}{rrrr}
16 & 2 & 3 & 13 \\
5 & 11 & 10 & 8 \\
9 & 7 & 6 & 12 \\
4 & 14 & 15 & 1
\end{tabular}
```

you would access the element at row 4 , column 2 with

```
A(4, 2)
ans =
    1 4
```

For arrays with more than two dimensions, specify additional indices following the row and column indices. See the section on "Multidimensional Arrays" on page 1-50.

## Linear Indexing

You can refer to the elements of a MATLAB matrix with a single subscript, $A(k)$. MATLAB stores matrices and arrays not in the shape that they appear when displayed in the MATLAB Command Window, but as a single column of elements. This single column is composed of all of the columns from the matrix, each appended to the last.

So, matrix A

```
A = [2 6 9; 4 2 8; 3 5 1]
A =
\begin{tabular}{lll}
2 & 6 & 9 \\
4 & 2 & 8 \\
3 & 5 & 1
\end{tabular}
```

is actually stored in memory as the sequence

```
2, 4, 3, 6, 2, 5, 9, 8, 1
```

The element at row 3, column 2 of matrix A (value $=5$ ) can also be identified as element 6 in the actual storage sequence. To access this element, you have a choice of using the standard $A(3,2)$ syntax, or you can use $A(6)$, which is referred to as linear indexing.

If you supply more subscripts, MATLAB calculates an index into the storage column based on the dimensions you assigned to the array. For example, assume a two-dimensional array like A has size [d1 d2], where d1 is the number of rows in the array and d2 is the number of columns. If you supply two subscripts ( $\mathrm{i}, \mathrm{j}$ ) representing row-column indices, the offset is

$$
(j-1) * d 1+i
$$

Given the expression $A(3,2)$, MATLAB calculates the offset into A's storage column as $(2-1)$ * $3+3$, or 6 . Counting down six elements in the column accesses the value 5 .

## Functions That Control Indexing Style

If you have row-column subscripts but want to use linear indexing instead, you can convert to the latter using the sub2ind function. In the 3 -by- 3 matrix

A used in the previous section, sub2ind changes a standard row-column index of $(3,2)$ to a linear index of 6 :

```
A = [2 6 9; 4 2 8; 3 5 1];
linearindex = sub2ind(size(A), 3, 2)
linearindex =
    6
```

To get the row-column equivalent of a linear index, use the ind2sub function:

```
[row col] = ind2sub(size(A), 6)
row =
    3
col =
    2
```

## Accessing Multiple Elements

For the 4 -by- 4 matrix A shown below, it is possible to compute the sum of the elements in the fourth column of A by typing

```
A = magic(4);
A(1,4) + A(2,4) + A(3,4) + A(4,4)
```

You can reduce the size of this expression using the colon operator. Subscript expressions involving colons refer to portions of a matrix. The expression

$$
\mathrm{A}(1: \mathrm{m}, \mathrm{n})
$$

refers to the elements in rows 1 through $m$ of column $n$ of matrix $A$. Using this notation, you can compute the sum of the fourth column of A more succinctly:

```
sum(A(1:4, 4))
```

## Nonconsecutive Elements

To refer to nonconsecutive elements in a matrix, use the colon operator with a step value. The m:3:n in this expression means to make the assignment to every third element in the matrix. Note that this example uses linear indexing:

```
\(B=A ;\)
\(B(1: 3: 16)=-10\)
B =
\begin{tabular}{rrrr}
-10 & 2 & 3 & -10 \\
5 & 11 & -10 & 8 \\
9 & -10 & 6 & 12 \\
-10 & 14 & 15 & -10
\end{tabular}
```

MATLAB supports a type of array indexing that uses one array as the index into another array. You can base this type of indexing on either the values or the positions of elements in the indexing array.

Here is an example of value-based indexing where array $B$ indexes into elements $1,3,6,7$, and 10 of array A. In this case, the numeric values of array $B$ designate the intended elements of $A$ :

```
A = 5:5:50
A =
    5
B = [11 3 6 7 10];
A(B)
ans =
    5 15 30 35 50
```

If you index into a vector with another vector, the orientation of the indexed vector is honored for the output:

```
A(B')
ans =
l}\begin{array}{l}{5}\\{A1= 15 (1)}\end{array}\mp@code{A0
    5
15
30
35
```

If you index into a vector with a nonvector, the shape of the indices is honored.:

```
C = [1 3 6; 7 9 10];
A(C)
ans =
    5 15 30
    35 45 50
```

## The end Keyword

MATLAB provides the keyword end to designate the last element in a particular dimension of an array. This keyword can be useful in instances where your program does not know how many rows or columns there are in a matrix. You can replace the expression in the previous example with

$$
B(1: 3: \text { end })=-10
$$

Note The keyword end has several meanings in MATLAB. It can be used as explained above, or to terminate a conditional block of code such as if and for blocks, or to terminate a nested function.

## Specifying All Elements of a Row or Column

The colon by itself refers to all the elements in a row or column of a matrix. Using the following syntax, you can compute the sum of all elements in the second column of a 4 -by- 4 magic square A :

```
sum(A(:, 2))
ans =
    34
```

By using the colon with linear indexing, you can refer to all elements in the entire matrix. This example displays all the elements of matrix A, returning them in a column-wise order:

$$
A(:)
$$

ans $=$
16
5
9
4
.
.

12
1

## Using Logicals in Array Indexing

A logical array index designates the elements of an array A based on their position in the indexing array, B, not their value. In this masking type of operation, every true element in the indexing array is treated as a positional index into the array being accessed.

In the following example, B is a matrix of logical ones and zeros. The position of these elements in $B$ determines which elements of $A$ are designated by the expression $A(B)$ :

```
A = [1 2 3; 4 5 6; 7 8 9]
A =
    1 2 
    4 5 6
    7 8 9
B = logical([0 1 0; 1 0 1; 0 0 1]);
B =
    0 1 0
    1 0 1
    0 0
A(B)
ans =
    4
    2
    6
    9
```

The find function can be useful with logical arrays as it returns the linear indices of nonzero elements in $B$, and thus helps to interpret $A(B)$ :

```
find(B)
ans =
    2
    4
    8
    9
```

## Logical Indexing - Example 1

This example creates logical array $B$ that satisfies the condition $A>0.5$, and uses the positions of ones in $B$ to index into $A$ :

```
rand('twister', 5489); % Initialize the state of the
    % random number generator.
A = rand(5);
B = A > 0.5;
A(B) = 0
A =
\begin{tabular}{rrrrr}
0 & 0.0975 & 0.1576 & 0.1419 & 0 \\
0 & 0.2785 & 0 & 0.4218 & 0.0357 \\
0.1270 & 0 & 0 & 0 & 0 \\
0 & 0 & 0.4854 & 0 & 0 \\
0 & 0 & 0 & 0 & 0
\end{tabular}
```

A simpler way to express this is

$$
A(A>0.5)=0
$$

## Logical Indexing - Example 2

The next example highlights the location of the prime numbers in a magic square using logical indexing to set the nonprimes to 0 :

```
A = magic(4)
A =
\begin{tabular}{rrrr}
16 & 2 & 3 & 13 \\
5 & 11 & 10 & 8 \\
9 & 7 & 6 & 12
\end{tabular}
```

```
    4 14 15 1
B = isprime(A)
B =
\begin{tabular}{llll}
0 & 1 & 1 & 1 \\
1 & 1 & 0 & 0
\end{tabular}
\begin{tabular}{llll}
1 & 1 & 0 & 0 \\
0 & 1 & 0 & 0
\end{tabular}
    llll
A(~B) = 0; % Logical indexing
A
A =
            0}3031
            5 11 0
            0
            0 0 0 0
find(B)
ans =
2
5
6
7
9
1 3
```

## Logical Indexing with a Smaller Array

In most cases, the logical indexing array should have the same number of elements as the array being indexed into, but this is not a requirement. The indexing array may have smaller (but not larger) dimensions:

```
A = [1 2 3;4 5 6;7 8 9]
A =
    1 2 3
    4 5 6
    7 8 9
```

```
B = logical([0 1 0; 1 0 1])
B =
    0 1 0
    1 0
isequal(numel(A), numel(B))
ans =
    0
A(B)
ans =
    4
    7
    8
```

MATLAB treats the missing elements of the indexing array as if they were present and set to zero, as in array C below:

```
% Add zeros to indexing array C to give it the same number of
% elements as A.
C = logical([B(:);0;0;0]);
isequal(numel(A), numel(C))
ans =
    1
A(C)
ans =
    4
    7
    8
```

## Single-Colon Indexing with Different Array Types

When you index into a standard MATLAB array using a single colon, MATLAB returns a column vector (see variable $n$, below). When you index into a structure or cell array using a single colon, you get a comma-separated list (see "Returning Data from a Struct Array" and "Returning Data from a Cell Array" for more information.)

Create three types of arrays:

```
n = [1 2 3; 4 5 6];
c = {1 2; 3 4};
s = cell2struct(c, {'a', 'b'}, 1); s(:,2)=s(:,1);
```

Use single-colon indexing on each:

| n (: ) | c \{ : $\}$ | s (:) . a |
| :---: | :---: | :---: |
| ans = | ans = | ans = |
| 1 | 1 | 1 |
| 4 | ans = | ans = |
| 2 | 3 | 2 |
| 5 | ans = | ans = |
| 3 | 2 | 1 |
| 6 | ans = | ans = |
|  | 4 | 2 |

## Indexing on Assignment

When assigning values from one matrix to another matrix, you can use any of the styles of indexing covered in this section. Matrix assignment statements also have the following requirement.

In the assignment $A(J, K, \ldots)=B(M, N, \ldots)$, subscripts $J, K, M, N$, etc. may be scalar, vector, or array, provided that all of the following are true:

- The number of subscripts specified for $B$, not including trailing subscripts equal to 1 , does not exceed ndims ( $B$ ).
- The number of nonscalar subscripts specified for $A$ equals the number of nonscalar subscripts specified for B. For example, A(5, 1:4, 1, 2 ) $=B(5: 8)$ is valid because both sides of the equation use one nonscalar subscript.
- The order and length of all nonscalar subscripts specified for A matches the order and length of nonscalar subscripts specified for B. For example, $A(1: 4,3,3: 9)=B(5: 8,1: 7)$ is valid because both sides of the equation (ignoring the one scalar subscript 3 ) use a 4 -element subscript followed by a 7 -element subscript.

## Getting Information About a Matrix

## In this section...

"Dimensions of the Matrix" on page 1-22
"Classes Used in the Matrix" on page 1-23
"Data Structures Used in the Matrix" on page 1-24

## Dimensions of the Matrix

These functions return information about the shape and size of a matrix.

| Function | Description |
| :--- | :--- |
| length | Return the length of the longest dimension. (The length of a <br> matrix or array with any zero dimension is zero.) |
| ndims | Return the number of dimensions. |
| numel | Return the number of elements. |
| size | Return the length of each dimension. |

The following examples show some simple ways to use these functions. Both use the 3 -by- 5 matrix A shown here:

```
A = 10*gallery('uniformdata',[5],0);
A(4:5, :) = []
A =
\begin{tabular}{lllll}
9.5013 & 7.6210 & 6.1543 & 4.0571 & 0.5789 \\
2.3114 & 4.5647 & 7.9194 & 9.3547 & 3.5287 \\
6.0684 & 0.1850 & 9.2181 & 9.1690 & 8.1317
\end{tabular}
```

## Example Using numel

Using the numel function, find the average of all values in matrix $A$ :

```
sum(A(:))/numel(A)
ans =
    5.8909
```

## Example Using ndims, numel, and size

Using ndims and size, go through the matrix and find those values that are between 5 and 7, inclusive:

```
if ndims(A) ~= 2
    return
end
[rows cols] = size(A);
for m = 1:rows
    for n = 1:cols
        x = A(m, n);
        if x >= 5 && x <= 7
            disp(sprintf('A(%d, %d) = %5.2f', m, n, A(m,n)))
        end
    end
end
```

The code returns the following:

```
A(1, 3) = 6.15
A(3, 1) = 6.07
```

## Classes Used in the Matrix

These functions test elements of a matrix for a specific data type.

| Function | Description |
| :--- | :--- |
| isa | Detect if input is of a given data type. |
| iscell | Determine if input is a cell array. |
| iscellstr | Determine if input is a cell array of strings. |
| ischar | Determine if input is a character array. |
| isfloat | Determine if input is a floating-point array. |
| isinteger | Determine if input is an integer array. |

| Function | Description |
| :--- | :--- |
| islogical | Determine if input is a logical array. |
| isnumeric | Determine if input is a numeric array. |
| isreal | Determine if input is an array of real numbers. |
| isstruct | Determine if input is a MATLAB structure array. |

## Example Using isnumeric and isreal

Pick out the real numeric elements from this vector:

```
A = [5+7i 8/7 4.23 39j pi 9-2i];
for m = 1:numel(A)
    if isnumeric(A(m)) && isreal(A(m))
        disp(A(m))
    end
end
```

The values returned are
1.1429
4.2300
3.1416

## Data Structures Used in the Matrix

These functions test elements of a matrix for a specific data structure.

| Function | Description |
| :--- | :--- |
| isempty | Determine if input has any dimension with size zero. |
| isscalar | Determine if input is a 1-by-1 matrix. |
| issparse | Determine if input is a sparse matrix. |
| isvector | Determine if input is a 1-by-n or n-by-1 matrix. |

## Resizing and Reshaping Matrices

In this section...<br>"Expanding the Size of a Matrix" on page 1-25<br>"Diminishing the Size of a Matrix" on page 1-29<br>"Reshaping a Matrix" on page 1-30<br>"Preallocating Memory" on page 1-32

## Expanding the Size of a Matrix

You can expand the size of any existing matrix as long as doing so does not give the resulting matrix an irregular shape. (See "Keeping Matrices Rectangular" on page 1-7). For example, you can vertically combine a 4-by-3 matrix and 7 -by- 3 matrix because all rows of the resulting matrix have the same number of columns (3).

Two ways of expanding the size of an existing matrix are

- Concatenating new elements onto the matrix
- Storing to a location outside the bounds of the matrix

Note If you intend to expand the size of a matrix repeatedly over time as it requires more room (usually done in a programming loop), it is advisable to preallocate space for the matrix when you initially create it. See "Preallocating Memory" on page 1-32.

## Concatenating Onto the Matrix

Concatenation is most useful when you want to expand a matrix by adding new elements or blocks that are compatible in size with the original matrix. This means that the size of all matrices being joined along a specific dimension must be equal along that dimension. See "Concatenating Matrices" on page 1-6.

This example runs a user-defined function compareResults on the data in matrices stats04 and stats03. Each time through the loop, it concatenates the results of this function onto the end of the data stored in comp04:

```
col = 10;
comp04 = [];
for k = 1:50
    t = compareResults(stats04(k,1:col), stats03(k,1:col));
    comp04 = [comp04; t];
end
```

Concatenating to a Structure or Cell Array. You can add on to arrays of structures or cells in the same way as you do with ordinary matrices. This example creates a 3 -by- 8 matrix of structures $S$, each having 3 fields: $x, y$, and $z$, and then concatenates a second structure matrix $S 2$ onto the original:

Create a 3 -by- 8 structure array S :

```
for k = 1:24
    S(k) = struct('x', 10*k, 'y', 10*k+1, 'z', 10*k+2);
end
S = reshape(S, 3, 8);
```

Create a second array that is 3 -by- 2 and uses the same field names:

```
for k = 25:30
    S2(k-24) = struct('x', 10*k, 'y', 10*k+1, 'z', 10*k+2);
end
S2= reshape(S2, 3, 2);
```

Concatenate S2 onto S along the horizontal dimension:

```
S = [S S2]
S =
3x10 struct array with fields:
    X
    y
    z
```

## Adding Smaller Blocks to a Matrix

To add one or more elements to a matrix where the sizes are not compatible, you can often just store the new elements outside the boundaries of the original matrix. The MATLAB software automatically pads the matrix with zeros to keep it rectangular.

Construct a 3-by-5 matrix, and attempt to add a new element to it using concatenation. The operation fails because you are attempting to join a one-column matrix with one that has five columns:

```
A = [\begin{array}{llllll}{10}&{20}&{30}&{40}&{50; ...}\end{array}]
    60 70 80 90 100; ...
    110 120 130 140 150];
A = [A; 160]
??? Error using ==> vertcat
All rows in the bracketed expression must have the same
number of columns.
```

Try this again, but this time do it in such a way that enables MATLAB to make adjustments to the size of the matrix. Store the new element in row 4, a row that does not yet exist in this matrix. MATLAB expands matrix A by an entire new row by padding columns 2 through 5 with zeros:

| $A(4,1)=160$ |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| $\mathrm{A}=$ |  |  |  |  |
| 10 | 20 | 30 | 40 | 50 |
| 60 | 70 | 80 | 90 | 100 |
| 110 | 120 | 130 | 140 | 150 |
| 160 | 0 | 0 | 0 | 0 |

Note Attempting to read from nonexistent matrix locations generates an error. You can only write to these locations.

You can also expand the matrix by adding a matrix instead of just a single element:

$$
A(4: 6,1: 3)=\operatorname{magic}(3)+100
$$

$A=$|  |  |  |  |  |
| ---: | ---: | ---: | ---: | ---: |
| 10 | 20 | 30 | 40 | 50 |
| 60 | 70 | 80 | 90 | 100 |
| 110 | 120 | 130 | 140 | 150 |
| 108 | 101 | 106 | 0 | 0 |
| 103 | 105 | 107 | 0 | 0 |
| 104 | 109 | 102 | 0 | 0 |

You do not have to add new elements sequentially. Wherever you store the new elements, MATLAB pads with zeros to make the resulting matrix rectangular in shape:

| $\mathrm{A}(4,8)$ | $=300$ |  |  |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| $\mathrm{~A}=$ |  |  |  |  |  |  |  |
|  |  |  |  |  |  |  |  |
| 10 | 20 | 30 | 40 | 50 | 0 | 0 | 0 |
| 60 | 70 | 80 | 90 | 100 | 0 | 0 | 0 |
| 110 | 120 | 130 | 140 | 150 | 0 | 0 | 0 |
| 0 | 0 | 0 | 0 | 0 | 0 | 0 | 300 |

Expanding a Structure or Cell Array. You can expand a structure or cell array in the same way that you can a matrix. This example adds an additional cell to a cell array by storing it beyond the bounds of the original array. MATLAB pads the data structure with empty cells ([ ]) to keep it rectangular.

The original array is 2 -by- 3 :

```
C = {'Madison', 'G', [5 28 1967]; ...
    46, '325 Maple Dr', 3015.28}
```

Add a cell to $C\{3,1\}$ and MATLAB appends an entire row:

```
C{3, 1} = ...
struct('Fund_A', .45, 'Fund_E', .35, 'Fund_G', 20);
C =
    'Madison' 'G' [1x3 double]
    [ 46] '325 Maple Dr' [3.0153e+003]
    [1x1 struct] [] []
```

Expanding a Character Array. You can expand character arrays in the same manner as other MATLAB arrays, but it is generally not recommended. MATLAB expands any array by padding uninitialized elements with zeros. Because zero is interpreted by MATLAB and some other programming languages as a string terminator, you may find that some functions treat the expanded string as if it were less than its full length.

Expand a 1-by-5 character array to twelve characters. The result appears at first to be a typical string:

```
greeting = 'Hello'; greeting(1,8:12) = 'World'
greeting =
    Hello World
```

Closer inspection however reveals string terminators at the point of expansion:

```
uint8(greeting)
ans =
    72
```

This causes some functions, like strcmp, to return what might be considered an unexpected result:

```
strcmp(greeting, 'Hello World')
ans =
    0
```

## Diminishing the Size of a Matrix

You can delete rows and columns from a matrix by assigning the empty array [ ] to those rows or columns. Start with

| $\mathrm{A}=\mathrm{magic}(4)$ |  |  |  |
| :---: | :---: | :---: | :---: |
| $\mathrm{A}=$ |  |  |  |
| 16 | 2 | 3 | 13 |
| 5 | 11 | 10 | 8 |
| 9 | 7 | 6 | 12 |
| 4 | 14 | 15 | 1 |

Then, delete the second column of A using

$$
A(:, 2)=[]
$$

This changes matrix A to

$A=$|  |  |  |
| ---: | ---: | ---: |
| 16 | 3 | 13 |
| 5 | 10 | 8 |
| 9 | 6 | 12 |
| 4 | 15 | 1 |

If you delete a single element from a matrix, the result is not a matrix anymore. So expressions like

$$
A(1,2)=[]
$$

result in an error. However, you can use linear indexing to delete a single element, or a sequence of elements. This reshapes the remaining elements into a row vector:

$$
A(2: 2: 10)=[]
$$

results in

```
A =
\begin{tabular}{lllllll}
16 & 9 & 3 & 6 & 13 & 12 & 1
\end{tabular}
```

## Reshaping a Matrix

The following functions change the shape of a matrix.

| Function | Description |
| :--- | :--- |
| reshape | Modify the shape of a matrix. |
| rot90 | Rotate the matrix by 90 degrees. |
| fliplr | Flip the matrix about a vertical axis. |
| flipud | Flip the matrix about a horizontal axis. |
| flipdim | Flip the matrix along the specified direction. |

| Function | Description |
| :--- | :--- |
| transpose | Flip a matrix about its main diagonal, turning row <br> vectors into column vectors and vice versa. |
| ctranspose | Transpose a matrix and replace each element with its <br> complex conjugate. |

## Examples

Here are a few examples to illustrate some of the ways you can reshape matrices.

Reshaping a Matrix. Reshape 3-by-4 matrix A to have dimensions 2-by-6:

```
A = [1 4 7 10; 2 5 8 11; 3 6 9 12]
A =
    1 4 7 7 10
    2 5 8 11
    3 6 9 12
B = reshape(A, 2, 6)
B =
    1
    2
```

Transposing a Matrix. Transpose A so that the row elements become columns. You can use either the transpose function or the transpose operator (. ') to do this:
$B=A$.
$B=$

| 1 | 2 | 3 |
| ---: | ---: | ---: |
| 4 | 5 | 6 |
| 7 | 8 | 9 |
| 10 | 11 | 12 |

There is a separate function called ctranspose that performs a complex conjugate transpose of a matrix. The equivalent operator for ctranpose on a matrix $A$ is $A^{\prime}$ :

```
A = [1+9i 2-8i 3+7i; 4-6i 5+5i 6-4i]
A =
    1.0000 + 9.0000i 2.0000 -8.0000i 3.0000 + 7.0000i
    4.0000-6.0000i 5.0000 + 5.0000i 6.0000 -4.0000i
B = A'
B =
    1.0000 -9.0000i 4.0000 + 6.0000i
    2.0000 + 8.0000i 5.0000 -5.0000i
    3.0000 -7.0000i 6.0000 + 4.0000i
```

Rotating a Matrix. Rotate the matrix by 90 degrees:

```
B = rot90(A)
B =
    10 11 12
        7 8 9
        4 5 6
        1 2 3
```

Flipping a Matrix. Flip A in a left-to-right direction:

```
B = fliplr(A)
B \(=\)
    \(\begin{array}{llll}10 & 7 & 4 & 1\end{array}\)
    \(11 \quad 8 \quad 5 \quad 2\)
    1296
```

## Preallocating Memory

Repeatedly expanding the size of an array over time, (for example, adding more elements to it each time through a programming loop), can adversely affect the performance of your program. This is because

- MATLAB has to spend time allocating more memory each time you increase the size of the array.
- This newly allocated memory is likely to be noncontiguous, thus slowing down any operations that MATLAB needs to perform on the array.

The preferred method for sizing an array that is expected to grow over time is to estimate the maximum possible size for the array, and preallocate this amount of memory for it at the time the array is created. In this way, your program performs one memory allocation that reserves one contiguous block.

The following command preallocates enough space for a 25,000 by 10,000 matrix, and initializes each element to zero:

$$
A=\operatorname{zeros}(25000,10000) ;
$$

## Building a Preallocated Array

Once memory has been preallocated for the maximum estimated size of the array, you can store your data in the array as you need it, each time appending to the existing data. This example preallocates a large array, and then reads blocks of data from a file into the array until it gets to the end of the file:

```
blocksize = 5000;
maxrows = 2500000; cols = 20;
rp = 1; % row pointer
% Preallocate A to its maximum possible size
A = zeros(maxrows, cols);
% Open the data file, saving the file pointer.
fid = fopen('statfile.dat', 'r');
while true
    % Read from file into a cell array. Stop at EOF.
    block = textscan(fid, '%n', blocksize*cols);
    if isempty(block{1}) break, end;
    % Convert cell array to matrix, reshape, place into A.
    A(rp:rp+blocksize-1, 1:cols) = ...
        reshape(cell2mat(block), blocksize, cols);
    % Process the data in A.
    evaluate_stats(A); % User-defined function
    % Update row pointer
```

```
    rp = rp + blocksize;
end
```

Note If you eventually need more room in a matrix than you had preallocated, you can preallocate additional storage in the same manner, and concatenate this additional storage onto the original array.

## Shifting and Sorting Matrices

In this section...<br>"Shift and Sort Functions" on page 1-35<br>"Shifting the Location of Matrix Elements" on page 1-35<br>"Sorting the Data in Each Column" on page 1-37<br>"Sorting the Data in Each Row" on page 1-37<br>"Sorting Row Vectors" on page 1-38

## Shift and Sort Functions

Use these functions to shift or sort the elements of a matrix.

| Function | Description |
| :--- | :--- |
| circshift | Circularly shift matrix contents. |
| sort | Sort array elements in ascending or descending order. |
| sortrows | Sort rows in ascending order. |
| issorted | Determine if matrix elements are in sorted order. |

You can sort matrices, multidimensional arrays, and cell arrays of strings along any dimension and in ascending or descending order of the elements. The sort functions also return an optional array of indices showing the order in which elements were rearranged during the sorting operation.

## Shifting the Location of Matrix Elements

The circshift function shifts the elements of a matrix in a circular manner along one or more dimensions. Rows or columns that are shifted out of the matrix circulate back into the opposite end. For example, shifting a 4 -by- 7 matrix one place to the left moves the elements in columns 2 through 7 to columns 1 through 6 , and moves column 1 to column 7 .

Create a 5 -by- 8 matrix named $A$ and shift it to the right along the second (horizontal) dimension by three places. (You would use [0, -3] to shift to the left by three places):

```
A = [1:8; 11:18; 21:28; 31:38; 41:48]
A =
\begin{tabular}{rrrrrrrr}
1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\
11 & 12 & 13 & 14 & 15 & 16 & 17 & 18 \\
21 & 22 & 23 & 24 & 25 & 26 & 27 & 28 \\
31 & 32 & 33 & 34 & 35 & 36 & 37 & 38 \\
41 & 42 & 43 & 44 & 45 & 46 & 47 & 48
\end{tabular}
B = circshift(A, [0, 3])
B =
\begin{tabular}{rrrrrrrr}
6 & 7 & 8 & 1 & 2 & 3 & 4 & 5 \\
16 & 17 & 18 & 11 & 12 & 13 & 14 & 15 \\
26 & 27 & 28 & 21 & 22 & 23 & 24 & 25 \\
36 & 37 & 38 & 31 & 32 & 33 & 34 & 35 \\
46 & 47 & 48 & 41 & 42 & 43 & 44 & 45
\end{tabular}
```

Now take A and shift it along both dimensions: three columns to the right and two rows up:

```
A = [1:8; 11:18; 21:28; 31:38; 41:48];
B = circshift(A, [-2, 3])
B =
\begin{tabular}{rrrrrrrr}
26 & 27 & 28 & 21 & 22 & 23 & 24 & 25 \\
36 & 37 & 38 & 31 & 32 & 33 & 34 & 35 \\
46 & 47 & 48 & 41 & 42 & 43 & 44 & 45 \\
6 & 7 & 8 & 1 & 2 & 3 & 4 & 5 \\
16 & 17 & 18 & 11 & 12 & 13 & 14 & 15
\end{tabular}
```

Since circshift circulates shifted rows and columns around to the other end of a matrix, shifting by the exact size of A returns all rows and columns to their original location:

```
B = circshift(A, size(A));
all(B(:) == A(:)) % Do all elements of B equal A?
ans =
    1 % Yes
```

## Sorting the Data in Each Column

The sort function sorts matrix elements along a specified dimension. The syntax for the function is

```
sort(matrix, dimension)
```

To sort the columns of a matrix, specify 1 as the dimension argument. To sort along rows, specify dimension as 2 .

This example makes a 6 -by- 7 arbitrary test matrix:
A=floor (gallery ('uniformdata', $\left[\begin{array}{llllllr}6 & 7], 0) * 100) \\ \mathrm{A}= \\ 95 & 45 & 92 & 41 & 13 & 1 & 84 \\ 23 & 1 & 73 & 89 & 20 & 74 & 52 \\ 60 & 82 & 17 & 5 & 19 & 44 & 20 \\ 48 & 44 & 40 & 35 & 60 & 93 & 67 \\ 89 & 61 & 93 & 81 & 27 & 46 & 83 \\ 76 & 79 & 91 & 0 & 19 & 41 & 1\end{array}\right.$

Sort each column of A in ascending order:

```
c = sort(A, 1)
C =
\begin{tabular}{rrrrrrr}
23 & 1 & 17 & 0 & 13 & 1 & 1 \\
48 & 44 & 40 & 5 & 19 & 41 & 20 \\
60 & 45 & 73 & 35 & 19 & 44 & 52 \\
76 & 61 & 91 & 41 & 20 & 46 & 67 \\
89 & 79 & 92 & 81 & 27 & 74 & 83 \\
95 & 82 & 93 & 89 & 60 & 93 & 84
\end{tabular}
issorted(c(:, 1))
ans =
    1
```

## Sorting the Data in Each Row

Use issorted to sort data in each row. Using the example above, if you sort each row of A in descending order, issorted tests for an ascending sequence. You can flip the vector to test for a sorted descending sequence:

```
A=floor(gallery('uniformdata',[6 7],0)*100);
r = sort(A, 2, 'descend')
r =
    95 92 84 84 45 41 13 13
    89
    82 60 44 44 20 19 19 17 5
    93 67 60 40 48 44 40 40
    93 89 83 83 81 
    91
issorted(fliplr(r(1, :)))
ans =
    1
```

When you specify a second output, sort returns the indices of the original matrix A positioned in the order they appear in the output matrix. In this next example, the second row of index contains the sequence 4325 1, which means that the sorted elements in output matrix $r$ were taken from $A(2,4)$, $A(2,3), A(2,2), A(2,5)$, and $A(2,1)$ :

## Sorting Row Vectors

The sortrows function keeps the elements of each row in its original order, but sorts the entire row of vectors according to the order of the elements in the specified column.

The next example creates a random matrix A:

```
A=floor(gallery('uniformdata',[6 7],0)*100);
A =
\begin{tabular}{rrrrrrr}
95 & 45 & 92 & 41 & 13 & 1 & 84 \\
23 & 1 & 73 & 89 & 20 & 74 & 52 \\
60 & 82 & 17 & 5 & 19 & 44 & 20 \\
48 & 44 & 40 & 35 & 60 & 93 & 67 \\
89 & 61 & 93 & 81 & 27 & 46 & 83 \\
76 & 79 & 91 & 0 & 19 & 41 & 1
\end{tabular}
```

To sort in ascending order based on the values in column 1, you can call sortrows with just the one input argument:

| sortrows (A) <br> $r=$ |  |  |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: |
| 23 | 1 | 73 | 89 | 20 | 74 | 52 |
| 48 | 44 | 40 | 35 | 60 | 93 | 67 |
| 60 | 82 | 17 | 5 | 19 | 44 | 20 |
| 76 | 79 | 91 | 0 | 19 | 41 | 1 |
| 89 | 61 | 93 | 81 | 27 | 46 | 83 |
| 95 | 45 | 92 | 41 | 13 | 1 | 84 |

To base the sort on a column other than the first, call sortrows with a second input argument that indicates the column number, column 4 in this case:

| $r=$ | $\operatorname{sortrows}(A, 4)$ |  |  |  |  |  |
| ---: | :--- | ---: | ---: | ---: | ---: | ---: |
| $r=$ |  |  |  |  |  |  |
| 76 | 79 | 91 | 0 | 19 | 41 | 1 |
| 60 | 82 | 17 | 5 | 19 | 44 | 20 |
| 48 | 44 | 40 | 35 | 60 | 93 | 67 |
| 95 | 45 | 92 | 41 | 13 | 1 | 84 |
| 89 | 61 | 93 | 81 | 27 | 46 | 83 |
| 23 | 1 | 73 | 89 | 20 | 74 | 52 |

## Operating on Diagonal Matrices

## In this section...

"Diagonal Matrix Functions" on page 1-40
"Constructing a Matrix from a Diagonal Vector" on page 1-40
"Returning a Triangular Portion of a Matrix" on page 1-41
"Concatenating Matrices Diagonally" on page 1-41

## Diagonal Matrix Functions

There are several MATLAB functions that work specifically on diagonal matrices.

| Function | Description |
| :--- | :--- |
| blkdiag | Construct a block diagonal matrix from input arguments. |
| diag | Return a diagonal matrix or the diagonals of a matrix. |
| trace | Compute the sum of the elements on the main diagonal. |
| tril | Return the lower triangular part of a matrix. |
| triu | Return the upper triangular part of a matrix. |

## Constructing a Matrix from a Diagonal Vector

The diag function has two operations that it can perform. You can use it to generate a diagonal matrix:

| A $=\operatorname{diag}([12: 4: 32])$ |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| A $=$ |  |  |  |  |  |
| 12 | 0 | 0 | 0 | 0 | 0 |
| 0 | 16 | 0 | 0 | 0 | 0 |
| 0 | 0 | 20 | 0 | 0 | 0 |
| 0 | 0 | 0 | 24 | 0 | 0 |
| 0 | 0 | 0 | 0 | 28 | 0 |
| 0 | 0 | 0 | 0 | 0 | 2 |

You can also use the diag function to scan an existing matrix and return the values found along one of the diagonals:

```
A = magic(5)
A =
\begin{tabular}{rrrrr}
17 & 24 & 1 & 8 & 15 \\
23 & 5 & 7 & 14 & 16 \\
4 & 6 & 13 & 20 & 22 \\
10 & 12 & 19 & 21 & 3 \\
11 & 18 & 25 & 2 & 9
\end{tabular}
diag(A, 2) % Return contents of second diagonal of A
ans =
    1
    14
    22
```

## Returning a Triangular Portion of a Matrix

The tril and triu functions return a triangular portion of a matrix, the former returning the piece from the lower left and the latter from the upper right. By default, the main diagonal of the matrix divides these two segments. You can use an alternate diagonal by specifying an offset from the main diagonal as a second input argument:

```
A = magic(6);
B = tril(A, -1)
B =
\begin{tabular}{rrrrrr}
0 & 0 & 0 & 0 & 0 & 0 \\
3 & 0 & 0 & 0 & 0 & 0 \\
31 & 9 & 0 & 0 & 0 & 0 \\
8 & 28 & 33 & 0 & 0 & 0 \\
30 & 5 & 34 & 12 & 0 & 0 \\
4 & 36 & 29 & 13 & 18 & 0
\end{tabular}
```

## Concatenating Matrices Diagonally

You can diagonally concatenate matrices to form a composite matrix using the blkdiag function. See "Creating a Block Diagonal Matrix" on page 1-9 for more information on how this works.

## Empty Matrices, Scalars, and Vectors

In this section...<br>"Overview" on page 1-42<br>"The Empty Matrix" on page 1-43<br>"Scalars" on page 1-45<br>"Vectors" on page 1-46

## Overview

Although matrices are two dimensional, they do not always appear to have a rectangular shape. A 1-by-8 matrix, for example, has two dimensions yet is linear. These matrices are described in the following sections:

- "The Empty Matrix" on page 1-43

An empty matrix has one of more dimensions that are equal to zero. A two-dimensional matrix with both dimensions equal to zero appears in the MATLAB application as []. The expression A = [] assigns a 0-by-0 empty matrix to $A$.

- "Scalars" on page 1-45

A scalar is 1-by-1 and appears in MATLAB as a single real or complex number (e.g., 7, 583.62, -3.51, 5.46097e-14, 83+4i).

- "Vectors" on page 1-46

A vector is 1-by-n or n-by-1, and appears in MATLAB as a row or column of real or complex numbers:

```
Column Vector Row Vector
    53.2 53.2 87.39 4-12i 43.9
    87.39
    4-12i
    4 3 . 9
```

## The Empty Matrix

A matrix having at least one dimension equal to zero is called an empty matrix. The simplest empty matrix is 0 -by- 0 in size. Examples of more complex matrices are those of dimension 0 -by- 5 or 10-by- 0 .

To create a 0 -by- 0 matrix, use the square bracket operators with no value specified:

```
A = [];
whos A
    Name Size Bytes Class
    A 0x0 0 double array
```

You can create empty matrices (and arrays) of other sizes using the zeros, ones, rand, or eye functions. To create a 0 -by- 5 matrix, for example, use

```
A = zeros(0,5)
```

## Operating on an Empty Matrix

The basic model for empty matrices is that any operation that is defined for $m$-by-n matrices, and that produces a result whose dimension is some function of $m$ and $n$, should still be allowed when $m$ or $n$ is zero. The size of the result of this operation is consistent with the size of the result generated when working with nonempty values, but instead is evaluated at zero.

For example, horizontal concatenation

$$
C=\left[\begin{array}{ll}
A & B
\end{array}\right]
$$

requires that $A$ and $B$ have the same number of rows. So if $A$ is $m-b y-n$ and $B$ is $m$-by- $p$, then $C$ is $m-b y-(n+p)$. This is still true if $m$ or $n$ or $p$ is zero.

As with all matrices in MATLAB, you must follow the rules concerning compatible dimensions. In the following example, an attempt to add a 1-by-3 matrix to a 0 -by- 3 empty matrix results in an error:

```
[1 2 3] + ones(0,3)
??? Error using ==> +
Matrix dimensions must agree.
```

Common Operations. The following operations return zero on an empty array:

```
A = [];
size(A), length(A), numel(A), any(A), sum(A)
```

These operations return a nonzero value on an empty array :

```
A = [];
ndims(A), isnumeric(A), isreal(A), isfloat(A), isempty(A), ...
    all(A), prod(A)
```

## Using Empty Matrices in Relational Operations

You can use empty matrices in relational operations such as "equal to" (==) or "greater than" (>) as long as both operands have the same dimensions, or the nonempty operand is scalar. The result of any relational operation involving an empty matrix is the empty matrix. Even comparing an empty matrix for equality to itself does not return true, but instead yields an empty matrix:

```
x = ones(0,3);
y = x;
y == x
ans =
    Empty matrix: 0-by-3
```

## Using Empty Matrices in Logical Operations

MATLAB has two distinct types of logical operators:

- Short-circuit (\&\&, ||) — Used in testing multiple logical conditions (e.g., $x>=50 \& \& x<100)$ where each condition evaluates to a scalar true or false.
- Element-wise (\&, |) - Performs a logical AND, OR, or NOT on each element of a matrix or array.

Short-circuit Operations. The rule for operands used in short-circuit operations is that each operand must be convertible to a logical scalar value. Because of this rule, empty matrices cannot be used in short-circuit logical operations. Such operations return an error.

The only exception is in the case where MATLAB can determine the result of a logical statement without having to evaluate the entire expression. This is true for the following two statements because the result of the entire statements are known by considering just the first term:

```
true || []
ans =
    1
false && []
ans =
    0
```

Elementwise Operations. Unlike the short-circuit operators, all elementwise operations on empty matrices are considered valid as long as the dimensions of the operands agree, or the nonempty operand is scalar. Element-wise operations on empty matrices always return an empty matrix:

```
true | []
ans =
```

    []
    Note This behavior is consistent with the way MATLAB does scalar expansion with binary operators, wherein the nonscalar operand determines the size of the result.

## Scalars

Any individual real or complex number is represented in MATLAB as a 1-by-1 matrix called a scalar value:

```
A = 5;
```

```
ndims(A) % Check number of dimensions in A
```

```
ans =
    2
size(A) % Check value of row and column dimensions
ans =
    1 1
```

Use the isscalar function to tell if a variable holds a scalar value:

```
isscalar(A)
ans =
    1
```

## Vectors

Matrices with one dimension equal to one and the other greater than one are called vectors. Here is an example of a numeric vector:

```
A = [5.73 2-4i 9/7 25e3 .046 sqrt(32) 8j];
size(A) % Check value of row and column dimensions
ans =
    1 7
```

You can construct a vector out of other vectors, as long as the critical dimensions agree. All components of a row vector must be scalars or other row vectors. Similarly, all components of a column vector must be scalars or other column vectors:

```
A = [29 43 77 9 21];
B = [0 46 11];
C = [A 5 ones(1,3) B]
C =
    29
```

Concatenating an empty matrix to a vector has no effect on the resulting vector. The empty matrix is ignored in this case:

```
A = [5.36; 7.01; []; 9.44]
A =
```

> 5.3600
> 7.0100
> 9.4400

Use the isvector function to tell if a variable holds a vector:

```
isvector(A)
```

ans =
1

## Full and Sparse Matrices

In this section...<br>"Overview" on page 1-48<br>"Sparse Matrix Functions" on page 1-48

## Overview

It is not uncommon to have matrices with a large number of zero-valued elements and, because the MATLAB software stores zeros in the same way it stores any other numeric value, these elements can use memory space unnecessarily and can sometimes require extra computing time.

Sparse matrices provide a way to store data that has a large percentage of zero elements more efficiently. While full matrices internally store every element in memory regardless of value, sparse matrices store only the nonzero elements and their row indices. Using sparse matrices can significantly reduce the amount of memory required for data storage.

You can create sparse matrices for the double and logical classes. All MATLAB built-in arithmetic, logical, and indexing operations can be applied to sparse matrices, or to mixtures of sparse and full matrices. Operations on sparse matrices return sparse matrices and operations on full matrices return full matrices.

See the section on Sparse Matrices in the MATLAB Mathematics documentation for more information on working with sparse matrices.

## Sparse Matrix Functions

This table shows some of the functions most commonly used when working with sparse matrices.

| Function | Description |
| :--- | :--- |
| full | Convert a sparse matrix to a full matrix. |
| issparse | Determine if a matrix is sparse. |

| Function | Description |
| :--- | :--- |
| nnz | Return the number of nonzero matrix elements. |
| nonzeros | Return the nonzero elements of a matrix. |
| nzmax | Return the amount of storage allocated for nonzero <br> elements. |
| spalloc | Allocate space for a sparse matrix. |
| sparse | Create a sparse matrix or convert full to sparse. |
| speye | Create a sparse identity matrix. |
| sprand | Create a sparse uniformly distributed random matrix. |

## Overview

An array having more than two dimensions is called a multidimensional array in the MATLAB application. Multidimensional arrays in MATLAB are an extension of the normal two-dimensional matrix. Matrices have two dimensions: the row dimension and the column dimension.

You can access a two-dimensional matrix element with two subscripts: the first representing the row index, and the second representing the column index.

Multidimensional arrays use additional subscripts for indexing. A three-dimensional array, for example, uses three subscripts:

- The first references array dimension 1 , the row.
- The second references dimension 2 , the column.
- The third references dimension 3. This illustration uses the concept of a page to represent dimensions 3 and higher.

To access the element in the second row, third column of page 2, for example, you use the subscripts $(2,3,2)$.

As you add dimensions to an array, you also add subscripts. A four-dimensional array, for example, has four subscripts. The first two
reference a row-column pair; the second two access the third and fourth dimensions of data.

Most of the operations that you can perform on matrices (i.e., two-dimensional arrays) can also be done on multidimensional arrays.

Note The general multidimensional array functions reside in the datatypes directory.

## Creating Multidimensional Arrays

You can use the same techniques to create multidimensional arrays that you use for two-dimensional matrices. In addition, MATLAB provides a special concatenation function that is useful for building multidimensional arrays.

This section discusses

- "Generating Arrays Using Indexing" on page 1-52
- "Extending Multidimensional Arrays" on page 1-53
- "Generating Arrays Using MATLAB Functions" on page 1-54
- "Building Multidimensional Arrays with the cat Function" on page 1-54

## Generating Arrays Using Indexing

One way to create a multidimensional array is to create a two-dimensional array and extend it. For example, begin with a simple two-dimensional array A.

$$
A=[578 ; 019 ; 436] ;
$$

A is a 3 -by- 3 array, that is, its row dimension is 3 and its column dimension is 3 . To add a third dimension to A ,

$$
A(:,:, 2)=[104 ; 356 ; 987]
$$

MATLAB responds with

$$
A(:,:, 1)=
$$

| 5 | 7 | 8 |
| :---: | :---: | :---: |
| 0 | 1 | 9 |
| 4 | 3 | 6 |
| $\mathrm{~A}(:,:, 2)$ |  |  |
| 1 | 0 | 4 |
| 3 | 5 | 6 |
| 9 | 8 | 7 |

You can continue to add rows, columns, or pages to the array using similar assignment statements.

## Extending Multidimensional Arrays

To extend A in any dimension:

- Increment or add the appropriate subscript and assign the desired values.
- Assign the same number of elements to corresponding array dimensions. For numeric arrays, all rows must have the same number of elements, all pages must have the same number of rows and columns, and so on.

You can take advantage of the MATLAB scalar expansion capabilities, together with the colon operator, to fill an entire dimension with a single value:

```
A(:,:,3) = 5;
A(:,:,3)
ans =
\begin{tabular}{lll}
5 & 5 & 5 \\
5 & 5 & 5 \\
5 & 5 & 5
\end{tabular}
```

To turn A into a 3-by-3-by-3-by-2, four-dimensional array, enter
$A(:,:, 1,2)=\left[\begin{array}{lllllllll}1 & 2 & 3 ; & 4 & 5 & 6 ; 7 & 8 & 9\end{array}\right] ;$
$A(:,:, 2,2)=\left[\begin{array}{lllll}9 & 8 & 7 ; & 6 & 5 \\ 4 & 3 & 3 & 2 & 1\end{array}\right] ;$
$A(:,:, 3,2)=\left[\begin{array}{lllllll}1 & 0 & 1 ; & 1 & 1 & 0 ; & 1\end{array}\right]$

Note that after the first two assignments MATLAB pads A with zeros, as needed, to maintain the corresponding sizes of dimensions.

## Generating Arrays Using MATLAB Functions

You can use MATLAB functions such as randn, ones, and zeros to generate multidimensional arrays in the same way you use them for two-dimensional arrays. Each argument you supply represents the size of the corresponding dimension in the resulting array. For example, to create a 4 -by- 3 -by- 2 array of normally distributed random numbers:

$$
B=\operatorname{randn}(4,3,2)
$$

To generate an array filled with a single constant value, use the repmat function. repmat replicates an array (in this case, a 1-by-1 array) through a vector of array dimensions.

| $B=\operatorname{repmat}(5, \quad[342])$ |  |  |  |
| :---: | :---: | :---: | :---: |
| $B(:,:, 1)=$ |  |  |  |
| 5 | 5 | 5 |  |
| 5 | 5 | 5 |  |
| 5 | 5 | 5 |  |
| $\mathrm{B}(:, \mathrm{l}, 2)=$ |  |  |  |
| 5 | 5 | 5 |  |
| 5 | 5 | 5 |  |
| 5 | 5 | 5 |  |

Note Any dimension of an array can have size zero, making it a form of empty array. For example, 10-by-0-by-20 is a valid size for a multidimensional array.

## Building Multidimensional Arrays with the cat Function

The cat function is a simple way to build multidimensional arrays; it concatenates a list of arrays along a specified dimension:

```
B = cat(dim, A1, A2...)
```

where A1, A2, and so on are the arrays to concatenate, and dim is the dimension along which to concatenate the arrays.

For example, to create a new array with cat:

```
\(B=\operatorname{cat}(3,[28 ; 05],[13 ; 79])\)
\(B(:,:, 1)=\)
    28
    \(0 \quad 5\)
B(:,:,2) =
    13
    79
```

The cat function accepts any combination of existing and new data. In addition, you can nest calls to cat. The lines below, for example, create a four-dimensional array.

```
A = cat(3, [9 2; 6 5], [7 1; 8 4])
B = cat(3, [3 5; 0 1], [5 6; 2 1])
D = cat(4, A, B, cat(3, [1 2; 3 4], [4 3;2 1]))
```

cat automatically adds subscripts of 1 between dimensions, if necessary. For example, to create a 2 -by-2-by-1-by- 2 array, enter

```
C = cat(4, [1 2; 4 5], [7 8; 3 2])
```

In the previous case, cat inserts as many singleton dimensions as needed to create a four-dimensional array whose last dimension is not a singleton dimension. If the dim argument had been 5 , the previous statement would have produced a 2 -by-2-by-1-by-1-by- 2 array. This adds additional 1 s to indexing expressions for the array. To access the value 8 in the four-dimensional case, use

index

## Accessing Multidimensional Array Properties

You can use the following MATLAB functions to get information about multidimensional arrays you have created.

- size - Returns the size of each array dimension.

```
size(C)
ans =
\begin{tabular}{cccc}
2 & 2 & 1 & 2 \\
rows & columns & dim3 & \(\operatorname{dim} 4\)
\end{tabular}
```

- ndims - Returns the number of dimensions in the array.
ndims(C)
ans $=$
4
- whos - Provides information on the format and storage of the array.

| whos |  |  |  |
| :--- | :--- | ---: | :--- |
| Name | Size | Bytes | Class |
| A | 2x2x2 | 64 | double array |
| B | 2x2x2 | 64 | double array |
| C | $4-D$ | 64 | double array |
| D | $4-D$ | 192 | double array |

Grand total is 48 elements using 384 bytes

## Indexing Multidimensional Arrays

Many of the concepts that apply to two-dimensional matrices extend to multidimensional arrays as well.

To access a single element of a multidimensional array, use integer subscripts. Each subscript indexes a dimension-the first indexes the row dimension, the second indexes the column dimension, the third indexes the first page dimension, and so on.

Consider a 10 -by- 5 -by- 3 array nddata of random integers:

```
nddata = fix(8 * randn(10,5,3));
```

To access element $(3,2)$ on page 2 of nddata, for example, use nddata $(3,2,2)$.
You can use vectors as array subscripts. In this case, each vector element must be a valid subscript, that is, within the bounds defined by the dimensions of the array. To access elements $(2,1),(2,3)$, and $(2,4)$ on page 3 of nddata, use

```
nddata(2,[11 3 4],3);
```

## The Colon and Multidimensional Array Indexing

The MATLAB colon indexing extends to multidimensional arrays. For example, to access the entire third column on page 2 of nddata, use nddata(:,3,2).

The colon operator is also useful for accessing other subsets of data. For example, nddata $(2: 3,2: 3,1)$ results in a 2 -by- 2 array, a subset of the data on page 1 of nddata. This matrix consists of the data in rows 2 and 3, columns 2 and 3 , on the first page of the array.

The colon operator can appear as an array subscript on both sides of an assignment statement. For example, to create a 4 -by- 4 array of zeros:

$$
C=\operatorname{zeros}(4,4)
$$

Now assign a 2 -by- 2 subset of array nddata to the four elements in the center of C.

$$
C(2: 3,2: 3)=\operatorname{nddata}(2: 3,1: 2,2)
$$

## Linear Indexing with Multidimensional Arrays

MATLAB linear indexing also extends to multidimensional arrays. In this case, MATLAB operates on a page-by-page basis to create the storage column, again appending elements columnwise. See "Linear Indexing" on page 1-13 for an introduction to this topic.

For example, consider a 5 -by-4-by-3-by- 2 array C.
Matlabdisplays $C$ as
MATLABstores C as

Again, a single subscript indexes directly into this column. For example, C(4) produces the result

```
ans =
```

0
If you specify two subscripts ( $i, j$ ) indicating row-column indices, MATLAB calculates the offset as described above. Two subscripts always access the first page of a multidimensional array, provided they are within the range of the original array dimensions.

If more than one subscript is present, all subscripts must conform to the original array dimensions. For example, $\mathrm{C}(6,2)$ is invalid because all pages of $C$ have only five rows.

If you specify more than two subscripts, MATLAB extends its indexing scheme accordingly. For example, consider four subscripts (i, j, k, l) into a four-dimensional array with size [d1 d2 d3 d4]. MATLAB calculates the offset into the storage column by

$$
(\mathrm{l}-1)(\mathrm{d} 3)(\mathrm{d} 2)(\mathrm{d} 1)+(\mathrm{k}-1)(\mathrm{d} 2)(\mathrm{d} 1)+(\mathrm{j}-1)(\mathrm{d} 1)+\mathrm{i}
$$

For example, if you index the array C using subscripts (3, 4, 2, 1), MATLAB returns the value 5 (index 38 in the storage column).

In general, the offset formula for an array with dimensions [ $\begin{array}{lll}d_{1} & d_{2} & d_{3}\end{array} \ldots$ $d_{n}$ ] using any subscripts ( $\mathrm{s}_{1} \mathrm{~s}_{2} \mathrm{~s}_{3} \ldots \mathrm{~s}_{\mathrm{n}}$ ) is

$$
\left(s_{n}-1\right)\left(d_{n-1}\right)\left(d_{n-2}\right) \ldots\left(d_{1}\right)+\left(s_{n-1}-1\right)\left(d_{n-2}\right) \ldots\left(d_{1}\right)+\ldots+\left(s_{2}-1\right)\left(d_{1}\right)+s_{1}
$$

Because of this scheme, you can index an array using any number of subscripts. You can append any number of 1 s to the subscript list because these terms become zero. For example,

$$
C(3,2,1,1,1,1,1,1)
$$

is equivalent to

```
C(3,2)
```

## Avoiding Ambiguity in Multidimensional Indexing

Some assignment statements, such as

$$
A(:,:, 2)=1: 10
$$

are ambiguous because they do not provide enough information about the shape of the dimension to receive the data. In the case above, the statement tries to assign a one-dimensional vector to a two-dimensional destination. MATLAB produces an error for such cases. To resolve the ambiguity, be sure you provide enough information about the destination for the assigned data, and that both data and destination have the same shape. For example:

$$
A(1,:, 2)=1: 10 ;
$$

## Reshaping Multidimensional Arrays

Unless you change its shape or size, a MATLAB array retains the dimensions specified at its creation. You change array size by adding or deleting elements. You change array shape by respecifying the array's row, column, or page dimensions while retaining the same elements. The reshape function performs the latter operation. For multidimensional arrays, its form is

```
B = reshape(A,[s1 s2 s3 ...])
```

$s 1, s 2$, and so on represent the desired size for each dimension of the reshaped matrix. Note that a reshaped array must have the same number of elements as the original array (that is, the product of the dimension sizes is constant).

| M | reshape(M, [6 5]) |
| :---: | :---: |
| $\ldots{ }^{(4)}$ | $\left\lvert\, \begin{array}{lllll}1 & 3 & 5 & 7 & 5 \\ 9 & 6 & 7 & 5 & 5 \\ 8 & 5 & 2 & 9 & 3 \\ 2 & 4 & 9 & 8 & 2\end{array}\right.$ |
| $\left.\begin{array}{lllll}1 & 2 & 3 & 4 & 5 \\ 9 & 0 & 6 & 3 & 7 \\ 8 & 1 & 5 & 0 & 2\end{array}\right]$ | $\begin{array}{lllll}2 & 4 & 9 & 8 & 2 \\ 0 & 3 & 3 & 8 & 1 \\ 1 & 0 & 6 & 4 & 3\end{array}$ |

The reshape function operates in a columnwise manner. It creates the reshaped matrix by taking consecutive elements down each column of the original data construct.

| C | reshape(C, [6 2]) |
| :---: | :---: |
|  | 1 6 <br> 3 8 <br> 2 9 <br> 4 11 <br> 5 10 <br> 7 12 |

Here are several new arrays from reshaping nddata:

```
B = reshape(nddata, [6 25])
C = reshape(nddata, [5 3 10])
D = reshape(nddata, [5 3 2 5])
```

## Removing Singleton Dimensions

MATLAB creates singleton dimensions if you explicitly specify them when you create or reshape an array, or if you perform a calculation that results in an array dimension of one:

```
B = repmat(5, [2 3 1 4]);
size(B)
ans =
    2 3 1 4
```

The squeeze function removes singleton dimensions from an array:

```
C = squeeze(B);
size(C)
ans =
    2 3 4
```

The squeeze function does not affect two-dimensional arrays; row vectors remain rows.

## Permuting Array Dimensions

The permute function reorders the dimensions of an array:

$$
B=\text { permute(A, dims); }
$$

dims is a vector specifying the new order for the dimensions of A , where 1 corresponds to the first dimension (rows), 2 corresponds to the second dimension (columns), 3 corresponds to pages, and so on.

For a more detailed look at the permute function, consider a four-dimensional array A of size 5 -by- 4 -by-3-by-2. Rearrange the dimensions, placing the column dimension first, followed by the second page dimension, the first page dimension, then the row dimension. The result is a 4 -by- 2 -by- 3 -by- 5 array.

```
Move dimension 2 of A to first subscipt position of \(B\), dimension 4 to second subscript position, and so on.
```

> The order of dimensions in pe rmut e's argument list determines the size and shope of the output array. In this exomple, the second dimension moves to the first position. Becouse the second dimension of the originol aroy had size 4, the output arroy's first dimension abo hos size 4.

You can think of permute's operation as an extension of the transpose function, which switches the row and column dimensions of a matrix. For permute, the order of the input dimension list determines the reordering of the subscripts. In the example above, element $(4,2,1,2)$ of $A$ becomes element $(2,2,1,4)$ of $B$, element $(5,4,3,2)$ of $A$ becomes element $(4,2,3,5)$ of $B$, and so on.

## Inverse Permutation

The ipermute function is the inverse of permute. Given an input array $A$ and a vector of dimensions $v$, ipermute produces an array $B$ such that permute ( $B, v$ ) returns $A$.

For example, these statements create an array E that is equal to the input array C:

```
D = ipermute(C, [14 4 2 3]);
E = permute(D, [1 1 4 2 3])
```

You can obtain the original array after permuting it by calling ipermute with the same vector of dimensions.

## Computing with Multidimensional Arrays

Many of the MATLAB computational and mathematical functions accept multidimensional arrays as arguments. These functions operate on specific dimensions of multidimensional arrays; that is, they operate on individual elements, on vectors, or on matrices.

## Operating on Vectors

Functions that operate on vectors, like sum, mean, and so on, by default typically work on the first nonsingleton dimension of a multidimensional array. Most of these functions optionally let you specify a particular dimension on which to operate. There are exceptions, however. For example, the cross function, which finds the cross product of two vectors, works on the first nonsingleton dimension having length 3 .

Note In many cases, these functions have other restrictions on the input arguments - for example, some functions that accept multiple arrays require that the arrays be the same size. Refer to the online help for details on function arguments.

## Operating Element-by-Element

MATLAB functions that operate element-by-element on two-dimensional arrays, like the trigonometric and exponential functions in the elfun directory, work in exactly the same way for multidimensional cases. For example, the sin function returns an array the same size as the function's input argument. Each element of the output array is the sine of the corresponding element of the input array.

Similarly, the arithmetic, logical, and relational operators all work with corresponding elements of multidimensional arrays that are the same size in every dimension. If one operand is a scalar and one an array, the operator applies the scalar to each element of the array.

## Operating on Planes and Matrices

Functions that operate on planes or matrices, such as the linear algebra and matrix functions in the matfun directory, do not accept multidimensional
arrays as arguments. That is, you cannot use the functions in the matfun directory, or the array operators *, ^, <br>, or /, with multidimensional arguments. Supplying multidimensional arguments or operands in these cases results in an error.

You can use indexing to apply a matrix function or operator to matrices within a multidimensional array. For example, create a three-dimensional array A:

```
A = cat(3, [1 2 3; 9 8 7; 4 6 5], [0 3 2; 8 8 4; 5 3 5], ...
    [6 4 7; 6 8 5; 5 4 3]);
```

Applying the eig function to the entire multidimensional array results in an error:

```
eig(A)
??? Error using ==> eig
Input arguments must be 2-D.
```

You can, however, apply eig to planes within the array. For example, use colon notation to index just one page (in this case, the second) of the array:

```
eig(A(:,:,2))
ans =
    12.9129
    -2.6260
    2.7131
```

Note In the first case, subscripts are not colons; you must use squeeze to avoid an error. For example, eig(A(2,:,:)) results in an error because the size of the input is $\left[\begin{array}{lll}1 & 3 & 3\end{array}\right]$. The expression eig(squeeze $\left.(A(2,:,:))\right)$, however, passes a valid two-dimensional matrix to eig.

## Organizing Data in Multidimensional Arrays

You can use multidimensional arrays to represent data in two ways:

- As planes or pages of two-dimensional data. You can then treat these pages as matrices.
- As multivariate or multidimensional data. For example, you might have a four-dimensional array where each element corresponds to either a temperature or air pressure measurement taken at one of a set of equally spaced points in a room.

For example, consider an RGB image. For a single image, a multidimensional array is probably the easiest way to store and access data.

To access an entire plane of the image, use

$$
\text { redPlane }=\operatorname{RGB}(:,:, 1) ;
$$

To access a subimage, use

```
subimage = RGB(20:40,50:85,:);
```

The RGB image is a good example of data that needs to be accessed in planes for operations like display or filtering. In other instances, however, the data itself might be multidimensional. For example, consider a set of temperature measurements taken at equally spaced points in a room. Here the location of each value is an integral part of the data set-the physical placement in three-space of each element is an aspect of the information. Such data also lends itself to representation as a multidimensional array.

Now to find the average of all the measurements, use

```
mean(mean(mean(TEMP)));
```

To obtain a vector of the "middle" values (element (2,2)) in the room on each page, use

$$
B=\operatorname{TEMP}(2,2,:) ;
$$

## Multidimensional Cell Arrays

Like numeric arrays, the framework for multidimensional cell arrays in MATLAB is an extension of the two-dimensional cell array model. You can use the cat function to build multidimensional cell arrays, just as you use it for numeric arrays.

For example, create a simple three-dimensional cell array C:

```
A{1,1} = [1 2;4 5];
A{1,2} = 'Name';
A{2,1} = 2-4i;
```

```
A{2,2} = 7;
B{1,1} = 'Name2';
B{1,2} = 3;
B{2,1} = 0:1:3;
B{2,2} = [4 5]';
C = cat(3, A, B);
```

The subscripts for the cells of C look like

## Multidimensional Structure Arrays

Multidimensional structure arrays are extensions of rectangular structure arrays. Like other types of multidimensional arrays, you can build them using direct assignment or the cat function:

```
patient(1,1,1).name = 'John Doe';
patient(1,1,1).billing = 127.00;
patient(1,1,1).test = [79 75 73; 180 178 177.5; 220 210 205];
patient(1,2,1).name = 'Ann Lane';
patient(1,2,1).billing = 28.50;
patient(1,2,1).test = [68 70 68; 118 118 119; 172 170 169];
patient(1,1,2).name = 'Al Smith';
patient(1,1,2).billing = 504.70;
patient(1,1,2).test = [80 80 80; 153 153 154; 181 190 182];
patient(1,2,2).name = 'Dora Jones';
```

## Applying Functions to Multidimensional Structure Arrays

To apply functions to multidimensional structure arrays, operate on fields and field elements using indexing. For example, find the sum of the columns of the test array in patient $(1,1,2)$ :

```
sum((patient(1,1,2).test));
```

Similarly, add all the billing fields in the patient array:

```
total = sum([patient.billing]);
```

## Summary of Matrix and Array Functions

This section summarizes the principal functions used in creating and handling matrices. Most of these functions work on multidimensional arrays as well.

Functions to Create a Matrix

| Function | Description |
| :--- | :--- |
| $[\mathrm{a}, \mathrm{b}]$ or $[\mathrm{a} ; \mathrm{b}]$ | Create a matrix from specified elements, or concatenate <br> matrices together. |
| accumarray | Construct a matrix using accumulation. |
| blkdiag | Construct a block diagonal matrix. |
| cat | Concatenate matrices along the specified dimension. |
| diag | Create a diagonal matrix from a vector. |
| horzcat | Concatenate matrices horizontally. |
| magic | Create a square matrix with rows, columns, and <br> diagonals that add up to the same number. |
| ones | Create a matrix of all ones. |
| rand | Create a matrix of uniformly distributed random <br> numbers. |
| repmat | Create a new matrix by replicating or tiling another. |
| vertcat | Concatenate two or more matrices vertically. |
| zeros | Create a matrix of all zeros. |

Functions to Modify the Shape of a Matrix

| Function | Description |
| :--- | :--- |
| ctranspose | Flip a matrix about the main diagonal and replace each <br> element with its complex conjugate. |
| flipdim | Flip a matrix along the specified dimension. |
| fliplr | Flip a matrix about a vertical axis. |

## Functions to Modify the Shape of a Matrix (Continued)

| Function | Description |
| :--- | :--- |
| flipud | Flip a matrix about a horizontal axis. |
| reshape | Change the dimensions of a matrix. |
| rot90 | Rotate a matrix by 90 degrees. |
| transpose | Flip a matrix about the main diagonal. |

Functions to Find the Structure or Shape of a Matrix

| Function | Description |
| :--- | :--- |
| isempty | Return true for 0-by-0 or 0-by-n matrices. |
| isscalar | Return true for 1-by-1 matrices. |
| issparse | Return true for sparse matrices. |
| isvector | Return true for 1-by-n matrices. |
| length | Return the length of a vector. |
| ndims | Return the number of dimensions in a matrix. |
| numel | Return the number of elements in a matrix. |
| size | Return the size of each dimension. |

## Functions to Determine Class

| Function | Description |
| :--- | :--- |
| iscell | Return true if the matrix is a cell array. |
| ischar | Return true if matrix elements are characters or <br> strings. |
| isfloat | Determine if input is a floating point array. |
| isinteger | Determine if input is an integer array. |
| islogical | Return true if matrix elements are logicals. |
| isnumeric | Return true if matrix elements are numeric. |

## Functions to Determine Class (Continued)

| Function | Description |
| :--- | :--- |
| isreal | Return true if matrix elements are real numbers. |
| isstruct | Return true if matrix elements are MATLAB <br> structures. |

Functions to Sort and Shift Matrix Elements

| Function | Description |
| :--- | :--- |
| circshift | Circularly shift matrix contents. |
| issorted | Return true if the matrix elements are sorted. |
| sort | Sort elements in ascending or descending order. |
| sortrows | Sort rows in ascending order. |

## Functions That Work on Diagonals of a Matrix

| Function | Description |
| :--- | :--- |
| blkdiag | Construct a block diagonal matrix. |
| diag | Return the diagonals of a matrix. |
| trace | Compute the sum of the elements on the main diagonal. |
| tril | Return the lower triangular part of a matrix. |
| triu | Return the upper triangular part of a matrix. |

## Functions to Change the Indexing Style

| Function | Description |
| :--- | :--- |
| ind2sub | Convert a linear index to a row-column index. |
| sub2ind | Convert a row-column index to a linear index. |

## Functions for Working with Multidimensional Arrays

| Function | Description |
| :--- | :--- |
| cat | Concatenate arrays. |
| circshift | Shift array circularly. |
| ipermute | Inverse permute array dimensions. |
| ndgrid | Generate arrays for n-dimensional functions and <br> interpolation. |
| ndims | Return the number of array dimensions. |
| permute | Permute array dimensions. |
| shiftdim | Shift array dimensions. |
| squeeze | Remove singleton dimensions. |

## MATLAB Linear Algebra Functions

The MATLAB matfun directory contains linear algebra functions. For a complete list, brief descriptions, and links to reference pages, type:

```
help matfun
```

The following table lists the MATLAB linear algebra functions by category.

## Function Summary

| Category | Function | Description |
| :--- | :--- | :--- |
| Matrix analysis | norm | Matrix or vector norm |
|  | normest | Estimate the matrix <br> 2-norm |
|  | rank | Matrix rank |
|  | det | Determinant |
|  | trace | Sum of diagonal <br> elements |
|  | null | Null space |
|  | orth | Orthogonalization |
|  | rref | Reduced row echelon <br> form |
|  | subspace | Angle between two <br> subspaces |

## Function Summary (Continued)

| Category | Function | Description |
| :--- | :--- | :--- |
| Linear equations | l and / | Linear equation <br> solution |
|  | inv | Matrix inverse |
|  | cond | Condition number for <br> inversion |
|  | condest | 1-norm condition <br> number estimate |
|  | chol | Cholesky factorization |
| cholinc | Incomplete Cholesky <br> factorization |  |
|  | linsolve | Solve a system of linear <br> equations |
|  | lu | LU factorization |
| ilu | Incomplete LU <br> factorization |  |
|  | luinc | Incomplete LU <br> factorization |
|  | qr | Orthogonal-triangular <br> decomposition |
|  | lsqnonneg | Nonnegative <br> least-squares |
|  | pinv | Least squares with <br> known covariance |
| lscov |  |  |

## Function Summary (Continued)

| Category | Function | Description |
| :--- | :--- | :--- |
| Eigenvalues and <br> singular values | eig | Eigenvalues and <br> eigenvectors |
|  | svd | Singular value <br> decomposition |
|  | eigs | A few eigenvalues |
|  | svds | A few singular values |
| poly | Characteristic <br> polynomial |  |
|  | polyeig | Polynomial eigenvalue <br> problem |
|  | condeig | Condition number for <br> eigenvalues |
|  | hess | Hessenberg form |
|  | qz | QZ factorization |
| Matrix functions | schur | Schur decomposition |
|  | expm | Matrix exponential |
|  | logm | Matrix logarithm |
|  | sqrtm | Matrix square root |
| funm | Evaluate general <br> matrix function |  |

## Creating Matrices

The MATLAB environment uses the term matrix to indicate a variable containing real or complex numbers arranged in a two-dimensional grid. An array is, more generally, a vector, matrix, or higher-dimensional grid of numbers. All arrays in MATLAB are rectangular, in the sense that the component vectors along any dimension are all the same length.

Symbolic Math Toolbox ${ }^{\text {TM }}$ software extends the capabilities of MATLAB software to matrices of mathematical expressions.

MATLAB has dozens of functions that create different kinds of matrices. There are two functions you can use to create a pair of 3 -by- 3 example matrices for use throughout this chapter. The first example is symmetric:
$A=\operatorname{pascal}(3)$
$A=$

1 |  |  |  |
| :--- | :--- | :--- |
| 1 | 1 | 1 |
| 1 | 3 | 3 |
|  |  | 3 |

The second example is not symmetric:

```
B = magic(3)
B =
\begin{tabular}{lll}
8 & 1 & 6 \\
3 & 5 & 7 \\
4 & 9 & 2
\end{tabular}
```

Another example is a 3 -by- 2 rectangular matrix of random integers:

```
C = fix(10*rand(3,2))
C =
    9 4
    2
    6
```

A column vector is an $m$-by- 1 matrix, a row vector is a 1-by- $n$ matrix, and a scalar is a 1 -by- 1 matrix. The statements

```
u = [3; 1; 4]
v = [2 0 -1]
s = 7
```

produce a column vector, a row vector, and a scalar:
$u=$
3
1
4
v =
$2 \quad 0 \quad-1$
s =
7
For more information about creating and working with matrices, see in MATLAB Programming Fundamentals.

## Adding and Subtracting Matrices

Addition and subtraction of matrices is defined just as it is for arrays, element by element. Adding A to B and then subtracting A from the result recovers B:

```
A = pascal(3);
B = magic(3);
X = A + B
X =
    9
    4 7 10
    5 12 8
Y = X - A
Y =
    8 1 6
    3
    4 9 2
```

Addition and subtraction require both matrices to have the same dimension, or one of them be a scalar. If the dimensions are incompatible, an error results:

```
C = fix(10*rand(3,2))
X = A + C
Error using ==> +
Matrix dimensions must agree.
w = v + s
w =
    9 7 6
```

## Vector Products and Transpose

A row vector and a column vector of the same length can be multiplied in either order. The result is either a scalar, the inner product, or a matrix, the outer product :

```
u = [3; 1; 4];
v = [2 0 -1];
```

```
\(\mathrm{x}=\mathrm{v} * u\)
x =
            2
\(\mathrm{X}=\mathrm{u*} \mathrm{v}\)
X =
\(6 \quad 0 \quad-3\)
\(20-1\)
\(8 \quad 0 \quad-4\)
```

For real matrices, the transpose operation interchanges $a_{i j}$ and $\alpha_{j i}$. MATLAB uses the apostrophe operator (') to perform a complex conjugate transpose, and uses the dot-apostrophe operator (. ') to transpose without conjugation. For matrices containing all real elements, the two operators return the same result.

The example matrix A is symmetric, so $\mathrm{A}^{\prime}$ is equal to A . But B is not symmetric:

```
B = magic(3);
X = B'
X =
    8 3 4
    1 5 9
    6
```

Transposition turns a row vector into a column vector:

$$
\begin{aligned}
& x=v^{\prime} \\
& x=
\end{aligned}
$$

$$
2
$$

$$
0
$$

$$
-1
$$

If $x$ and $y$ are both real column vectors, the product $x * y$ is not defined, but the two products

```
x'*y
```

and

$$
y^{\prime *} x
$$

are the same scalar. This quantity is used so frequently, it has three different names: inner product, scalar product, or dot product.

For a complex vector or matrix, z, the quantity z' not only transposes the vector or matrix, but also converts each complex element to its complex conjugate. That is, the sign of the imaginary part of each complex element changes. So if

```
z = [1+2i 7-3i 3+4i; 6-2i 9i 4+7i]
z =
    1.0000 + 2.0000i 7.0000 - 3.0000i 3.0000 + 4.0000i
    6.0000-2.0000i 0 + 9.0000i 4.0000 + 7.0000i
```

then
z'
ans =

| $1.0000-2.0000 i$ | $6.0000+2.0000 i$ |
| ---: | ---: |
| $7.0000+3.0000 i$ | $0-9.0000 i$ |
| $3.0000-4.0000 i$ | $4.0000-7.0000 i$ |

The unconjugated complex transpose, where the complex part of each element retains its sign, is denoted by z.':

```
z.'
ans =
    1.0000 + 2.0000i 6.0000 - 2.0000i
    7.0000-3.0000i 0 + 9.0000i
    3.0000 + 4.0000i 4.0000 + 7.0000i
```

For complex vectors, the two scalar products $\mathrm{x}^{\prime}$ *y and $\mathrm{y}^{\prime}$ *x are complex conjugates of each other, and the scalar product $\mathrm{x}^{\prime *} \mathrm{x}$ of a complex vector with itself is real.

## Multiplying Matrices

Multiplication of matrices is defined in a way that reflects composition of the underlying linear transformations and allows compact representation of
systems of simultaneous linear equations. The matrix product $C=A B$ is defined when the column dimension of $A$ is equal to the row dimension of $B$, or when one of them is a scalar. If $A$ is $m$-by- $p$ and $B$ is $p$-by- $n$, their product $C$ is $m$-by- $n$. The product can actually be defined using MATLAB for loops, colon notation, and vector dot products:

```
A = pascal(3);
B = magic(3);
m = 3; n = 3;
for i = 1:m
    for j = 1:n
        C(i,j) = A(i,:)*B(:,j);
    end
end
```

MATLAB uses a single asterisk to denote matrix multiplication. The next two examples illustrate the fact that matrix multiplication is not commutative; $A B$ is usually not equal to $B A$ :

```
\(X=A * B\)
X =
    \(15 \quad 15 \quad 15\)
    \(26 \quad 38 \quad 26\)
    \(41 \quad 70 \quad 39\)
\(Y=B^{*} A\)
Y =
    \(\begin{array}{lll}15 & 28 & 47\end{array}\)
    \(1534 \quad 60\)
    \(15 \quad 28 \quad 43\)
```

A matrix can be multiplied on the right by a column vector and on the left by a row vector:

```
u = [3; 1; 4];
x = A*u
x =
```

```
    1 7
    30
v = [2 0-1];
y = v*B
y =
    12 -7 10
```

Rectangular matrix multiplications must satisfy the dimension compatibility conditions:

```
C = fix(10*rand(3,2));
X = A*C
X =
    17 19
    31 41
    51 70
Y = C*A
Error using ==> *
Inner matrix dimensions must agree.
```

Anything can be multiplied by a scalar:

```
s = 7;
w = s*v
W =
    14 0
```

## Identity Matrix

Generally accepted mathematical notation uses the capital letter $I$ to denote identity matrices, matrices of various sizes with ones on the main diagonal and zeros elsewhere. These matrices have the property that $A I=A$ and $I A=A$ whenever the dimensions are compatible. The original version of MATLAB could not use $I$ for this purpose because it did not distinguish between
uppercase and lowercase letters and $i$ already served as a subscript and as the complex unit. So an English language pun was introduced. The function

$$
\operatorname{eye}(m, n)
$$

returns an $m$-by- $n$ rectangular identity matrix and eye( n ) returns an $n$-by- $n$ square identity matrix.

## Kronecker Tensor Product

The Kronecker product, $\mathrm{kron}(\mathrm{X}, \mathrm{Y})$, of two matrices is the larger matrix formed from all possible products of the elements of $X$ with those of $Y$. If $X$ is $m$-by- $n$ and Y is $p$-by- $q$, then $\mathrm{kron}(\mathrm{X}, \mathrm{Y})$ is $m p$-by- $n q$. The elements are arranged in the following order:

```
[X(1,1)*Y X(1,2)*Y . . . X(1,n)*Y
X(m,1)*Y X(m,2)*Y . . . X(m,n)*Y]
```

The Kronecker product is often used with matrices of zeros and ones to build up repeated copies of small matrices. For example, if X is the 2 -by- 2 matrix

```
X =
    1 2
    3 4
```

and $I=\operatorname{eye}(2,2)$ is the 2 -by- 2 identity matrix, then the two matrices

```
kron(X,I)
```

and

```
    kron(I,X)
```

are

| 1 | 0 | 2 | 0 |
| :--- | :--- | :--- | :--- |
| 0 | 1 | 0 | 2 |
| 3 | 0 | 4 | 0 |
| 0 | 3 | 0 | 4 |

and

| 1 | 2 | 0 | 0 |
| :--- | :--- | :--- | :--- |
| 3 | 4 | 0 | 0 |
| 0 | 0 | 1 | 2 |
| 0 | 0 | 3 | 4 |

## Vector and Matrix Norms

The $p$-norm of a vector $x$,

$$
\|x\|_{p}=\left(\sum\left|x_{i}\right|^{p}\right)^{1 / p},
$$

is computed by norm $(\mathrm{x}, \mathrm{p})$. This is defined by any value of $p>1$, but the most common values of $p$ are 1,2 , and $\infty$. The default value is $p=2$, which corresponds to Euclidean length:

```
v = [2 0 -1];
[norm(v,1) norm(v) norm(v,inf)]
ans =
    3.0000 2.2361 2.0000
```

The $p$-norm of a matrix $A$,

$$
\|A\|_{p}=\max _{x} \frac{\|A x\|_{p}}{\|x\|_{p}}
$$

can be computed for $p=1,2$, and $\infty$ by norm (A, p). Again, the default value is $p=2$ :

```
C = fix(10*rand(3,2));
[norm(C,1) norm(C) norm(C,inf)]
ans =
    19.0000 14.8015 13.0000
```

## Using Multithreaded Computation with Linear Algebra Functions

MATLAB software supports multithreaded computation for a number of linear algebra and element-wise numerical functions. These functions automatically execute on multiple threads. For a function or expression to execute faster on multiple CPUs, a number of conditions must be true:

1 The function performs operations that easily partition into sections that execute concurrently. These sections must be able to execute with little communication between processes. They should require few sequential operations.

2 The data size is large enough so that any advantages of concurrent execution outweigh the time required to partition the data and manage separate execution threads. For example, most functions speed up only when the array contains than several thousand elements or more.

3 The operation is not memory-bound; processing time is not dominated by memory access time. As a general rule, complex functions speed up more than simple functions.

The matrix multiply ( $\mathrm{X} * \mathrm{Y}$ ) and matrix power ( $\mathrm{X}^{\wedge} \mathrm{p}$ ) operators show significant increase in speed on large double-precision arrays (on order of 10,000 elements). The matrix analysis functions det, rcond, hess, and expm also show significant increase in speed on large double-precision arrays. To learn more about mulithreading, see in the MATLAB Programming Fundamentals documentation.

## Systems of Linear Equations

"Overdetermined Systems" on page 2-21
"Using Multithreaded Computation with Systems of Linear Equations"
on page 2-24
"Iterative Methods for Solving Systems of Linear Equations" on page 2-25
```

## Computational Considerations

One of the most important problems in technical computing is the solution of systems of simultaneous linear equations.

In matrix notation, the general problem takes the following form: Given two matrices $A$ and $B$, does there exist a unique matrix $X$ so that $A X=B$ or $X A=B$ ?

It is instructive to consider a 1-by-1 example. For example, does the equation

$$
7 x=21
$$

have a unique solution?
The answer, of course, is yes. The equation has the unique solution $x=3$. The solution is easily obtained by division:

$$
x=21 / 7=3 .
$$

The solution is not ordinarily obtained by computing the inverse of 7 , that is $7^{-1}=0.142857 \ldots$, and then multiplying $7^{-1}$ by 21 . This would be more work and, if $7^{-1}$ is represented to a finite number of digits, less accurate. Similar considerations apply to sets of linear equations with more than one unknown;
the MATLAB software solves such equations without computing the inverse of the matrix.

Although it is not standard mathematical notation, MATLAB uses the division terminology familiar in the scalar case to describe the solution of a general system of simultaneous equations. The two division symbols, slash,/, and backslash, <br>, correspond to the two MATLAB functions mldivide and mrdivide. mldivide and mrdivide are used for the two situations where the unknown matrix appears on the left or right of the coefficient matrix:

$$
\begin{array}{ll}
\mathrm{X}=\mathrm{B} / \mathrm{A} & \begin{array}{l}
\text { Denotes the solution to the matrix equation } \\
\\
X A=B . \\
\mathrm{X}=\mathrm{A} \backslash \mathrm{~B}
\end{array} \\
& \text { Denotes the solution to the matrix equation } \\
A X=B .
\end{array}
$$

Think of "dividing" both sides of the equation $A X=B$ or $X A=B$ by $A$. The coefficient matrix A is always in the "denominator."

The dimension compatibility conditions for $X=A \backslash B$ require the two matrices $A$ and $B$ to have the same number of rows. The solution $X$ then has the same number of columns as $B$ and its row dimension is equal to the column dimension of A. For $X=B / A$, the roles of rows and columns are interchanged.

In practice, linear equations of the form $A X=B$ occur more frequently than those of the form $X A=B$. Consequently, the backslash is used far more frequently than the slash. The remainder of this section concentrates on the backslash operator; the corresponding properties of the slash operator can be inferred from the identity:

$$
(B / A)^{\prime}=\left(A^{\prime} \backslash B^{\prime}\right)
$$

The coefficient matrix A need not be square. If A is $m$-by- $n$, there are three cases:

| $\mathrm{m}=\mathrm{n}$ | Square system. Seek an exact solution. |
| :--- | :--- |
| $\mathrm{m}>\mathrm{n}$ | Overdetermined system. Find a least squares <br> solution. |
| $\mathrm{m}<\mathrm{n}$ | Underdetermined system. Find a basic solution <br> with at most $m$ nonzero components. |

## The mldivide Algorithm

The mldivide operator employs different algorithms to handle different kinds of coefficient matrices. The various cases are diagnosed automatically by examining the coefficient matrix.

## Permutations of Triangular Matrices

mldivide checks for triangularity by testing for zero elements. If a matrix A is triangular, MATLAB software uses a substitution to compute the solution vector $x$. If $A$ is a permutation of a triangular matrix, MATLAB software uses a permuted substitution algorithm.

## Square Matrices

If A is symmetric and has real, positive diagonal elements, MATLAB attempts a Cholesky factorization. If the Cholesky factorization fails, MATLAB performs a symmetric, indefinite factorization. If A is upper Hessenberg, MATLAB uses Gaussian elimination to reduce the system to a triangular matrix. If $A$ is square but is neither permuted triangular, symmetric and positive definite, or Hessenberg, MATLAB performs a general triangular factorization using LU factorization with partial pivoting (see lu).

## Rectangular Matrices

If A is rectangular, mldivide returns a least-squares solution. MATLAB solves overdetermined systems with QR factorization (see qr). For an underdetermined system, MATLAB returns the solution with the maximum number of zero elements.

The mldivide function reference page contains a more detailed description of the algorithm.

## General Solution

The general solution to a system of linear equations $A X=b$ describes all possible solutions. You can find the general solution by:

1 Solving the corresponding homogeneous system $A X=0$. Do this using the null command, by typing null(A). This returns a basis for the solution space to $A X=0$. Any solution is a linear combination of basis vectors.

2 Finding a particular solution to the nonhomogeneous system $A X=b$.
You can then write any solution to $A X=b$ as the sum of the particular solution to $A X=b$, from step 2 , plus a linear combination of the basis vectors from step 1.

The rest of this section describes how to use MATLAB to find a particular solution to $A X=b$, as in step 2 .

## Square Systems

The most common situation involves a square coefficient matrix A and a single right-hand side column vector b .

## Nonsingular Coefficient Matrix

If the matrix $A$ is nonsingular, the solution, $x=A \backslash b$, is then the same size as b. For example:

```
A = pascal(3);
u = [3; 1; 4];
\(x=A \backslash u\)
x =
    10
    -12
        5
```

It can be confirmed that $A * x$ is exactly equal to $u$.
If $A$ and $B$ are square and the same size, $X=A \backslash B$ is also that size:

```
B = magic(3);
```

```
\(X=A \backslash B\)
\(X=\)
    \(19-3-1\)
    \(-17 \quad 413\)
    \(6 \quad 0 \quad-6\)
```

It can be confirmed that $A * X$ is exactly equal to $B$.
Both of these examples have exact, integer solutions. This is because the coefficient matrix was chosen to be pascal(3), which has a determinant equal to 1 .

## Singular Coefficient Matrix

A square matrix $A$ is singular if it does not have linearly independent columns. If $A$ is singular, the solution to $A X=B$ either does not exist, or is not unique. The backslash operator, $\mathrm{A} \backslash \mathrm{B}$, issues a warning if A is nearly singular and raises an error condition if it detects exact singularity.

If $A$ is singular and $A X=b$ has a solution, you can find a particular solution that is not unique, by typing

$$
P=\operatorname{pinv}(A) * b
$$

P is a pseudoinverse of $A$. If $A X=b$ does not have an exact solution, $\operatorname{pinv}(\mathrm{A})$ returns a least-squares solution.

For example:
$\left.A=\left[\begin{array}{rrr}1 & 3 & 7 \\ -1 & 4 & 4 \\ & 1 & 10\end{array}\right] \quad 18 \quad\right]$
is singular, as you can verify by typing

```
det(A)
ans =
    0
```

Note For information about using pinv to solve systems with rectangular coefficient matrices, see "Pseudoinverses" on page 2-27.

Exact Solutions. For $\mathrm{b}=[5 ; 2 ; 12]$, the equation $A X=b$ has an exact solution, given by

```
pinv(A)*b
ans =
    0.3850
    -0.1103
    0.7066
```

Verify that pinv (A)*b is an exact solution by typing

```
A*pinv(A)*b
ans =
    5.0000
    2.0000
    12.0000
```

Least-Squares Solutions. On the other hand, if $\mathrm{b}=[3 ; 6 ; 0], A X=b$ does not have an exact solution. In this case, pinv (A)*b returns a least squares solution. If you type

```
A*pinv(A)*b
ans =
    -1.0000
    4.0000
    2.0000
```

you do not get back the original vector $b$.
You can determine whether $A X=b$ has an exact solution by finding the row reduced echelon form of the augmented matrix [A b]. To do so for this example, enter

```
rref([A b])
ans =
\begin{tabular}{rrrr}
1.0000 & 0 & 2.2857 & 0 \\
0 & 1.0000 & 1.5714 & 0 \\
0 & 0 & 0 & 1.0000
\end{tabular}
```

Since the bottom row contains all zeros except for the last entry, the equation does not have a solution. In this case, pinv (A) returns a least-squares solution.

## Overdetermined Systems

Overdetermined systems of simultaneous linear equations are often encountered in various kinds of curve fitting to experimental data. Here is a hypothetical example. A quantity $y$ is measured at several different values of time, $t$, to produce the following observations:

| $\boldsymbol{t}$ | $\boldsymbol{y}$ |
| :--- | :--- |
| 0.0 | 0.82 |
| 0.3 | 0.72 |
| 0.8 | 0.63 |
| 1.1 | 0.60 |
| 1.6 | 0.55 |
| 2.3 | 0.50 |

Enter the data into MATLAB with the statements

```
t = [0 .3 . . 1.1 1.6 2.3]';
y = [.82 .72 .63 .60 .55 .50]';
```

Try modeling the data with a decaying exponential function:

$$
y(t)=c_{1}+c_{2} e^{-t} .
$$

The preceding equation says that the vector y should be approximated by a linear combination of two other vectors, one the constant vector containing all ones and the other the vector with components $e^{-t}$. The unknown coefficients,
$c_{1}$ and $c_{2}$, can be computed by doing a least-squares fit, which minimizes the sum of the squares of the deviations of the data from the model. There are six equations in two unknowns, represented by the 6 -by- 2 matrix:

```
E = [ones(size(t)) exp(-t)]
E =
\begin{tabular}{ll}
1.0000 & 1.0000 \\
1.0000 & 0.7408 \\
1.0000 & 0.4493 \\
1.0000 & 0.3329 \\
1.0000 & 0.2019 \\
1.0000 & 0.1003
\end{tabular}
```

Use the backslash operator to get the least-squares solution:

$$
\begin{aligned}
& c=E \backslash y \\
& c= \\
& \\
& \\
& \\
& \\
& 0.4760 \\
& 0.3413
\end{aligned}
$$

In other words, the least-squares fit to the data is

$$
y(t)=0.4760+0.3413 e^{-t} .
$$

The following statements evaluate the model at regularly spaced increments in $t$, and then plot the result, together with the original data:

```
T = (0:0.1:2.5)';
Y = [ones(size(T)) exp(-T)]*c;
plot(T,Y,'-',t,y,'o')
```

$E * C$ is not exactly equal to $y$, but the difference might well be less than measurement errors in the original data.

A rectangular matrix $A$ is rank deficient if it does not have linearly independent columns. If $A$ is rank deficient, the least-squares solution to $A X$ $=B$ is not unique. The backslash operator, $A \backslash B$, issues a warning if $A$ is rank deficient and produces a least-squares solution if the system has no solution and a basic solution if the system has infinitely many solutions.

Use the format command to display the solution in rational format. The particular solution is obtained with

```
format rat
p = R\b
p =
    O
    -3/7
    0
    29/7
```

One of the nonzero components is $p(2)$ because $R(:, 2)$ is the column of $R$ with largest norm. The other nonzero component is $p(4)$ because $R(:, 4)$ dominates after $R(:, 2)$ is eliminated.

The complete solution to the underdetermined system can be characterized by adding an arbitrary vector from the null space, which can be found using the null function with an option requesting a rational basis:

```
Z = null(R,'r')
Z =
    -1/2 -7/6
    -1/2 1/2
    1 0
    0 1
```

It can be confirmed that $R * Z$ is zero and that any vector $x$ where

$$
x=p+z^{*} q
$$

for an arbitrary vector $q$ satisfies $R^{*} x=b$.

## Using Multithreaded Computation with Systems of Linear Equations

MATLAB software supports multithreaded computation for a number of linear algebra and element-wise numerical functions. These functions automatically execute on multiple threads. For a function or expression to execute faster on multiple CPUs, a number of conditions must be true:

1 The function performs operations that easily partition into sections that execute concurrently. These sections must be able to execute with little communication between processes. They should require few sequential operations.

2 The data size is large enough so that any advantages of concurrent execution outweigh the time required to partition the data and manage separate execution threads. For example, most functions speed up only when the array contains than several thousand elements or more.

3 The operation is not memory-bound; processing time is not dominated by memory access time. As a general rule, complex functions speed up more than simple functions.
inv, lscov, linsolve, and mldivide show significant increase in speed on large double-precision arrays (on order of 10,000 elements or more) when
multithreading is enabled. To learn more about mulithreading, see in the MATLAB Programming Fundamentals documentation.

## Iterative Methods for Solving Systems of Linear Equations

If the coefficient matrix A is large and sparse, factorization methods are generally not efficient. Iterative methods generate a series of approximate solutions. MATLAB provides several iterative methods to handle large, sparse input matrices.

## Inverses and Determinants

## In this section...

"Introduction" on page 2-26
"Pseudoinverses" on page 2-27

## Introduction

If $A$ is square and nonsingular, the equations $A X=I$ and $X A=I$ have the same solution, $X$. This solution is called the inverse of $A$, is denoted by $A^{-1}$, and is computed by the function inv.

The determinant of a matrix is useful in theoretical considerations and some types of symbolic computation, but its scaling and roundoff error properties make it far less satisfactory for numeric computation. Nevertheless, the function det computes the determinant of a square matrix:

| A = pascal(3) |  |  |
| :---: | :---: | :---: |
| A $=$ |  |  |
| 1 | 1 | 1 |
| 1 | 2 | 3 |
| 1 | 3 | 6 |
| $d=\operatorname{det}(\mathrm{A})$ |  |  |
| X = inv(A) |  |  |
| d $=$ |  |  |
| 1 |  |  |
| $\mathrm{X}=$ |  |  |
| 3 | -3 | 1 |
| -3 | 5 | -2 |
| 1 | -2 | 1 |

Again, because A is symmetric, has integer elements, and has determinant equal to one, so does its inverse. On the other hand,

```
B = magic(3)
```

```
B =
            8 1 6
            3 5 7
            4 9
d = det(B)
X = inv(B)
d =
            -360
X =
\begin{tabular}{rrr}
0.1472 & -0.1444 & 0.0639 \\
-0.0611 & 0.0222 & 0.1056 \\
-0.0194 & 0.1889 & -0.1028
\end{tabular}
```

Closer examination of the elements of $X$, or use of format rat, would reveal that they are integers divided by 360 .

If $A$ is square and nonsingular, then, without roundoff error, $X=\operatorname{inv}(A) * B$ is theoretically the same as $X=A \backslash B$ and $Y=B * i n v(A)$ is theoretically the same as $Y=B / A$. But the computations involving the backslash and slash operators are preferable because they require less computer time, less memory, and have better error-detection properties.

## Pseudoinverses

Rectangular matrices do not have inverses or determinants. At least one of the equations $A X=I$ and $X A=I$ does not have a solution. A partial replacement for the inverse is provided by the Moore-Penrose pseudoinverse, which is computed by the pinv function:

```
format short
C = fix(10*gallery('uniformdata',[3 2],0));
X = pinv(C)
X =
    0.1159 -0.0729 0.0171
    -0.0534 0.1152 0.0418
```

The matrix

$$
\begin{aligned}
& Q=X * C \\
& Q=\begin{array}{ll}
Q & \\
& \\
& 1.0000 \\
& 0.0000
\end{array} \\
&
\end{aligned}
$$

is the 2-by- 2 identity, but the matrix

| $P=C * X$ |  |  |
| :--- | ---: | ---: |
| $P=$ |  |  |
| 0.8293 | -0.1958 | 0.3213 |
|  | -0.1958 | 0.7754 |
|  | 0.3213 | 0.3685 |
|  | 0.3955 |  |

is not the 3-by-3 identity. However, P acts like an identity on a portion of the space in the sense that $P$ is symmetric, $P * C$ is equal to $C$, and $X * P$ is equal to $X$.

## Solving a Rank-Deficient System

If A is $m$-by- $n$ with $m>n$ and full rank $n$, each of the three statements

```
x = A\b
x = pinv(A)*b
x = inv(A'*A)*A'*b
```

theoretically computes the same least-squares solution $x$, although the backslash operator does it faster.

However, if A does not have full rank, the solution to the least-squares problem is not unique. There are many vectors $x$ that minimize

```
norm(A*x -b)
```

The solution computed by $\mathrm{x}=\mathrm{A} \backslash \mathrm{b}$ is a basic solution; it has at most $r$ nonzero components, where $r$ is the rank of A. The solution computed by $\mathrm{x}=$ pinv (A)*b is the minimal norm solution because it minimizes norm ( $x$ ). An attempt to compute a solution with $x=\operatorname{inv}\left(A^{\prime} * A\right) * A ' * b$ fails because $A^{\prime}{ }^{*} A$ is singular.

Here is an example that illustrates the various solutions:

$$
A=\left[\begin{array}{rrr}
1 & 2 & 3 \\
4 & 5 & 6 \\
7 & 8 & 9 \\
10 & 11 & 12
\end{array}\right]
$$

does not have full rank. Its second column is the average of the first and third columns. If

$$
b=A(:, 2)
$$

is the second column, then an obvious solution to $A^{*} x=b$ is $x=\left[\begin{array}{lll}0 & 1 & 0\end{array}\right]^{\prime}$. But none of the approaches computes that $x$. The backslash operator gives

```
x = A\b
Warning: Rank deficient, rank = 2.
X =
    0.5000
    0
    0.5000
```

This solution has two nonzero components. The pseudoinverse approach gives

```
y = pinv(A)*b
y =
    0.3333
    0.3333
    0.3333
```

There is no warning about rank deficiency. But norm(y) $=0.5774$ is less than $\operatorname{norm}(x)=0.7071$. Finally,

```
z = inv(A'*A)*A'*b
```

fails completely:

```
Warning: Matrix is close to singular or badly scaled.
            Results may be inaccurate. RCOND = 9.868649e-018.
Z =
    -0.8594
```

[^0]
## Factorizations

## In this section...

"Introduction" on page 2-31
"Cholesky Factorization" on page 2-31
"LU Factorization" on page 2-33
"QR Factorization" on page 2-34
"Using Multithreaded Computation for Factorization" on page 2-38

## Introduction

All three of the matrix factorizations discussed in this section make use of triangular matrices, where all the elements either above or below the diagonal are zero. Systems of linear equations involving triangular matrices are easily and quickly solved using either forward or back substitution.

## Cholesky Factorization

The Cholesky factorization expresses a symmetric matrix as the product of a triangular matrix and its transpose

$$
A=R^{\prime} R
$$

where $R$ is an upper triangular matrix.
Not all symmetric matrices can be factored in this way; the matrices that have such a factorization are said to be positive definite. This implies that all the diagonal elements of $A$ are positive and that the offdiagonal elements are "not too big." The Pascal matrices provide an interesting example. Throughout this chapter, the example matrix A has been the 3 -by- 3 Pascal matrix. Temporarily switch to the 6-by-6:

```
A = pascal(6)
A =
\begin{tabular}{llllll}
1 & 1 & 1 & 1 & 1 & 1 \\
1 & 2 & 3 & 4 & 5 & 6
\end{tabular}
```

| 1 | 3 | 6 | 10 | 15 | 21 |
| ---: | ---: | ---: | ---: | ---: | ---: |
| 1 | 4 | 10 | 20 | 35 | 56 |
| 1 | 5 | 15 | 35 | 70 | 126 |
| 1 | 6 | 21 | 56 | 126 | 252 |

The elements of A are binomial coefficients. Each element is the sum of its north and west neighbors. The Cholesky factorization is

| $R=\operatorname{chol}(A)$ |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | ---: |
| $R=$ |  |  |  |  |  |
| 1 | 1 | 1 | 1 | 1 | 1 |
| 0 | 1 | 2 | 3 | 4 | 5 |
| 0 | 0 | 1 | 3 | 6 | 10 |
| 0 | 0 | 0 | 1 | 4 | 10 |
| 0 | 0 | 0 | 0 | 1 | 5 |
| 0 | 0 | 0 | 0 | 0 | 1 |

The elements are again binomial coefficients. The fact that $R^{1 *} R$ is equal to $A$ demonstrates an identity involving sums of products of binomial coefficients.

Note The Cholesky factorization also applies to complex matrices. Any complex matrix that has a Cholesky factorization satisfies $A^{\prime}=A$ and is said to be Hermitian positive definite.

The Cholesky factorization allows the linear system

$$
A x=b
$$

to be replaced by

$$
R^{\prime} R x=b .
$$

Because the backslash operator recognizes triangular systems, this can be solved in the MATLAB environment quickly with

$$
x=R \backslash\left(R^{\prime} \backslash b\right)
$$

If A is $n$-by- $n$, the computational complexity of $\operatorname{chol}(\mathrm{A})$ is $\mathrm{O}\left(n^{3}\right)$, but the complexity of the subsequent backslash solutions is only $\mathrm{O}\left(n^{2}\right)$.

## LU Factorization

LU factorization, or Gaussian elimination, expresses any square matrix $A$ as the product of a permutation of a lower triangular matrix and an upper triangular matrix

$$
A=L U,
$$

where $L$ is a permutation of a lower triangular matrix with ones on its diagonal and $U$ is an upper triangular matrix.

The permutations are necessary for both theoretical and computational reasons. The matrix

$$
\left[\begin{array}{ll}
0 & 1 \\
1 & 0
\end{array}\right]
$$

cannot be expressed as the product of triangular matrices without interchanging its two rows. Although the matrix

$$
\left[\begin{array}{ll}
\varepsilon & 1 \\
1 & 0
\end{array}\right]
$$

can be expressed as the product of triangular matrices, when $\varepsilon$ is small, the elements in the factors are large and magnify errors, so even though the permutations are not strictly necessary, they are desirable. Partial pivoting ensures that the elements of $L$ are bounded by one in magnitude and that the elements of $U$ are not much larger than those of $A$.

For example:

$$
\begin{aligned}
& {[L, U]=\operatorname{lu}(B)} \\
& L= \\
& 1.0000
\end{aligned}
$$

```
    0.5000 1.0000 0
U =
\begin{tabular}{rrr}
8.0000 & 1.0000 & 6.0000 \\
0 & 8.5000 & -1.0000 \\
0 & 0 & 5.2941
\end{tabular}
```

The LU factorization of A allows the linear system

$$
A^{*} x=b
$$

to be solved quickly with

$$
x=U \backslash(L \backslash b)
$$

Determinants and inverses are computed from the LU factorization using

```
det(A) = det(L)*det(U)
```

and

```
inv(A) = inv(U)*inv(L)
```

You can also compute the determinants using $\operatorname{det}(A)=\operatorname{prod}(\operatorname{diag}(U))$, though the signs of the determinants may be reversed.

## QR Factorization

An orthogonal matrix, or a matrix with orthonormal columns, is a real matrix whose columns all have unit length and are perpendicular to each other. If $Q$ is orthogonal, then

$$
Q^{\prime} Q=1 .
$$

The simplest orthogonal matrices are two-dimensional coordinate rotations:

$$
\left[\begin{array}{cc}
\cos (\theta) & \sin (\theta) \\
-\sin (\theta) & \cos (\theta)
\end{array}\right] .
$$

For complex matrices, the corresponding term is unitary. Orthogonal and unitary matrices are desirable for numerical computation because they preserve length, preserve angles, and do not magnify errors.

The orthogonal, or QR , factorization expresses any rectangular matrix as the product of an orthogonal or unitary matrix and an upper triangular matrix. A column permutation may also be involved:

$$
A=Q R
$$

or

$$
A P=Q R,
$$

where $Q$ is orthogonal or unitary, $R$ is upper triangular, and $P$ is a permutation.

There are four variants of the QR factorization-full or economy size, and with or without column permutation.

Overdetermined linear systems involve a rectangular matrix with more rows than columns, that is $m$-by- $n$ with $m>n$. The full-size QR factorization produces a square, $m$-by- $m$ orthogonal $Q$ and a rectangular $m$-by- $n$ upper triangular $R$ :

```
C=gallery('uniformdata',[5 4], 0);
[Q,R] = qr(C)
Q =
    0.6191 0.1406 -0.1899 -0.5058 0.5522
    0.1506 0.4084 0.5034 0.5974 0.4475
    0.3954 -0.5564 0.6869 -0.1478 -0.2008
    0.3167 0.6676 0.1351 -0.1729 -0.6370
    0.5808 -0.2410 -0.4695 0.5792 -0.2207
R =
    1.5346 1.0663 1.2010 1.4036
```

| 0 | 0.7245 | 0.3474 | -0.0126 |
| ---: | ---: | ---: | ---: |
| 0 | 0 | 0.9320 | 0.6596 |
| 0 | 0 | 0 | 0.6648 |
| 0 | 0 | 0 | 0 |

In many cases, the last $m-n$ columns of $Q$ are not needed because they are multiplied by the zeros in the bottom portion of $R$. So the economy-size QR factorization produces a rectangular, $m$-by- $n Q$ with orthonormal columns and a square $n$-by- $n$ upper triangular $R$. For the 5 -by- 4 example, this is not much of a saving, but for larger, highly rectangular matrices, the savings in both time and memory can be quite important:

| 0.6191 | 0.1406 | -0.1899 | -0.5058 |
| :---: | :---: | :---: | :---: |
| 0.1506 | 0.4084 | 0.5034 | 0.5974 |
| 0.3954 | -0.5564 | 0.6869 | -0.1478 |
| 0.3167 | 0.6676 | 0.1351 | -0.1729 |
| 0.5808 | -0.2410 | -0.4695 | 0.5792 |
| $\mathrm{R}=$ |  |  |  |
| 1.5346 | 1.0663 | 1.2010 | 1.4036 |
| 0 | 0.7245 | 0.3474 | -0.0126 |
| 0 | 0 | 0.9320 | 0.6596 |
| 0 | 0 | 0 | 0.6648 |

In contrast to the LU factorization, the QR factorization does not require any pivoting or permutations. But an optional column permutation, triggered by the presence of a third output argument, is useful for detecting singularity or rank deficiency. At each step of the factorization, the column of the remaining unfactored matrix with largest norm is used as the basis for that step. This ensures that the diagonal elements of $R$ occur in decreasing order and that any linear dependence among the columns is almost certainly be revealed by examining these elements. For the small example given here, the second column of C has a larger norm than the first, so the two columns are exchanged:

```
[Q,R,P] = qr(C)
Q =
    -0.3522 0.8398 -0.4131
    -0.7044 -0.5285 -0.4739
    -0.6163 0.1241 0.7777
R =
    -11.3578 -8.2762
        0 7.2460
        0
P =
    0
```

When the economy-size and column permutations are combined, the third output argument is a permutation vector, rather than a permutation matrix:

```
[Q,R,p] = qr(C,0)
Q =
    -0.3522 0.8398
    -0.7044 -0.5285
    -0.6163 0.1241
R =
    -11.3578 -8.2762
    0 7.2460
p =
    2 1
```

The QR factorization transforms an overdetermined linear system into an equivalent triangular system. The expression

```
norm(A*x - b)
```

equals

```
norm(Q*R*x - b)
```

Multiplication by orthogonal matrices preserves the Euclidean norm, so this expression is also equal to

```
norm(R*x - y)
```

where $\mathrm{y}=Q^{\prime}$ *b. Since the last $m-n$ rows of $R$ are zero, this expression breaks into two pieces:

```
norm(R(1:n,1:n)*x - y(1:n))
```

and

```
norm(y(n+1:m))
```

When A has full rank, it is possible to solve for x so that the first of these expressions is zero. Then the second expression gives the norm of the residual. When A does not have full rank, the triangular structure of R makes it possible to find a basic solution to the least-squares problem.

## Using Multithreaded Computation for Factorization

MATLAB software supports multithreaded computation for a number of linear algebra and element-wise numerical functions. These functions automatically execute on multiple threads. For a function or expression to execute faster on multiple CPUs, a number of conditions must be true:

1 The function performs operations that easily partition into sections that execute concurrently. These sections must be able to execute with little communication between processes. They should require few sequential operations.

2 The data size is large enough so that any advantages of concurrent execution outweigh the time required to partition the data and manage separate execution threads. For example, most functions speed up only when the array contains several thousand elements or more.

3 The operation is not memory-bound; processing time is not dominated by memory access time. As a general rule, complex functions speed up more than simple functions.
lu and qr show significant increase in speed on large double-precision arrays (on order of 10,000 elements). To learn more about mulithreading, see in the MATLAB Programming Fundamentals documentation.

## Powers and Exponentials

## In this section...

"Positive Integer Powers" on page 2-40
"Inverse and Fractional Powers" on page 2-40
"Element-by-Element Powers" on page 2-41
"Exponentials" on page 2-41

## Positive Integer Powers

If $A$ is a square matrix and $p$ is a positive integer, $A^{\wedge} p$ effectively multiplies A by itself p-1 times. For example:

```
A = [11 1 1;1 2 3;1 3 6]
A =
\begin{tabular}{lll}
1 & 1 & 1 \\
1 & 2 & 3 \\
1 & 3 & 6
\end{tabular}
X = A^2
X =
        3 6 10
        6 14 25
        10 25 46
```

## Inverse and Fractional Powers

If $A$ is square and nonsingular, $A^{\wedge}(-p)$ effectively multiplies inv (A) by itself p-1 times:

```
Y = A^(-3)
Y =
    145.0000 -207.0000 81.0000
    -207.0000 298.0000 -117.0000
```

```
81.0000-117.0000 46.0000
```

Fractional powers, like $A^{\wedge}(2 / 3)$, are also permitted; the results depend upon the distribution of the eigenvalues of the matrix.

## Element-by-Element Powers

The .^ operator produces element-by-element powers. For example:

```
X = A.^2
A =
\begin{tabular}{llr}
1 & 1 & 1 \\
1 & 4 & 9 \\
1 & & 9
\end{tabular}
```

## Exponentials

The function

```
sqrtm(A)
```

computes $A^{\wedge}(1 / 2)$ by a more accurate algorithm. The $m$ in sqrtm distinguishes this function from sqrt(A), which, like A.^(1/2), does its job element by element.

A system of linear, constant coefficient, ordinary differential equations can be written

$$
d x / d t=A x,
$$

where $x=x(t)$ is a vector of functions of $t$ and $A$ is a matrix independent of $t$. The solution can be expressed in terms of the matrix exponential:

$$
x(t)=e^{t A} x(0) .
$$

The function

```
expm(A)
```

computes the matrix exponential. An example is provided by the 3-by-3 coefficient matrix

$$
A=\begin{array}{rrr} 
& & \\
0 & -6 & -1 \\
6 & 2 & -16 \\
-5 & 20 & -10
\end{array}
$$

and the initial condition, $x(0)$

```
x0 =
    1
    1
    1
```

The matrix exponential is used to compute the solution, $x(t)$, to the differential equation at 101 points on the interval $0 \leq t \leq 1$ with

```
X = [];
for t = 0:.01:1
    X = [X expm(t*A)*x0];
end
```

A three-dimensional phase plane plot obtained with
plot3(X(1,:),X(2,:),X(3,:), '-0')
shows the solution spiraling in towards the origin. This behavior is related to the eigenvalues of the coefficient matrix, which are discussed in the next section.

## Eigenvalues

## In this section...

"Eigenvalue Decomposition" on page 2-44
"Multiple Eigenvalues" on page 2-45
"Schur Decomposition" on page 2-46

## Eigenvalue Decomposition

An eigenvalue and eigenvector of a square matrix $A$ are, respectively, a scalar $\lambda$ and a nonzero vector $v$ that satisfy

$$
A v=\lambda v .
$$

With the eigenvalues on the diagonal of a diagonal matrix $\Lambda$ and the corresponding eigenvectors forming the columns of a matrix $V$, you have

$$
A V=V \Lambda .
$$

If $V$ is nonsingular, this becomes the eigenvalue decomposition

$$
A=V \Lambda V^{-1} .
$$

A good example is provided by the coefficient matrix of the ordinary differential equation in the previous section:

```
A =
    0 -6 -1
    6 2 -16
    -5 20 -10
```

The statement

```
lambda = eig(A)
```

produces a column vector containing the eigenvalues. For this matrix, the eigenvalues are complex:
lambda =

$$
\begin{aligned}
& -3.0710 \\
& -2.4645+17.6008 i \\
& -2.4645-17.6008 i
\end{aligned}
$$

The real part of each of the eigenvalues is negative, so $e^{\lambda t}$ approaches zero as $t$ increases. The nonzero imaginary part of two of the eigenvalues, $\pm \omega$, contributes the oscillatory component, $\sin (\omega t)$, to the solution of the differential equation.

With two output arguments, eig computes the eigenvectors and stores the eigenvalues in a diagonal matrix:

```
[V,D] = eig(A)
V =
    -0.8326 0.2003 - 0.1394i 0.2003 + 0.1394i
    -0.3553 -0.2110-0.6447i -0.2110 + 0.6447i
    -0.4248 -0.6930 -0.6930
D =
    -3.0710 0 0
    0 -2.4645+17.6008i 0
        0 0 -2.4645-17.6008i
```

The first eigenvector is real and the other two vectors are complex conjugates of each other. All three vectors are normalized to have Euclidean length, norm ( $v, 2$ ), equal to one.

The matrix $\mathrm{V} * \mathrm{D} * i n v(\mathrm{~V})$, which can be written more succinctly as $\mathrm{V} * \mathrm{D} / \mathrm{V}$, is within roundoff error of $A$. And, inv $(V) * A * V$, or $V \backslash A * V$, is within roundoff error of $D$.

## Multiple Eigenvalues

Some matrices do not have an eigenvector decomposition. These matrices are not diagonalizable. For example:

$$
A=\left[\begin{array}{rrr}
6 & 12 & 19 \\
-9 & -20 & -33 \\
4 & 9 & 15
\end{array}\right]
$$

For this matrix

```
[V,D] = eig(A)
```

produces

```
V =
\begin{tabular}{rrr}
-0.4741 & -0.4082 & -0.4082 \\
0.8127 & 0.8165 & 0.8165 \\
-0.3386 & -0.4082 & -0.4082
\end{tabular}
D =
\begin{tabular}{rrr}
-1.0000 & 0 & 0 \\
0 & 1.0000 & 0 \\
0 & 0 & 1.0000
\end{tabular}
```

There is a double eigenvalue at $\lambda=1$. The second and third columns of V are the same. For this matrix, a full set of linearly independent eigenvectors does not exist.

## Schur Decomposition

The MATLAB advanced matrix computations do not require eigenvalue decompositions. They are based, instead, on the Schur decomposition

$$
A=U S U^{T} .
$$

where $U$ is an orthogonal matrix and $S$ is a block upper triangular matrix with 1-by-1 and 2-by-2 blocks on the diagonal. The eigenvalues are revealed by the diagonal elements and blocks of $S$, while the columns of $U$ provide a basis with much better numerical properties than a set of eigenvectors. The Schur decomposition of this defective example is

```
[U,S] = schur(A)
U =
\begin{tabular}{rrr}
-0.4741 & 0.6648 & 0.5774 \\
0.8127 & 0.0782 & 0.5774 \\
-0.3386 & -0.7430 & 0.5774
\end{tabular}
```

```
S =
    \(\begin{array}{lll}-1.0000 & 20.7846 & -44.6948\end{array}\)
    \(0 \quad 1.0000 \quad-0.6096\)
    \(0 \quad 0 \quad 1.0000\)
```

The double eigenvalue is contained in the lower 2 -by- 2 block of S .

Note If A is complex, schur returns the complex Schur form, which is upper triangular with the eigenvalues of $A$ on the diagonal.

## Singular Values

A singular value and corresponding singular vectors of a rectangular matrix $A$ are, respectively, a scalar $\sigma$ and a pair of vectors $u$ and $v$ that satisfy

$$
\begin{aligned}
& A v=\sigma u \\
& A^{T} u=\sigma v .
\end{aligned}
$$

With the singular values on the diagonal of a diagonal matrix $\Sigma$ and the corresponding singular vectors forming the columns of two orthogonal matrices $U$ and $V$, you have

$$
\begin{aligned}
& A V=U \Sigma \\
& A^{T} U=V \Sigma
\end{aligned}
$$

Since $U$ and $V$ are orthogonal, this becomes the singular value decomposition

$$
A=U \Sigma V^{T} .
$$

The full singular value decomposition of an $m$-by- $n$ matrix involves an $m$-by- $m$ $U$, an $m$-by- $n \Sigma$, and an $n$-by- $n V$. In other words, $U$ and $V$ are both square and $\Sigma$ is the same size as $A$. If $A$ has many more rows than columns, the resulting $U$ can be quite large, but most of its columns are multiplied by zeros in $\Sigma$. In this situation, the economy sized decomposition saves both time and storage by producing an $m$-by- $n U$, an $n$-by- $n \Sigma$ and the same $V$.

The eigenvalue decomposition is the appropriate tool for analyzing a matrix when it represents a mapping from a vector space into itself, as it does for an ordinary differential equation. On the other hand, the singular value decomposition is the appropriate tool for analyzing a mapping from one vector space into another vector space, possibly with a different dimension. Most systems of simultaneous linear equations fall into this second category.

If $A$ is square, symmetric, and positive definite, then its eigenvalue and singular value decompositions are the same. But, as $A$ departs from symmetry and positive definiteness, the difference between the two decompositions increases. In particular, the singular value decomposition of a real matrix is always real, but the eigenvalue decomposition of a real, nonsymmetric matrix might be complex.

For the example matrix

```
A =
    9 4
6
2 7
```

the full singular value decomposition is

```
[U,S,V] = svd(A)
U =
    0.6105 -0.7174 0.3355
    0.6646 0.2336 -0.7098
    0.4308 0.6563 0.6194
S =
    14.9359 0
        0 5.1883
        0 0
V =
```

    \(0.6925-0.7214\)
    \(0.7214 \quad 0.6925\)
    You can verify that $U * S * V$ ' is equal to $A$ to within round-off error. For this small problem, the economy size decomposition is only slightly smaller:

```
[U,S,V] = svd(A,O)
U =
    0.6105 -0.7174
    0.6646 0.2336
    0.4308 0.6563
```

```
S =
    14.9359 0
                        0.1883
V =
    0.6925 -0.7214
    0.7214 0.6925
```

Again, $U^{*} S^{*} V^{\prime}$ is equal to $A$ to within round-off error.

## Random Numbers

- "Generating Random Numbers" on page 3-2
- "Managing the Default Stream" on page 3-3
- "Creating and Controlling a Random Number Stream" on page 3-10
- "Multiple streams" on page 3-19
- "Updating Your Random Number Generator Syntax" on page 3-22
- "Selected Bibliography" on page 3-26

Pseudorandom numbers are generated by deterministic algorithms. They are "random" in the sense that, on average, they pass statistical tests regarding their distribution and correlation. They differ from true random numbers in that they are generated by an algorithm, rather than a truly random process. Random number generators (RNGs), like those in MATLAB are algorithms for generating pseudorandom numbers with a specified distribution. A given number may be repeated many times during the sequence, but the entire sequence is not repeated.

A pseudorandom sequence is described by several properties. A random stream is the sequence of values that are returned by a generator. The period of a sequence is its length, that is, the number of values it generates before the entire sequence is repeated. The state is the information the generator keeps internally in order to create successive values in the stream. The seed of a sequence is a single value to define its starting point.

## Generating Random Numbers

The rand function returns uniformly distributed random numbers between 0 and 1.

```
rand(1,5)
ans =
    0.8147 0.9058 0.1270 0.9134 0.6324
```

MATLAB software initializes a default stream at startup. The rand function accesses the default stream and draws a set of numbers to create the output. This means that every time rand is called, the state of the default stream is changed and the output is different.

```
A=rand(1,5);B=rand(1,5);
A,B
A =
    0.0975 0.2785 0.5469 0.9575 0.9649
B =
    0.1576
    0.9706
    0.9572
    0.4854
    0.8003
```

- rand returns pseudorandom numbers from a uniform distribution.
- randn returns pseudorandom numbers from a normal distribution.
- randi returns pseudorandom numbers from a uniform discrete distribution.

## Managing the Default Stream

rand, randn, and randi draw random numbers from an underlying random number stream, called the default stream. The @RandStream class allows you to get a handle to the default stream and control random number generation.

Get a handle to the default stream as follows:

```
defaultStream=RandStream.getDefaultStream
defaultStream =
mt19937ar random stream (current default)
    Seed: 0
    RandnAlg: Ziggurat
```

Return the properties of the stream object with the get method:

```
get(defaultStream)
                            Type: 'mt19937ar'
            NumStreams: 1
            StreamIndex: 1
            Substream: 1
                    Seed: 0
                    State: [625x1 uint32]
            RandnAlg: 'Ziggurat'
            Antithetic: 0
FullPrecision: 1
```

Now, use the rand function to generate uniform random values from the default stream.

```
rand(1,5);
```

Use the randn and randi functions to generate normal random values and integer random values from the default stream.

```
A=randi(100,1,5);
A=randn(1,5);
```

The State property is the internal state of the generator. You can save the State of defaultStream.

```
myState=defaultStream.State;
```

Using myState, you can restore the state of defaultStream and reproduce previous results.

```
myState=defaultStream.State;
A=rand(1,100);
defaultStream.State=myState;
B=rand(1,100);
isequal(A,B)
ans =
```

1
rand, randi, and randn access the default stream. Since all of these functions access the same underlying stream, a call to one affects the values produced by the others at subsequent calls.

```
defaultStream.State=myState;
A=rand(1,100);
defaultStream.State=myState;
randi(100);
B=rand(1,100);
isequal(A,B)
ans =
    0
```

The default stream is a handle object of the @RandStream class. RandStream.getDefaultStream returns a handle. The properties of the default stream can be viewed or modified from any handle to the stream.

```
stream1=RandStream.getDefaultStream;
stream2=RandStream.getDefaultStream;
stream1.RandnAlg='Polar';
stream2.RandnAlg
ans =
Polar
```

The following table shows the methods available for the @RandStream class. Static methods are indicated with the syntax RandStream.methodName.

| Method | Description |
| :--- | :--- |
| RandStream | Create a random number stream |
| RandStream.create | Create multiple independent random <br> number streams |
| get | Get the properties of a random <br> stream |
| RandStream.list | List available random number <br> generator algorithms |
| RandStream.getDefaultStream | Get the default random number <br> stream |
| RandStream.setDefaultStream | Set the default random number <br> stream |
| set | Set a property of a random stream |
| reset | Reset a stream to its initial internal <br> state |
| rand | Generate pseudorandom numbers <br> from a uniform distribution |
| randn | Generate pseudorandom numbers <br> from a standard normal distribution |
| randi | Generate pseudorandom integers <br> from a uniform discrete distribution |
| randperm | Random permutation of a set of <br> values |

The properties of a random stream are given the following table.

| Property | Description |
| :--- | :--- |
| Type | (Read-only) Generator <br> algorithm used by the stream. <br> RandStream. list specifies the <br> possible generators. |
| Seed | (Read-only) Seed value used to <br> create the stream. |
| NumStreams | (Read-only) Number of streams <br> in the group in which the current <br> stream was created. |
| StreamIndex | (Read-only) Index of the current <br> stream from among the group of <br> streams with which the current <br> stream was created. |
| State | Internal state of the generator. Do <br> not depend on the format of this <br> property. The value you assign to <br> S.State must be a value previously <br> read from S.State. |
| Substream | Index of the substream to which <br> the stream is currently set. The <br> default is 1. Multiple substreams <br> are not supported by all generator |
| types; the multiplicative lagged |  |
| Fibonacci generator (mlfg6331_64) |  |
| and combined multiple recursive |  |
| generator (mrg32k3a) support |  |
| substreams. |  |

| Property | Description |
| :--- | :--- |
| Antithetic | Logical value indicating whether S <br> generates antithetic pseudorandom <br> values. For uniform values, these <br> are the usual values subtracted from <br> 1. The default is false. |
| FullPrecision | Logical value indicating whether <br> s generates values using its full <br> precision. Some generators can <br> create pseudorandom values faster, <br> but with fewer random bits, if <br> FullPrecision is false. The default <br> is true. |

Suppose you want to repeat a simulation. The @RandStream class gives you several ways to replicate output. As shown in the previous example, you can save the state of the default stream.

```
myState=defaultStream.State;
A=rand(1,100);
defaultStream.State=myState;
B=rand (1,100);
isequal(A,B)
ans =
```

1

You can also reset a stream to its initial settings with the method reset.

```
reset(defaultStream)
A=rand(1,100);
reset(defaultStream)
B=rand(1,100);
isequal(A,B)
ans =
```

## Random Number Data Types

rand and randn generate values in double precision by default.

```
defaultStream=RandStream.getDefaultStream;
myState=defaultStream.State;
A=rand(1,5);
class(A)
ans =
double
```

To specify the class as double explicitly:
defaultStream.State=myState;
$B=r a n d\left(1,5\right.$, 'double' $\left.^{\prime}\right)$;
class(B)
ans $=$
double
isequal(A,B)
ans $=$
rand and randn will also generate values in single precision.

```
defaultStream.State=myState;
A=rand(1,5,'single');
class(A)
ans =
single
```

The values are the same as if you had cast the double precision values from the previous example. The random stream that the functions draw from advances the same way regardless of what class of values is returned.

```
A,B
A =
    0.8235 0.6948 0.3171 0.9502 0.0344
B =
    0.8235 0.6948 0.3171 0.9502 0.0344
```

randi supports both integer types and single or double precision.

```
A=randi([[1 10],1,5,'double');
class(A)
ans =
double
B=randi([1 10],1,5,'uint8');
class(B)
ans =
uint8
```

## Creating and Controlling a Random Number Stream

The @RandStream class allows you to create a random number stream. This is useful for several reasons. For example, you might want to generate random values without affecting the state of the default stream. You might want separate sources of randomness in a simulation. Or you may need to use a different generator algorithm than the one MATLAB software uses at startup. With the RandStream constructor, you can create your own stream, set the writable properties, and use it to generate random numbers. You can control the stream you create the same way you control the default stream. You can even replace the default stream with the stream you create.

To create a stream, use the RandStream constructor.

```
myStream=RandStream('mlfg6331_64');
rand(myStream,1,5)
ans =
    0.6530 0.8147 0.7167 0.8615 0.0764
```

The random stream myStream acts separately from the default stream. The functions rand, randn, and randi will continue to draw from the default stream, and will not affect the results of the @RandStream methods rand, randn and randi applied to myStream.

You can make myStream the default stream using the RandStream.setDefaultStream method.

RandStream.setDefaultStream(myStream)
RandStream.getDefaultStream
ans $=$
mlfg6331_64 random stream (current default)
Seed: 0
RandnAlg: Ziggurat
RandStream.getDefaultStream==myStream

## Substreams

You may want to return to a previous part of a simulation. A random stream can be controlled by having it jump to fixed checkpoints, called substreams. The Substream property allows you to jump back and forth among multiple substreams. To use the Substream property, create a stream using a generator that supports substreams. (See "Choosing a Random Number Generator" on page 3-12 for a list of generator algorithms and their properties.)

```
stream=RandStream('mlfg6331_64');
RandStream.setDefaultStream(stream)
```

The initial value of Substream is 1 .

```
stream.Substream
```

ans =

1
Substreams are useful in serial computation. Substreams can recreate all or part of a simulation by returning to a particular checkpoint in stream. For example, they can be used in loops.

```
for i=1:5
    stream.Substream=i;
    rand(1,i)
end
ans =
    0.6530
ans =
    0.3364 0.8265
ans =
    0.9539 0.6446 0.4913
ans =
    0.0244 0.5134 0.6305 0.6534
ans =
    0.3323 0.9296 0.5767 0.1233 0.6934
```

Each of these substreams can reproduce its loop iteration. For example, you can return to the 5 th substream. The result will return the same values as the 5th output above.

```
stream.Substream=5;
rand(1,5)
ans =
    0.3323 0.9296 0.5767 0.1233 0.6934
```

## Choosing a Random Number Generator

MATLAB software offers six generator algorithms. The following table summarizes the key properties of the available generator algorithms and the keywords used to create them. To return a list of all the available generator algorithms, use the RandStream. list method.

## Generator algorithms

| Keyword | Generator | Multiple <br> Stream and <br> Substream <br> Support | Approximate <br> Period In Full <br> Precision |
| :--- | :--- | :--- | :--- |
| mt19937ar | Mersenne <br> twister (default) | No | $2^{19937-1}$ |
| mcg16807 | Multiplicative <br> congruential <br> generator | No | $2^{31}-2$ |
| mlfg6331_64 | Multiplicative <br> lagged Fibonacci <br> generator | Yes | $2^{124}$ |
| mrg32k3a | Combined <br> multiple <br> recursive <br> generator | Yes | $2^{127}$ |
| shr3cong | Shift-register <br> generator <br> summed <br> with linear <br> congruential <br> generator | No | $2^{64}$ |
|  | Modified <br> subtract with <br> borrow generator | No | $2^{1492}$ |
| swb2712 |  |  |  |

Some of the generators (mcg16807, shr3cong, swb2712) provide for backwards compatibility with earlier versions of MATLAB. Two generators (mrg32k3a, mlfg6331_64) provide explicit support for parallel random number generation. The remaining generator (mt19937ar) is designed primarily for sequential applications. Depending on the application, some generators may be faster or return values with more precision.

Another reason for the choice of generators has to do with applications. All pseudorandom number generators are based on deterministic algorithms, and
all will fail a sufficiently specific statistical test for randomness. One way to check the results of a Monte Carlo simulation is to rerun the simulation with two or more different generator algorithms, and MATLAB software's choice of generators provide you with the means to do that. Although it is unlikely that your results will differ by more than Monte Carlo sampling error when using different generators, there are examples in the literature where this kind of validation has turned up flaws in a particular generator algorithm (see [10] for an example).

## Generator Algorithms

mcg16807
A 32-bit multiplicative congruential generator, as described in [11], with multiplier $a=7^{5}$, modulo $m=2^{31}-1$. This generator has a period of $2^{31}-2$ and does not support multiple streams or substreams. Each $U(0,1)$ value is created using a single 32 -bit integer from the generator;
the possible values are all multiples of $\left(2^{31}-1\right)^{-1}$ strictly within the interval $(0,1)$. The randn algorithm used by default for mcg16807 streams is the polar algorithm (described in [1]). Note: This generator is identical to the one used beginning in MATLAB Version 4 by both the rand and randn functions, activated using rand('seed', s) or randn('seed',s).
mlfg6331_64
A 64-bit multiplicative lagged Fibonacci generator, as described in [8], with lags $l=63, k=31$. This generator is similar to the MLFG implemented in the SPRNG package. It has a period of approximately $2^{124}$. It supports up to $2^{61}$ parallel streams, via parameterization, and $2^{51}$ substreams each of length $2^{72}$. Each $U(0,1)$ value is created using one 64 -bit integer from the generator; the possible values are all multiples of $2^{-53}$ strictly within the interval $(0,1)$. The randn algorithm used by default for mlfg6331_64 streams is the ziggurat algorithm [5], but with the mlfg6331_64 generator underneath.
mrg32k3a
A 32 -bit combined multiple recursive generator, as described in [3]. This generator is similar to the CMRG implemented in the RngStreams
package. It has a period of $2^{127}$, and supports up to $2^{63}$ parallel streams, via sequence splitting, and $2^{51}$ substreams each of length $2^{76}$. Each $U(0,1)$ value is created using two 32 -bit integers from the generator; the possible values are multiples of $2^{-53}$ strictly within the interval $(0,1)$. The randn algorithm used by default for mrg32k3a streams is the ziggurat algorithm [5], but with the mrg32k3a generator underneath.
mt19937ar
The Mersenne Twister, as described in [9], with Mersenne prime $2^{19937}-1$. This is the generator documented at http://www.math.sci.hiroshima-u.ac.jp/~m-mat/MT/emt.html. It has a period of $2^{19937}-1$. Each $U(0,1)$ value is created using two 32 -bit integers from the generator; the possible values are all multiples of $2^{-53}$ strictly within the interval $(0,1)$. This generator does not support multiple streams or substreams. The randn algorithm used by default for mt19937ar streams is the ziggurat algorithm [5], but with the mt19937ar generator underneath. Note: This generator is identical to the one used by the rand function beginning in MATLAB Version 7, activated using rand('twister', s).
shr3cong
Marsaglia's SHR3 shift-register generator summed with a linear congruential generator with multiplier $a=69069$, addend $b=1234567$, and modulus $2^{-32}$. SHR3 is a 3 -shift-register generator defined as $u=u\left(\mathbf{I}+\mathbf{L}^{17}\right)\left(\mathbf{I}+\mathbf{R}^{13}\right)\left(\mathbf{I}+\mathbf{L}^{5}\right)$, where $\mathbf{I}$ is the identity operator, $\mathbf{L}$ is the left shift operator, and $\mathbf{R}$ is the right shift operator. The combined generator (described in [4]) has a period of approximately $2^{64}$. This generator does not support multiple streams or substreams. Each $\mathrm{U}(0,1)$ value is created using one 32 -bit integer from the generator; the possible values are all multiples of $2^{-32}$ strictly within the interval $(0,1)$. The randn algorithm used by default for shr3cong streams is the earlier form of the ziggurat algorithm [7], but with the shr3cong generator underneath. Note: This generator is identical to the one used by the randn function beginning in MATLAB Version 5, activated using randn('state',s).
swb2712
A modified Subtract-with-Borrow generator, as described in [6]. This generator is similar to an additive lagged Fibonacci generator with lags 27 and 12 , but is modified to have a much longer period of approximately $2^{1492}$. The generator works natively in double precision to create $\mathrm{U}(0,1)$ values, and all values in the open interval $(0,1)$ are possible. The randn algorithm used by default for swb2712 streams is the ziggurat algorithm [5], but with the swb2712 generator underneath. Note: This generator is identical to the one used by the rand function beginning in MATLAB Version 5, activated using rand('state', s).

## Transformation Algorithms

## Inversion

Computes a normal random variate by applying the standard normal inverse cumulative distribution function to a uniform random variate. Exactly one uniform value is consumed per normal value.

Polar
The polar rejection algorithm, as described in [1]. Approximately 1.27 uniform values are consumed per normal value, on average.

## Ziggurat

The ziggurat algorithm, as described in [5]. Approximately 2.02 uniform values are consumed per normal value, on average.

## Compatibility Considerations

In MATLAB versions 7.6 and prior, the way to replicate results involving random numbers was to use keyword and seed value arguments with the rand and randn functions.

```
rand('twister',5489)
rand
ans =
    0.8147
rand('twister',5489)
rand
ans =
    0.8147
```

or to control the output by saving and restoring the state of the generator:

```
oldstate=rand('twister');
rand
ans =
    0.8147
rand('twister',oldstate)
rand
ans =
    0.8147
```

Using a @RandStream stream object simplifies this procedure. In the previous example, you need to know that you are using the generator for 'twister' in order to restore the saved state oldstate. With the @RandStream syntax, you can check what type of generator is active using the Type property. You can even reproduce results without knowing what type of generator is active or what properties are set. All that is necessary is to get a handle to the default stream with RandStream.getDefaultStream.

```
savedStream=RandStream.getDefaultStream;
savedState=savedStream.State;
A=rand(100);
```

```
savedStream.State=savedState;
B=rand (100);
isequal(A,B)
ans =
1
```

See the section "Legacy Random Stream" on page 3-24 for more information on compatibility issues.

## Multiple streams

MATLAB software includes generator algorithms that allow you to create multiple independent random number streams. The RandStream.create factory method allows you to create three streams that have the same generator algorithm and seed value but are statistically independent.

```
[s1,s2,s3]=RandStream.create('mlfg6331_64','NumStreams',3)
s1 =
mlfg6331_64 random stream
    StreamIndex: 1
        NumStreams: 3
            Seed: 0
            RandnAlg: Ziggurat
s2 =
mlfg6331_64 random stream
        StreamIndex: 2
        NumStreams: 3
            Seed: 0
            RandnAlg: Ziggurat
s3 =
mlfg6331_64 random stream
        StreamIndex: 3
        NumStreams: 3
            Seed: 0
            RandnAlg: Ziggurat
```

As evidence of independence, you can see that these streams are largely uncorrelated.

```
r1=rand(s1,100000,1);
r2=rand(s2, 100000,1);
r3=rand(s3,100000,1);
corrcoef([r1,r2,r3])
ans =
\begin{tabular}{rrr}
1.0000 & -0.0017 & -0.0010 \\
-0.0017 & 1.0000 & -0.0050 \\
-0.0010 & -0.0050 & 1.0000
\end{tabular}
```

By using different seeds, you can create streams that return different values and act separately from one another.

```
s1=RandStream('mt19937ar','seed',1);
s2=RandStream('mt19937ar','seed',2);
s3=RandStream('mt19937ar','seed',3);
```

Seed values must be integers between 0 and $2^{32}-1$. With different seeds, streams typically return values that are uncorrelated.

```
r1=rand(s1,100000,1);
r2=rand(s2,100000,1);
r3=rand(s3,100000,1);
corrcoef([r1,r2,r3])
ans =
\begin{tabular}{rrr}
1.0000 & 0.0030 & 0.0045 \\
0.0030 & 1.0000 & -0.0015 \\
0.0045 & -0.0015 & 1.0000
\end{tabular}
```

For generator types that do not explicitly support independent streams, different seeds provide a method to create multiple streams. However, using a generator specifically designed for multiple independent streams is a better option, as the statistical properties across streams are better understood.

Depending on the application, it might be useful to create only some of the streams in a set of independent streams. The StreamIndex property returns the index of a specified stream from a set of factory-generated streams.

```
numLabs=256;
labIndex=4;
s1=RandStream.create('mlfg6331_64',
    'NumStreams',numLabs,'StreamIndices',labIndex)
S1=
mlfg6331_64 random stream
    StreamIndex: 4
        NumStreams: 256
            Seed: 0
            RandnAlg: Ziggurat
```

Multiple streams, since they are statistically independent, can be used to verify the precision of a simulation. For example, a set of independent streams can be used to repeat a Monte Carlo simulation several times in different MATLAB sessions or on different processors and determine the variance in the results. This makes multiple streams useful in large-scale parallel simulations.

Note Not all generators algorithms support multiple streams. See the table of generator algorithms in "Choosing a Random Number Generator" on page 3-12 for a summary of generator properties.

# Updating Your Random Number Generator Syntax 

Before MATLAB Version 7.7 (R2008b), the rand and randn functions used a different syntax for controlling the random number generators. In addition, rand and randn had separate underlying random number streams.

For example, in MATLAB Version 7.5 (R2007b), the syntax to reset the rand function to its startup setting in MATLAB was:

```
rand('twister',5489)
```

The syntax to reset the randn function to its startup setting in MATLAB was:

```
randn('state',0)
```

Note The syntaxes rand('keyword',seed_value) and randn('keyword', seed_value) are still supported in the current version of MATLAB, though they are not recommended.

The old control syntaxes for rand and randn do two things:

- The first argument-the keyword—selected a random number generator.
- The second argument specified an integer seed or a state vector with which to reinitialize that generator.

For example, the 'state' keyword in rand('state', 0) did not initialize the state of whatever generator was currently active, but rather activated the MATLAB Version 5 generator and initialized it with the seed 0. Similarly, the 'seed' keyword in rand('seed', 0) did not set the seed of whatever generator was currently active, but rather activated the MATLAB Version 4 generator and initialized it with the seed 0 .

In the new RandStream syntax, the first argument to RandStream selects the generator type. The other arguments are name-value pairs that allow you to set a seed value and choose a transformation algorithm for randn. To update your code so that you get the same sequences of random numbers as in your old code, use the following tables:

| Instead of this rand usage: | Do this: | Generator algorithm |
| :---: | :---: | :---: |
| rand('twister',5489) | ```s = RandStream('mt19937ar','Seed', 5489) RandStream.setDefaultStream(s)``` | Mersenne Twister (the default in MATLAB versions 7.4 and later). |
| rand('state'0) | $\begin{aligned} & \hline s=\text { RandStream('swb2712','Seed', 0) } \\ & \text { RandStream.setDefaultStream(s) } \end{aligned}$ | Modified subtract with borrow algorithm (the default in MATLAB versions 5 through 7.3). |
| rand('seed', 0) | $\mathrm{s}=\text { RandStream('mcg16807', 'Seed', } 0)$ RandStream.setDefaultStream(s) | Multiplicative congruential algorithm (the default in MATLAB version 4 and before). |

| Instead of this randn usage: | Do this: | Transformation algorithm |
| :---: | :---: | :---: |
| randn('seed', 0) | s = RandStream('mcg16807', 'Seed',0) RandStream.setDefaultStream(s) | Marsaglia's ziggurat algorithm (the default in MATLAB versions 5 and later). |
| randn('state', 0) | s = RandStream('shr3cong') RandStream.setDefaultStream(s) | Polar algorithm (the default in MATLAB version 4 and before). |

Tip In MATLAB V7.6 (R2008a) and above, the functions rand and randn draw from the same random number stream and apply a transformation to produce the desired distribution. When using the the legacy random stream, however, rand and randn have completely separate streams. Using RandStream, there is no simple way to replicate the exact number sequences created by running this sequence of commands, for example:

```
rand('state',0)
randn(`state',0)
rand( )
randn( )
```

You should use the legacy random stream to replicate such sequences.

## Legacy Random Stream

Any use of the syntax rand('keyword', value), where value is an integer will activate the legacy random stream.

```
rand('twister',5489)
RandStream.getDefaultStream
ans =
legacy random stream (current default)
    RAND algorithm: V7.4 (Mersenne Twister)
    RANDN algorithm: V5 (Ziggurat)
```

While the legacy random stream is active, rand and randn use separate generators. The generator used for each function is determined by the keyword argument of the function. For example, the twister keyword will activate the Mersenne Twister generator for rand and the ziggurat algorithm for randn. While the legacy random stream is active, you can use the old control syntax to activate other legacy generators as well. The old control syntaxes for rand and randn and their equivalents with the RandStream constructor are given in the tables above. (The randi function is new in MATLAB Version 7.7 (R2008b) and does not accept legacy random stream keyword arguments. It can be used with the legacy random stream; in which case it uses the same generator as rand.)

While the legacy random stream is active, you may still create random stream objects and generate values from those streams using RandStream methods. All of the generator and transformation algorithms that were available in MATLAB Version 7.6 (R2008a) and earlier are available in the current version.

## Deactivating the Legacy Random Stream

Use of an old syntax (rand('keyword', value), randn('keyword', value)) will will activate the legacy random stream. To deactivate the legacy random stream, create a new random stream with the RandStream constructor and make it the default stream.

1 Create a number stream:

$$
s=\text { RandStream('mt19937ar') }
$$

2 Make it the default stream:

```
RandStream.setDefaultStream(s)
```

## Functions That Support Sparse Matrices

Sparse matrix functions are located in the MATLAB sparfun directory. For a complete list, brief descriptions, and links to reference pages, type:
help sparfun
Sparse matrix functions fall into the following categories:

- "Elementary Sparse Matrices" on page 4-2
- "Full to Sparse Conversion" on page 4-3
- "Working with Sparse Matrices" on page 4-3
- "Graph Theory" on page 4-4
- "Reordering Algorithms" on page 4-4
- "Linear Algebra" on page 4-4
- "Linear Equations (Iterative Methods)" on page 4-5
- "Other Miscellaneous Functions" on page 4-5

Elementary Sparse Matrices

| Function | Description |
| :--- | :--- |
| speye | Sparse identity matrix |
| sprand | Sparse uniformly distributed random matrix |
| sprandn | Sparse normally distributed random matrix |

| Function | Description |
| :--- | :--- |
| sprandsym | Sparse random symmetric matrix |
| spdiags | Sparse matrix formed from diagonals |

## Full to Sparse Conversion

| Function | Description |
| :--- | :--- |
| sparse | Create sparse matrix |
| full | Convert sparse matrix to full matrix |
| find | Find indices of nonzero elements |
| spconvert | Import from sparse matrix external format |

## Working with Sparse Matrices

| Function | Description |
| :--- | :--- |
| nnz | Number of nonzero matrix elements |
| nonzeros | Nonzero matrix elements |
| nzmax | Amount of storage allocated for nonzero matrix <br> elements |
| spones | Replace nonzero sparse matrix elements with ones |
| spalloc | Allocate space for sparse matrix |
| issparse | True for sparse matrix |
| spfun | Apply function to nonzero matrix elements |
| spy | Visualize sparsity pattern |

## Graph Theory

| Function | Description |
| :--- | :--- |
| gplot | Plot graph, as in "graph theory" |
| etree | Elimination tree |
| etreeplot | Plot elimination tree |
| treelayout | Lay out tree or forest |
| treeplot | Plot picture of tree |

## Reordering Algorithms

| Function | Description |
| :--- | :--- |
| colamd | Column approximate minimum degree permutation |
| symamd | Symmetric approximate minimum degree <br> permutation |
| symrcm | Symmetric reverse Cuthill-McKee permutation |
| colperm | Column permutation |
| randperm | Random permutation |
| dmperm | Dulmage-Mendelsohn permutation |

## Linear Algebra

| Function | Description |
| :--- | :--- |
| eigs | A few eigenvalues |
| svds | A few singular values |
| luinc | Incomplete LU factorization |
| ilu | Incomplete LU factorization |
| cholinc | Incomplete Cholesky factorization |
| normest | Estimate the matrix 2-norm |

| Function | Description |
| :--- | :--- |
| condest | 1-norm condition number estimate |
| sprank | Structural rank |

## Linear Equations (Iterative Methods)

| Function | Description |
| :--- | :--- |
| bicg | Biconjugate gradients method |
| bicgstab | Biconjugate gradients stabilized method |
| bicgstabl | Biconjugate gradients stabilized(l) method |
| cgs | Conjugate gradients squared method |
| gmres | Generalized minimum residual method |
| lsqnonneg | Solve nonnegative least-squares constraints <br> problem |
| lsqr | LSQR method |
| minres | Minimum residual method |
| pcg | Preconditioned conjugate gradients method |
| qmr | Quasi-minimal residual method |
| tfqmr | Transpose-free quasi-minimal residual method |
| symmlq | Symmetric LQ method |

## Other Miscellaneous Functions

| Function | Description |
| :--- | :--- |
| spaugment | Form least squares augmented system |
| spparms | Set parameters for sparse matrix routines |
| symbfact | Symbolic factorization analysis |

## Functions That Do Not Support Sparse Matrices

- "Elementary Matrices and Arrays" on page 4-6
- "Elementary Math Functions" on page 4-6
- "Bit-Wise Functions" on page 4-7
- "Eigenvalue and Singular Value Functions" on page 4-7
- "Matrix Analysis Functions" on page 4-8
- "Factorization Functions" on page 4-8
- "Linear Equation Functions" on page 4-8
- "Specialized Math Functions" on page 4-9
- "Filtering and Convolution Functions" on page 4-9
- "Fourier Transform Functions" on page 4-9
- "Histogram Plotting Functions" on page 4-10

These built-in functions do not accept sparse matrices as input.

## Elementary Matrices and Arrays

| Function | Description |
| :--- | :--- |
| rand | Uniformly distributed pseudorandom numbers |

## Elementary Math Functions

## Complex Functions.

| Function | Description |
| :--- | :--- |
| complex | Construct complex data from real and imaginary <br> components |

## Real Array Exponential Functions.

| Function | Description |
| :--- | :--- |
| reallog | Natural logarithm for nonnegative real arrays |
| realpow | Array power for real-only output |
| realsqrt | Square root for nonnegative real arrays |

## Bit-Wise Functions

| Function | Description |
| :--- | :--- |
| bitand | Bitwise AND |
| bitcmp | Bitwise complement |
| bitget | Bit at specified position |
| bitmax | Maximum double-precision floating-point integer |
| bitor | Bitwise OR |
| bitset | Set bit at specified position |
| bitshift | Shift bits specified number of places |
| bitxor | Bitwise XOR |

Eigenvalue and Singular Value Functions

| Function | Description |
| :--- | :--- |
| hess | Hessenberg form of matrix |
| ordeig | Eigenvalues of quasitriangular matrices |
| ordqz | Reorder eigenvalues in QZ factorization |
| ordschur | Reorder eigenvalues in Schur factorization |

| Function | Description |
| :--- | :--- |
| schur | Schur decomposition |
| svd | Singular value decomposition |

## Matrix Analysis Functions

| Function | Description |
| :--- | :--- |
| cond | Condition number with respect to inversion |
| null | Null space |
| orth | Range space of matrix |
| rcond | Matrix reciprocal condition number estimate |

## Factorization Functions

| Function | Description |
| :--- | :--- |
| cholupdate | Rank 1 update to Cholesky factorization |
| gsvd | Generalized singular value decomposition |
| qz | QZ factorization for generalized eigenvalues |

## Linear Equation Functions

| Function | Description |
| :--- | :--- |
| linsolve | Solve linear system of equations |
| pinv | Moore-Penrose pseudoinverse of matrix |

## Specialized Math Functions

| Function | Description |
| :--- | :--- |
| airy | Airy functions |
| besselh | Bessel function of third kind (Hankel function) |
| besseli | Modified Bessel function of first kind |
| besselj | Bessel function of first kind |
| besselk | Modified Bessel function of second kind |
| bessely | Bessel function of second kind |
| erfc | Error function |
| erf | Error function |
| erfcx | Error function |
| gamma | Gamma function |
| gammaln | Gamma function |
| psi | Psi (polygamma) function |

## Filtering and Convolution Functions

| Function | Description |
| :--- | :--- |
| conv2 | 2-D convolution |
| convn | N-D convolution |
| filter | 1-D digital filter |
| filter2 | 2-D digital filter |

## Fourier Transform Functions

| Function | Description |
| :--- | :--- |
| $f f t$ | Discrete Fourier transform |
| $f f t n$ | N-D discrete Fourier transform |

| Function | Description |
| :--- | :--- |
| ifft | Inverse discrete Fourier transform |
| ifftn | N-D inverse discrete Fourier transform |

## Histogram Plotting Functions

| Function | Description |
| :--- | :--- |
| histc | Histogram count |

## Functions with Sparse Alternatives

These functions do not accept sparse inputs, but you can use other functions in their place.

| Function | Replacement Function Supporting Sparse Inputs |
| :--- | :--- |
| cond | Use condest instead. |
| eig | Syntax d $=$ eig(S) accepts a sparse symmetric matrix <br> S. Otherwise, use eigs in place of eig. |
| norm(S,2) | Use normest for the 2-norm of a sparse matrix S. |
| svd | Use svds instead. |

## Computational Advantages

## In this section...

"Memory Management" on page 4-10
"Computational Efficiency" on page 4-11

## Memory Management

Using sparse matrices to store data that contains a large number of zero-valued elements can both save a significant amount of memory and
speed up the processing of that data. sparse is an attribute that you can assign to any two-dimensional MATLAB matrix that is composed of double or logical elements.

The sparse attribute allows MATLAB to:

- Store only the nonzero elements of the matrix, together with their indices.
- Reduce computation time by eliminating operations on zero elements.

For full matrices, MATLAB stores every matrix element internally. Zero-valued elements require the same amount of storage space as any other matrix element. For sparse matrices, however, MATLAB stores only the nonzero elements and their indices. For large matrices with a high percentage of zero-valued elements, this scheme significantly reduces the amount of memory required for data storage.

The whos command provides high-level information about matrix storage, including size and storage class. For example, this whos listing shows information about sparse and full versions of the same matrix.

| M_full $=$ magic (1100) ; |  | \% Create 1100-by-1100 matrix. |  |  |
| :---: | :---: | :---: | :---: | :---: |
| M_full (M_full > 50) = 0; |  | \% Set elements >50 to zero. |  |  |
| M_sparse $=$ sparse(M_full); $\quad$ Create sparse matrix of same. |  |  |  |  |
| whos |  |  |  |  |
| Name | Size | Bytes | Class | Attributes |
| M_full | $1100 \times 1100$ | 9680000 | double |  |
| M sparse | $1100 \times 1100$ | 5004 | double | sparse |

Notice that the number of bytes used is fewer in the sparse case, because zero-valued elements are not stored.

## Computational Efficiency

Sparse matrices also have significant advantages in terms of computational efficiency. Unlike operations with full matrices, operations with sparse matrices do not perform unnecessary low-level arithmetic, such as zero-adds ( $x+0$ is always $x$ ). The resulting efficiencies can lead to dramatic improvements in execution time for programs working with large amounts of sparse data.

For more information, see "Sparse Matrix Operations" on page 4-25.

## Constructing Sparse Matrices

In this section...<br>"Creating Sparse Matrices" on page 4-13<br>"Importing Sparse Matrices" on page 4-18

## Creating Sparse Matrices

- "Converting Full to Sparse" on page 4-13
- "Creating Sparse Matrices Directly" on page 4-14
- "Creating Sparse Matrices from Their Diagonal Elements" on page 4-16

MATLAB software never creates sparse matrices automatically. Instead, you must determine if a matrix contains a large enough percentage of zeros to benefit from sparse techniques.

The density of a matrix is the number of nonzero elements divided by the total number of matrix elements. For matrix M, this would be

```
nnz(M) / prod(size(M));
nnz(M) / numel(M);
```

or

Matrices with very low density are often good candidates for use of the sparse format.

## Converting Full to Sparse

You can convert a full matrix to sparse storage using the sparse function with a single argument.

```
S = sparse(A)
```

For example:

$$
A=\left[\begin{array}{llll}
{[0} & 0 & 0 & 5
\end{array}\right.
$$

$$
\begin{array}{cccc}
0 & 2 & 0 & 0 \\
1 & 3 & 0 & 0 \\
0 & 0 & 4 & 0] ; \\
\mathrm{S}=\underset{\operatorname{sparse}(\mathrm{A})}{ }
\end{array}
$$

produces
S =

| $(3,1)$ | 1 |
| :--- | :--- |
| $(2,2)$ | 2 |
| $(3,2)$ | 3 |
| $(4,3)$ | 4 |
| $(1,4)$ | 5 |

The printed output lists the nonzero elements of S, together with their row and column indices. The elements are sorted by columns, reflecting the internal data structure.

You can convert a sparse matrix to full storage using the full function, provided the matrix order is not too large. For example $A=$ full(S) reverses the example conversion.

Converting a full matrix to sparse storage is not the most frequent way of generating sparse matrices. If the order of a matrix is small enough that full storage is possible, then conversion to sparse storage rarely offers significant savings.

## Creating Sparse Matrices Directly

You can create a sparse matrix from a list of nonzero elements using the sparse function with five arguments.

$$
S=\operatorname{sparse}(i, j, s, m, n)
$$

i and $j$ are vectors of row and column indices, respectively, for the nonzero elements of the matrix. $s$ is a vector of nonzero values whose indices are specified by the corresponding ( $i, j$ ) pairs. $m$ is the row dimension for the resulting matrix, and n is the column dimension.

The matrix $S$ of the previous example can be generated directly with

```
S = sparse([3 2 3 4 1],[1 2 2 3 4],[1 2 3 4 5],4,4)
S =
\begin{tabular}{ll}
\((3,1)\) & 1 \\
\((2,2)\) & 2 \\
\((3,2)\) & 3 \\
\((4,3)\) & 4 \\
\((1,4)\) & 5
\end{tabular}
```

The sparse command has a number of alternate forms. The example above uses a form that sets the maximum number of nonzero elements in the matrix to length(s). If desired, you can append a sixth argument that specifies a larger maximum, allowing you to add nonzero elements later without reallocating the sparse matrix.

The matrix representation of the second difference operator is a good example of a sparse matrix. It is a tridiagonal matrix with -2 s on the diagonal and 1 s on the super- and subdiagonal. There are many ways to generate it-here's one possibility.

```
D = sparse(1:n,1:n,-2*ones(1,n),n,n);
E = sparse(2:n,1:n-1,ones(1,n-1),n,n);
S = E+D+E'
For \(n=5\), MATLAB responds with
S =
```

| $(1,1)$ | -2 |
| :--- | ---: |
| $(2,1)$ | 1 |
| $(1,2)$ | 1 |
| $(2,2)$ | -2 |
| $(3,2)$ | 1 |
| $(2,3)$ | 1 |
| $(3,3)$ | -2 |
| $(4,3)$ | 1 |
| $(3,4)$ | 1 |
| $(4,4)$ | -2 |

| $(5,4)$ | 1 |
| :--- | ---: |
| $(4,5)$ | 1 |
| $(5,5)$ | -2 |

Now $F=$ full(S) displays the corresponding full matrix.
F = full(S)
F =

| -2 | 1 | 0 | 0 | 0 |
| ---: | ---: | ---: | ---: | ---: |
| 1 | -2 | 1 | 0 | 0 |
| 0 | 1 | -2 | 1 | 0 |
| 0 | 0 | 1 | -2 | 1 |
| 0 | 0 | 0 | 1 | -2 |

## Creating Sparse Matrices from Their Diagonal Elements

Creating sparse matrices based on their diagonal elements is a common operation, so the function spdiags handles this task. Its syntax is

$$
S=\operatorname{spdiags}(B, d, m, n)
$$

To create an output matrix S of size $m$-by- $n$ with elements on $p$ diagonals:

- B is a matrix of size $\min (m, n)$-by- $p$. The columns of B are the values to populate the diagonals of $S$.
- $d$ is a vector of length $p$ whose integer elements specify which diagonals of $S$ to populate.

That is, the elements in column j of B fill the diagonal specified by element j of $d$.

Note If a column of $B$ is longer than the diagonal it's replacing, super-diagonals are taken from the lower part of the column of $B$, and sub-diagonals are taken from the upper part of the column of B.

As an example, consider the matrix B and the vector d.

$$
\begin{array}{ccc}
B=\left[\begin{array}{ccc}
41 & 11 & 0 \\
52 & 22 & 0 \\
63 & 33 & 13 \\
74 & 44 & 24
\end{array}\right] ; \\
& d=\left[\begin{array}{cc}
-3 & \\
0 & \\
2] ; &
\end{array}\right]
\end{array}
$$

Use these matrices to create a 7 -by- 4 sparse matrix A:

```
A = spdiags(B,d,7,4)
A =
    (1,1) 11
    (4,1) 41
    (2,2) 22
    (5,2) 52
    (1,3) 13
    (3,3) 33
    (6,3) 63
    (2,4) 24
    (4,4) 44
    (7,4) 74
```

In its full form, A looks like this:

```
full(A)
ans =
\begin{tabular}{rrrr}
11 & 0 & 13 & 0 \\
0 & 22 & 0 & 24 \\
0 & 0 & 33 & 0 \\
41 & 0 & 0 & 44 \\
0 & 52 & 0 & 0 \\
0 & 0 & 63 & 0 \\
0 & 0 & 0 & 74
\end{tabular}
```

spdiags can also extract diagonal elements from a sparse matrix, or replace matrix diagonal elements with new values. Type help spdiags for details.

## Importing Sparse Matrices

You can import sparse matrices from computations outside the MATLAB environment. Use the spconvert function in conjunction with the load command to import text files containing lists of indices and nonzero elements. For example, consider a three-column text file T.dat whose first column is a list of row indices, second column is a list of column indices, and third column is a list of nonzero values. These statements load T. dat into MATLAB and convert it into a sparse matrix S :

```
load T.dat
S = spconvert(T)
```

The save and load commands can also process sparse matrices stored as binary data in MAT-files.

## Accessing Sparse Matrices

## In this section...

"Nonzero Elements" on page 4-19
"Indices and Values" on page 4-21
"Indexing in Sparse Matrix Operations" on page 4-21
"Visualizing Sparse Matrices" on page 4-24

## Nonzero Elements

There are several commands that provide high-level information about the nonzero elements of a sparse matrix:

- nnz returns the number of nonzero elements in a sparse matrix.
- nonzeros returns a column vector containing all the nonzero elements of a sparse matrix.
- nzmax returns the amount of storage space allocated for the nonzero entries of a sparse matrix.

To try some of these, load the supplied sparse matrix west0479, one of the Harwell-Boeing collection.
load west0479
whos

| Name | Size | Bytes | Class | Attributes |
| :--- | :---: | ---: | :--- | :--- |
|  |  |  |  |  |
| M_full | $1100 \times 1100$ | 9680000 | double |  |
| M_sparse | $1100 \times 1100$ | 5004 | double | sparse |
| west0479 | $479 \times 479$ | 24564 | double | sparse |

This matrix models an eight-stage chemical distillation column.
Try these commands.
nnz(west0479)

```
ans =
1887
format short e
west0479
west0479 =
    (25,1) 1.0000e+00
    (31,1) -3.7648e-02
    (87,1) -3.4424e-01
    (26,2) 1.0000e+00
    (31,2) -2.4523e-02
    (88,2) -3.7371e-01
    (27,3) 1.0000e+00
    (31,3) -3.6613e-02
    (89,3) -8.3694e-01
    (28,4) 1.3000e+02
nonzeros(west0479);
        ans =
        1.0000e+00
    -3.7648e-02
    -3.4424e-01
        1.0000e+00
    -2.4523e-02
    -3.7371e-01
        1.0000e+00
    -3.6613e-02
    -8.3694e-01
    1.3000e+02
        .
        .
```

Note Use Ctrl+C to stop the nonzeros listing at any time.

Note that initially nnz has the same value as nzmax by default. That is, the number of nonzero elements is equivalent to the number of storage locations allocated for nonzeros. However, MATLAB software does not dynamically release memory if you zero out additional array elements. Changing the value of some matrix elements to zero changes the value of nnz, but not that of nzmax.

However, you can add as many nonzero elements to the matrix as desired. You are not constrained by the original value of nzmax.

## Indices and Values

For any matrix, full or sparse, the find function returns the indices and values of nonzero elements. Its syntax is

$$
[i, j, s]=\text { find }(S)
$$

find returns the row indices of nonzero values in vector $i$, the column indices in vector $j$, and the nonzero values themselves in the vector $s$. The example below uses find to locate the indices and values of the nonzeros in a sparse matrix. The sparse function uses the find output, together with the size of the matrix, to recreate the matrix.

```
[i,j,s] = find(S)
[m,n] = size(S)
S = sparse(i,j,s,m,n)
```

## Indexing in Sparse Matrix Operations

Because sparse matrices are stored in compressed sparse column format, there are different costs associated with indexing into a sparse matrix than there are indexing into a full matrix. For example, consider the 4 -by- 4 identity matrix:

$$
A=\operatorname{eye}(4) \text {; }
$$

To replace the 2,1 entry with the number 3 , you would do this:

```
A(2,1)=3
A =
\begin{tabular}{llll}
1 & 0 & 0 & 0 \\
3 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{tabular}
```

Now suppose you were working on a sparse matrix:

```
B=speye(4);
```

The find command returns the indices and values of the nonzero components of a matrix:

```
[i,j,s]=find(B);
[i,j,s]
ans =
\begin{tabular}{lll}
1 & 1 & 1 \\
2 & 2 & 1 \\
3 & 3 & 1 \\
4 & 4 & 1
\end{tabular}
```

If you wanted to change a value in this matrix, you might be tempted to use the same indexing:

$$
B(3,1)=42 ;
$$

This code does work, however, it is slow. Since MATLAB stores sparse matrices in compressed sparse column format, it needs to overwrite multiple entries in B.

```
[i,j,s]=find(B);
[i,j,s]
ans =
    1 1 1
```

| 3 | 1 | 42 |
| ---: | ---: | ---: |
| 2 | 2 | 1 |
| 3 | 3 | 1 |
| 4 | 4 | 1 |

In order to store the new matrix with ' 42 ' at (3,1), MATLAB overwrites all matrix values after 3,1 and adds an additional row to the nonzero values vector and the row indices vectors.

Instead of using subscripted assignment, try using the sparse command to construct the matrix from the triplets. For example, suppose you wanted the sparse form of the coordinate matrix C :

$$
\mathrm{C}=\begin{array}{rrrr}
4 & 0 & 0 & -1 \\
0 & 4 & 0 & -1 \\
0 & 0 & 4 & -1 \\
-1 & -1 & -1 & 4
\end{array}
$$

You can use indexing:

$$
\begin{aligned}
& C=4 * \text { speye ( } 4) ; \\
& C(1: 3,4)=-1 ; \\
& C(4,1: 3)=-1 ;
\end{aligned}
$$

but this has the same issue that many of the entries in C need to be overwritten. If you use a loop, you exacerbate the inefficiency:

```
C=4*speye(4);
for k=1:3
    C(k,4)=-1;
    C(4,k)=-1;
end
```

Instead of rewriting every matrix entry when you want to rewrite one, construct the three-column matrix directly with the sparse function:

```
i = [1 4 4 2 4 3 3 4 1 2 3 4]';
j = [1 1 1 2 2 2 3 3 4 4 4 4]';
s = [4 [-1 4 4-1 4 4-1 -1 -1 -1 4]';
CSP = sparse(i,j,s);
```

For more information on how MATLAB stores sparse matrices, see John R. Gilbert, Cleve Moler, and Robert Schreiber's Sparse Matrices In Matlab: Design and Implementation, (SIAM Journal on Matrix Analysis and Applications , 13:1, 333-356 (1992)).

## Visualizing Sparse Matrices

It is often useful to use a graphical format to view the distribution of the nonzero elements within a sparse matrix. The MATLAB spy function produces a template view of the sparsity structure, where each point on the graph represents the location of a nonzero array element.

For example:
spy (west0479)

## Sparse Matrix Operations

In this section...<br>"Efficiency of Operations" on page 4-25<br>"Permutations and Reordering" on page 4-26<br>"Factoring Sparse Matrices" on page 4-30<br>"Systems of Linear Equations" on page 4-37<br>"Eigenvalues and Singular Values" on page 4-40<br>"Performance Limitations" on page 4-42

## Efficiency of Operations

- "Computational Complexity" on page 4-25
- "Algorithmic Details" on page 4-25

## Computational Complexity

The computational complexity of sparse operations is proportional to nnz, the number of nonzero elements in the matrix. Computational complexity also depends linearly on the row size $m$ and column size $n$ of the matrix, but is independent of the product $m * n$, the total number of zero and nonzero elements.

The complexity of fairly complicated operations, such as the solution of sparse linear equations, involves factors like ordering and fill-in, which are discussed in the previous section. In general, however, the computer time required for a sparse matrix operation is proportional to the number of arithmetic operations on nonzero quantities.

## Algorithmic Details

Sparse matrices propagate through computations according to these rules:

- Functions that accept a matrix and return a scalar or constant-size vector always produce output in full storage format. For example, the size function always returns a full vector, whether its input is full or sparse.
- Functions that accept scalars or vectors and return matrices, such as zeros, ones, rand, and eye, always return full results. This is necessary to avoid introducing sparsity unexpectedly. The sparse analog of zeros (m,n) is simply sparse ( $m, n$ ). The sparse analogs of rand and eye are sprand and speye, respectively. There is no sparse analog for the function ones.
- Unary functions that accept a matrix and return a matrix or vector preserve the storage class of the operand. If $S$ is a sparse matrix, then chol $(S)$ is also a sparse matrix, and diag(S) is a sparse vector. Columnwise functions such as max and sum also return sparse vectors, even though these vectors can be entirely nonzero. Important exceptions to this rule are the sparse and full functions.
- Binary operators yield sparse results if both operands are sparse, and full results if both are full. For mixed operands, the result is full unless the operation preserves sparsity. If $S$ is sparse and $F$ is full, then $S+F, S * F$, and $F \backslash S$ are full, while S. *F and S\&F are sparse. In some cases, the result might be sparse even though the matrix has few zero elements.
- Matrix concatenation using either the cat function or square brackets produces sparse results for mixed operands.
- Submatrix indexing on the right side of an assignment preserves the storage format of the operand unless the result is a scalar. $T=S(i, j)$ produces a sparse result if $S$ is sparse and either $i$ or $j$ is a vector. It produces a full scalar if both $i$ and $j$ are scalars. Submatrix indexing on the left, as in $T(i, j)=S$, does not change the storage format of the matrix on the left.

## Permutations and Reordering

- "Reordering for Sparsity" on page 4-29
- "Reordering to Reduce Bandwidth" on page 4-29
- "Approximate Minimum Degree Ordering" on page 4-29

A permutation of the rows and columns of a sparse matrix $S$ can be represented in two ways:

- A permutation matrix $P$ acts on the rows of $S$ as $P * S$ or on the columns as $\mathrm{S}^{*} \mathrm{P}^{\prime}$.
- A permutation vector $p$, which is a full vector containing a permutation of $1: n$, acts on the rows of $S$ as $S(p,:)$, or on the columns as $S(:, p)$.

For example, the statements

```
p = [llllll
I = eye(5,5);
P = I(p,:);
e = ones(4,1);
S = diag(11:11:55) + diag(e,1) + diag(e,-1)
```

produce:

```
p =
    1 3 4 4 2 5
P =
\begin{tabular}{lllll}
1 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 \\
0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1
\end{tabular}
S =
\begin{tabular}{rrrrr}
11 & 1 & 0 & 0 & 0 \\
1 & 22 & 1 & 0 & 0 \\
0 & 1 & 33 & 1 & 0 \\
0 & 0 & 1 & 44 & 1 \\
0 & 0 & 0 & 1 & 55
\end{tabular}
```

You can now try some permutations using the permutation vector $p$ and the permutation matrix $P$. For example, the statements $S(p,:)$ and $P * S$ produce

```
ans =
\begin{tabular}{rrrrr}
11 & 1 & 0 & 0 & 0 \\
0 & 1 & 33 & 1 & 0 \\
0 & 0 & 1 & 44 & 1
\end{tabular}
```

| 1 | 22 | 1 | 0 | 0 |
| ---: | ---: | ---: | ---: | ---: |
| 0 | 0 | 0 | 1 | 55 |

Similarly, S(:, p) and S*P' produce

```
ans =
```

| 11 | 0 | 0 | 1 | 0 |
| ---: | ---: | ---: | ---: | ---: |
| 1 | 1 | 0 | 22 | 0 |
| 0 | 33 | 1 | 1 | 0 |
| 0 | 1 | 44 | 0 | 1 |
| 0 | 0 | 1 | 0 | 55 |

If $P$ is a sparse matrix, then both representations use storage proportional to $n$ and you can apply either to $S$ in time proportional to $n n z(S)$. The vector representation is slightly more compact and efficient, so the various sparse matrix permutation routines all return full row vectors with the exception of the pivoting permutation in LU (triangular) factorization, which returns a matrix compatible with the full LU factorization.

To convert between the two representations, let I = speye( $n$ ) be an identity matrix of the appropriate size. Then,

```
P = I (p,:)
P' = I(:,p)
p = (1:n)*P'
p = (P*(1:n)')'
```

The inverse of $P$ is simply $R=P^{\prime}$. You can compute the inverse of $p$ with $r(p)=1: n$.

```
\(r(p)=1: 5\)
\(r=\)
\(\begin{array}{lllll}1 & 4 & 2 & 3 & 5\end{array}\)
```

## Reordering for Sparsity

Reordering the columns of a matrix can often make its LU or QR factors sparser. Reordering the rows and columns can often make its Cholesky factors sparser. The simplest such reordering is to sort the columns by nonzero count. This is sometimes a good reordering for matrices with very irregular structures, especially if there is great variation in the nonzero counts of rows or columns.

The function $p=$ colperm(S) computes this column-count permutation. The colperm code has only a single line.

```
[ignore,p] = sort(sum(spones(S)));
```

This line performs these steps:
1 The inner call to spones creates a sparse matrix with ones at the location of every nonzero element in $S$.

2 The sum function sums down the columns of the matrix, producing a vector that contains the count of nonzeros in each column.

## 3 full converts this vector to full storage format.

4 sort sorts the values in ascending order. The second output argument from sort is the permutation that sorts this vector.

## Reordering to Reduce Bandwidth

The reverse Cuthill-McKee ordering is intended to reduce the profile or bandwidth of the matrix. It is not guaranteed to find the smallest possible bandwidth, but it usually does. The function symrcm (A) actually operates on the nonzero structure of the symmetric matrix $\mathrm{A}+\mathrm{A}^{\prime}$, but the result is also useful for asymmetric matrices. This ordering is useful for matrices that come from one-dimensional problems or problems that are in some sense "long and thin."

## Approximate Minimum Degree Ordering

The degree of a node in a graph is the number of connections to that node. This is the same as the number of off-diagonal nonzero elements in the corresponding row of the adjacency matrix. The approximate minimum
degree algorithm generates an ordering based on how these degrees are altered during Gaussian elimination or Cholesky factorization. It is a complicated and powerful algorithm that usually leads to sparser factors than most other orderings, including column count and reverse Cuthill-McKee. Because the keeping track of the degree of each node is very time-consuming, the approximate minimum degree algorithm uses an approximation to the degree, rather than the exact degree.

The following MATLAB functions implement the approximate minimum degree algorithm:

- symamd - Use with symmetric matrices.
- colamd - Use with nonsymmetric matrices and symmetric matrices of the form $A^{*} A^{\prime}$ or $A^{\prime *} A$.

See "Reordering and Factorization" on page 4-31 for an example using symamd.
You can change various parameters associated with details of the algorithms using the spparms function.

For details on the algorithms used by colamd and symamd, see [5]. The approximate degree the algorithms use is based on [1].

## Factoring Sparse Matrices

- "LU Factorization" on page 4-30
- "Cholesky Factorization" on page 4-33
- "QR Factorization" on page 4-34
- "Incomplete Factorizations" on page 4-35

## LU Factorization

If $S$ is a sparse matrix, the following command returns three sparse matrices $L, U$, and $P$ such that $P * S=L * U$.

$$
[L, U, P]=\operatorname{lu}(S)
$$

lu obtains the factors by Gaussian elimination with partial pivoting. The permutation matrix $P$ has only $n$ nonzero elements. As with dense matrices, the statement $[\mathrm{L}, \mathrm{U}]=\operatorname{lu}(\mathrm{S})$ returns a permuted unit lower triangular matrix and an upper triangular matrix whose product is $S$. By itself, lu(S) returns $L$ and $U$ in a single matrix without the pivot information.

The three-output syntax

$$
[L, U, P]=\operatorname{lu}(S)
$$

selects P via numerical partial pivoting, but does not pivot to improve sparsity in the LU factors. On the other hand, the four-output syntax

$$
[L, U, P, Q]=\operatorname{lu}(S)
$$

selects $P$ via threshold partial pivoting, and selects $P$ and $Q$ to improve sparsity in the LU factors.

You can control pivoting in sparse matrices using
lu(S,thresh)
where thresh is a pivot threshold in [0,1]. Pivoting occurs when the diagonal entry in a column has magnitude less than thresh times the magnitude of any sub-diagonal entry in that column. thresh $=0$ forces diagonal pivoting. thresh $=1$ is the default. (The default for thresh is 0.1 for the four-output syntax).

When you call 1 l with three or less outputs, MATLAB automatically allocates the memory necessary to hold the sparse $L$ and $U$ factors during the factorization. Except for the four-output syntax, MATLAB does not use any symbolic LU prefactorization to determine the memory requirements and set up the data structures in advance.

Reordering and Factorization. If you obtain a good column permutation $p$ that reduces fill-in, perhaps from symrcm or colamd, then computing lu(S(:, p)) takes less time and storage than computing lu(S). Two permutations are the symmetric reverse Cuthill-McKee ordering and the symmetric approximate minimum degree ordering.

```
r = symrcm(B);
```

$$
\mathrm{m}=\operatorname{symamd}(\mathrm{B}) ;
$$

The three spy plots produced by the lines below show the three adjacency matrices of the Bucky Ball graph with these three different numberings. The local, pentagon-based structure of the original numbering is not evident in the other three.

```
spy(B)
spy(B(r,r))
spy(B(m,m))
```

The reverse Cuthill-McKee ordering, $r$, reduces the bandwidth and concentrates all the nonzero elements near the diagonal. The approximate minimum degree ordering, m, produces a fractal-like structure with large blocks of zeros.

To see the fill-in generated in the LU factorization of the Bucky ball, use speye ( $n, n$ ), the sparse identity matrix, to insert -3 s on the diagonal of $B$.

$$
B=B-3 * \operatorname{speye}(n, n) ;
$$

Since each row sum is now zero, this new B is actually singular, but it is still instructive to compute its LU factorization. When called with only one output argument, lu returns the two triangular factors, $L$ and $U$, in a single sparse matrix. The number of nonzeros in that matrix is a measure of the time and storage required to solve linear systems involving B. Here are the nonzero counts for the three permutations being considered.

| Original | $\operatorname{lu}(B)$ | 1022 |
| :--- | :--- | :--- |
| Reverse Cuthill-McKee | $\operatorname{lu}(B(r, r))$ | 968 |
| Approximate minimum <br> degree | $\operatorname{lu}(B(m, m))$ | 636 |

Even though this is a small example, the results are typical. The original numbering scheme leads to the most fill-in. The fill-in for the reverse Cuthill-McKee ordering is concentrated within the band, but it is almost as extensive as the first two orderings. For the approximate minimum degree ordering, the relatively large blocks of zeros are preserved during the elimination and the amount of fill-in is significantly less than that generated by the other orderings. The spy plots below reflect the characteristics of each reordering.

## Cholesky Factorization

If $S$ is a symmetric (or Hermitian), positive definite, sparse matrix, the statement below returns a sparse, upper triangular matrix $R$ so that $R^{\prime *} R=S$.

$$
R=\operatorname{chol}(S)
$$

chol does not automatically pivot for sparsity, but you can compute approximate minimum degree and profile limiting permutations for use with $\operatorname{chol}(S(p, p))$.

Since the Cholesky algorithm does not use pivoting for sparsity and does not require pivoting for numerical stability, chol does a quick calculation of the amount of memory required and allocates all the memory at the start of the factorization. You can use symbfact, which uses the same algorithm as chol, to calculate how much memory is allocated.

## QR Factorization

MATLAB computes the complete QR factorization of a sparse matrix $S$ with

$$
[Q, R]=\operatorname{qr}(S)
$$

or

$$
[Q, R, E]=\operatorname{qr}(S)
$$

but this is often impractical. The unitary matrix $Q$ often fails to have a high proportion of zero elements. A more practical alternative, sometimes known as "the Q-less QR factorization," is available.

With one sparse input argument and one output argument

$$
R=\operatorname{qr}(S)
$$

returns just the upper triangular portion of the QR factorization. The matrix R provides a Cholesky factorization for the matrix associated with the normal equations:

$$
R^{\prime *} R=S^{\prime *} S
$$

However, the loss of numerical information inherent in the computation of $\mathrm{S}^{\prime *} \mathrm{~S}$ is avoided.

With two input arguments having the same number of rows, and two output arguments, the statement

$$
[C, R]=\operatorname{qr}(S, B)
$$

applies the orthogonal transformations to $B$, producing $C=Q$ '*B without computing Q.

The Q -less QR factorization allows the solution of sparse least squares problems

$$
\operatorname{minimize}\|A x-b\|_{2}
$$

with two steps

$$
\begin{aligned}
& {[c, R]=\operatorname{qr}(A, b)} \\
& x=R \backslash c
\end{aligned}
$$

If A is sparse, but not square, MATLAB uses these steps for the linear equation solving backslash operator:

$$
x=A \backslash b
$$

Or, you can do the factorization yourself and examine R for rank deficiency.
It is also possible to solve a sequence of least squares linear systems with different right-hand sides, $b$, that are not necessarily known when $R=\operatorname{qr}(A)$ is computed. The approach solves the "semi-normal equations"

$$
R^{\prime *} R^{*} x=A^{\prime *} b
$$

with

$$
x=R \backslash\left(R^{\prime} \backslash\left(A^{\prime} * b\right)\right)
$$

and then employs one step of iterative refinement to reduce round off error:

```
r=b - A*x
e = R\(R'\(A'*r))
x = x + e
```

## Incomplete Factorizations

The luinc, ilu, and cholinc functions provide approximate, incomplete factorizations, which are useful as preconditioners for sparse iterative methods.

The luinc function produces two different kinds of incomplete LU (ILU) factorizations, one involving a drop tolerance and one involving fill-in level. The ilu function produces three incomplete LU factorizations, the ILU with level 0 fill-in (ILU(0)), the Crout version of ILU (ILUC), and the ILU with threshold and pivoting (ILUTP).

For example:

```
A = gallery('neumann', 1600) + speye(1600);
nnz(A)
ans =
    7 8 4 0
nnz(lu(A))
ans =
    126478
```

shows that A has 7840 nonzeros, and its complete LU factorization has 126478 nonzeros:

```
nnz(luinc(A,'O'))
ans =
    7 8 4 0
setup.type = 'nofill';
nnz(ilu(A,setup))
ans =
    7 8 4 0
nnz(luinc(A,1e-6))
ans =
    5 1 5 4 1
setup.type = 'ilutp';
setup.droptol = 1e-6;
nnz(luinc(A,setup))
ans =
    5 1 5 4 1
```

These calculations, with both the luinc and ilu functions, show that with level 0 fill-in it has 7840 nonzeros, and with a drop tolerance of $1 e-6$ it has 51541 nonzeros. See the luinc and ilu reference pages for more options and details.

The cholinc function provides drop tolerance and level 0 fill-in Cholesky factorizations of symmetric, positive definite sparse matrices. See the cholinc reference page for more information.

## Systems of Linear Equations

There are two different classes of methods for solving systems of simultaneous linear equations:

- Direct methods are usually variants of Gaussian elimination. These methods involve the individual matrix elements directly, through matrix operations such as LU or Cholesky factorization. MATLAB implements direct methods through the matrix division operators / and $\backslash$, which you can use to solve linear systems.
- Iterative methods produce only an approximate solution after a finite number of steps. These methods involve the coefficient matrix only indirectly, through a matrix-vector product or an abstract linear operator. Iterative methods are usually applied only to sparse matrices.

## Direct Methods

Direct methods are usually faster and more generally applicable than indirect methods, if there is enough storage available to carry them out. Iterative methods are usually applicable to restricted cases of equations and depend on properties like diagonal dominance or the existence of an underlying differential operator. Direct methods are implemented in the core of the MATLAB software and are made as efficient as possible for general classes of matrices. Iterative methods are usually implemented in MATLAB-language files and can use the direct solution of subproblems or preconditioners.

Using a Different Preordering. If A is not diagonal, banded, triangular, or a permutation of a triangular matrix, backslash $(\backslash)$ reorders the indices of $A$ to reduce the amount of fill-in-that is, the number of nonzero entries that are added to the sparse factorization matrices. The new ordering, called a preordering, is performed before the factorization of A. In some cases, you might be able to provide a better preordering than the one used by the backslash algorithm.

To use a different preordering, first turn off both of the automatic preorderings that backslash might perform by default, using the function spparms as follows:

```
spparms('autoamd',0);
spparms('autommd',0);
```

Now, assuming you have created a permutation vector $p$ that specifies a preordering of the indices of A, apply backslash to the matrix $A(:, p)$, whose columns are the columns of A, permuted according to the vector $p$.

```
x = A (:,p) \ b;
x(p) = x;
spparms('autoamd',1);
spparms('autommd',1);
```

The commands spparms('autoamd',1) and spparms('autommd',1) turns the automatic preordering back on, in case you use $A \backslash b$ later without specifying an appropriate preordering.

## Iterative Methods

Nine functions are available that implement iterative methods for sparse systems of simultaneous linear systems.

## Functions for Iterative Methods for Sparse Systems

| Function | Method |
| :--- | :--- |
| bicg | Biconjugate gradient |
| bicgstab | Biconjugate gradient stabilized |
| cgs | Conjugate gradient squared |

Functions for Iterative Methods for Sparse Systems (Continued)

| Function | Method |
| :--- | :--- |
| gmres | Generalized minimum residual |
| lsqr | Least squares |
| minres | Minimum residual |
| pcg | Preconditioned conjugate gradient |
| qmr | Quasiminimal residual |
| symmlq | Symmetric LQ |

These methods are designed to solve $A x=b$ or minimize the norm of $b-$ $A x$. For the Preconditioned Conjugate Gradient method, pcg, $A$ must be a symmetric, positive definite matrix. minres and symmlq can be used on symmetric indefinite matrices. For lsqr, the matrix need not be square. The other five can handle nonsymmetric, square matrices.

All nine methods can make use of preconditioners. The linear system

$$
A x=b
$$

is replaced by the equivalent system

$$
M^{-1} A x=M^{-1} b
$$

The preconditioner $M$ is chosen to accelerate convergence of the iterative method. In many cases, the preconditioners occur naturally in the mathematical model. A partial differential equation with variable coefficients can be approximated by one with constant coefficients, for example. Incomplete matrix factorizations can be used in the absence of natural preconditioners.

The five-point finite difference approximation to Laplace's equation on a square, two-dimensional domain provides an example. The following statements use the preconditioned conjugate gradient method preconditioner $\mathrm{M}=R^{*} R$, where $R$ is the incomplete Cholesky factor of $A$.
A = delsq(numgrid('S',50));

```
b = ones(size(A,1),1);
tol = 1.e-3;
maxit = 10;
R = cholinc(A,tol);
[x,flag,err,iter,res] = pcg(A,b,tol,maxit,R',R);
```

Only four iterations are required to achieve the prescribed accuracy.
Background information on these iterative methods and incomplete factorizations is available in [2] and [7].

## Eigenvalues and Singular Values

Two functions are available that compute a few specified eigenvalues or singular values. svds is based on eigs that uses ARPACK [6].

## Functions to Compute a Few Eigenvalues or Singular Values

| Function | Description |
| :--- | :--- |
| eigs | Few eigenvalues |
| svds | Few singular values |

These functions are most frequently used with sparse matrices, but they can be used with full matrices or even with linear operators defined in MATLAB code.

The statement
[V,lambda] = eigs(A,k,sigma)
finds the $k$ eigenvalues and corresponding eigenvectors of the matrix $A$ that are nearest the "shift" sigma. If sigma is omitted, the eigenvalues largest in magnitude are found. If sigma is zero, the eigenvalues smallest in magnitude are found. A second matrix, B, can be included for the generalized eigenvalue problem: $\mathrm{Au}=\lambda \mathrm{Bu}$.

The statement

$$
[U, S, V]=\operatorname{svds}(A, k)
$$

finds the $k$ largest singular values of $A$ and

$$
[U, S, V]=\operatorname{svds}(A, k, 0)
$$

finds the k smallest singular values.
For example, the statements

```
L = numgrid('L',65);
A = delsq(L);
```

set up the five-point Laplacian difference operator on a 65 -by- 65 grid in an $L$-shaped, two-dimensional domain. The statements

```
size(A)
nnz(A)
```

show that A is a matrix of order 2945 with 14,473 nonzero elements.
The statement

$$
[\mathrm{v}, \mathrm{~d}]=\operatorname{eigs}(\mathrm{A}, 1,0) ;
$$

computes the smallest eigenvalue and eigenvector. Finally,

```
L(L>0) = full(v(L(L>0)));
x = -1:1/32:1;
contour(x,x,L,15)
axis square
```

distributes the components of the eigenvector over the appropriate grid points and produces a contour plot of the result.

The numerical techniques used in eigs and svds are described in [6].

## Performance Limitations

- "Creating Sparse Matrices" on page 4-43
- "Manipulating Sparse Matrices" on page 4-44

This section describes some limitations of the sparse matrix storage format and their impact on matrix creation, manipulation, and operations.

## Creating Sparse Matrices

The best way to create a sparse matrix is to use the sparse function. If you do not have prior knowledge of the nonzero indices or their values, it is much more efficient to create the vectors containing these values, and then create the sparse matrix.

Preallocating the memory for a sparse matrix and filling it in an elementwise manner causes a significant amount of overhead in indexing into the sparse array:

```
S1 = spalloc(1000,1000,100000);
tic;
for n = 1:100000
    i = ceil(1000*rand(1,1));
    j = ceil(1000*rand(1,1));
    S1(i,j) = rand(1,1);
end
toc
Elapsed time is 26.281000 seconds.
```

Whereas constructing the vectors of indices and values eliminates the need to index into the sparse array, and thus is significantly faster:

```
i = ceil(1000*rand(100000,1));
j = ceil(1000*rand(100000,1));
v = zeros(size(i));
for n = 1:100000
    v(n) = rand(1,1);
end
tic;
S2 = sparse(i,j,v,1000,1000);
toc
Elapsed time is 0.078000 seconds.
```

## Manipulating Sparse Matrices

Sparse matrices are stored in a column-major format. In some cases, accessing the matrix by columns may be more efficient than accessing by rows. To do this, you can transpose the matrix, perform operations on the columns, and then retranspose the result:

```
S = sparse(10000,10000,1);
for n = 1:1000
    A = S(100,:)' + S(200,:)';
    A = A';
end;
```

The time required to transpose the matrix is negligible. Note that the sparse matrix memory requirements could prevent you from transposing a sparse matrix having a large number of rows. This might occur even when the number of nonzero values is small.

Using linear indexing to access or assign an element in a large sparse matrix will fail if the linear index exceeds intmax. To access an element whose linear index is greater than intmax, use array indexing:

```
S = spalloc(216^2, 216^2, 2)
S(1) = 1
S(end) = 1
S(216^2,216^2) = 1
```

## Function Summary

The following table lists the MATLAB polynomial functions.

| Function | Description |
| :--- | :--- |
| conv | Multiply polynomials |
| deconv | Divide polynomials |
| fzero | Find root of continuous function of one variable |
| poly | Polynomial with specified roots |
| polvder | Polvnomial derivative |
| polyfit | Polynomial curve fitting |
| polyval | Polynomial evaluation |
| polyvalm | Matrix polynomial evaluation |
| residue | Partial-fraction expansion (residues) |
| roots | Find polynomial roots |

Symbolic Math Toolbox software contains additional specialized support for polynomial operations.

## Representing Polynomials

MATLAB software represents polynomials as row vectors containing coefficients ordered by descending powers. For example, consider the equation

$$
p(x)=x^{3}-2 x-5
$$

This is the celebrated example Wallis used when he first represented Newton's method to the French Academy. To enter this polynomial into MATLAB, use

```
p = [1 0 -2 -5];
```

## Evaluating Polynomials

The polyval function evaluates a polynomial at a specified value. To evaluate p at $s=5$, use

```
polyval(p,5)
ans =
    1 1 0
```

It is also possible to evaluate a polynomial in a matrix sense. In this case $p(x)=x^{3}-2 x-5$ becomes $p(X)=X^{3}-2 X-5 I$, where $X$ is a square matrix and $I$ is the identity matrix. For example, create a square matrix X and evaluate the polynomial p at X :

```
X = [2 4 5; -1 0 3; 7 1 5];
Y = polyvalm(p,X)
Y =
    377 179 439
    111 81 136
    490 253 639
```

## Roots of Polynomials

The roots function calculates the roots of a polynomial:

```
r = roots(p)
r =
```

```
2.0946
```

2.0946
-1.0473 + 1.1359i
-1.0473 + 1.1359i
-1.0473 - 1.1359i

```
    -1.0473 - 1.1359i
```

By convention, the MATLAB software stores roots in column vectors. The function poly returns to the polynomial coefficients:

```
p2 = poly(r)
p2 =
    1 8.8818e-16 -2 -5
```

poly and roots are inverse functions, up to ordering, scaling, and roundoff error.

## Roots of Scalar Functions

```
In this section...
"Solving a Nonlinear Equation in One Variable" on page 5-6
"Using a Starting Interval" on page 5-8
"Using a Starting Point" on page 5-9
```

## Solving a Nonlinear Equation in One Variable

The fzero function attempts to find a root of one equation with one variable. You can call this function with either a one-element starting point or a two-element vector that designates a starting interval. If you give fzero a starting point $\mathrm{x0}$, fzero first searches for an interval around this point where the function changes sign. If the interval is found, fzero returns a value near where the function changes sign. If no such interval is found, fzero returns NaN . Alternatively, if you know two points where the function value differs in sign, you can specify this starting interval using a two-element vector; fzero is guaranteed to narrow down the interval and return a value near a sign change.

The following sections contain two examples that illustrate how to find a zero of a function using a starting interval and a starting point. The examples use the function humps.m, which is provided with MATLAB. The following figure shows the graph of humps.

## Setting Options For fzero

You can control several aspects of the fzero function by setting options. You set options using optimset. Options include:

- Choosing the amount of display fzero generates - see "Setting Options" on page 8-12, "Using a Starting Interval" on page $5-8$, and "Using a Starting Point" on page 5-9.
- Choosing various tolerances that control how fzero determines it is at a root - see "Setting Options" on page 8-12.
- Choosing a plot function for observing the progress of fzero towards a root — see "Plot Functions" on page 8-24.
- Using a custom-programmed output function for observing the progress of fzero towards a root - see "Output Functions" on page 8-16.

## Using a Starting Interval

The graph of humps indicates that the function is negative at $\mathrm{x}=-1$ and positive at $x=1$. You can confirm this by calculating humps at these two points.

```
humps(1)
ans =
    1 6
humps(-1)
ans =
    -5.1378
```

Consequently, you can use [-1 1] as a starting interval for fzero.
The iterative algorithm for fzero finds smaller and smaller subintervals of [-1 1 1]. For each subinterval, the sign of humps differs at the two endpoints. As the endpoints of the subintervals get closer and closer, they converge to zero for humps.

To show the progress of fzero at each iteration, set the Display option to iter using the optimset function.

```
options = optimset('Display','iter');
```

Then call fzero as follows:

```
a = fzero(@humps,[-1 1],options)
```

This returns the following iterative output:

```
a = fzero(@humps,[-1 1],options)
```

| Func-count | $x$ | $f(x)$ | Procedure |
| :---: | ---: | :--- | :--- |
| 2 | -1 | -5.13779 | initial |
| 3 | -0.513876 | -4.02235 | interpolation |
| 4 | -0.513876 | -4.02235 | bisection |
| 5 | -0.473635 | -3.83767 | interpolation |
| 6 | -0.115287 | 0.414441 | bisection |

| 7 | -0.115287 | 0.414441 | interpolation |
| ---: | ---: | ---: | :--- |
| 8 | -0.132562 | -0.0226907 | interpolation |
| 9 | -0.131666 | -0.0011492 | interpolation |
| 10 | -0.131618 | $1.88371 \mathrm{e}-007$ | interpolation |
| 11 | -0.131618 | $-2.7935 \mathrm{e}-011$ | interpolation |
| 12 | -0.131618 | $8.88178 \mathrm{e}-016$ | interpolation |
| 13 | -0.131618 | $8.88178 \mathrm{e}-016$ | interpolation |

Zero found in the interval [-1, 1]
$\mathrm{a}=$
$-0.1316$

Each value x represents the best endpoint so far. The Procedure column tells you whether each step of the algorithm uses bisection or interpolation.

You can verify that the function value at a is close to zero by entering

```
humps(a)
ans =
    8.8818e-016
```

## Using a Starting Point

Suppose you do not know two points at which the function values of humps differ in sign. In that case, you can choose a scalar $x 0$ as the starting point for fzero. fzero first searches for an interval around this point on which the function changes sign. If fzero finds such an interval, it proceeds with the algorithm described in the previous section. If no such interval is found, fzero returns NaN.

For example, set the starting point to -0.2, the Display option to Iter, and call fzero:

```
options = optimset('Display','iter');
a = fzero(@humps,-0.2,options)
```

fzero returns the following output:

| Func-count | - a | $f(\mathrm{a})$ | b | $f(b)$ | Procedure |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | -0.2 | -1.35385 | -0.2 | -1.35385 | initial interval |
| 3 | -0.194343 | -1.26077 | -0.205657 | -1.44411 | search |
| 5 | -0.192 | -1.22137 | -0.208 | -1.4807 | search |
| 7 | -0.188686 | -1.16477 | -0.211314 | -1.53167 | search |
| 9 | -0.184 | -1.08293 | -0.216 | -1.60224 | search |
| 11 | -0.177373 | -0.963455 | -0.222627 | -1.69911 | search |
| 13 | -0.168 | -0.786636 | -0.232 | -1.83055 | search |
| 15 | -0.154745 | -0.51962 | -0.245255 | -2.00602 | search |
| 17 | -0.136 | -0.104165 | -0.264 | -2.23521 | search |
| 18 | -0.10949 | 0.572246 | -0.264 | -2.23521 | search |
| Search for a zero in the interval [-0.10949, -0.264]: |  |  |  |  |  |
| Func-count | t x | $f(x)$ | Proced |  |  |
| 18 | -0.10949 | 0.572246 | initia |  |  |
| 19 | -0.140984 | -0.219277 | interp | ion |  |
| 20 | -0.132259 | -0.0154224 | interp | ion |  |
| 21 | -0.131617 | 3.40729e-005 | interp | ion |  |
| 22 | -0.131618 | -6.79505e-008 | interp | ion |  |
| 23 | -0.131618 | -2.98428e-013 | interp | ion |  |
| 24 | -0.131618 | 8.88178e-016 | interp | ion |  |
| 25 | -0.131618 | 8.88178e-016 | interp | ion |  |
| Zero found in the interval [-0.10949, -0.264] |  |  |  |  |  |
| $\mathrm{a}=$ |  |  |  |  |  |

The endpoints of the current subinterval at each iteration are listed under the headings a and b , while the corresponding values of humps at the endpoints are listed under $f(a)$ and $f(b)$, respectively.

Note The endpoints a and b are not listed in any specific order: a can be greater than $b$ or less than $b$.

For the first nine steps, the sign of humps is negative at both endpoints of the current subinterval, which is shown in the output. At the tenth step, the sign of humps is positive at the endpoint, -0.10949 , but negative at the endpoint, -0.264 . From this point on, the algorithm continues to narrow down the interval $[-0.10949-0.264]$, as described in the previous section, until it reaches the value -0.1316.

## Derivatives

The polyder function computes the derivative of any polynomial. To obtain the derivative of the polynomial $p=\left[\begin{array}{lll}1 & 0 & -2\end{array}\right.$-5],

```
q = polyder(p)
q =
    3 0 -2
```

polyder also computes the derivative of the product or quotient of two polynomials. For example, create two polynomials a and b:

```
a = [lllll
b = [2 4 6];
```

Calculate the derivative of the product $a * b$ by calling polyder with a single output argument:

```
c = polyder(a,b)
c =
    8 30 56 38
```

Calculate the derivative of the quotient $\mathrm{a} / \mathrm{b}$ by calling polyder with two output arguments:

```
[q,d] = polyder(a,b)
q =
    -2 --8 -2
d =
    4
```

$q / d$ is the result of the operation.

## Convolution

Polynomial multiplication and division correspond to the operations convolution and deconvolution. The functions conv and deconv implement these operations.

Consider the polynomials $a(s)=s^{2}+2 s+3$ and $b(s)=4 s^{2}+5 s+6$. To compute their product,

```
a = [1 2 3]; b = [4 5 6];
c = conv(a,b)
c =
    4 13 28 27
1 8
```

Use deconvolution to divide $a(s)$ back out of the product:

```
[q,r] = deconv(c,a)
q =
            4 5 6
r =
```

## Partial Fraction Expansions

residue finds the partial fraction expansion of the ratio of two polynomials. This is particularly useful for applications that represent systems in transfer function form. For polynomials $b$ and $a$, if there are no multiple roots,

$$
\frac{b(s)}{a(s)}=\frac{r_{1}}{s-p_{1}}+\frac{r_{2}}{s-p_{2}}+\ldots+\frac{r_{n}}{s-p_{n}}+k_{s}
$$

where $r$ is a column vector of residues, $p$ is a column vector of pole locations, and $k$ is a row vector of direct terms. Consider the transfer function

```
\frac{-4s+8}{\mp@subsup{s}{}{2}+6s+8}
b = [-4 8];
a = [1 6 8];
[r,p,k] = residue(b,a)
r =
    -12
    8
p =
    -4
    -2
k =
    []
```

Given three input arguments ( $r, p$, and $k$ ), residue converts back to polynomial form:

```
[b2,a2] = residue(r,p,k)
b2 =
    -4 8
a2 =
    1 6 8
```

## Polynomial Curve Fitting

polyfit finds the coefficients of a polynomial that fits a set of data in a least-squares sense:
p = polyfit(x,y,n)
x and y are vectors containing the $x$ and $y$ data to be fitted, and n is the degree of the polynomial to return. For example, consider the $x-y$ test data

```
x = [1 2 3 4 5]; y = [5.5 43.1 128 290.7 498.4];
```

A third degree polynomial that approximately fits the data is

```
p = polyfit(x,y,3)
p =
    -0.1917 31.5821 -60.3262 35.3400
```

Compute the values of the polyfit estimate over a finer range, and plot the estimate over the real data values for comparison:

```
x2 = 1:.1:5;
y2 = polyval(p,x2);
plot(x,y,'o',x2,y2)
grid on
```

Note Least squares fitting of data is treated in the Data Analysis section of the MATLAB documentation.

## Characteristic Polynomials

The poly function also computes the coefficients of the characteristic polynomial of a matrix:

```
A = [1.2 3 -0.9; 5 1.75 6; 9 0 1];
poly(A)
ans =
    1.0000 -3.9500 -1.8500 -163.2750
```

The roots of this polynomial, computed with roots, are the characteristic roots, or eigenvalues, of the matrix A. (Use eig to compute the eigenvalues of a matrix directly.)

- "Delaunay Triangulation" on page 6-17
- "Spatial Searching" on page 6-47
- "Voronoi Diagrams" on page 6-57
- "Convex Hulls" on page 6-66

## Overview

MATLAB software provides a variety of tools to solve problems that are geometric in nature. These problems encompass simple geometric queries such as point-in-polygon tests, to more complex problems such as nearest-neighbor queries. Convex hulls, Delaunay triangulations, and Voronoi diagrams are examples of fundamental geometric algorithms that MATLAB provides. These algorithms have many practical uses in the scientific development.

MATLAB provides both function-based and class-based tools for computational geometry. The function-based tools are convenient when the output from the function is sufficiently complete to get you to the solution. The class-based tools are more versatile because they provide complementary methods that are often needed to work with the resulting data. A function typically takes input, performs some computation, and outputs the result in matrix format.

In contrast, a class may take input, perform some computation, cache the result and provide methods that allow you to query and work with the result more efficiently. For example, the delaunay function creates a triangulation from a set of points and returns the triangulation in an array. The DelaunayTri class also triangulates a set of points. In addition, it allows you to modify the triangulation and it provides methods for finding nearest neighbors and traversing the triangulation data structure, etc. These methods are very efficient because the class holds the triangulation in memory.

## Triangulation Representations

## 2-D and 3-D Domains

Triangulations are often used to represent 2-D and 3-D geometric domains in application areas such as computer graphics, physical modeling, geographic information systems, medical imaging, and more. The map polygon shown here

can be represented by the triangulation on the map shown here

The triangulation decomposes a complex polygon into a collection of simpler triangular polygons. You can use these polygons when developing geometric-based algorithms or graphics applications. Similarly, you can represent the boundary of a 3-D geometric domain by a triangulation.

The next figure shows the convex hull of a set of points in 3-D space. Each facet of the hull is a triangle.

## Triangulation Face-Vertex Format

The triangulation face-vertex format is a basic data structure that represents triangulations. It has two parts:

- Vertices, which consist of an array of point coordinates
- Faces, which define the triangles in terms of the vertex indices

The following figure illustrates the face-vertex format for a simple 2-D triangulation

| Vertex Data |  |
| :--- | :--- |
| 2.5 | 8.0 |
| 6.5 | 8.0 |
| 2.5 | 5.0 |
| 6.5 | 5.0 |

| Vertex Data |  |  |
| :--- | :--- | :--- |
| 1.0 | 6.5 |  |
| 8.0 | 6.5 |  |
| Face Data |  |  |
|  |  |  |
| 5 | 3 | 1 |
| 3 | 2 | 1 |
| 3 | 4 | 2 |
| 4 | 6 | 2 |

To minimize the data required to represent the triangulation, the vertex and face annotations are not included above. They are included below for clarification.

| Vertex Data |  |  |
| :--- | :--- | :--- |
| V1 | 2.5 | 8.0 |
| V2 | 6.5 | 8.0 |
| V3 | 2.5 | 5.0 |
| V4 | 6.5 | 5.0 |
| V5 | 1.0 | 6.5 |
| V6 | 8.0 | 6.5 |

Face Data

| Face Dara |  |  |  |
| :--- | :--- | :--- | :--- |
| T1 | 5 | 3 | 1 |
| T2 | 3 | 2 | 1 |
| T3 | 3 | 4 | 2 |
| T4 | 4 | 6 | 2 |

You can see that triangle T1 is defined by vertices \{V5, V3, V1\}. Similarly, T4 is defined by vertices \{V4, V6, V2\}. This data structure extends naturally to higher dimensions. In more general terms, the face represents a triangle, tetrahedron, or higher dimensional simplex. The delaunay function uses the face-vertex format to represent triangulations. The input represents the
coordinates of the vertices, and the output represents the triangles that are indexed with respect to the vertices. The output from the convhull function also uses the face-vertex format to represent the convex hull.

## Querying Triangulations Using TriRep

The face-vertex format provides a compact low-level array-based representation for triangulations. When using triangulations to development algorithms, you might need more information about geometric properties, topology, and adjacency information, etc.

For example, to plot the annotated triangulation shown below compute the triangle incenters so the triangle labels could be displayed within the respective triangles. To plot the boundary in red, you need to determine the edges that are referenced by only one triangle.

When working with triangulations you might need to know the triangles attached to a vertex, the triangles neighboring a triangle, the triangles attached to an edge, or other information.

## The TriRep Class

MATLAB provides a TriRep class that allows you to query triangulations in an efficient manner. TriRep is an abbreviation for Triangulation Representation. It supports 2-D and 3-D triangulations composed of triangles, and 3-D triangulations composed of tetrahedra. It lets you represent triangulations you imported into MATLAB or created directly in MATLAB using the computational geometry tools. The TriRep class supports many geometric and topological queries that simplify the development of triangulation-based algorithms.

Note that TriRep does not create triangulations. Use TriRep to represent triangulations that you import into MATLAB or create using one of the computational geometry tools.

Create a TriRep in one of two ways:

- You can create a TriRep from face-vertex data. This data may be the output from a MATLAB function such as delaunay or a 3-D convex hull computation using convhull. You also can import face-vertex data that was created by another application outside of MATLAB. When working with imported data you should ensure the face data uses 1-based indexing to refer to the vertex array as opposed to 0 -based indexing.
- MATLAB creates a TriRep when you create a Delaunay triangulation using the DelaunayTri class. That's because a Delaunay triangulation (DelaunayTri) is a triangulation representation (TriRep). This doesn't mean they are identical; the DelaunayTri class has additional function-like methods specific to Delaunay triangulations. If you view TriRep as a set of triangulations, you could say the DelaunayTri is a subset. It's a specific type of triangulation. In more formal MATLAB language terms, DelaunayTri is a subclass of TriRep.

Creating a TriRep from Face-Vertex Data. You can use the triangulation face-vertex data from the previous section to create a TriRep explore what it is, and what it can do.

Create a matrix $x$ that represents the vertex data:
$x=\left[\begin{array}{ll}2.5 & 8.0 \\ 6.5 & 8.0\end{array}\right.$

| 2.5 | 5.0 |
| :--- | :--- |
| 6.5 | 5.0 |
| 1.0 | 6.5 |
| 8.0 | $6.5] ;$ |

Let tri represent the face data:

```
tri = [\begin{array}{lll}{5}&{3}&{1;}\end{array}]
    3 2 1;
    3 4 2;
    4 2];
```

You can create a TriRep from this data as follows:

```
tr = TriRep(tri,x)
```

When MATLAB creates the TriRep, it outputs:

```
tr =
```

    TriRep
    Properties:
        X: [6x2 double]
        Triangulation: [4x3 double]
    Methods
    The X property represents the vertices. The Triangulation property represents the triangles. Together these two properties define the face-vertex format for the triangulation. If you click the TriRep link you get help for the TriRep class. If you click the Methods link, MATLAB will return a list of available methods for the class. To get help on the TriRep and its methods, type:

```
help TriRep
methods('TriRep')
```

or

```
methods(tr)
```

The TriRep class is a wrapper around the face-vertex format. The real benefit is the useful methods that TriRep provides. The methods are like functions that a TriRep object can call.

You can access the properties in a TriRep in the same way as you would for a Struct.
tr. $X$
returns the vertex data.
tr.Triangulation
returns the Triangulation data.
TriRep provides a shorthand way to index into the Triangulation property matrix. To access the first triangle in the triangulation, type:
tr.Triangulation(1, :)
The shorthand way of getting the first triangle is:

```
tr(1, :)
```

Likewise, you can get the first vertex of the first triangle:

```
tr(1, 1)
```

Or the second vertex of the first triangle:
$\operatorname{tr}(1,2)$
Or you can get all the triangles in the triangulation:

```
tr(:, :)
```

You can use triplot to plot the TriRep. While it's not a method of the class, triplot knows what a TriRep is and how to plot it.

```
triplot(tr);
```

axis equal

You can now use the TriRep to query the free boundary and add it to the plot as a red outline. TriRep provides a method called freeBoundary to do this. This method returns the edges of the triangulation that are shared by only one triangle. The returned edges are expressed in terms of the vertex indices.

```
boundaryedges = freeBoundary(tr)';
```

Now plot the boundary edges in a thick red line

```
hold on;
plot(x(boundaryedges,1),x(boundaryedges,2),'-r','LineWidth',2);
hold off;
```

The freeBoundary method is useful for validating a triangulation. For example, if you observed red edges in the interior of the triangulation it would indicate a problem in how the triangles are connected.

Creating a TriRep Using DelaunayTri. When you create a Delaunay triangulation using DelaunayTri, you automatically get access to the TriRep methods because DelaunayTri is a subclass of TriRep.

There are two ways to create a Delaunay triangulation in MATLAB:

- You can call the delaunay function by passing an array of points. The result is a triangulation in face-vertex format.
- You can create a DelaunayTri object by passing an array of points and then using the Triangulation property.

If you are new to working with classes in MATLAB, the examples in the help for DelaunayTri and the Delaunay Tri Demo (help demoDelaunayTri) show you how to create a DelaunayTri and make triangulation-based queries.

The documentation on DelaunayTri also provides introductory material and examples.

You can create a simple Delaunay triangulation using DelaunayTri, and then query this triangulation using one of the methods provided by the parent class, TriRep. This example uses the point data set from the previous example. In this instance, DelaunayTri automatically generates the triangulation from the point set.

Create a set of points:

```
x = [ 2.5 8.0
    6.5 8.0
    2.5 5.0
    6.5 5.0
    1.0 6.5
    8.0 6.5];
```

Create a DelaunayTri from the set of points:

```
dt = DelaunayTri(x)
```

When MATLAB creates the DelaunayTri, it outputs:
dt =
DelaunayTri
Properties:
X: [6x2 double]
Triangulation: [4×3 double]
Methods

DelaunayTri has properties X and Triangulation like TriRep. Triangulation is the Delaunay triangulation MATLAB creates. Just like TriRep, the triangulation is in face-vertex format.

Access the triangulation using direct indexing, just like TriRep:

```
dt(1, :) % Returns the 1st triangle
dt(:, :) % Returns the Triangulation data
```

Use the triplot function to plot the triangulation:

```
triplot(dt)
axis equal
```

The parent class, TriRep, provides the incentersmethod to compute the incenters of the triangles in the triangulation. incenters is a method of TriRep because computing incenters is not specific to Delaunay triangulations. It's something you would like to be able to do for any general triangulation and that's what a TriRep is. Call the incenters method as follows:

```
ic = incenters(dt)
ic =
    1.8787 6.5000
    3.5000 7.0000
    5.5000 6.0000
    7.1213 6.5000
```

The returned value, ic, is an array of coordinates representing the incenters of the triangles.

Add text to the plot to place the labels within the triangles. Use the incenters to locate the text.

```
hold on
numtri = size(dt,1);
trilabels = arrayfun(@(x) {sprintf('T%d', x)}, (1:numtri)');
Htl = text(ic(:,1), ic(:,2), trilabels,'FontWeight','bold', ...
'HorizontalAlignment', 'center', 'Color', 'blue');
hold off
```

Instead of creating a Delaunay triangulation using DelaunayTri, you could use the delaunay function create the triangulation in face-vertex format, and then create a TriRep from that. For example you could do the following:

$$
\begin{array}{rll}
x=\left[\begin{array}{ll}
2.5 & 8.0 \\
6.5 & 8.0
\end{array}\right.
\end{array}
$$

$$
\begin{array}{ll}
2.5 & 5.0 \\
6.5 & 5.0 \\
1.0 & 6.5 \\
8.0 & 6.5] ; \\
& \\
\text { tri }=\text { delaunay }(X) ; \\
t r= & \text { TriRep(tri,X) } \\
\text { ic }=\text { incenters (tr) }
\end{array}
$$

Both approaches are valid in this example, but generally to create a Delaunay triangulation and query that triangulation, working with DelaunayTri may be the preferred approach. This is because DelaunayTri provides additional methods that are useful when working with triangulations. For example, DelaunayTri allows you to perform nearest-neighbor and point-in-triangle searches. It allows you to edit the triangulation to add, remove, or move points. You also can create constrained Delaunay triangulations using the DelaunayTri class. This allows you to create a triangulation for a 2-D domain,
such as the map polygon illustrated in "Triangulation Representations" on page 6-3.
"Delaunay Triangulation" on page 6-17 provides you with more information and examples on how to create, query, and work with DelaunayTri.
"Spatial Searching" on page 6-47 provides further information on searching triangulations including non-Delaunay triangulations.

## Delaunay Triangulation

## In this section...

"Definition of Delaunay Triangulation" on page 6-17
"Creating Delaunay Triangulations" on page 6-19
"Triangulation of Point Sets Containing Duplicate Locations" on page 6-44

## Definition of Delaunay Triangulation

Delaunay triangulations are widely used in scientific computing in many diverse applications. While there are numerous algorithms for computing triangulations, it is the favorable geometric properties of the Delaunay triangulation that make it so useful.

The fundamental property is the Delaunay criterion. In the case of 2-D triangulations this is often called the empty circumcircle criterion. For a set of points in 2-D, a Delaunay triangulation of these points ensures the circumcircle associated with each triangle contains no other point in its interior. This property is important.The circumcircle associated with T1 is empty. It does not contain a point in its interior. The circumcircle associated with T2 is empty. It does not contain a point in its interior.

This triangulation is a Delaunay triangulation.

By contrast: The circumcircle associated with T1 is not empty; it contains V3 in its interior. The circumcircle associated with T2 is not empty; it contains V1 in its interior.

This triangulation is not a Delaunay triangulation.
Delaunay triangles are said to be "well shaped" because in fulfilling the empty circumcircle property, triangles with large internal angles are selected over ones with small internal angles. The triangles in the non-Delaunay triangulation have sharp angles at vertices V2 and V4. If the edge \{V2, V4\} were replaced by an edge joining V1 and V3, the minimum angle would be maximized and the triangulation would become a Delaunay triangulation. Also, the Delaunay triangulation connects points in a nearest-neighbor manner. These two characteristics, well-shaped triangles and the nearest-neighbor relation, have important implications in practice and motivate the use of Delaunay triangulations in scattered data interpolation.

While the Delaunay property is well defined, the topology of the triangulation is not unique in the presence of degenerate point sets. In two dimensions, degeneracies arise when four or more unique points lie on the same circle. The vertices of a square, for example, have a nonunique Delaunay triangulation.

The properties of Delaunay triangulations extend to higher dimensions. The triangulation of a $3-\mathrm{D}$ set of points is composed of tetrahedra. The next illustration shows a simple 3-D Delaunay triangulation made up of two tetrahedra. The circumsphere of one tetrahedron is shown to highlight the empty circumsphere criterion.

A 3-D Delaunay triangulation produces tetrahedra that satisfy the empty circumsphere criterion.

## Creating Delaunay Triangulations

MATLAB provides two ways to create Delaunay triangulations:

- The functions delaunay and delaunayn
- The DelaunayTri class

The delaunay function supports the creation of 2-D and 3-D Delaunay triangulations. The delaunayn function supports creating Delaunay triangulations in 4-D and higher.

Tip Creating Delaunay triangulations in dimensions higher than 6-D is generally not practical for moderate to large point sets due to the exponential growth in required memory.

The DelaunayTri class supports creating Delaunay triangulations in $2-\mathrm{D}$ and 3-D. It provides many methods that are useful for developing triangulation-based algorithms. These class methods are like functions, but they are restricted to work with triangulations created using DelaunayTri. The DelaunayTri class also supports the creation of related constructs such as the convex hull and Voronoi diagram. It also supports the creation of constrained Delaunay triangulations.

In summary:

- The delaunay function is useful when you only require the basic triangulation data, and that data is sufficiently complete for the application at hand.
- The DelaunayTri class is useful when you require the triangulation and in addition you want to perform any of these operations:
- Search the triangulation for triangles/tetrahedral enclosing a query point.
- Use the triangulation to perform a nearest-neighbor point search.
- Query the triangulation's topological adjacency or geometric properties.
- Modify the triangulation to insert or remove points.
- Constrain edges in the triangulation-this is called a constrained Delaunay triangulation.
- Triangulate a polygon and optionally remove the triangles that are outside of the domain.
- Use the Delaunay triangulation to compute the convex hull or Voronoi diagram.

In short, the DelaunayTri class offers more functionality to develop triangulation-based applications. "Delaunay Triangulation Using delaunay and delaunayn" on page 6-21 and "Delaunay Triangulation Using the DelaunayTri Class" on page 6-25 highlights the function-based approach and the class-based approach to creating Delaunay triangulations.

## Delaunay Triangulation Using delaunay and delaunayn

The delaunay and delaunayn functions take a set of points and produce a triangulation in face-vertex format. Refer to "Triangulation Face-Vertex Format" on page 6-5 for more information on this data structure. In 2-D, the delaunay function is often used to produce a triangulation that can be used to plot a surface defined in terms of a set of scattered data points. In this application, it's important to note that this approach can only be used if the surface is single-valued. For example, it could not be used to plot a spherical surface because there are two $z$ values corresponding to a single ( $x$, y) coordinate. A simple example demonstrates how the delaunay function can be used to plot a surface representing a sampled data set.

The following example uses the seamount data set. A seamount is an underwater mountain. The data set consists of a set of longitude ( $x$ ) and latitude ( $y$ ) locations, and corresponding seamount elevations ( $z$ ) measured at those coordinates. Plot the surface representing this data set using a Delaunay triangulation of the ( $x, y$ ) locations.

1 Load the seamount data set and view the ( $\mathrm{x}, \mathrm{y}$ ) data as a scatter plot:

```
load seamount
plot(x,y,'.','markersize',12)
xlabel('Longitude'), ylabel('Latitude')
grid on
```

2 Construct a Delaunay triangulation from this point set and use triplot to plot the triangulation in our existing figure:

```
tri = delaunay(x,y);
hold on, triplot(tri,x,y), hold off
```

3 Add the depth data (z) from seamount to lift the vertices and create the surface. Create a new figure and use trimesh to plot the surface in wireframe mode:

```
figure
hidden on
trimesh(tri,x,y,z)
xlabel('Longitude'),ylabel('Latitude'),zlabel('Depth in Feet');
```

To plot the surface in shaded mode use trisurf instead of trimesh.
A 3-D Delaunay triangulation also can be created using the delaunay function. This triangulation is composed of tetrahedra. The following example shows how to create a 3-D Delaunay triangulation of a random data set. The triangulation can be plotted using tetramesh and to visualize the interior of the triangulation you can set the FaceAlpha option to add transparency to the plot.

```
X = gallery('uniformdata',[30 3],0);
tet = delaunay(X);
faceColor = [0.6875 0.8750 0.8984];
tetramesh(tet,X,'FaceColor', faceColor,'FaceAlpha',0.3);
```

MATLAB provides the delaunayn function to support the creation of Delaunay triangulations in dimension 4-D and higher. Two complementary functions tsearchn and dsearchn are also provided to support spatial searching for N-D triangulations. See "Spatial Searching" on page 6-47 for more information on triangulation-based search.

## Delaunay Triangulation Using the DelaunayTri Class

The DelaunayTri class provides another way to create Delaunay triangulations in MATLAB. While delaunay and DelaunayTri use the same underlying algorithm and produce the same triangulation, DelaunayTri provides complementary methods that are useful for developing Delaunay-based algorithms. These methods are like functions that are packaged together with the triangulation data into a container called a class. Keeping everything together in a class provides a more organized setup that improves ease of use. It also improves the performance of triangulation-based
searches such as point location and nearest neighbor. DelaunayTri supports incremental editing of the Delaunay triangulation. You can also impose edge constraints in 2-D.
"Triangulation Representations" on page $6-3$ presents the class TriRep that represents triangulations. In addition, TriRep provides many methods that allow you to make topological and geometric queries. DelaunayTri also represents a triangulation and in fact, represents it in terms of a TriRep. You can view DelaunayTri as a subset of TriRep, (in MATLAB language terms, DelaunayTri is a subclass of TriRep). This simply means that a DelaunayTri (Delaunay triangulation) is a TriRep (triangulation representation) that has something extra. In this instance the difference is the Delaunay criterion that the triangulation satisfies and the extra methods that DelaunayTri provides that are unique to Delaunay triangulations.

These distinctions will become clearer with examples. The next example uses the seamount data to explore how you can create, query, and edit a Delaunay triangulation with DelaunayTri. The seamount data set contains ( $x, y$ ) locations and corresponding elevations ( $z$ ) that define the surface of the seamount.

Load and triangulate the ( $\mathrm{x}, \mathrm{y}$ ) data:

```
load seamount
dt = DelaunayTri(x,y)
```

MATLAB outputs the following when it creates the DelaunayTri:

```
dt =
    DelaunayTri
        Properties:
            Constraints: []
                    X: [294x2 double]
        Triangulation: [566x3 double]
    Methods, Superclasses
```

The Constraints property is empty because you have not imposed edge constraints (see "Constrained Delaunay Triangulation" on page 6-37 for more information about constraints). The $X$ property represents the coordinates of the vertices, and the Triangulation property represents the triangles. Together these two properties define the face-vertex format for the triangulation. If you click on the DelaunayTri link you will get help for the DelaunayTri class, and if you click on the Methods link, MATLAB will return a list of available methods for the class. You can also type the following to get help on the DelaunayTri class and see its list of methods:

```
help DelaunayTri
methods('DelaunayTri')
Or
methods(dt);
```

The Superclasses link provides help for TriRep, the superclass for DelaunayTri. As in the case of TriRep, the DelaunayTri class is a wrapper around the face-vertex format together with a set of complementary methods. Similarly, you can access the properties in a DelaunayTri in the same way as you would for a Struct.

To access the vertex data:

```
dt.X
```

To access the triangulation:

```
dt.Triangulation
```

To access the first triangle in the Triangulation property:

```
dt.Triangulation(1, :)
```

DelaunayTri provides a shorthand way of indexing into the Triangulation property matrix. The shorthand way to get the first triangle is:

```
dt(1, :)
```

You can get the first vertex of the first triangle:

```
dt(1, 1)
```

Or the second vertex of the first triangle:

```
dt(1, 2)
```

Or get all the triangles in the triangulation:

```
dt(:, :)
```

Indexing into the DelaunayTri output dt works like indexing into a triangulation the output from delaunay. The difference between the two are the extra methods that you can call on dt. You can use triplot to plot the DelaunayTri; while it's not a method of the class, triplot recognizes a DelaunayTri and knows how to plot it.

```
triplot(dt);
axis equal
xlabel('Longitude'), ylabel('Latitude')
grid on
```

You could use

```
triplot(dt(:,:), dt.X(:,1), dt.X(:,2));
```

to get the same plot.

DelaunayTri provides all of the methods of TriRep together with the following exclusive methods.

| DelaunayTri Method | Description |
| :--- | :--- |
| convexHull | Returns the convex hull |
| voronoiDiagram | Returns the Voronoi diagram |
| nearestNeighbor | Searches for the point closest to the <br> specified location |
| pointLocation | Locates the simplex containing the <br> specified location |
| inOutStatus | Returns the in/out status of the <br> triangles in a 2-D constrained <br> Delaunay |

You can use the convexHull method to compute the convex hull and add it to the plot. Since you already have a Delaunay triangulation, this method allows you to derive the convex hull more efficiently than a full computation using convhull:

```
hold on
k = convexHull(dt)
xHull = dt.X(k,1);
yHull = dt.X(k,2);
plot(xHull, yHull, 'r','LineWidth',2);
hold off
```

You can incrementally edit the DelaunayTri to add or remove points. If you need to add points to an existing triangulation, then an incremental addition is faster than a complete retriangulation of the augmented point set. Incremental removal of points is more efficient when the number of points to be removed is small relative to the existing number of points. You can edit the triangulation to remove the points on the convex hull that from the previous computation.

```
% Plot the result in a new figure
figure
plot(xHull, yHull, 'r','LineWidth',2);
axis equal
xlabel('Longitude'), ylabel('Latitude')
grid on
```

\% The convex hull topology duplicates the start
\% and end vertex. To remove the duplicate entry:
k(end) = [];
\% Now remove the points on the convex hull
dt. $\mathrm{X}(\mathrm{k},:$ ) = []
\% Plot the new triangulation
hold on
triplot(dt);
hold off

There is one vertex that is just inside the boundary of the convex hull that was not removed. The fact that it's interior to the hull can be seen using the Zoom-In tool in the figure. You could plot the vertex labels to determine the index of this vertex and remove it from the triangulation. You can also use the nearestNeighbor method to identify the index more readily.

```
% The point is close to location (211.6, -48.15)
% Use the nearestNeighbor method to find the nearest vertex
vertexId = nearestNeighbor(dt, 211.6, -48.15)
% Now remove that vertex from the triangulation
dt.X(vertexId,:) = []
% Plot the new triangulation
figure
plot(xHull, yHull, 'r','LineWidth',2);
axis equal
xlabel('Longitude'), ylabel('Latitude')
grid on
hold on
triplot(dt);
hold off
```

Add points to the existing triangulation as follows:
\% Add 4 points to form a rectangle around the triangulation Xadditional $=$ [210.9-48.5; 211.6-48.5; ...
211.6-47.9; 210.9-47.9];
dt. $X($ end+(1:4), :) = Xadditional
\% Close all existing figures
close all
\% Plot the new triangulation
figure
plot(xHull, yHull, 'r','LineWidth',2);
axis equal
xlabel('Longitude'), ylabel('Latitude')
grid on
hold on

```
triplot(dt);
hold off
```

You can edit the points in the triangulation to move them to a new location. To edit the first of the additional point set (the vertex ID 274):

```
dt.X(274,:) = [211 -48.4];
% Close all existing figures
close all
% Plot the new triangulation
figure
plot(xHull, yHull, 'r','LineWidth',2);
axis equal
xlabel('Longitude'), ylabel('Latitude')
grid on
hold on
```

Note TriRep methods are available to DelaunayTri because DelaunayTri is a subclass of TriRep. You can use a TriRep method to query the triangles attached to the vertex you just moved. Use the vertexAttachments method to find the attached triangles. Since the number of triangles attached to a vertex is variable, the method returns the attached triangle indices in a cell array. You need braces to extract the contents.

```
attTris = vertexAttachments(dt,274);
hold on
triplot(dt(attTris{:},:),dt.X(:,1),dt.X(:,2),'g')
hold off
```

DelaunayTri can also be used to triangulate points in 3-D space; the resulting triangulation is composed of tetrahedra. The following example shows how to use a DelaunayTri to create and plot the triangulation of 3-D points.

```
X = rand(30,3);
dt = DelaunayTri(X)
faceColor = [0.6875 0.8750 0.8984];
tetramesh(dt,'FaceColor', faceColor,'FaceAlpha',0.3);
```

The tetramesh function plots both the internal and external faces of the triangulation. For large 3-D triangulations, plotting the internal faces may be an unnecessary use of resources and a plot of the boundary may be more appropriate. This can be done using the freeBoundary method which can return the boundary triangulation in face-vertex format which can then be used to call trimesh or trisurf.

## Constrained Delaunay Triangulation

The DelaunayTri class allows you to constrain edges in a 2-D triangulation. This means you can chose a pair of points in the triangulation and constrain an edge to join those points. You can picture this as "forcing" an edge between one or more pairs of points. We can examine how this behaves using a simple example.

This triangulation is a Delaunay triangulation because it respects the empty circumcircle criterion. What would happen if you were to triangulate this set of points with an edge constraint specified between vertex V1 and V3:

```
% The point set:
X = [2 4; 6 1; 9 4; 6 7]
% C defines a constraint between V1 and V3:
C = [11 3];
dt = DelaunayTri(X, C);
triplot(dt)
```

Note The code for plotting the labels and circles is omitted for brevity.

The constraint between vertices (V1, V3) was honored, but in doing so the Delaunay criterion was invalidated. This also invalidates the nearest-neighbor relation that is inherent in a Delaunay triangulation. This means the nearestNeighbor search method provided by DelaunayTri cannot be supported if the triangulation has constraints. For information on handling this restriction, refer to "Spatial Searching" on page 6-47.

In typical applications the triangulation may be composed of many points, and a relatively small number of edges in the triangulation may be constrained. Such a triangulation is said to be locally non-Delaunay, because many triangles in the triangulation may respect the Delaunay criterion, but locally there may be some triangles that do not. In many applications, local relaxation of the empty circumcircle property is not a concern.

Constrained triangulations are generally used to triangulate a nonconvex polygon. The constraints give us a correspondence between the polygon edges and the triangulation edges and enable you to extract a triangulation that represents the region. The following example shows how to use a constrained DelaunayTri to triangulate a nonconvex polygon.

Suppose the polygon is defined as follows:

Triangulating the coordinates of the vertices returns the following:

```
figure('Color', 'white')
subplot(2,1,1);
axis([-1 17 -1 6]);
axis equal
% Create and plot the triangulation
% together with the polygon boundary
dt = DelaunayTri(X);
triplot(dt)
hold on;
patch(X(:,1),X(:,2),'-r','LineWidth',2,'FaceColor',...
    'none','EdgeColor','r');
hold off
% Plot the standalone triangulation
% triangulation in a subplot
```

```
subplot(2,1,2);
axis([-1 17 -1 6]);
axis equal
triplot(dt)
```

This triangulation cannot be used to represent the domain of the polygon because some triangles cut across the boundary. You need to impose a constraint on the edges that are cut by triangulation edges. Since all edges have to be respected you need to constrain all edges. The steps are as follows:

1 Observe from the annotated figure where you need constraints (between (V1, V2), (V2, V3), and so on). Enter the constrained edge definition:

$$
C=[12 ; 23 ; 34 ; 45 ; 56 ; 67 ; 78 ; 81] ;
$$

In general, if you have $N$ points in a sequence that define a polygonal boundary, the constraints can be expressed as; C = [(1:(N-1))' (2:N)'; N 1];

2 You can specify the constraints when you create the DelaunayTri:

```
dt = DelaunayTri(X,C)
```

You can also impose constraints on an existing triangulation by setting the Constraints property:

```
dt.Constraints = C;
```

3 Plot the triangulation and polygon as before:

```
figure('Color', 'white')
subplot(2,1,1);
axis([-1 17 -1 6]);
axis equal
dt = DelaunayTri(X);
triplot(dt)
hold on;
patch(X(:,1),X(:,2),'-r', 'LineWidth', 2, ...
    'FaceColor','none', 'EdgeColor','r');
hold off
% Plot the standalone triangulation
% triangulation in a subplot
subplot(2,1,2);
axis([-1 17 -1 6]);
axis equal
triplot(dt)
```

The plot shows that the edges of the triangulation respect the boundary of the polygon. However, the triangulation fills the concavities. What is needed is a triangulation that represents the polygonal domain. You can extract the triangles within the polygon using the inOutStatus method that DelaunayTri provides. This method returns a logical array that reports the in/out status of each triangle in the triangulation. The analysis is based on the Jordan Curve theorem and the boundaries are defined by the edge constraints. The ith triangle in the triangulation is considered to be inside the domain if the ith logical flag is true, otherwise it is outside.

You can now use the inOutStatus method to compute and plot the set of domain triangles:

```
% Plot the constrained edges in red
figure('Color', 'white')
subplot(2,1,1);
plot(X(C'),X(C'+size(X,1)),'-r', 'LineWidth', 2);
axis([-1 17 -1 6]);
% Compute the in/out status
```

    IO = inOutStatus(dt);
    subplot (2,1,2);
    hold on;
    axis([-1 \(\left.17 \begin{array}{lll}-1 & 6\end{array}\right]\);
    \% Use triplot to plot the triangles that are inside.
    \% Uses logical indexing and dt(i,j) shorthand
    \% format to access the triangulation.
triplot(dt(IO, :), dt.X(:,1), dt.X(:,2), 'LineWidth', 2)
hold off;

## Triangulation of Point Sets Containing Duplicate Locations

The Delaunay algorithms in MATLAB construct a triangulation from a unique set of points. If the points passed to the triangulation function, or class, are not unique, the duplicate locations are detected and the duplicate
point is ignored. This produces a triangulation that does not reference some points in the original input, namely the duplicate points. When working with the delaunay and delaunayn functions the presence of duplicates may be of little consequence. However, since many of the queries provided by the DelaunayTri class are index based, it is important to understand that DelaunayTri triangulates and works with the unique data set. Therefore, indexing based on the unique point set is the convention; this data is maintained by the X property of DelaunayTri.

The following example illustrates the importance of referencing the unique data set stored within the property when working with DelaunayTri:

```
X = gallery('uniformdata',[25 2],0);
X(18,:) = X(8,:)
X(16,:) = X(6,:)
X(12,:) = X(2,:)
dt = DelaunayTri(X)
```

When the triangulation is created MATLAB issues a warning. The $X$ property shows that the duplicate points have been removed from the data.

```
dt =
    DelaunayTri
        Properties:
    Constraints: []
        X: [22x2 double]
Triangulation: [31x3 double]
    Methods, Superclasses
```

If for example, the Delaunay triangulation is used to compute the convex hull, the indices of the points on the hull are indices with respect to the unique point set, dt . X . Therefore, to compute and plot the convex hull, the steps are as follows:

```
K = dt.convexHull();
plot(dt.X(:,1), dt.X(:,2),'.');
hold on
```

```
plot(dt.X(K,1), dt.X(K,2),'-r')
```

If the original data set containing the duplicates were used in conjunction with the indices provided by DelaunayTri then the result would be incorrect. The DelaunayTri works with indices that are based on the unique data set dt . X . For example, the following would produce an incorrect plot, because K is indexed with respect to $\mathrm{dt} . \mathrm{X}$ and not X :

```
K = dt.convexHull();
plot(X(:,1), X(:,2),'.');
hold on
plot(X(K,1), X(K,2),'-r')
```

It's often more convenient to create a unique data set by removing duplicates prior to creating the DelaunayTri as it eliminates the potential for confusion. This can be accomplished using the unique function as follows:

```
X = gallery('uniformdata',[25 2],0);
X(18,:) = X(8,:)
X(16,:) = X(6,:)
X(12,:) = X(2,:)
[~, I, ~] = unique(X,'first','rows');
I = sort(I);
X = X(I,:);
dt = DelaunayTri(X) % The point set is unique
```

## Spatial Searching

In this section...<br>"Introduction" on page 6-47<br>"Nearest-Neighbor Search" on page 6-47<br>"Point Location" on page 6-50<br>"Searching Non-Delaunay Triangulations" on page 6-53

## Introduction

MATLAB provides you with the necessary functions to perform a spatial search using a Delaunay triangulation. The Delaunay-based search queries that MATLAB supports are:

- Nearest-neighbor search (sometimes called closest-point search or proximity search),
- Point-location search (sometimes called point-in-triangle search or point-in-simplex search, where a simplex is a triangle, tetrahedron or higher dimensional equivalent).

Given a set of points $X$ and a query point q in Euclidean space, the nearest-neighbor search locates a point $p$ in $X$ that is closer to $q$ than to any other point in X. Given a Delaunay triangulation of $X$, the point location search locates the simplex that contains the query point $q$.

While MATLAB supports these search schemes in N dimensions, exact spatial searches usually become prohibitive in 6 dimensions. You should consider approximate alternatives for large problems in up to 10 dimensions.

## Nearest-Neighbor Search

There are two Delaunay-based approaches to computing nearest neighbors in MATLAB, depending on the dimensionality of the problem:

- For 2-D and 3-D search, use the nearestNeighbor method provided by the DelaunayTri class.
- For 4-D and higher, use the delaunayn function to construct the triangulation and the complementary dsearchn function to perform the search. While these N-D functions support 2-D and 3-D, they are not as efficient as the search methods provided by DelaunayTri.

The following example demonstrates how to perform a nearest-neighbor search in 2-D with DelaunayTri. Begin by creating a random set of 15 points and plotting the points showing ID labels:

```
X = [3.5 8.2; 6.8 8.3; 1.3 6.5; 3.5 6.3; 5.8 6.2; 8.3 6.5;...
    1 4; 2.7 4.3; 5 4.5; 7 3.5; 8.7 4.2; 1.5 2.1; 4.1 1.1; ...
    7 1.5; 8.5 2.75];
```

Plot the points and add annotations:

```
plot(X(:,1),X(:,2),'ob')
hold on
vxlabels = arrayfun(@(n) {sprintf('X%d', n)}, (1:15)');
Hpl = text(X(:,1)+0.2, X(:,2)+0.2, vxlabels, 'FontWeight', ...
    'bold', 'HorizontalAlignment','center', 'BackgroundColor', ...
    'none');
hold off
```

Create a Delaunay triangulation from the points:

```
dt = DelaunayTri(X);
```

Create some query points and for each query point find the index of its corresponding nearest neighbor in X using the nearestNeighbor method:

```
numq = 10;
q = 2+rand(numq,2)*6;
xi = nearestNeighbor(dt, q);
```

Add the query points to the plot and add line segments joining the query points to their nearest neighbors:

```
xnn = X(xi,:);
hold on
plot(q(:, 1),q(:,2),'or');
```

```
plot([xnn(:,1) q(:,1)]',[xnn(:,2) q(:,2)]','-r');
vxlabels = arrayfun(@(n) {sprintf('q%d', n)}, (1:numq)');
Hpl = text(q(:,1)+0.2, q(:,2)+0.2, vxlabels, 'FontWeight', ...
    'bold', 'HorizontalAlignment','center', ...
    'BackgroundColor','none');
hold off
```

(48

Performing a nearest-neighbor search in 3-D is a direct extension of the 2-D example based on DelaunayTri. For 4-D and higher use the delaunayn and dsearchn functions as illustrated in the following example:

Create a random sample of points in 4-D and triangulate the points using delaunayn:

```
X = 20*rand(50,4) -10;
tri = delaunayn(X);
```

Create some query points and for each query point find the index of its corresponding nearest neighbor in X using the dsearchn function:

```
q = rand(5,4);
xi = dsearchn(X,tri, q)
```

The nearestNeighbor method and the dsearchn function allow the Euclidean distance between the query point and its nearest neighbor to be returned as an optional argument. In the 4-D example, you can compute the distances (dnn) as follows:
[xi dnn] = dsearchn(X,tri, q)

## Point Location

A point location search is a triangulation-search algorithm that locates the simplex (triangle, tetrahedron, and so on) enclosing a query point. As in the case of the nearest-neighbor search, there are two approaches to performing a point-location search in MATLAB, depending on the dimensionality of the problem:

- For 2-D and 3-D, use the class-based approach with the pointLocation method provided by the DelaunayTri class.
- For 4-D and higher, use the delaunayn function to construct the triangulation and the complementary tsearchn function performs the point location search. Although supporting 2-D and 3-D, these N-D functions are not as efficient as the search methods provided by DelaunayTri.

The following example demonstrates how to use the DelaunayTri class to perform a point location search in 2-D.

Begin with a set of 2-D points. Create the triangulation and plot it showing the triangle ID labels at the incenters of the triangles:

```
X = [3.5 8.2; 6.8 8.3; 1.3 6.5; 3.5 6.3; 5.8 6.2; ...
    8.3 6.5; 1 4; 2.7 4.3; 5 4.5; 7 3.5; 8.7 4.2; ...
    1.5 2.1; 4.1 1.1; 7 1.5; 8.5 2.75];
dt = DelaunayTri(X);
triplot(dt);
```

```
hold on
ic = incenters(dt);
numtri = size(dt,1);
trilabels = arrayfun(@(x) {sprintf('T%d', x)}, (1:numtri)');
Htl = text(ic(:,1), ic(:,2), trilabels, 'FontWeight', ...
    'bold', 'HorizontalAlignment', 'center', 'Color', ...
    'blue');
hold off
```

Now create some query points and add them to the plot. Then find the index of the corresponding enclosing triangles using the pointLocation method:

```
numq = 10;
q = 2+rand(numq,2)*6;
hold on;
plot(q(:,1),q(:,2),'*r');
vxlabels = arrayfun(@(n) {sprintf('q%d', n)}, (1:numq)');
Hpl = text(q(:,1)+0.2, q(:,2)+0.2, vxlabels, 'FontWeight', ...
    'bold', 'HorizontalAlignment','center', ...
    'BackgroundColor', 'none');
hold off
ti = pointLocation(dt, q)
```

Performing a point-location search in 3-D is a direct extension of performing a point-location search in 2-D with DelaunayTri. For 4-D and higher, use the delaunayn and tsearchn functions as illustrated in the following example:

Create a random sample of points in 4-D and triangulate them using delaunayn:

```
X = 20*rand(50,4) -10;
tri = delaunayn(X);
```

Create some query points and find the index of the corresponding enclosing simplices using the tsearchn function:

```
q = rand(5,4);
ti = tsearchn(X,tri, q)
```

The pointLocation method and the tsearchn function allow the corresponding barycentric coordinates to be returned as an optional argument. In the 4-D example, you can compute the barycentric coordinates as follows:
[ti bc] = tsearchn(X,tri, q)

The barycentric coordinates are useful for performing linear interpolation. These coordinates provide you with weights that you can use to scale the values at each vertex of the enclosing simplex. See "Interpolating Scattered Data" on page 7-12 for further details.

## Searching Non-Delaunay Triangulations

You only can use the search functions tsearchn and dsearchn to search convex, fully connected Delaunay triangulations that were created in MATLAB. If you create a Delaunay triangulation using delaunayn and subsequently modify the location of the coordinates, then the Delaunay criterion could be invalid. Therefore, you should not use the search functions as they may not converge. The search functions do not check the validity of the Delaunay triangulation as this would introduce a significant performance penalty. Imported triangulations, such as triangulations used for finite element analysis, tend to be nonconvex. They could have holes, or they might not respect the Delaunay criterion. Hence, you cannot reliably use the search functions tsearchn and dsearchn on triangulations like these.

The class DelaunayTri is more secure in this respect because you only can use the search methods to search a DelaunayTri. However, you cannot perform a nearestNeighbor search on a DelaunayTri that has constrained edges as it is locally non-Delaunay.

To perform a nearest-neighbor search on a constrained DelaunayTri, do one of the following:

- Delete the constraints
- Create a new unconstrained DelaunayTri using the same point set, and use the unconstrained triangulation to perform the search.

Similarly, to perform a nearest-neighbor search on a triangulation that is represented in face-vertex format, create a DelaunayTri from the vertex coordinates and use it to perform the search.

MATLAB does not provide dedicated functions for performing a point location search on a 2-D (triangle) or 3-D (tetrahedral) triangulations that are in face vertex format and do not meet the search function requirements. However, for relatively small triangulations a brute-force search might be viable. For a 2-D triangulation, you might can recreate the triangulation topology using a constrained DelaunayTri

You can perform the brute-force search by checking the query point against every triangle (or tetrahedron) and selecting the one that contains the point. For example, suppose you have the following triangulation in face-vertex format and you want to perform a brute-force point location search that finds a triangle enclosing a point.

```
X = [3.5 8.2; 6.8 8.3; 1.3 6.5; 3.5 6.3; 5.8 6.2; 8.3 6.5; ...
    1 4; 2.7 4.3; 5 4.5; 7 3.5; 8.7 4.2; 1.5 2.1; 4.1 1.1; ...
    7 1.5; 8.5 2.75];
tri = delaunay(X);
% Remove first triangle to make the triangulation nonconvex
tri(1,:) = [];
```

The first thing you can do is create a TriRep to represent this triangulation:

```
tr = TriRep(tri,X)
```

The TriRep has many useful query methods, but it does not have a pointLocation or a nearestNeighbor method. A TriRep can represent a nonconvex triangulation with holes and non-Delaunay triangulations, but the search algorithms preclude these.

TriRep provides a useful method that you can use to check if a query point lies within a specified triangle (or tetrahedron). The method is cartToBary. Given a point expressed in Cartesian coordinates and a specified triangle in the triangulation, this method returns the barycentric coordinates of the point with respect to the triangle. If all three barycentric coordinates are positive, the point is within the triangle. Otherwise, the point is outside the triangle. Plot the triangulation to explore this method:

```
triplot(tr)
axis equal
```

```
hold on
ic = incenters(tr);
numtri = size(tr,1);
trilabels = arrayfun(@(x) {sprintf('T%d', x)}, (1:numtri)');
Htl = text(ic(:,1), ic(:,2), trilabels, 'FontWeight', ...
    'bold', 'HorizontalAlignment', 'center', 'Color', ...
    'blue');
hold off
```

Search for the triangle enclosing $(6,3)$ :

```
numtri = size(tr,1);
B = cartToBary(tr, (1:numtri)', repmat([6 3], numtri,1));
posB = (B >= 0);
enclosingTri = find(posB(:,1) & posB(:,2) & posB(:,3))
```

You can now use a constrained DelaunayTri to perform the search. You should start with the TriRep you created in the brute-force search and use it to find all edges in the triangulation so you can constrain them.:

```
Cedges = edges(tr);
```

Now create the constrained DelaunayTri and plot it in a separate figure so you can compare both triangulations.:

```
dt = DelaunayTri(X, Cedges)
figure
triplot(dt)
axis equal
hold on
ic = incenters(dt);
numtri = size(dt,1);
trilabels = arrayfun(@(x) {sprintf('T%d', x)}, (1:numtri)');
Htl = text(ic(:,1), ic(:,2), trilabels, 'FontWeight', ...
    'bold', 'HorizontalAlignment', 'center', 'Color', ...
    'blue');
hold off
```

Since the triangle numbering is different in each triangle, you need to build an array of indices to map triangle IDs from the DelaunayTri to the TriRep.

To do this mapping you will compute the incenters of the TriRep and find the corresponding enclosing triangles in the DelaunayTri:

```
dtTotrIndex = nan(size(dt,1),1);
ic = incenters(tr);
dtid = pointLocation(dt,ic)
dtTotrIndex(dtid) = 1:size(tr,1);
```

Now you use the DelaunayTri to perform the point location search. Next, use the map to find the corresponding triangle in the TriRep:

```
trid = pointLocation(dt, 6,3);
if isfinite(trid)
    trid = dtTotrIndex(trid);
end
trid
```

## Voronoi Diagrams

The Voronoi diagram of a discrete set of points $X$ decomposes the space around each point $X(i)$ into a region of influence $R\{i\}$. This decomposition has the property that an arbitrary point $P$ within the region $R\{i\}$ is closer to point $i$ than any other point. The region of influence is called a Voronoi region and the collection of all the Voronoi regions is the Voronoi diagram.

The Voronoi diagram is an N-D geometric construct; however, most practical applications are in 2-D and 3-D space. The properties of the Voronoi diagram are best understood using an example. This example uses the 2 -D voronoi function:

```
figure('Color', 'white')
X = [-1.5 3.2; 1.8 3.3; -3.7 1.5; -1.5 1.3; ...
    0.8 1.2; 3.3 1.5; -4.0 -1.0;-2.3 -0.7; ...
    0-0.5; 2.0 -1.5; 3.7 -0.8; -3.5 -2.9; ...
    -0.9 -3.9; 2.0 -3.5; 3.5 -2.25]
voronoi(X(:,1),X(:,2))
```

Assign labels to the points as follows:

```
nump = size(X,1);
plabels = arrayfun(@(n) {sprintf('X%d', n)}, (1:nump)');
hold on
Hpl = text(X(:,1), X(:,2), plabels, 'FontWeight', ...
    'bold', 'HorizontalAlignment','center', ...
    'BackgroundColor', 'none');
```

Add a query point P at $(0,-1.5)$. Observe that P is closer to X 9 than to any other point in $X$, which is true for any point $P$ within the region that bounds $X 9$ :

```
P = [0 -1];
plot(P(1),P(2), '*r');
text(P(1), P(2), 'P', 'FontWeight', 'bold', ...
    'HorizontalAlignment','center', ...
    'BackgroundColor', 'none');
hold off
```

The Voronoi diagram of a set of points X is closely related to the Delaunay triangulation of $X$. To see this relationship, construct a Delaunay triangulation of the point set $X$ and superimpose the triangulation plot on the Voronoi diagram:

```
dt = DelaunayTri(X);
hold on
triplot(dt, '-r');
hold off
```

From the plot you can see that the Voronoi region associated with the point X9 is defined by the perpendicular bisectors of the Delaunay edges attached to X9. Also, the vertices of the Voronoi edges are located at the circumcenters of the Delaunay triangles. You can illustrate these associations by plotting the circumcenter of triangle $\{\mathrm{X} 9, \mathrm{X} 4, \mathrm{X} 8\}$.

To find the index of this triangle, query the triangulation. The triangle contains the location ( $-1,0$ ):

```
tidx = dt.pointLocation(-1, 0);
```

Now, find the circumcenter of this triangle and plot it in green:

```
cc = dt.circumcenters(tidx);
hold on
plot(cc(1),cc(2), '*g');
hold off
```

The Delaunay triangulation and Voronoi diagram are geometric duals of each other. You can compute the Voronoi diagram from the Delaunay triangulation and vice versa.

Observe that the Voronoi regions associated with points on the convex hull are unbounded (for example, the Voronoi region associated with X13). The edges this region "end" at infinity and this infinite vertex is first vertex in the in the V array represents the vertex of X 13 . The Voronoi edges that bisect Delaunay edges ( $\mathrm{X} 13, \mathrm{X} 12$ ) and ( $\mathrm{X} 13, \mathrm{X} 14$ ) extend to infinity. While the Voronoi diagram provides a nearest-neighbor decomposition of the space around each point in the set, it does not directly support nearest-neighbor queries. However, the geometric constructions used to compute the Voronoi diagram are also used to perform nearest-neighbor searches. Refer to "Spatial Searching" on page 6-47 for further information on nearest-neighbor queries.

## Computing the Voronoi Diagram

MATLAB software provides functions to plot the Voronoi diagram in 2-D and to compute the topology of the Voronoi diagram in N-D. In practice, Voronoi computation is not practical in dimensions beyond 6-D for moderate to large data sets, due to the exponential growth in required memory.

The voronoi plot function plots the Voronoi diagram for a set of points in 2-D space. In MATLAB there are two ways to compute the topology of the Voronoi diagram of a point set:

- Using the MATLAB function voronoin
- Using the DelaunayTri.voronoiDiagram method provided by the DelaunayTri class.

The voronoin function supports the computation of the Voronoi topology for discrete points in N-D ( $\mathrm{N} \geq 2$ ). The DelaunayTri.voronoiDiagram method supports computation of the Voronoi topology for discrete points 2-D or 3-D.

The DelaunayTri.voronoiDiagram method is recommended for 2-D or 3-D topology computations as it is more robust and gives better performance for large data sets. This method supports incremental insertion and removal of points and complementary queries, such as nearest-neighbor point search.

The voronoin function and the DelaunayTri.voronoiDiagram method represent the topology of the Voronoi diagram using a face-vertex format. See "Triangulation Face-Vertex Format" on page 6-5 for further details on this data structure. Given a set of points X, obtain the topology of the Voronoi diagram as follows:

- Using the voronoin function
dt = DelaunayTri(X)
[V, R] = dt.voronoiDiagram(X)
- Using the DelaunayTri.voronoiDiagram method

```
dt = DelaunayTri(X)
[V, R] = dt.voronoiDiagram(X)
```

$V$ is a matrix representing the coordinates of the Voronoi vertices (the vertices are the end points of the Voronoi edges). R is a vector cell array length size ( $X, 1$ ), representing the Voronoi region associated with each point. Hence, the Voronoi region associated with the ith point $X(i)$ is $R\{i\}$.

Reusing the previous data helps to clarify the V , R datastructure.

```
X = [-1.5 3.2; 1.8 3.3; -3.7 1.5; -1.5 1.3; 0.8 1.2; ...
    3.3 1.5;-4.0-1.0; -2.3 -0.7; 0 -0.5; 2.0 -1.5; ...
    3.7-0.8; -3.5 -2.9; -0.9 -3.9; 2.0 -3.5; 3.5 -2.25]
[VX, VY] = voronoi(X(:,1),X(:,2));
h = plot(VX,VY,'-b',X(:,1),X(:,2),'.r');
set(h(1:end-1),'xliminclude','off','yliminclude','off')
```

Assign labels to the points X :

```
nump = size(X,1);
plabels = arrayfun(@(n) {sprintf('X%d', n)}, (1:nump)');
hold on
Hpl = text(X(:,1), X(:,2)+0.2, plabels, 'color', 'r', ...
    'FontWeight', 'bold', 'HorizontalAlignment',...
    'center', 'BackgroundColor', 'none');
```

Compute the Voronoi diagram:

```
dt = DelaunayTri(X);
[V R] = dt.voronoiDiagram();
```

Assign labels to the Voronoi vertices V. By convention the first vertex is at infinity:

```
numv = size(V,1);
vlabels = arrayfun(@(n) {sprintf('V%d', n)}, (2:numv)');
hold on
Hpl = text(V(2:end,1), V(2:end,2)+.2, vlabels, ...
    'FontWeight', 'bold', 'HorizontalAlignment',...
    'center', 'BackgroundColor', 'none');
```

$R\{9\}$ gives the indices of the Voronoi vertices associated with the point site X9:

```
R{9}
ans =
    5
```

The indices of the Voronoi vertices are the indices with respect to the V array.
Similarly, $\mathbf{R}\{4\}$ gives the indices of the Voronoi vertices associated with the point site X 4 :

```
R{4}
ans =
    5
```

In 3-D a Voronoi region is a convex polyhedron, the syntax for creating the Voronoi diagram is similar. However the geometry of the Voronoi region is more complex. The following example illustrates the creation of a 3-D Voronoi diagram and the plotting of a single region.

Create a sample of 25 points in 3-D space and compute the topology of the Voronoi diagram for this point set:

```
X = -3 + 6.*gallery('uniformdata',[25 3],0);
dt = DelaunayTri(X)
```

Compute the topology of the Voronoi diagram:

```
[V R] = dt.voronoiDiagram();
```

Find the point closest to the origin and plot the Voronoi region associated with this point:

```
tid = dt.nearestNeighbor(0,0,0)
XR10 = V(R{tid},:)
K = convhull(XR10);
defaultFaceColor = [0.6875 0.8750 0.8984]
trisurf(K, XR10(:,1) ,XR10(:,2) ,XR10(:,3) , ...
    'FaceColor', defaultFaceColor, 'FaceAlpha',0.8);
```

## 3-D Voronoi Region

## Convex Hulls

The convex hull of a set of points in N-D space is the smallest convex region enclosing all points in the set. If you think of a $2-\mathrm{D}$ set of points as pegs in a peg board, the convex hull of that set would be formed by taking an elastic band and using it to enclose all the pegs.

## The Convex Hull of a Set of Points

A convex polygon is a polygon that does not have concave vertices, for example:

## Convex Polygon

A nonconvex polygon has concave vertices:

## Nonconvex Polygon

The convex hull has numerous applications. You can compute the upper bound on the area bounded by a discrete point set in the plane from the convex hull of the set. The convex hull simplifies the representation of more complex polygons or polyhedra. For instance, to determine whether two nonconvex bodies intersect, you could apply a series of fast rejection steps to avoid the penalty of a full intersection analysis:

- Check if the axis-aligned bounding boxes around each body intersect.
- If the bounding boxes intersect, you can compute the convex hull of each body and check intersection of the hulls.

If the convex hulls did not intersect, this would avoid the expense of a more comprehensive intersection test.

## Computing the Convex Hull

MATLAB provides two ways to compute the convex hull:

- Using the MATLAB functions convhull and convhulln
- Using the convexHull method provided by the DelaunayTri class

The convhull function supports the computation of convex hulls in 2-D and 3-D. The convhulln function supports the computation of convex hulls in N-D ( $\mathrm{N} \geq 2$ ). The convhull function is recommended for 2-D or 3-D computations due to better robustness and performance.

The DelaunayTri class supports 2-D or 3-D computation of the convex hull from the Delaunay triangulation. This computation is not as efficient as the dedicated convhull and convhulln functions. However, if you have a DelaunayTri of a point set and require the convex hull, the convexHull method can compute the convex hull more efficiently from the existing triangulation.

## Computing the Convex Hull Using convhull and convhulln

The convhull and convhulln functions take a set of points and output the indices of the points that lie on the boundary of the convex hull. The point index-based representation of the convex hull supports plotting and convenient data access. The following examples illustrate the computation and representation of the convex hull.

The first example uses a 2-D point set from the seamount dataset as input to the convhull function.

Load the data:

```
load seamount
plot(x,y,'.','markersize',12)
xlabel('Longitude'), ylabel('Latitude')
```

Compute the convex hull of the point set:

$$
K=\operatorname{convhull}(x, y)
$$

K represents the indices of the points arranged in a counter-clockwise cycle around the convex hull. Use the plot function to plot the convex hull:

Add point labels to the points on the convex hull to observe the structure of K :
[K A] = convhull(x, y)
convhull can compute the convex hull of both 2-D and 3-D point sets. You can reuse the seamount dataset to illustrate the computation of the 3-D convex hull. In this instance, include the seamount z-coordinate data elevations:

```
close(gcf)
K = convhull(x,y,z);
```

In 3-D the boundary of the convex hull, K , is represented by a triangulation. This is a set of triangular facets in face-vertex format that is indexed with respect to the point array. Each row of the matrix K represents a triangle. See "Triangulation Face-Vertex Format" on page 6-5 for a more detailed description of this data structure.

Since the boundary of the convex hull is represented as a triangulation, you can use the triangulation plotting function trisurf.

```
trisurf(K,x,y,z, 'Facecolor','cyan'); axis equal;
```

## Convex Hull of the seamount Data Set

The volume bounded by the 3-D convex hull can optionally be returned by convhull, the syntax is as follows:
[K V] = convhull(x,y,z);

The convhull function also provides the option of simplifying the representation of the convex hull by removing vertices that do not contribute to the area or volume. For example, if boundary facets of the convex hull are collinear or coplanar, you can merge them to give a more concise representation. The following example illustrates use of this option:

```
[x,y,z] = meshgrid(-2:1:2, -2:1:2, -2:1:2);
x = x(:); y = y(:); z = z(:);
K1 = convhull(x,y,z);
subplot(1,2,1);
defaultFaceColor = [0.6875 0.8750 0.8984];
trisurf(K1,x,y,z, 'Facecolor', defaultFaceColor); axis equal;
title(sprintf('Convex hull with simplify\nset to false'));
K2 = convhull(x,y,z, 'simplify',true);
subplot(1,2,2);
trisurf(K2,x,y,z, 'Facecolor', defaultFaceColor); axis equal;
title(sprintf('Convex hull with simplify\nset to true'));
```

MATLAB provides the convhulln function to support the computation of convex hulls and hypervolumes in higher dimensions. Though convhulln supports N-D, problems in more than 10 dimensions present challenges due to the rapidly growing memory requirements.

Tip The convhull function is superior to convhulln in 2-D and 3-D as it is more robust and gives better performance.

## Convex Hull Computation Using the DelaunayTri Class

The DelaunayTri class supports computation of Delaunay triangulations in 2 -D and 3-D space. This class also provides a convexHull method to derive the convex hull from the triangulation. The following example illustrates the relationship between a Delaunay triangulation of a set of points in 2-D and the convex hull of that set of points:

```
X = [-1.5 3.2; 1.8 3.3; -3.7 1.5; -1.5 1.3; 0.8 1.2; ...
    3.3 1.5; -4.0-1.0; -2.3 -0.7; 0 -0.5; 2.0 -1.5; ...
    3.7 -0.8; -3.5 -2.9; -0.9 -3.9; 2.0 -3.5; 3.5 -2.25]
dt = DelaunayTri(X)
triplot(dt)
```

Highlighting the edges that are shared only by a single triangle reveals the convex hull:

```
fe = freeBoundary(dt)';
hold on; plot(X(fe,1), X(fe,2), '-r', 'LineWidth',2); hold off;
```

## Computing the Convex Hull from a Delaunay Triangulation

In 3-D, the facets of the triangulation that are shared only by one tetrahedron represent the boundary of the convex hull.

The dedicated convhull function is generally more efficient than a computation based on the DelaunayTri.convexHull method. However, the triangulation based approach is appropriate if:

- You have a DelaunayTri of the point set already and the convex hull is also required
- You need to add or remove points from the set incrementally and need to recompute the convex hull frequently after you have edited the points.

For more information on editing a DelaunayTri to add/remove points, refer to the section "Delaunay Triangulation Using the DelaunayTri Class" on page 6-25.

## Interpolation

- "Interpolating Structured Data" on page 7-3
- "Interpolating Scattered Data" on page 7-12

Interpolation is a method for estimating the value at a query location that lies within the domain of a set of sample data points. A sample data set defined by locations X and corresponding values V can be interpolated to produce a function of the form $V=F(X)$. This function can then be used to evaluate a query point $X q$, to give $V q=F(X q)$. This is a single-valued function; for any query $X q$ within the domain of $X$ it will produce a unique value Vq. The sample data is assumed to respect this property in order to produce a satisfactory interpolation. One other interesting characteristic is that the interpolating function passes through the data points. This is an important distinction between interpolation and curve/surface fitting. In fitting, the function does not necessarily pass through the sample data points.

The computation of the value Vq is generally based on the data points in the neighborhood of the query point Xq. There are numerous approaches to performing interpolation. In MATLAB interpolation is classified into two categories depending on the structure of the sample data. The sample data may be ordered in a Cartesian axis-aligned grid or they may be scattered. In the case of a gridded distribution of sample points, you can leverage the organized structure of the data to efficiently find the sample points in the neighborhood of the query. Interpolation of scattered data on the other hand requires a triangulation of the data points, and this introduces an additional level of computation.

The two approaches to interpolation are covered in the following sections:

- The "Interpolating Structured Data" on page 7-3 section covers 1-D interpolation, and the $\mathrm{N}-\mathrm{D}(\mathrm{N} \geq 2)$ interpolation of sample data in Cartesian axis-aligned grid format

- The "Interpolating Scattered Data" on page 7-12 section covers the N-D (N $\geq 2$ ) interpolation of scattered data

## Interpolating Structured Data

In this section...<br>"One-Dimensional Data" on page 7-3<br>"Two-Dimensional Data" on page 7-5<br>"Multidimensional Data" on page 7-8

## One-Dimensional Data

- "Polynomial Interpolation" on page 7-3
- "FFT-Based Interpolation" on page 7-4

## Polynomial Interpolation

The function interp1 performs one-dimensional interpolation. This function uses polynomial techniques, fitting the supplied data with polynomial functions between data points and evaluating the appropriate function at the desired interpolation points. Its most general form is

```
yi = interp1(x,y,xi,method)
```

$y$ is a vector containing the values of a function, and $x$ is a vector of the same length containing the points for which the values in $y$ are given. xi is a vector containing the points at which to interpolate. method is an optional string specifying an interpolation method:

- Nearest neighbor interpolation (method = 'nearest'). This method sets the value of an interpolated point to the value of the nearest existing data point.
- Linear interpolation (method = 'linear'). This method fits a different linear function between each pair of existing data points, and returns the value of the relevant function at the points specified by xi. This is the default method for the interp1 function.
- Cubic spline interpolation (method = 'spline'). This method fits a different cubic function between each pair of existing data points, and uses the spline function to perform cubic spline interpolation at the data points.
- Cubic interpolation (method = 'pchip' or 'cubic'). These methods are identical. They use the pchip function to perform piecewise cubic Hermite interpolation within the vectors $x$ and $y$. These methods preserve monotonicity and the shape of the data.

If any element of $x i$ is outside the interval spanned by $x$, the specified interpolation method is used for extrapolation. Alternatively, yi = interp1(x,Y,xi,method,extrapval) replaces extrapolated values with extrapval. NaN is often used for extrapval.

All methods work with nonuniformly spaced data.
Speed, Memory, and Smoothness Considerations. When choosing an interpolation method, keep in mind that some require more memory or longer computation time than others. However, you may need to trade off these resources to achieve the desired smoothness in the result:

- Nearest neighbor interpolation is the fastest method. However, it provides the worst results in terms of smoothness.
- Linear interpolation uses more memory than the nearest neighbor method, and requires slightly more execution time. Unlike nearest neighbor interpolation its results are continuous, but the slope changes at the vertex points.
- Cubic spline interpolation has the longest relative execution time, although it requires less memory than cubic interpolation. It produces the smoothest results of all the interpolation methods. You may obtain unexpected results, however, if your input data is nonuniform and some points are much closer together than others.
- Cubic interpolation requires more memory and execution time than either the nearest neighbor or linear methods. However, both the interpolated data and its derivative are continuous.

## FFT-Based Interpolation

The function interpft performs one-dimensional interpolation using an FFT-based method. This method calculates the Fourier transform of a vector that contains the values of a periodic function. It then calculates the inverse Fourier transform using more points. Its form is

$$
\mathrm{y}=\text { interpft }(\mathrm{x}, \mathrm{n})
$$

$x$ is a vector containing the values of a periodic function, sampled at equally spaced points. $n$ is the number of equally spaced points to return.

## Two-Dimensional Data

- "Two-Dimensional Methods" on page 7-5
- "A Comparison of Methods" on page 7-6

## Two-Dimensional Methods

The function interp2 performs two-dimensional interpolation, an important operation for image processing and data visualization. Its most general form is

$$
Z I=\text { interp2(X,Y,Z,XI, YI, method) }
$$

$Z$ is a rectangular array containing the values of a two-dimensional function, and $X$ and $Y$ are arrays of the same size containing the points for which the values in $Z$ are given. XI and YI are matrices containing the points at which to interpolate the data. method is an optional string specifying an interpolation method.

There are three different interpolation methods for two-dimensional data:

- Nearest neighbor interpolation (method = 'nearest'). This method fits a piecewise constant surface through the data values. The value of an interpolated point is the value of the nearest point.
- Bilinear interpolation (method = 'linear'). This method fits a bilinear surface through existing data points. The value of an interpolated point is a combination of the values of the four closest points. This method is piecewise bilinear, and is faster and less memory-intensive than bicubic interpolation.
- Bicubic interpolation (method $=$ 'cubic'). This method fits a bicubic surface through existing data points. The value of an interpolated point is a combination of the values of the sixteen closest points. This method is piecewise bicubic, and produces a much smoother surface than bilinear interpolation. This can be a key advantage for applications like image
processing. Use bicubic interpolation when the interpolated data and its derivative must be continuous.

All of these methods require that $X$ and $Y$ be monotonic, that is, either always increasing or always decreasing from point to point. You should prepare these matrices using the meshgrid function, or else be sure that the "pattern" of the points emulates the output of meshgrid. In addition, each method automatically maps the input to an equally spaced domain before interpolating. If $X$ and $Y$ are already equally spaced, you can speed execution time by prepending an asterisk to the method string, for example, '*cubic '.

## A Comparison of Methods

This example compares two-dimensional interpolation methods on a 7-by-7 matrix of data:

1 Generate the peaks function at low resolution:

$$
\begin{aligned}
& {[x, y]=\text { meshgrid }(-3: 1: 3) ;} \\
& z=\operatorname{peaks}(x, y) ; \\
& \operatorname{surf}(x, y, z)
\end{aligned}
$$

2 Generate a finer mesh for interpolation:
[xi,yi] = meshgrid(-3:0.25:3);

3 Interpolate using nearest neighbor interpolation:
zi1 = interp2(x,y,z,xi,yi,'nearest');

4 Interpolate using bilinear interpolation:

```
zi2 = interp2(x,y,z,xi,yi,'bilinear');
```

5 Interpolate using bicubic interpolation:
zi3 = interp2(x,y,z,xi,yi,'bicubic');

6 Compare the surface plots for the different interpolation methods.

7 Compare the contour plots for the different interpolation methods.

contour(xi,yi,zi1)
\% nearest

contour(xi,yi,zi2)
\% bilinear

contour(xi,yi,zi3) \% bicubic

Notice that the bicubic method, in particular, produces smoother contours. This is not always the primary concern, however. For some applications, such as medical image processing, a method like nearest neighbor may be preferred because it doesn't generate any "new" data values.

## Multidimensional Data

- "Function Summary" on page 7-8
- "Interpolation of Three-Dimensional Data" on page 7-8
- "Interpolation of Higher Dimensional Data" on page 7-9
- "Multidimensional Data Gridding" on page 7-10

## Function Summary

The following table lists functions that operate specifically on multidimensional data.

Interpolation Functions for Multidimensional Data

| Function | Description |
| :--- | :--- |
| interp3 | Three-dimensional data interpolation |
| interpn | Multidimensional data interpolation |
| ndgrid | Multidimensional data gridding (elmat directory) |

## Interpolation of Three-Dimensional Data

The function interp3 performs three-dimensional interpolation, finding interpolated values between points of a three-dimensional set of samples V . You must specify a set of known data points:

- $X, Y$, and $Z$ matrices specify the points for which values of $V$ are given.
- A matrix V contains values corresponding to the points in $\mathrm{X}, \mathrm{Y}$, and Z .

The most general form for interp3 is
VI = interp3(X,Y,Z,V,XI,YI,ZI, method)

XI, YI, and ZI are the points at which interp3 interpolates values of V. For out-of-range values, interp3 returns NaN.

There are three different interpolation methods for three-dimensional data:

- Nearest neighbor interpolation (method = 'nearest'). This method chooses the value of the nearest point.
- Trilinear interpolation (method = 'linear'). This method uses piecewise linear interpolation based on the values of the nearest eight points.
- Tricubic interpolation (method = 'cubic'). This method uses piecewise cubic interpolation based on the values of the nearest sixty-four points.

All of these methods require that $X, Y$, and $Z$ be monotonic, that is, either always increasing or always decreasing in a particular direction. In addition, you should prepare these matrices using the meshgrid function, or else be sure that the "pattern" of the points emulates the output of meshgrid.

Each method automatically maps the input to an equally spaced domain before interpolating. If $x$ is already equally spaced, you can speed execution time by prepending an asterisk to the method string, for example, '*cubic'.

## Interpolation of Higher Dimensional Data

The function interpn performs multidimensional interpolation, finding interpolated values between points of a multidimensional set of samples V. The most general form for interpn is

$$
V I=\text { interpn(X1,X2,X3...,V,Y1,Y2,Y3, ..., method })
$$

$1,2,3, \ldots$ are matrices that specify the points for which values of $V$ are given. V is a matrix that contains the values corresponding to these points. $1,2,3, \ldots$ are the points for which interpn returns interpolated values of V. For out-of-range values, interpn returns NaN.

Y1, Y2, Y3, ... must be either arrays of the same size, or vectors. If they are vectors of different sizes, interpn passes them to ndgrid and then uses the resulting arrays.

There are three different interpolation methods for multidimensional data:

- Nearest neighbor interpolation (method = 'nearest'). This method chooses the value of the nearest point.
- Linear interpolation (method = 'linear'). This method uses piecewise linear interpolation based on the values of the nearest two points in each dimension.
- Cubic interpolation (method = 'cubic'). This method uses piecewise cubic interpolation based on the values of the nearest four points in each dimension.

All of these methods require that $\mathrm{X} 1, \mathrm{X} 2, \mathrm{X} 3$ be monotonic. In addition, you should prepare these matrices using the ndgrid function, or else be sure that the "pattern" of the points emulates the output of ndgrid.

Each method automatically maps the input to an equally spaced domain before interpolating. If $X$ is already equally spaced, you can speed execution time by prepending an asterisk to the method string; for example, '*cubic '.

## Multidimensional Data Gridding

The ndgrid function generates arrays of data for multidimensional function evaluation and interpolation. ndgrid transforms the domain specified by a series of input vectors into a series of output arrays. The ith dimension of these output arrays are copies of the elements of input vector $\mathrm{x}_{\mathrm{i}}$.

The syntax for ndgrid is

$$
[\mathrm{X} 1, \mathrm{X} 2, \mathrm{X} 3, \ldots]=\operatorname{ndgrid}(\mathrm{x} 1, \mathrm{x} 2, \mathrm{x} 3, \ldots)
$$

For example, assume that you want to evaluate a function of three variables over a given range. Consider the function

$$
z=x_{2} e^{\left(-x_{1}^{2}-x_{2}^{2}-x_{3}^{2}\right)}
$$

for $-2 \pi \leq x_{1} \leq 0,2 \pi \leq x_{2} \leq 4 \pi$, and $0 \leq x_{3} \leq 2 \pi$. To evaluate and plot this function,

$$
x 1=-2: 0.2: 2 ;
$$

```
    x2 = -2:0.25:2;
    x3 = -2:0.16:2;
    [X1,X2,X3] = ndgrid(x1,x2,x3);
    z = X2.*exp(-X1.^2 - X2.^2 -X3.^2);
    slice(X2,X1,X3,z,[-1.2 0.8 2],2,[-2 0.2])
```

## Interpolating Scattered Data

## In this section...

"Scattered Data" on page 7-12
"Interpolating Scattered Data Using griddata and griddatan" on page 7-15
"Interpolating Scattered Data Using the TriScatteredInterp Class" on page 7-19
"Addressing Problems in Scattered Data Interpolation" on page 7-32

## Scattered Data

Scattered data consists of a set of points X and corresponding values V , where the points have no structure or order between their relative locations. There are various approaches to interpolating scattered data. One widely used approach uses a Delaunay triangulation of the points. You can construct an interpolating surface by triangulating the points and lifting the vertices by a magnitude V into a dimension orthogonal to X .

The following example illustrates this process. There are variations on how you can apply this approach. In this example, the interpolation is broken down into separate steps; typically, the overall interpolation process is accomplished with one function call.

1 Create a scattered data set on the surface of a paraboloid:

```
X = [-1.5 3.2; 1.8 3.3; -3.7 1.5; -1.5 1.3; ...
    0.8 1.2; 3.3 1.5; -4.0 -1.0; -2.3 -0.7;
    0 -0.5; 2.0 -1.5; 3.7 -0.8; -3.5 -2.9; ...
    -0.9 -3.9; 2.0 -3.5; 3.5 -2.25];
V = X(:,1).^2 + X(:,2).^2;
hold on
plot3(X(:, 1),X(:, 2),zeros(15,1), '*r')
axis([-4, 4, -4, 4, 0, 25]);
grid
stem3(X(:,1),X(:, 2),V,'^','fill')
hold off
view(322.5, 30);
```

2 Create a Delaunay triangulation and lift the vertices:
figure('Color', 'white')
$\mathrm{t}=$ delaunay $(\mathrm{X}(:, 1), \mathrm{X}(:, 2))$;
hold on
trimesh(t,X(:,1),X(:,2), zeros(15,1), ...
'EdgeColor', 'r', 'FaceColor', 'none')
defaultFaceColor $=$ [0.6875 0.8750 0.8984];
trisurf(t, X(:,1),X(:,2), V, 'FaceColor', ...
defaultFaceColor, 'FaceAlpha', 0.9);
plot3(X(:,1), X(: , 2), zeros (15,1), '*r')
axis([-4, 4, -4, 4, 0, 25]);
grid
plot3(-2.6,-2.6,0, '*b', 'LineWidth', 1.6)
plot3([-2.6-2.6]',[-2.6-2.6]',[0 13.52]','-b','LineWidth', 1.6)
hold off

```
view(322.5, 30);
text(-2.0, -2.6, 'Xq', 'FontWeight', 'bold', ...
    'HorizontalAlignment','center', 'BackgroundColor', 'none');
```

3 Evaluate the interpolant at the query point Xq :

This step generally involves traversing of the triangulation data structure to find the triangle that encloses the query point. Once you find the point, the subsequent steps to compute the value depend on the interpolation method. You could compute the nearest point in the neighborhood and use the value at that point (the nearest-neighbor interpolation method). You could also compute the weighted sum of values of the three vertices of the enclosing triangle (the linear interpolation method). These methods and their variants are covered in texts and references on scattered data interpolation.

Though the illustration highlights 2-D interpolation, you can apply this technique to higher dimensions. In more general terms, given a set of points $X$ and corresponding values V , you can construct an interpolant of the form $\mathrm{V}=$ $F(X)$. You can evaluate the interpolant at a query point $X q$, to give $V q=F(X q)$. This is a single-valued function; for any query point $X q$ within the convex hull of $X$ it will produce a unique value Vq . The sample data is assumed to respect this property in order to produce a satisfactory interpolation.

MATLAB provides two ways to perform triangulation-based scattered data interpolation:

- The functions griddata and griddatan
- The TriScatteredInterp class

The griddata function supports N-D scattered data interpolation. The griddatan function supports scattered data interpolation in N-D; however, it is not practical in dimensions higher than 6-D for moderate to large point sets, due to the exponential growth in memory required by the underlying triangulation.

The TriScatteredInterp class supports scattered data interpolation in 2-D and 3-D space. Use of this class is encouraged as it is more efficient and readily adapts to a wider range of interpolation problems. In addition, the calling syntax is more intuitive.

## Interpolating Scattered Data Using griddata and griddatan

The griddata and griddatan functions take a set of sample points X , corresponding values V , and query points Xq and return the interpolated values Vq . The calling syntax is similar for each function; the distinction is the 2-D griddata function lets you define the points in terms of $\mathrm{X}, \mathrm{Y}$ coordinates. These two functions interpolate scattered data at predefined grid-point locations; the intent is to produce gridded data, hence the name. Interpolation is more general in practice. You might want to query at arbitrary locations within the convex hull of the points.

The following example demonstrates how the griddata function interpolates scattered data at a set of grid points and uses this gridded data to create a
contour plot. The example uses the seamount data set (a seamount is an underwater mountain). The data set consists of a set of longitude (x) and latitude (y) locations, and corresponding seamount elevations ( $z$ ) measured at those coordinates.

1 Plot the data set:

```
load seamount
plot3(x,y,z,'.','markersize',12)
xlabel('Longitude'), ylabel('Latitude'), zlabel('Depth in Feet')
grid on
```

2 Use meshgrid to create a set of 2-D grid points in the longitude-latitude plane and then use griddata to interpolate the corresponding depth at those points:
figure
[xi, yi] = meshgrid(210.8:0.01:211.8, -48.5:0.01:-47.9);

```
zi = griddata(x,y,z, xi,yi);
surf(xi,yi,zi);
xlabel('Longitude'), ylabel('Latitude'), zlabel('Depth in Feet')
```

3 Now that the data is in a gridded format you can compute and plot the the contours:
figure
[ch] = contour(xi,yi,zi, 'b-');
clabel(c,h);
xlabel('Longitude'), ylabel('Latitude')

You can also use griddata to interpolate at arbitrary locations within the convex hull of the dataset. For example, the depth at coordinates (211.3, -48.2) is given by:

```
zi = griddata(x,y,z, 211.3, -48.2);
```

The underlying triangulation is computed each time the griddata function is called. This can impact performance if the same data set is interpolated repeatedly with different query points. The TriScatteredInterp class described in "Interpolating Scattered Data Using the TriScatteredInterp Class" on page 7-19 is more efficient in this respect.

MATLAB software also provides griddatan to support interpolation in higher dimensions. The calling syntax is similar to griddata.

The griddata function supports the following interpolation methods:

- 'nearest' - Nearest-neighbor interpolation, where the interpolating surface is discontinuous.
- 'linear' - Linear interpolation (default), where the interpolating surface is C 0 continuous.
- 'cubic' - Cubic interpolation, where the interpolating surface is C2 continuous.

The griddatan function supports the following interpolation methods:

- 'nearest' - Nearest-neighbor interpolation, where the interpolating surface is discontinuous, and
- 'linear' - Linear interpolation (default), where the interpolating surface is C0 continuous.

The 'nearest'and 'linear' methods are computationally more efficient than the 'cubic' method. The 'cubic' method is generally used when higher order continuity of the interpolating function is required. However, ' cubic' is not supported by the higher dimensional griddatan function.

## Interpolating Scattered Data Using the TriScatteredInterp Class

The griddata function is useful when you need to interpolate to find the values at a set of predefined grid-point locations. In practice, interpolation problems are often more general, and the TriScatteredInterp class provides greater flexibility. The class has the following advantages:

- It produces an interpolating function that can be queried efficiently. That is, the underlying triangulation is created once and reused for subsequent queries.
- The interpolation method can be changed independently of the triangulation.
- The values at the data points can be changed independently of the triangulation.
- Data points can be incrementally added to the existing interpolant without triggering a complete recomputation. Data points can also be removed and
moved efficiently, provided the number of points edited is small relative to the total number of sample points.
- It supports natural-neighbor interpolation (which is an improvement over linear interpolation) and works well with larger data sets that have uneven sampling.

TriScatteredInterp provides the following interpolation methods:

- 'nearest' - Nearest-neighbor interpolation, where the interpolating surface is discontinuous.
- 'linear' - Linear interpolation (default), where the interpolating surface is C 0 continuous.
- 'natural' - Natural-neighbor interpolation, where the interpolating surface is C 1 continuous except at the sample points.

The TriScatteredInterp class supports scattered data interpolation in 2-D and 3-D space. You can create the interpolant by calling the TriScatteredInterp constructor and passing the point locations and corresponding values, and optionally the interpolation method. The point locations can be expressed in terms of individual coordinate vectors ( $x, y$ ), ( $x, y$, $z$ ), or as an $m$-by- $n$ matrix $X$, where $m$ is the number of points and $n$ the number of dimensions (2 or 3). Typical calling syntaxes have the following forms.
$1 \mathrm{x}, \mathrm{y}$, and v are Mx 1 vectors, where M is the number of sample points. This creates a 2-D interpolant.
F = TriScatteredInterp(x,y,v)
$2 \mathrm{x}, \mathrm{y}, \mathrm{z}$, and vare Mx1 vectors. This creates a 3-D interpolant

```
F = TriScatteredInterp(x,y,z,v)
```

3 X is a Mx 2 or Mx 3 matrix, where M is the number of sample points. This creates a 2-D or 3-D interpolant respectively.
F = TriScatteredInterp(X,V)

4 You can also specify an interpolation method when constructing the interpolant. This example specifies natural-neighbor interpolation.

```
F = TriScatteredInterp(x,y,v, `natural')
```

You can also construct a TriScatteredInterp from a DelaunayTri triangulation. This method provides more control over the interpolating triangulation. This approach is useful for querying the triangulation with a view to adjusting data, removing outliers, or diagnosing anomalies in the interpolation. See "Addressing Problems in Scattered Data Interpolation" on page 7-32 for further information.

The TriScatteredInterp interpolant is evaluated the same way as evaluating a function.

For example, you can evaluate a 2-D interpolant at the query locations defined by $\mathrm{Xq}, \mathrm{Yq}$. You return the computed values in Vq :

$$
V q=F(X q, Y q) ;
$$

Similarly, you can express the query points as an M-by-2 matrix Xq and return the computed values in Vq :

$$
\mathrm{Vq}=\mathrm{F}(\mathrm{Xq}) ;
$$

You can evaluate a 3-D interpolant at the query locations defined by $\mathrm{Xq}, \mathrm{Yq}$, Zq,:

$$
V q=F(X q, \quad Y q, Z q)
$$

Similarly, you can express the query points as an M-by-3 matrix Xq and return the computed values in Vq :

$$
V q=F(X q) ;
$$

Refer to the function reference pages for further information on the constructor and calling syntax for TriScatteredInterp.

Using TriScatteredInterp features is best demonstrated with this example, which uses the gallery and peaks functions to generate a scattered data set.

1 Create the scattered data set:

```
X = -3 + 6.*gallery('uniformdata',[250 2],0);
V = peaks(X(:,1),X(:,2));
```

2 Create the interpolant:

```
F = TriScatteredInterp(X,V)
```

When MATLAB creates the TriScatteredInterp, it outputs the following:

```
F =
    TriScatteredInterp
```

        Properties:
            X: [250x2 double]
            V: [250x1 double]
            Method: 'linear'
    The $X$ property represents the coordinates of the data points and the $V$ property represents the associated values. The Method property represents the interpolation method that performs the interpolation. Get help by clicking the TriScatteredInterp or typinghelp TriScatteredInterp.

You can access the properties the same way as for a Struct:

| F.X | \% Gives us the point locations |
| :--- | :--- |
| F.V | \% Gives the accompanying values |
| F.Method | \% Gives the interpolation method |

3 Evaluate the interpolant.
TriScatteredInterp provides subscripted evaluation of the interpolant. It is evaluated the same way as a function. You can evaluate the interpolant as follows. In this case, the value at the query location is given by Vq. You can evaluate at a single query point:

```
Vq = F([1.5 1.25])
Vq =
```

1.3966

You can also pass individual coordinates:

$$
V q=F(1.5,1.25)
$$

$$
\mathrm{Vq}=
$$

1.3966

You can evaluate at a vector of point locations:

```
Xq = [0.5 0.25; 0.75 0.35; 1.25 0.85]
Vq = F(Xq) % Or, you could call with F(Xq(:,1), Xq(:,2))
Vq =
    1.0880
    1.8127
    2.3472
```

You can evaluate at grid-point locations followed by a plot:

```
[Xq Yq] = meshgrid(-2.5:0.125:2.5);
Vq = F(Xq, Yq);
surf(Xq, Yq, Vq);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Value - V', 'fontweight','b')
title('Linear Interpolation Method', 'fontweight','b')
```

## Linear Interpolation Method

4 Changing the interpolation method
You can change the interpolation method on the fly. Set the method to 'nearest':

```
F.Method = 'nearest';
```

Reevaluate and plot the interpolant as before:
$V q=F(X q, Y q) ;$
figure
surf(Xq, Yq, Vq);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Value - V', 'fontweight','b')
title('Nearest neighbor Interpolation Method','fontweight','b');

Switch the method to natural neighbor, reevaluate, and plot:

Natural neighbor Interpolation Method

5 Change the values at the sample data locations.
You can change the values $V$ at the sample data locations $X$ on the fly. This has useful applications in practice. Suppose you want to interpolate a 3-D velocity field that is defined by locations ( $x, y, z$ ) and corresponding componentized velocity vectors (Vxq, Vyq, Vzq). You can interpolate the velocity components at a query location by setting the value property to each component in turn and evaluating.

The following steps show how to change the values in our example. You will compute the values using the expression $v=x .{ }^{*} \exp \left(-x .^{\wedge} 2-y .^{\wedge} 2\right)$.

```
V = X(:,1).*exp(-X(:,1).^2-X(:,2).^2);
F.V = V;
```

Evaluate the interpolant and plot the result:

```
Vq=F(Xq, Yq);
figure
surf(Xq, Yq, Vq);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Value - V', 'fontweight','b')
```

## Natural neighbor interpolation of $\mathbf{v}=\mathbf{x} .{ }^{*} \exp \left(-x . \wedge^{\wedge} \mathbf{2 - y .}{ }^{\wedge} \mathbf{2}\right)$

6 Add additional point locations and values to the existing interpolant. This performs an efficient update as opposed to a complete recomputation using the augmented data set.

Tip When adding sample data, it is important to add both the point locations and the corresponding values.

Continuing the example, create new sample points as follows:

$$
x=-1.5+3 . * \operatorname{rand}(100,2) ;
$$

```
V = X(:,1).*exp(-X(:,1).^2-X(:,2).^2);
```

Add the new points and corresponding values to the triangulation:

```
F.X(end+(1:100),:) = X;
F.V(end+(1:100)) = V;
```

Evaluate the refined interpolant and plot the result:

```
Vq = F(Xq, Yq);
figure
surf(Xq, Yq, Vq);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Value - V', 'fontweight','b')
```

7 Incrementally remove sample data points from the interpolant. You can also remove data points and corresponding values from the interpolant. This is useful for removing spurious outliers.

Tip When removing sample data it is important to remove both the point location and the corresponding value.

Remove the 25th point:

$$
\begin{aligned}
& F . X(25,:)=[] ; \\
& F . V(25)=[] ;
\end{aligned}
$$

Remove points 5 to 15 :

```
F.X(5:15,:) = [];
F.V(5:15) = [];
```

Retain 150 points and remove the rest:

```
F.X(150:end,:) = [];
F.V(150:end) = [];
```

This creates a coarser surface when you evaluate and plot:

```
Vq = F(Xq, Yq);
figure
surf(Xq, Yq, Vq);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Value - V', 'fontweight','b')
```

Interpolation of $\mathbf{v}=\mathbf{x} .{ }^{*} \exp \left(-x .{ }^{\wedge} \mathbf{2}-\mathbf{y} .{ }^{\wedge} \mathbf{2}\right)$ with sample points removed
8 Interpolate complex-valued data.
In some applications you need to interpolate scattered data where the value at each sample location is a complex value. You can do this in two passes. You interpolate over the real component in the first pass, then switch the value to the imaginary component and interpolate the imaginary data in the second pass. The following example illustrates the technique.

Create the sample data:

```
X = -3 + 6.*gallery('uniformdata',[250 2],0);
V = complex(X(:,1).*X(:,2), X(:,1).^2 + X(:,2).^2);
```

Interpolate the real component in the first pass:

```
F = TriScatteredInterp(X, real(V));
```

Evaluate at the grid-point locations and then plot:

```
[Xq Yq] = meshgrid(-2.5:0.125:2.5);
VqReal = F(Xq, Yq);
figure
surf(Xq, Yq, VqReal);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Real Value - V', 'fontweight','b')
title('Interpolation of Real Component', 'fontweight','b')
```

Interpolation of Real Component

Set the value of the interpolant to the imaginary component:
F.V = imag(V) ;

Interpolate and plot the imaginary component:

```
VqImag = F(Xq, Yq);
figure
surf(Xq, Yq, VqImag);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
```

```
zlabel('Imaginary Value - V', 'fontweight','b')
title('Interpolation of Complex Component', 'fontweight','b')
```

The complete result at $\mathrm{Xq}, \mathrm{Yq}$ is:

```
Vq = complex(VqReal, VqImag);
```

## Addressing Problems in Scattered Data Interpolation

Many of the illustrative examples in the previous sections dealt with the interpolation of point sets that were sampled on smooth surfaces. In addition, the points were relatively uniformly spaced. For example, clusters of points were not separated by relatively large distances. In addition, the interpolant was evaluated well within the convex hull of the point locations.

When dealing with real-world interpolation problems the data may be more challenging. It may come from measuring equipment that is likely to produce inaccurate readings or outliers. The underlying data may not vary smoothly,
the values may jump abruptly from point to point. This section provides you with some guidelines to identify and address problems with scattered data interpolation.

## Input Data Containing NaNs

You should preprocess sample data that contains NaN values to remove the NaN values as this data cannot contribute to the interpolation. If a NaN is removed, the corresponding data values/coordinates should also be removed to ensure consistency. If NaN values are present in the sample data, the constructor will error when called.

The following example illustrates how to remove NaNs.
Create some data and replace some entries with NaN:

```
x = rand(25,1)*4-2;
y = rand (25,1)*4-2;
V = x.^2 + y.^2;
x(5) = NaN; x(10) = NaN; y(12) = NaN; V(14) = NaN;
```

This code errors:

```
F = TriScatteredInterp(x,y,V)
```

Instead, find the sample point indices of the NaNs and then construct the interpolant:

```
nan_flags = isnan(x) | isnan(y) | isnan(V);
x(nan_flags) = [];
y(nan_flags) = [];
V(nan_flags) = [];
F = TriScatteredInterp(x,y,V)
```

The following example is similar if the point locations are in matrix form. First, create data and replace some entries with NaNs:

```
X = rand(25,2)*4-2;
V = X(:,1).^2 + X(:,2).^2;
```

$$
X(5,1)=\operatorname{NaN} ; X(10,1)=\operatorname{NaN} ; X(12,2)=\mathrm{NaN} ; V(14)=\mathrm{NaN} \text {; }
$$

This code errors:
F = TriScatteredInterp(X,V)

Find the sample point indices of the NaN and then construct the interpolant:

```
nan_flags = isnan(X(:,1)) | isnan(X(:,2)) | isnan(V);
X(nan_flags,:) = [];
V(nan_flags) = [];
F = TriScatteredInterp(X,V)
```

## Interpolant Outputs NaN Values

The linear and natural-neighbor interpolation methods produce an interpolant that is valid within the convex hull of the point locations. The 'nearest' method does not have a restricted domain as a nearest neighbor to a query point always exists. An interpolant that uses the 'linear' or 'natural' method will return NaN values when evaluated at a query point outside the convex hull. These methods do not perform extrapolation outside of the convex hull of the point locations. However, you can identify such points and assign a value or reevaluate the interpolant using the 'nearest' method to get a representative value at that location. The following example demonstrates this approach.

Create some sample data that lies on the surface of a paraboloid:

```
x = rand(100,1)*6-3;
y = rand(100,1)*6-3;
V = x.^2 + y.^2;
```

The sample point locations are in the range $-2 \leq(x, y) \leq 2$. You can compute and plot the convex hull to get a clearer picture of the supported domain for 'linear' and 'natural' interpolation.

```
plot(x,y, '.');
k = convhull(x,y)
```

```
hold on, plot(x(k), y(k), '-r'), hold off
```

You can now construct the interpolant and use it to evaluate a grid. Choose a grid that extends beyond the convex hull to observe the behavior.

```
F = TriScatteredInterp(x,y,V)
[Xq, Yq] = meshgrid(-3.5:.25:3.5, -3.5:.25:3.5);
Vq = F(Xq, Yq);
figure
mesh(Xq, Yq, Vq);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Value - V', 'fontweight','b')
title('Linear Interpolation', 'fontweight','b');
```

Plot Shows Linear Interpolation Within the Convex Hull

Check for NaN output values using the following call reveals numerous NaNs:

```
any(isnan(Vq))
% Use linear indexing to find the indices of the query
% points that produce NaN values when interpolated
nanidx = find(isnan(Vq));
```

Use nearest-neighbor interpolation to replace these NaN values with the value at the nearest sample point:

```
F.Method = 'nearest'
Vq(nanidx) = F(Xq(nanidx), Yq(nanidx));
figure
mesh(Xq, Yq, Vq);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Value - V', 'fontweight','b')
```

## Linear Interpolation with Nearest Neighbor Extrapolation

You could also assign your own chosen extrapolation value as follows:

```
Vq(nanidx) = 15;
figure
mesh(Xq, Yq, Vq);
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Value - V', 'fontweight','b')
```

## Linear Interpolation with Predefined Extrapolation Value

## Handling of Duplicate Point Locations

Input data is rarely "perfect" and your application may produce data points that have coincident locations. In this scenario, TriScatteredInterp will merge the points and compute the average of the corresponding values. The following example illustrates the behavior.

Create some sample data that lies on the surface of a paraboloid:

```
x = rand(100,1)*6-3;
y = rand(100,1)*6-3;
V = x + y;
```

Introduce a duplicate point location:

```
x(50) = x(100);
y(50) = y(100);
```

Create the interpolation:

```
F = TriScatteredInterp(x,y,V)
F.V(50)
(V(50)+V(100))/2
```

In this scenario the interpolant resolves the ambiguity in a reasonable manner. However, in some instances data points may be close rather than coincident, and the values at those locations may be very different.

## Interpolation Results Poor Near the Convex Hull

The Delaunay triangulation is well suited to scattered data interpolation problems because it has favorable geometric properties that produce good results. Namely the rejection of sliver-shaped triangles/tetrahedra in favor of more equilateral-shaped ones, and the empty circumcircle property that implicitly defines a nearest-neighbor relation between the points. This latter property ensures the interpolated values are influenced by sample points in the neighborhood of the query location. Despite these qualities, in some situations the distribution of the data points may lead to poor results and this typically happens near the convex hull of the sample data set. When the interpolation produces unexpected results, a plot of the sample data and underlying triangulation can often provide insight into the problem. The following example illustrates such behavior.

Create a sample data set that will exhibit problems near the boundary :

```
t = 0.4*pi:0.02:0.6*pi;
x1 = cos(t)';
y1 = sin(t)'-1.02;
x2 = x1;
y2 = y1*(-1);
x3 = linspace(-0.3,0.3,16)';
y3 = zeros(16,1);
x = [x1;x2;x3];
y = [y1;y2;y3];
```

Now lift these sample points onto the surface $z=x . \wedge^{\wedge} 2+y . \wedge 2$ and interpolate the surface.

```
z = x.^2 + y.^2;
F = TriScatteredInterp(x,y,z);
[xi,yi] = meshgrid(-0.3:.02:0.3, -0.0688:0.01:0.0688);
zi = F(xi,yi);
mesh(xi,yi,zi)
xlabel('X', 'fontweight','b'), ylabel('Y','fontweight','b')
zlabel('Value - V', 'fontweight','b')
title('Interpolated surface', 'fontweight','b');
Interpolated surface
```

The actual surface is:

```
zi = xi.^2 + yi.^2;
figure
mesh(xi,yi,zi)
```

To understand why the interpolating surface deteriorates near the boundary, it is helpful to look at the underlying triangulation:

```
dt = DelaunayTri(x,y);
figure('Color', 'white')
plot(x,y, '*r')
axis equal
hold on
triplot(dt)
plot(x1,y1,'-r')
plot(x2,y2,'-r')
hold off
```

Triangulation Used to Create the Interpolant

The triangles within the red boundaries are relatively well shaped; they are constructed from points that are in close proximity and the interpolation to works well in this region. Outside the red boundary, the triangles are sliver-like and connect points that are remote from each other. There is not sufficient sampling to accurately capture the surface, so it is not surprising that the results in these regions are poor. In 3-D, visual inspection of the triangulation gets a bit trickier, but looking at the point distribution can often help illustrate potential problems.

## Optimization

- "Function Summary" on page 8-2

- "Reference" on page 8-29

## Function Summary

The following table lists the MATLAB optimization functions.

| Function | Description |
| :--- | :--- |
| fminbnd | Minimize a function of one variable on a fixed <br> interval |
| fminsearch | Minimize a function of several variables |
| fzero | Find zero of a function of one variable |
| lsqnonneg | Linear least squares with nonnegativity <br> constraints |
| optimget | Get optimization options structure parameter <br> values |
| optimset | Create or edit optimization options parameter <br> structure |

To maximize a function, see "Maximizing Functions" on page 8-7. For information on solving single-variable nonlinear equations, see "Roots of Scalar Functions" on page 5-6.

For more optimization capabilities, see the Optimization Toolbox ${ }^{\text {TM }}$ User's Guide.

## Optimizing Nonlinear Functions

In this section...
"Minimizing Functions of One Variable" on page 8-3
"Minimizing Functions of Several Variables" on page 8-5
"fminsearch Algorithm" on page 8-5
"Maximizing Functions" on page 8-7

## Minimizing Functions of One Variable

Given a mathematical function of a single variable, you can use the fminbnd function to find a local minimizer of the function in a given interval. For example, consider the humps.m function, which is provided with MATLAB. The following figure shows the graph of humps.

To find a minimum of the humps function in the range $(0.3,1)$, use

```
x = fminbnd(@humps,0.3,1)
```

which returns

$$
x=0.6370
$$

You can ask for a tabular display of output by passing a fourth argument created by the optimset command to fminbnd

```
x = fminbnd(@humps,0.3,1,optimset('Display','iter'))
```

which gives the output

| Func-count | $x$ | $f(x)$ | Procedure |
| :---: | ---: | :--- | :--- |
| 3 | 0.567376 | 12.9098 | initial |
| 4 | 0.732624 | 13.7746 | golden |
| 5 | 0.465248 | 25.1714 | golden |
| 6 | 0.644416 | 11.2693 | parabolic |
| 7 | 0.6413 | 11.2583 | parabolic |
| 8 | 0.637618 | 11.2529 | parabolic |
| 9 | 0.636985 | 11.2528 | parabolic |
| 10 | 0.637019 | 11.2528 | parabolic |
| 11 | 0.637052 | 11.2528 | parabolic |

Optimization terminated: the current $x$ satisfies the termination criteria using OPTIONS.TolX of $1.000000 \mathrm{e}-004$

```
x =
```

0.6370

This shows the current value of $x$ and the function value at $f(x)$ each time a function evaluation occurs. For fminbnd, one function evaluation corresponds to one iteration of the algorithm. The last column shows what procedure is being used at each iteration, either a golden section search or a parabolic interpolation. For more information, see "Iterative Display" on page 8-14.

## Minimizing Functions of Several Variables

The fminsearch function is similar to fminbnd except that it handles functions of many variables, and you specify a starting vector $x_{0}$ rather than a starting interval. fminsearch attempts to return a vector $x$ that is a local minimizer of the mathematical function near this starting vector.

To try fminsearch, create a function three_var of three variables, $x, y$, and $z$.

```
function b = three_var(v)
x = v(1);
y = v(2);
z = v(3);
b = x.^2 + 2.5*sin(y) - z^2*x^2*y^2;
```

Now find a minimum for this function using $x=-0.6, y=-1.2$, and $z=0.135$ as the starting values.

```
v = [-0.6 -1.2 0.135];
a = fminsearch(@three_var,v)
a =
    0.0000 -1.5708 0.1803
```

## fminsearch Algorithm

fminsearch uses the Nelder-Mead simplex algorithm as described in Lagarias et al. [1]. This algorithm uses a simplex of $n+1$ points for $n$-dimensional vectors $x$. The algorithm first makes a simplex around the initial guess $x_{0}$ by adding $5 \%$ of each component $x_{0}(i)$ to $x_{0}$, and using these $n$ vectors as elements of the simplex in addition to $x_{0}$. (It uses 0.00025 as component $i$ if $x_{0}(i)=0$.) Then, the algorithm modifies the simplex repeatedly according to the following procedure.

Note The keywords for the fminsearch iterative display appear in bold after the description of the step.

1 Let $x(i)$ denote the list of points in the current simplex, $i=1, \ldots, n+1$.

2 Order the points in the simplex from lowest function value $f(x(1))$ to highest $f(x(n+1))$. At each step in the iteration, the algorithm discards the current worst point $x(n+1)$, and accepts another point into the simplex. [Or, in the case of step 7 below, it changes all $n$ points with values above $f(x(1))]$.

3 Generate the reflected point

$$
r=2 m-x(n+1)
$$

where

$$
m=\Sigma x(i) / n, i=1 \ldots n,
$$

and calculate $f(r)$.
4 If $f(x(1)) \leq f(r)<f(x(n))$, accept $r$ and terminate this iteration. Reflect
5 If $f(r)<f(x(1))$, calculate the expansion point $s$

$$
s=m+2(m-x(n+1)),
$$

and calculate $f(s)$.
a If $f(s)<f(r)$, accept $s$ and terminate the iteration. Expand
b Otherwise, accept $r$ and terminate the iteration. Reflect
6 If $f(r) \geq f(x(n)$ ), perform a contraction between $m$ and the better of $x(n+1)$ and $r$ :
a If $f(r)<f(x(n+1))$ (i.e., $r$ is better than $x(n+1)$ ), calculate

$$
c=m+(r-m) / 2
$$

and calculate $f(c)$. If $f(c)<f(r)$, accept $c$ and terminate the iteration. Contract outside Otherwise, continue with Step 7 (Shrink).
b If $f(r) \geq f(x(n+1))$, calculate

$$
c c=m+(x(n+1)-m) / 2
$$

and calculate $f(c c)$. If $f(c c)<f(x(n+1))$, accept $c c$ and terminate the iteration. Contract inside Otherwise, continue with Step 7 (Shrink).

7 Calculate the $n$ points

$$
v(i)=x(1)+(x(i)-x(1)) / 2
$$

and calculate $f(v(i)), i=2, \ldots, n+1$. The simplex at the next iteration is $x(1)$, $v(2), \ldots, v(n+1)$. Shrink

The following figure shows the points that fminsearch might calculate in the procedure, along with each possible new simplex. The original simplex has a bold outline. The iterations proceed until they meet a stopping criterion.

## Maximizing Functions

The fminbnd and fminsearch solvers attempt to minimize an objective function. If you have a maximization problem, that is, a problem of the form

$$
\max _{x} f(x),
$$

then define $g(x)=-f(x)$, and minimize $g$.
For example, to find the maximum of $\tan (\cos (x))$ near $x=5$, evaluate:

$$
[x \text { fval] }=\text { fminbnd }(@(x)-\tan (\cos (x)), 3,8)
$$

```
x =
    6.2832
fval =
    -1.5574
```

The maximum is 1.5574 (the negative of the reported fval), and occurs at $x=6.2832$. This answer is correct since, to five digits, the maximum is $\tan (1)=1.5574$, which occurs at $x=2 \pi=6.2832$.

## Example: Curve Fitting via Optimization

In this section...<br>"Curve Fitting by Optimization" on page 8-9<br>"Creating an Example File" on page 8-9<br>"Running the Example" on page 8-10<br>"Plotting the Results" on page 8-10

## Curve Fitting by Optimization

This section gives an example that shows how to fit an exponential function of the form $A e^{-\lambda t}$ to some data. The example uses the fminsearch solver to minimize the sum of squares of errors between the data and an exponential function $A e^{-\lambda t}$ for varying parameters $A$ and $\lambda$.

## Creating an Example File

To run the example, first create a file that:

- Accepts vectors corresponding to the $x$ - and $y$-coordinates of the data
- Returns the parameters of the exponential function that best fits the data

To do so, copy and paste the following code into a file and save it as fitcurvedemo in a directory on the MATLAB path.

```
function [estimates, model] = fitcurvedemo(xdata, ydata)
% Call fminsearch with a random starting point.
start_point = rand(1, 2);
model = @expfun;
estimates = fminsearch(model, start_point);
% expfun accepts curve parameters as inputs, and outputs sse,
% the sum of squares error for A*exp(-lambda*xdata)-ydata,
% and the FittedCurve. FMINSEARCH only needs sse, but we want
% to plot the FittedCurve at the end.
    function [sse, FittedCurve] = expfun(params)
            A = params(1);
            lambda = params(2);
```

```
    FittedCurve = A .* exp(-lambda * xdata);
    ErrorVector = FittedCurve - ydata;
    sse = sum(ErrorVector .^ 2);
    end
end
```

The file calls the function fminsearch, which finds parameters A and lambda that minimize the sum of squares of the differences between the data and the exponential function $A^{*} \exp (-1$ ambda*t). The nested function expfun computes the sum of squares.

## Running the Example

To run the example, first create some random data to fit. The following commands create random data that is approximately exponential with parameters $\mathrm{A}=40$ and lambda $=.5$.

```
xdata = (0:.1:10)';
ydata = 40 * exp(-.5 * xdata) + randn(size(xdata));
```

To fit an exponential function to the data, enter

```
[estimates, model] = fitcurvedemo(xdata,ydata)
```

This returns estimates for the parameters A and lambda,

```
estimates =
```

$$
40.1334 \quad 0.5025
$$

and a function handle, model, to the function that computes the exponential function $A * \exp (-1$ ambda*t).

## Plotting the Results

To plot the fit and the data, enter the following commands.

```
plot(xdata, ydata, '*')
hold on
[sse, FittedCurve] = model(estimates);
plot(xdata, FittedCurve, 'r')
```

```
xlabel('xdata')
ylabel('f(estimates,xdata)')
title(['Fitting to function ', func2str(model)]);
legend('data', ['fit using ', func2str(model)])
hold off
```

The resulting plot displays the data points and the exponential fit.

## Setting Options

You can specify control options that set some minimization parameters using an options structure that you create using the optimset function. You then pass options as an input to the optimization function, for example, by calling fminbnd with the syntax

$$
x=\text { fminbnd(fun }, x 1, x 2, \text { options) }
$$

or fminsearch with the syntax

```
x = fminsearch(fun, x0,options)
```

For example, to display output from the algorithm at each iteration, set the Display option to 'iter':

```
options = optimset('Display','iter');
```

| Option | Description | Solvers |
| :--- | :--- | :--- |
| Display | A flag indicating whether intermediate <br> steps appear on the screen. | fminbnd, <br> fminsearch, <br> fzero, |
|  | - 'notify' (default) displays output <br> only if the function does not converge. <br> - 'iter' displays intermediate steps <br> (not available with" lsqnonneg). See <br> "Iterative Display" on page 8-14. | - 'off' displays no intermediate steps. <br> - 'final' displays just the final output. |
| FunValCheck | Check whether objective function and <br> constraints values are valid. 'on' <br> displays an error when the objective <br> function or constraints return a value <br> that is complex or NaN. The default <br> 'off' displays no error. | fminbnd, <br> fminsearch, <br> fzero |

| Option | Description | Solvers |
| :---: | :---: | :---: |
| MaxFunEvals | The maximum number of function evaluations allowed. The default value is 500 for fminbnd and 200*length (x0) for fminsearch. | fminbnd, fminsearch |
| MaxIter | Maximum number of iterations allowed. The default value is 500 for fminbnd and 200*length (x0) for fminsearch. | fminbnd, fminsearch |
| OutputFen | Display information on the iterations of the solver. The default is [] (none). For details, see "Output Functions" on page 8-16. | fminbnd, <br> fminsearch, fzero |
| PlotFcns | Plot information on the iterations of the solver. The default is [ ] (none). For available predefined functions, see "Plot Functions" on page 8-24. | fminbnd, fminsearch, fzero |
| TolFun | The termination tolerance for the function value. The default value is 1.e-4. | fminsearch |
| TolX | The termination tolerance for $x$. The default value is 1.e-4. | fminbnd, <br> fminsearch, <br> fzero, <br> lsqnonneg |

The output structure includes the number of function evaluations, the number of iterations, and the algorithm. The structure appears when you provide fminbnd or fminsearch with a fourth output argument, as in
[x,fval,exitflag,output] = fminbnd(@humps, 0.3,1);
or
[x,fval,exitflag,output] = fminsearch(@three_var, v);

## Iterative Display

You obtain details of the steps solvers take by setting the Display option to 'iter' with optimset. The displayed output contains headings and items from the following list.

| Heading | Information Displayed | Solvers |
| :--- | :--- | :--- |
| Iteration | Iteration number, meaning the number <br> of steps the algorithm has taken | fminsearch |
| Func-count | Cumulative number of function <br> evaluations | fminbnd, <br> fminsearch, <br> fzero |
| $x$ | Current point | fminbnd, fzero |
| $f(x)$ | Current objective function value | fminbnd, fzero |
| min f(x) | Smallest objective function value found | fminsearch |
| Procedure | Algorithm used during the iteration |  |
|  | - initial | fminbnd |
|  | - initial simplex <br> - expand <br> - reflect <br> - shrink <br> - contract inside <br> - contract outside | fminsearch |
|  | For details, see "fminsearch Algorithm" <br> on page 8-5. |  |
| - initial (initial point) |  |  |
| - search (search for an interval |  |  |
| containing a zero) |  |  |
| - bisection |  |  |

| Heading | Information Displayed | Solvers |
| :--- | :--- | :--- |
|  - interpolation (linear interpolation <br> or inverse quadratic interpolation) <br> a, f(a), b, <br> $f(b)$ Search points and their function values <br> while looking for an interval with <br> function values of opposite signs | fzero |  |

## Output Functions

```
In this section...
"What Is an Output Function?" on page 8-16
"Creating and Using an Output Function" on page 8-16
"Structure of the Output Function" on page 8-18
"Example of a Nested Output Function" on page 8-19
"Fields in optimValues" on page 8-21
"States of the Algorithm" on page 8-21
"Stop Flag" on page 8-22
```

## What Is an Output Function?

An output function is a function that an optimization function calls at each iteration of its algorithm. Typically, you might use an output function to generate graphical output, record the history of the data the algorithm generates, or halt the algorithm based on the data at the current iteration. You can create an output function as a function file, a subfunction, or a nested function.

You can use the OutputFen option with the following MATLAB optimization functions:

- fminbnd
- fminsearch
- fzero

## Creating and Using an Output Function

The following is a simple example of an output function that plots the points generated by an optimization function.

```
function stop = outfun(x, optimValues, state)
stop = false;
hold on;
plot(x(1),x(2),'.');
```

You can use this output function to plot the points generated by fminsearch in solving the optimization problem

$$
\min _{x} f(x)=\min _{x} e^{x_{1}}\left(4 x_{1}^{2}+2 x_{2}^{2}+4 x_{1} x_{2}+2 x_{2}+1\right) .
$$

To do so,
1 Create a file containing the preceding code and save it as outfun.m in a directory on the MATLAB path.

2 Enter the command

```
options = optimset('OutputFcn', @outfun);
```

to set the value of the Outputfen field of the options structure to a function handle to outfun.

3 Enter the following commands:

```
hold on
objfun=@(x) exp(x(1))*(4*x(1)^2+2*x(2)^2+x(1)*x(2)+2*x(2));
[x fval] = fminsearch(objfun, [-1 1], options)
hold off
```

This returns the solution

```
x =
    0.1290 -0.5323
fval =
    -0.5689
```

and displays the following plot of the points generated by fminsearch:

## Structure of the Output Function

The function definition line of the output function has the following form:

```
stop = outfun(x, optimValues, state)
```

where

- stop is a flag that is true or false depending on whether the optimization routine should quit or continue. See "Stop Flag" on page 8-22.
- $x$ is the point computed by the algorithm at the current iteration.
- optimValues is a structure containing data from the current iteration. "Fields in optimValues" on page 8-21 describes the structure in detail.
- state is the current state of the algorithm. "States of the Algorithm" on page 8-21 lists the possible values.

The optimization function passes the values of the input arguments to outfun at each iteration.

## Example of a Nested Output Function

The example in "Creating and Using an Output Function" on page 8-16 does not require the output function to preserve data from one iteration to the next. When this is the case, you can write the output function as a function file and call the optimization function directly from the command line. However, if you want your output function to record data from one iteration to the next, you should write a single file that does the following:

- Contains the output function as a nested function-see "Nested Functions" in MATLAB Programming Fundamentals for more information.
- Calls the optimization function.

In the following example, the function file also contains the objective function as a subfunction, although you could also write the objective function as a separate file or as an anonymous function.

Since the nested function has access to variables in the file that contains it, this method enables the output function to preserve variables from one iteration to the next.

The following example uses an output function to record the points generated by fminsearch in solving the optimization problem

$$
\min _{x} f(x)=\min _{x} e^{x_{1}}\left(4 x_{1}^{2}+2 x_{2}^{2}+4 x_{1} x_{2}+2 x_{2}+1\right) .
$$

The output function returns the sequence of points as a matrix called history.
To run the example, do the following steps:
1 Open a new file in the MATLAB Editor.
2 Copy and paste the following code into the file.

```
function [x fval history] = myproblem(x0)
    history = [];
    options = optimset('OutputFcn', @myoutput);
    [x fval] = fminsearch(@objfun, x0,options);
```

```
    function stop = myoutput(x,optimvalues,state);
        stop = false;
        if state == 'iter'
            history = [history; x];
        end
    end
    function z = objfun(x)
        z = exp(x(1))*(4*x(1)^2+2*x(2)^2+x(1)*x(2)+2*x(2));
end
end
```

3 Save the file as myproblem.m in a directory on the MATLAB path.
4 At the MATLAB prompt, enter

```
[x fval history] = myproblem([-1 1])
```

The function fminsearch returns $x$, the optimal point, and fval, the value of the objective function at $x$.

```
x =
    0.1290 -0.5323
fval =
    -0.5689
```

In addition, the output function myoutput returns the matrix history, which contains the points generated by the algorithm at each iteration, to the MATLAB workspace. The first four rows of history are

```
history(1:4,:) =
\begin{tabular}{ll}
-1.0000 & 1.0000 \\
-1.0000 & 1.0000 \\
-1.0750 & 0.9000 \\
-1.0125 & 0.8500
\end{tabular}
```

The final row of points is the same as the optimal point, x .

```
history(end,:)
ans =
    0.1290 -0.5323
objfun(history(end,:))
ans =
    -0.5689
```

## Fields in optimValues

The following table lists the fields of the optimValues structure that are provided by all three optimization functions, fminbnd, fminsearch, and fzero.

The "Command-Line Display Headings" column of the table lists the headings, corresponding to the optimValues fields that are displayed at the command line when you set the Display parameter of options to 'iter'.

| optimValues Field <br> (optimValues.field) | Description | Command-Line <br> Display Heading |
| :--- | :--- | :--- |
| funcCount | Cumulative number of <br> function evaluations | Func-count |
| fval | Function value at <br> current point | min $\mathrm{f}(\mathrm{x})$ |
| iteration | Iteration number - <br> starts at 0 | Iteration |
| procedure | Procedure messages | Procedure |

## States of the Algorithm

The following table lists the possible values for state:

| State | Description |
| :--- | :--- |
| 'init' | The algorithm is in the initial state before the <br> first iteration. |
| 'interrupt' | The algorithm is performing an iteration. In <br> this state, the output function can interrupt <br> the current iteration of the optimization. You <br> might want the output function to do this to <br> improve the efficiency of the computations. <br> When state is set to 'interrupt ', the values <br> of x and optimValues are the same as at the <br> last call to the output function, in which state <br> is set to 'iter'. |
| 'iter' | The algorithm is at the end of an iteration. |
| 'done' | The algorithm is in the final state after the <br> last iteration. |

The following code illustrates how the output function might use the value of state to decide which tasks to perform at the current iteration.

```
switch state
    case 'init'
        % Setup for plots or guis
    case 'iter'
        % Make updates to plot or guis as needed.
    case 'interrupt'
        % Check conditions to see whether optimization
        % should quit.
        case 'done'
        % Cleanup of plots, guis, or final plot
otherwise
end
```

## Stop Flag

The output argument stop is a flag that is true or false. The flag tells the optimization function whether the optimization should quit or continue. The following examples show typical ways to use the stop flag.

## Stopping an Optimization Based on Data in optimValues

The output function can stop an optimization at any iteration based on the current data in optimValues. For example, the following code sets stop to true if the objective function value is less than 5:

```
function stop = myoutput(x, optimValues, state)
stop = false;
% Check if objective function is less than 5.
if optimValues.fval < 5
    stop = true;
end
```

## Stopping an Optimization Based on GUI Input

If you design a GUI to perform optimizations, you can make the output function stop an optimization when a user clicks a Stop button on the GUI. The following code shows how to do this, assuming that the Stop button callback stores the value true in the optimstop field of a handles structure called hObject stored in appdata.

```
function stop = myoutput(x, optimValues, state)
stop = false;
% Check if user has requested to stop the optimization.
stop = getappdata(hObject,'optimstop');
```

## Plot Functions

In this section...<br>"What Is A Plot Function?" on page 8-24<br>"Example: Plot Function" on page 8-25

## What Is A Plot Function?

The PlotFcns field of the options structure specifies one or more functions that an optimization function calls at each iteration to plot various measures of progress while the algorithm executes. Pass a function handle or cell array of function handles. The structure of a plot function is the same as the structure of an output function. For more information on this structure, see "Output Functions" on page 8-16.

You can use the PlotFcns option with the following MATLAB optimization functions:

- fminbnd
- fminsearch
- fzero

The predefined plot functions for these optimization functions are:

- @optimplotx plots the current point
- @optimplotfval plots the function value
- @optimplotfunccount plots the function count (not available for fzero)

To view or modify a predefined plot function, open the function file in the MATLAB Editor. For example, to view the function file for plotting the current point, enter:

```
edit optimplotx.m
```

## Example: Plot Function

View the progress of a minimization using fminsearch with the plot function @optimplotfval:

1 Write a file for the objective function. For this example, use:

```
function f = onehump(x)
r = x(1)^2 + x(2)^2;
s = exp(-r);
f = x(1)*s+r/20;
```

2 Set the options to use the plot function:

```
options = optimset('PlotFcns',@optimplotfval);
```

3 Call fminsearch starting from [2,1]:

```
[x ffinal] = fminsearch(@onehump,[2,1],options)
```

4 MATLAB returns the following:

```
X =
    -0.6691 0.0000
ffinal =
    -0.4052
```

## Troubleshooting and Tips

Here is a list of typical problems and recommendations for dealing with them.

| Problem | Recommendation |
| :--- | :--- |
| The solution found by fminbnd or <br> fminsearch does not appear to be a <br> global minimum. | There is no guarantee that you have a global minimum <br> unless your problem is continuous and has only one <br> minimum. Starting the optimization from a number <br> of different starting points (or intervals in the case of <br> fminbnd) may help to locate the global minimum or <br> verify that there is only one minimum. Use different <br> methods, where possible, to verify results. |
| Sometimes an optimization problem <br> has values of x for which it is impossible <br> to evaluate f. | Modify your function to include a penalty function to <br> give a large positive value to f when infeasibility is <br> encountered. |
| The minimization routine appears <br> to enter an infinite loop or returns a <br> solution that is not a minimum (or not <br> a zero in the case of fzero). | Your objective function (fun) may be returning NaN <br> or complex values. The optimization routines expect <br> only real numbers to be returned. Any other values <br> may cause unexpected results. To determine whether <br> this is the case, set |
| options = optimset ( ' FunValCheck' , 'on ') |  |

Optimization problems may take many iterations to converge. Most optimization problems benefit from good starting guesses. Providing good starting guesses improves the execution efficiency and may help locate the global minimum instead of a local minimum.

Sophisticated problems are best solved by an evolutionary approach, whereby a problem with a smaller number of independent variables is solved first. Solutions from lower order problems can generally be used as starting points for higher order problems by using an appropriate mapping.

The use of simpler cost functions and less stringent termination criteria in the early stages of an optimization problem can also reduce computation time. Such an approach often produces superior results by avoiding local minima.

## Function Handles

- "Introduction" on page 9-2
- "Defining Functions In Files" on page 9-3
- "Anonymous Functions" on page 9-4
- "Example: Function Plotting Function" on page 9-5
- "Parameterizing Functions" on page 9-8

## Introduction

MATLAB functions are written to named files or are produced at the command line as anonymous functions. In either case, a function handle is used to pass the function as an input argument to a function function.

## Defining Functions In Files

Consider the example function:

$$
f(x)=\frac{1}{(x-0.3)^{2}+0.01}+\frac{1}{(x-0.9)^{2}+0.04}-6 .
$$

A file for the function is humps.m. Its contents look like this:

```
function y = humps(x)
y = 1./((x - 0.3).^2 + 0.01) ...
    + 1./((x - 0.9).^2 + 0.04) - 6;
```

To evaluate humps at 2.0 , first use @ to obtain a function handle. Use the function handle in the same way you would use a function name to call a function:

```
fh = @humps;
fh(2.0)
ans =
    -4.8552
```

## Anonymous Functions

Consider again the example function:

$$
f(x)=\frac{1}{(x-0.3)^{2}+0.01}+\frac{1}{(x-0.9)^{2}+0.04}-6 .
$$

A second way to represent the function in the MATLAB is to create an anonymous function at the command line, as follows:

$$
\begin{aligned}
f h=@(x) & \left(1 . /\left((x-0.3) .^{\wedge} 2+0.01\right) \ldots\right. \\
& \left.+1 . /\left((x-0.9) .^{\wedge} 2+0.04\right)-6\right) ;
\end{aligned}
$$

You evaluate fh at 2.0 the same way you do with a function handle for a file-defined function:

```
fh(2.0)
ans =
    -4.8552
```

Anonymous functions can have any number of arguments. The following anonymous function has two input arguments $x$ and $y$ :

```
fh = @(x,y)(y*sin(x)+x*\operatorname{cos}(y));
fh(pi,2*pi)
ans =
    3.1416
```

## Example: Function Plotting Function

The fplot function plots a mathematical function between a given set of axes limits. You can control the $x$-axis limits only, or both the $x$ - and $y$-axis limits. For example, to plot the humps.m function over the $x$-axis range [-5 5], use

```
fplot(@humps,[-5 5])
```

grid on

You can zoom in on the function by selecting $y$-axis limits of -10 and 25, using

```
fplot(@humps,[-5 5 -10 25])
```

grid on

You can also pass the function handle for an anonymous function for fplot to graph, as in

$$
\text { fplot }\left(@(x) 2^{*} \sin (x+3),\left[\begin{array}{ll}
-1 & 1
\end{array}\right]\right) \text {; }
$$

You can plot more than one function on the same graph with one call to fplot. If you use this with a function, then the function must take a column vector $x$ and return a matrix where each column corresponds to each function, evaluated at each value of $x$.

If you pass an anonymous function consisting of several functions to fplot, the anonymous function also must return a matrix where each column corresponds to each function evaluated at each value of $x$, as in

```
fplot(@(x)[2*sin(x+3),humps(x)],[-5 5])
```

which plots the first and second functions on the same graph.

Note that the anonymous function

$$
f h=@(x)[2 * \sin (x+3), \operatorname{humps}(x)]
$$

evaluates to a matrix of two columns, one for each function, when $x$ is a column vector.

```
fh([1;2;3])
```

returns

$$
\begin{array}{ll}
-1.5136 & 16.0000 \\
-1.9178 & -4.8552 \\
-0.5588 & -5.6383
\end{array}
$$

## Parameterizing Functions

In this section...<br>"Using Nested Functions" on page 9-8<br>"Using Anonymous Functions" on page 9-9

## Using Nested Functions

One way to provide additional parameters to a functional argument of a function function is to write a file that

- Accepts the additional parameters as inputs
- Invokes the function function
- Contains the function called by the function function as a nested function

The following example illustrates how to find a zero of the cubic polynomial $x^{3}+b x+c$, for different values of the coefficients b and c , using this method. To do so, write a file with the following code:

```
function y = findzero(b, c, x0)
options = optimset('Display', 'off'); % Turn off Display
y = fzero(@poly, x0, options);
    function y = poly(x) % Compute the polynomial.
    y = x^3 + b*x + c;
    end
end
```

The main function, findzero, does two things:

- Invokes the function fzero to find a zero of the polynomial
- Computes the polynomial in a nested function, poly, which is called by fzero

You can call findzero with any values of the coefficients b and c, which are seen by poly because it is a nested function.

As an example, to find a zero of the polynomial with $\mathrm{b}=2$ and $\mathrm{c}=3.5$, using the starting point $x 0=0$, call findzero as follows.

```
x = findzero(2, 3.5, 0)
```

This returns the zero
$x=$
$-1.0945$

## Using Anonymous Functions

Suppose you have already written a standalone file for the function poly containing the following code, which computes the polynomial for any coefficients b and c ,

```
function y = poly(x, b, c) % Compute the polynomial.
y = x^3 + b*x + c;
```

You then want to find a zero for the coefficient values $b=2$ and $c=3.5$. You cannot simply apply fzero to poly, which has three input arguments, because fzero only accepts functions with a single input argument.

As an alternative to rewriting poly as a nested function (see "Using Nested Functions" on page 9-8) you can pass poly to fzero as a function handle to an anonymous function that has the form $@(x)$ poly ( $\mathrm{x}, \mathrm{b}, \mathrm{c}$ ). The function handle has just one input argument $x$, so fzero accepts it.

```
b = 2;
c = 3.5;
x = fzero(@(x) poly(x, b, c), 0)
```

This returns the zero
$x=$
$-1.0945$
"Anonymous Functions" on page 9-4 explains how to create anonymous functions.

If you later decide to find a zero for different values of $b$ and $c$, you must redefine the anonymous function using the new values. For example,

```
b = 4;
c = -1;
fzero(@(x) poly(x, b, c), 0)
ans =
0.2463
```

For more complicated objective functions, it is usually preferable to write the function as a nested function.

## Ordinary Differential Equations

In this section...<br>"Function Summary" on page 10-2<br>"Initial Value Problems" on page 10-4<br>"Types of Solvers" on page 10-6<br>"Solver Syntax" on page 10-8<br>"Integrator Options" on page 10-9<br>"Examples" on page 10-10<br>"Troubleshooting" on page 10-39

## Function Summary

- "ODE Solvers" on page 10-2
- "Evaluation and Extension" on page 10-3
- "Solver Options" on page 10-3
- "Output Functions" on page 10-4

## ODE Solvers

The following table lists the initial value problem solvers, the kind of problem you can solve with each solver, and the method each solver uses.

| Solver | Solves These Kinds of <br> Problems | Method |
| :--- | :--- | :--- |
| ode45 | Nonstiff differential <br> equations | Runge-Kutta |
| ode23 | Nonstiff differential <br> equations | Runge-Kutta |
| ode113 | Nonstiff differential <br> equations | Adams |

| Solver | Solves These Kinds of <br> Problems | Method |
| :--- | :--- | :--- |
| ode15s | Stiff differential equations <br> and DAEs | NDFs (BDFs) |
| ode23s | Stiff differential equations | Rosenbrock |
| ode23t | Moderately stiff <br> differential equations <br> and DAEs | Trapezoidal rule |
| ode23tb | Stiff differential equations | TR-BDF2 |
| ode15i | Fully implicit differential <br> equations | BDFs |

## Evaluation and Extension

You can use the following functions to evaluate and extend solutions to ODEs.

| Function | Description |
| :--- | :--- |
| deval | Evaluate the numerical solution using the output <br> of ODE solvers. |
| odextend | Extend the solution of an initial value problem for <br> an ODE |

## Solver Options

An options structure contains named properties whose values are passed to ODE solvers, and which affect problem solution. Use these functions to create, alter, or access an options structure.

| Function | Description |
| :--- | :--- |
| odeset | Create or alter options structure for input to <br> ODE solver. |
| odeget | Extract properties from options structure <br> created with odeset. |

## Output Functions

If an output function is specified, the solver calls the specified function after every successful integration step. You can use odeset to specify one of these sample functions as the OutputFen property, or you can modify them to create your own functions.

| Function | Description |
| :--- | :--- |
| odeplot | Time-series plot |
| odephas2 | Two-dimensional phase plane plot |
| odephas3 | Three-dimensional phase plane plot |
| odeprint | Print to command window |

## Initial Value Problems

- "First Order ODEs" on page 10-4
- "Higher Order ODEs" on page 10-5
- "Initial Values" on page 10-5

## First Order ODEs

An ordinary differential equation (ODE) contains one or more derivatives of a dependent variable $y$ with respect to a single independent variable $t$, usually referred to as time. The derivative of $y$ with respect to $t$ is denoted as $y^{\prime}$, the second derivative as $y^{\prime \prime}$, and so on. Often $y(t)$ is a vector, having elements $y_{1}, y_{2}, \ldots, y_{\mathrm{n}}$.

MATLAB solvers handle the following types of first-order ODEs:

- Explicit ODEs of the form $y^{\prime}=f(t, y)$
- Linearly implicit ODEs of the form $M(t, y) y^{\prime}=f(t, y)$, where $M(t, y)$ is a matrix
- Fully implicit ODEs of the form $f\left(t, y, y^{\prime}\right)=0$ (ode15i only)

## Higher Order ODEs

MATLAB ODE solvers accept only first-order differential equations. To use the solvers with higher-order ODEs, you must rewrite each equation as an equivalent system of first-order differential equations of the form

$$
y^{\prime}=f(t, y)
$$

You can write any ordinary differential equation

$$
y^{(n)}=f\left(t, y, y^{\prime}, \ldots, y^{(n-1)}\right)
$$

as a system of first-order equations by making the substitutions

$$
y_{1}=y, \quad y_{2}=y^{\prime}, \ldots, \quad y_{n}=y^{(n-1)}
$$

The result is an equivalent system of $n$ first-order ODEs.

$$
\begin{aligned}
y_{1}^{\prime} & =y_{2} \\
y_{2}^{\prime} & =y_{3} \\
& \vdots \\
y_{n}^{\prime} & =f\left(t, y_{1}, y_{2}, \ldots, y_{n}\right)
\end{aligned}
$$

Rewrite the second-order van der Pol equation

$$
y_{1}^{\prime \prime}-\mu\left(1-y_{1}^{2}\right) y_{1}^{\prime}+y_{1}=0
$$

as a system of first-order ODEs.

## Initial Values

Generally there are many functions $y(t)$ that satisfy a given ODE, and additional information is necessary to specify the solution of interest. In an initial value problem, the solution of interest satisfies a specific initial condition, that is, $y$ is equal to $y_{0}$ at a given initial time $t_{0}$. An initial value problem for an ODE is then

$$
\begin{aligned}
& y^{\prime}=f(t, y) \\
& y\left(t_{0}\right)=y_{0}
\end{aligned}
$$

If the function $f(t, y)$ is sufficiently smooth, this problem has one and only one solution. Generally there is no analytic expression for the solution, so it is necessary to approximate $y(t)$ by numerical means.

## Types of Solvers

- "Nonstiff Problems" on page 10-6
- "Stiff Problems" on page 10-7
- "Fully Implicit ODEs" on page 10-7

## Nonstiff Problems

There are three solvers designed for nonstiff problems:

| ode45 | Based on an explicit Runge-Kutta (4,5) formula, the <br> Dormand-Prince pair. It is a one-step solver - in <br> computing $y\left(t_{n}\right)$, it needs only the solution at the <br> immediately preceding time point, $y\left(t_{n-1}\right)$. In general, <br> ode45 is the best function to apply as a "first try" for <br> most problems. |
| :--- | :--- |
| ode23 |  |
| Based on an explicit Runge-Kutta (2,3) pair of Bogacki |  |
| and Shampine. It may be more efficient than ode45 at |  |
| crude tolerances and in the presence of mild stiffness. |  |
| Like ode45, ode23 is a one-step solver. |  |

## Stiff Problems

Not all difficult problems are stiff, but all stiff problems are difficult for solvers not specifically designed for them. Solvers for stiff problems can be used exactly like the other solvers. However, you can often significantly improve the efficiency of these solvers by providing them with additional information about the problem. (See "Integrator Options" on page 10-9.)

There are four solvers designed for stiff problems:

| ode15s | Variable-order solver based on the numerical <br> differentiation formulas (NDFs). Optionally it uses the <br> backward differentiation formulas, BDFs (also known <br> as Gear's method). Like ode113, ode15s is a multistep <br> solver. If you suspect that a problem is stiff or if ode45 <br> failed or was very inefficient, try ode15s. |
| :---: | :--- |
| ode23s | Based on a modified Rosenbrock formula of order 2. <br> Because it is a one-step solver, it may be more efficient <br> than ode15s at crude tolerances. It can solve some <br> kinds of stiff problems for which ode15s is not effective. |
| ode23t | An implementation of the trapezoidal rule using a <br> "free" interpolant. Use this solver if the problem is <br> only moderately stiff and you need a solution without <br> numerical damping. |
| ode23tb | An implementation of TR-BDF2, an implicit <br> Runge-Kutta formula with a first stage that is a <br> trapezoidal rule step and a second stage that is a <br> backward differentiation formula of order 2. Like <br> ode23s, this solver may be more efficient than ode15s <br> at crude tolerances. |

## Fully Implicit ODEs

The solver ode15i solves fully implicit differential equations of the form
$f\left(t, y, y^{\prime}\right)=0$
using the variable order BDF method. The basic syntax for ode15i is

```
[t,y] = ode15i(odefun,tspan,y0,yp0,options)
```

The input arguments are

| odefun | A function that evaluates the left side of the differential <br> equation of the form $f\left(t, y, y^{\prime}\right)=0$. |
| :--- | :--- |
| tspan | A vector specifying the interval of integration, [t0, tf ]. <br> To obtain solutions at specific times (all increasing or all <br> decreasing), use tspan $=[\mathrm{t} 0, \mathrm{t} 1, \ldots, \mathrm{tf}]$. |
| y0, yp0 | Vectors of initial conditions for $y\left(t_{0}\right)$ and $y^{\prime}\left(t_{0}\right)$, respectively. <br> The specified values must be consistent; that is, they must <br> satisfy $f(\mathrm{t} 0, \mathrm{y} 0, y p 0)=0$. |
| options | Optional integration argument created using the odeset <br> function. See the odeset reference page for details. |

The output arguments contain the solution approximated at discrete points:

$$
\begin{array}{ll}
\mathrm{t} & \text { Column vector of time points } \\
\mathrm{y} & \begin{array}{l}
\text { Solution array. Each row in } \mathrm{y} \text { corresponds to the solution at } \\
\text { a time returned in the corresponding row of } \mathrm{t} .
\end{array}
\end{array}
$$

See the ode15i reference page for more information about these arguments.

## Solver Syntax

All of the ODE solver functions, except for ode15i, share a syntax that makes it easy to try any of the different numerical methods, if it is not apparent which is the most appropriate. To apply a different method to the same problem, simply change the ODE solver function name. The simplest syntax, common to all the solver functions, is

$$
[t, y]=\text { solver(odefun,tspan, } \mathrm{y} 0 \text {,options) }
$$

where solver is one of the ODE solver functions listed previously.
The basic input arguments are

| odefun | Handle to a function that evaluates the system of |
| :---: | :---: |
|  | dydt = odefun(t,y) |
|  | where $t$ is a scalar, and dydt and $y$ are column vectors. See "Function Handles" in MATLAB Programming Fundamentals for more information. |
| tspan | Vector specifying the interval of integration. The solver imposes the initial conditions at tspan(1), and integrates from tspan(1) to tspan(end). |
| yo | Vector of initial conditions for the problem |
|  | See also "Initial Value Problems" on page 10-4. |
| options | Structure of optional parameters that change the default integration properties. |
|  | "Integrator Options" on page 10-9 tells you how to create the structure and describes the properties you can specify. |

The output arguments contain the solution approximated at discrete points:

| t | Column vector of time points |
| :--- | :--- |
| y | Solution array. Each row in y corresponds to the <br> solution at a time returned in the corresponding row <br> of t |

See the reference page for the ODE solvers for more information about these arguments.

## Integrator Options

The default integration properties in the ODE solvers are selected to handle common problems. In some cases, you can improve ODE solver performance by overriding these defaults. You do this by supplying the solvers with an options structure that specifies one or more property values.

For example, to change the value of the relative error tolerance of the solver from the default value of $1 \mathrm{e}-3$ to $1 \mathrm{e}-4$,

1 Create an options structure using the function odeset by entering

```
options = odeset('RelTol', 1e-4);
```

2 Pass the options structure to the solver as follows:

- For all solvers except ode15i, use the syntax

$$
[\mathrm{t}, \mathrm{y}]=\text { solver(odefun,tspan, } \mathrm{y} 0 \text {,options) }
$$

- For ode15i, use the syntax

$$
[t, y]=\text { ode15i(odefun,tspan, } \mathrm{y} 0, \mathrm{yp0} \text {,options) }
$$

For a complete description of the available options, see the reference page for odeset.

## van der Pol Equation (Nonstiff)

This example illustrates the steps for solving an initial value ODE problem:
1 Rewrite the problem as a system of first-order ODEs. Rewrite the van der Pol equation (second-order)

$$
y_{1}^{\prime \prime}-\mu\left(1-y_{1}^{2}\right) y_{1}^{\prime}+y_{1}=0
$$

where $\mu>0$ is a scalar parameter, by making the substitution $y^{\prime}{ }_{1}=y_{2}$. The resulting system of first-order ODEs is

$$
\begin{aligned}
& y_{1}^{\prime}=y_{2} \\
& y_{2}^{\prime}=\mu\left(1-y_{1}^{2}\right) y_{2}-y_{1}
\end{aligned}
$$

2 Code the system of first-order ODEs. Once you represent the equation as a system of first-order ODEs, you can code it as a function that an ODE solver can use. The function must be of the form

```
dydt = odefun(t,y)
```

Although t and y must be the function's two arguments, the function does not need to use them. The output dydt, a column vector, is the derivative of $y$.

The code below represents the van der Pol system in the function, vdp1. The vdp1 function assumes that $\mu=1$. The variables $y_{1}$ and $y_{2}$ are the entries $y(1)$ and $y(2)$ of a two-element vector.

```
function dydt = vdp1(t,y)
dydt = [y(2); (1-y(1)^2)*y(2)-y(1)];
```

Note that, although vdp1 must accept the arguments $t$ and $y$, it does not use $t$ in its computations.

3 Apply a solver to the problem.

Decide which solver you want to use to solve the problem. Then call the solver and pass it the function you created to describe the first-order system of ODEs, the time interval on which you want to solve the problem, and an initial condition vector.

For the van der Pol system, you can use ode45 on time interval [0 20] with initial values $\mathrm{y}(1)=2$ and $\mathrm{y}(2)=0$.

$$
[t, y]=\text { ode45(@vdp1,[0 20],[2; 0]); }
$$

This example uses @ to pass vdp1 as a function handle to ode45. The resulting output is a column vector of time points $t$ and a solution array $y$. Each row in y corresponds to a time returned in the corresponding row of t . The first column of y corresponds to $y_{1}$, and the second column to $y_{2}$.

Note For information on function handles, see the function_handle (@), func2str, and str2func reference pages, and the "Function Handles" section in MATLAB Programming Fundamentals.

4 View the solver output. You can simply use the plot command to view the solver output.

```
plot(t,y(:,1),'-',t,y(:,2),'--')
title('Solution of van der Pol Equation, \mu = 1');
xlabel('time t');
ylabel('solution y');
legend('y_1','y_2')
```

As an alternative, you can use a solver output function to process the output. The solver calls the function specified in the integration property OutputFen after each successful time step. Use odeset to set OutputFon to the desired function. See Solver Output Properties, in the reference page for odeset, for more information about OutputFcn.

## van der Pol Equation (Stiff)

This example presents a stiff problem. For a stiff problem, solutions can change on a time scale that is very short compared to the interval of integration, but the solution of interest changes on a much longer time scale. Methods not designed for stiff problems are ineffective on intervals where the solution changes slowly because they use time steps small enough to resolve the fastest possible change.

When $\mu$ is increased to 1000 , the solution to the van der Pol equation changes dramatically and exhibits oscillation on a much longer time scale. Approximating the solution of the initial value problem becomes a more difficult task. Because this particular problem is stiff, a solver intended for nonstiff problems, such as ode45, is too inefficient to be practical. A solver such as ode15s is intended for such stiff problems.

The vdp1000 function evaluates the van der Pol system from the previous example, but with $\mu=1000$.

```
function dydt = vdp1000(t,y)
dydt = [y(2); 1000*(1-y(1)^2)*y(2)-y(1)];
```

Note This example hardcodes $\mu$ in the ODE function. The vdpode example solves the same problem, but passes a user-specified $\mu$ as a parameter to the ODE function.

Now use the ode15s function to solve the problem with the initial condition vector of [2; 0], but a time interval of [0 3000]. For scaling reasons, plot just the first component of $y(t)$.

```
[t,y] = ode15s(@vdp1000,[0 3000],[2; 0]);
plot(t,y(:,1),'-');
title('Solution of van der Pol Equation, \mu = 1000');
xlabel('time t');
ylabel('solution y_1');
```

## van der Pol Equation (Parameterizing the ODE)

The preceding sections showed how to solve the van der Pol equation for two different values of the parameter $\mu$. In those examples, the values $\mu=1$ and $\mu=1000$ are hard-coded in the ODE functions. If you are solving an ODE for several different parameter values, it might be more convenient to include the parameter in the ODE function and assign a value to the parameter each time you run the ODE solver. This section explains how to do this for the van der Pol equation.

One way to provide parameter values to the ODE function is to write a MATLAB file that

- Accepts the parameters as inputs.
- Contains ODE function as a nested function, internally using the input parameters.
- Calls the ODE solver.

The following code illustrates this:

```
function [t,y] = solve_vdp(mu)
tspan = [0 max(20, 3*mu)];
y0 = [2; 0];
% Call the ODE solver ode15s.
[t,y] = ode15s(@vdp,tspan,y0);
    % Define the ODE function as nested function,
    % using the parameter mu.
    function dydt = vdp(t,y)
    dydt = [y(2); mu*(1-y(1)^2)*y(2)-y(1)];
    end
end
```

Because the ODE function vdp is a nested function, the value of the parameter mu is available to it.

To run the MATLAB file for $m u=1$, enter

```
[t,y] = solve_vdp(1);
```

To run the code for $\mu=1000$, enter

$$
[t, y]=\text { solve_vdp(1000); }
$$

See the vdpode code for a complete example based on these functions.

## van der Pol Equation (Evaluating the Solution)

The numerical methods implemented in the ODE solvers produce a continuous solution over the interval of integration $[a, b]$. You can evaluate the approximate solution, $S(x)$, at any point in $[a, b]$ using the function deval and the structure sol returned by the solver. For example, if you solve the problem described in "van der Pol Equation (Nonstiff)" on page 10-11 by calling ode45 with a single output argument sol,

```
sol = ode45(@vdp1,[0 20],[2; 0]);
```

ode45 returns the solution as a structure. You can then evaluate the approximate solution at points in the vector xint $=1: 5$ as follows:

```
xint = 1:5;
Sxint = deval(sol,xint)
Sxint =
```

| 1.5081 | 0.3235 | -1.8686 | -1.7407 | -0.8344 |
| ---: | ---: | ---: | ---: | ---: |
| -0.7803 | -1.8320 | -1.0220 | 0.6260 | 1.3095 |

The deval function is vectorized. For a vector xint, the ith column of Sxint approximates the solution $y$ (xint(i)).

## Euler Equations (Nonstiff)

rigidode illustrates the solution of a standard test problem proposed by Krogh for solvers intended for nonstiff problems [8].

The ODEs are the Euler equations of a rigid body without external forces.

$$
\begin{aligned}
& y_{1}^{\prime}=y_{2} y_{3} \\
& y_{2}^{\prime}=-y_{1} y_{3} \\
& y_{3}^{\prime}=-0.51 y_{1} y_{2}
\end{aligned}
$$

For your convenience, the entire problem is defined and solved in a single MATLAB file. The differential equations are coded as a subfunction $f$. Because the example calls the ode45 solver without output arguments, the solver uses the default output function odeplot to plot the solution components.

To run this example, click the example name, or type rigidode at the command line.

```
function rigidode
%RIGIDODE Euler equations: rigid body without external forces
tspan = [0 12];
y0 = [0; 1; 1];
% Solve the problem using ode45
ode45(@f,tspan,y0);
% ----------------------------------------------------------------
function dydt = f(t,y)
dydt = [ y(2)*y(3)
    -y(1)*y(3)
    -0.51*y(1)*y(2) ];
```

## Fully Implicit ODE

The following example shows how to use the function ode15i to solve the implicit ODE problem defined by Weissinger's equation

$$
t y^{2}\left(y^{\prime}\right)^{3}-y^{3}\left(y^{\prime}\right)^{2}+t\left(t^{2}+1\right) y^{\prime}-t^{2} y=0
$$

with the initial value $y(1)=\sqrt{3 / 2}$. The exact solution of the ODE is

$$
y(t)=\sqrt{t^{2}+0.5}
$$

The example uses the function weissinger, which is provided with MATLAB, to compute the left-hand side of the equation.

Before calling ode15i, the example uses a helper function decic to compute a consistent initial value for $y^{\prime}\left(t_{0}\right)$. In the following call, the given initial value $y(1)=\sqrt{3 / 2}$ is held fixed and a guess of 0 is specified for $y^{\prime}(1)$. See the reference page for decic for more information.

```
t0 = 1;
y0 = sqrt(3/2);
ypO = 0;
[y0,yp0] = decic(@weissinger,t0,y0,1,yp0,0);
```

You can now call ode15i to solve the ODE and then plot the numerical solution against the analytical solution with the following commands.

```
[t,y] = ode15i(@weissinger,[1 10],y0,yp0);
ytrue = sqrt(t.^2 + 0.5);
plot(t,y,t,ytrue,'o');
```

## Finite Element Discretization

fem1ode illustrates the solution of ODEs that result from a finite element discretization of a partial differential equation. The value of $N$ in the call fem1ode( $N$ ) controls the discretization, and the resulting system consists of $N$ equations. By default, $N$ is 19 .

This example involves a mass matrix. The system of ODEs comes from a method of lines solution of the partial differential equation

$$
e^{-t} \frac{\partial u}{\partial t}=\frac{\partial^{2} u}{\partial x^{2}}
$$

with initial condition $u(0, x)=\sin (x)$ and boundary conditions $u(t, 0)=u(t, \pi)=0$. An integer $N$ is chosen, $h$ is defined as $\pi /(N+1)$, and
the solution of the partial differential equation is approximated at $x_{k}=k h$ for $k=0,1, \ldots, N+1$ by

$$
u\left(t, x_{k}\right)=\sum_{k=1}^{N} c_{k}(t) \phi_{k}(x)
$$

Here $\phi_{k}(x)$ is a piecewise linear function that is 1 at $x_{k}$ and 0 at all the other ${ }^{x}{ }_{j}$. A Galerkin discretization leads to the system of ODEs

$$
M(t) c^{\prime}=J c \text { where } c(t)=\left[\begin{array}{l}
c_{1}(t) \\
c_{N}(t)
\end{array}\right]
$$

and the tridiagonal matrices $M(t)$ and $J$ are given by

$$
M_{i j}= \begin{cases}2 h / 3 \exp (-t) & \text { if } i=j \\ h / 6 \exp (-t) & \text { if } i=j \pm 1 \\ 0 & \text { otherwise }\end{cases}
$$

and

$$
J_{i j}= \begin{cases}-2 / h & \text { if } i=j \\ 1 / h & \text { if } i=j \pm 1 \\ 0 & \text { otherwise }\end{cases}
$$

The initial values $c(0)$ are taken from the initial condition for the partial differential equation. The problem is solved on the time interval $[0, \pi]$.

In the fem1ode example, the properties

```
options = odeset('Mass',@mass,'MStateDep','none','Jacobian',J)
```

indicate that the problem is of the form $M(t) y^{\prime}=J y$. The nested function mass ( t$)$ evaluates the time-dependent mass matrix $M(t)$ and $J$ is the constant Jacobian.

To run this example, click the example name, or type fem1ode at the command line. From the command line, you can specify a value of $N$ as an argument to fem1ode. The default is $N=19$.

```
function fem1ode(N)
%FEM10DE Stiff problem with a time-dependent mass matrix
if nargin < 1
    N = 19;
end
h = pi/(N+1);
y0 = sin(h*(1:N)');
tspan = [O; pi];
% The Jacobian is constant.
e = repmat(1/h,N,1); % e=[(1/h) ... (1/h)];
d = repmat(-2/h,N,1); % d=[(-2/h) ... (-2/h)];
% J is shared with the derivative function.
J = spdiags([e d e], -1:1, N, N);
d = repmat(h/6,N,1);
%M is shared with the mass matrix function.
M = spdiags([d 4*d d], -1:1, N, N);
options = odeset('Mass',@mass,'MStateDep','none', ...
    'Jacobian',J);
[t,y] = ode15s(@f,tspan,y0,options);
figure;
surf((1:N)/(N+1),t,y);
set(gca,'ZLim',[0 1]);
view(142.5,30);
title(['Finite element problem with time-dependent mass ' ...
    'matrix, solved by ODE15S']);
xlabel('space ( x/\pi )');
ylabel('time');
zlabel('solution');
%-----------------------------------------------------------------
function yp = f(t,y)
```

% Derivative function.
% Derivative function.
yp = J*y; % Constant Jacobian provided by outer function
yp = J*y; % Constant Jacobian provided by outer function
end % End nested function f
end % End nested function f
%-------------------
%-------------------
% Mass matrix function.
% Mass matrix function.
Mt = exp(-t)*M; % M is provided by outer function
Mt = exp(-t)*M; % M is provided by outer function
end % End nested function mass
end % End nested function mass
%-
%-
end
end

## Large Stiff Sparse Problem

brussode illustrates the solution of a potentially large stiff sparse problem. The problem is the classic "Brusselator" system [3] that models diffusion in a chemical reaction

$$
\begin{aligned}
& u_{i}^{\prime}=1+u_{i}^{2} v_{i}-4 u_{i}+\alpha(N+1)^{2}\left(u_{i-1}-2 u_{i}+u_{i+1}\right) \\
& v_{i}^{\prime}=3 u_{i}-u_{i}^{2} v_{i}+\alpha(N+1)^{2}\left(v_{i-1}-2 v_{i}+v_{i+1}\right)
\end{aligned}
$$

and is solved on the time interval $[0,10]$ with $\alpha=1 / 50$ and

$$
\left.\begin{array}{l}
u_{i}(0)=1+\sin \left(2 \pi x_{i}\right) \\
v_{i}(0)=3
\end{array}\right\} \quad \text { with } x_{i}=i /(N+1), \text { for } i=1, \ldots, N
$$

There are $2 N$ equations in the system, but the Jacobian is banded with a constant width 5 if the equations are ordered as ${ }^{u_{1}}, v_{1}, u_{2}, v_{2}, \ldots$

In the call brussode ( N ), where N corresponds to $N$, the parameter $\mathrm{N} \geq 2$ specifies the number of grid points. The resulting system consists of 2 N equations. By default, N is 20. The problem becomes increasingly stiff and the Jacobian increasingly sparse as $N$ increases.

The nested function $f(t, y)$ returns the derivatives vector for the Brusselator problem. The subfunction jpattern(N) returns a sparse matrix of 1 s and 0 s showing the locations of nonzeros in the Jacobian $\partial f / \partial y$. The example assigns this matrix to the property JPattern, and the solver uses the sparsity pattern to generate the Jacobian numerically as a sparse matrix. Providing a sparsity pattern can significantly reduce the number of function evaluations required to generate the Jacobian and can accelerate integration.

For the Brusselator problem, if the sparsity pattern is not supplied, 2 N evaluations of the function are needed to compute the 2 N -by- 2 N Jacobian matrix. If the sparsity pattern is supplied, only four evaluations are needed, regardless of the value of N .

To run this example, click on the example name, or type brussode at the command line. From the command line, you can specify a value of $N$ as an argument to brussode. The default is $N=20$.

```
function brussode(N)
%BRUSSODE Stiff problem modeling a chemical reaction
if nargin < 1
    N = 20;
end
tspan = [0; 10];
y0 = [1+sin((2*pi/(N+1))*(1:N));
repmat(3,1,N)];
```

```
options = odeset('Vectorized','on','JPattern',jpattern(N));
[t,y] = ode15s(@f,tspan,y0,options);
u = y(:,1:2:end);
x = (1:N)/(N+1);
surf(x,t,u);
view(-40,30);
xlabel('space');
ylabel('time');
zlabel('solution u');
title(['The Brusselator for N = ' num2str(N)]);
%
function dydt = f(t,y)
c = 0.02 * (N+1)^2;
dydt = zeros(2*N,size(y,2)); % preallocate dy/dt
% Evaluate the two components of the function at one edge of
% the grid (with edge conditions).
i = 1;
dydt(i,:) = 1 + y(i+1,:).*y(i,:).^2 - 4*y(i,:) + ...
    c*(1-2*y(i,:)+y(i+2,:));
dydt(i+1,:) = 3*y(i,:) - y(i+1,:).*y(i,:).^2 + ...
    c*(3-2*y(i+1,:)+y(i+3,:));
% Evaluate the two components of the function at all interior
% grid points.
i = 3:2:2*N-3;
dydt(i,:) = 1 + y(i+1,:).*y(i,:).^2 - 4*y(i,:) + ...
    c*(y(i-2,:)-2*y(i,:)+y(i+2,:));
dydt(i+1,:) = 3*y(i,:) - y(i+1,:).*y(i,:).^2 + ...
    c*(y(i-1,:)-2*y(i+1,:)+y(i+3,:));
% Evaluate the two components of the function at the other edge
% of the grid (with edge conditions).
i = 2*N-1;
dydt(i,:) = 1 + y(i+1,:).*y(i,:).^2 - 4*y(i,:) + ...
    c*(y(i-2,:)-2*y(i,:)+1);
dydt(i+1,:) = 3*y(i,:) - y(i+1,:).*y(i,:).^2 + ...
                    c*(y(i-1,:)-2*y(i+1,:)+3);
end % End nested function f
end % End function brussode
```

## Event Location

ballode models the motion of a bouncing ball. This example illustrates the event location capabilities of the ODE solvers.

The equations for the bouncing ball are:

$$
\begin{aligned}
& y_{1}^{\prime}=y_{2} \\
& y_{2}^{\prime}=-9.8
\end{aligned}
$$

In this example, the event function is coded in a subfunction events
[value,isterminal,direction] = events(t,y)
which returns

- A value of the event function
- The information whether or not the integration should stop when value $=0$ (isterminal $=1$ or 0 , respectively)
- The desired directionality of the zero crossings:

| -1 | Detect zero crossings in the negative direction only |
| :--- | :--- |
| 0 | Detect all zero crossings |
| 1 | Detect zero crossings in the positive direction only |

The length of value, isterminal, and direction is the same as the number of event functions. The ith element of each vector, corresponds to the ith event function. For an example of more advanced event location, see orbitode ("Advanced Event Location" on page 10-28).

In ballode, setting the Events property to @events causes the solver to stop the integration (isterminal $=1$ ) when the ball hits the ground (the height $y(1)$ is 0 ) during its fall (direction $=-1$ ). The example then restarts the integration with initial conditions corresponding to a ball that bounced.

To run this example, click on the example name, or type ballode at the command line.

```
function ballode
%BALLODE Run a demo of a bouncing ball.
tstart = 0;
tfinal = 30;
y0 = [0; 20];
refine = 4;
options = odeset('Events',@events,'OutputFcn', @odeplot,...
    'OutputSel',1,'Refine',refine);
set(gca,'xlim',[0 30],'ylim',[0 25]);
box on
hold on;
tout = tstart;
yout = y0.';
```

```
teout = [];
yeout = [];
ieout = [];
for i = 1:10
    % Solve until the first terminal event.
    [t,y,te,ye,ie] = ode23(@f,[tstart tfinal],y0,options);
    if ~ishold
        hold on
    end
    % Accumulate output.
    nt = length(t);
    tout = [tout; t(2:nt)];
    yout = [yout; y(2:nt,:)];
    teout = [teout; te]; % Events at tstart are never reported.
    yeout = [yeout; ye];
    ieout = [ieout; ie];
    ud = get(gcf,'UserData');
    if ud.stop
        break;
    end
    % Set the new initial conditions, with . }9\mathrm{ attenuation.
    y0(1) = 0;
    y0(2) = -.9*y(nt,2);
    % A good guess of a valid first time step is the length of
    % the last valid time step, so use it for faster computation.
    options = odeset(options,'InitialStep',t(nt)-t(nt-refine),...
                            'MaxStep',t(nt)-t(1));
    tstart = t(nt);
end
plot(teout,yeout(:,1),'ro')
xlabel('time');
ylabel('height');
title('Ball trajectory and the events');
hold off
odeplot([],[],'done');
%
```

function dydt $=f(t, y)$
function dydt $=f(t, y)$
dydt $=$ [y(2); -9.8];
dydt $=$ [y(2); -9.8];

function [value,isterminal, direction] = events(t,y)
\% Locate the time when height passes through zero in a
\% decreasing direction and stop integration.
value $=\mathrm{y}(1) ; \quad \%$ Detect height $=0$
isterminal $=1 ; \quad \%$ Stop the integration
direction $=-1$; $\%$ Negative direction only

## Advanced Event Location

orbitode illustrates the solution of a standard test problem for those solvers that are intended for nonstiff problems. It traces the path of a spaceship traveling around the moon and returning to the earth (Shampine and Gordon [8], p. 246).

The orbitode problem is a system of the following four equations:

$$
\begin{aligned}
& y_{1}^{\prime}=y_{3} \\
& y_{2}^{\prime}=y_{4} \\
& y_{3}^{\prime}=2 y_{4}+y_{1}-\frac{\mu^{*}\left(y_{1}+\mu\right)}{r_{1}^{3}}-\frac{\mu\left(y_{1}-\mu^{*}\right)}{r_{2}^{3}} \\
& y_{4}^{\prime}=-2 y_{3}+y_{2}-\frac{\mu^{*} y_{2}}{r_{1}^{3}}-\frac{\mu y_{2}}{r_{2}^{3}}
\end{aligned}
$$

where

$$
\begin{aligned}
& \mu=1 / 82.45 \\
& \mu^{*}=1-\mu \\
& r_{1}=\sqrt{\left(y_{1}+\mu\right)^{2}+y_{2}^{2}} \\
& r_{2}=\sqrt{\left(y_{1}-\mu^{*}\right)^{2}+y_{2}^{2}}
\end{aligned}
$$

The first two solution components are coordinates of the body of infinitesimal mass, so plotting one against the other gives the orbit of the body. The initial conditions have been chosen to make the orbit periodic. The value of $\mu$ corresponds to a spaceship traveling around the moon and the earth. Moderately stringent tolerances are necessary to reproduce the qualitative behavior of the orbit. Suitable values are 1e-5 for RelTol and 1e-4 for AbsTol.

The nested events function includes event functions that locate the point of maximum distance from the starting point and the time the spaceship returns to the starting point. Note that the events are located accurately, even though the step sizes used by the integrator are not determined by the location of the events. In this example, the ability to specify the direction of the zero crossing is critical. Both the point of return to the initial point and the point of maximum distance have the same event function value, and the direction of the crossing is used to distinguish them.

To run this example, click on the example name, or type orbitode at the command line. The example uses the output function odephas2 to produce
the two-dimensional phase plane plot and let you to see the progress of the integration.

```
function orbitode
%ORBITODE Restricted three-body problem
```

```
mu = 1 / 82.45;
mustar = 1 - mu;

direction = [1; -1]; % [local minimum, local maximum]
end % End nested function events
end
```

## Differential-Algebraic Equations

hb1dae reformulates the hb1ode example as a differential-algebraic equation (DAE) problem. The Robertson problem coded in hb1ode is a classic test problem for codes that solve stiff ODEs.

$$
\begin{aligned}
& y_{1}^{\prime}=-0.04 y_{1}+10^{4} y_{2} y_{3} \\
& y_{2}^{\prime}=0.04 y_{1}-10^{4} y_{2} y_{3}-3 \cdot 10^{7} y_{2}^{2} \\
& y_{3}^{\prime}=3 \cdot 10^{7} y_{2}^{2}
\end{aligned}
$$

Note The Robertson problem appears as an example in the prolog to LSODI [4].

In hb1ode, the problem is solved with initial conditions $y_{1}(0)=1, y_{2}(0)=0$, $y_{3}(0)=0$ to steady state. These differential equations satisfy a linear conservation law that is used to reformulate the problem as the DAE

$$
\begin{aligned}
y_{1}^{\prime} & =-0.04 y_{1}+10^{4} y_{2} y_{3} \\
y_{2}^{\prime} & =0.04 y_{1}-10^{4} y_{2} y_{3}-3 \cdot 10^{7} y_{2}^{2} \\
0 & =y_{1}+y_{2}+y_{3}-1
\end{aligned}
$$

These equations do not have a solution for $y(0)$ with components that do not sum to 1 . The problem has the form of $M y^{\prime}=f(t, y)$ with

$$
M=\left[\begin{array}{lll}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 0
\end{array}\right]
$$

$M$ is singular, but hb1dae does not inform the solver of this. The solver must recognize that the problem is a DAE, not an ODE. Similarly, although consistent initial conditions are obvious, the example uses an inconsistent value $y_{3}(0)=10^{-3}$ to illustrate computation of consistent initial conditions.

To run this example, click on the example name, or type hb1dae at the command line. Note that hb1dae

- Imposes a much smaller absolute error tolerance on $y_{2}$ than on the other components. This is because $y_{2}$ is much smaller than the other components and its major change takes place in a relatively short time.
- Specifies additional points at which the solution is computed to more clearly show the behavior of $y_{2}$.
- Multiplies $y_{2}$ by $10^{4}$ to make $y_{2}$ visible when plotting it with the rest of the solution.
- Uses a logarithmic scale to plot the solution on the long time interval.

```
function hb1dae
%HB1DAE Stiff differential-algebraic equation (DAE)
% A constant, singular mass matrix
M = [1 0 0
    0 1 0
    O O 0];
% Use inconsistent initial condition to test initialization.
y0 = [1; 0; 1e-3];
tspan = [O 4*logspace(-6,6)];
% Use the LSODI example tolerances.'MassSingular' is left
% at its default 'maybe' to test the automatic detection
% of a DAE.
options = odeset('Mass',M,'RelTol',1e-4,...
    'AbsTol',[1e-6 1e-10 1e-6],...
    'Vectorized','on');
[t,y] = ode15s(@f,tspan,y0,options);
y(:,2) = 1e4*y(:,2);
semilogx(t,y);
ylabel('1e4 * y(:,2)');
title(['Robertson DAE problem with a Conservation Law, '...
    'solved by ODE15S']);
xlabel('This is equivalent to the stiff ODEs in HB1ODE.');
%---------------------------------------------------------
function out = f(t,y)
```

$$
\begin{aligned}
\text { out }= & -0.04 * y(1,:)+1 e 4 * y(2,:) . * y(3,:) \\
& 0.04 * y(1,:)-1 e 4 * y(2,:) . * y(3,:)-3 e 7 * y(2,:) . \wedge 2 \\
& y(1,:)+y(2,:)+y(3,:)-1] ;
\end{aligned}
$$

## Nonnegative Solutions

If certain components of the solution must be nonnegative, use odeset to set the NonNegative property for the indices of these components.

Note This option is not available for ode23s, ode15i, or for implicit solvers (ode15s, ode23t, ode23tb) applied to problems where there is a mass matrix.

Imposing nonnegativity is not always a trivial task. We suggest that you use this option only when necessary, for example in instances in which the application of a solution or integration will fail otherwise.

Consider the following initial value problem solved on the interval [0, 40]:

$$
y^{\prime}=-|y|, y(0)=1
$$

The solution of this problem decays to zero. If a solver produces a negative approximate solution, it begins to track the solution of the ODE through this
value, the solution goes off to minus infinity, and the computation fails. Using the NonNegative property prevents this from happening.

In this example, the first call to ode45 uses the defaults for the solver parameters:

```
ode = @(t,y) -abs(y);
[t0,y0] = ode45(ode,[0, 40], 1);
```

The second uses options to impose nonnegativity conditions:

```
options = odeset('NonNegative',1);
[t1,y1] = ode45(ode,[0, 40], 1, options);
```

This plot compares the numerical solution to the exact solution.

Here is a more complete view of the code used to obtain this plot:

```
ode = @(t,y) - abs(y);
options = odeset('Refine',1);
[t0,y0] = ode45(ode,[0, 40], 1,options);
options = odeset(options,'NonNegative',1);
[t1,y1] = ode45(ode,[0, 40], 1, options);
t = linspace(0,40,1000);
y = exp(-t);
plot(t,y,'b-',t0,y0,'ro',t1,y1,'b*');
legend('Exact solution','No constraints','Nonnegativity', ...
    'Location','SouthWest')
```

The kneeode Demo. The MATLAB kneeode demo solves the "knee problem" by imposing a nonnegativity constraint on the numerical solution. The initial value problem is

$$
{ }^{*} y^{\prime}=(1-x) * y-y^{\wedge} 2, \quad y(0)=1
$$

For $0<\varepsilon<1$, the solution of this problem approaches null isoclines $y=1$ - x and $\mathrm{y}=0$ for $\mathrm{x}<1$ and $\mathrm{x}>1$, respectively. The numerical solution, when computed with default tolerances, follows the $y=1-x$ isocline for the whole interval of integration. Imposing nonnegativity constraints results in the correct solution.

Here is the code that makes up the kneeode demo:

```
function kneeode
%KNEEODE The "knee problem" with Nonnegativity constraints.
% Problem parameter
epsilon = 1e-6;
y0 = 1;
xspan = [0, 2];
% Solve without imposing constraints
options = [];
[x1,y1] = ode15s(@odefcn,xspan,y0,options);
% Impose nonnegativity constraint
options = odeset('NonNegative',1);
```

```
[x2,y2] = ode15s(@odefcn,xspan,y0,options);
figure
plot(x1,y1,'b.-',x2,y2,'g-')
axis([0,2,-1,1]);
title('The "knee problem"');
legend('No constraints','nonnegativity')
xlabel('x');
ylabel('solution y')
    function yp = odefcn(x,y)
        yp = ((1 - x)*y - y^2)/epsilon;
    end
end % kneeode
```

The derivative function is defined within nested function odefcn. The value of epsilon used in odefen is obtained from the outer function:

```
function yp = odefcn(x,y)
yp = ((1 - x)*y - y^2)/epsilon;
end
```

The demo solves the problem using the ode15s function, first with the default options, and then by imposing a nonnegativity constraint. To run the demo, type kneeode at the MATLAB command prompt.

Here is the output plot. The plot confirms correct solution behavior after imposing constraints.

## Additional Examples

The following additional examples are available. Type
edit examplename
to view the code and
examplename
to run the example.

| Example Name | Description |
| :--- | :--- |
| amp1dae | Stiff DAE - electrical circuit |
| ballode | Simple event location - bouncing ball |
| batonode | ODE with time- and state-dependent mass <br> matrix - motion of a baton |

| Example Name | Description |
| :--- | :--- |
| brussode | Stiff large problem - diffusion in a chemical <br> reaction (the Brusselator) |
| burgersode | ODE with strongly state-dependent mass <br> matrix - Burgers' equation solved using a <br> moving mesh technique |
| fem1ode | Stiff problem with a time-dependent mass <br> matrix - finite element method |
| fem2ode | Stiff problem with a constant mass matrix - <br> finite element method |
| hb1ode | Stiff ODE problem solved on a very long <br> interval - Robertson chemical reaction |
| hb1dae | Robertson problem - stiff, linearly implicit <br> DAE from a conservation law |
| inb1dae | Robertson problem - stiff, fully implicit DAE |
| iburgersode | Burgers' equation solved as implicit ODE <br> system |
| kneeode | The "knee problem" with nonnegativity <br> constraints |
| orbitode | Advanced event location - restricted three <br> body problem |
| rigidode | Nonstiff problem - Euler equations of a rigid <br> body without external forces |
| vdpode | Parameterizable van der Pol equation (stiff for <br> large $\mu)$ |

## General Questions

| Question | Answer |
| :--- | :--- |
| How do the ODE solvers differ from quad or | quad and quadl solve problems of the form <br> quadl? |
|  | $y^{\prime}=f(t)$. The ODE solvers handle more <br> general problems $y^{\prime}=f(t, y)$, linearly <br> implicit problems that involve a mass matrix <br> $M(t, y) y^{\prime}=f(t, y)$, and fully implicit problems <br> $f\left(t, y, y^{\prime}\right)=0$. |
| Can I solve ODE systems in which there are <br> more equations than unknowns, or vice versa? | No. |

## Memory and Computational Efficiency

| Question |
| :--- |
| How large a problem can I solve with the ODE <br> suite? |

## Answer

The primary constraints are memory and time. At each time step, the solvers for nonstiff problems allocate vectors of length $n$, where $n$ is the number of equations in the system. The solvers for stiff problems allocate vectors of length $n$ but also allocate an $n$-by- $n$ Jacobian matrix. For these solvers it may be advantageous to use the sparse option.

If the problem is nonstiff, or if you are using the sparse option, it may be possible to solve a problem with thousands of unknowns. In this case, however, storage of the result can be problematic. Try asking the solver to evaluate the solution at specific points only, or call the solver with no output arguments and use an output function to monitor the solution.

## Memory and Computational Efficiency (Continued)

| Question | Answer |
| :--- | :--- |
| I'm solving a very large system, but only care <br> about a couple of the components of y. Is there <br> any way to avoid storing all of the elements? | Yes. The user-installable output function <br> capability is designed specifically for this <br> purpose. When you call the solver with no <br> output arguments, the solver does not allocate <br> storage to hold the entire solution history. <br> Instead, the solver calls OutputFcn(t,y, flag) <br> at each time step. To keep the history of specific <br> elements, write an output function that stores <br> or plots only the elements you care about. |
| What is the startup cost of the integration and <br> how can I reduce it? | The biggest startup cost occurs as the solver <br> attempts to find a step size appropriate to the <br> scale of the problem. If you happen to know <br> an appropriate step size, use the InitialStep <br> property. For example, if you repeatedly call <br> the integrator in an event location loop, the <br> last step that was taken before the event is <br> probably on scale for the next integration. See <br> ballode for an example. |

## Time Steps for Integration

| Question | Answer |
| :--- | :--- |
| The first step size that the integrator takes is <br> too large, and it misses important behavior. | You can specify the first step size with the <br> InitialStep property. The integrator tries <br> this value, then reduces it if necessary. |
| Can I integrate with fixed step sizes? | No. |

## Error Tolerance and Other Options

| Question | Answer |
| :--- | :--- |
| How do I choose RelTol and AbsTol? | RelTol, the relative accuracy tolerance, <br> controls the number of correct digits in the <br> answer. AbsTol, the absolute error tolerance, <br> controls the difference between the answer <br> and the solution. At each step, the error e in <br> component i of the solution satisfies <br> $\|e(i)\| \quad$ max (RelTol*abs (y (i)) , AbsTol (i)) <br> Roughly speaking, this means that you want <br> RelTol correct digits in all solution components <br> except those smaller than thresholds <br> AbsTol(i). Even if you are not interested in a <br> component y (i) when it is small, you may have <br> to specify AbsTol (i) small enough to get some <br> correct digits in y(i) so that you can accurately <br> compute more interesting components. |
| I want answers that are correct to the precision <br> of the computer. Why can't I simply set RelTol <br> to eps? | You can get close to machine precision, but not <br> that close. The solvers do not allow RelTol <br> near eps because they try to approximate a <br> continuous function. At tolerances comparable <br> to eps, the machine arithmetic causes all <br> functions to look discontinuous. |
| How do I tell the solver that I don't care about <br> getting an accurate answer for one of the <br> solution components? | You can increase the absolute error tolerance <br> corresponding to this solution component. If <br> the tolerance is bigger than the component, this <br> specifies no correct digits for the component. <br> The solver may have to get some correct <br> digits in this component to compute other <br> components accurately, but it generally <br> handles this automatically. |

## Other Types of Equations

| Question | Answer |
| :--- | :--- |
| Can the solvers handle partial differential <br> equations (PDEs) that have been discretized <br> by the method of lines? | Yes, because the discretization produces <br> a system of ODEs. Depending on the <br> discretization, you might have a form involving <br> mass matrices - the ODE solvers provide <br> for this. Often the system is stiff. This is to <br> be expected when the PDE is parabolic and <br> when there are phenomena that happen on <br> very different time scales such as a chemical <br> reaction in a fluid flow. In such cases, use one <br> of the four solvers: ode15s, ode23s, ode23t, <br> ode23tb. <br> If there are many equations, set the JPattern <br> property. This might make the difference |
| between success and failure due to the |  |
| computation being too expensive. For an |  |
| example that uses JPattern, see "Large Stiff |  |
| exp |  |
| Sparse Problem" on page 10-22. When the |  |
| system is not stiff, or not very stiff, ode23 or |  |
| ode45 is more efficient than ode15s, ode23s, |  |
| ode23t, or ode23tb. |  |
| Parabolic-elliptic partial differential equations |  |
| in 1-D can be solved directly with the MATLAB |  |

## Other Types of Equations (Continued)

| Question | Answer |
| :--- | :--- |
| Can I integrate a set of sampled data? | Not directly. You have to represent the data <br> as a function by interpolation or some other <br> scheme for fitting data. The smoothness of this <br> function is critical. A piecewise polynomial fit <br> like a spline can look smooth to the eye, but <br> rough to a solver; the solver takes small steps <br> where the derivatives of the fit have jumps. <br> Either use a smooth function to represent <br> the data or use one of the lower order solvers <br> (ode23, ode23s, ode23t, ode23tb) that is less <br> sensitive to this. |
| What do I do when I have the final and not the <br> initial value? | All the solvers of the ODE suite allow you <br> to solve backwards or forwards in time. <br> The syntax for the solvers is [ $t, y]=$ <br> ode45(odefun, [to tf],y0); and the syntax <br> accepts to > tf. |

## Other Common Problems

| Question | Answer |
| :--- | :--- |
| The solution doesn't look like what I expected. | If you're right about its appearance, you need to <br> reduce the error tolerances from their default <br> values. A smaller relative error tolerance is <br> needed to compute accurately the solution <br> of problems integrated over "long" intervals, <br> as well as solutions of problems that are <br> moderately unstable. |
| You should check whether there are solution |  |
| components that stay smaller than their |  |
| absolute error tolerance for some time. If so, |  |
| you are not asking for any correct digits in |  |
| these components. This may be acceptable for |  |
| these components, but failing to compute them |  |

## Other Common Problems (Continued)

| Question | Answer |
| :--- | :--- |
|  | accurately may degrade the accuracy of other <br> components that depend on them. |
| My plots aren't smooth enough. | Increase the value of Refine from its default <br> of 4 in ode45 and 1 in the other solvers. The <br> bigger the value of Refine, the more output <br> points. Execution speed is not affected much <br> by the value of Refine. |
| I'm plotting the solution as it is computed and <br> it looks fine, but the code gets stuck at some <br> point. | First verify that the ODE function is smooth <br> near the point where the code gets stuck. If it <br> isn't, the solver must take small steps to deal <br> with this. It may help to break tspan into <br> pieces on which the ODE function is smooth. |
| If the function is smooth and the code is |  |
| If the |  |
| taking extremely small steps, you are probably |  |
| trying to solve a stiff problem with a solver not |  |
| intended for this purpose. Switch to ode15s, |  |
| ode23s, ode23t, or ode23tb. |  |

## Other Common Problems (Continued)

| Question | Answer |
| :--- | :--- |
|  | the ODE function. Rather than recompute <br> complicated constant parameters at each <br> evaluation, store them in globals or calculate <br> them once and pass them to nested functions. |
| I know that the solution undergoes a radical <br> change at time t where | If you know there is a sharp change at time t, <br> it might help to break the tspan interval into <br> two pieces, [t0 t] and [t tf], and call the <br> integrator twice. |
| to t tf |  |
| but the integrator steps past without "seeing" |  |
| it. | If the differential equation has periodic <br> coefficients or solution, you might restrict the <br> maximum step size to the length of the period <br> so the integrator won't step over periods. |

## Delay Differential Equations

In this section...<br>"Function Summary" on page 10-47<br>"Initial Value Problems" on page 10-48<br>"Types of Solvers" on page 10-49<br>"Discontinuities" on page 10-50<br>"Integrator Options" on page 10-51<br>"Examples" on page 10-51

## Function Summary

- "DDE Solvers" on page 10-47
- "DDE Helper Functions" on page 10-47
- "DDE Solver Options" on page 10-48

## DDE Solvers

| Solver | Description |
| :--- | :--- |
| dde23 | Solve initial value problems for delay <br> differential equations with constant delays. |
| ddesd | Solve initial value problems for delay <br> differential equations with general delays. |

## DDE Helper Functions

| Function | Description |
| :--- | :--- |
| deval | Evaluate the numerical solution using the <br> output of dde23 or ddesd. |

## DDE Solver Options

Use these functions to create, alter, or access an options structure. An options structure contains named properties, the values of which are passed to dde23 or ddesd, thus affecting the solution of the problem.

| Function | Description |
| :--- | :--- |
| ddeset | Create/alter the DDE options structure. |
| ddeget | Extract properties from options structure <br> created with ddeset. |

## Initial Value Problems

The DDE dde23 solver can solve systems of ordinary differential equations, such as

$$
y^{\prime}(t)=f\left(t, y(t), y\left(t-\tau_{1}\right), \ldots, y\left(t-\tau_{k}\right)\right)
$$

where $t$ is the independent variable, $y$ is the dependent variable, and $y^{\prime}$ represents (derivative of y with respect to t ) $d y / d t$. The delays (lags) $\tau_{1}, \ldots, \tau_{k}$ are positive constants. The solver ddesd allows delays that depend on $t$ and $y$.

## History and Initial Values

In an initial value problem, you seek the solution on an interval $\left.{ }^{[ } t_{0}, t_{f}\right]$ with $t_{0}<t_{f}$. The DDE shows that $y^{\prime}(t)$ depends on values of the solution at times prior to $t$. In particular, $y^{\prime}\left(t_{0}\right)$ depends on $y\left(t_{0}-\tau_{1}\right), \ldots, y\left(t_{0}-\tau_{k}\right)$. Because of this, a solution on ${ }^{\left[t_{0}, t_{f}\right]}$ depends on its values for $t \leq t_{0}$, i.e., its history $S(t)$.

## Propagation of Discontinuities

Generally, the solution $y(t)$ of an IVP for a system of DDEs has a jump in its first derivative at the initial point $t_{0}$ because the first derivative of the history function does not satisfy the DDE there. A discontinuity in any derivative propagates into the future at spacings of $\tau_{1}, \tau_{2}, \ldots, \tau_{k}$ when the delays are constant, and in a more complicated way when they are not. For the DDEs solved by dde23 and ddesd, the solution becomes smoother as the integration proceeds.

## Types of Solvers

This section describes:

- "DDE Solver dde23" on page 10-49
- "DDE Solver ddesd" on page 10-49

The basic syntax for the two solvers is shown in the function reference pages for dde23 and ddesd.

## DDE Solver dde23

The function dde23 solves initial value problems for DDEs with constant delays. It integrates a system of first-order differential equations

$$
y^{\prime}(t)=f\left(t, y(t), y\left(t-\tau_{1}\right), \ldots, y\left(t-\tau_{k}\right)\right)
$$

on the interval $\left[t_{0}, t_{f}\right]$, with $t_{0}<t_{f}$ and given history $y(t)=S(t)$ for $t \leq t_{0}$. dde23 produces a solution that is continuous on ${ }^{\left[t_{0}, t_{f}\right] \text {. You can use the }}$ function deval and the output of dde23 to evaluate the solution at specific points on the interval of integration.
dde23 tracks low-order discontinuities and integrates the differential equations with the explicit Runge-Kutta $(2,3)$ pair and interpolant used by ode23. The Runge-Kutta formulas are implicit for step sizes longer than the delays. When the solution is smooth enough that steps this big are justified, the implicit formulas are evaluated by a predictor-corrector iteration.

## DDE Solver ddesd

The function ddesd solves initial value problems for DDEs with general delays. It integrates a system of first-order differential equations

$$
y^{\prime}(t)=f(t, y(t), y(d(1)), \ldots, y(d(k)))
$$

on the interval $\left[t_{0}, t_{f}\right]$, with $t_{0}<t_{f}$, where delays $d(j)$ can depend on both $t$ and $y(t)$. Use the function deval and the output of ddesd to evaluate the solution at specific points on the interval of integration.
ddesd integrates with the classic four-stage, fourth-order explicit Runge-Kutta method, and controls the size of the residual of a natural interpolant. It uses iteration to take steps that are longer than the delays. For further details, see "Solving ODEs and DDEs with Residual Control," L.F. Shampine, Applied Numerical Mathematics, 52 (2005), pp 113-127.

## Discontinuities

dde23 performs better if it is informed of discontinuities in the history and at known locations. Discontinuities may be specified by event functions. There is a property with which you can specify a solution that is different from the value given by the history function.

| Discontinuity | Property | Comments |
| :--- | :--- | :--- |
| At the initial value <br> $t=t_{0}$ | InitialY | Generally the initial value $y\left(t_{0}\right)$ <br> is the value $S\left(t_{0}\right)$ returned <br> by the history function, which <br> is to say that the solution is <br> continuous at the initial point. <br> However, if this is not the case, <br> supply a different initial value <br> using the InitialY property. |
| In the history, i.e., <br> the solution at $t<t_{0}$ <br> or in the equation <br> coefficients for $t>t_{0}$ | Jumps | Provide the known locations $t$ of <br> the discontinuities in a vector as |

## Integrator Options

The default integration properties in the DDE solver dde23 are selected to handle common problems. In some cases, you can improve solver performance by overriding these defaults. You do this by supplying dde23 with an options structure that specifies one or more property values.

For example, to change the relative error tolerance of dde23 from the default value of $1 e-3$ to $1 e-4$,

1 Create an options structure using the function ddeset by entering

```
options = ddeset('RelTol', 1e-4);
```

2 Pass the options structure to dde23 as follows:

```
sol = dde23(ddefun,lags,history,tspan,options)
```

For a complete description of the available options, see the reference page for ddeset.

## Examples

- "Constant Delay" on page 10-52
- "State-Dependent Delay" on page 10-54
- "Cardiovascular Model" on page 10-55
- "Additional Examples" on page 10-57

## Constant Delay

- "Solving the System" on page 10-52
- "Evaluating the Solution" on page 10-54

Solving the System. This example illustrates the straightforward formulation, computation, and display of the solution of a system of DDEs with constant delays. The history is constant, which is often the case. The differential equations are

$$
\begin{aligned}
& y_{1}{ }^{\prime}(t)=y_{1}(t-1) \\
& y_{2}{ }^{\prime}(t)=y_{1}(t-1)+y_{2}(t-0.2) \\
& y_{3}{ }^{\prime}(t)=y_{2}(t)
\end{aligned}
$$

The example solves the equations on [0,5] with history

$$
\begin{aligned}
& y_{1}(t)=1 \\
& y_{2}(t)=1 \\
& y_{3}(t)=1
\end{aligned}
$$

for $t \leq 0$

Note The demo ddex1 contains the complete code for this example. To see the code in an editor, click the example name, or type edit ddex1 at the command line. To run the example type ddex1 at the command line.

1 Rewrite the problem as a first-order system. To use dde23, you must rewrite the equations as an equivalent system of first-order differential equations. Do this just as you would when solving IVPs and BVPs for ODEs. However, this example needs no such preparation because it already has the form of a first-order system of equations.

2 Identify the lags. The delays (lags) $\tau_{1}, \ldots, \tau_{k}$ are supplied to dde23 as a vector. For the example we could use

```
lags = [1,0.2];
```

In coding the differential equations, ${ }^{\boldsymbol{\tau}} \mathrm{j}=\operatorname{lags}(\mathrm{j})$.
3 Code the system of first-order DDEs. Once you represent the equations as a first-order system, and specify lags, you can code the equations as a function that dde23 can use.

This code represents the system in the function, ddex1de.

```
function dydt = ddex1de(t,y,Z)
ylag1 = Z(:,1);
ylag2 = Z(:,2);
dydt = [ylag1(1)
    ylag1(1) + ylag2(2)
    y(2) ];
```

4 Code the history function. The history function for this example is

```
function S = ddex1hist(t)
S = ones(3,1);
```

5 Apply the DDE solver. The example now calls dde23 with the functions ddex1de and ddex1hist.

```
sol = dde23(@ddex1de,lags,@ddex1hist,[0,5]);
```

Here the example supplies the interval of integration [0,5] directly.
Because the history is constant, we could also call dde23 by

```
sol = dde23(@ddex1de,lags,ones(3,1),[0,5]);
```

6 View the results. Complete the example by displaying the results. dde23 returns the mesh it selects and the solution there as fields in the solution structure sol. Often, these provide a smooth graph.

```
plot(sol.x,sol.y);
title('An example of Wille'' and Baker');
xlabel('time t');
ylabel('solution y');
legend('y_1','y_2','y_3',2)
```

Evaluating the Solution. The method implemented in dde23 produces a continuous solution over the whole interval of integration $\left[t_{0}, t_{f}\right]$. You can evaluate the approximate solution, $S(t)$, at any point in ${ }^{\left[t_{0}, t_{f}\right]}$ using the helper function deval and the structure sol returned by dde23.

```
Sint = deval(sol,tint)
```

The deval function is vectorized. For a vector tint, the ith column of Sint approximates the solution $y$ (tint(ii)).

Using the output sol from the previous example, this code evaluates the numerical solution at 100 equally spaced points in the interval $[0,5]$ and plots the result.

```
tint = linspace(0,5);
Sint = deval(sol,tint);
plot(tint,Sint);
```

## State-Dependent Delay

This example solves a system of two DDEs with state-dependent delay that was used as a test problem by W.H. Enright and H. Hayashi [10] because it has an analytical solution. The differential equations are

$$
\begin{aligned}
& y_{1}^{\prime}(t)=y_{2}(t) \\
& y_{2}^{\prime}(t)=-y_{2}\left(e^{\left(1-y_{2}(t)\right)}\right) \times y_{2}(t)^{2} \times e^{\left(1-y_{2}(t)\right)}
\end{aligned}
$$

The analytical solution

$$
\begin{aligned}
& y_{1}(t)=\log (t) \\
& y_{2}(t)=1 / t
\end{aligned}
$$

is used as the history for $t \leq 0.1$ and the equations are solved on [0.1, 5]. The only thing different about solving this example is that it must be solved with ddesd rather than dde23. This is because the first factor in the second equation has the form $y_{2}(d(y))$ with a delay that depends on the second component of the solution. The delay is provided to ddesd with a function like

```
function d = ddex3delay(t,y)
% State dependent delay function for DDEX3
d = exp(1 - y(2));
```

Note The demo ddex3 contains the complete code for this example. To see the code in an editor, click the example name, or type edit ddex3 at the command line. To run the example type ddex3 at the command line.

## Cardiovascular Model

This example solves a cardiovascular model due to J. T. Ottesen [6]. The equations are integrated over the interval [ 0,1000 ]. The situation of interest is when the peripheral pressure $R$ is reduced exponentially from its value of 1.05 to 0.84 beginning at $t=600$.

This is a problem with one delay, a constant history, and three differential equations with fourteen physical parameters. It has a discontinuity in a low order derivative at $\mathrm{t}=600$.

Note The demo ddex2 contains the complete code for this example. To see the code in an editor, click the example name, or type edit ddex2 at the command line. To run the example type ddex2 at the command line.

In ddex2, the fourteen physical parameters are set as fields in a structure $p$ that is shared with nested functions. The function ddex2de for evaluating the equations begins with

```
function dydt = ddex2de(t,y,Z)
if t <= 600
    p.R = 1.05;
else
    p.R = 0.21 * exp(600-t) + 0.84;
end
.
.
```

Jumps Property. The peripheral pressure $R$ is a continuous function of $t$, but it does not have a continuous derivative at $t=600$. The example uses the Jumps property to inform dde23 about the location of this discontinuity.

```
opts = ddeset('Jumps',600);
```

After defining the delay tau and the constant history, the call is

```
sol = dde23(@ddex2de,tau,history,[0, 1000],opts);
```

The demo ddex2 plots only the third component, the heart rate, which shows a sharp change at $\mathrm{t}=600$.

Restarting. The example could have solved this problem by breaking it into two pieces

```
sol = dde23(@ddex2de,tau,history,[0, 600]);
sol = dde23(@ddex2de,tau,sol,[600, 1000]);
```

The solution structure sol on the interval [ 0,600 ] serves as history for restarting the integration at $t=600$. In the second call, dde23 extends sol so that on return the solution is available on the whole interval $[0,1000]$. That is, after this second return,

```
Sint = deval(sol,[300,900]);
```

evaluates the solution obtained in the first integration at $t=300$, and the solution obtained in the second integration at $\mathrm{t}=900$.

When discontinuities occur in low order derivatives at points known in advance, it is better to use the Jumps property. This is not an option with ddesd, which handles discontinuities in a different way. When you use event functions to locate such discontinuities, you must restart the integration at discontinuities.

## Additional Examples

The following additional examples are available. Type
edit examplename
to view the code and
examplename
to run the example.

| Example | Description |
| :--- | :--- |
| ddex1 | Straightforward example |
| ddex2 | Cardiovascular model with discontinuities |
| ddex3 | Problem involving state-dependent delays |

Additional examples are provided by "Tutorial on Solving DDEs with DDE23," available at http://www.mathworks.com/dde_tutorial.

## Boundary-Value Problems

In this section...<br>"Function Summary" on page 10-59<br>"Boundary Value Problems" on page 10-60<br>"BVP Solver" on page 10-61<br>"Integrator Options" on page 10-64<br>"Examples" on page 10-65

## Function Summary

- "BVP Solver" on page 10-59
- "BVP Helper Functions" on page 10-59
- "BVP Solver Options" on page 10-60

## BVP Solver

| Solver | Description |
| :--- | :--- |
| bvp4c | Solve boundary value problems for ordinary <br> differential equations. |
| bvp5c | Solve boundary value problems for ordinary <br> differential equations. |

## BVP Helper Functions

| Function | Description |
| :--- | :--- |
| bvpinit | Form the initial guess for bvp4c. |
| deval | Evaluate the numerical solution using the output <br> of bvp4c. |

## BVP Solver Options

An options structure contains named properties whose values are passed to bvp4c, and which affect problem solution. Use these functions to create, alter, or access an options structure.

| Function | Description |
| :--- | :--- |
| bvpset | Create/alter the BVP options structure. |
| bvpget | Extract properties from options structure created <br> with bvpset. |

## Boundary Value Problems

The BVP solver is designed to handle systems of ordinary differential equations

$$
y^{\prime}=f(x, y)
$$

where $x$ is the independent variable, $y$ is the dependent variable, and $y^{\prime}$ represents the derivative of $y$ with respect to $x d y / d x$.

See "First Order ODEs" on page 10-4 for general information about ODEs.

## Boundary Conditions

In a boundary value problem, the solution of interest satisfies certain boundary conditions. These conditions specify a relationship between the values of the solution at more than one $x$. In its basic syntax, bvp4c is designed to solve two-point BVPs, i.e., problems where the solution sought on an interval $[a, b]$ must satisfy the boundary conditions

$$
g(y(a), y(b))=0
$$

Unlike initial value problems, a boundary value problem may not have a solution, may have a finite number of solutions, or may have infinitely many solutions. As an integral part of the process of solving a BVP, you need to provide a guess for the required solution. The quality of this guess can be critical for the solver performance and even for a successful computation.

There may be other difficulties when solving BVPs, such as problems imposed on infinite intervals or problems that involve singular coefficients. Often BVPs involve unknown parameters $p$ that have to be determined as part of solving the problem

$$
\begin{aligned}
& y^{\prime}=f(x, y, p) \\
& g(y(a), y(b), p)=0
\end{aligned}
$$

In this case, the boundary conditions must suffice to determine the value of $p$.

## BVP Solver

- "The BVP Solver" on page 10-61
- "BVP Solver Syntax" on page 10-62
- "BVP Solver Options" on page 10-64

## The BVP Solver

The function bvp4c solves two-point boundary value problems for ordinary differential equations (ODEs). It integrates a system of first-order ordinary differential equations

$$
y^{\prime}=f(x, y)
$$

on the interval $[a, b]$, subject to general two-point boundary conditions

$$
b c(y(a), y(b))=0
$$

It can also accommodate other types of BVP problems, such as those that have any of the following:

- Unknown parameters
- Singularities in the solutions
- Multipoint conditions

In this case, the number of boundary conditions must be sufficient to determine the solution and the unknown parameters.
bvp4c produces a solution that is continuous on [ $a, b$ ] and has a continuous first derivative there. You can use the function deval and the output of bvp4c to evaluate the solution at specific points on the interval of integration.
bvp4c is a finite difference code that implements the 3 -stage Lobatto IIIa formula. This is a collocation formula and the collocation polynomial provides a $\mathrm{C}^{1}$-continuous solution that is fourth-order accurate uniformly in the interval of integration. Mesh selection and error control are based on the residual of the continuous solution.

The collocation technique uses a mesh of points to divide the interval of integration into subintervals. The solver determines a numerical solution by solving a global system of algebraic equations resulting from the boundary conditions, and the collocation conditions imposed on all the subintervals. The solver then estimates the error of the numerical solution on each subinterval. If the solution does not satisfy the tolerance criteria, the solver adapts the mesh and repeats the process. The user must provide the points of the initial mesh as well as an initial approximation of the solution at the mesh points.

## BVP Solver Syntax

The basic syntax of the BVP solver is

```
sol = bvp4c(odefun,bcfun,solinit)
```

The input arguments are
odefun Handle to a function that evaluates the differential equations. It has the basic form

$$
d y d x=\operatorname{odefun}(x, y)
$$

where x is a scalar, and dydx and y are column vectors. See "Function Handles" in MATLAB Programming Fundamentals for more information. odefun can also accept a vector of unknown parameters and a variable number of known parameters, (see "BVP Solver Options" on page 10-64).

```
bcfun Handle to a function that evaluates the residual in the
    boundary conditions. It has the basic form
res = bcfun(ya,yb)
where ya and yb are column vectors representing y(a) and
y(b), and res is a column vector of the residual in satisfying
the boundary conditions. bcfun can also accept a vector
of unknown parameters and a variable number of known
parameters, (see "BVP Solver Options" on page 10-64).
solinit Structure with fields x and y:
x
Ordered nodes of the initial mesh. Boundary
conditions are imposed at a= solinit.x(1)
and b = solinit.x(end).
y
Initial guess for the solution with solinit.y(:,i) a guess for the solution at the node solinit.x(i).
The structure can have any name, but the fields must be named \(x\) and \(y\). It can also contain a vector that provides an initial guess for unknown parameters. You can form solinit with the helper function bvpinit. See the bvpinit reference page for details.
```

The output argument sol is a structure created by the solver. In the basic case the structure has fields $x, y, y p$, and solver.

```
sol.x Nodes of the mesh selected by bvp4c
sol.y Approximation to y(x) at the mesh points of sol.x
sol.yp Approximation to }\mp@subsup{y}{}{\prime}(x)\mathrm{ at the mesh points of sol.x
sol.solver 'bvp4c'
```

The structure sol returned by bvp4c contains an additional field if the problem involves unknown parameters:
sol.parameters Value of unknown parameters, if present, found by the solver.

The function deval uses the output structure sol to evaluate the numerical solution at any point from [a, b].

## BVP Solver Options

For more advanced applications, you can specify solver options by passing an input argument options.

| options | Structure of optional parameters that change the default <br> integration properties. This is the fourth input argument. <br> sol = bvp4c (odefun, bcfun, solinit, options) |
| :--- | :--- |
|  | You can create the structure options using the function <br> bvpset. The bvpset reference page describes the <br> properties you can specify. |

## Integrator Options

The default integration properties in the BVP solver bvp4c are selected to handle common problems. In some cases, you can improve solver performance by overriding these defaults. You do this by supplying bvp4c with an options structure that specifies one or more property values.

For example, to change the value of the relative error tolerance of bvp4c from the default value of $1 \mathrm{e}-3$ to $1 \mathrm{e}-4$,

1 Create an options structure using the function bvpset by entering

```
options = bvpset('RelTol', 1e-4);
```

2 Pass the options structure to bvp4c as follows:

```
sol = bvp4c(odefun,bcfun,solinit,options)
```

For a complete description of the available options, see the reference page for bvpset.

## Examples

- "Mathieu's Equation" on page 10-65
- "Continuation" on page 10-69
- "Singular BVPs" on page 10-77
- "Multipoint BVPs" on page 10-81
- "Additional Examples" on page 10-85

## Mathieu's Equation

- "Solving the Problem" on page 10-65
- "Finding Unknown Parameters" on page 10-69
- "Evaluating the Solution" on page 10-69

Solving the Problem. This example determines the fourth eigenvalue of Mathieu's Equation. It illustrates how to write second-order differential equations as a system of two first-order ODEs and how to use bvp4c to determine an unknown parameter $\lambda$.

The task is to compute the fourth $(q=5)$ eigenvalue lambda $\lambda$ of Mathieu's equation

$$
y^{\prime \prime}+(\lambda-2 q \cos 2 x) y=0
$$

Because the unknown parameter $\lambda$ is present, this second-order differential equation is subject to three boundary conditions

$$
\begin{aligned}
y(0) & =1 \\
y^{\prime}(0) & =0 \\
y^{\prime}(\pi) & =0
\end{aligned}
$$

Note The demo mat4bvp contains the complete code for this example. The demo uses nested functions to place all functions required by bvp4c in a single MATLAB file. To run this example type mat4bvp at the command line. See "BVP Solver Syntax" on page 10-62 for more information.

1 Rewrite the problem as a first-order system. To use bvp4c, you must rewrite the equations as an equivalent system of first-order differential equations. Using a substitution $y_{1}=y$ and $y_{2}=y^{\prime}$, the differential equation is written as a system of two first-order equations

$$
\begin{aligned}
& y_{1}^{\prime}=y_{2} \\
& y_{2}^{\prime}=-(\lambda-2 q \cos 2 x) y_{1}
\end{aligned}
$$

Note that the differential equations depend on the unknown parameter $\lambda$. The boundary conditions become

$$
\begin{aligned}
y_{1}(0)-1 & =0 \\
y_{2}(0) & =0 \\
y_{2}(\pi) & =0
\end{aligned}
$$

2 Code the system of first-order ODEs. Once you represent the equation as a first-order system, you can code it as a function that bvp4c can use. Because there is an unknown parameter, the function must be of the form

```
dydx = odefun(x,y,parameters)
```

The following code represents the system in the function, mat4ode. Variable $q$ is shared with the outer function:

```
function dydx = mat4ode(x,y,lambda)
dydx = [ y(2)
    -(lambda - 2*q*}\operatorname{cos(2*x))*y(1) ];
end % End nested function mat4ode
```

3 Code the boundary conditions function. You must also code the boundary conditions in a function. Because there is an unknown parameter, the function must be of the form

```
res = bcfun(ya,yb,parameters)
```

The code below represents the boundary conditions in the function, mat4bc.

```
function res = mat4bc(ya,yb,lambda)
res = [ ya(2)
    yb(2)
    ya(1)-1 ];
```

4 Create an initial guess. To form the guess structure solinit with bvpinit, you need to provide initial guesses for both the solution and the unknown parameter.

The function mat4init provides an initial guess for the solution. mat4init uses $y=\cos 4 x$ because this function satisfies the boundary conditions and has the correct qualitative behavior (the correct number of sign changes).

```
function yinit = mat4init(x)
yinit = [ cos(4*x)
    -4*sin(4*x) ];
```

In the call to bvpinit, the third argument, lambda, provides an initial guess for the unknown parameter $\lambda$.

```
lambda = 15;
solinit = bvpinit(linspace(0,pi,10),@mat4init,lambda);
```

This example uses @ to pass mat4init as a function handle to bvpinit.

Note See the function_handle (@), func2str, and str2func reference pages, and see "Function Handles" in MATLAB Programming Fundamentals.

5 Apply the BVP solver. The mat4bvp example calls bvp4c with the functions mat4ode and mat4bc and the structure solinit created with bvpinit.

```
sol = bvp4c(@mat4ode,@mat4bc,solinit);
```

6 View the results. Complete the example by displaying the results:
a Print the value of the unknown parameter $\lambda$ found by bvp4c.

```
fprintf('Fourth eigenvalue is approximately %7.3f.\n',...
    sol.parameters)
```

b Use deval to evaluate the numerical solution at 100 equally spaced points in the interval $[0, \pi]$, and plot its first component. This component approximates $y(x)$.

```
xint = linspace(0,pi);
Sxint = deval(sol,xint);
plot(xint,Sxint(1,:))
axis([0 pi -1 1.1])
title('Eigenfunction of Mathieu''s equation.')
xlabel('x')
ylabel('solution y')
```

The following plot shows the eigenfunction associated with the final eigenvalue $\lambda=17.097$.

Eigenunction of Mathieu's equation.

Finding Unknown Parameters. The bvp4c solver can find unknown parameters $p$ for problems of the form

$$
\begin{aligned}
& y^{\prime}=f(x, y, p) \\
& b c(y(a), y(b), p)=0
\end{aligned}
$$

You must provide bvp4c an initial guess for any unknown parameters in the vector solinit. parameters. When you call bvpinit to create the structure solinit, specify the initial guess as a vector in the additional argument parameters.

```
solinit = bvpinit(x,v,parameters)
```

The bvp4c function arguments odefun and bcfun must each have a third argument.

```
dydx = odefun(x,y,parameters)
res = bcfun(ya,yb,parameters)
```

While solving the differential equations, bvp4c adjusts the value of unknown parameters to satisfy the boundary conditions. The solver returns the final values of these unknown parameters in sol.parameters.

Evaluating the Solution. The collocation method implemented in bvp4c produces a $\mathrm{C}^{1}$-continuous solution over the whole interval of integration $[a, b]$. You can evaluate the approximate solution, $S(x)$, at any point in [ $a, b$ ] using the helper function deval and the structure sol returned by bvp4c.

```
Sxint = deval(sol,xint)
```

The deval function is vectorized. For a vector xint, the ith column of Sxint approximates the solution $y$ (xint(ii)).

## Continuation

- "Introduction" on page 10-70
- "Using Continuation to Solve a BVP" on page 10-70
- "Using Continuation to Verify Consistency" on page 10-73

Introduction. To solve a boundary value problem, you need to provide an initial guess for the solution. The quality of your initial guess can be critical to the solver performance, and to being able to solve the problem at all. However, coming up with a sufficiently good guess can be the most challenging part of solving a boundary value problem. Certainly, you should apply the knowledge of the problem's physical origin. Often a problem can be solved as a sequence of relatively simpler problems, i.e., a continuation.

This example shows how to use continuation to:

- Solve a difficult BVP
- Verify a solution's consistent behavior

Using Continuation to Solve a BVP. This example solves the differential equation

$$
\varepsilon y^{\prime \prime}+x y^{\prime}=\varepsilon \pi^{2} \cos (\pi x)-\pi x \sin (\pi x)
$$

for $\varepsilon=10^{-4}$, on the interval [-11], with boundary conditions $y(-1)=-2$ and $y(1)=0$. For $0<\varepsilon<1$, the solution has a transition layer at $x=0$. Because of this rapid change in the solution for small values of $\varepsilon$, the problem becomes difficult to solve numerically.

The example solves the problem as a sequence of relatively simpler problems, i.e., a continuation. The solution of one problem is used as the initial guess for solving the next problem.

Note The demo shockbvp contains the complete code for this example. The demo uses nested functions to place all required functions in a single MATLAB file. To run this example type shockbvp at the command line.

Note This problem appears in [1] to illustrate the mesh selection capability of a well established BVP code COLSYS.

1 Code the ODE and boundary condition functions. Code the differential equation and the boundary conditions as functions that bvp4c can use:

The code below represents the differential equation and the boundary conditions in the functions shockODE and shockBC. Note that shockODE is vectorized to improve solver performance. The additional parameter $\varepsilon_{\varepsilon}$ is represented by e and is shared with the outer function.

```
function dydx = shockODE(x,y)
pix = pi*x;
dydx = [ y(2,:)
    -x/e.*y(2,:) - pi^2*cos(pix) - pix/e.*sin(pix) ];
end % End nested function shockODE
function res = shockBC(ya,yb)
res = [ ya(1)+2
    yb(1) ];
end % End nested function shockBC
```

2 Provide analytical partial derivatives. For this problem, the solver benefits from using analytical partial derivatives. The code below represents the derivatives in functions shockJac and shockBCJac.

```
function jac = shockJac(x,y)
jac = [ 0 1
    0 -x/e ];
end % End nested function shockJac
function [dBCdya,dBCdyb] = shockBCJac(ya,yb)
dBCdya = [ 1 0
    0 0 ];
dBCdyb = [ 0 0
    1 0 ];
end % End nested function shockBCJac
```

shockJac shares e with the outer function.
Tell bvp4c to use these functions to evaluate the partial derivatives by setting the options FJacobian and BCJacobian. Also set 'Vectorized'
to 'on' to indicate that the differential equation function shockODE is vectorized.

```
options = bvpset('FJacobian',@shockJac,...
    'BCJacobian',@shockBCJac,...
    'Vectorized','on');
```

3 Create an initial guess. You must provide bvp4c with a guess structure that contains an initial mesh and a guess for values of the solution at the mesh points. A constant guess of $y(x) \equiv 1$ and $y^{\prime}(x) \equiv 0$, and a mesh of five equally spaced points on $[-11]$ suffice to solve the problem for $\varepsilon=10^{-2}$. Use bvpinit to form the guess structure.

```
sol = bvpinit([-1 -0.5 0 0.5 1],[1 0]);
```

4 Use continuation to solve the problem. To obtain the solution for the parameter $_{\varepsilon}=10^{-4}$, the example uses continuation by solving a sequence of problems for $\varepsilon=10^{-2}, 10^{-3}, 10^{-4}$. The solver bvp4c does not perform continuation automatically, but the code's user interface has been designed to make continuation easy. The code uses the output sol that bvp4c produces for one value of $e$ as the guess in the next iteration.

```
e = 0.1;
for i=2:4
    e = e/10;
    sol = bvp4c(@shockODE,@shockBC,sol,options);
end
```

5 View the results. Complete the example by displaying the final solution

```
plot(sol.x,sol.y(1,:))
axis([-1 1 -2.2 2.2])
title(['There is a shock at x = O when \epsilon = '...
    sprintf('%.e',e) '.'])
xlabel('x')
ylabel('solution y')
```

Using Continuation to Verify Consistency. Falkner-Skan BVPs arise from similarity solutions of viscous, incompressible, laminar flow over a flat plate. An example is

$$
f^{\prime \prime}+f f^{\prime}+\beta\left(1-\left(f^{\prime}\right)^{2}\right)=0
$$

for $\beta=0.5$ on the interval $[0, \infty)$ with boundary conditions $f(0)=0, f^{\prime}(0)=0$, and $f^{\prime}(\infty)=1$.

The BVP cannot be solved on an infinite interval, and it would be impractical to solve it for even a very large finite interval. So, the example tries to solve a sequence of problems posed on increasingly larger intervals to verify the solution's consistent behavior as the boundary approaches ${ }_{\infty}$.

The example imposes the infinite boundary condition at a finite point called infinity. The example then uses continuation in this end point to get convergence for increasingly larger values of infinity. It uses bvpinit to extrapolate the solution sol for one value of infinity as an initial guess for the new value of infinity. The plot of each successive solution is
superimposed over those of previous solutions so they can easily be compared for consistency.

Note The demo fsbvp contains the complete code for this example. The demo uses nested functions to place all required functions in a single MATLAB file. To run this example type fsbvp at the command line.

1 Code the ODE and boundary condition functions. Code the differential equation and the boundary conditions as functions that bvp4c can use. The problem parameter beta is shared with the outer function.

```
function dfdeta = fsode(eta,f)
dfdeta = [ f(2)
    f(3)
    -f(1)*f(3) - beta*(1 - f(2)^2) ];
end % End nested function fsode
function res = fsbc(f0,finf)
res = [f0(1)
    f0(2)
    finf(2) - 1];
end % End nested function fsbc
```

2 Create an initial guess. You must provide bvp4c with a guess structure that contains an initial mesh and a guess for values of the solution at the mesh points. A crude mesh of five points and a constant guess that satisfies the boundary conditions are good enough to get convergence when infinity $=3$.

```
infinity = 3;
maxinfinity = 6;
solinit = bvpinit(linspace(0,infinity,5),[0 0 1]);
```

3 Solve on the initial interval. The example obtains the solution for infinity $=3$. It then prints the computed value of $f^{\prime}(0)$ for comparison with the value reported by Cebeci and Keller [2]:

```
sol = bvp4c(@fsode,@fsbc,solinit);
```

```
eta = sol.x;
f = sol.y;
fprintf('\n');
fprintf('Cebeci & Keller report that f''''(0) = 0.92768.\n')
fprintf('Value computed using infinity = %g is %7.5f.\n', ...
    infinity,f(3,1))
```

The example prints

```
Cebeci & Keller report that f''(0) = 0.92768.
Value computed using infinity = 3 is 0.92915.
```

4 Setup the figure and plot the initial solution.

```
figure
plot(eta,f(2,:),eta(end),f(2,end),'o');
axis([0 maxinfinity 0 1.4]);
title('Falkner-Skan equation, positive wall shear, ...
    \beta = 0.5.')
xlabel('\eta')
ylabel('df/d\eta')
hold on
drawnow
shg
```

5 Use continuation to solve the problem and plot subsequent solutions. The example then solves the problem for infinity $=4,5,6$. It uses bvpinit to extrapolate the solution sol for one value of infinity as an initial guess for the next value of infinity. For each iteration, the example prints the computed value of $f^{\prime}(0)$ and superimposes a plot of the solution in the existing figure.

```
for Bnew = infinity+1:maxinfinity
    solinit = bvpinit(sol,[0 Bnew]); % Extend solution to Bnew.
    sol = bvp4c(@fsode,@fsbc,solinit);
    eta = sol.x;
    f = sol.y;
    fprintf('Value computed using infinity = %g is %7.5f.\n', ...
        Bnew,f(3,1))
    plot(eta,f(2,:),eta(end),f(2,end), 'o');
    drawnow
end
hold off
```

The example prints

```
Value computed using infinity = 4 is 0.92774.
Value computed using infinity = 5 is 0.92770.
Value computed using infinity = 6 is 0.92770.
```

Note that the values approach 0.92768 as reported by Cebeci and Keller. The superimposed plots confirm the consistency of the solution's behavior.

## Singular BVPs

- "Introduction" on page 10-77
- "Emden's equation" on page 10-78

Introduction. The function bvp4c solves a class of singular BVPs of the form

$$
\begin{align*}
y^{\prime} & =\frac{1}{x} S y+f(x, y) \\
0 & =g(y(0), y(b)) \tag{10-1}
\end{align*}
$$

It can also accommodate unknown parameters for problems of the form

$$
\begin{aligned}
y^{\prime} & =\frac{1}{x} S y+f(x, y, p) \\
0 & =g(y(0), y(b), p)
\end{aligned}
$$

Singular problems must be posed on an interval $[0, b]$ with $b>0$. Use bvpset to pass the constant matrix $S$ to bvp4c as the value of the 'SingularTerm' integration property. Boundary conditions at $x_{x}=0$ must be consistent with the necessary condition for a smooth solution, $S y(0)=0$. An initial guess should also satisfy this necessary condition.

When you solve a singular BVP using

```
sol = bvp4c(@odefun,@bcfun,solinit,options)
```

bvp4c requires that your function odefun $(x, y)$ return only the value of the $f(x, y)$ term in Equation 5-2.

Emden's equation. Emden's equation arises in modeling a spherical body of gas. The PDE of the model is reduced by symmetry to the ODE

$$
y^{\prime \prime}+\frac{2}{x} y^{\prime}+y^{5}=0
$$

on an interval $[0,1]$. The coefficient $2 / x$ is singular at $x=0$, but symmetry implies the boundary condition $y^{\prime}(0)=0$. With this boundary condition, the term

$$
\frac{2}{x} y^{\prime}(0)
$$

is well-defined as $x$ approaches 0 . For the boundary condition $y(1)=\sqrt{3} / 2$, this BVP has the analytical solution

$$
y(x)=\left(1+\frac{x^{2}}{3}\right)^{-1 / 2}
$$

Note The demo emdenbvp contains the complete code for this example. The demo uses subfunctions to place all required functions in a single MATLAB file. To run this example type emdenbvp at the command line.

1 Rewrite the problem as a first-order system and identify the singular term. Using a substitution $y_{1}=y$ and $y_{2}=y^{\prime}$, write the differential equation as a system of two first-order equations

$$
\begin{aligned}
& y_{1}^{\prime}=y_{2} \\
& y_{2}^{\prime}=-\frac{2}{x} y_{2}-y_{1}^{5}
\end{aligned}
$$

The boundary conditions become

$$
\begin{gathered}
y_{2}(0)=0 \\
y_{1}(1)=\sqrt{3} / 2
\end{gathered}
$$

Writing the ODE system in a vector-matrix form

$$
\left[\begin{array}{l}
y_{1}{ }^{\prime} \\
y_{2}{ }^{\prime}
\end{array}\right]=\frac{1}{x}\left[\begin{array}{cc}
0 & 0 \\
0 & -2
\end{array}\right]\left[\begin{array}{l}
y_{1} \\
y_{2}
\end{array}\right]+\left[\begin{array}{c}
y_{2} \\
-y_{1}^{5}
\end{array}\right]
$$

the terms of Equation 5-2 are identified as

$$
S=\left[\begin{array}{cc}
0 & 0 \\
0 & -2
\end{array}\right]
$$

and

$$
f(x, y)=\left[\begin{array}{c}
y_{2} \\
-y_{1}^{5}
\end{array}\right]
$$

2 Code the ODE and boundary condition functions. Code the differential equation and the boundary conditions as functions that bvp4c can use.

```
function dydx = emdenode(x,y)
dydx = [ y(2)
    -y(1)^5 ];
function res = emdenbc(ya,yb)
res = [ ya(2)
    yb(1) - sqrt(3)/2 ];
```

3 Setup integration properties. Use the matrix as the value of the 'SingularTerm' integration property.

```
S = [0,0;0,-2];
options = bvpset('SingularTerm',S);
```

4 Create an initial guess. This example starts with a mesh of five points and a constant guess for the solution.

$$
\begin{aligned}
& y_{1}(x) \equiv \sqrt{3} / 2 \\
& y_{2}(x) \equiv 0
\end{aligned}
$$

Use bvpinit to form the guess structure

```
guess = [sqrt(3)/2;0];
solinit = bvpinit(linspace(0,1,5),guess);
```

5 Solve the problem. Use the standard bvp4c syntax to solve the problem.

```
sol = bvp4c(@emdenode,@emdenbc,solinit,options);
```

6 View the results. This problem has an analytical solution

$$
y(x)=\left(1+\frac{x^{2}}{3}\right)^{-1 / 2}
$$

The example evaluates the analytical solution at 100 equally spaced points and plots it along with the numerical solution computed using bvp4c.

```
x = linspace(0,1);
truy = 1 ./ sqrt(1 + (x.^2)/3);
plot(x,truy,sol.x,sol.y(1,:),'ro');
title('Emden problem -- BVP with singular term.')
legend('Analytical','Computed');
xlabel('x');
ylabel('solution y');
```

## Multipoint BVPs

In multipoint boundary value problems, the solution of interest satisfies conditions at points inside the interval of integration. The bvp4c function is useful in solving such problems.

The following example shows how the multipoint capability in bvp4c can improve efficiency when you are solving a nonsmooth problem. The following equations are solved on $0 \leq x \leq \lambda$ for constant parameters $n, \kappa, \lambda>1$, and $\eta=\lambda^{2} /\left(\mathrm{n} \times \kappa^{2}\right)$. These are subject to boundary conditions $v(0)=0$ and $C(\lambda)=1:$

```
v' = (C - 1)/n
C' = (v * C - min(x,1))/\eta
```

The term $\min (x, 1)$ is not smooth at $x c=1$, and this can affect the solver's efficiency. By introducing an interface point at $x c=1$, smooth solutions can be obtained on $[0,1]$ and $[1, \lambda]$. To get a continuous solution over the entire interval $[0, \lambda]$, the example imposes matching conditions at the interface.

Note The demo threebvp contains the complete code for this example and solves the problem for $\lambda=2, n=0.05$, and several values of $\kappa$. The demo uses nested functions to place all functions required by bvp4c in a single MATLAB file and to communicate problem parameters efficiently. To run this example, type threebvp at the MATLAB command prompt.

The demo takes you through the following steps:
1 Determine the interfaces and divide the interval of integration into regions. Introducing an interface point at $\mathrm{xc}=1$ divides the problem into two regions in which the solutions remain smooth. The differential equations for the two regions are

Region 1: $0 \leq x \leq 1$

$$
\begin{aligned}
& v^{\prime}=(C-1) / n \\
& C^{\prime}=(v * C-x) / \eta
\end{aligned}
$$

Region 2: $1 \leq x \leq \lambda$

```
v' = (C - 1)/n
C' = (v * C - 1)/\eta
```

Note that the interface $\mathrm{xc}=1$ is included in both regions. At $\mathrm{xc}=1$, bvp4c produces a left and right solution. These solutions are denoted as $\mathrm{v}(1-), \mathrm{C}(1-)$ and $\mathrm{v}(1+), \mathrm{C}(1+)$ respectively.

2 Determine the boundary conditions. Solving two first-order differential equations in two regions requires imposing four boundary conditions. Two of these conditions come from the original formulation; the others enforce the continuity of the solution across the interface xc $=1$ :

```
v(0) = 0
C(\lambda)-1 = 0
```

```
v(1-) - v(1+) = 0
C(1-) - C(1+) = 0
```

Here, $v(1-), C(1-)$ and $v(1+), C(1+)$ denote the left and right solution at the interface.

3 Code the derivative function. In the derivative function, $y(1)$ corresponds to $\mathrm{V}(\mathrm{x})$, and $\mathrm{y}(2)$ corresponds to $\mathrm{C}(\mathrm{x})$. The additional input argument region identifies the region in which the derivative is evaluated. bvp4c enumerates regions from left to right, starting with 1 . Note that the problem parameters $n$ and $\eta$ are shared with the outer function:

```
function dydx = f(x,y,region)
    dydx = zeros(2,1);
    dydx(1) = (y(2) - 1)/n;
    % The definition of C'(x) depends on the region.
    switch region
        case 1 % x in [0 1]
            dydx(2)=(y(1)*y(2)-x)/\eta;
        case 2 % x in [11 \lambda]
            dydx(2) = (y(1)*y(2) - 1)/\eta;
    end
end % End nested function f
```

4 Code the boundary conditions function. For multipoint BVPs, the arguments of the boundary conditions function, YL and YR, become matrices. In particular, the kth column YL(: ,k) represents the solution at the left boundary of the kth region. Similarly, YR (: , k) represents the solution at the right boundary of the kth region.

In the example, $\mathrm{y}(0)$ is approximated by $\mathrm{YL}(:, 1)$, while $\mathrm{y}(\lambda)$ is approximated by YR (: , end). Continuity of the solution at the internal interface requires that $Y R(:, 1)=Y L(:, 2)$. Nested function bc computes the residual in the boundary conditions:

```
function res = bc(YL,YR)
    res = [YL(1,1) % v(0) = 0
            YR(1,1) - YL(1,2) % Continuity of v(x) at x=1
            YR(2,1) - YL(2,2) % Continuity of C(x) at x=1
```

```
    YR(2,end) - 1]; %C(\lambda) = 1
end
% End nested function bc
```

5 Create an initial guess. For multipoint BVPs, when creating an initial guess using bvpinit, use double entries in xinit for the interface point xc. This example uses a constant guess yinit = [1;1]:

```
xc = 1;
xinit = [0, 0.25, 0.5, 0.75, xc, xc, 1.25, 1.5, 1.75, 2];
solinit = bvpinit(xinit,yinit)
```

For multipoint BVPs, you can use different guesses in different regions. To do that, you specify the initial guess for $y$ as a function using the following syntax:

```
solinit = bvpinit(xinit,@yinitfen)
```

The initial guess function must have the following general form:

```
function y = yinitfcn(x,region)
    switch region
    case 1 % x in [0, 1]
        y = [1;1]; % initial guess for y(x) 0 \leqx\leq1
    case 2 % x in [1, \lambda]
        y = [1;1]; % initial guess for y(x), 1\leqx\leq\lambda
end
```

6 Apply the solver. The bvp4c function uses the same syntax for multipoint BVPs as it does for two-point BVPs:

```
sol = bvp4c(@f,@bc,solinit);
```

The mesh points returned in sol.x are adapted to the solution behavior, but the mesh still includes a double entry for the interface point xc $=1$. Corresponding columns of sol.y represent the left and right solution at xc.

7 View the results. Using deval, the solution can be evaluated at any point in the interval of integration.

Note that, with the left and right values computed at the interface, the solution is not uniquely defined at $\mathrm{xc}=1$. When evaluating the solution
exactly at the interface, deval issues a warning and returns the average of the left and right solution values. Call deval at xc-eps (xc) and $\mathrm{xc}+\mathrm{eps}(\mathrm{xc})$ to get the limit values at xc .

The example plots the solution approximated at the mesh points selected by the solver:

```
plot(sol.x,sol.y(1,:),sol.x,sol.y(2,:),'--')
legend('v(x)','C(x)')
title('A three-point BVP solved with BVP4C')
xlabel(['\\lambda = ',num2str( }\lambda\mathrm{ ), ...
    ', \}\mp@subsup{\textrm{K}}{~}{\prime}=',num2str(\kappa),'.']
ylabel('v and C')
```

## Additional Examples

The following additional examples are available. Type

```
edit examplename
```

to view the code and
examplename
to run the example.

| Example Name | Description |
| :--- | :--- |
| emdenbvp | Emden's equation, a singular BVP |
| fsbvp | Falkner-Skan BVP on an infinite interval |
| mat4bvp | Fourth eigenfunction of Mathieu's equation |
| shockbvp | Solution with a shock layer near $\mathrm{x}=0$ |
| twobvp | BVP with exactly two solutions |
| threebvp | Three-point boundary value problem |

Additional examples are provided by "Tutorial on Solving BVPs with BVP4C," available at http://www.mathworks.com/bvp_tutorial.

- "PDE Helper Function" on page 10-87

## PDE Solver

This is the MATLAB PDE solver.

| PDE <br> Initial-Boundary <br> Value Problem <br> Solver | Description |
| :--- | :--- |
| pdepe | Solve initial-boundary value problems for systems <br> of parabolic and elliptic PDEs in one space variable <br> and time. |

## PDE Helper Function

| PDE Helper Function | Description |
| :--- | :--- |
| pdeval | Evaluate the numerical solution of a PDE using <br> the output of pdepe. |

## Initial Value Problems

pdepe solves systems of parabolic and elliptic PDEs in one spatial variable $x$ and time $t$, of the form

$$
\begin{equation*}
=\left(x, t, u, \frac{\partial u}{\partial x}\right) \frac{\partial u}{\partial t}=x^{-m} \frac{\partial}{\partial x}\left(x^{m} f\left(x, t, u, \frac{\partial u}{\partial x}\right)\right)+s\left(x, t, u, \frac{\partial u}{\partial x}\right) \tag{10-2}
\end{equation*}
$$

The PDEs hold for $t_{0} \leq t \leq t_{f}$ and $a \leq x \leq b$. The interval [ $a, b$ ] must be finite. $m$ can be 0,1 , or 2 , corresponding to slab, cylindrical, or spherical symmetry, respectively. If $m>0$, then $a \geq 0$ must also hold.

In Equation 10-2, $f(x, t, u, \partial u / \partial x)$ is a flux term and $s(x, t, u, \partial u / \partial x)$ is a source term. The flux term must depend on $\partial u / \partial x$. The coupling of the partial derivatives with respect to time is restricted to multiplication by a diagonal matrix $c(x, t, u, \partial u / \partial x)$. The diagonal elements of this matrix are either identically zero or positive. An element that is identically zero corresponds to an elliptic equation and otherwise to a parabolic equation. There must be at least one parabolic equation. An element of $c$ that corresponds to a parabolic equation can vanish at isolated values of $x$ if they are mesh points. Discontinuities in $c$ and/or $s$ due to material interfaces are permitted provided that a mesh point is placed at each interface.

At the initial time $t=t_{0}$, for all $x$ the solution components satisfy initial conditions of the form

$$
\begin{equation*}
u\left(x, t_{0}\right)=u_{0}(x) \tag{10-3}
\end{equation*}
$$

At the boundary $x=a$ or $x=b$, for all $t$ the solution components satisfy a boundary condition of the form

$$
\begin{equation*}
p(x, t, u)+q(x, t) f\left(x, t, u, \frac{\partial u}{\partial x}\right)=0 \tag{10-4}
\end{equation*}
$$

$q(x, t)$ is a diagonal matrix with elements that are either identically zero or never zero. Note that the boundary conditions are expressed in terms of the $f$ rather than partial derivative of $u$ with respect to $x \partial u / \partial x$. Also, of the two coefficients, only $p$ can depend on $u$.

## PDE Solver

## The PDE Solver

The MATLAB PDE solver, pdepe, solves initial-boundary value problems for systems of parabolic and elliptic PDEs in the one space variable $x$ and time $t$. There must be at least one parabolic equation in the system.

The pdepe solver converts the PDEs to ODEs using a second-order accurate spatial discretization based on a fixed set of user-specified nodes. The discretization method is described in [9]. The time integration is done with ode15s. The pdepe solver exploits the capabilities of ode15s for solving the differential-algebraic equations that arise when Equation 10-2 contains elliptic equations, and for handling Jacobians with a specified sparsity pattern. ode15s changes both the time step and the formula dynamically.

After discretization, elliptic equations give rise to algebraic equations. If the elements of the initial conditions vector that correspond to elliptic equations are not "consistent" with the discretization, pdepe tries to adjust them before beginning the time integration. For this reason, the solution returned for the initial time may have a discretization error comparable to that at any other time. If the mesh is sufficiently fine, pdepe can find consistent initial conditions close to the given ones. If pdepe displays a message that it has difficulty finding consistent initial conditions, try refining the mesh. No adjustment is necessary for elements of the initial conditions vector that correspond to parabolic equations.

## PDE Solver Syntax

The basic syntax of the solver is:

```
sol = pdepe(m,pdefun,icfun,bcfun,xmesh,tspan)
```

Note Correspondences given are to terms used in "Initial Value Problems" on page 10-88.

The input arguments are

Specifies the symmetry of the problem. $m$ can be $0=$ slab, $1=$ cylindrical, or $2=$ spherical. It corresponds to $m$ in Equation 10-2.

Function that defines the components of the PDE. It computes the terms of $f$, and ${ }_{s}$ in Equation 10-2, and has the form

$$
[c, f, s]=\operatorname{pdefun}(x, t, u, d u d x)
$$

where $x$ and $t$ are scalars, and $u$ and dudx are vectors that approximate the solution $u$ and its partial derivative with respect to $x . \mathrm{c}, \mathrm{f}$, and s are column vectors. $c$ stores the diagonal elements of the matrix $c$

Function that evaluates the initial conditions. It has the form

$$
u=i c f u n(x)
$$

When called with an argument $x$, icfun evaluates and returns the initial values of the solution components at $x$ in the column vector $u$.

Function that evaluates the terms $p$ and $q$ of the boundary conditions. It has the form

$$
[p l, q l, p r, q r]=\operatorname{bcfun}(x l, u l, x r, u r, t)
$$

where $u l$ is the approximate solution at the left boundary $x l=a$ and ur is the approximate solution at the right boundary $x r=b . \mathrm{pl}$ and ql are column vectors corresponding to $p$ and the diagonal of $q$ evaluated at xl . Similarly, pr and qr correspond to xr . When $m>$ 0 and $a=0$, boundedness of the solution near $x=0$ requires that the $f$ vanish at $a=0$. pdepe imposes this boundary condition automatically and it ignores values returned in pl and ql .

| xmesh | Vector $[x 0, x 1, \ldots, x n]$ specifying the points at which a numerical solution is requested for every value in tspan. x0 and xn correspond to $a$ and $b$, respectively. |
| :---: | :---: |
|  | Second-order approximation to the solution is made on the mesh specified in xmesh. Generally, it is best to use closely spaced mesh points where the solution changes rapidly. pdepe does not select the mesh in $x$ automatically. You must provide an appropriate fixed mesh in xmesh. The cost depends strongly on the length of xmesh. When $m>0$, it is not necessary to use a fine mesh near $x=0$ to account for the coordinate singularity. |
|  | The elements of xmesh must satisfy $\mathrm{x} 0<\mathrm{x} 1<\ldots<\mathrm{xn}$. The length of xmesh must be $\geq 3$. |
| tspan | Vector [t0, t1, .., tf] specifying the points at which a solution is requested for every value in xmesh. t0 and tf correspond to $t_{0}$ and ${ }^{t} f$, respectively. |
|  | pdepe performs the time integration with an ODE solver that selects both the time step and formula dynamically. The solutions at the points specified in tspan are obtained using the natural continuous extension of the integration formulas. The elements of tspan merely specify where you want answers and the cost depends weakly on the length of tspan. |
|  | The elements of tspan must satisfy t0 $<\mathrm{t} 1<\ldots<\mathrm{tf}$. The length of tspan must be $\geq 3$. |

The output argument sol is a three-dimensional array, such that

- $\operatorname{sol}(:,:, \mathrm{k})$ approximates component k of the solution $u$.
- $\operatorname{sol}(i,:, k)$ approximates component $k$ of the solution at time tspan(i) and mesh points xmesh(:).
- $\operatorname{sol}(i, j, k)$ approximates component $k$ of the solution at time tspan(i) and the mesh point xmesh(j).

## PDE Solver Options

For more advanced applications, you can also specify as input arguments solver options and additional parameters that are passed to the PDE functions.

```
options Structure of optional parameters that change the
    default integration properties. This is the seventh input
    argument.
```

```
sol = pdepe(m,pdefun,icfun,bcfun,...
```

sol = pdepe(m,pdefun,icfun,bcfun,...
xmesh,tspan,options)

```
    xmesh,tspan,options)
```

See "Integrator Options" on page 10-92 for more information.

## Integrator Options

The default integration properties in the MATLAB PDE solver are selected to handle common problems. In some cases, you can improve solver performance by overriding these defaults. You do this by supplying pdepe with one or more property values in an options structure.

```
sol = pdepe(m,pdefun,icfun,bcfun,xmesh,tspan,options)
```

Use odeset to create the options structure. Only those options of the underlying ODE solver shown in the following table are available for pdepe. The defaults obtained by leaving off the input argument options are generally satisfactory. "Integrator Options" on page 10-9 tells you how to create the structure and describes the properties.

## PDE Properties

Solving the Equation. This example illustrates the straightforward formulation, solution, and plotting of the solution of a single PDE

$$
\pi^{2} \frac{\partial u}{\partial t}=\frac{\partial^{2} u}{\partial x^{2}}
$$

This equation holds on an interval $0 \leq x \leq 1$ for times $\mathrm{t} \geq 0$. At $t=0$, the solution satisfies the initial condition

$$
u(x, 0)=\sin \pi x
$$

At $x=0$ and $x=1$, the solution satisfies the boundary conditions

$$
\begin{aligned}
& u(0, t)=0 \\
& \pi e^{-t}+\frac{\partial u}{\partial x}(1, t)=0
\end{aligned}
$$

Note The demo pdex1 contains the complete code for this example. The demo uses subfunctions to place all functions it requires in a single MATLAB file. To run the demo type pdex1 at the command line. See "PDE Solver Syntax" on page 10-89 for more information.

1 Rewrite the PDE. Write the PDE in the form

$$
=\left(x, t, u, \frac{\partial u}{\partial x}\right) \frac{\partial u}{\partial t}=x^{-m} \frac{\partial}{\partial x}\left(x^{m} f\left(x, t, u, \frac{\partial u}{\partial x}\right)\right)+s\left(x, t, u, \frac{\partial u}{\partial x}\right)
$$

This is the form shown in Equation 10-2 and expected by pdepe. See "Initial Value Problems" on page $10-88$ for more information. For this example, the resulting equation is

$$
\pi^{2} \frac{\partial u}{\partial t}=x^{0} \frac{\partial}{\partial x}\left(x^{0} \frac{\partial u}{\partial x}\right)+0
$$

with parameter $m=0$ and the terms

$$
\begin{aligned}
& c\left(x, t, u, \frac{\partial u}{\partial x}\right)=\pi^{2} \\
& f\left(x, t, u, \frac{\partial u}{\partial x}\right)=\frac{\partial u}{\partial x} \\
& s\left(x, t, u, \frac{\partial u}{\partial x}\right)=0
\end{aligned}
$$

2 Code the PDE. Once you rewrite the PDE in the form shown above (Equation 10-2) and identify the terms, you can code the PDE in a function that pdepe can use. The function must be of the form

$$
[c, f, s]=\operatorname{pdefun}(x, t, u, d u d x)
$$

where $\mathrm{c}, \mathrm{f}$, and s correspond to the ${ }_{c} f$, and $s_{s}$ terms. The code below computes $\mathrm{c}, \mathrm{f}$, and s for the example problem.

```
function [c,f,s] = pdex1pde(x,t,u,DuDx)
c = pi^2;
f = DuDx;
s = 0;
```

3 Code the initial conditions function. You must code the initial conditions in a function of the form

$$
u=\operatorname{icfun}(x)
$$

The code below represents the initial conditions in the function pdex1ic.

```
function u0 = pdex1ic(x)
u0 = sin(pi*x);
```

4 Code the boundary conditions function. You must also code the boundary conditions in a function of the form

$$
[p l, q l, p r, q r]=\operatorname{bcfun}(x l, u l, x r, u r, t)
$$

The boundary conditions, written in the same form as Equation 10-4, are

$$
u(0, t)+0 \cdot \frac{\partial u}{\partial x}(0, t)=0 \quad \text { at } x=0
$$

and

$$
\pi e^{-t}+1 \cdot \frac{\partial u}{\partial x}(1, t)=0 \quad \text { at } x=1
$$

The code below evaluates the components $p(x, t, u)$ and $q(x, t)$ of the boundary conditions in the function pdex1bc.

```
function [pl,ql,pr,qr] = pdex1bc(xl,ul,xr,ur,t)
pl = ul;
ql = 0;
pr = pi * exp(-t);
qr = 1;
```

In the function $\mathrm{pdex} 1 \mathrm{bc}, \mathrm{pl}$ and ql correspond to the left boundary conditions ( $x=0$ ), and pr and qr correspond to the right boundary condition $x=1$.

5 Select mesh points for the solution. Before you use the MATLAB PDE solver, you need to specify the mesh points $(t, x)$ at which you want pdepe to evaluate the solution. Specify the points as vectors $t$ and $x$.

The vectors $t$ and $x$ play different roles in the solver (see "PDE Solver" on page $10-89$ ). In particular, the cost and the accuracy of the solution depend strongly on the length of the vector $x$. However, the computation is much less sensitive to the values in the vector $t$.

This example requests the solution on the mesh produced by 20 equally spaced points from the spatial interval $[0,1]$ and five values of $t$ from the time interval [0,2].

```
x = linspace(0,1,20);
t = linspace(0,2,5);
```

6 Apply the PDE solver. The example calls pdepe with $m=0$, the functions pdex1pde, pdex1ic, and pdex1bc, and the mesh defined by $x$ and $t$ at which pdepe is to evaluate the solution. The pdepe function returns the numerical solution in a three-dimensional array sol, where sol(i,j,k) approximates the kth component of the solution, $u_{k}$, evaluated at $\mathrm{t}(\mathrm{i})$ and $\mathrm{x}(\mathrm{j})$.

```
m = 0;
sol = pdepe(m,@pdex1pde,@pdex1ic,@pdex1bc,x,t);
```

This example uses @ to pass pdex1pde, pdex1ic, and pdex1bc as function handles to pdepe.

Note See the function_handle (@), func2str, and str2func reference pages, and the @ section of MATLAB Programming Fundamentals for information about function handles.

7 View the results. Complete the example by displaying the results:
a Extract and display the first solution component. In this example, the solution ${ }_{u}$ has only one component, but for illustrative purposes, the example "extracts" it from the three-dimensional array. The surface plot shows the behavior of the solution.

```
u = sol(:,:,1);
surf(x,t,u)
title('Numerical solution computed with 20 mesh points')
xlabel('Distance x')
ylabel('Time t')
```

b Display a solution profile at ${ }^{t_{f}}$, the final value of $t$. In this example, $t_{f}=t=2$.

```
figure
plot(x,u(end,:))
title('Solution at t = 2')
xlabel('Distance x')
ylabel('u(x,2)')
```

Evaluating the Solution. After obtaining and plotting the solution above, you might be interested in a solution profile for a particular value of $t$, or the time changes of the solution at a particular point $x$. The kth column $u(:, k)$ (of the solution extracted in step 7) contains the time history of the solution at $x(k)$. The $j$ th row $u(j,:)$ contains the solution profile at $t(j)$.

Using the vectors x and $\mathrm{u}(\mathrm{j},:)$, and the helper function pdeval, you can evaluate the solution $u$ and its derivative $\partial u / \partial x$ at any set of points xout

```
[uout,DuoutDx] = pdeval(m,x,u(j,:),xout)
```

The example pdex3 uses pdeval to evaluate the derivative of the solution at xout $=0$. See pdeval for details.

## System of PDEs

This example illustrates the solution of a system of partial differential equations. The problem is taken from electrodynamics. It has boundary layers at both ends of the interval, and the solution changes rapidly for small $t$.

The PDEs are

$$
\begin{aligned}
& \frac{\partial u_{1}}{\partial t}=0.024 \frac{\partial^{2} u_{1}}{\partial x^{2}}-F\left(u_{1}-u_{2}\right) \\
& \frac{\partial u_{2}}{\partial t}=0.170 \frac{\partial^{2} u_{2}}{\partial x^{2}}+F\left(u_{1}-u_{2}\right)
\end{aligned}
$$

where $F(y)=\exp (5.73 y)-\exp (-11.46 y)$. The equations hold on an interval 0 less than or equal to x less than or equal to $10 \leq x \leq 1$ for times $t \geq 0$

The solution ${ }_{u}$ satisfies the initial conditions

$$
\begin{aligned}
& u_{1}(x, 0) \equiv 1 \\
& u_{2}(x, 0) \equiv 0
\end{aligned}
$$

and boundary conditions

$$
\begin{aligned}
& \frac{\partial u_{1}}{\partial x}(0, t) \equiv 0 \\
& u_{2}(0, t) \equiv 0 \\
& u_{1}(1, t) \equiv 1 \\
& \frac{\partial u_{2}}{\partial x}(1, t) \equiv 0
\end{aligned}
$$

Note The demo pdex4 contains the complete code for this example. The demo uses subfunctions to place all required functions in a single MATLAB file. To run this example type pdex4 at the command line.

1 Rewrite the PDE. In the form expected by pdepe, the equations are

$$
\left[\begin{array}{l}
1 \\
1
\end{array}\right], * \frac{\partial}{\partial t}\left[\begin{array}{l}
u_{1} \\
u_{2}
\end{array}\right]=\frac{\partial}{\partial x}\left[\begin{array}{l}
0.024\left(\partial u_{1} / \partial x\right) \\
0.170\left(\partial u_{2} / \partial x\right)
\end{array}\right]+\left[\begin{array}{r}
-F\left(u_{1}-u_{2}\right) \\
F\left(u_{1}-u_{2}\right)
\end{array}\right]
$$

The boundary conditions on the partial derivatives of ${ }_{u}$ have to be written in terms of the flux. In the form expected by pdepe, the left boundary condition is

$$
\left[\begin{array}{c}
0 \\
u_{2}
\end{array}\right]+\left[\begin{array}{l}
1 \\
0
\end{array}\right] \cdot\left[\begin{array}{l}
0.024\left(\partial u_{1} / \partial x\right) \\
0.170\left(\partial u_{2} / \partial x\right)
\end{array}\right]=\left[\begin{array}{l}
0 \\
0
\end{array}\right]
$$

and the right boundary condition is

$$
\left[\begin{array}{c}
u_{1}-1 \\
0
\end{array}\right]+\left[\begin{array}{l}
0 \\
1
\end{array}\right] \cdot\left[\begin{array}{l}
0.024\left(\partial u_{1} / \partial x\right) \\
0.170\left(\partial u_{2} / \partial x\right)
\end{array}\right]=\left[\begin{array}{l}
0 \\
0
\end{array}\right]
$$

2 Code the PDE. After you rewrite the PDE in the form shown above, you can code it as a function that pdepe can use. The function must be of the form

$$
[c, f, s]=\operatorname{pdefun}(x, t, u, d u d x)
$$

where c, f , and scorrespond to the $\boldsymbol{c}, f$, and $s$ terms in Equation 10-2.

```
function [c,f,s] = pdex4pde(x,t,u,DuDx)
c = [1; 1];
f = [0.024; 0.17] .* DuDx;
y = u(1) - u(2);
F = exp(5.73*y)-exp(-11.47*y);
s = [-F; F];
```

3 Code the initial conditions function. The initial conditions function must be of the form

```
u = icfun(x)
```

The code below represents the initial conditions in the function pdex4ic.

```
function u0 = pdex4ic(x);
uO = [1; 0];
```

4 Code the boundary conditions function. The boundary conditions functions must be of the form

```
[pl,ql,pr,qr] = bcfun(xl,ul,xr,ur,t)
```

The code below evaluates the components $p(x, t, u)$ and $q(x, t)$ (Equation $10-4$ ) of the boundary conditions in the function pdex4bc.

```
function [pl,ql,pr,qr] = pdex4bc(xl,ul,xr,ur,t)
pl = [O; ul(2)];
ql = [1; 0];
pr = [ur(1)-1; 0];
qr = [0; 1];
```

5 Select mesh points for the solution. The solution changes rapidly for small $t$. The program selects the step size in time to resolve this sharp change, but to see this behavior in the plots, output times must be selected accordingly. There are boundary layers in the solution at both ends of $[0,1]$, so mesh points must be placed there to resolve these sharp changes. Often some experimentation is needed to select the mesh that reveals the behavior of the solution.

```
x = [0 0.005 0.01 0.05 0.1 0.2 0.5 0.7 0.9 0.95 0.99 0.995 1];
t = [0 0.005 0.01 0.05 0.1 0.5 1 1.5 2];
```

6 Apply the PDE solver. The example calls pdepe with $m=0$, the functions pdex4pde, pdex4ic, and pdex4bc, and the mesh defined by $x$ and $t$ at which pdepe is to evaluate the solution. The pdepe function returns the numerical solution in a three-dimensional array sol, where sol ( $i, j, k$ ) approximates the kth component of the solution, $u_{k}$, evaluated at t (i) and $\mathrm{x}(\mathrm{j})$.

```
m = 0;
sol = pdepe(m,@pdex4pde,@pdex4ic,@pdex4bc,x,t);
```

7 View the results. The surface plots show the behavior of the solution components.

```
u1 = sol(:,:,1);
u2 = sol(:,:,2);
```

```
figure
surf(x,t,u1)
title('u1(x,t)')
xlabel('Distance x')
```

ylabel('Time t')

```
figure
surf(x,t,u2)
title('u2(x,t)')
xlabel('Distance x')
ylabel('Time t')
```

## Additional Examples

## Integration

## In this section...

"Quadrature Functions" on page 10-106
"Example: Arc Length" on page 10-107
"Example: Double Integration" on page 10-107

## Quadrature Functions

The area beneath a section of a function $F(x)$ can be determined by numerically integrating $F(x)$, a process referred to as quadrature. The MATLAB quadrature functions are:

| quad | Use adaptive Simpson quadrature |
| :--- | :--- |
| quadl | Use adaptive Lobatto quadrature |
| quadgk | Use adaptive Gauss-Kronrod quadrature |
| quadv | Vectorized quadrature |
| quad2d | Numerically evaluate double integral over planar region |
| dblquad | Numerically evaluate double integral |
| triplequad | Numerically evaluate triple integral |

To integrate the function defined by humps.m from 0 to 1 , use

```
q = quad(@humps,0,1)
q =
    29.8583
```

Both quad and quadl operate recursively. If either method detects a possible singularity, it prints a warning.

You can include a fourth argument for quad or quadl that specifies an absolute error tolerance for the integration. If a nonzero fifth argument is passed to quad or quadl, the function evaluations are traced.

## Example: Arc Length

You can use quad or quadl to compute the length of a curve. Consider the curve parameterized by the equations

$$
x(t)=\sin (2 t), \quad y(t)=\cos (t), \quad z(t)=t
$$

where $t \in[0,3 \pi]$.
A three-dimensional plot of this curve is

```
t = 0:0.1:3*pi;
plot3(sin(2*t),\operatorname{cos(t),t)}
```

The arc length formula says the length of the curve is the integral of the norm of the derivatives of the parameterized equations

$$
\int_{0}^{3 \pi} \sqrt{4 \cos (2 t)^{2}+\sin (t)^{2}+1} d t
$$

The function hcurve computes the integrand

```
function f = hcurve(t)
f = sqrt(4* cos(2*t).^2 + sin(t).^2 + 1);
```

Integrate this function with a call to quad

```
len = quad(@hcurve,0,3*pi)
len =
    1.7222e+01
```

The length of this curve is about 17.2.

## Example: Double Integration

Consider the numerical solution of

$$
\int_{y \min }^{y \max } \int_{x \min }^{x \max } f(x, y) d x d y .
$$

For this example $f(x, y)=y \sin (x)+x \cos (y)$. The first step is to build the function to be evaluated. The function must be capable of returning a vector output when given a vector input. You must also consider which variable is in the inner integral, and which goes in the outer integral. In this example, the inner variable is $x$ and the outer variable is $y$ (the order in the integral is $d x d y$ ). In this case, the integrand function is

```
function out = integrnd(x,y)
out = y*sin(x) + x* cos(y);
```

To perform the integration, two functions are available in the funfun directory. The first, dblquad, is called directly from the command line. This function evaluates the outer loop using quad. At each iteration, quad calls the second helper function that evaluates the inner loop.

To evaluate the double integral, use

```
result = dblquad(@integrnd,xmin,xmax,ymin,ymax);
```

The first argument is a string with the name of the integrand function. The second to fifth arguments are

| xmin | Lower limit of inner integral |
| :--- | :--- |
| xmax | Upper limit of the inner integral |
| ymin | Lower limit of outer integral |
| $y \max$ | Upper limit of the outer integral |

Here is a numeric example that illustrates the use of dblquad.

```
xmin = pi;
xmax = 2*pi;
ymin = 0;
ymax = pi;
result = dblquad(@integrnd,xmin,xmax,ymin,ymax)
```

The result is -9.8698 .
By default, dblquad calls quad. To integrate the previous example using quadl (with the default values for the tolerance argument), use

```
result = dblquad(@integrnd,xmin,xmax,ymin,ymax,[],@quadl);
```

Alternatively, you can pass any user-defined quadrature function name to dblquad as long as the quadrature function has the same calling and return arguments as quad.

## Discrete Fourier Transform (DFT)

In this section...<br>"Introduction" on page 11-2<br>"Visualizing the DFT" on page 11-3

## Introduction

Spectral analysis is the process of identifying component frequencies in data. For discrete data, the computational basis of spectral analysis is the discrete Fourier transform (DFT). The DFT transforms time- or space-based data into frequency-based data.

The DFT of a vector $x$ of length $n$ is another vector $y$ of length $n$ :

$$
y_{p+1}=\sum_{j=0}^{n-1} \omega^{j p} x_{j+1}
$$

where $\omega$ is a complex $n$th root of unity:

$$
\omega=e^{-2 \pi i / n}
$$

This notation uses $i$ for the imaginary unit, and $p$ and $j$ for indices that run from 0 to $n-1$. The indices $p+1$ and $j+1$ run from 1 to $n$, corresponding to ranges associated with MATLAB vectors.

Data in the vector $x$ are assumed to be separated by a constant interval in time or space, $d t=1 / f_{s}$ or $d s=1 / f_{s}$, where $f_{s}$ is the sampling frequency. The DFT $y$ is complex-valued. The absolute value of $y$ at index $p+1$ measures the amount of the frequency $f=p\left(f_{s} / n\right)$ present in the data.

The first element of $y$, corresponding to zero frequency, is the sum of the data in $x$. This $D C$ component is often removed from $y$ so that it does not obscure the positive frequency content of the data.

## Visualizing the DFT

The documentation example function fftgui opens a graphical user interface that allows you to explore the real and imaginary parts of a data vector and its DFT. (Here fft refers to efficient computation of the DFT by the MATLAB fft function, as discussed in "Fast Fourier Transform (FFT)" on page 11-8.)

Note Documentation example files for MATLAB mathematics are located in the \help\techdoc \math \examples subfolder of your MATLAB root folder (matlabroot). This suibfolder is not on the MATLAB path at installation. To use the MATLAB files in this subfolder, either add the subfolder to the MATLAB path (addpath) or make the subfolder your current working folder (cd).

If $x$ is a vector,
fftgui(x)
plots the real and imaginary parts of both $x$ and its DFT (fft $(x)$ ). Use your mouse to drag points in any of the plots and the points in the other plots respond to the changes.

For example, use fftgui to display the DFT of a unit impulse at $x(1)$ :
$x=[1$ zeros(1,11)];
fftgui(x)
real ( $x$ )

imag ( $x$ )

imag(fft(x))

The transform is quite different if the unit impulse is at $\times(2)$ :

```
x = [0 1 zeros(1,10)];
fftgui(x)
```

real(x)

real (fft(x))

imag(x)

imag (fft(x))

The following commands display DFTs of square and sine waves, respectively:

```
x = [ones(1,25),-ones(1,25)];
fftgui(x)
```

t = linspace(0,1,50);
t = linspace(0,1,50);
x = sin(2*pi*t);
x = sin(2*pi*t);
fftgui(x)
fftgui(x)
real ( x )

real (fft(x))

imag (x)

imag (fft(x))

The midpoint of the DFT (or the point just to the right of the midpoint if the length is even), corresponding to half the sampling frequency of the data, is the Nyquist point. For real x, the real part of the DFT is symmetric about the Nyquist point, and the imaginary part is antisymmetric about the Nyquist point.

## Fast Fourier Transform (FFT)

In this section...<br>"Introduction" on page 11-8<br>"The FFT in One Dimension" on page 11-9<br>"The FFT in Multiple Dimensions" on page 11-23

## Introduction

DFTs with a million points are common in many applications. Modern signal and image processing applications would be impossible without an efficient method for computing the DFT.

Direct application of the definition of the DFT (see "Discrete Fourier Transform (DFT)" on page 11-2) to a data vector of length $n$ requires $n$ multiplications and $n$ additions-a total of $2 n^{2}$ floating-point operations. This does not include the generation of the powers of the complex $n$th root of unity $\omega$. To compute a million-point DFT, a computer capable of doing one multiplication and addition every microsecond requires a million seconds, or about 11.5 days.

Fast Fourier Transform (FFT) algorithms have computational complexity $O(n$ $\log n$ ) instead of $O\left(n^{2}\right)$. If $n$ is a power of 2 , a one-dimensional FFT of length $n$ requires less than $3 n \log _{2} n$ floating-point operations (times a proportionality constant). For $n=220$, that is a factor of almost 35,000 faster than $2 n^{2}$.

The MATLAB functions fft, fft2, and fftn (and their inverses ifft, ifft2, and ifftn, respectively) all use fast Fourier transform algorithms to compute the DFT.

Note MATLAB FFT algorithms are based on FFTW, "The Fastest Fourier Transform in the West" (http: / /www.fftw. org). See fft and fftw for details.

When using FFT algorithms, a distinction is made between the window length and the transform length. The window length is the length of the input data vector. It is determined by, for example, the size of an external buffer. The
transform length is the length of the output, the computed DFT. An FFT algorithm pads or chops the input to achieve the desired transform length. The following figure illustrates the two lengths.

The execution time of an FFT algorithm depends on the transform length. It is fastest when the transform length is a power of two, and almost as fast when the transform length has only small prime factors. It is typically slower for transform lengths that are prime or have large prime factors. Time differences, however, are reduced to insignificance by modern FFT algorithms such as those used in MATLAB. Adjusting the transform length for efficiency is usually unnecessary in practice.

## The FFT in One Dimension

- "Introduction" on page 11-9
- "Example: Basic Spectral Analysis" on page 11-10
- "Example: Spectral Analysis of a Whale Call" on page 11-14
- "Example: Data Interpolation" on page 11-18

## Introduction

The MATLAB fft function returns the DFT y of an input vector $x$ using a fast Fourier transform algorithm:

$$
y=f f t(x) ;
$$

In this call to fft , the window length $\mathrm{m}=$ length $(\mathrm{x})$ and the transform length $\mathrm{n}=$ length(y) are the same.

The transform length is specified by an optional second argument:

$$
y=f f t(x, n) ;
$$

In this call to fft , the transform length is n . If the length of x is less than n , $x$ is padded with trailing zeros to increase its length to $n$ before computing the DFT. If the length of $x$ is greater than $n$, only the first $n$ elements of $x$ are used to compute the transform.

## Example: Basic Spectral Analysis

The FFT allows you to efficiently estimate component frequencies in data from a discrete set of values sampled at a fixed rate. Relevant quantities in a spectral analysis are listed in the following table. For space-based data, replace references to time with references to space.

| Quantity | Description |
| :--- | :--- |
| $x$ | Sampled data |
| $m=$ length $(x)$ | Window length (number of samples) |
| $f s$ | Samples/unit time |
| $d t=1 / f s$ | Time increment per sample |
| $t=(0: m-1) / f s$ | Time range for data |
| $y=f f t(x, n)$ | Discrete Fourier transform (DFT) |
| $a b s(y)$ | Amplitude of the DFT |
| $\left(a b s(y) .^{\wedge} 2\right) / n$ | Power of the DFT |
| $f s / n$ | Frequency increment |
| $f=(0: n-1)^{*}(f s / n)$ | Frequency range |
| $f s / 2$ | Nyquist frequency |

For example, consider the following data x with two component frequencies of differing amplitude and phase buried in noise:

```
fs = 100; % Sample frequency (Hz)
t = 0:1/fs:10-1/fs; % 10 sec sample
x = (1.3)*sin(2*pi*15*t) ... % 15 Hz component
    + (1.7)*sin(2*pi*40*(t-2)) ... % 40 Hz component
    + (2.5)*randn(size(t)); % Gaussian noise;
```

Use fft to compute the DFT y and its power:

```
m = length(x); % Window length
n = pow2(nextpow2(m)); % Transform length
y = fft(x,n); % DFT
f = (0:n-1)*(fs/n); % Frequency range
power = y.*conj(y)/n; % Power of the DFT
```

nextpow finds the exponent of the next power of two greater than or equal to the window length (ceil $(\log 2(m))$ ), and pow2 computes the power. Using a power of two for the transform length optimizes the FFT algorithm, though in practice there is usually little difference in execution time from using $n=m$.

To visualize the DFT, plots of abs(y), abs(y).^2, and $\log (a b s(y))$ are all common. A plot of power versus frequency is called a periodogram:

```
plot(f,power)
xlabel('Frequency (Hz)')
ylabel('Power')
title('{\bf Periodogram}')
```

The first half of the frequency range (from 0 to the Nyquist frequency fs/2) is sufficient to identify the component frequencies in the data, since the second half is just a reflection of the first half.

In many applications it is traditional to center the periodogram at 0 . The fftshift function rearranges the output from fft with a circular shift to produce a 0 -centered periodogram:

```
y0 = fftshift(y); % Rearrange y values
f0 = (-n/2:n/2-1)*(fs/n); % O-centered frequency range
power0 = y0.*conj(y0)/n; % 0-centered power
plot(f0,power0)
xlabel('Frequency (Hz)')
ylabel('Power')
title('{\bf O-Centered Periodogram}')
```

The rearrangement makes use of the periodicity in the definition of the DFT (see "Discrete Fourier Transform (DFT)" on page 11-2).

Use the MATLAB angle and unwrap functions to create a phase plot of the DFT:

```
phase = unwrap(angle(y0));
plot(f0,phase*180/pi)
xlabel('Frequency (Hz)')
ylabel('Phase (Degrees)')
grid on
```

Component frequencies are mostly hidden by the randomness in phase at adjacent values. The upward trend in the plot is due to the unwrap function, which in this case adds $2 \pi$ to the phase more often than it subtracts it.

## Example: Spectral Analysis of a Whale Call

The documentation example file bluewhale.au contains audio data from a Pacific blue whale vocalization recorded by underwater microphones off the coast of California. The file is from the library of animal vocalizations maintained by the Cornell University Bioacoustics Research Program.

Note Documentation example files for MATLAB mathematics are located in the \help\techdoc \math \examples subfolder of your MATLAB root folder (matlabroot). This subfolder is not on the MATLAB path at installation. To use the MATLAB files in this subfolder, either add the subfolder to the MATLAB path (addpath) or make the subfolder your current working folder (cd).

Because blue whale calls are so low, they are barely audible to humans. The time scale in the data is compressed by a factor of 10 to raise the pitch and make the call more clearly audible. The following reads, plots, and plays the data:

```
[x,fs] = auread('bluewhale.au');
plot(x)
xlabel('Sample Number')
ylabel('Amplitude')
title('{\bf Blue Whale Call}')
sound(x,fs)
```

An A "trill" is followed by a series of B "moans."
The B call is simpler and easier to analyze. Use the previous plot to determine approximate indices for the beginning and end of the first B call. Correct the time base for the factor of 10 speed-up in the data:

```
bCall = x(2.45e4:3.10e4);
tb = 10*(0:1/fs:(length(bCall)-1)/fs); % Time base
plot(tb,bCall)
xlim([0 tb(end)])
xlabel('Time (seconds)')
ylabel('Amplitude')
title('{\bf Blue Whale B Call}')
```

Blue Whale B Call

Use fft to compute the DFT of the signal. Correct the frequency range for the factor of 10 speed-up in the data:

```
m = length(bCall); % Window length
n = pow2(nextpow2(m)); % Transform length
y = fft(bCall); % DFT of signal
f = (0:n-1)*(fs/n)/10; % Frequency range
p = y.*conj(y)/n; % Power of the DFT
```

Plot the first half of the periodogram, up to the Nyquist frequency:

```
plot(f(1:floor(n/2)),p(1:floor(n/2)))
xlabel('Frequency (Hz)')
ylabel('Power')
title('{\bf Component Frequencies of a Blue Whale B Call}')
```

The B call is composed of a fundamental frequency around 17 Hz and a sequence of harmonics, with the second harmonic emphasized.

## Example: Data Interpolation

This example demonstrates the FFT in a context other than spectral analysis-estimating coefficients of a trigonometric polynomial that interpolates a set of regularly-spaced data. This approach to data interpolation is described in [1].

Several people discovered fast DFT algorithms independently, and many people have contributed to their development. A 1965 paper by John Tukey and John Cooley [2] is generally credited as the starting point for modern usage of the FFT. However, a paper by Gauss published posthumously in 1866
[3] (and dated to 1805) contains indisputable use of the splitting technique that forms the basis of modern FFT algorithms.

Gauss was interested in the problem of computing accurate asteroid orbits from observations of their positions. His paper contains 12 data points on the position of the asteroid Pallas, through which he wished to interpolate a trigonometric polynomial with 12 coefficients. Instead of solving the resulting 12 -by- 12 system of linear equations by hand, Gauss looked for a shortcut. He discovered how to separate the equations into three subproblems that were much easier to solve, and then how to recombine the solutions to obtain the desired result. The solution is equivalent to estimating the DFT of the data with an FFT algorithm.

Here is the data that appears in Gauss' paper:

```
asc = 0:30:330;
dec = [l408 89 -66 10 338 807 1238 1511 1583 1462 1183 804];
plot(asc,dec,'ro','Linewidth',2)
xlim([0 360])
xlabel('Ascension (Degrees)')
ylabel('Declination (Minutes)')
title('{\bf Position of the Asteroid Pallas}')
grid on
```

Gauss wished to interpolate a trigonometric polynomial of the form:

$$
\begin{aligned}
y=a_{0}+ & a_{1} \cos (2 \pi(x / 360))+b_{1} \sin (2 \pi(x / 360)) \\
& a_{2} \cos (2 \pi(2 x / 360))+b_{2} \sin (2 \pi(2 x / 360)) \\
& \cdots \\
& a_{5} \cos (2 \pi(5 x / 360))+b_{5} \sin (2 \pi(5 x / 360)) \\
& a_{6} \cos (2 \pi(6 x / 360))
\end{aligned}
$$

The following uses fft to perform an equivalent of Gauss' calculation:

```
d = fft(dec);
m = length(dec);
M = floor((m+1)/2);
```

```
a0 = d(1)/m;
an = 2*real(d(2:M))/m;
a6 = d(M+1)/m;
bn = -2*imag(d(2:M))/m;
```

Plot the interpolant with the data:

```
hold on
x = 0:0.01:360;
n = 1:length(an);
y = a0 + an*cos(2*pi*n'*x/360) ...
    + bn*sin(2*pi*n'*x/360) ...
    + a6*cos(2*pi*6*x/360);
plot(x,y,'Linewidth',2)
legend('Data','DFT Interpolant','Location','NW')
```

## The FFT in Multiple Dimensions

- "Introduction" on page 11-23
- "Example: Diffraction Patterns" on page 11-24

## Introduction

This section discusses generalizations of the DFT in one dimension (see "Discrete Fourier Transform (DFT)" on page 11-2).

In two dimensions, the DFT of an $m$-by- $n$ array $X$ is another $m$-by- $n$ array $Y$ :

$$
Y_{p+1, q+1}=\sum_{j=0}^{m-1} \sum_{k=0}^{n-1} \omega_{m}^{j p} \omega_{n}^{k q} X_{j+1, k+1}
$$

where $\omega_{m}$ and $\omega_{n}$ are complex roots of unity:

$$
\begin{aligned}
& \omega_{m}=e^{-2 \pi i / m} \\
& \omega_{n}=e^{-2 \pi i / n}
\end{aligned}
$$

This notation uses $i$ for the imaginary unit, $p$ and $j$ for indices that run from 0 to $m-1$, and $q$ and $k$ for indices that run from 0 to $n-1$. The indices $p+1$ and $j+1$ run from 1 to $m$ and the indices $q+1$ and $k+1$ run from 1 to $n$, corresponding to ranges associated with MATLAB arrays.

The MATLAB function fft2 computes two-dimensional DFTs using a fast Fourier transform algorithm. $Y=f f t 2(X)$ is equivalent to $Y=f f t(f f t(X) . ') \cdot$ ', that is, to computing the one-dimensional DFT of
each column X followed by the one-dimensional DFT of each row of the result. The inverse transform of the two-dimensional DFT is computed by ifft2.

The MATLAB function fftn generalizes fft2 to $N$-dimensional arrays. $Y=f f t n(X)$ is equivalent to:

```
Y = X;
for p = 1:length(size(X))
    Y = fft(Y,[],p);
end
```

That is, to computing in place the one-dimensional DFT along each dimension of X. The inverse transform of the $N$-dimensional DFT is computed by ifftn.

## Example: Diffraction Patterns

The theory of optics predicts that the diffraction pattern produced by a plane wave incident on an optical mask with a small aperture is described, at a distance, by the Fourier transform of the mask. See, for example, [1].

The following creates a logical array describing an optical mask $M$ with a circular aperture A of radius R:

```
n = 2^10;
M = zeros(n);
I = 1:n;
x = I-n/2;
y = n/2-I;
[X,Y] = meshgrid(x,y);
R = 10;
A = (X.^2 + Y.^2 <= R^2);
M(A) = 1;
imagesc(M)
colormap([0 0 0; 1 1 1])
axis image
title('{\bf Circular Aperture}')
```

## Circular Aperture

Use fft2 to compute the two-dimensional DFT of the mask and fftshift to rearrange the output so that the zero-frequency component is at the center:

```
D1 = fft2(M);
D2 = fftshift(D1);
imagesc(abs(D2))
axis image
colormap(hot)
title('{\bf Diffraction Pattern}')
```

The logarithm helps to bring out details of the DFT in regions where the amplitude is small:

```
D3 = log2(D2);
imagesc(abs(D3))
axis image
colormap(hot)
title('{\bf Enhanced Diffraction Pattern}')
```

Very small amplitudes are affected by numerical round-off. The lack of radial symmetry is an artifact of the rectangular arrangement of data.

## Function Summary

MATLAB functions related to Fourier transforms include:

| Function | Description |
| :--- | :--- |
| fft | One-dimensional fast Fourier transform |
| ifft | One-dimensional inverse fast Fourier transform |
| fft2 | Two-dimensional fast Fourier transform |
| ifft2 | Two-dimensional inverse fast Fourier transform |
| fftn | $N$-dimensional fast Fourier transform |
| ifftn | $N$-dimensional inverse fast Fourier transform |
| fftshift | Rearrange DFT data to center zero-frequency component |
| fftw | Interface to FFTW run-time algorithm |
| abs | Amplitude of the DFT |
| angle | Phase of the DFT |
| unwrap | Correct phase angles with jumps greater than or equal to pi |
| nextpow2 | Next power of two greater than or equal to a given length |
| pow2 | Compute powers of two |

The MATLAB software also includes demos that use these functions in combination for Fourier analysis:

- FFT for Spectral Analysis - Reviews basic spectral analysis with the FFT
- Using FFT in MATLAB - Example of time series analysis with the FFT that looks for periodicity in historical data on sunspot activity
